Chemical, physical, microbiological, and animal assays, as well as basic techniques and instrumentation for biochemical determinations are presented. The entire volume deals with well-established methods or techniques which have undergone sufficient improvement to render recapitulation or reappraisal beneficial and relatively new approaches which have shown promise of being potentially useful in biochemical analysis. The materials presented should be of particular value because the contributors of the various sections are either workers who have originated or have had intimate personal experience with the methods which they discuss. Additionally, experimental details are given in a manner which will furnish the laboratory worker with the complete information required to carry out the analyses discussed.

Progress in Drug Research. Vol. IV. Edited by ERNST JUCKER. Interscience Publishers, 440 Park Ave. South, New York 16, N. Y. 606 pp. 17 × 24.5 cm. Price $30.

Subjects presented in this fourth volume of this survey series discussing the chemical, pharmacological, and clinical aspects of pharmaceutical research include recent developments in therapeutically useful organic sulfur compounds, drug latentiation, antihypertensive agents, structure-activity relationships of local anesthetics, and molecular geometry and mechanism of action of chemical carcinogens. The subjects are presented in the language of the contributor, either English or German. The subject index, also in the language of the respective contributions, includes trade names as well as chemical and trivial names—an excellent feature of the work.

A Survey of Drugs. By HAKIM ABDUL WAHID and H. H. SIDDIQUI. Institute of the History of Medicine and Medical Research, Hamdard Buildings, Delhi 6, India. xv + 168 pp. 16 × 24 cm. Price $1.

A systematic classification of information on indigenous drugs of India and the surrounding regions is presented to bring together available information of the drugs used in Indian systems of medicine which may be of interest to pharmaceutical investigators. The classification is effected through different lists, 19 in all. The lists classifying the indigenous drugs added by Unani physicians to their materia medica, vegetable drugs used exclusively in Unani medicine and the comparable information for Ayurvedic medicine, and drugs according to their uses and action in Unani medicine may be of particular interest. A brief textual section covers the background of the different systems of medicine of the area and helps the reader orient himself when considering the various classifications established.

First International Pharmacological Meeting. Vol. VI. General Editor: BORJE UVNASS. The Macmillan Company, 60 Fifth Ave., New York 11, N. Y. xiii + 330 pp. 16 × 24 cm. Price $15.

A symposium covering biochemistry and pharmacology is reported. The list of 41 author-participants from this and other countries is composed of eminently qualified scientists. The first part is devoted to enzymes that metabolize drugs—excluding, however, antitumor drugs. The second part of the program concerns factors that influence the amount of drug available to the enzymes and factors which change their activity. Specific topics presented include: detoxication mechanisms *in vivo*, demethylation and methylation of drugs and physiologically active compounds, desulfuration, urinary excretion of drugs, duration of action of drugs as affected by tissue distribution, and species differences and individual variations in drug metabolism.

First International Pharmacological Meeting. Vol. VIII. Edited by W. D. M. PATON. The Macmillan Company, 60 Fifth Ave. New York 11, N. Y. xvi + 330 pp. 15.5 × 23 cm. Price $15.

A symposium designed to concentrate on the mechanism of action and analytical aspects of drugs active on the central nervous system and various approaches to central nervous system pharmacology is reported. Thirty-one papers fitting within the format described above were selected for publication and these include: inhibitory factors in the brain; central amines and behavorial states: a critique and new data; unusual central depressant properties of a new piperidine compound; drug-induced changes in behavior; and controlled environment: a method of measuring the drug response–behavior in humans.

Encyclopedia of Chemical Technology. Vol. 1. Edited by ANTHONY STANDEN. John Wiley & Sons, Inc., 440 Park Ave. South, New York 16, N. Y. xvi + 990 pp. 19 × 27 cm. Price $45.

The first volume of the second edition promises to be as useful a resource and reference work as the first edition. The aim of this thorough revision, volume by volume, is to provide a comprehensive summary of knowledge on the industrial methods, materials, processes, and equipment of chemical technology. The second edition will be broadened in scope to include information from abroad as well as the United States. The encyclopedia will contain articles on pharmaceuticals and cosmetics. About one-half of the articles deal with single or compound chemical substance.

Infrared Absorption Spectroscopy, Practical. By KOJI NAKANISHI. Holden-Day, Inc., 728 Montgomery St., San Francisco 11, Calif. ix + 233 pp. 18 × 26 cm. Price $8.

Actual infrared curves are presented to acquaint the reader with the range of absorption of the various characteristic absorption bands. Factors which influence band positions and intensities are discussed. The work is a translation of a Japanese book first published in 1960.

used in the synthesis of peptides; Brown, D. M., of the University Chemical Laboratory, Cambridge, England,—phosphorylation; McOmie, J. F. W., of the University, Bristol, England,—protective groups; and Reed, R. I., of The University, Glasgow, Scotland,—mass spectrometry as a structural tool. An extensive bibliography follows each section. Author and subject indexes, as well as a cumulative index for volumes 1–3 are included.

Methods of Biochemical Analysis. Vol. XI. Edited by DAVID GLICK. Interscience Publishers, 440 Park Ave. South, New York 16, N. Y. ix +442 pp. 15.5 × 23.5 cm. Price $14.50.

Chemical, physical, microbiological, and animal assays, as well as basic techniques and instrumentation for biochemical determinations are presented. The entire volume deals with well-established methods or techniques which have undergone sufficient improvement to render recapitulation or reappraisal beneficial and relatively new approaches which have shown promise of being potentially useful in biochemical analysis. Methods of Biochemical Analysis. Vol. XI. Edited by DAVID GLICK. Interscience Publishers, 440 Park Ave. South, New York 16, N. Y. ix +442 pp. 15.5 × 23.5 cm. Price $14.50.

Chemical, physical, microbiological, and animal assays, as well as basic techniques and instrumentation for biochemical determinations are presented. The entire volume deals with well-established methods or techniques which have undergone sufficient improvement to render recapitulation or reappraisal beneficial and relatively new approaches which have shown promise of being potentially useful in biochemical analysis. The materials presented should be of particular value because the contributors of the various sections are either workers who have originated or have had intimate personal experience with the methods which they discuss. Additionally, experimental details are given in a manner which will furnish the laboratory worker with the complete information required to carry out the analyses discussed.

Progress in Drug Research. Vol. IV. Edited by ERNST JUCKER. Interscience Publishers, 440 Park Ave. South, New York 16, N. Y. 606 pp. 17 × 24.5 cm. Price $30.

Subjects presented in this fourth volume of this survey series discussing the chemical, pharmacological, and clinical aspects of pharmaceutical research include recent developments in therapeutically useful organic sulfur compounds, drug latentiation, antihypertensive agents, structure-activity relationships of local anesthetics, and molecular geometry and mechanism of action of chemical carcinogens. The subjects are presented in the language of the contributor, either English or German. The subject index, also in the language of the respective contributions, includes trade names as well as chemical and trivial names—an excellent feature of the work.

A Survey of Drugs. By HAKIM ABDUL WAHID and H. H. SIDDIQUI. Institute of the History of Medicine and Medical Research, Hamdard Buildings, Delhi 6, India. xv + 168 pp. 16 × 24 cm. Price $1.

A systematic classification of information on indigenous drugs of India and the surrounding regions is presented to bring together available information of the drugs used in Indian systems of medicine which may be of interest to pharmaceutical investigators. The classification is effected through different lists, 19 in all. The lists classifying the indigenous drugs added by Unani physicians to their materia medica, vegetable drugs used exclusively in Unani medicine and the comparable information for Ayurvedic medicine, and drugs according to their uses and action in Unani medicine may be of particular interest. A brief textual section covers the background of the different systems of medicine of the area and helps the reader orient himself when considering the various classifications established.

First International Pharmacological Meeting. Vol. VI. General Editor: BORJE UVNASS. The Macmillan Company, 60 Fifth Ave., New York 11, N. Y. xiii + 330 pp. 16 × 24 cm. Price $15.

A symposium covering biochemistry and pharmacology is reported. The list of 41 author-participants from this and other countries is composed of eminently qualified scientists. The first part is devoted to enzymes that metabolize drugs—excluding, however, antitumor drugs. The second part of the program concerns factors that influence the amount of drug available to the enzymes and factors which change their activity. Specific topics presented include: detoxication mechanisms *in vivo*, demethylation and methylation of drugs and physiologically active compounds, desulfuration, urinary excretion of drugs, duration of action of drugs as affected by tissue distribution, and species differences and individual variations in drug metabolism.

First International Pharmacological Meeting. Vol. VIII. Edited by W. D. M. PATON. The Macmillan Company, 60 Fifth Ave. New York 11, N. Y. xvi + 330 pp. 15.5 × 23 cm. Price $15.

A symposium designed to concentrate on the mechanism of action and analytical aspects of drugs active on the central nervous system and various approaches to central nervous system pharmacology is reported. Thirty-one papers fitting within the format described above were selected for publication and these include: inhibitory factors in the brain; central amines and behavorial states: a critique and new data; unusual central depressant properties of a new piperidine compound; drug-induced changes in behavior; and controlled environment: a method of measuring the drug response–behavior in humans.

Encyclopedia of Chemical Technology. Vol. 1. Edited by ANTHONY STANDEN. John Wiley & Sons, Inc., 440 Park Ave. South, New York 16, N. Y. xvi + 990 pp. 19 × 27 cm. Price $45.

The first volume of the second edition promises to be as useful a resource and reference work as the first edition. The aim of this thorough revision, volume by volume, is to provide a comprehensive summary of knowledge on the industrial methods, materials, processes, and equipment of chemical technology. The second edition will be broadened in scope to include information from abroad as well as the United States. The encyclopedia will contain articles on pharmaceuticals and cosmetics. About one-half of the articles deal with single or compound chemical substance.

Infrared Absorption Spectroscopy, Practical. By KOJI NAKANISHI. Holden-Day, Inc., 728 Montgomery St., San Francisco 11, Calif. ix + 233 pp. 18 × 26 cm. Price $8.

Actual infrared curves are presented to acquaint the reader with the range of absorption of the various characteristic absorption bands. Factors which influence band positions and intensities are discussed. The work is a translation of a Japanese book first published in 1960.

BUT WHERE WAS PHARMACY?

The Commission on Drug Safety—an eminent body of recognized medical scientists established through a grant from the Pharmaceutical Manufacturers Association in the aftermath of the thalidomide incident—sponsored a *Conference of Professional and Scientific Societies* this past June 27–28 as its first major undertaking in discharging the responsibilities it has assumed. The expressed purpose of the Conference was to inform the many various scientific and professional societies of the responsibility which all groups share in the area of drug safety.

The activities and responsibilities of many medical and medically-oriented groups were formally presented during the Conference program by an array of distinguished physicians who are active in clinical research, education, government, administration, and industry. In addition, enlightening papers were delivered by nonmedical authorities from government and law.

This writer had the pleasure of attending the Conference as the invited representative from the A.PH.A., and was accompanied by two representatives from the A.PH.A. Scientific Section. As we listened to the program presentations, however, the writer could not help but reflect upon the fact that pharmaceutical scientists were completely absent from the program roster. In view of the fact that the charter of the Commission states that it will exist to "recommend means for expansion of scientific knowledge of the predictability of action of drugs in man," it must be concluded that the Commission does not recognize that the manner in which a specific pharmaceutical dosage form is constructed plays a fundamental role in whether or not the particular drug will be safe and effective when it is administered.

When one considers that the Commission was fathered by an industry which places considerable significance on the variations in safety and effectiveness which may be encountered in finished dosage forms of the same drug substance when manufactured by different firms, then it becomes all the more difficult to understand why this important aspect of drug safety was ignored on an otherwise very comprehensive and enlightening Conference program.

Review Article

Pharmaceutical Sciences—1962. Part II

A Literature Review

By WAYNE McKEEHAN

CONTENTS

[Contents for Part I of this review appeared in the July issue, THIS JOURNAL, 52, 613(1963).]

RADIOISOTOPES

BOUSQUET has reviewed radioisotope applications to cosmetic analysis and product evaluation (536). Methods and apparatus were described for the investigation of aqueous properties and structure of disperse bodies with the aid of radioactive isotopes (537). Appino, *et al.*, presented a radioisotopic method for the evaluation of emulsions which was applicable to either water-in-oil or oil-in-water systems (538). Radioactive tracer techniques were used by Banker to study uniformity of distribution of phosphorus compounds in tablet matrices (539). Scintillation counting was employed for studying adsorption and hydrogenation of radioactive crotonic and vinylacetic acids on thiophene-poisoned palladium (540). Continuous measurement of diffusion coefficients of gases in liquids using glass scintillators made it possible to monitor slow diffusion processes for several hundred hours without disturbing the system by sampling (541). Labeled atoms were also used in the determination of diffusion coefficients of drugs in polymers (542). Radioactive isotopes were used in studying vitamin B_{12} absorption (543), and Ruggiero

Received from the Pharmaceutical Research Department of The Lilly Research Laboratories, Eli Lilly and Co., Indianapolis, Ind.

EDITOR'S NOTE: Part I of this review appeared in the July issue, THIS JOURNAL. 52, 613(1963).

and Skauen have described a chick embryo technique for evaluation of radioactive sodium iodide absorption from various ointment bases (544, 545).

A few papers dealt with the use of radioactive isotopes in pharmaceutical sterilization methods. Sterilization by means of ionizing radiation was reported to be advantageous only for preparations containing compounds such as proteins, enzymes, and steroids which cannot be sterilized by conventional techniques (546). Radiation sterilization of antibiotics (547) and sterilization of ampuled drugs and drug solutions (548) have also been investigated. Schwenker and Vogt discussed the effects of sterilization doses of ionizing radiation on liquid and solid petrolatum (549).

Rames and Bailey studied the chemical effect of high level gamma irradiation on blood glucose *in vitro* (550). A review of the preparation and production control of iodine-131 and colloidal gold-198 was published (551). Two methods for the preparation of tritium-labeled oxytocin were reported (552), and Peng described a method for the preparation of soluble radiophosphate (553). The effects of ionizing radiation on two gelatin fractions were studied (554). When vitamin B_1 hydrochloride crystals were irradiated with Co^{60} γ-rays, a more dense, less hygroscopic material was obtained (555). Radiochemical purity of tritium exchange-labeled barbital was the subject of another paper (556). A review article discussed the application of radioisotopic indicators to paper chromatography (557). Stability of labeled sodium polymetaphosphate was investigated by means of a chromatographic method (558). In studying the mechanism of action of phenolic disinfectants, Judis investigated the release of radioactivity from C^{14}-labeled *Escherichia coli* (559).

Christian, *et al.*, described a 2π liquid scintillation counter for determining the radioactivity of large samples, including man and animals (560). The assembly and operating characteristics of a 4π liquid scintillation detector were reported by Dunavant (561). A Co^{60} γ-irradiator with an unusually high radiation intensity per curie of cobalt has been developed for use in chemical research (562). Rhodes disclosed a simple formula for mass absorption coefficients near the K absorption edge (563), and Evans proposed a simplified self-absorption correction for isotopes emitting weak β-particles (564). Parameters affecting the resolution of a proportional counter have been discussed (565). In another publication, Meade and Stiglitz considered improved solvent systems for liquid scintillation counting of body fluids and tissues (566).

BIOPHARMACEUTICS

Biopharmaceutics is that area of pharmaceutical science primarily concerned with effects of pharmaceutical formulation on the biological activity of medicinal agents. Research in this area requires a certain amount of knowledge in allied fields such as biochemistry, pharmacology, and physiology, to name just a few. Several references in these related areas have been included as part of the review.

Friend discussed the importance of pharmaceutical formulation on the clinical efficacy of drugs and suggested some factors to be considered in the development of pharmaceuticals (567). Problems encountered in the design and presentation of medicinal substances were reviewed (568). Three papers discussed evaluation of new drugs (569), clinical trials of drugs (570), and drug screening and evaluation procedures (571). Pfeiffer described some problems encountered in exploratory trials of new drugs in man and ways of overcoming them (572). The use and abuse of mixtures of active drugs were reviewed (573), while another paper discussed unexpected hazards associated with drugs and chemicals (574).

Automation in biopharmaceutics and related areas was treated by several writers. Applications of data-processing equipment in clinical drug evaluation were reviewed (575). Machine retrieval of pharmacodynamic data was reported by Dietrich (576). An automatic digital computer was employed for the solution of some chemotherapeutic problems (577). Also published was a paper on the use of program-controlled automatic calculators for dosage computations (578).

Bousquet, in a review on the pharmacology and biochemistry of drug metabolism, discussed some of the biochemical reactions undergone by drugs (579). Another writer considered the relation of pharmacology to medicine and pharmacy (580), and contributions to medicine by research in pharmacology were summarized by Riker (581). In a symposium on clinical drug evaluation, Brodie described some of the difficulties in extrapolating data on metabolism of drugs from animal to man; he pointed out that the greatest difficulty is species difference in biotransformation of drugs (582). Several references were cited in a review of methods for studying the anti-inflammatory steroids (583). Kirsner, *et al.*, discussed some problems in the evaluation

of gastrointestinal drugs and ways of overcoming them (584). The effect of intestinal motility on the absorption of sodium in man was investigated (585). Regulation of gastric emptying after meals containing citric acid and salts of citric acid was studied by Hunt and Knox (586).

A theoretical and experimental approach to various facets of drug-receptor interaction has been published (587). In their studies on drug receptors in smooth muscle, Takagi and Iwaki (588) and Iwaki (589, 590) investigated the action of reversible and irreversible antagonists on vascular smooth muscles. A gel filtration method was described for the study of drug-protein binding; quantitative separation of bound and unbound drug was obtained from Sephadex columns (591). Barlow, *et al.*, also measured drug-plasma binding with the aid of Sephadex (592). Semipermeable membranes and electrophoresis were used to study the interaction of sulfapyroxyline and sulfamerazine with serum protein (593). The binding of nitrofurans by proteins was also investigated (594). Scholtan examined the binding of long-acting sulfonamides on human serum proteins with a new small-capacity dialyzator (595), while Scholtan and Schmid showed that the binding of penicillin to serum and tissue proteins was directly related to penicillin concentration but inversely related to temperature (596). Dialysis experiments and radioactive histamine were used in studying histamine binding by heparin (597). Another report described the interactions of xanthine molecules with bovine serum albumin (598).

Effects of Formulation.—Two methods have been described for determining whether patients are actually taking their medication: Swintosky used riboflavin as a marker which could be detected in urine (599), and Ryan, *et al.*, proposed a similar procedure using phenolsulfonphthalein (600). If phenolsulfonphthalein is present, the urine will turn violet when made basic. Aerosol administration of ergotamine tartrate for the treatment of migraine headache was investigated in a study which compared aerosol administration with parenteral injection, oral and sublingual dosage, and rectal suppositories (601). Atropine micro-aerosols and their effects on airway resistance in man were studied (602). In another study a new noscapine formulation for relief of symptoms associated with respiratory tract disorders was also described (603). Schnell and Husa studied the permeability of red corpuscles to water-soluble organic iodine compounds (604), while Shaw and Husa observed the hemolysis of red corpuscles by various substances in the presence of sodium chloride (605). Experimental work on the cause of pain following injection of parenteral pharmaceuticals was published (606, 607). Thoma, *et al.*, examined the effect of bentonite and Veegum on the activity of a series of antiseptics (608). Two papers were published on the subject of physiological availability: one discussed the influence of granulating agents on biological availability of tablet medication (609); the other dealt with the relationship between disintegration time and physiological availability of medication in long-acting tablet formulations (610). Antibacterial activity of mixtures of quaternary ammonium compounds and hexachlorophene was investigated (611).

An *in vitro* method which complies with biological behavior was described for the evaluation of antacids (612), and Newey reported that peptone should be included in artificial gastric juices for antacid testing (613). Clinical and experimental observations on a new antacid were also published (614). Beekman discussed the preparation and properties of some new antacids containing aluminum and magnesium (615, 616). In a study of the influence of common antacids on intragastric pH, dihydroxy aluminum sodium carbonate was found to have a more significant prolonged effect than other compounds investigated (617). Continuous recording of pH by a glass electrode *in situ* was used in assessing the results of diet, antacids, and anticholinergic agents on gastric and duodenal acidity (618). Davison, *et al.*, studied the effects of buffered and unbuffered acetylsalicylic acid on the gastric acidity of normal humans; compared with a control, neither aspirin nor buffered aspirin produced appreciable changes (619). Toxicity of aspirin preparations to the gastrointestinal tract was the topic of another paper (620).

Effects of Physicochemical Properties.—Nelson has discussed physicochemical and pharmaceutic properties of drugs that influence the results of clinical trials (621). The role of ionization constants in the absorption of drugs from the gastrointestinal tract was reviewed (622). An absorption-rate hypothesis, based on physicochemical properties, for the absorption of drugs after subcutaneous implantation was presented by Ballard and Nelson (623). Aqueous/lipid partition coefficient was found to be an important factor in percutaneous absorption of weak electrolytes (624). Treadwell, *et al.*, investigated conditions controlling sterol absorption (625). Hofmann and Borgström suggested that lipids are probably absorbed from the in-

testinal tract as micelles with bile salts acting as transport carriers (626).

Physicochemical factors influencing the absorption of erythromycin and its esters were investigated by Nelson; dissolution rates of erythromycin and some of its esters in fluids simulating gastric and intestinal juices were presented (627). A biological study of some new derivatives of demethylchlortetracycline has been published (628). A report on factors influencing the absorption of griseofulvin from the gastrointestinal tract has also been published (629). Physiological availability of riboflavin and thiamine from "chewable" vitamin products was determined by Morrison and Campbell (630). Of the nine products they studied, six showed incomplete riboflavin availability as measured by urinary excretion. A chromatographic method for testing the availability of ionic iron from iron chelates was published (631). In another article, the use of an iron-sorbitol-citric acid complex in iron-deficiency anemia was disclosed (632). Dettbarn suggested that the cationic form of local anesthetics is intrinsically the most potent (633). A series of papers was published on the relations between physicochemical properties and the action of local anesthetics (634–637). Truitt and Morgan compared gastrointestinal absorption rates of plain and buffered acetylsalicylic acid (638). The potentiation of injectibles through Al_2O_3 adsorption has been studied (639, 640).

Effect of Particle Size.—The influence of particle size on systemic effects after breathing potent medicated aerosols was investigated (641). Three papers relating griseofulvin absorption to particle size were published: Kraml, *et al.*, studied the effect of particle size and addition of surfactants and corn oil on the serum levels of griseofulvin in rats (642). In another paper, Kraml, *et al.*, found that micronized griseofulvin was absorbed better from the gastrointestinal tract than nonmicronized material (643). The third paper, by Atkinson, *et al.*, discussed the relation of griseofulvin particle size to human blood levels (644). They found that 2.7 μ diam. griseofulvin was twice as effectively absorbed as particles measuring 10 μ in diameter. Rabbit blood levels were compared after administration of metal salts and various particle sizes of chloramphenicol (645). In another study, the effects of particle size and dissolution rate on blood concentration following oral administration of N′-(5-ethyl-1,3,4-thiadiazol-2-yl) sulfanilamide were reported; an instrument for measuring dissolution rate was also described (646). The influence of particle size and solubilizers on the absorption of spironolactone from the gastrointestinal tract was studied (647). Purity was found to be more important than particle size to the anthelmintic efficacy of phenothiazine (648).

Absorption Control.—Several reviews were published on various aspects of prolonged-action medication (649–652). An article on the dangers of using oral sustained-release medication was also published (653). Horstman used a double-blind study to show that an extended-action tablet was more effective than a regular tablet of a given drug (654). Two-layer tablets with prolonged action were investigated (655). Exponential release of cyclobarbital calcium from different oral sustained-action dosage forms in artificial gastric juices was reported (656).

Moeller and Rider evaluated a long-acting anticholinergic-antacid preparation in the treatment of peptic ulcer and other diseases of the digestive tract (657), while Hock described clinical evaluation of an anticholinergic agent in a sustained-release dosage form (658). The relationship between dissolution of sustained-release granules and rabbit blood levels of chloramphenicol was investigated (659). Clinical observations of several diabetic patients taking phenethylbiguanide timed-disintegrating capsules were reviewed (660). Weller, *et al.*, also studied the use of phenethylbiguanide timed-disintegrating capsules in the management of diabetic patients (661). The effect of sustained-release acetazolamide on intraocular pressure in man was investigated (662). Rudolph, *et al.*, discussed the use of multiple miniature long-acting antihistamine tablets in allergy (663), and the clinical and physiological effectiveness of timed-release coronary dilator therapy was investigated by Robbins and Thompson (664). Two reports dealt with the release of iron from oral sustained-action dosage forms (665, 666).

The rate of absorption and duration of plasma level after administration of different pharmaceutical preparations of meprobamate were investigated (667). Hollister compared blood levels from compressed tablets and two delayed-action capsule forms of meprobamate (668). In another study, Hollister evaluated two phenothiazine tranquilizers administered in coated tablet and prolonged-action dosage forms (669). S^{35}-labeled trimeprazine tartrate was used to study the effect of sustained release on absorption and excretion (670). Cass and Frederik discussed clinical evaluation of long-release and capsule forms of pentobarbital sodium (671). Enteric-

coated tablets of prednisolone (672) and an oral sustained-release form of methylprednisolone have been investigated (673). A vitamin B_{12} preparation with retarded absorption was reported by Schwartz, *et al.* (674), and Arnold, *et al.*, found that an oil-aluminum monostearate depot preparation of vitamin B_{12} prolonged levels up to 27 days (675).

A study of iron dosage and absorption demonstrated the existence of a linear relationship between dose and absorption when both are plotted on logarithmic scales (676). Blood and urine levels after oral doses of a new soluble tetracycline have been investigated (677). Atkinson, *et al.*, analyzed human blood levels produced by different dosage schedules of griseofulvin; rate of absorption and blood level appeared to be linearly related to the logarithm of the dose (678). Different dose schedules of amethopterin and the resultant serum and tissue concentrations and urinary excretion patterns were examined (679). The stimulating effects of some inhibitors of drug metabolism on excretion of ascorbic acid and drug metabolism were also studied (680).

Kinetic Studies.—Applications of chemical kinetics to the absorption and excretion of chemicals have been reviewed (681). Taylor and Wiegand have demonstrated the usefulness of an analog computer in analyzing models of biological processes involving plasma-drug kinetics (682). To illustrate, they examined drug-plasma kinetics after sustained-release medication. The use of digital computers for fitting kinetic data to models was reported by Berman, *et al.* (683). Berman, *et al.*, also described some formal approaches to the analysis of kinetic data in terms of linear compartmental systems (684). Another researcher described a method for the determination of absorption rates by integration of rates of appearance and disappearance in blood (685).

An *in vitro* study of the kinetics of penetration of sulfonamides through the intestinal barrier was published (686). Nelson, *et al.*, have studied the influence of tolbutamide absorption rate on the rate of decline of blood sugar levels in normal humans (687), and Nelson discussed the zero-order oxidation of tolbutamide *in vivo* (688). In another paper, Nelson examined the kinetics of excretion of sulfonamides during therapeutic dosage regimens (689). A kinetic investigation of blood sugar lowering by various types of insulin preparations resulted in a method for the determination of rate constants (690).

Schwarz, *et al.*, studied the resorption and biological half-life of glycerin in humans (691). The relationship between plasma salicylate concentration and rate of urinary salicylate excretion was explored (692). Also investigated was the effect of protein binding on the renal excretion rate of salicylic acid derivatives; constants for excretion velocity and half-life were reported (693). Penetration kinetics of basic drugs such as aminopyrine through the intestinal barrier *in vitro* were discussed (694). Garrett, *et al.*, used an analog computer to study the influence of steroids on Ca^{47} dynamics in dogs (695). Kinetic studies were also used for investigating fungicidal action (696) and the activity of pilocarpine and eserine (697). Distribution and excretion kinetics of a new dextran were reported (698). This new dextran was made by direct microbiological conversion of sucrose into a material of appropriate molecular weight. Moll and Code investigated the rates of absorption of sodium and potassium from the stomach and upper small bowel of rats (699, 700). The kinetics of accumulation of radioiodine by the thyroid over both short- and long-time intervals was also investigated (701, 702).

Absorption Mechanisms.—Mechanisms of drug absorption and excretion have been reviewed (703). Hindle and Code reported some differences between duodenal and ileal absorption; the duodenal process appeared directed toward establishment of an equilibrium with blood, while the ileal process tended more toward absorption (704). The relationship between pharmacological antagonsim and membrane potential has been investigated (705). Rectal absorption of antibiotics was also studied (706). Ballard and Nelson reviewed absorption of implanted solid drug (707), and Barr cited over 200 references in a review of percutaneous absorption (708). Barriers to skin penetration were reported in another paper (709). The influence of urinary pH on the excretion and biotransformation of salicylic acid derivatives was investigated (710). Kostenbauder, *et al.*, described methods for controlling urinary pH and the resultant effect on sulfaethidole excretion in humans (711). Other investigators discussed the adjustment of urine pH in chemotherapy of urinary-tract infections (712).

An active transport system for absorption of folic acid from the small intestine of the rat has been reported (713). Amino acid absorption in the rat upper small intestine was found to be an active process dependent, at least in part, on vitamin B_6 (714). Considerable research effort was devoted to mechanisms involved in vitamin B_{12} absorption (715–718). Measurements of

folic acid and D-xylose absorption have been used as tests of small-intestine function (719). Beck, *et al.*, described the use of D-xylose blood level time curves as an index of intestinal absorption (720). In their studies on the mechanism of intestinal absorption of sugars, Bihler and Crane (721), and Bihler, *et al.* (722), investigated the influence of cations on the active transport of sugars. Renal disposal of salicyluric acid has been discussed (723). Schanker and Jeffrey (724) and Schanker and Tocco (725) have reported their work on the pyrimidine transport process of the small intestine. The influence of bioelectric potentials on absorption and distribution of organic electrolytes was investigated (726). Barry, *et al.*, concluded that potential differences arising from ion movements across the gut were not responsible for water transport (727).

Drug Absorption: Antibiotics.—Physical, chemical, and pharmacodynamic studies of viomycin have been reviewed (728). Griffith and Black presented a comparison of blood levels after oral administration of erythromycin and erythromycin estolate (729). They reported that a 1000-mg. oral dose of erythromycin is needed to obtain the same blood levels produced by a 250-mg. oral dose of erythromycin estolate. Serum levels following parenteral administration of paromomycin (730) and modes of excretion and accumulation of water-soluble and basic antibiotics in the mouse (731) have been investigated.

Serum binding, distribution, and excretion of tetracycline and a new analog, methacycline, were compared in humans (732). Scheiner and Altemeier studied the factors inhibiting absorption and effective therapeutic levels of demethylchlortetracycline hydrochloride and found that milk, milk products, and aluminum hydroxide gel inhibited absorption (733). When combined with lysine, tetracycline and chlortetracycline were absorbed into the rat intestine *in vitro* at a faster rate than either antibiotic alone (734). Antibacterial activity, *in vitro* absorption, diffusion, and elimination of tetracycline-L-methylenelysine by man have been investigated (735). Krondl, *et al.*, studied the influence of chlortetracycline and neomycin on fat digestion and absorption in rats (736).

The absorption of some new chloramphenicol esters has been reported (737). In their studies on the absorption and excretion of drugs, Kakemi, *et al.*, measured chloramphenicol blood levels after administration of the free drug or its esters (738). In another paper, they discussed determination of chloramphenicol in urine and its metabolic rate (739). They also studied absorption of chloramphenicol and the effect of metal salts on chloramphenicol absorption from the rat stomach and small intestine (740).

Russell reviewed some of the properties and pharmacological actions of new synthetic penicillins (741). Bacteriological and clinical pharmacological investigations of methicillin and oxacillin have been reported; methicillin was found unstable in acid solution but oxacillin was well absorbed orally from an empty stomach (742). The effect of ascorbic acid on the absorption of potassium phenoxymethylpenicillin was examined (743). Cheng and White studied the effect of orally administered neomycin on the absorption of penicillin V and discovered that neomycin inhibited absorption (744). Chemotherapeutic properties of some α-substituted benzylpenicillins have been described (745). Administration of penicillin decreased the coefficient of intestinal absorption of *p*-aminohippuric acid in man and rat (746).

Drug Absorption: Organic.—Richmond and Girdwood (747) and Christensen (748) have published papers dealing with amino acid absorption. Everted hamster intestinal sacs were used to study amino group requirement for transintestinal transport of amino acids against a concentration gradient (749). Absorption, distribution, and excretion of ϵ-aminocaproic acid following oral or intravenous administration to man were investigated (750). Absorption of amino acid mixtures from the small intestine of the rat was also investigated (751). Equimolar mixtures and mixtures simulating the amino acid composition of egg albumin, casein, and zein were studied. Gastrointestinal absorption and renal excretion of hydroxyproline peptides in humans (752) and glucose, amino acid, and urea absorption from the canine intestine (753) were explored.

Levy and Sahli compared the gastrointestinal absorption of aluminum acetylsalicylate and acetylsalicylic acid (754) and Leonards demonstrated the presence of acetylsalicylic acid in plasma following oral ingestion of aspirin (755). Water and electrolyte pharmacodynamics of aspirin absorption were investigated (756). Tanaka, *et al.*, studied the effect of glucosamine on absorption and excretion of salicylic acid derivatives in rabbits and dogs (757, 758). Absorption of salicylic acid derivatives from the rat stomach and small intestine was investigated by Kakemi, *et al.* (759, 760). In another paper, Kakemi, *et al.*, described a method for the sepa-

ratory determination of human urinary metabolites of *p*-aminosalicylic acid (761). The influence of a nonionic surfactant on percutaneous penetration of diethylamine salicylate was studied (762), and coefficients of intestinal absorption of *p*-aminohippuric acid in man and some laboratory animals were reported (763).

Studies on the digestion, absorption, and metabolism of castor oil were published (764). Absorption, metabolism, and excretion of some edible dyes have been investigated (765, 766). Urinary excretion of tritiated butylated hydroxyanisole and butylated hydroxytoluene in the rat was studied by Golder, *et al.* (767). The absorption of bretylium and related quaternary ammonium salts from the alimentary tract has been investigated (768). Kaul studied the urinary excretion of tetrahydroaminoacridine (769), and Weiner and Lack found that little, if any, absorption of bile salts took place in the proximal portion of the guinea pig intestine (770).

Results of studies on absorption by the guinea pig intestine of cyanocobalamin incubated with intrinsic factor were published (771). Rat utilization of riboflavin and thiamine given orally or parenterally at periodic intervals was investigated (772). Booth and Brian studied the absorption of tritium-labeled pyridoxine hydrochloride in the rat (773). They found pyridoxine to be rapidly absorbed from the upper intestinal tract regardless of the amount administered. Percutaneous absorption of nicotinic acid and ethyl nicotinate through human skin was also investigated (774).

In their studies on the absorption and excretion of medicaments, Kakemi, *et al.*, used ion-exchange resins to separate metabolic products of isoniazide from the urine (775). The absorption of a bronchodilator, isoetharine (776), and absorption and excretion of sulfamethomidine, a "long-acting" sulfonamide (777), have been investigated. Oral absorption of sulfadimethylpyrimidine was studied (778). Gantt, *et al.*, discussed the gastrointestinal absorption of spironolactone (779). Studies on the distribution and excretion of mebrophenhydramine in rats have been reported (780). Absorption, excretion, and fate of prodilidine were studied in the rat by perfusing the small intestine and measuring drug concentration in the effluent (781).

Drug Absorption: Inorganic.—Interrelation of calcium and magnesium absorption was investigated by Alcock and MacIntyre (782). Normal rates of absorption of water, sodium, and potassium in man and animal have been investigated (783). The influence of osmolarity on water and electrolyte flux rates in the duodenum, jejunum, ileum, and colon was explored; net flux of sodium ions and chloride ions in the dog ileum was found to be entirely due to diffusion (784). Edelman described a four-component system for the transfer of water and sodium in blood and tissues (785), and Ginsburg discussed the equilibration of potassium in blood and tissues (786).

Numerous publications appeared on the subject of iron absorption. Cantrill and Walsh (787, 788) and Cantrill, *et al.* (789), investigated iron absorption from the intestinal tract. Brise (790, 791) and Brise and Hallberg (792–795) studied various aspects of iron absorption using radioactive iron-55 or iron-59. Absorption of radioactive iron from segments of the duodenum and ileum of dogs was studied (796). Kinetics of iron absorption in mice has been investigated (797). The effects of oral iron and pregnancy on the active transport of iron by the intestine were reported (798), and Manis and Schachter described a two-step mechanism for the active transport of iron by the intestine (799). Other investigators discussed the role of the duodenum in iron absorption (800). Evidence of serosal "absorption" by the small intestine after intraperitoneal iron injections was presented (801). Results of an investigation by Loria, *et al.*, indicated that concurrent administration of sorbital improved iron absorption in man (802). Ferroglycine sulfate was found to have no advantage over ferrous sulfate (803). Radio-iron was used to study iron absorption following rectal administration (804).

PLANT CHEMISTRY[2]

The volume of literature published in this area during 1962 is tremendous. This is not too surprising since such a small percentage of the world's plants have been investigated from a medicinal point of view. References in this area have been divided into two groups. First is a *Phytochemical Investigation* section which is concerned with studies of specific plants and/or alkaloids; second is a section on *Methodology*.

Phytochemical Investigations.—Several methods of presenting the references for this section were considered. A listing of references according to the plant(s) studied was finally adopted. Such a procedure provides easy reference to the work on a particular plant which may be of interest to the individual phytochemist. Table I, therefore, lists alphabetically each

[2] The writer thanks Dr. G. H. Svoboda for many helpful suggestions concerning the preparation of this section.

TABLE I.—PHYTOCHEMICAL INVESTIGATIONS

Plant	Reference
Acrospira asphodeloides	(805)
Allium sativum	(806)
Amphipterygium adstringens	(807)
Anabasis articulata	(805, 808)
Anabasis setifera	(805)
Angelica edulis	(809, 810)
Arachis hypogaea	(811)
Argemone mexicana	(812)
Aristolochia triangularis	(813)
Artemisia annua	(814)
Artemisia vulgaris	(815)
Aspergillus terreus	(816)
Athyrium mesosorum	(817, 818)
Baccania cordata	(819)
Balanops australiana	(820)
Bersama abyssinica	(821)
Caccinia glauca	(822)
Calophyllum inophyllum	(823)
Casearia sylvestris	(813)
Cassia auriculata	(824)
Cassia goratensis	(824)
Catalpa ovata	(825)
Catha edulis	(826)
Cestrum parqui	(827)
Chenopodium ambrosioides	(828)
Claviceps species	(829)
Cochlospermum gossypium	(830)
Corydalis incisa	(831–834)
Corydalis solida	(835)
Cynanchum caudatum	(836, 837)
Datura species	(838–842)
Daucas carota	(843)
Decodon verticillatus	(844)
Digitalis species	(845–850)
Dryopteris barbigera	(851)
Dryopteris cochleata	(851)
Erysimum diffusum	(852)
Ficus religiosa	(806)
Geissospermum vellosii	(853)
Genista raetam	(854)
Ginkgo biloba	(855, 856)
Ginseng	(857, 858)
Haloxylon salicornicum	(854)
Helenium species	(859, 860)
Leonurus sibiricus	(861, 862)
Leucojum aestivum	(863)
Liriodendron tulipifera	(864)
Litsea japonica	(865)
Lobelia species	(866, 867)
Lopharia papyracea	(868)
Lychnis alba	(869)
Lycopodium species	(870–873)
Magnolia coco	(874)
Magnolia kachirachirai	(874)
Marsdenia tomentosa	(875)
Matricaria chamomilla	(876)
Menispermaceae alkaloids	(877–881)
Metaplexis japonica	(882)
Michelia alba	(883)
Michelia compressa	(884–887)
Mollugo nudicaulis	(888)
Ornithogalum umbellatum	(889)
Orixa japonica	(890)
Papaver species	(891, 892)
Pancratium maritimum	(854)
Pancratium sickenbergeri	(854)
Phegopteris polypodioides	(893)
Pinus species	(894, 895)
Pisum sativum	(896)
Pteryxia terebinthina	(897)
Rauwolfia species	(898, 899)
Rhamnus alaternus	(900)
Rivea corymbosa	(901)
Schinopsis balansae	(813)
Schinus terebinthefolius	(902–904)
Serratia plymuthicum	(905)
Sinapis alba	(906)
Swartzia madagascariensis	(805)
Thalictrum actaefolium	(907)
Thalictrum thunbergii	(908–911)
Tillandsia usneoides	(912)
Tylophora crebriflora	(913)
Veratrum grandiflorum	(914)
Veratrum stamineum	(915)
Vinca major	(916)
Vinca rosea (*Catharanthus roseus*)	(917–920)
Wrightia tinctora	(921)

plant studied, followed by an appropriate reference to the bibliography.

Methodology.—For the purpose of this review, a rather broad interpretation of the subsection title is necessary. While it is intended to be a section primarily concerned with phytochemical methodology, a few references which would not fit conveniently into the preceding sections were included.

A general review of the technology and chemistry of alkaloids was published by Poisson (922). Other investigators studied the preparation of a dry extract of belladonna (923) and the action of boric acid and some of its polyhydroxy complexes on plants (924). Three publications on essential oils discussed such topics as methods of separation, production, composition, and industrial mechanization (925–927). Natural plant hydrocolloids were the subject of three papers by Meer and Meer; origin, physical chemistry, and applications of several gum and gumlike materials were discussed (928–930). Differential studies on plant gums have also been reported (931). Saiki considered the application of statistics to the field of plant internal morphology (932–934). Statistical evaluation of two parameters permitted the classification of Japanese aconites into five types. Two papers dealt with the adsorption of extracted materials on powdered herb residues (935) and the adsorption of ergot alkaloids on activated charcoal (936).

Tissue culture has been successfully used in the field of plant chemistry. Babcock and Carew initiated cultures of callus tissue from several species of *Apocynaceae* (937). In another paper, Staba studied nutritional requirements in tissue cultures of *Digitalis lanata* and *D. purpurea* (938). As part of a study on enzymatic and nonenzymatic oxidation of therapeutically active plant substances, the oxidation of pyrocatechols by peroxydase was investigated (939). Another report dealt with conditions for precipitation of alkaloids

and synthetic bases with Reinecke salt (940). Ali and Guth explored the possibilities of freeze-drying water infusions of alkaloid-containing drug plants (941).

Drug extraction with isopropyl and ethyl alcohols has been reviewed (942). One investigator described an enzymatic procedure for the extraction of alkaloids from *Rauwolfia serpentina* (943), while another studied the dynamics of extraction of rutin from *Sophora japonica* (944). Better extraction and less solvent loss resulted from the application of centrifugal force to the extraction of plant materials (945). Kubiak explored the effect of ultrasonics on the quantitative and qualitative results of plant extraction (946). The ultrasonic energy appeared to increase the extraction of active materials with no decomposition. The action of ultrasound on alkaloids has also been investigated (947).

Several papers were published in the past year on the use of chromatography in phytochemical studies. Farnsworth and Euler reported an alkaloid-screening procedure utilizing thin-layer chromatography (948). Thin-layer chromatography was also used for separation of the active principles of *Ammi visnaga* and *Ammi majus* (949). Sjoholm employed a two-dimensional thin-layer chromatography technique for studying some digitalis glycosides (950). A new solvent system was recommended for the paper chromatography of some veratrum alkaloids and their derivatives (951). Ascending chromatography on a hydrophobic paper was used in a study of the constituents of *Cannabis sativa* (952), and Meer, *et al.*, reported a rapid method which utilizes an ascending paper chromatography technique for the identification and evaluation of botanical extracts (953). Other investigators discussed chromatographic evaluation of glycoalkaloids in *Solanum aviculare* (954). Paper chromatography was also used in a study of the hydrolysis of some alkaloid esters; R_f values for several alkaloids and their hydrolysis products were reported (955).

EQUIPMENT

Automation in the pharmaceutical industry was the subject of several papers published last year. One reported on the automated production of aspirin (956), while two others discussed automation in antibiotic and vitamin manufacturing (957, 958). Automatic coating of tablets was studied (959), and Gabrysh, *et al.*, described an automatic rotational viscometer and high pressure apparatus for the study of non-Newtonian systems (960). Dunlop discussed the mechanization of tablet and capsule packaging (961). In another paper, Schroeter, *et al.*, presented an apparatus for automated dissolution rate studies of capsules and tablets (962).

A review of grinding and pulverizing equipment was published (963). In a series on small-scale processing machinery, Fowler discussed mixers for powders and semisolids (964, 965). A flow-ultramicroscopic method of determining the number concentration and particle-size analysis of aerosols and hydrosols was described (966). Another group of investigators also reported a particle-size analyzer for aerosols (967). An electronic-microscopic method for precise size measurement and analysis of particulate pharmaceutical materials was published by Barnett and Timbrell (968).

Recent advances in freeze-drying were reviewed by Greaves (969). The application of spray-drying techniques to the production of anti-anemia concentrates was also reported (970). Muller discussed rotation viscometers and their application to non-Newtonian measurements (971), and Fairgrieve developed a thermostated bath for viscometry (972). A modified dual-unit organ bath for isolated tissues was also described (973). Continuous recording methods for measuring perspiration were reported by O'Malley (974) and Marchisotto (975).

An apparatus for testing the resistance to wet heat of bacterial spores on paper carriers was described (976). Preparation of sterile ophthalmic solutions in the pharmacy was the subject of an article by Putney (977). A small-scale sterilization apparatus was made by an adaptation of a 5-ml. syringe (978). Three papers were published on the properties of filter materials (979–981). Wolffgang described a simple apparatus for rapid dialysis of small samples (982), and Hart presented some general considerations to aid in centrifuge selection (983). A comparison of Bittel and Cornish systems for separation of stereoisomers by countercurrent distribution was also published (984).

CONCLUSION

The scope of the literature covered in this review is an indication of the complexity of pharmaceutical research today. As pharmaceutical research becomes even more complex in the years ahead, the pharmaceutical scientist will be increasingly dependent on developments in other disciplines. An up-to-date knowledge of the literature provides a sound basis for interdisciplinary communication.

Gastrointestinal Absorption of Aspirin Anhydride

By GERHARD LEVY and BERNICE A. GAGLIARDI

The gastrointestinal absorption of aspirin anhydride by humans has been found to be slow and incomplete. This explains and is consistent with a reported lack of therapeutic efficacy of this drug. It is concluded that aspirin anhydride is less satisfactory for salicylate therapy than aspirin itself.

CONTINUOUS ATTEMPTS have been made to develop new derivatives and dosage forms of salicylic acid having greater effectiveness, better absorption characteristics, and less tendency to cause gastrointestinal irritation and bleeding than presently used salicylate preparations. It has been suggested (1) that (based on physical-chemical evidence) aspirin anhydride should be a superior form for the oral administration of aspirin. While aspirin anhydride has been studied recently with respect to its tendency to cause gastrointestinal bleeding (2, 3), no information concerning the gastrointestinal absorption and physiological availability of this substance has yet appeared in the literature.

There has been particular reason to question the absorption efficacy of aspirin anhydride since its solubility in aqueous media is extremely low, namely 3.2 mg. per 100 ml. at 37.5° (1), which is less than one-hundredth the solubility of undissociated aspirin itself. Another poorly soluble and slow-dissolving salicylate, aluminum acetylsalicylate, recently has been found to be absorbed not only very slowly but even incompletely (4). In the present communication the results of our absorption studies with aspirin anhydride are reported and related to available pharmacologic and physical-chemical data.

EXPERIMENTAL

Materials.—Micronized acetylsalicylic acid U.S.P. and micronized aspirin anhydride were utilized. Both compounds were assayed colorimetrically in terms of salicylic acid (9) after alkaline hydrolysis. One gram of acetylsalicylic acid was found to be equivalent to 0.96 Gm. aspirin anhydride (theoretical: 0.95 Gm.) on the basis of the salicylic acid assay. The drugs were handfilled into hard gelatin capsules, size 00, which were weighed individually before and after filling to obtain exact dosage. The specific surface area of each drug was determined by the nitrogen adsorption method and was found to be 1.22 M.²/Gm. for micronized aspirin and 2.24 M.²/Gm. for micronized aspirin anhydride.[1]

Absorption Tests.—Male adults in apparent good health served as test subjects. Their weights and ages are listed in Tables I and II. In the study of early absorption, each subject received two capsules containing a total of either 1 Gm. aspirin or 0.96 Gm. aspirin anhydride about 1 hour after a light noon meal. The medication was administered together with 100 ml. of water, and another 100 ml. water was given exactly 1 hour later. The two drugs were administered in crossover fashion, 1 week apart. One-half the group received aspirin first, while the other half received aspirin anhydride first. All subjects were instructed to observe similar dietary habits on the two days scheduled for the studies. A small urine sample was collected immediately prior to drug administration to obtain blank values and to make certain that the subjects had not inadvertently ingested a salicylate-containing medication during the 24 hours preceding the test. Exactly 2 hours after drug administration, total urine was collected from each subject.

The total absorption study was initiated in the morning after an overnight fast. The subjects were instructed to empty their bladder of overnight urine and to drink one glass of water. One hour later, after collection of a small urine sample, either 1 Gm. of aspirin or aspirin anhydride in two hard gelatin capsules was administered, together with 100 ml. of water. Total urine was collected exactly 2 hours after drug administration and from then on at 2–3 hour intervals (except for a greater night-time interval) for at least 36 hours. The subjects did not eat until 1 hour after drug administration.

The urinary excretion method for measuring salicylate absorption has been employed previously in our laboratory (4, 5) and by other workers cited in a previous publication (6). Urinary salicylate excretion data correlate well with plasma salicylate levels (5) as can be expected, although excretion data are possibly more accurate since they represent cumulative rather than transitory values.

Received December 4, 1962, from the Biopharmaceutics Laboratory, School of Pharmacy, State University of New York at Buffalo, Buffalo 14.

Accepted for publication December 17, 1962.

We thank the volunteers who participated in this study and The Upjohn Co. for the supply of micronized aspirin and aspirin anhydride.

[1] We thank Mr. E. L. Rowe, Pharmacy Research Section, Product Research and Development, The Upjohn Co., for the surface area measurements.

Urine pH.—The pH of each urine sample was determined with a Leeds and Northrup pH meter, model 7664. The salicylate excretion rate increases rapidly when urinary pH exceeds 7.0 (7, 8), and an unusually high urinary pH during one test period but not during the other could distort significantly the comparative data. These considerations caused the elimination of one subject participating in the early absorption test since the pH of his urine exceeded 7.0 in one instance.[2]

Analytical Methods.—Salicylate in the urine was determined colorimetrically according to Trinder (9) with a Bausch and Lomb Spectronic 20 colorimeter. All readings were corrected for blank values. Zero-hour blank values were used for second-hour urine samples, and average blank values obtained from previous 24-hour urine collections were used in the assay of all other samples.

RESULTS AND DISCUSSION

Table I shows the results of the study of early absorption. On the basis of the amounts of salicylate excreted 2 hours after drug administration, it is apparent that aspirin anhydride is absorbed considerably less rapidly than aspirin. The difference in amounts of excreted salicylate is statistically significant ($p < 0.05$), although there is considerable variation within each group. This is quite usual since our previous salicylate absorption studies and those of others indicate that subjects can be classified on a fairly consistent basis as either rapid, average, or slow absorbers.[3] This is evidenced in the present study by the much more consistent results obtained when the data are expressed as a ratio of salicylate excreted from aspirin to salicylate excreted from aspirin anhydride (see Table I). As shown in the tabulation, average urinary pH was essentially the same in both groups. Since the pH scale is nonlinear, and therefore nonadditive as such, the individual pH values were first converted to molar terms, then averaged, and finally the average molar concentration was reconverted to pH units. There may be some question as to the propriety of averaging pH values even in this manner, but it was done here as an aid in summarizing the data.

Urine flow rate has been found to have a small though noticeable effect on salicylate excretion (8, 10). It is unlikely that the small differences in urine flow noted in the present study had a significant effect on salicylate excretion, but even if they did, it could only be in favor of the aspirin anhydride results.

Results of the total absorption study are listed in Table II for aspirin and in Table III for aspirin anhydride. Average urinary pH and volume did not differ significantly after administration of the two substances. Since the subjects who participated in this study took the drugs on empty stomachs, absorption as evidenced by second-hour salicylate excretion was faster than in the other group of subjects who took the drug after a light meal. The average ratio of salicylate excreted from aspirin to salicylate excreted from aspirin anhydride was, however, essentially the same in both groups, namely 2.3 and 2.2. The total amount of apparent salicylate excreted after aspirin anhydride administration was considerably less than after aspirin administration. This shows that aspirin anhydride is not absorbed completely. It

[2] Similar precautions are appropriate in the case of blood level studies, since drug concentrations in the blood are a function of both absorption and elimination rates.

[3] This phenomenon is apparently related to differences in gastric emptying rates.

[a] Expressed as salicylic acid. [b] Ages and weights are listed in Table II. [c] Calculated according to a method described in the text.

has been established previously that the effect of absorption rate on the ratio of the principal metabolites of salicylic acid appearing in the urine is negligible at the dosage used in this study (4). Of interest is the fact that the total amount of apparent salicylate excreted after a given dose differed significantly among the subjects. This is apparently due to quantitative differences in the biotransformation of salicylate, causing different degrees of formation of metabolites not identifiable by the colorimetric method. These differences reflect the biochemical individuality of each subject. Total excretion data from a previous aspirin absorption study were available for two subjects and are listed in Table II. It can be seen that the values are very similar to those obtained in the present study, suggesting that these individual biotransformation patterns are quite stable.

The physiologic availability of aspirin anhydride was calculated according to the method used in the human bioassay procedure of Melnick, *et al.* (11), which has been applied previously to salicylates by Morrison and Campbell (12) and by the authors (4). Thus, upon administration of equal doses, by weight, of the two salicylates

$$\% \text{ physiologic availability} = \frac{\text{amount excreted after aspirin anhydride}}{\text{amount excreted after aspirin}} \times 100 \times 0.96,$$

the latter term being a correction factor for the slightly higher salicylate content of aspirin anhydride. The data in Table III show that physiologic availability ranged from 47 to 71%, indicating that a significant portion of orally administered aspirin anhydride was not absorbed. It should be pointed out that the drug was used in this study in a physical form highly favorable for absorption, namely as the micronized powder, and that the physiologic availability may be even less when aspirin anhydride is administered in the form of compressed tablets containing drug solids of conventional particle size. The particle size of the aspirin anhydride used in this study was considerably smaller than that of aspirin. Had the specific surface areas of the two drugs been the same, it is likely that the absorption rate of aspirin anhydride would have compared even less favorably with that of aspirin.

Our findings explain the observation by Wood, *et al.* (2), that, in a significant portion of their patients, aspirin anhydride did not produce such satisfactory relief of symptoms as did aspirin. Our data, indicating poor and incomplete gastrointestinal absorption of aspirin anhydride, are also consistent with the toxicologic data reported by Gray, *et al.* (13). These workers found that the LD_{50} of aspirin anhydride in rats was about 50% higher than the LD_{50} of aspirin. Furthermore, death after administration of aspirin anhydride occurred much later than after administration of aspirin.

The gastrointestinal absorption of salicylates, when administered in solid form, is rate-limited by the dissolution process (6, 14), and the slow and incomplete gastrointestinal absorption of aspirin anhydride can be attributed to its extremely low dissolution rate in aqueous media (15). This factor was not taken into account in earlier work by others (1). Moreover, it appears in the light of present knowledge that the theoretical calculations presented in the early work (1) resulted in an underestimation of the absorption rate of aspirin from solution, partly because absorption of this drug from the stomach (16, 17) was neglected in the calculations, but primarily because the absorption rate of aspirin was assumed to change with pH of the gastrointestinal fluids exactly according to theory. Subsequently, it has been established, however, that the decrease in absorption rate of weak acids with increasing pH of intestinal fluids is much less than predicted by the Henderson-Hasselbalch equation, because the pH directly at the site of absorption remains lower than that of the intestinal fluids (18).

Synthesis of Some γ-Substituted α-Amino γ-Lactones

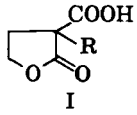
By METRO FEDORCHUK† and FRED T. SEMENIUK

γ-Substituted α-amino γ-lactones were synthesized as potential antibacterial agents. A series of new γ-substituted α-aceto and α-oximino γ-lactones is reported.

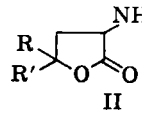
THE OCCURRENCE of the lactone ring in many physiologically active compounds has been reported throughout the literature. Of interest here are the γ- and δ-lactones with antibacterial activity.

The mechanisms by which these antibacterials exert their activity differ from one series to the next. Nevertheless, the presence of the lactone structure cannot be ignored. Patulin (1), crepin (2), the active principles of *Spiraea aruncus* (2), and *Arctium minus* (3), for example, lose their antibacterial activity after their lactone moieties are broken. Similarly the macrolide, etamycin (4), is inactivated on hydrolysis of the lactone ring. Geiger and Conn (5) theorized that, since both penicillic acid and patulin are inactivated by an excess of thiol, their antibacterial activities are probably due to the addition of the —SH groups of bacterial enzyme systems or the —SH groups of essential metabolites with the double bond of the α-unsaturated lactones. They were able to show that α,β-unsaturated ketones closely resembled patulin and penicillic acid, both in their reactivity toward thiols and in their bacteriostatic and fungistatic properties. Cavallito and Haskell (6) pointed out that these reactions appear to proceed by addition of the thiol group to the double bond, followed (in the case of the β-angelicalactone and cysteine or homocysteine) by reaction of the lactone with the amino group and loss of water. Cavallito, *et al.* (7), indicated that a series of lactone aliphatic acids of type I showed a close parallelism in the ability to inhibit growth and in their power to lower surface tension. Asano, *et al.* (8), suggested that the lactones of the γ-hydroxy fatty acids prepared by them inhibited the growth of avian tubercle bacilli through antagonism of the many fatty acids that make up the cell wall.

Since the simple lactone structure appears to confer possible antibacterial activity, the authors have chosen for their study a series of γ-substituted α-amino γ-lactones of type II. These are cyclized γ-hydroxy amino acids. It has been previously found (9) that the exchange of hydrogen atoms for hydroxyl groups in some amino acids converts them into antimetabolites. Many antibiotics (10, 11) derived from bacteria and fungi are amino acid derivatives, peptides, or polypeptides. These naturally occurring antibiotics frequently contain amino acids not found in ordinary proteins. Hence, the authors have modified the simple γ-lactone structure to α-amino acid analogs by varying R and R′ in II, providing a series of new γ-lactones as possible antibacterial agents.



I



II

Based upon analogy to published results of previous researches, a plausible route for the synthesis of a series of α-amino γ-lactones would have been through the interaction of the epoxide and diethyl acetamidomalonate as illustrated in Fig. 1. In such a manner Sudo, *et al.* (12), prepared α-acetamido-γ-butyrolactone in a 100% yield. Beasley, *et al.* (13), reacted diethyl acetamidomalonate with 1,2-epoxy-3-*o*-toloxypropane, hydrolyzed the resultant α-acetamido γ-lactone, and obtained the α-amino-δ-*o*-toloxy-γ-valerolactone hydrochloride in a 15.2% yield. Sudo, *et al.* (12), used ethanolic sodium ethoxide as a condensing medium, while Beasley, *et al.* (13), used methanolic sodium methoxide as a medium. Dakin (14) was unsuccessful in using ethanolic sodium ethoxide in condensing isobutylene oxide with diethyl acetamidomalonate, but by the use of dry sodium methoxide (with or without dioxane as a solvent) he obtained the desired product in a 50% yield.

In the initial part of this program the authors attempted to condense styrene oxide with diethyl acetamidomalonate in an ethanolic sodium ethoxide medium at room temperature, and at reflux temperature. In both cases attempts failed to isolate the α-acetamido-γ-phenyl-γ-butyrolactone, or the corresponding hydrochloride. When the reaction was carried out at room temperature, 44.2% of the styrene oxide was recovered as the β-ethoxy-α-phenylethyl alcohol resulting from the reaction of sodium ethoxide with styrene oxide; 31.5% of the diethyl acetamidomalonate was also recovered. When the reaction mixture was refluxed, the yield of β-ethoxy-α-phenylethyl alcohol was 56% and only 6% of the diethyl acetamidomalonate was recovered. In the latter case an additional 32.5% of the diethyl acetamidomalonate was recovered as glycine hydrochloride when the residue, assumed to contain the α-acetamido-γ-phenyl-γ-butyrolactone, was hydrolyzed with concentrated hydrochloric acid. Dakin (14) and Beasley, *et al.* (13), also found

† Present address: Wallace and Tiernan, Inc., 25 Main Street, Belleville 9, N. J.

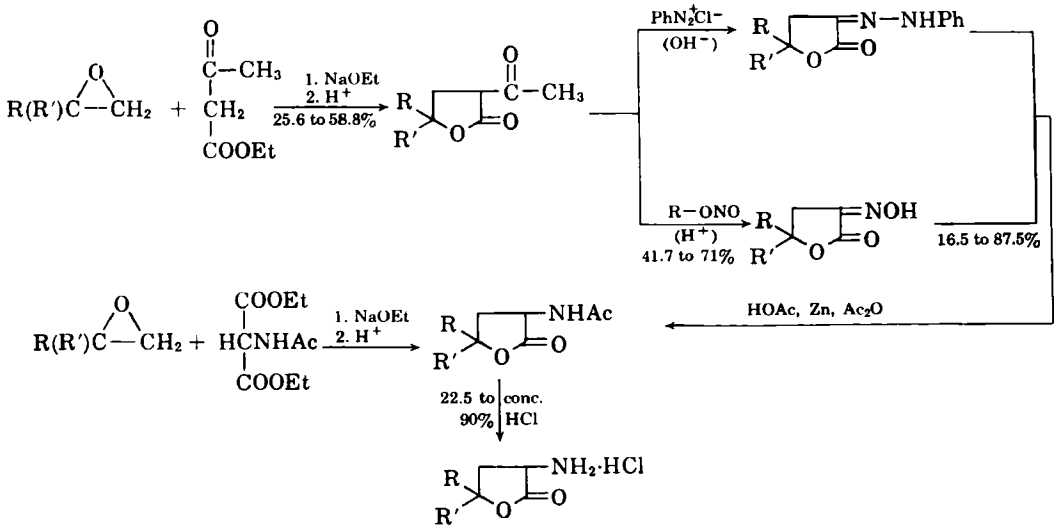

Fig. 1.—Pathways for γ-substituted α-amino γ-lactone syntheses.

that glycine hydrochloride (from hydrolysis of the unreacted diethyl acetamidomalonate) contaminated their final products, presenting some difficulty in purification.

The condensation of propylene oxide with diethyl acetamidomalonate in an ethanolic sodium ethoxide medium at room temperature yielded 3.3% of α-amino-γ-valerolactone hydrochloride on hydrolysis of the corresponding amide—36.6% of the diethyl acetamidomalonate was recovered.

In view of the apparent difficulty to reproduce satisfactorily the published success of others in condensing an epoxide with diethyl acetamidomalonate in an ethanolic sodium ethoxide medium and of the difficulty of separating the unreacted diethyl acetamidomalonate from any product formed, another route for the synthesis of γ-substituted α-amino γ-lactones was sought.

A feasible method for the preparation of these γ-lactones was found in the interaction of the epoxide and ethyl acetoacetate as illustrated in Fig. 1. Four of the α-oximino γ-lactones were not isolated. These were the γ-ethyl-, γ-butyl-γ-ethyl-, and γ-phenyl-substituted α-oximino-γ-butyrolactones, and α-oximino-δ-hydroxy-γ-valerolactone. Attempts to crystallize these oximes from the reaction mixtures failed. Since oximes are known to decompose violently when subjected to elevated temperatures no attempt was made to isolate them by distillation. Consequently the reaction mixtures containing these oximes were subjected to reductive acetylations and the α-acetamido γ-lactones were isolated in all cases except the α-acetamido-δ-hydroxy-γ-valerolactone. In the latter case, the reaction mixture was treated with concentrated hydrochloric acid and the corresponding α-amino-δ-hydroxy-γ-valerolactone hydrochloride isolated.

The yields at the various steps are indicated in Fig. 1 for all cases where the compounds were isolated. α-Acetamido-δ,δ-diethoxy-γ-valerolactone

was obtained in a 16.5% yield by the reductive acetylation of the corresponding oxime. The other six α-acetamido γ-lactones similarly prepared were obtained in 73 to 87.5% yields.

The reductive acetylation of α-keto γ-lactone phenylhydrazones was also studied as a possible method for the preparation of α-amino γ-lactones. In this study phenylhydrazones of α-keto-γ-valerolactone and α-keto-γ-phenyl-γ-butyrolactone were prepared by the Japp-Klingemann reaction from α-aceto-γ-valerolactone and α-aceto-γ-phenyl-γ-butyrolactone, respectively. The phenylhydrazones were obtained in yields comparable to the yields of oximes obtained from nitrosation reactions. However, upon reductive acetylation of these phenylhydrazones, the yields of the resulting α-acetamido γ-lactones were lower than those obtained when the corresponding oximes were similarly reduced. The most significant disadvantage of this method was the difficulty in separating the acetanilide, formed as a by-product, from the reaction mixture and the product.

α-Amino-γ-phenyl-γ-butyrolactone hydrochloride, α-acetamido-γ-valerolactone, α-amino-γ-valerolactone hydrochloride, and α-amino-γ-pentyl-γ-butyrolactone hydrochloride were screened for biological

[a] Analyses by Weiler and Strauss, Oxford, England. [b] Previously reported (17).

activity.[1] The two latter compounds showed some antibacterial activity.

EXPERIMENTAL

The chemical procedures used for the preparation of the various intermediates and products are illustrated by examples which follow.

Epoxides.—1,2-Epoxyoctane, 1,2-epoxydecane, 1,2-epoxy-2-ethylhexane, and 1,2-epoxy-3-*p*-methoxyphenylpropane were prepared according to the method described in "Organic Synthesis" (18) for preparing styrene oxide from styrene. Glycidaldehyde diethyl acetal was prepared according to the method described for preparing acrolein diethyl acetal from acrolein (19).[2]

α-Aceto γ-Lactones (see Table I).—The procedure is essentially that used by Adams and VanderWerf (15) for preparing α-aceto-γ-valerolactone, modified with features used by Van Zyl and Van Tamelen (20) for preparing α-carbethoxy-γ-butyrolactones.

To a cooled solution of 23.0 Gm. (1.0 mole) of sodium in 400 ml. of absolute ethanol (prepared in a three-necked flask equipped with a sealed mechanical stirrer and a reflux condenser fitted with a drying tube), 130.2 Gm. (1.0 mole) of ethyl acetoacetate was added rapidly. The mixture was again cooled in an ice bath and 58.1 Gm. (1.0 mole) of propylene oxide was added dropwise with stirring over a period of 30 minutes. While being stirred, the mixture was kept in the ice bath for several hours and then allowed to come to room temperature. Stirring at room temperature was continued overnight. After cooling the resulting yellow-orange solution in an ice bath to 10°, 60.0 Gm. (1.0 mole) of glacial acetic acid was added; a slurry of sodium acetate formed immediately. The ethanol was removed under reduced pressure, the temperature never being permitted to rise above 50°. Sufficient ice water was added to dissolve the sodium acetate and to separate the resulting oily layer. The aqueous layer was extracted with several portions of ether and the combined crude lactone and extracts were dried overnight over anhydrous magnesium sulfate. The ether was removed and the residue was distilled from a modified Claisen flask equipped with a 15-cm. Vigreux column. Yield was 83.5 Gm. (58.8%) of a colorless oil, b.p.$_2$ = 84–86°, n_D^{25} = 1.4525; reported (15) b.p.$_2$ = 88–90°, n_D^{25} = 1.4489.

α-Oximino γ-Lactones (see Table II).—All of the oximes were prepared by the procedure described for α-oximino-γ-valerolactone: a stream of dry hydrogen chloride gas was introduced for 30 seconds into 60 ml. of cold (0 to −5°) absolute methanol in a three-necked flask, fitted with a mechanical stirrer and thermometer, protected with a drying tube, and surrounded by a freezing mixture. To the methanolic hydrogen chloride solution was added 14.2 Gm. (0.1 mole) of α-aceto-γ-valerolactone. To the cold (0 to −5°) mixture 9.4 Gm. of *n*-propyl nitrite was added dropwise, with stirring, at such a

[1] The authors thank Mead Johnson and Co. for having gratuitously screened these compounds for biological activity.

[2] A sample of glycidaldehyde was provided by the Shell Development Co. 1,2-Butylene oxide was provided by The Dow Chemical Co., glycidol by Roberts Chemicals, Inc.

rate that the temperature did not rise above 0°. On addition of the *n*-propyl nitrite the reaction mixture immediately turned blue. The mixture was maintained at 0° for several hours and was then placed in a refrigerator (5°) overnight. At this point the reaction mixture had assumed a pale yellow color. The methanol and excess *n*-propyl nitrite were removed under reduced pressure with the aid of moderate heat from a water bath. The resulting yellow oil crystallized into a solid mass. This was recrystallized from benzene to give 9.1 Gm. (71.0%) of α-oximino-γ-valerolactone. A sample for analysis, three times recrystallized from benzene, melted at 106–107°.

α-Acetamido γ-Lactones (see Table III).—The procedure used by Fillman and Albertson (21) for the preparation of α-acetamido-γ-butyrolactone was followed as described for α-acetamido-γ-valerolactone. To a solution of 12.9 Gm. (0.1 mole) of α-oximino-γ-valerolactone in 250 ml. of glacial acetic acid and 100 ml. of acetic anhydride 30 Gm. of zinc dust was added portionwise while stirring. The zinc was added at such a rate as to maintain the temperature of the reaction mixture of 50°. After addition of the zinc the temperature was maintained at 50° by applying heat. At the end of 9 hours the warm reaction mixture was filtered. The filtrate was concentrated under reduced pressure and the product distilled at 140–155° at 2 mm. of Hg to give 11.7 Gm. (74.5%) of a clear, slightly yellow, viscid oil, $n_D^{27} = 1.4820$.

α-Amino γ-Lactone Hydrochlorides (see Table IV).—All of the hydrochlorides were prepared by the procedure described for α-amino-γ-valerolactone hydrochloride. A mixture of 5.88 Gm. (0.0375 mole) of α-acetamido-γ-valerolactone and 40 ml. of concentrated hydrochloric acid was refluxed for 5.5 hours. The reaction mixture was then evaporated to dryness under reduced pressure. The crystalline residue was digested with 7 ml. of absolute ethanol, cooled, and the crystals removed by filtration to yield 2.68 Gm. (47%) of the product, m.p. 194–198°. After three recrystallizations from absolute ethanol, the hydrochloride melted at 200–201°; reported (17) m.p. 198–200°.

Gravimetric Evaluation of Paper Chromatograms I

Theory, Instrumentation, and Procedure

By ALBERT E. H. HOUK

Theory, instrumentation, and procedure are given for the gravimetric determination of the distribution of compounds over an entire paper chromatogram. After the chromatogram is developed, the paper is cut into a series of $^3/_{16}$-in. strips at right angles to direction of development. The portion of the sample on each strip is eluted into a tared cup. The results are graphed, using the weights of the dried residues in the cups as the ordinates and the number of the strips from the bottom of the chromatogram as the abscissas. This procedure permits the quantitation and isolation of components in low concentrations which may be missed by conventional methods of detection and eliminates the need for a reference standard for quantitative evaluation. The isolated fractions may be used for additional studies.

PAPER CHROMATOGRAPHY has been used successfully for the separation and determination of chemicals in almost every field of science. Most of the standard procedures are inadequate since unknown impurities present may escape detection if they do not respond to the test used to detect the major components of the mixture. In many cases, the quantitative evaluation of the results is based on a visual comparison with reference standards (1–4).

In investigations in this laboratory of the purity of some U.S.P. reference standards and commercial drugs, these limitations of paper chromatography have been overcome by rapidly eluting fractions covering the entire paper chromatogram and by weighing the dried fractions obtained. The theory, instrumentation, and procedures developed and used during the past 3 years for obtaining weight-distribution curves from paper chromatograms are given. The application of the procedure to ouabain, other glycosides, and prednisone is presented in another paper (5).

THEORY

A solution of Sample A (Fig. 1) was streaked on the starting line, and the paper chromatogram developed by ascending technique in a sealed tank or by the continuous process (6). Where possible, volatile solvents were used as the mobile and immobile phases. Sample A was separated into four apparent components: *a*, *b*, *c*, and *d*. The chromatogram was cut into a series of narrow strips parallel to the starting line but were held together at the left edge by an uncut area. Components on the strips were eluted simultaneously into tared Teflon[1] cups. The solvent was evaporated, and the weight of the residue in each cup was determined. The results were graphed, using the weights of the residues as the ordinates and the number of the strip (counting from bottom of paper) as the abscissas. Usually, inflections obtained over those given by blank chromatograms indicated the presence of a component of the mixture, and its quantity was the sum of the weights from the strips producing the inflection less the weight given by the blanks or overlapping components.

The weight-distribution curve of Sample A shows that components *a*, *c*, and *d* were successfully isolated in a relatively pure form. The curve obtained for *b*, however, indicated the presence of more than one compound. The residues from the fractions in this area were combined, and a better separation of the components was achieved on another chromatogram with a modified solvent system.

INSTRUMENTATION

Sample Applicator Box (A, Fig. 2).—To prevent excessive evaporation of the more volatile immobile solvents from the chromatographic paper during application of sample to the starting line, a box of the following design is used: the box is 11 × 18 in. inside dimensions, and 5 in. in height at the sides and back; the front of the box is $4^1/_4$ in. in height, extending within $^3/_4$ in. to the top of the sides.

Place a crosspiece 4 in. from the inside front of the box and extending within $1^1/_2$ in. to the top. Inside and near the bottom of the front compartment thus formed, install two light sockets to take 25-watt light bulbs for back-lighting the starting line. Immediately above the light bulbs, insert a glass plate for heat insulation. Cut a groove around the inside periphery of the box $1^1/_2$ in. below the top and extending through the front panel to allow for the introduction of a glass plate to support the chromatographic paper. To prevent paper from adhering to the glass plate, it has been found advisable to cover the plate with a sheet of 100-gauge Teflon film[2] which can be replaced as needed. Place two $^5/_{16}$-in. glass rods (covered with closely fitting

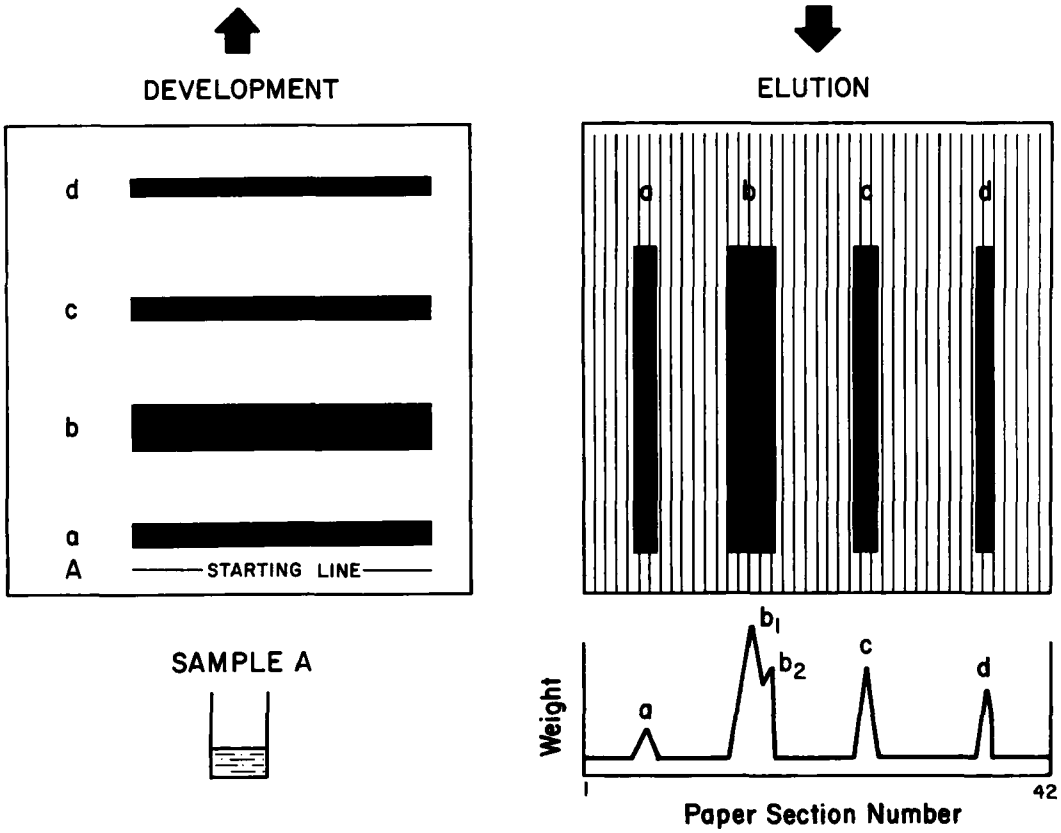

Fig. 1.—Determination of a weight-distribution curve of a paper chromatogram.

spaghetti tubing,[3]) 1/8 in. above the upper glass plate and 1 and 3 in., respectively, from the inside front of the box. Suspend these rods in the U-slots of two brackets made of 1/8-in. metal and fastened to the sides of the box. Cut grooves in the sides and back of the box 1/2 in. below the top to permit the introduction of a cover made from 1/16- in. aluminum sheet. Near the front of the cover, a slot 1/4 in. wide and 10 in. long is made so that (with the cover in position) the slot is midway between the glass rods. Fasten cross ribs to support blotting paper wetted with a suitable solvent to the underside of the cover. Mount the box on 3/4-in. thick blocks at each corner for ventilation.

Cutting Equipment (B, Fig. 2).—As a guide to be used in cutting the chromatogram, make a template 6 1/8 × 12 in. from 3/16-in. hardened aluminum plate. Using a milling machine equipped with a 1/32-in. circular saw, cut thirty 10-in. slots through the plate at 3/16-in. intervals, leaving a 1/2-in. border at the left and a 1-in. border at the top and bottom. With a scriber, make two guide lines at the top of the plate, perpendicular to and 3/8 and 1/2 in., respectively, below the top of the slits. Through the upper line, drill six 7/64-in. holes, approximately evenly spaced across the plate so that the top of the chromatogram can be brought even with the top line. Sometimes difficulties may be enountered in sawing the slots in the plate. In this case, several smaller sections (satisfactorily made) can be fastened together with metal strips at the top and bottom.

Place the paper and the template on a hardwood cutting board. Place two metal bars across the top and bottom of the template and bolt the extremities of the bars to the board to prevent the movement of the template during use. The bars should be long enough to permit the template to be moved across the entire width of the paper.

Weighing Cups (C, Fig. 2).—The weighing cups are made from disks of 50-gauge Teflon film 1 1/4 in. in diameter. Using a film 2 in. in width, attach the end of the film with adhesive tape to a cardboard strip 1 1/2 in. in width and make 50 superimposed layers of film around the strip. Fasten the end of the film with adhesive tape to the top layer on the cardboard. Place the cardboard strip with film between two sheets of bond paper and lay on a 1/4-in. sheet of polyethylene. Cut a block of disks using a 1 1/4-in. steel punch.

The molds for forming the cups are made from 13 1/2 × 2 7/8-in. strips of 1/2-in. hardened aluminum plate. Starting with the centers 2 1/4 in. from one end and 3/4 in. from either side of the strip, inscribe two parallel rows of nine 1 1/4-in. circles. At the center of each circle, drill a 15/32-in. hole through the plate. Remove sharp edges of the holes by reaming. For molding cups, make cylindrical plugs from 1/2-in. aluminum rod reduced in diameter on a lathe until it and a Teflon disk can be fitted easily but firmly into the holes of the mold. Cut plugs

[3] Teflon tubing, Pennsylvania Fluorocarbon Co., Inc. Philadelphia 4, Pa.

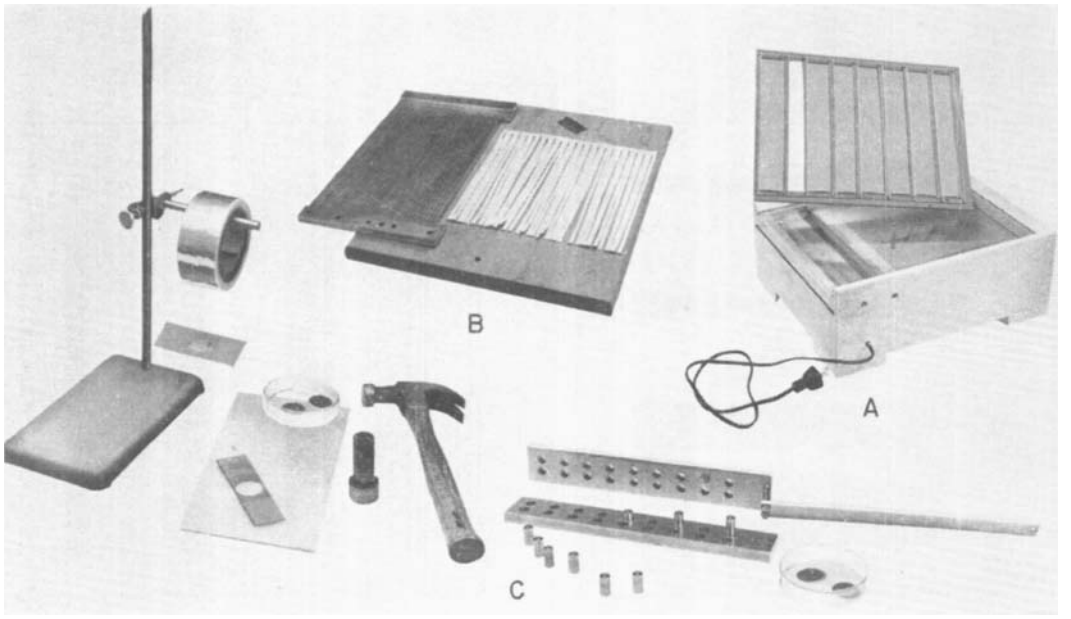

Fig. 2.—*A*, Sample applicator box; *B*, equipment for cutting paper chromatogram; and *C*, equipment for making Teflon weighing cups.

7/8 in. in length from the rod and round the edges with a cutting tool and a fine file. Polish both the holes of the mold and the plugs consecutively with 200-mesh aluminum oxide and talc wetted with alcohol.

To handle the hot molds, drill two 5/16-in. holes, 5/8 in. apart, 1/4 in. from the clear end of the mold. Make a detachable handle from a 14 × 1-in. strip of 1/4-in. aluminum. Attach to it two 1/4-in. brass rods so placed as to fit into the holes at the end of the mold.

Analytical Balance.—Balances with a suitable counterbalancing device and a sensitivity of 1 mcg. can be used for weighing the cups. The Cahn gram electrobalance[4] is satisfactory. However, an experimental automatic model 1700 AH electrobalance[4] (*A*, Fig. 3) developed for this study simplifies the weighing procedure greatly. This balance is connected to a precision four-digit voltmeter[5] which automatically indicated the weight. A 500-μc. radioactive ionizing unit is placed inside the weighing chamber to aid in the weighing of cups having a static charge. When weighing hygroscopic residues, two 5-ml. beakers containing P_2O_5 desiccant are placed in the weighing chamber.

Multifraction Elutor (B, C, Fig. 3).—The details of the construction of the component parts of the elutor canot be described adequately in a presentation of this type. Detailed drawings and instructions for making the complete elutor are available upon request to the author. The following is a functional description of this part of the equipment.

The assembled elutor is represented by *B*, Fig. 3. In *C*, Fig. 3, the elutor is pictured partly disassembled to show the component parts. The rigid frame work of the elutor consists of two sides and a bottom made of hardened aluminum plate. A crosspiece placed on either side lends rigidity to the sides Two bars are fastened to the bottom plate to prevent tipping.

A spacer bar (4, Fig. 3) made of extruded aluminum tee is used to hold the paper in position. The leg of the tee is sharpened to a wedge shape; the base of the tee is cut to have 21 slots on each side so positioned to accommodate the strips of paper. The spacer bar is placed on shelves fastened to the inside of the frame.

A cup holder (2, Fig. 3) containing four staggered rows of 12 holes each is placed on the bottom of the frame. The ends of the paper strips are held immediately above the proper cups by a needle rack (3, Fig. 3) fastened to the median line of the cup holder. To decrease the possibility of creeping of the eluting solvents, the cup holder and needle rack are coated with a TFE-fluorocarbon resin primer.[6] A flat heating element connected to the electric receptacle on the side of the frame is placed in the base of the frame under the cup holder to aid in the evaporation of the solvent collected in the cups.

A syringe rack (6, Fig. 3), carrying twenty-one 1-ml. syringes in two staggered rows, is mounted on each side of the frame. When in position, the tip of each syringe is in contact with a strip of paper. The plungers of the syringes are moved by crosspieces which are driven by a demountable clock motor and gears (8, Fig. 3).

To prevent the evaporation of volatile eluting solvents from the paper, two side panels (5, Fig. 3), equipped with metal ribs to hold sheets of blotting paper wetted with the solvent, are placed in grooves in the sides and base of the frame. A lid (7, Fig. 3) with a silicon rubber gasket is also provided so that with the side panels, the syringe racks, and the lid in place, the elutor is essentially airtight.

PROCEDURE

Preparation of Cups.—Using disks prepared as described in the preceding section, center a disk in each of the circles on the mold. Form the cups by pushing the disks into the holes with the cylindrical plugs and leave the plugs in place. Using the mold handle, place the mold on its side in a muffle furnace at 365°. Avoid movement of plugs while the mold is hot. After 17 minutes, remove the mold, cool at room temperature for 5 minutes, then quench with cold water. Rinse the mold with 95% alcohol, remove plugs, and separate cups. Cups are usually made in lots of 1,000 and sorted by weight into groups covering a 1-mg. weight range.

The plug and plastic disk should fit snugly into the hole in the mold to prevent the plug from falling out and to assure bonding of the folds in the sides of the cup. If the plug is too large, it may stretch or tear the plastic disk. The heating time can be varied to achieve good bonding of the folds and to prevent the film from adhering to the mold. Detect improper bonding of the folds or the presence of small leaks by placing a few sample cups on a piece of absorbent paper and half filling each cup with methanol. Press the cups firmly against the absorbent paper with a smooth glass rod. Dry the rod and rotate it around the outside of the cups. If the rod adheres to the outside of the cup or a moist spot appears on the paper, a breakage of the film is indicated. Place a few crystals of a methanol-soluble fluorescent material in the cup and allow the solvent to evaporate overnight at room temperature. Appearance of capillary streaks up the sides of the cup or the presence of fluorescent material on the outside of the cup when it is examined under ultraviolet light indicates poor bonding or breakage of the film. Repetition of this test is unnecessary when satis-

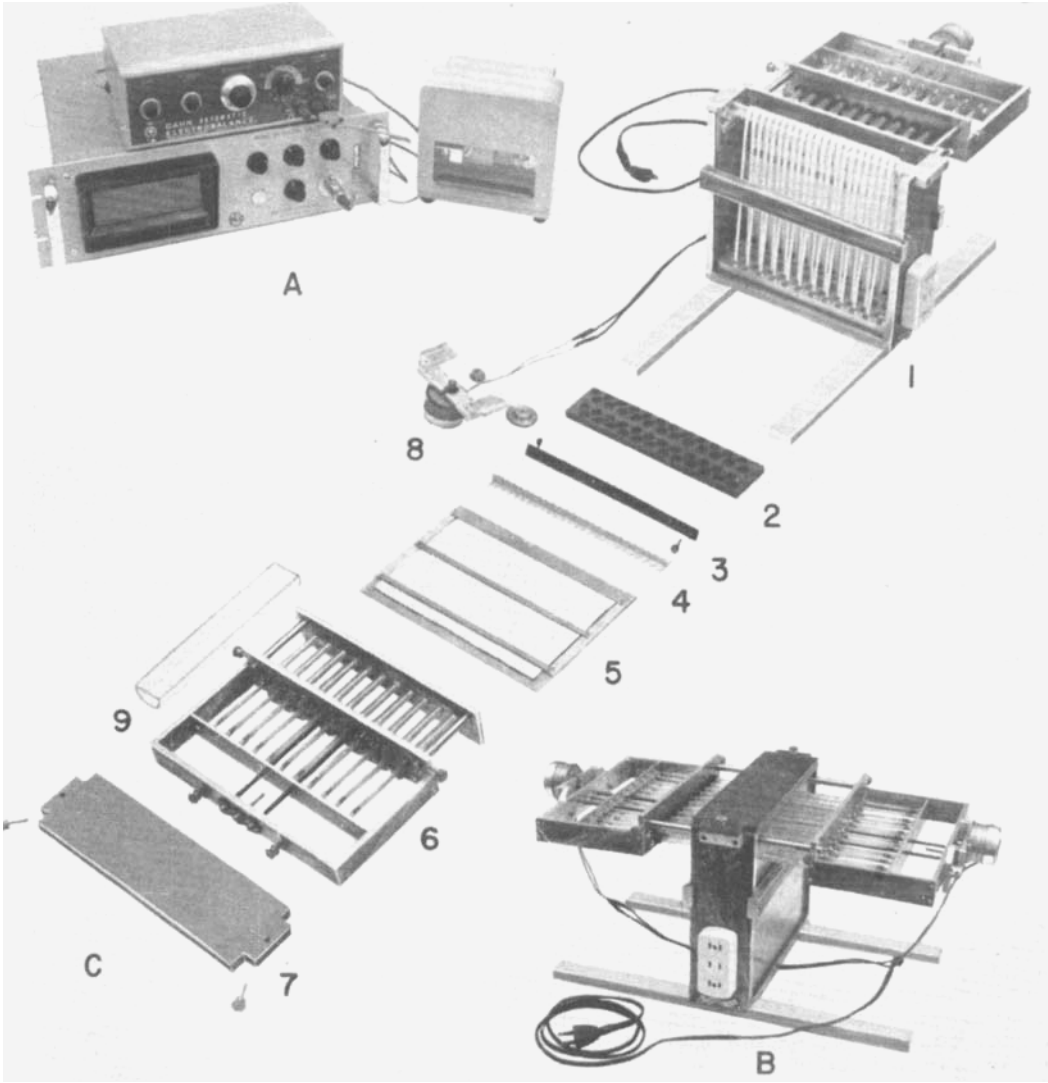

Fig. 3.—*A*, Automatic electrobalance with digital voltmeter; *B*, assembled; and *C*, breakdown view of multifraction elutor showing: 1, elutor with one side removed; 2, cup holder; 3, needle rack; 4, spacer bar; 5, side panel; 6, syringe rack; 7, lid; 8, motor with supporting frame; 9, glass trough.

factory conditions for producing suitable cups have been established.

Push the bottom of the cup outward by gentle pressure with a forceps so that the cups will rest securely on the balance loop. Immerse the cups successively in water, acetone, and petroleum ether; dry for 2 hours at 120° and store in a desiccator.

Preparation of Chromatographic Paper.—Draw lightly (with a lead pencil) a starting line 1 in. from the bottom of the paper, beginning $2^1/_2$ in. from the left edge and ending $^3/_4$ in. from the right edge of the paper.

Chromatographic paper may contain substances which will be removed by the eluting fluid and influence the weight of material determined. In most instances the major portion of these substances can be removed by successively washing the paper by descending chromatography with a solution of nitric acid in water (1–500), water, 95% ethanol, acetone, and petroleum ether. Dry the paper at room temperature and store to prevent contamination with dust or exposure to ammonia or other fumes. The procedure for washing the paper may be varied to suit the requirements of the problem.

Sometimes the successful separation of components of a mixture will require the addition of a chemical to act as an immobile phase. Since these chemicals may be removed from the paper by the eluting solvent, they should (whenever possible) be volatile or insoluble so that they will not contribute to the weight of the material in the cup after drying. When a nonvolatile substance is desirable as an immobile phase and it is soluble in the eluting solvent, correction for its weight may be possible through the use of a blank or from analysis of the residues in the cups. To prevent the contamination of the paper through handling following the application of the immobile phase, attach a glass rod to the top edge of the paper with Teflon-coated clips. This rod should be of the length required to support the paper in the development tank. After the paper has been saturated with the immobile phase, it is allowed to drain without blotting.

Application of Sample to the Paper.—Place the prepared paper in the applicator box (*A*, Fig. 2) with the starting line supported by the rods and immediately beneath the slit in the top of the box. If the paper carries a volatile material as the immobile phase, prevent excessive evaporation by wetting the blotting paper in the top of the box with the same material.

Weigh the desired quantity of the sample into a tared Teflon cup and dissolve in about 0.3 ml. of solvent. Using a weighed capillary tube with a fire-polished tip, transfer the sample solution to the paper by repeatedly streaking it uniformly along the entire length of the starting line. Rinse the cup and tube by adding two successive portions of about 0.1 ml. of the solvent and streak the resulting solutions on the starting line. The cup and the capillary tube are dried with the cups from the elution apparatus and reweighed to determine the weight of sample placed on the paper. Remove the paper from the box and evaporate the solvents used to dissolve the sample and the immobile phase by air drying in a hood briefly.

Development of Chromatogram.—The chromatogram may be developed by ascending chromatography using either a sealed tank or the continuous slit technique (6). If the latter technique is used, coating of the slit in the cover of the chamber with TFE-fluorocarbon resin primer[6] prevents the developing solvent from depositing some of the sample on the cover. Reattach the glass rod to the top of the paper after development. Remove the paper from the tank and evaporate excess mobile solvent by air drying in a hood. If the paper is to be cut after drying, wrap the paper loosely in Teflon-resin-coated aluminum foil and complete the drying in a vacuum oven. If the paper is to be cut while wet, place it between two Teflon sheets prior to cutting.

Cutting of the Paper.—Using the cutting equipment (*B*, Fig. 2), the paper is cut into strips at right angles to direction of development. Place the chromatogram and the template on the hardwood cutting board so that the right-hand edges coincide and the top edge of the paper is centered in the holes of the upper guideline of the template. Place the metal bars across the template to hold it in position. With either razor or surgical blades (the latter being preferred), cut paper into strips starting at the lower guideline. Any fractional strip remaining at the bottom of the chromatogram may be discarded.

Elution.—The required number of cups with a weight range of not more than 1 mg. are weighed to the nearest mcg. by counterbalancing and placed in the holes of the cup holder. Extra holes in the cup holder not required by the number of strips to be eluted can be used for controls which are desired. Attach the needle rack to the cup holder and place the holder in the elution apparatus.

With the aid of forceps, insert a $^1/_8$-in. aluminum rod immediately below the uncut portion of the chromatogram so that adjacent strips are on alternate sides of the rod. If Teflon sheets were used in cutting the chromatogram, they are now removed. With the aluminum rod, transfer the chromatogram to the spacer bar. When in position, adjacent strips should be on alternate sides of the spacer bar and in the appropriate slits. The tip of the strips should be about $^1/_8$ in. above the top of the cups. Adjust this distance by placing aluminum strips between each shelf and the ends of the spacer bar. Draw each strip taut and center it in front of the corresponding needle with metal forceps. Using a thin-walled glass tube of about $^1/_8$ in. in diameter, push the paper on the needle until the strip is centered over the cup.

The strips have a tendency to sag and buckle when wet with some eluting solvents. To prevent this, raise the spacer bar further by placing an additional metal strip $^1/_8$-in. thick between each end of the bar and the shelves. Thus the weight of the suspended cup holder exerts a constant tension on the strips.

Adjust the position of the movable crosspiece in each syringe rack so that the plungers can be pulled out slightly past the 1-ml. mark. Loosen the knurled knobs on the sides of the syringe rack, move the front plate back so that the ends of the syringes protrude about 1 in. from its face, and retighten the screws. Fill the trough (9, Fig. 3) with the eluting solvent. Immerse the ends of the syringes in the solvent. Remove the air in the syringes by filling and discharging the solvent. Finally, fill each syringe by drawing out the plunger until it is in

contact with the movable bar. Readjust the front plate of the carrier so that the syringes protrude about 1/2 in.

Moisten the blotter paper in the side panels with eluting solvent and put them in place. Insert the syringe racks into the appropriate slots and adjust so that the tips of the syringes are in firm contact with the centers of all strips. Attach the lid and the motor assemblies.

The motors are started after about 10 minutes to permit the partial saturation of the air in the elutor with the solvent. The time of elution can be varied by using different gears on the motor assembly. A short elution period is desirable with highly volatile, nonpolar solvents. The elution process can be automatically stopped when the plungers are near the bottom of the syringe barrel by powering the motors through a timer.

After allowing the solvent to drain from the strips into the cups for 10 minutes, remove the lid and the motor assemblies of the elutor. Adjust the syringe rack so the ends of the syringes will clear the spacer bar; remove the racks and the side panels. Evaporate the more volatile solvents by connecting the variable heater in the base of the elutor. Detach the needle rack from the cup holder and remove the spacer bar with attached paper and needle rack. Retain this assembly for additional studies which are indicated. Complete the drying of the cups by loosely wrapping the cup holder in aluminum foil and placing it in a vacuum oven. After drying, cool the cup holder to room temperature in a desiccating cabinet and reweigh the cups. Treat the results as indicated in the section on *Theory*.

Gravimetric Evaluation of Paper Chromatograms II

Studies on Ouabain, Other Glycosides, and Prednisone

By ALBERT E. H. HOUK

Results are reported on the analyses of milligram quantities of some pure and crude steroid preparations. Samples are chromatographed on paper, and the entire sheet is rapidly eluted by a previously described technique. Components, in concentrations of 0.2 per cent or less, can theoretically be separated and detected. This technique may be found of equal benefit in the study of other compounds which can be separated by paper chromatography.

ANALYSES of steroid preparations by paper chromatography have been impeded by the difficulty in locating, rapidly eluting, and quantitating all components separated. This led to the development in this laboratory of new instrumentation and procedures reported previously (1). Results of some applications of this technique to steroid analyses are now given.

EXPERIMENTAL

Solvents

Neutral, readily volatile solvents were used. All solvents were percolated rapidly through a column of anion-cation exchange resin.[1] The first effluent through the column was discarded; the remainder was collected and redistilled. Formamide was redistilled under vacuum and stored in a desiccator over sulfuric acid until free of ammonia. Constant boiling fractions were returned to their original glass containers. Teflon[2] liners were placed in each bottle cap.

Chromatographic Paper

Whatman No. 3-mm. chromatographic paper in 8 × 8-in. sheets was ordinarily used. When required, 8 × 11 1/4-in. sheets were cut from a 23-cm. roll. Guidelines for streaking and development of paper were marked on all sheets; the paper was washed, dried, and stored (1).

Equipment

(*a*) Thomas-Mitchell chromatographic tank assembly with glass rods, troughs, and continuous technique accessories[3] was used with 8 × 8-in. sheets. The slotted cover and clips were coated with Teflon (1). (*b*) Thomas-Kolb chromatographic jar[3] was used with 8 × 11 1/4-in. sheets. A double-slotted cover, similar to the above accessory, was made for the jar and was coated with Teflon. (*c*) Two Pyrex 3-quart utility baking dishes,[4] each 9 1/4 × 14

contact with the movable bar. Readjust the front plate of the carrier so that the syringes protrude about 1/2 in.

Moisten the blotter paper in the side panels with eluting solvent and put them in place. Insert the syringe racks into the appropriate slots and adjust so that the tips of the syringes are in firm contact with the centers of all strips. Attach the lid and the motor assemblies.

The motors are started after about 10 minutes to permit the partial saturation of the air in the elutor with the solvent. The time of elution can be varied by using different gears on the motor assembly. A short elution period is desirable with highly volatile, nonpolar solvents. The elution process can be automatically stopped when the plungers are near the bottom of the syringe barrel by powering the motors through a timer.

After allowing the solvent to drain from the strips into the cups for 10 minutes, remove the lid and the motor assemblies of the elutor. Adjust the syringe rack so the ends of the syringes will clear the spacer bar; remove the racks and the side panels. Evaporate the more volatile solvents by connecting the variable heater in the base of the elutor. Detach the needle rack from the cup holder and remove the spacer bar with attached paper and needle rack. Retain this assembly for additional studies which are indicated. Complete the drying of the cups by loosely wrapping the cup holder in aluminum foil and placing it in a vacuum oven. After drying, cool the cup holder to room temperature in a desiccating cabinet and reweigh the cups. Treat the results as indicated in the section on *Theory*.

× 2½-in. and covered with a glass plate, were used to hold the immobile solvent during impregnation of the paper. (*d*) A drying rack similar to the commercial item[3] but 17 in. high; (*e*) desiccating cabinet[3] with glass trays and phosphorus pentoxide desiccant; (*f*) disposable plastic gloves[3] for handling the paper; (*g*) capillary melting point tubes,[5] each 1.2 mm. × 8 cm.-size and approximately 114 mg. weight. A 2-cm. section was broken off each and discarded; the remainder was fire polished. (*h*) Aluminum rod ⅛ × 10 in. was used to handle the cut chromatogram. (*i*) Thin-walled glass tube ⅛ × 6 in. was used to attach ends of paper strips to needle rack. (*j*) Sample applicator box, paper chromatogram cutting equipment, Teflon weighing cups, microbalance, and elutor apparatus (1).

General Procedure

Conclusions drawn from data obtained by this procedure are usually based on weights of small magnitude. Consequently, it is essential that precautions be taken to avoid nonvolatile contaminants. Glassware should be washed with chromic acid cleaning solution, thoroughly rinsed, drained, and stored in a dust-free cabinet. When in use, the equipment should be protected as far as possible from such contaminants as dust, fingerprints, chemical fumes, etc. The use of polyethylene gloves has been found helpful.

For initial quantitative analyses, three approximately equal aliquots of a sample were weighed in Teflon microcups. The first aliquot was used for gravimetric paper chromatography as previously described (1); the second aliquot was used to prepare a standard reference solution; the third aliquot was used as a control. To it and also to an empty, preweighed Teflon cup were added immobile, mobile, and eluting solvents equivalent approximately to that from an eluted paper strip. These cups were dried later with the cups from the elution apparatus and reweighed to determine nonvolatile components in solvents used, efficiency of drying, and weight changes of sample during processing. Chemical studies were conducted on solutions (equivalent to the reference solution) made from the residues in these cups and from the residues of the eluted fractions and the corresponding blank chromatogram. Thus both the recovery by weight and the recovery by chemical analysis of the fractions isolated were determined. Weighable residues remaining in the cup and capillary tube (after transfer of the sample to the paper for chromatography) were determined chemically also. Once a procedure for a sample was established, unnecessary control work was eliminated. Often the average of the blank areas of a sample chromatogram, eliminating the solvent front, was used to calculate the weight of the "fractions" above the "background weight."

Dry weight of the sample placed on the paper for fractionation normally agrees with summation of the dry weights of fractions isolated. If results indicate incomplete elution, the same chromatographic paper may be re-extracted, with the same or different solvent, into the same cups. Increases in weight of residue over increased blank confirm initial incomplete elution. There is no limit to the number of times the paper may be re-extracted, provided the solvent is evaporated between each operation. Further indication of the completeness of the extraction can be obtained by drying and dipping or spraying the eluted chromatogram with a developing reagent. Any fluorescence or color on the paper, characteristic of the sample and usually near the bottom of the strips, indicates incomplete elution.

The Teflon cups used to collect the fractions are chemically inert to most chemicals. Spot tests often were done directly in each cup. The cups were placed also in separate test tubes and color reactions completed there without transfer of residue.

Ouabain (Sample A).—Sample—7.556 mg. commercial ouabain (20.2% water) dissolved in water-methanol (1 + 2). Paper size—8 × 11¼ in. Immobile solvent—*n*-butanol-saturated water in meth-

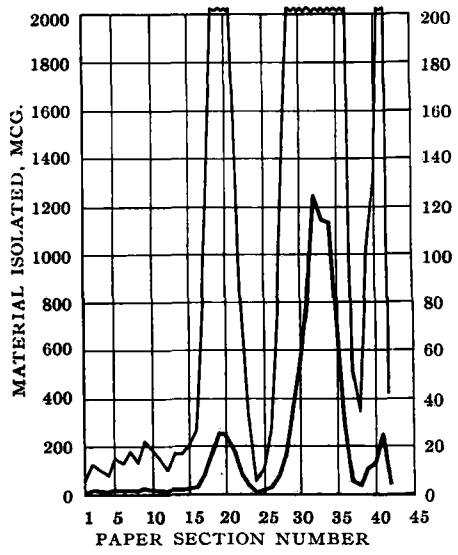

Fig. 2.—Weight-distribution curve of commercial ouabain (Sample B).

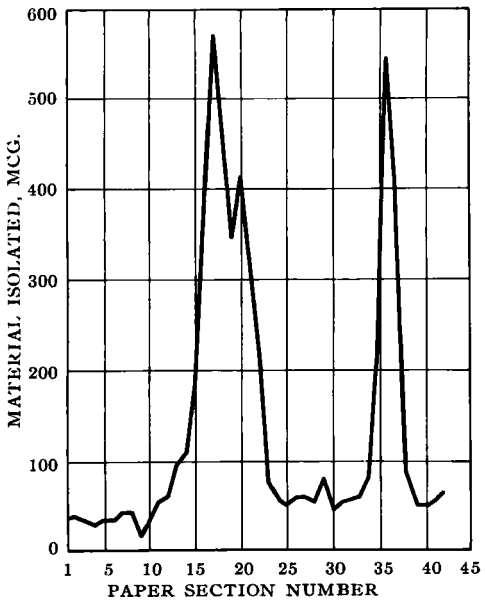

Fig. 3.—Weight-distribution curve of a mixture of ouabain, K-strophanthoside, and strophanthidin.

anol (3 + 1). Mobile solvent—water-saturated *n*-butanol. Development—20 hours at 28° by continuous ascending slit technique. Chromatogram—vacuum dried at 105° for 1 hour and cut into 59 strips. Elution—50% ethanol for 80 minutes. Drying—eluting solvent evaporated at 28° overnight (2), and residues vacuum dried in the presence of P_2O_5, at 130° for 5 hours.

Ouabain (Sample B).—Sample—9.999 mg. commercial ouabain (19.3% water) dissolved in water-methanol (1 + 2). Paper size—8 × 8 in. Immobile solvent—*n*-butanol-saturated water in acetone (1 + 1). Other techniques were as given under *Ouabain (Sample A)*, except the chromatogram was cut into 42 strips.

Mixture of Glycosides.—Sample—approximately 2 mg. each of ouabain (20.2% water), K-strophanthoside (strophosid; 4% water), and strophanthidin dissolved in methanol. Paper size—8 × 8 in. Immobile solvent—*n*-butanol-saturated water (paper was air dried until it appeared damp). Mobile solvent—water-saturated *n*-butanol. Development—to finish line by ascending technique in a sealed tank (approximately 4 hours at 28°). Chromatogram—vacuum dried at 105° for 1 hour and cut into 42 strips. Other techniques were as given under *Ouabain (Sample A)*.

Strophanthin K.—Sample—approximately 10 mg. commercial strophanthin K dissolved in water-methanol (1 + 2). Other techniques were as given under procedure for *Mixture of Glycosides*.

Digitoxin.—Sample—approximately 5 mg. commercial digitoxin dissolved in methanol-chloroform (1 + 3). Paper size—8 × 8 in. Immobile solvent—35% formamide in acetone. Mobile solvent—benzene-chloroform (1 + 1). Development—to finish line by ascending technique in a sealed tank (approximately 1 hour at 28°). Chromatogram—dried in a stream of air at 105° for 45 minutes and cut into 42 strips. Elution—50% aqueous pyridine for 60 minutes. Drying—solvent evaporated and residue dried in vacuum at 130° for 2 hours.

Prednisone.—Sample—approximately 3 mg. commercial prednisone dissolved in chloroform. Paper size—8 × 8 in. Immobile solvent—40% formamide in methanol. Mobile solvent—petroleum ether-chloroform (1 + 2). Development—2 hours at 28° by continuous ascending slit technique. Chromatogram—vacuum dried at 105° for 1 hour and cut into 42 strips. Elution—95% ethanol for 60 minutes. Drying—solvent evaporated and residue dried at 105° for 5 hours.

RESULTS

Figures 1 and 2 show the quantitative weight-distribution curves of two samples of ouabain. These are the purest and the most contaminated of eight samples examined for selecting reference standard material and evaluating the chemical assay procedures in current use. The left ordinate of each graph is for the lower curve, the right ordinate for the ten-fold expanded upper curve. The latter shows small weight variations in the base line.

On a dry weight basis, ouabain (Sample A) was recovered 100 ± 1% in the main fraction. Its "weight background" or base line averaged 22 mcg. per cup with extreme variations of ±8 mcg. The material recovered from the solvent front, where evaporation took place for 20 hours during development, weighed 81 mcg. A blank chromatogram gave an equivalent baseline and solvent front. On the basis of alkaline picrate color reaction (3), 99.5 ± 0.5% of the active component was recovered in the main fraction. The solvent front contained no chromogenic material. The extracted dried chromatogram sprayed with zinc chloride reagent (3) was negative.

With Sample B, 81.5 ± 1% of the starting material was recovered on a dry weight basis from the main fraction. When the alkaline picrate color reaction was applied to the unchromatographed material, the results indicated the presence of 87.4 ± 0.5% of ouabain. However, impurities less polar than ouabain and equal to 5.0% of the sample subjected to chromatography were found superimposed on the solvent front. This fraction gave a strong re-

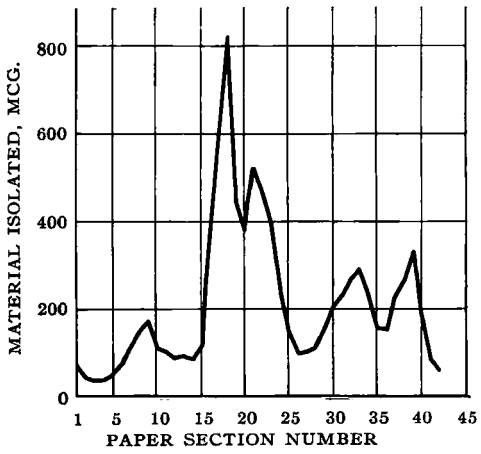

Fig. 4.—Weight-distribution curve of commercial strophanthin K.

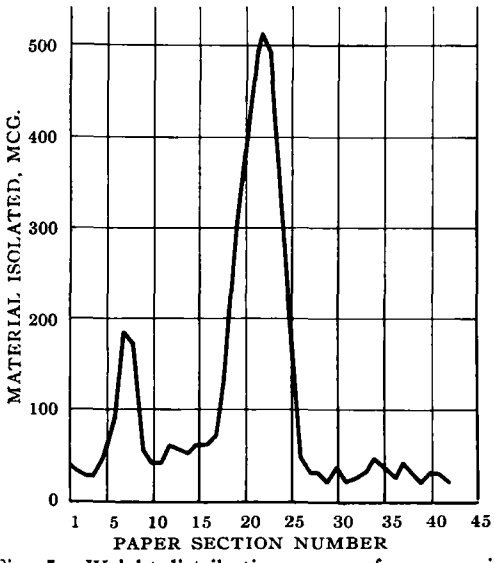

Fig. 5.—Weight-distribution curve of commercial digitoxin.

action with the alkaline picrate reagent and thus was included in the colorimetric assay of the unchromatographed sample. In addition to the above, impurities more polar than ouabain accounted for 13.4% of the dry weight of sample and gave little alkaline picrate color but had a strong anthrone color reactivity. We have occasionally observed the type of asymmetry seen at the apex of the main fraction. It usually disappears in subsequent weight-determination curves and may be associated with the physical characteristics of the zone and the finite width of the paper strips. The two examples cited above are typical of the quantitative recoveries which can be achieved by this technique.

Figures 3–6 show the type of general information that may be obtained from rapid qualitative weight-distribution measurements. Figure 3 shows the weight-distribution curve of a synthetic mixture of ouabain with two other glycosides, K-strophanthoside and strophanthidin. This figure illustrates the curve characteristics under two extreme conditions: (*a*) when a component is at or near the solvent front, and (*b*) when two components overlap. Strophanthidin (very close to the solvent front) gave a typical sharp inflection, indicating a buildup behind the solvent line. K-strophanthoside (slightly ahead of ouabain) easily showed its presence by a very sharp inflection above the ouabain background. A similar chromatogram when dried, sprayed with zinc chloride reagent, and viewed under ultraviolet light, showed only one fluorescent band for the ouabain-K-strophanthoside fraction. Where required, the fraction containing such an overlapping mixture could be rechromatographed, using a solvent system which would give a complete separation of the components.

Figure 4 shows a more complex type of weight-distribution curve obtained from strophanthin K. This sample was obtained as a possible pure reference standard. A chromatogram when dried, sprayed with zinc chloride reagent, and viewed under ultraviolet light, showed a series of overlapping fluorescent bands of varying intensity from the starting to the finishing line. It was difficult to estimate the quality of the product. However, the weight curve clearly showed it was unsuitable for a standard. It contained five major and five minor components; three were colored pigments with peaks near paper section numbers 8, 22, and 37. It was a mixture of glycosides similar to strophanthin N. F. X.

Figures 5 and 6 show the weight-distribution curves for commercial digitoxin and prednisone samples in which high boiling point formamide was used successfully as an immobile solvent. When the paper was dried before elution, it was difficult to remove completely the more nonpolar steroids because of adsorption by the paper. However, complete removal was readily obtained by cutting and eluting the wet paper with alcohol. The alcohol then was evaporated from the cups and the formamide removed under vacuum at 90°. The weight curve for digitoxin shows gitoxin near the starting line and traces of two components near paper sections numbers 12 and 15 more polar than digitoxin. The two minor components had not been observed previously by conventional paper chromatography but were confirmed by high concentration chromatography and use of slit technique. The weight curve for prednisone indicates absence of marked impurities. It does show a broad solvent front due to evaporation of the highly volatile mobile solvents within the developing chamber and below the slit of its lid. Multiple solvent fronts, due to different evaporation points from the paper by mixed mobile solvents, were no problem in these systems.

DISCUSSION

In conventional chromatography, it is becoming more important to control the purity of the paper and solvents used. It is critical in the gravimetric procedure herein described, since the presence of nonvolatile, soluble contaminants influences the accuracy of quantitative studies and may obscure the presence of minor components of the sample. Washing with acetone removed 2.8 mg. of soluble material from one sheet of Whatman No. 1 filter

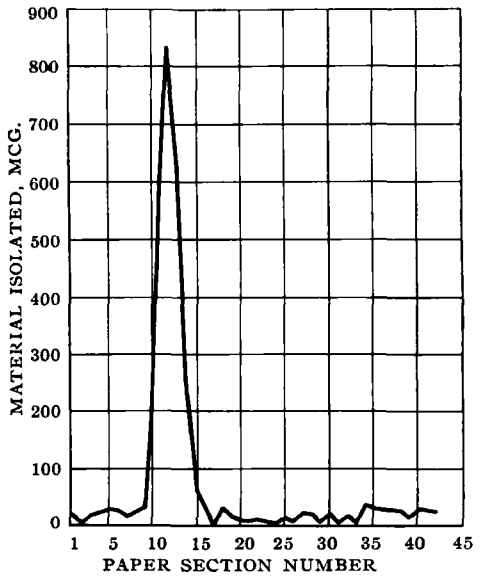

Fig. 6.—Weight-distribution curve of prednisone.

paper.[6] Total and acetone-soluble materials were even higher in Whatman No. 3 paper. These substances are particularly troublesome when aqueous solvents are used as eluents.

Several precautions may aid in controlling this difficulty. The amount of extraneous material eluted varies with the volume of solvent used. Therefore, the eluting solvent should be kept to the *minimum* required for the complete removal of the components of the sample. The selection of solvent systems which tend to concentrate the fraction to be studied in a narrow band reduces the amount of background material since a smaller area of paper is eluted to obtain the desired fraction.

When it is sufficient to measure the sum of the minor components, the accuracy can be enhanced by using the slit technique and concentrating the less polar materials at the solvent front. Similarly, the more polar components may be concentrated on or near the starting line by the proper choice of solvents.

The limit of sensitivity of the method may be determined by comparing the weight of the sample used and the weight of the background. For example, in ouabain (Sample A), a 10-mg. sample was used and the background weight determined on a blank chromatogram averaged 22 mcg. per cup with extreme variations of ±8 mcg. Since these extremes differ by a maximum of 16 mcg., impurities present in quantities of more than 16 mcg. or 0.16% of a 10-mg. sample and concentrated on a single strip, should produce discernible peaks. The sensitivity is reduced where the impurity is distributed over two or more strips.

If one is interested only in the amount of the main component present, it is not necessary to elute quantitatively the entire chromatogram. The desired result can be obtained by comparing the dry weight of the sample and the dry weight of chief component eluted from the paper.

The elution apparatus described was designed to accommodate an 8 × 8-in. paper cut into 42 strips. Obviously, shorter chromatograms can be used equally well. Long paper may also be used by cutting it into two or more sections and eluting each section separately. In using small samples it may be desirable to use thinner or more narrow paper and with large samples to increase the weight or width of the paper. In the latter case, it will be necessary to increase the height of the elution equipment and the capacity of the cups.

SUMMARY

In a previous publication (1), theory, instrumentation, and procedure were given for the gravimetric determination of the distribution of compounds over an entire paper chromatogram. Some applications of this technique to analysis of steroids are now reported. The method measures components of a drug or other product which are separated by paper chromatography and may be missed by conventional techniques of detection. It eliminates the need for reference standards which for impurities or decomposition products may not be readily available. Precautions in using the method are given. Upon completion of the gravimetric analyses, the isolated fractions were used for additional studies.

Effects of Some Hypnotic Drugs on Respiration and Oxidative Phosphorylation in Rat Brain

By V. G. ERWIN and HAROLD C. HEIM

Pentobarbital and glutethimide inhibited respiration of rat brain homogenates in the presence of glucose, pyruvate, malate, or glutamate. These effects were not evoked by ethinamate or methyprylon. None of the drugs produced effects on malic dehydrogenase activity, but both pentobarbital and glutethimide inhibited the oxidation of reduced diphosphopyridine nucleotide. Of the four drugs studied only pentobarbital produced significant effects on oxidative phosphorylation by mitochondria.

ALTHOUGH NUMEROUS investigators have studied the effects of narcotics on metabolic processes of the brain *in vitro*, the mechanisms by which these drugs evoke pharmacologic effects are not well understood. It has been demonstrated that barbiturates inhibit oxidation of carbohydrate by brain slices and minces (1–4). Other studies have revealed indications that these drugs interfere with hydrogen transport (5, 6) and with the oxidation of pyruvate (7). It has furthermore been shown that barbiturates in concentrations which more closely approach those present in the brain during anesthesia uncouple oxidation from phosphorylation *in vitro* (8).

More recently the hypnotic drugs glutethimide,[1] methyprylon,[2] and ethinamate[3] have been introduced. A search of the literature indicates that the effects of these drugs on metabolic processes of the brain have not been extensively studied. Accordingly, a series of experiments was designed to ascertain whether these drugs evoke effects similar to those of pentobarbital on brain homogenates and mitochondrial preparations.

EXPERIMENTAL

Young, adult Sprague-Dawley rats of both sexes were used as the experimental animals. Each rat was stunned and decapitated, the brain was immediately removed, washed in cold 0.1 *M* phosphate buffer, blotted dry, and weighed on a torsion balance. The brain was then ground in a Ten Broek homogenizer containing sufficient cold 0.1 *M* potassium phosphate buffer, pH 7.4, so that there were 100 mg. of brain per ml. of homogenate.

Mitochondria were isolated from homogenates of whole brain prepared in cold 0.25 *M* sucrose solution according to the method of Brody and Bain (8). Centrifugation was accomplished in a Servall RC-2 centrifuge equipped with an SS-34 rotor. The mitochondrial suspension was adjusted with 0.25 *M* sucrose solution so that each milliliter contained mitochondria representing 200 mg. of brain, wet weight.

Conventional manometric techniques were used for measuring oxygen consumption. In the preparation of the homogenates no more than 10 minutes elapsed between the time the animals were sacrificed and the flasks placed in the bath. All results represent the average of determinations obtained with eight rats and duplicate flasks were used in each instance. The pH of the contents of a representative number of flasks was determined at the end of the experiments to insure that the observed effects were not due to a change in pH.

All flasks used in studying respiration of the homogenates contained in the main compartments 1.0 ml. of 0.1 *M* potassium phosphate buffer (pH 7.4), 0.3 ml. 5×10^{-4} *M* cytochrome c, 0.5 ml. of homogenate, and 0.3 ml. of drug solution to yield the concentrations listed in Table I. Four-tenths of a milliliter of 0.1 *M* substrate was tipped from the sidearm at zero time and the center wells contained 0.2 ml. of 10% KOH together with a strip of filter paper.

When endogenous uptake was determined, water rather than substrate was added from the sidearm.

[a] Experimental conditions described in text. Each result represents the average obtained with six different animals. [b] Standard deviation; results significant at the 99% probability level as shown by Student "t" test.

With glucose as the substrate the flasks contained the reagents listed above plus 0.1 ml. of 5×10^{-2} M adenosine triphosphate (ATP) and 0.1 ml. of 10^{-2} M $MgCl_2$ in the main compartment, and 0.1 ml. of 10^{-3} M DPN added with the substrate from the sidearm. In the experiments with pyruvate as the substrate flasks contained, in addition to the above reagents, 0.1 ml. of 5×10^{-2} M ATP; 0.1 ml. of 10^{-2} M $MgCl_2$ and 0.1 ml. of 2.5×10^{-2} M nicotinamide all added to the main compartment, while the pyruvate plus 0.1 ml. of 10^{-2} M malate was added from the sidearm.

Water was used to make the final volume of flask contents 3.0 ml. and, with the exception of the experiments with malate which were run at 30°, the temperature of the bath was 37°. The equilibration period was 10 minutes after which the manometers were closed and readings taken at 15-minute intervals for 90 minutes.

Flasks used in the study of oxidative phosphorylation contained, in the main compartment, 0.4 ml. of mitochondrial suspension; 0.5 ml. of 0.1 M phosphate buffer, pH 7.4; 0.1 ml. of 5×10^{-4} M cytochrome c; 0.4 ml. of 0.1 M glycylglycine buffer, pH 7.4; 0.1 ml. of 1.5×10^{-2} M DPN; 0.1 ml. of 0.5 M KCl; 0.1 ml. of 0.3 M $MgCl_2$; 0.1 ml. of 0.8 M glucose; 0.1 ml. of hexokinase solution containing 600 units per ml.; 0.1 ml. of 5×10^{-2} M ATP; and 0.1 ml. of 0.5 M NaF. Three-tenths of a milliliter of 0.1 M pyruvate together with 0.1 ml. of 10^{-2} M malate was added as substrate. Three-tenths of a milliliter of drug solution was added to yield the concentrations listed in Table II. The center wells contained 0.2 ml. of 10% KOH together with a strip of filter paper, and the temperature of the bath was 30°.

The control flasks, which contained water in place of drug solution, were removed at the end of the 10-minute equilibration period and immediately placed in ice, following which 0.5 ml. of chilled 20% trichloracetic acid (TCA) was added to denature proteins. The same procedure was followed with the flasks containing the drugs after the oxygen uptake had been measured for 30 minutes. The contents of the TCA-treated flasks were pipetted into centrifuge tubes and the denatured protein separated by centrifugation at 3000 × g for 10 minutes. Inorganic phosphate was determined in the supernatant fluid by the method of Fiske and SubbaRow (9). A Beckman model DU spectrophotometer was used and the absorbance was determined at 660 mμ. The inorganic phosphate uptake was determined as the difference between the amount of phosphate in the vessels to which TCA had been added at the end of the equilibration period and those to which TCA was added after measuring oxygen uptake for 30 minutes. The phosphate-to-oxygen ratio was calculated as the ratio of micromoles of inorganic phosphate uptake to the microatoms of oxygen consumed, in conformance to the methods followed by Brody and Bain (8).

The effect of the drugs on malic dehydrogenase activity was determined by the method of Ochoa (10). The oxidation of dihydro-β-diphosphopyridine nucleotide (DPNH) to diphosphopyridine nucleotide (DPN) with the concomitant reduction of oxaloacetate to malate was measured, in the presence and in the absence of the drugs, by following the decrease in absorbance at 340 mμ with the Beckman model DU spectrophotometer. In these experiments the reaction mixture contained, in a total volume of 3.0 ml., 40 units of malic dehydrogenase, 5×10^{-5} M DPNH, 5×10^{-5} M oxaloacetate, and 10^{-3} M of the various drugs.

In those instances where the drugs produced an inhibitory effect on the respiration of homogenates, additional experiments were performed to determine

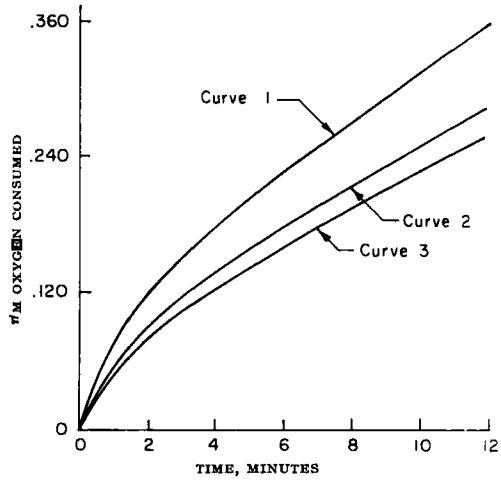

Fig. 1.—The effect of pentobarbital and glutethimide on respiration of brain mitochondria in the presence of malate. Cell of the polarograph contained 0.5 ml. of 0.01 M phosphate buffer; 0.1 ml. of 5×10^{-4} M cytochrome c; 0.1 ml. of 0.05 M ATP; 0.1 ml. of 0.5 M KCl; 0.1 ml. of 1.5×10^{-2} M DPN; 0.1 ml. of 10^{-2} M $MgCl_2$; 0.3 ml. of 0.1 M malate; and 0.2 ml. mitochondrial suspension representing 100 mg. brain. Drug, when present, added as 0.2 ml. of 10^{-2} M. Water added to make volume 2.0 ml. Temperature 25°. Results represent averages obtained with six animals. Key: curve 1, control (no drug added); curve 2, glutethimide; and curve 3, pentobarbital.

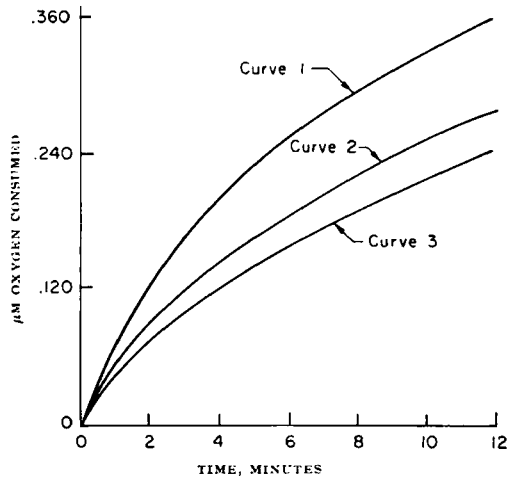

Fig. 2.—The effect of pentobarbital and glutethimide on respiration of brain mitochondria in the presence of pyruvate. Cell contents same as outlined in Fig. 1 with 0.3 ml. of 0.1 *M* pyruvate added. Experimental conditions identical to those used for Fig. 1. Results represent averages obtained with six animals. Key: curve 1, control (no drug added); curve 2, glutethimide; and curve 3, pentobarbital.

the effects of the rate of oxygen uptake by mitochondria. This was carried out by measuring the oxygen uptake polarographically, using a vibrating platinum electrode instrument[4] adapted from the method outlined by Chance (11). With such an instrument it was possible to measure the consumption of extremely small amounts of oxygen accurately over very short time intervals. The effects of pentobarbital and glutethimide on the respiration of mitochondria in the presence of malate, pyruvate, or DPNH as substrates were thus determined.

RESULTS

The data included in Table I indicate that either pentobarbital or glutethimide, at concentrations of 10^{-3} *M* and 5×10^{-4} *M*, inhibit the endogenous oxygen uptake of homogenates as well as oxygen uptake in the presence of added glucose, pyruvate, malate, or glutamate. Neither ethinamate nor methyprylon (at these concentrations) evoked appreciable effect. As further shown by Table I, pentobarbital produced somewhat more marked effects on respiration than did glutethimide.

Figures 1–3 illustrate the effects of pentobarbital and glutethimide on the oxidation of malate, pyruvate, and DPNH by brain mitochondrial preparations. It is apparent that both glutethimide and pentobarbital significantly depress the rate of oxidation of these substrates.

Table II shows that, of the four drugs studied, only pentobarbital evoked significant effects on oxidative phosphorylation by brain mitochondria.

None of the drugs produced significant effects on the activity of a purified malic dehydrogenase obtained from commercial sources.[5]

DISCUSSION

The oxidation of malate and glutamate by homogenates was inhibited by pentobarbital or glutethimide. Other investigators (7) have shown that pentobarbital does not block the oxidation of glucose to pyruvate. It has also been demonstrated that the major pathway for the metabolism of glucose by the brain occurs *via* glycolysis to pyruvate (12) with subsequent oxidation by way of the tricarboxylic acid cycle. It might be expected, therefore, that the inhibitory effect evoked on the oxidation of glucose would be very similar in magnitude to the effect on the oxidation of pyruvate. In this study it was found that pentobarbital inhibited the oxidation of glucose to about the same degree as was observed with pyruvate.

Although the oxidation of the substrates included in this study is dependent upon specific dehydrogenase systems, it is not correct to deduce that the inhibitory effects produced by the drugs are due to interference at the dehydrogenase level because the observations made with homogenates are not necessarily the same as those made with purified enzyme systems. The use of more discrete preparations, such as mitochondria, affords a means of measuring oxidation free from the influence of many of the reactions which simultaneously occur in homogenates. Polarographic determination of oxygen consumption by mitochondria showed that pentobarbital and glutethimide were inhibitory in the presence of added malate, pyruvate, or DPNH, while the activity of a purified malic dehydrogenase preparation was not altered. Such observations

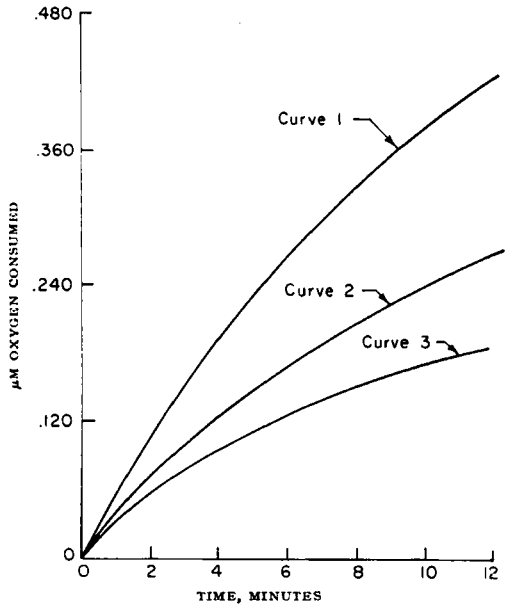

Fig. 3.—The effect of pentobarbital and glutethimide on the oxidation of reduced diphosphopyridine nucleotide (DPNH). Cell contents same as those for Fig. 1 except that the only substrate added was 0.3 ml. of 10^{-2} *M* DPNH. Experimental conditions identical to those used for Fig. 1. Results represent averages obtained with six animals. Key: curve 1, control (no drug added); curve 2, glutethimide; and curve 3, pentobarbital.

indicate that dehydrogenases are not directly inhibited by these drugs and lead to a consideration of possible effects of the drugs at the level of hydrogen transport.

It has been well established that mitochondria are rich in the enzymes of the tricarboxylic acid cycle, the electron transport and accompanying phosphorylating systems, and the cofactors associated with these enzymes (13, 14). The malate and pyruvic dehydrogenases both require DPN as a cofactor and utilize the same cytochrome c reductase system as the primary pathway for electron transport. Thus, the main difference between the oxidation of pyruvate and malate involves the dehydrogenases which transfer protons and electrons from these substrates to DPN. Pentobarbital or glutethimide, then, may conceivably produce an inhibition of oxygen uptake in the presence of malate or pyruvate by blocking at the dehydrogenase level or at some point in the hydrogen transport system beyond the step responsible for the reduction of DPN. The data in Fig. 3 reveal that the rate of oxygen uptake in the presence of added DPNH was inhibited by both pentobarbital and glutethimide.

The succinic oxidase system, in the presence of cytochrome c, will oxidize *p*-phenylene diamine with electrons being transferred directly to the cytochrome c, thus involving a bypass of the succinate-cytochrome b complex (15). It has been demonstrated that glutethimide (16) or pentobarbital (17) do not inhibit the oxidation of succinate or of *p*-phenylene diamine. It may be inferred, therefore, that the dehydrogenases which act on *p*-phenylene diamine or succinate transfer electrons to a point beyond the DPNH-dehydrogenase step in the electron transport system. There is evidence (18) that pentobarbital does not affect the DPN-linked dehydrogenases of the tricarboxylic acid cycle. The results of this study indicate that neither pentobarbital nor glutethimide inhibit the activity of a purified malic dehydrogenase system. However, the drugs inhibit the oxidation of DPNH and of other substrates which require DPN-linked dehydrogenases. Therefore, the results reported herein suggest that the effects produced by either pentobarbital or glutethimide *in vitro* are elicited at the level of the electron transport system between DPN and cytochrome c.

Of the four drugs studied, only pentobarbital was found to uncouple oxidation from phosphorylation. The concept of such uncoupling seems to be more widely accepted as a possible explanation of central nervous system depression than is the inhibitory effect of this drug on respiratory enzymes, perhaps because concentrations required to impair oxidative phosphorylation *in vitro* more closely approach the concentrations which produce *in vivo* effects. It is pertinent to point out, however, that not all depressants of the central nervous system are uncoupling agents, as shown by the fact that neither chloral hydrate nor paraldehyde uncouple oxidation from phosphorylation (19).

It seems of interest to note that neither ethinamate nor methyprylon had an effect on the oxidative processes included in this study even though the hypnotic potency of these drugs has been reported to be comparable to that of glutethimide (20–22).

Some Observations on the Kinetics of the C·4 Epimerization of Tetracycline

By EDWARD G. REMMERS, GEORGE M. SIEGER, and ALBERT P. DOERSCHUK

The C·4 epimerization of tetracycline has been shown to follow the kinetics of a first-order reversible reaction. Phosphate and citrate ions increased the rate of C·4 epimerization. The reaction rate in either 1.00 molar phosphate or 1.00 molar citrate buffer at pH 4.0 and 23° was approximately 70 times the rate observed in distilled water under the same conditions of temperature and pH. An Arrhenius plot indicated that the apparent energy of activation for the C·4 epimerization of tetracycline at pH 4.0 and 0.10 molar phosphate buffer was approximately 20 kilocalories/gram-mole. The equilibrium concentration and the rate at which equilibrium was approached were dependent on the pH. Of the five pH levels studied, a maximum C·4 epimer level of 55 per cent at equilibrium occurred at pH 3.2. Of the five pH levels studied, the rate at which equilibrium was approached was highest at pH 3.2, 4.0, and 5.0.

In 1955 Doerschuk, *et al.* (1), observed a reversible isomerization in members of the tetracycline family. This observation was confirmed by Stephens, *et al.* (2), in 1956 and by Kaplan, *et al.* (3), in 1957. The initial observations reported by Doerschuk, *et al.* (1), were extended by McCormick, *et al.* (4, 5), in a series of papers in which the preparation, properties, and proof of structure of several 4-epi-tetracyclines were described. In the paper by McCormick, *et al.* (5), a number of experimental conditions permitting the epimerization of members of the tetracycline family was presented with values of the equilibrium concentration of C·4 epimer in a variety of solvent systems.

The purpose of this paper is to describe the kinetics of the C·4 epimerization in solutions displaying pharmaceutical utility. A study of this type provides useful background information in formulating stable solutions of tetracycline.

EXPERIMENTAL

Analytical Procedure.—The analytical procedure used in this study for measuring 4-epi-tetracycline was a slight modification of the absorbancy-ratio assay described by McCormick, *et al.* (5). The assay is based on the observation that the ratio of absorbancies at 254 and 267 mμ differs for tetracycline and its C·4 epimer. To measure small amounts of C·4 epimer precisely, the original absorbancy ratio assay was modified by F. S. Chiccarelli (private communication) so that it might be run as a differential assay. Samples of the standards for tetracycline·HCl and 4-epi-tetracycline (ammonium salt) were obtained from F. S. Chiccarelli, Assay Development Department.

Experimental Procedure.—Solutions of various buffers were prepared and adjusted to the desired pH. The buffers were allowed to equilibrate at the desired temperature in a volumetric flask before tetracycline·HCl or its C·4 epimer was dissolved in the buffer. At frequent intervals aliquots were withdrawn to determine the C·4 epimer content by the method described above.

Estimation of Rate Constants.—The reaction rate constants for the C·4 epimerization were estimated from the equation describing the kinetics of a first-order reversible reaction

$$ln \frac{Ao - Ae}{A - Ae} = (k_1 + k_{-1})\, t \qquad \text{(Eq. 1)}$$

where Ao = per cent tetracycline·HCl at $t=o$; A = per cent tetracycline·HCL at $t=t$; Ae = per cent tetracycline·HCl at equilibrium; t = time, hours; k_1 = forward reaction rate constant, hours^{-1}; and k_{-1} = backward reaction rate constant, hours^{-1}.

Throughout this paper the symbol k_1 is used for the reaction rate constant for the forward reaction of tetracycline epimerizing to 4-epi-tetracycline. The symbol k_{-1} is used for the backward reaction of 4-epi-tetracycline to tetracycline. The symbols for the two reaction rates are used for the directions of the reactions as indicated above even though the principal starting material in the reaction may be 4-epi-tetracycline in some experiments.

Equation 1 indicates that if the logarithm of the reciprocal of the fraction of equilibrium attained at time t is plotted as a function of time, a straight line should be obtained whose slope is equal to $(k_1 + k_{-1})$. The method of least squares was used to estimate the slope of the straight line passing through the experimental points, thereby providing an estimate of $(k_1 + k_{-1})$. The individual rate constants k_1 and k_{-1} are readily determined from the equilibrium concentration of tetracycline using the relationship

$$\frac{1 - Ae}{Ae} = \frac{k_1}{k_{-1}}$$

The 95% confidence limits for k_1 and k_{-1} were determined from the least squares calculations presented in standard statistical texts. For all other computations of slopes and intercepts the method of least squares was used.

RESULTS AND DISCUSSION

Determination of Reaction Order for the Epimerization of Tetracycline to 4-epi-Tetracycline.—

Received August 29, 1962, from the Pharmaceutical Product Development Section of Lederle Laboratories, American Cyanamid Co., Pearl River, N. Y.
Accepted for publication December 28, 1962.

TABLE I.—EXPERIMENTAL DISAPPEARANCE RATES AND AVERAGE CONCENTRATIONS FOR TETRACYCLINE DURING FIRST 8.5 HOURS OF EPIMERIZATION

Initial Concn. of Tetracycline and C·4 Epimer	Tetracycline, Initial %	Tetracycline after 8.5 Hr., %	Rate of Disappearance $-\frac{\Delta(\text{Tetracycline})}{\Delta t}$	Average Concn. of Tetracycline During First 8.5 Hr. of Reaction
250 mcg./ml.	96.80	92.78	1.182 mcg./ml.-hr.	237.0 mcg./ml.
500 mcg./ml.	96.80	92.20	2.706 mcg./ml.-hr.	472.5 mcg./ml.
1,000 mcg./ml.	96.80	91.95	5.706 mcg./ml.-hr.	943.8 mcg./ml.

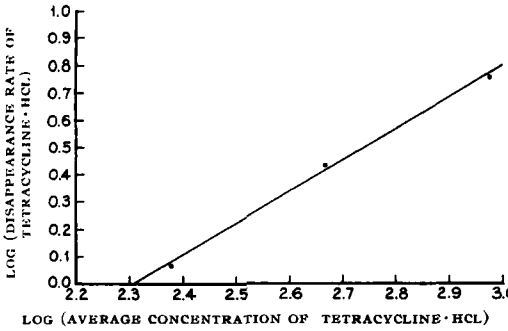

Fig. 1.—The rate of disappearance of tetracycline·HCl as a function of its average concentration at pH 4.0 and 23°C.

Three solutions of tetracycline were prepared in 0.10 *M* phosphate buffer at pH 4.0 and 23° at total tetracycline levels of 250, 500, and 1000 mcg./ml. Immediately after solution and 8.5 hours later, aliquots of the solutions were withdrawn and assayed for C·4 epimer. The experimental results are presented in Table I.

The reaction order for the C·4 epimerization was determined from the data in Table I using the differential method described by Laidler (6). In this method the logarithm of the rate of disappearance of tetracycline is plotted as a function of the logarithm of the average concentration of tetracycline as shown in Fig. 1. Such a plot should give a straight line, whose slope and intercept are equal to the reaction order and reaction rate constant, respectively.

In order to state that a reaction follows first-order reversible kinetics, (*a*) the slope of the line of the plot in Fig. 1 should be equal to 1.00, and (*b*) the experimental data when plotted according to Eq. 1 should give a straight line whose slope is equal to $k_1 + k_{-1}$.

Inspection of Fig. 1 indicates that the experimental observations appear to result in a straight line. The value obtained for the slope of the line was 1.134 with 95% confidence limits of 0.890 and 1.374. Since the value of 1.00 is within the confidence limits, the C·4 epimerization of tetracycline may be safely considered to satisfy condition (*a*) above for first-order reactions in the concentration range studied. The antilogarithm of the intercept gives a value of 2.443×10^{-3} hours^{-1} for the forward reaction rate constant. This value compares favorably with other values obtained in later experiments under the same conditions.

Determination of the Reaction Order for the Epimerization of 4-epi-Tetracycline to Tetracycline.—The experiment described above was repeated using 4-epi-tetracycline instead of tetracycline as the starting material. Three solutions of 4-epi-tetracycline were prepared in 0.10 *M* phosphate buffer at pH 4.0 and 23° at total tetracycline levels of 250, 500, and 1000 mcg./ml. Immediately after solution and at 7.5 hours later, aliquots of the solutions were withdrawn and assayed for C·4 epimer. The experimental results appear in Table II and are plotted in Fig. 2 in the same manner as for the previous experiment.

By the method outlined above, a value for the slope of 1.141 was obtained with 95% confidence limits of 0.823 and 1.449. Since the value of 1.00 is within the confidence limits, the epimerization of 4-epi-tetracycline to tetracycline may be considered to satisfy conditions (*a*) for first-order reactions in the concentration range studied. The antilogarithm of the intercept gives a value of 3.963×10^{-3} hours^{-1} for the backward reaction rate constant for the epimerization of tetracycline to 4-epi-tetracycline. This value compares favorably with

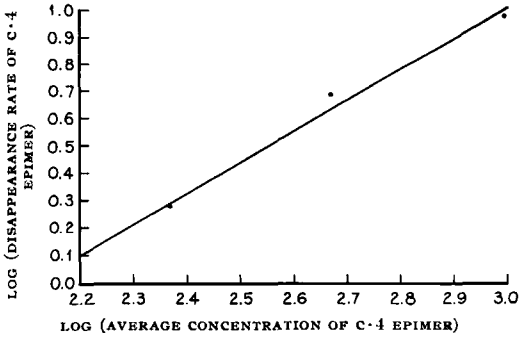

Fig. 2.—The rate of disappearance of C·4 epimer as a function of its average concentration at pH 4.0 and 23°.

0.10	2.48 (1.83–3.13)	4.05 (3.40–4.70)
1.00	15.7 (6.71–24.6)	25.5 (16.6–34.5)

subsequent values obtained in later experiments under identical conditions.

The second condition for first-order reactions is demonstrated in the following experiments.

Effect of Phosphate Ion Concentration on the Epimerization of Tetracycline to 4-epi-Tetracycline.—Three solutions of tetracycline were prepared at a total tetracycline level of 1500 mcg./ml. in 0.01, 0.10, and 1.00 *M* phosphate buffer at pH 4.0 and 23°. Aliquots of the solutions were withdrawn periodically and assayed for C·4 epimer to determine the reaction rate constants under these conditions. Table III presents the reaction rate constants with their 95% confidence limits in parentheses.

Figure 3 shows that when the reaction rate constants are plotted on log-log paper as a function of the molarity of the phosphate buffer, a linear relationship is obtained which may be represented by

$$k_1 \times 10^3 = 22.5\,(M)^{0.791}$$
$$k_{-1} \times 10^3 = 23.9\,(M)^{0.791}$$

where M is the molarity of the phosphate buffer. The 95% confidence limits for the exponent were 0.728 and 0.854. Since the confidence limits do not include zero, the phosphate ion concentration exerted a significant effect on the rate of epimerization of tetracycline to its C·4 epimer at pH 4.0.

The above experiment was repeated using 4-epitetracycline as the principal starting material to determine the reaction rate constants under these conditions. Table IV presents the reaction rate constants with their 95% confidence limits in parentheses.

Using the reaction rate constants presented in Tables III and IV, one can construct a family of curves showing the C·4 epimerization as a function of time in phosphate buffer starting with either member of the epimeric pair. Such a family of curves is presented in Fig. 4. This figure shows that the equilibrium between epimeric pairs may be approached from either direction.

The rate constants in this experiment were determined by the method described earlier in this paper. When the experimental data from this and subsequent experiments were plotted according to Eq. 1, a straight line resulted, thereby satisfying the second condition for a first-order reversible reaction.

Effect of Citrate Ion Concentration on Epimerization of Tetracycline to 4-epi-Tetracycline.—The previous experiment was repeated using citrate buffers at pH 4.0 and 23° in the place of phosphate buffers. Aliquots of the solutions were withdrawn frequently and assayed for C·4 epimer to determine the reaction rate constants under these conditions. Table V summarizes the reaction rate constants with the 95% confidence limits in parentheses.

The reaction rate constants when plotted on log-log paper as a function of citrate molarity resulted in straight lines which may be represented by

$$k_1 \times 10^3 = 16.3\,(M)^{0.723}$$
$$k_{-1} \times 10^3 = 26.7\,(M)^{0.723}$$

where M is the molarity of the citrate buffer. The 95% confidence limits for the exponent are 0.714

TABLE V.—REACTION RATE CONSTANTS AS A FUNCTION OF CITRATE BUFFER CONCENTRATION

Molar Concn. of Citrate Buffer, pH 4.0 at 23°C.	Forward Reaction Rate Constant, $k_1 \times 10^3$, hr.$^{-1}$	Backward Reaction Rate Constant, $k_{-1} \times 10^3$, hr.$^{-1}$
0.01	0.586 (0.439–0.733)	0.956 (0.717–1.195)
0.10	3.09 (2.23–3.87)	5.05 (3.79–6.31)
1.00	16.3 (12.3–20.4)	26.7 (20.0–33.3)

TABLE VI.—EFFECT OF TEMPERATURE ON THE C·4 EPIMERIZATION OF TETRACYCLINE

Temp., °C.	Forward Reaction Rate Constant, $k_1 \times 10^3$, hr.$^{-1}$	Backward Reaction Rate Constant, $k_{-1} \times 10^3$, hr.$^{-1}$
4	0.193 (0.165–0.221)	0.316 (0.288–0.344)
23	2.61 (2.20–3.02)	4.26 (3.85–4.67)
37	8.96 (6.86–11.0)	14.6 (12.5–16.7)
42	15.4 (8.62–2.22)	25.0 (18.2–31.8)
56	78.5 (20.5–178.0)	128.2 (29.2–227.0)

and 0.732. Since the confidence limits do not include zero, the citrate ion concentration exerted a significant effect on the rate of epimerization of tetracycline to its C·4 epimer at pH 4.0.

Rate of Epimerization of Tetracycline in Water.—A solution of tetracycline was prepared in distilled water at a total tetracycline level of 1500 mcg./ml. The solution was titrated to pH 4.0 with 0.1 *N* NaOH and allowed to epimerize at 23°. Aliquots of the solution were withdrawn periodically and assayed for C·4 epimer. During the aging of the unbuffered solution, the pH gradually fell from 4.0 to 3.5 in the first 10 days after which it remained constant at 3.5 for the remainder of the reaction. The reaction rate constants for this condition (with the 95% confidence limits in parentheses) can thus be summarized.

Forward Reaction-Rate Constants, $k_1 \times 10^3$, hr.$^{-1}$	Backward Reaction-Rate Constant, $k_{-1} \times 10^3$, hr.$^{-1}$
0.234 (0.014–0.454)	0.381 (0.161–0.601)

A comparison of the epimerization rates of tetracycline in 1.00 *M* phosphate and 1.0 *M* citrate buffer with that observed in distilled water under closely similar conditions of temperature and pH reveals that the epimerization rate in 1.00 *M* phosphate or citrate buffers proceeds approximately 70 times more rapidly than in distilled water.

Effect of Temperature on Epimerization of Tetracycline.—Solutions of tetracycline were prepared at a total tetracycline level of 1500 mcg./ml. in 0.10 *M* phosphate buffer at pH 4.0 that had been previously equilibrated at 4, 23, 37, 42, and 56°. Aliquots of the solutions were withdrawn frequently and assayed for C·4 epimer. Table VI presents the reaction rate constants with their 95% confidence limits in parentheses.

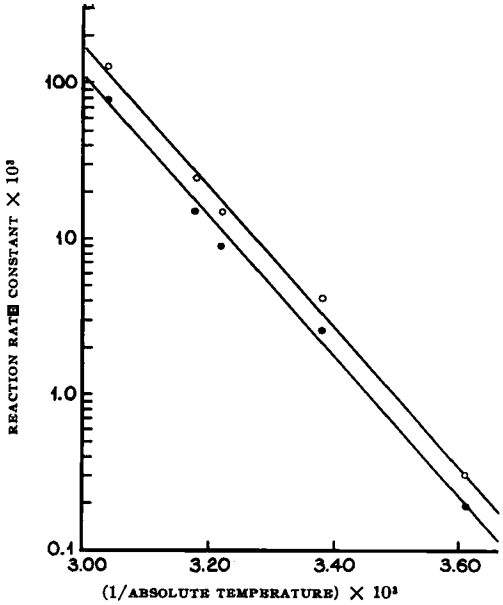

Fig. 5.—Arrhenius plot for the forward and backward reaction rates for the C·4 epimerization of tetracycline: ○—backward rate, ●—forward rate.

The above reaction rate constants were then plotted to give the Arrhenius plot presented in Fig. 5. Inspection of the figure reveals that the reaction rate constants fall rather closely on a straight line, the slope of which is equal to $-E/2.303\ R$ where E is the apparent energy of activation, and R is the gas constant, 1.986 calories per degree-mole.

The slope, activation energy, and frequency factors for the epimerization of tetracycline are presented in Table VII. The energy of activation and frequency factors from the Arrhenius plot have been obtained by a weighted regression analysis described by McBride and Villars (7). A weighted regression was used (*a*) to prevent equal weighting of rate constants determined with high precision with those obtained with low precision and (*b*) to compensate for the unequal weighting introduced by using the logarithm of the rate constant instead of the rate constant directly. McBride and Villars have shown that the above objections can be eliminated if the rate constants are weighted by a quantity directly proportional to the square of the rate constant and inversely proportional to its variance. The necessity for performing a weighted regression analysis can be seen from Table VI. At 56° the epimerization proceeded so rapidly that only three assays could be performed before the reaction was essentially complete. As a result, the reaction rate constant is estimated with low precision as indicated by the wide confidence interval. A weighted regression is used so that a rate constant determined

TABLE VII.—ACTIVATION ENERGY AND FREQUENCY FACTORS FOR THE C·4 EPIMERIZATION OF TETRACYCLINE

Reaction	Slope of Arrhenius Plot, 95% Confidence Limits	Activation Energy in Calories per Mole, 95% Confidence Limits	Frequency Factor, hr.$^{-1}$
Forward	−4.452 (−3.74)–(−5.16)	20,400 (17,100–23,600)	2.69×10^{15}
Backward	−4.452 (−3.89)–(−5.11)	20,400 (17,800–22,900)	3.61×10^{15}

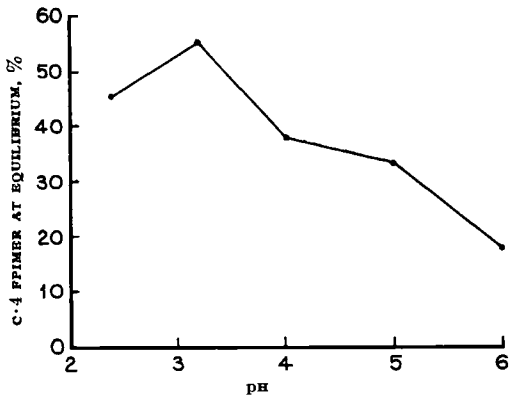

Fig. 6—Equilibrium concentrations of C-4 epimer as a function of pH.

with low precision is not weighted equally with one estimated with high precision.

Equilibrium Levels of C-4 Epimer at Various pH Levels.—The equilibrium concentrations of C-4 epimer and the rate at which equilibrium is approached were determined as a function of pH by aging solutions containing a total tetracycline level of 1500 mcg./ml. in 0.10 *M* phosphate buffer at 23° until the C-4 epimer level did not change with additional time. This concentration is considered to be the equilibrium concentration and is plotted in Fig. 6 as a function of pH. The equilibrium values employed in estimating reaction rate constants in this study are those presented in Fig. 6.

Inspection of Fig. 6 indicates that the equilibrium concentration of C-4 epimer is a function of the pH of the solution. Of the five pH levels studied, the maximum C-4 epimer concentration at equilibrium is 55% and occurs at pH 3.2.

The rate at which the epimerization occurred

TABLE VIII.—SUM OF FORWARD AND BACKWARD REACTION RATE CONSTANTS $[(k_1 + k_{-1}) \times 10^3]$ FOR TETRACYCLINE AS A FUNCTION OF pH (95% CONFIDENCE LIMITS)

pH	Rate Constants
2.4	7.45 (7.31–7.59)
3.2	8.76 (8.62–8.91)
4.0	8.90 (8.64–9.15)
5.0	8.71 (8.59–8.89)
6.0	5.39 (4.95–5.82)

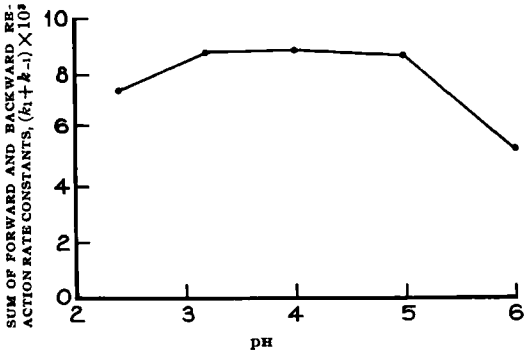

Fig. 7.—The sum of the forward and backward rate constants as a function of pH.

was also measured and is presented in Table VIII and Fig. 7. Inspection of the table and figure reveals that at pH 3.2, 4.0, and 5.0, the rates are essentially identical. As the pH is increased or decreased from the above pH range, the reaction rate declines.

SUMMARY

The C-4 epimerization of tetracycline to 4-epitetracycline follows first-order reversible kinetics at pH 4.0 in phosphate buffer. At pH 4.0 phosphate and citrate ions are effective in catalyzing the rate at which the equilibrium C-4 epimer concentration is approached.

The apparent energy of activation for the C-4 epimerization is approximately 20 kilocalories/gram-mole at pH 4.0 in phosphate buffer. The equilibrium concentration and the rate at which equilibrium is approached are dependent on the pH of the solution.

Powdered Particle Interactions: Suspension Flocculation and Caking I

By ROBERT G. WILSON and BERNARD ECANOW

The phenomena of caking and of flocculation in a sulfamerazine suspension system have been reported in the literature. The concept of zeta potential was used in measuring and explaining the effects obtained. Several questions have been raised with regard to this prior work, and both caking and flocculation have been examined and explained in terms of other mechanisms. Flocculation in the sulfamerazine suspension system is principally due to the chemical reaction that takes place between dioctyl sodium sulfosuccinate anions and the trivalent cations of the flocculating agent. Relatively strong bonding forces develop between the suspended particles, and floccules are formed. Caking of the sulfamerazine suspension system is seen when the particles settle to a dense sediment before bonds can be established between the closely-packed particles.

HAINES AND MARTIN have recently reported on the phenomenon of flocculation (1–3). They have shown that relationships exist between zeta potential, flocculation, and caking tendencies for the particular suspension systems under study. A careful appraisal of their work has raised several questions and has prompted this laboratory to engage in additional research on the same systems. Initially, our attention has been directed toward the sulfamerazine suspension system on which Haines and Martin worked.

Fischer (4) has said that the electrostatic charge carried by dispersed particles is an important factor in the stability of an aqueous suspension. The charge originates by ionization of the surface or by adsorption of ions from the solution. Martin (5) has said that colloidal particles, as a result of their large surface areas and great surface forces, tend to adsorb ions from the medium and become positively or negatively charged. Fischer and Martin, in their separate works, go on to refer to the distribution of other ions in the form of an ionic atmosphere surrounding the charged suspended particle. Adamson (6) has presented a graphical picture of this concept by plotting electrical potential against distance from the surface of the particle. He states that a particle surface charge may be inherent or may be due to an adsorbed desolvated layer of ions. As we move away from the particle surface, we pass through the "stern layer," which is composed of adsorbed solvated ions surrounding the particle and tightly held to its surface. Moving beyond the stern layer, we enter the "diffuse gouy layer," where a density of ionic charge has gathered in response to the underlying charges on the particle.

Received March 28, 1962, from the University of Illinois, College of Pharmacy, Chicago.

Accepted for publication January 25, 1963.

Abstracted from a thesis submitted by Robert G. Wilson to the Graduate Faculty, University of Illinois at the Medical Center, Chicago, in partial fulfillment of Master of Science degree requirements.

If an electrical field is imposed upon a colloidal system containing electrostatically charged particles, the charged particles will tend to move toward one or the other of the poles. Where other ions are present in the suspension medium, an individual particle as it moves will carry its adsorbed ions (stern layer) and a portion of its ionic atmosphere (diffuse gouy layer) along with it. A region of shear will be created between those ions moving with the particle, and those left behind to move independent of the particle. The electrical potential at this shear layer has been defined as the zeta potential (6). Zeta potential may be measured by observing the movement of a charged particle in a known electrical field or by measuring the magnitude of the electrical potential induced by the movement of the charged particle. The proper application of the concept of zeta potential has served to explain many of the phenomena exhibited by colloidal suspensions.

Fischer (7) has described the coagulation of colloidally dispersed charged particles in terms of the following hypothetical mechanism. Uncharged particles, when brought close together, adhere because of van der Waals attractive forces. In a stable suspension, where the particles are similarly charged, electrostatic repulsive forces predominate and the particles are prevented from adhering since the electrostatic forces are of longer range than the van der Waals forces. The magnitude of the repulsion is gauged roughly by the zeta potential. If the zeta potential is sufficiently high, the charges constitute a potential barrier and the colloidal system is stable. If the zeta potential is caused to decrease, as by the addition of an electrolyte, then the particles may have sufficient kinetic energy to cross the barrier and come within range of the van der Waals attractive forces. The

particles then adhere. The zeta potential corresponding to this limit is termed the critical potential.

Abramson (8) has discussed the work of Burton, who used potassium sulfate to coagulate a copper sol. With other conditions held constant, Burton modified the zeta potential on the copper particles by the addition of electrolyte. He reported his data in terms of electrophoretic velocity of the particles *versus* time for coagulation to occur, which is directly comparable to zeta potential *versus* the time for coagulation to occur. When enough potassium sulfate had been added to reduce the electrophoretic velocity to zero (a zeta potential of zero), it took 0.04 days (just under 60 minutes) for coagulation to occur. Burton thus demonstrated that (for this system) flocculation following the neutralization of zeta potential was a slow process. The rate of coagulation was dependent on the frequency of random collisions of the copper particles in the course of their Brownian movement. This seems to correlate with Fischer's thoughts, as reviewed in the preceding paragraph. With random Brownian movement, the particles may at times have sufficient kinetic energy and be properly oriented in their motion so that they will approach close enough to one another to be held by the van der Waals forces.

Zeta potential has thus been linked with colloidal systems and with the coagulation mechanism for a colloidal system.

Haines and Martin (1–3) worked with a sulfamerazine suspension system. They used a modified Northrop-Kunitz–type electrophoresis assembly and converted their electrophoretic velocity data to zeta potential values. Their summary (2) stated that the electrophoretic velocity in a nonflocculated sulfamerazine suspension was observed in a microscope electrophoresis apparatus and was found to be high because of the predominance of a negative charge on the particle. Electrical discharge of the particle by the addition of aluminum ions, which were opposite in charge to the particle, lowered the zeta potential and brought about flocculation of the particle, thereby reducing or eliminating the tendency to cake.

The ideas of Fischer (7) as given earlier in this paper, seem to have been confirmed by the findings of Haines and Martin. An important discrepancy, from the standpoint of this laboratory, is that Fischer had been discussing colloidal systems; Haines and Martin were working with particles larger than those normally considered to be within the colloidal range. Fischer (9) comments that the limits on colloidal particles have been variously stated, but sizes between 1 μ and 1 mμ encompass the usual extremes. Martin (10) gives the colloidal range as from 10 Å. up to 0.5 μ. The sulfamerazine particles used by Haines and Martin were in the 2 to 10-μ range and could be clearly seen under the microscope. Hauser (11) has said that colloidal dispersions are detectable only with the ultramicroscope, while coarse dispersions are microscopically resolvable. However, he adds that no sharp boundary exists between coarse dispersions, colloidal solutions, and true solutions. Hauser further states (12) that the principal differences between general and special types of disperse heterogeneous systems are the result of the appearance of special properties as the boundary surfaces are increased.

Among such special properties would be the van der Waals forces. Although they exist at the surface of all solid particles, they would be effective in bonding only when the solid was in an extremely fine state of subdivision, as for example in Burton's colloidal copper sol.

It is true that Kruyt (18), has referred to the theoretical existence of long-range London–van der Waals forces in connection with hydrophobic suspensions in the 2 to 5–μ range. However, he adds (19) that this kind of flocculation has not yet been verified experimentally. The sulfamerazine suspension under study is not a hydrophobic system, nor is it within the generally accepted colloidal range. It seems inappropriate to ascribe flocculation in such a system to the action of van der Waals forces following a neutralization of particle surface charge without experimental justification for such an assumption.

Initial work at this laboratory has shown that the flocculation of the sulfamerazine system by aluminum ions was virtually instantaneous on mixing. Burton (7) had been successful in applying zeta potential measurements to his copper sol only because the coagulation was slow to take place. The system was such that he had time to measure the zeta potential of the particles before they were lost to the coagulum. Haines and Martin were not so fortunate, and this has cast additional doubt on the use of zeta potential as a parameter for the flocculation of the sulfamerazine suspension system. They had calculated zeta potential from particle velocity data obtained in the electrophoretic cell and had assumed that cessation of particle movement was due to a neutralization of zeta potential. This does not necessarily follow, for the cessation of movement could be more aptly

explained by the flocculation phenomenon itself. Haines and Martin have indicated this to be the case, for in their discussion (2) they have said that the addition of flocculating agent caused the zeta potential to decrease, and at point B, the particles were observed in the microscope of the electrophoresis apparatus to exhibit maximum flocculation.

Two factors thus tend to negate the concept of a neutralization of zeta potential, followed by flocculation under the influence of van der Waals forces:

The particles are larger than those normally considered to be colloidal, and the effectiveness of inter-particulate van der Waals forces has not been demonstrated for suspensions of hydrophilic particles in this size range (2–10 μ).

When sufficient aluminum ions are present, flocculation is virtually immediate on mixing. Thus flocculation occurs before the zeta potential can be measured on the individual particles.

It seems desirable that an alternative explanation be given for the flocculation of a sulfamerazine suspension by aluminum ions. A word on the meaning of terms may be of assistance at this point. Fischer and Gans, in their chapter in Alexander (13), have defined the words "flocculation" and "deflocculation" as follows:

Flocculation—The formation of clusters of particles separable by a relatively weak mechanical force or by a change, as in chemical composition, at the interface between the particles and the suspending phase. Surface-active agents are often useful in reducing the extent of flocculation.

Deflocculation—The state of dispersion of a solid in a liquid in which each solid particle remains geometrically independent and unassociated with adjacent particles.

In an initial investigation, 2% of sulfamerazine was suspended in distilled water. A highly flocculated, bulky suspension was obtained. The uppermost curve of Fig. 1 serves to illustrate this fact. This suspension was then contrasted with a 2% suspension containing 0.010 moles per L. of aluminum chloride. There was no observable difference between the two suspensions. Both were equally flocculated according to the definition given by Fischer and Gans. It should be clearly recognized that aluminum ions have no effect on a simple sulfamerazine suspension.

Haines and Martin used dioctyl sodium sulfosuccinate (DSS)[1] as a wetting agent for the sulfamerazine to reduce the hydrophobic nature of the sulfamerazine particles. This was a typical deflocculation reaction as defined above. When aluminum ions were added to such a sulfamerazine suspension system, a return to a flocculated condition was obtained. It would appear that the DSS was playing an integral part in the flocculation phenomenon, even though Haines and Martin made it a point to say (1) that the addition of the surface-active agent was found to have little or no effect on the recorded observations.

[1] Marketed as Aerosol-OT by American Cyanamid Co., New York, N. Y.

EXPERIMENTAL

Suspension System—During the current studies, the suspension concentration was held at the 2% solids level. Haines and Martin had shown that higher concentrations brought on the problem of hindered settling, and lower concentrations increased the errors inherent in the reading of flocculation volumes. DSS concentrations were varied from 0.001% up to 0.25%. To prepare the suspensions, the sulfamerazine powder was weighed, transferred to a glass mortar, and triturated with the required amount of a concentrated wetting-agent solution until a smooth slurry was obtained. The slurry was then transferred, with rinsing of the mortar, to a cylindrical graduate and distilled water was added to bring the volume to the proper level. Where flocculating agents were under study, they were added in the form of a concentrated solution during the adjustment of the final volume of the suspension. The graduate was then stoppered, inverted, and agitated to insure both thorough mixing and the uniform initial suspension of the solid.

Settling Data.—The methods used by Ward and Kammermeyer (14) were utilized in obtaining, and in some cases in reporting, the sedimentation data. It becomes necessary to qualify the above statement, for the sulfamerazine systems are not consistent in their settling characteristics. In some of the flocculation reactions, as much as 25% of the flocculated material floated to the surface of the medium rather than sedimenting as would have been expected. The total volume of flocculated material, summing the volume of both floating and sedimented floccules, was reported and used in comparing one system to another.

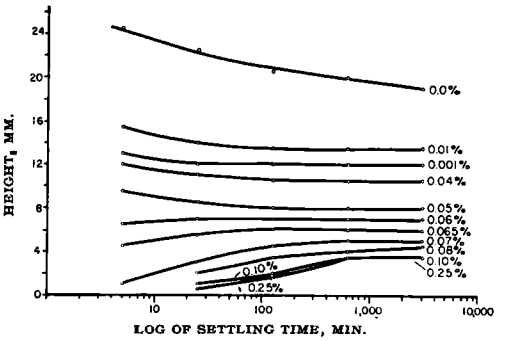

Fig. 1.—Height of sediment *vs.* log of settling time for 2% sulfamerazine suspended in various concentrations of dioctyl sodium sulfosuccinate solution.

Equipment.—Settling data was obtained in 100-ml. glass-stoppered cylindrical graduates. Suspension heights or flocculation volumes could be measured within ±0.5 ml. accuracy, which was more than sufficient to point out the differences between the various suspension formulations.

Materials.—A commercial grade of sulfamerazine U.S.P. as supplied by Merck Sharp & Dohme was used. The suspending medium was distilled water containing the wetting agent dioctyl sodium sulfosuccinate (100%) as supplied by American Cyanamid Co. The two flocculating agents, aluminum chloride ($AlCl_3 \cdot 6\ H_2O$) and ferric chloride ($FeCl_3 \cdot 6\ H_2O$), were reagent grade chemicals as supplied by Merck & Co.

RESULTS

Figure 1 presents the data on settling rates for 2% sulfamerazine suspensions containing various concentrations of the wetting agent. The critical micelle concentration for DSS has been given as approximately 0.07%, at 25° (5 to 15 seconds) (15).

At DSS levels above the critical micelle concentration, the sulfamerazine was held in a finely divided state and settled slowly to a dense sediment with definite caking tendencies. The sediment built up slowly at the bottom of the container and the supernatant liquid very slowly cleared to denote the completion of sedimentation. Above 0.1% DSS, changes in the wetting agent concentration gave practically no change in the settling rate curve.

Below the critical micelle concentration, the suspended sulfamerazine particles clumped and the flocculated material slowly compacted to its final volume. In this range of wetting-agent concentration, the suspension began to exhibit the hydrophobic properties of the basic sulfamerazine particle. As wetting-agent concentration decreased, increasing amounts of the solid tended to float to the surface until, in the absence of wetting agent, as much as 25% of the sulfamerazine floated to the surface.

Figure 2 illustrates the action of aluminum chloride as a flocculating agent for a 2% sulfamerazine suspension in 0.25% DSS solution. Small quantities of aluminum chloride had no apparent effect upon the suspension, other than to give the supernatant liquid a slight opalescence. The suspended particles acted just as they would at wetting-agent concentrations above the point of micelle formation.

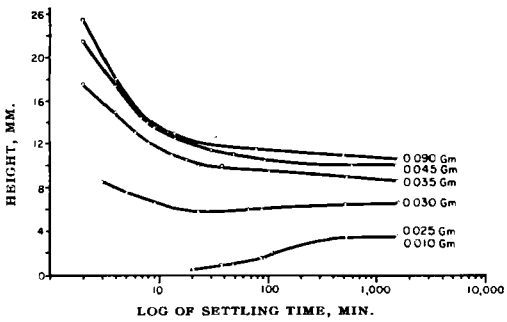

Fig. 2.—Height of sediment *vs.* log of settling time for 2% sulfamerazine suspended in 0.25% dioctyl sodium sulfosuccinate solution. Various amounts of aluminum chloride were added to cause flocculation.

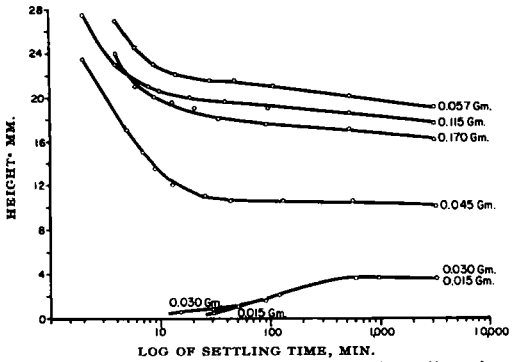

Fig. 3.—Height of sediment *vs.* log of settling time for 2% sulfamerazine suspended in 0.25% dioctyl sodium sulfosuccinate solution. Various amounts of ferric chloride were added to cause flocculation.

As aluminum chloride was added in larger amounts, the sulfamerazine particles grouped as clumps or floccules, and separated from the medium both as a loose, bulky precipitate, and as a floating layer of clumped material. At these higher levels of aluminum chloride addition, the supernatant liquid was clear and colorless.

Figure 3 charts the effect of ferric ion on a sulfamerazine suspension in 0.25% DSS solution. Small additions of ferric chloride had no apparent effect upon the suspension. The supernatant liquid became slightly opalescent, but the suspension performed just as it would at wetting-agent levels above the critical micelle concentration.

At the level of 0.045 Gm. ferric chloride per 100 ml., a definite soft floc was obtained. It sedimented, leaving an opalescent solution that contained no floating particles of sulfamerazine. The floc could be easily resuspended on shaking. When 0.057 Gm. ferric chloride per 100 ml. was added, the uppermost curve on the graph was obtained. At this level, the most fluffy and voluminous floc was formed. Half of the floccules floated to the surface, while the balance slowly settled out to leave a markedly opalescent supernatant liquid.

At the higher levels of ferric chloride addition, a slightly more compacted floc was obtained. It was of interest to note that the floc took on the color of the ferric ion, while the supernatant liquid became clear and essentially colorless.

The opalescence noted in many of the above preparations indicated a possible chemical interaction between the DSS anion and the trivalent cation. When a dilute solution of aluminum chloride was added (slowly and with stirring) to an 0.25% DSS solution, an opalescence was seen. As more aluminum ion was added, a milky, colloidal suspension formed and promptly coagulated to a few floating wax-like particles. These particles were filtered off, thoroughly washed with dilute ammonium chloride solution, dried, and a weighed amount ignited to a residue of aluminum oxide. The residue was 5.00% of the original weight.[2] Assuming the product had been an aluminum salt of dioctyl sulfosuccinic acid, the original compound was calculated to have the formula: $Al(C_{20}H_{37}O_7S)_2\ Cl \cdot xH_2O$. The above procedure was repeated

[2] Analytical data by Micro-Tek Laboratories, Skokie, Ill.

using ferric chloride as the precipitating agent. A milky, orange-colored colloidal suspension was formed, from which the organic material was extracted with ether. Upon evaporation of the ether, a viscous orange-brown residue was obtained. A weighed amount of the residue was ignited to ferric oxide and the weight of the oxide proved to be 7.24% of the original weight.[2] Assuming the residue was a ferric salt of dioctyl sulfosuccinic acid, it was calculated to have the following empirical formula: $Fe(C_{20}H_{37}O_7S)_2Cl \cdot xH_2O$.

Macroscopic observations on the various suspensions were correlated with microscopic studies. In those suspensions where the DSS was present in an amount above the critical micelle concentration, the sulfamerazine was present as discrete particles in a deflocculated condition. The particles were irregular, plate-like crystals of from 2 to 10 μ in size.

Where flocculating agents had been added in moderate amounts, the floccules were readily visible to the naked eye. On shaking, these relatively large flocculated masses were reduced in size, forming a finely divided suspension from which the original flocculated system was reformed within a few minutes. Microscopic observation indicated that there was some form of "adherence" between the sulfamerazine particles. The individual particles were grouped into small floccules, and these were further formed into loose, lacy masses. Higher concentrations of the flocculating agents gave floccules that were more granular in their macroscopic appearance. Microscopically, these floccules seemed to be larger in size and more compact than the flocculated masses obtained at lower levels of flocculating agent addition.

DISCUSSION

A 2% sulfamerazine suspension system has been used to study the phenomenon of flocculation. By itself, sulfamerazine in water is seen to give a highly flocculated suspension. If a small amount of an anionic wetting agent is introduced, some wetting occurs and the degree of flocculation is reduced. The suspension is further deflocculated as the concentration of wetting agent is increased until the critical micelle concentration has been exceeded. Above this level of wetting-agent concentration, the individual sulfamerazine particles have become coated by the anions of the wetting agent and are dispersed in the form of a completely deflocculated suspension.

An 0.25% DSS solution was selected for the further experimental work. The wetting-agent concentration was thus initially above the level of critical micelle concentration. As flocculating agent (aluminum or ferric ion) was added, there was no significant change in the state of the suspension until enough flocculating agent had been added to reduce the concentration of DSS anion below the level at which it could form micelles. From this point on, gradual addition of the flocculating agent gave increasing flocculation up to the maximum value obtained. Addition of agent beyond this point seemed to produce a slightly more compacted flocculation.

From the above, we can list several factors as being involved in the flocculation of this system: (*a*) the wetting agent concentration, (*b*) the neutralization or precipitation of wetting agent by the addition of flocculating agent, (*c*) other unknown factors, or (*d*) a combination of two or more of the above.

A chemical reaction has been shown to take place between aluminum or ferric ions and the dioctyl sulfosuccinate anion. If the sole effect of this reaction had been the neutralization of wetting-agent action, the flocculation curves would have coincided with those obtained by varying the amount of wetting agent in the suspension medium. This was certainly not the case with aluminum ions, and the divergence was even more marked when ferric ions were the flocculating agents. The chemical reaction thus appeared to be the most significant factor in the flocculation mechanism.

At the start of each experimental run, the sulfamerazine particles were coated with wetting-agent anions and the suspension was in a deflocculated condition. Each particle thus had a negative charge and was surrounded by its own ionic atmosphere. The general picture was that of hydrocarbon chains adsorbed to the surfaces of the particles with negative sulfonic acid radicals projecting into the surrounding medium. Aluminum ions were then added to the system, and they promptly reacted with DSS anions, whether these anions were adsorbed on particle surfaces or were available as ions in the suspension medium. Aluminum di-(dioctyl sulfosuccinate) chloride was formed as an insoluble product of the reaction. The sulfamerazine particles went into a state of flocculation which was modified by the presence of the aluminum compound.

The flocculation mechanism has been discussed, and it now remains for us to consider the phenomenon of caking in the sulfamerazine suspension system.

Haines and Martin (1) have said that when dispersed particles form into a compact mass at the bottom of the container, the suspension is said to have caked. They listed two types of structures that may be formed: the condensation or strongly bonded type, and the coagulation or weakly bonded type. Examples of both types were given. The coagulation or weakly bonded type of interaction was said to be due to the adhesion of particles by molecular interaction at points of contact between the particles. The weak bonds that are formed are due to a squeezing out of the dispersion medium at the points of contact, as in syneresis. The resulting residual layer of the dispersion medium prevents a strong molecular interaction at the points of contact. The strength of the cake which is formed depends upon the number of particles occupying a given volume. The particles may orient themselves in the sediment and, under the influence of gravity, coagulate in an arrangement of closest packing. Various clays, such as bentonite, were said to exhibit this type of sediment.

Hauser (17) has also commented on such a system. He has said that where suspended anisodimensional particles are allowed to settle of their own accord, they will tend to pack themselves in such a way that a sediment of minimum free energy results. This means that the particles will line up with their larger surfaces opposite each other. The solvated layer surrounding each particle will act somewhat like a lubricant, permitting the particles to slide over each other until they have found their proper location. With further sedimentation, the solvated

layers of the first settled particles will become distorted or deformed. Hauser goes on to say that this deformation will result in a coalescence of the solvated layers, since this would also represent a shift toward a system having a lower level of free energy. The heavier the particles, the greater the deformation of the solvated layers and thus the greater the chance for their coalescence.

Overbeek's chapter in Kruyt (19) contains the following observation: "There are, however, great differences in the sediments of stable and flocculated suspensions. The stable sediments are very closely packed because in forming the sediment the particles retain their individual freedom and roll over each other until the closest packing is reached. The flocculated sediments are more loosely built because once the sedimenting particles touch each other they adhere in the haphazard way in which they first touched and are no longer able to proceed into a more favorable position."

In the course of this study, three sulfamerazine systems were under observation:

Powered sulfamerazine in water. This suspension system was highly flocculated, and there was no caking problem.

Powdered sulfamerazine suspended in a DSS solution. This system gave a deflocculated suspension that settled to a dense sediment with definite caking tendencies.

Powdered sulfamerazine in DSS solution to which aluminum ions were added as a flocculating agent. A highly flocculated suspension with no evidence of caking was obtained.

This portion of the work has confirmed the findings of Haines and Martin (1) that a suspension in a state of fine deflocculated particles leads to rather than obviates caking. It also echoes the findings of Fischer (16) that flocculated particles settle rapidly to high volumes, while deflocculated particles settle slowly to low relative volumes. In flocculated systems, it would appear that the bonding forces between particles are relatively large, for the particles are held together in the form of loose clumps. When these clumps settle out, the particles remain distributed throughout a large volume of space. They cannot pack closely against one another and are thus unable to form into a cake.

The caking of sulfamerazine suspended in DSS solution is an example of the weakly bonded type of interaction. As originally prepared, the sulfamerazine particles are coated with DSS anions and are suspended as independent, charged particles in the medium. Since the system is not colloidal, gravity acts to pull the particles down into a sediment of low relative volume. As the particles settle, the suspension medium is squeezed out and the solvated layers surrounding each particle come into close contact with one another. Under the continuing influence of gravity, there is a coalescence of the solvated layers and a type of soft cake is formed. The cake can be returned to its original finely divided suspended state by shifting the particles enough to allow some of the suspension medium to come between them. The individual solvated layers are thus restored, and the particles can be resuspended in the deflocculated state. Aging studies are being conducted to see if the caking reaction becomes irreversible with time.

The concept of zeta potential does not provide us with a suitable picture of the sulfamerazine suspension systems. Attention should be focused upon the strength of bonding forces and the extent to which large areas of particle surfaces come into close contact with each other. As has been said, the interparticulate bonds in the flocculated system seem stronger and are more rapidly formed than are those in the deflocculated system. When the particles flocculate, bonding strengths are such that the particles are unable to settle to a closely packed sediment. For deflocculated particles, the bonding forces seem weak and are slow to establish themselves. The particles must settle and shift until large areas of surface are in close proximity to each other before the cake is formed. The relative strength of the bonds and the extent of contact between particle surfaces are thus the determining factors in the formation of a floc, a cake, or a densely packed sediment which shows no caking tendencies.

SUMMARY

The phenomena of caking and of flocculation in a sulfamerazine suspension system have been reported in the literature. The concept of zeta potential was used in measuring and explaining the effects obtained. Several questions have been raised with regard to this prior work, and both caking and flocculation have been examined and explained in terms of other mechanisms.

Flocculation in the sulfamerazine suspension system is principally due to the chemical reaction that takes place between dioctyl sodium sulfosuccinate anions and the trivalent cations of the flocculating agent. Relatively strong bonding forces develop between the suspended particles, and floccules are formed.

Caking of the sulfamerazine suspension system is seen when the particles settle to a dense sediment before bonds can be established between the closely packed particles.

Absorption, Metabolism, and Excretion of the Semisynthetic Penicillin 6-(2-Ethoxy-1-naphthamido)penicillanic Acid (Nafcillin)

By SIDNEY S. WALKENSTEIN, ROBERT WISER, EDITH LEBOUTILLIER, CATHRYN GUDMUNDSEN, and HAZEL KIMMEL

Nafcillin, 6-(2-ethoxy-1-naphthamido)penicillanic acid, a semisynthetic penicillin effective against penicillin G-resistant staphylococci, was labeled with carbon-14, and its absorption, metabolism, and excretion studied in dogs and rats after oral and intramuscular administration. Maximum plasma levels were attained within 15 minutes of an intramuscular dose and within 2 hours of an oral dose, although detectable levels appeared in plasma within 30 minutes in the latter case. Low levels of activity persisted in plasma up to 8 days, although about one-third was excreted in feces and about one-sixth in urine within 48 hours. Thirty minutes after injection, the drug was found in all major organs and tissues examined. Within the first 6 hours, about half the carbon-14 excreted in urine was due to nafcillin, about 30 per cent was due to a metabolite of similar R_f to unchanged drug, and the remaining 20 per cent was divided equally between two other metabolites.

AMONG THE NEWER penicillins synthesized from 6-aminopenicillanic acid, 6-(2-ethoxy-1-naphthamido)penicillanic acid, nafcillin (Wy-3277), has been found effective *in vitro* (1) and *in vivo* (2) against penicillin G -resistant staphylococci.

To enable us to investigate the metabolism, absorption, and excretion of the drug more completely than was possible in a non-isotopic study (3), C^{14}-labeled nafcillin was employed.

METHODS

2-Ethoxy-1-naphthoic acid-carboxyl-C^{14} (I) was synthesized by C^{14}-carbonation of the Grignard reagent prepared from 7.5 Gm. (0.03 mole) of 2-ethoxy-1-bromonaphthalene in tetrahydrofuran. The carbonation was performed in a manner previously described (4). Radioactive carbon dioxide was generated from 5.9 Gm. (0.03 mole) $BaC^{14}O_3$ (10 mc.). The product was isolated by acidification of the reaction mixture to pH 2 with 10% sulfuric acid, separation of the organic layer, and evaporation of the tetrahydrofuran. The residue was treated with 10% sodium hydroxide and cyclohexane, warmed to 50°, and cooled, the aqueous layer removed and adjusted to pH 7 with 5 *N* sulfuric acid. This solution was heated to 70° and filtered. The warm filtrate was acidified to pH 2, cooled, the solid filtered off and dried at 60°, m.p. 141–145°. The yield was 4 Gm. (61%).

The preparation of labeled 6-(2-ethoxy-1-naphthamido)penicillanic acid and its sodium salt involve only slight modifications of procedures described in the patent literature (5–7). Four grams of I were diluted with 1.2 Gm. of non-labeled acid (0.024 mole total) for conversion to the acid chloride. Thionyl chloride (1.9 ml.) was added dropwise to a stirred mixture of acid, 0.1 ml. dimethylformamide, and 9 ml. of dichloromethane. After addition was complete, the mixture was refluxed for 1 hour. The excess thionyl chloride was removed and the dichloromethane solution of the acid chloride used for the reaction with 6-APA.

6-APA (5.1 Gm., 0.024 mole) and triethylamine (5.1 Gm., 0.05 mole) were combined in 24 ml. of dichloromethane, cooled, and treated with the solution of the acid chloride. The mixture was stirred for 1.5 hours and then adjusted to pH 2 with 1 *N* sulfuric acid. The dichloromethane layer was separated, washed with water, and carefully extracted with 24 ml. of 1 *N* sodium bicarbonate. The phases were separated and the dichloromethane extracted again with 10 ml. of 1 *N* sodium bicarbonate. The sodium bicarbonate extracts were combined, treated with 3 ml. of methyl isobutyl ketone and acidified to pH 2 with 1 *N* sulfuric acid. After standing a short time, the water was decanted from the gummy precipitate and 5 ml. of methyl isobutyl ketone was added to the residue. Stirring caused the product to crystallize. The solid was filtered off, washed with 1.7 ml. of cold methyl isobutyl ketone, 6.8 ml. of cold butanol, and finally with 17 ml. of cold ether. The yield of light tan product, air dried overnight (m.p. 138–141°) was 4.1 Gm. (41%). This material was suspended in 3.5 ml. of acetone to which 5.5 ml. of 2 *N* sodium 2-ethylhexanoate in butanol was added, and the mixture stirred until solution was complete. The solution was treated with Darco and filtered. After dilution with *n*-butanol (17.5 ml.), cooling and stirring promoted crystallization of the salt. The product was washed several times with ether and recrystallized by dissolving in a minimum volume of acetone and diluting with four volumes of absolute ethanol. The yield was 2.2 Gm. of sodium salt with a specific activity of 1210 disintegrations per mcg. A second batch of labeled material was obtained by concentrating the filtrate to incipient dryness, adding 2 Gm. of non-labeled nafcillin and recovering the salt (407 disintegrations per mcg.)

Received November 6, 1962, from Wyeth Laboratories, Inc., Philadelphia 1, Pa.
Accepted for publication December 17, 1962.
The authors are indebted to James King and Charles A. Lung for technical assistance, to Sanford Rosenman, Larry Gordon, and Paul Horwitz for the bioassays, and to Felix Rauzzino, Alfonse Dervinis, and Robert Stewart for surgery in the bile collection experiments.

as described above. Both samples of radioactive product were chromatographically pure and when assayed microbiologically found to correspond with nonradioactive nafcillin (200 penicillin G units per mg.). The salt is hygroscopic.

Samples of tissue, plasma, and urine, ranging in size from 50 to 200 mcg. were placed in counting vials containing 2 ml. of Hyamine-10X, 1 *M* solution in methanol (Packard Instrument Co.) and kept at 55° for 48 hours. Each sample was then treated with 100 μl. of 30% hydrogen peroxide, and after 10 minutes at room temperature, the samples were acidified with concentrated hydrochloric acid. To each sample, 2 ml. of absolute ethanol and 10 ml. of scintillator solution (5 Gm. of 2,5-diphenyloxazole plus 100 mg. of 1,4-bis-2-(5-phenyloxazolyl)benzene per liter of toluene) was then added. The vials were read in a liquid scintillation spectrometer (Packard Instrument Co.) at 2°.

Feces were converted to carbon dioxide by wet Van Slyke combustion and assayed as such in a Nuclear-Chicago Dynacon electrometer. Urine, plasma, and bile were submitted for microbiological assay.

C^{14}-Nafcillin was given orally in gelatin capsules and intramuscularly in 10% water solution to dogs at a dose of 10 mg. of sodium salt per Kg. body weight. Samples of urine, feces, and plasma (heparinized) were taken at various time intervals for 8 days from the six dogs in each group. The bile ducts of four other dogs were cannulated and bile and urine collected continuously for 6 hours while the animals were kept under sedation with sodium pentothal. At the end of the sixth hour, collection balloons were affixed to the cannulae and the sedation was ended. At 24 hours the dogs were sacrificed and the bile was removed from the collection balloons. Two of the animals had been given 10 mg. per Kg. orally in gelatin capsules prior to the operation and two were injected with a similar dose intramuscularly following cannulation of the bile ducts, a procedure which took 15 minutes.

For the study of the distribution in the tissues of rats the drug was given in aqueous solution orally (stomach tube) and intramuscularly at a dose of 23.6 mg. per Kg. In each group, three rats were sacrificed per time interval up to 48 hours and dissected for radioassay of tissues.

Ascending paper chromatograms of urine samples were made on Whatman No. 1 paper developed in butanol, acetic acid, water (4:1:5, upper phase) and in butanol, pyridine, water (45:25:20). After development, the chromatograms were radioautographed on NO Screen X-ray film and subsequently cut into 1/2-in. sections for assay in a thin-window flow counter, or assayed microbiologically by application to the surface of agar seeded with *Staphylococcus aureus* followed by incubation at 37° for 16 hours.

RESULTS

Plasma Levels in Dogs.—Virtually all the radioactivity present in whole blood resided in the plasma fraction. Rapid absorption from the intramuscular injection site was indicated by a peak plasma level of C^{14} equivalent to 8.2 mcg. per ml. of nafcillin at 15 minutes, followed by a decline at a rate of about 2.5 mcg. per ml. per hour to the second hour (Fig. 1). After 8 days, the amount of radioactivity present in plasma amounted to the equivalent of approximately 1 mcg. per ml. Given by the oral route, the plasma level of C^{14} rose to about 1.4 mcg. per ml. by the second hour and then fell linearly to about 0.25 mcg. per ml. at the eighth day.

Urinary Excretion in Dogs.—Appreciable radioactivity amounting to an average of 1% of an intramuscular dose appeared in the urine within 15 minutes, 6% at 1 hour (Fig. 2). Following an oral dose, about 0.3% was excreted in the urine within the first hour. By the sixth hour 14% of the intra-

[a] Average values, three animals per group, expressed as equivalent amount of nafcillin in mcg./Gm. of tissue. [b] Total collection, expressed as per cent of dose.

muscular dose and 7% of the oral dose was excreted. However, by the third day, regardless of route of administration, roughly the same fraction of the dose of radioactivity, 18–19%, appeared in urine. After the third day, little additional radioactivity appeared and the total amounts excreted in the urine by the eighth day after intramuscular and oral dosing were 21 and 19.4%, respectively.

Fecal Excretion in Dogs.—Approximately the same amount of radioactivity was excreted in feces after both intramuscular and oral administration (Fig. 3), about 10% in the first 24 hours, 20–25% in the next 24 hours. The total by the eighth day amounted to almost 50% of the dose.

Distribution in Tissue of Rats.—Within 30 minutes of an intramuscular dose, radioactivity was found in all major organs and tissues (Table I). The highest concentrations appeared in small intestine, liver, and kidney. Since cecal wall was rinsed free of its contents prior to assay, the high values for this tissue indicate a fair degree of binding. The plasma level at 30 minutes, 17.5 mcg. per ml., was what one might anticipate from the results in dogs if one considers that the latter received half the dose given the rats. However, at 24 and 48 hours, the plasma levels were only one-eighth those of intramuscularly injected dogs. The relative amounts of radioactivity appearing in feces and urine correspond roughly with those of dog excreta, with a 2:1 ratio of fecal to urinary content.

Tissue levels following an oral dose of C^{14}-nafcillin in rats were lower than after an intramuscular dose (Table II). That these lowered values are partly the result of the slow rate of gastric emptying in the rat can be seen by the values for stomach which, at 4 hours, still contained an appreciable amount of the drug. The drug seems to be more poorly absorbed from the gut of the rat than from that of the dog (since plasma levels were lower than in dogs, though the dose was higher) and at 48 hours the rats had excreted only half as much radioactivity in the urine as had the dogs. Another indication of the poor absorption from the gut of the rat is the ratio of fecal to urinary excretion, about 10:1 (including cecal contents) in the oral-dosed rats compared with about 2:1 with the intramuscular-dosed rats. It will be recalled that the ratio was 2:1 in dogs for both routes of administration.

Metabolism.—It was shown in Fig. 2 that 14% of injected radioactivity was excreted in urine

24	14	0

[a] Values are per cent of total radioactivity contributed by unchanged nafcillin as determined by bioassay. Each value is the average from six dogs (see Figs. 1 and 2).

within 6 hours of an intramuscular dose of C^{14}-nafcillin. Bioassay of this urine indicated that only half of the C^{14} present was contributed by microbiologically active drug. From this, it was inferred that the major area of radioactivity at the R_f of nafcillin (0.82), representing 80% of the radioactivity on the paper chromatogram (Fig. 4), contained, in addition to nafcillin, one or more metabolites accounting for 30% of the C^{14} in urine. Two other metabolites, at R_f 0.62 and R_f 0.51, each accounting for 10% of the C^{14} in urine, were found by bioassay of the paper chromatogram to be microbiologically inactive, while the area at R_f 0.82 showed an amount of microbiological activity consistent with the idea that the C^{14} present was divided between nafcillin and metabolite in the ratio 5:3.

One substance considered as a possible metabolite, 2-ethoxynaphthoic acid, was excluded because of its high R_f value, 0.92, as compared with the highest zone of radioactivity at R_f 0.82. The possibility that 2-ethoxynaphthoic acid was formed, but escaped detection by being further metabolized was considered, but ruled out on two counts: when 2-ethoxynaphthoic acid was administered to dogs both unchanged acid and a metabolite (presumably the naphthuric acid) appeared in the urine in about equal quantities, and therefore, one would expect to find some free ethoxynaphthoic acid present if hydrolysis did occur; secondly, nafcillin is resistant to hydrolysis by cultures of *Alcaligenes faecalis* under conditions in which benzylpenicillin is cleaved.

Attempts to identify metabolite *A* as either the penicilloic or penilloic acid of nafcillin have thus far been inconclusive.

Bioassay/Radioassay Ratios.—Values obtained by bio- and radio-assay in urine and plasma showed a consistently lower ratio (bioassay/radioassay) in

plasma (Table III) than in urine. A ratio of one-half to two-thirds was maintained in the urine for the first 6 hours after intramuscular injection while the drop in plasma bioassay accompanied a change in the ratio from one-third to zero.

When bile and urine were collected after intramuscular administration of nafcillin in a separate experiment, bile and urine maintained fairly high bioassay/radioassay ratios for the first 6 hours (the bioassay ranging from 32 to 100% of the radioassay) but plasma samples bioassayed 20% or less for the first 4 hours and *nil* at the sixth hour. By comparing the amounts of the drug excreted in bile (Table IV) with those finally appearing in feces (Fig. 3), a fair degree of reabsorption of nafcillin from gut is apparent.

Physics of Tablet Compression XIII

Development of Die-Wall Pressure During Compression of Various Materials

By JOHN J. WINDHEUSER†, JAGDISH MISRA, STUART P. ERIKSEN, and TAKERU HIGUCHI

A method for determining the pressure transmitted to the die wall during tablet compression is described. Basically, the method involves strain-gauge measurement of die expansion and the relation of this to the transmitted pressure. The pressure transmitting behavior of a number of compounds, both organic and inorganic, have been studied; some correlations between observed response and physical properties are suggested. Limited studies on the effect of the addition of a lubricant to the crystals are also reported. It was noted that change in the magnitude of transmission to the die wall was not a simple linear function of lubricant concentration.

EARLIER reports (1–6) of measurements of several variables involved during compression of pharmaceutical tablets did not attempt to determine the relative magnitude of the lateral forces developed during formation of compressed tablets on the die wall by various types of materials. Nelson (7), reporting earlier from these laboratories, proposed and tested a method for possible measurement of these forces but did not study the comparative behavior of different materials. Results of direct measurements carried out on a number of organic and inorganic substances by a relatively simple technique are presented in this communication.

The perpendicular force developed in a die cavity during tablet formation obviously is related to the flow characteristics of the compressed material. If the confined substance acted simply as a hydraulic fluid, the lateral pressure should be essentially equal to the compressional pressure. Compaction of any common granular solid, on the other hand, would lead to development of much lower sideward pressure—the extent of lowering being (in a sense) a measure of ease of lateral distortion or flow of the compressed material. This property would be reflected in the relative ease of ejection of the formed tablet and the moldability of the compacted mass. All this may depend on such

Physics of Tablet Compression XIII

Development of Die-Wall Pressure During Compression of Various Materials

By JOHN J. WINDHEUSER†, JAGDISH MISRA, STUART P. ERIKSEN, and TAKERU HIGUCHI

A method for determining the pressure transmitted to the die wall during tablet compression is described. Basically, the method involves strain-gauge measurement of die expansion and the relation of this to the transmitted pressure. The pressure transmitting behavior of a number of compounds, both organic and inorganic, have been studied; some correlations between observed response and physical properties are suggested. Limited studies on the effect of the addition of a lubricant to the crystals are also reported. It was noted that change in the magnitude of transmission to the die wall was not a simple linear function of lubricant concentration.

EARLIER reports (1–6) of measurements of several variables involved during compression of pharmaceutical tablets did not attempt to determine the relative magnitude of the lateral forces developed during formation of compressed tablets on the die wall by various types of materials. Nelson (7), reporting earlier from these laboratories, proposed and tested a method for possible measurement of these forces but did not study the comparative behavior of different materials. Results of direct measurements carried out on a number of organic and inorganic substances by a relatively simple technique are presented in this communication.

The perpendicular force developed in a die cavity during tablet formation obviously is related to the flow characteristics of the compressed material. If the confined substance acted simply as a hydraulic fluid, the lateral pressure should be essentially equal to the compressional pressure. Compaction of any common granular solid, on the other hand, would lead to development of much lower sideward pressure—the extent of lowering being (in a sense) a measure of ease of lateral distortion or flow of the compressed material. This property would be reflected in the relative ease of ejection of the formed tablet and the moldability of the compacted mass. All this may depend on such

factors as the hardness, shape, and/or the frictional properties of the crystals involved.

Data are presented for a number of halide salts, certain antacids, and a number of organic compounds. Of particular interest are results obtained on phenacetin, acetanilide, and stearic acids—all substances having leaf-like crystalline structure.

EXPERIMENTAL

Instrumentation.—The apparatus used for compression of the tablets was a high force hydraulic press as previously described by Nelson (7). The force exerted by the press was measured with an electrical load cell. In these studies the force applied was measured on the moving upper punch operating against a fixed lower punch. The electrical response of the transducer was followed by a strain-gauge resistance bridge and recorded on one channel of a Sandborn dual-track magnetic oscillograph in the manner previously described (8). The force transmitted to the die wall was recorded simultaneously on the second channel of the recorder as described below. Punches used were $^3/_8$-inch flat faced; the die was adapted from a standard steel $^3/_8$-inch die for the Stokes model A-3 tablet machine.

The die was modified as shown in Fig. 1. A segment of the wall was ground out to increase the sensitivity of the system and to render the stress forces more parallel in the sensed area. Two strain gauges were mounted on the die wall, one normal and the other parallel to the die bore. The strain gauges formed a part of a Wheatstone bridge circuit as shown in Fig. 2. The gauge placed parallel to the die bore was introduced into the circuit to compensate for temperature changes during the compression cycle. The response of the strain gauges was measured and recorded on the Sanborn magnetic oscillograph as noted earlier for the upper punch response. This system offered the advantages of not altering the internal die bore and not having the measurements depend on extrusion characteristics (which have been shown to vary widely for different substances) (9).

Instrument Calibration.—The upper punch response was calibrated by applying known forces

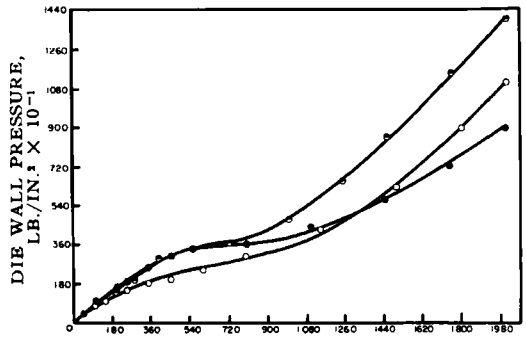

Fig. 4.—Die wall pressure response curve as a function of applied punch pressure for the chloride salts of lithium, sodium, and potassium. ●, LiCl; ○, NaCl; ◒, KCl.

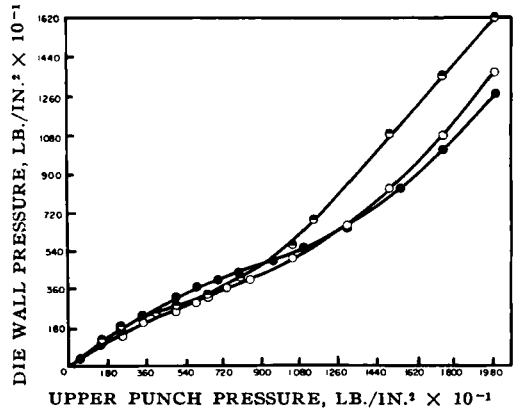

Fig. 5.—Die wall pressure response curve as a function of applied punch pressure for the bromide salts of lithium, sodium, and potassium. ●, LiBr; ○, NaBr; ◒, KBr.

with a lever arm, the applied force-response curve being essentially linear over the force range employed. The exact response of the die wall to known lateral pressure was determined by inserting a rubber plug into the die bore and measuring the response of the strain gauges to varying forces applied to the upper punch.

According to Adams and Gibson (10), rubber behaves under compression essentially as a liquid, so it was chosen for the calibration. Because of this apparent hydraulic behavior of rubber, the pressure applied by the upper punch can be assumed to be same as that transmitted directly to the die wall. Figure 3 shows a typical calibration curve for the electrical die wall response as a function of applied pressure. These determinations were repeated throughout the study to compensate for strain gauge drift. The response of the die wall strain gauges to a given normal compressional force obviously is a function of the rubber plug or tablet thickness. To eliminate this variable, a constant final thickness of 5 mm. was adopted for all experiments. Although some volume contraction occurs during compression, it was found that this change was not sufficient to alter seriously the results observed for rubber. In the case of tablets, only a 5% reduction in height was noted from the point of initial pressure response to the final thickness of 5 mm. This change appeared to be negligible based on experiments with tablets of varying final thickness.

Compression.—Compression of the material under test was carried out in a manner generally similar to that described previously (7) but with certain modifications. Since the observed response was dependent on final tablet thickness, preliminary trials were necessary for each compound to determine the weight which would yield a 5-mm. tablet. Also all dies were surface lubricated prior to use. In preliminary investigations apparent increases in die-wall forces were observed when unlubricated material was compressed in an unlubricated die as compared to a die with walls coated with a hydrocarbon lubricant.[1] It was felt that the increased response was a function of particle–die wall friction and may be due to the torque exerted on the die by the granulation during compression. As the purpose of the research was to study the effects of particle-particle interaction on the transmission of the forces to the die wall, all investigations were conducted using a die which was lubricated prior to each compression.

Compounds Tested.—All substances tested were of highest chemical purity commonly obtainable. They were dried at suitable temperatures and stored in vacuum dessicators prior to use. Storage was found necessary since variation in moisture content appeared to alter the compression characteristics.

RESULTS AND DISCUSSION

Effect of Particle Size

Changes in the particle size of the material subjected to compression appear to have only a minor (if any) effect on the side wall pressure transmission. A sample of sodium chloride crystals was fractionated by using standard screens in three general size ranges: larger than 20-mesh, through a 20-mesh and caught on a 40-mesh screen, through a 40-mesh and retained on a 60-mesh screen. Within experimental variation, the curves were identical with that for an unsegregated sample indicating no significant difference arising from particle-size variation over the range studied. For this reason no serious effort was made in the succeeding determinations to control particle sizes.

Compression of Inorganic Compounds

Alkali Metal Halides.—The compressional characteristics of the chloride, bromide, and iodide salts of lithium, sodium, and potassium were studied in some detail since these compounds were available in pure states and because of the availability of precise effective radii of the ionic components. Since the internal crystal attractions (and consequently crystal hardness) appear to depend on inter-ionic distances, some correlation was expected between these values and the efficiency of pressure transmission.

Figures 4–6 show the typical relationships found between applied pressure and the pressure transmitted to the die wall during several runs carried out on the halide salts. In all cases the general shapes of the curves were similar, they had an initial linear segment, then passed through an area having reduced transmittance characteristics, and then a subsequent linear portion which in most cases appeared to approach a slope of one. Although duplicate runs on a given material showed some variation, these variations were small relative to the dif-

ferences observed between materials. Usually replicate sidewall pressure determinations agreed within ±5% for a given substance at a particular compressional pressure.

Although the present state of knowledge cannot totally explain the observed results, some rationalization is possible. For example, the die-punch response curve may depend on crystal hardness, particle-particle friction, and/or shape of the crystal. Table I shows that the initial slopes of the curves plotted in Figs. 4–6 appear to follow the pattern of the hardest crystals (LiCl) having the highest initial slopes, and the softest (KI) having the lowest initial slopes, although exceptions appear to exist. The slopes seem to be somewhat more dependent on the nature of the anionic than on the cationic part.

The subsequent decrease in slopes occur in the compressional range associated with the fracturing of crystals and the assumption of increasingly closer packing. That the fraction of the pressure transmitted to die wall is reduced in this region is certainly not unexpected. The final slope, approaching a direct transmission condition, may represent a void-free, solid-state compression and flow. Table II represents a tabulation of the apparent "yield values" for the salts investigated. These values, which are the extrapolations of the final slopes back to zero die wall response, may be expected to increase with crystal hardness if the previous assumptions have some validity. This seems to be generally the case.

Some Antacids.—Figures 7 and 8 show the data obtained when dihydroxy aluminum sodium carbonate[2] and potassium carbonate were compressed. Both exhibited a rather low degree of transmission of the punch force to the die wall, indicating relatively poor flow tendency. During the compression and ejection of the tablets, the machine emitted sounds which indicated marked binding between tablet and die wall. The low initial slope shown by the DASC curve was also reflected by stratification within the finished tablet (inidicative of layer formation).

[2] DASC-Chatanooga Chemical Brand of dihydroxy aluminum sodium carbonate.

Compression of Organic Substances

Lateral pressure transmission characteristics of some organic compounds of pharmaceutical importance were studied. The results of these investigations are shown in Figs. 9 and 10. Although the shapes of the curves are similar to those observed with the alkali metal halides, the curves for benzocaine, aspirin, and phenobarbital do not exhibit the pronounced leveling that was previously found. This might be attributed to the crushing of the crystals even at low pressure and the assumption of a state of closest packing, followed by essentially void-free compression. In the case of the carbohydrates, the plateau is more extended as might be expected from the relative hardness of the sugars (in comparison to the other compounds tested). From Figs. 9 and 10 the "yield values" of aspirin and lactose were found to be 5800 lb./in.² and 12,700 lb./in.², respectively. Higuchi, *et al.* (3), had found earlier that lactose appeared to be three to four times as hard as aspirin. This investigation agreed qualitatively with the apparent "yield values" found in this study.

It is a well known fact that certain compounds are relatively difficult to compress into acceptable tablets. Phenacetin is an outstanding example of a

substance yielding tablets which are prone to capping. Such tablets when cleaved show indications of lamination. It was felt that this behavior may be reflected in the die wall–punch response curve.

Figure 11 shows the results obtained during compression of crystalline stearic acid, acetanilid, and phenacetin. The essentially zero initial slope in the plots is common to all three compounds, indicating almost no lateral force transmission during the initial phase of compression. After this stage the shape of the curve is similar to that observed with the alkali halides, except that the plateau region is less pronounced than that previously observed.

This behavior may be related to the shape factor mentioned earlier. Each of these three compounds exists in plate-like crystals which might tend to form layers under compression. This layering effect would reduce the lateral forces observed and possibly contribute to the tendency to cap. Although "yield values" were not determined since the final slopes did not appear linear at the higher pressures, it is apparent that qualitatively they would be in the expected order of the softest crystal—stearic acid having the lowest value and the hardest phenacetin having the highest.

Effect of Lubricants

In the previous work by Nelson (7), it appeared that the addition of to 1.6% magnesium stearate to a sulfathiazole granulation increased the force transmitted to the die wall by approximately 25%. Observations made as a part of this study with sulfathiazole and potassium chloride crystals lubricated by addition of 0.25, 0.5, and 1% magnesium stearate differed to some extent. The lubricant was incorporated into the system by trituration. The results are depicted in Figs. 12 and 13. In sulfathiazole, the unlubricated material exhibited the typical sigmoid curve but with lower transmittance than other organic compounds tested.

The lubricated samples, contrary to expectations, showed lower transmission characteristics at low punch pressures than the unlubricated materials, but higher ratios of the die-wall response at high pressures. It was surprising that transmission decreased with an increased addition of lubricant after an initial rise. A maximum increase of 10% transmission was found at higher pressures when 0.25% magnesium stearate was added, but only a 5–7% increase was recorded at 1% lubricant concentration. Similar results were found in the compression of potassium chloride, except that the increase with 0.25% magnesium stearate was more pronounced

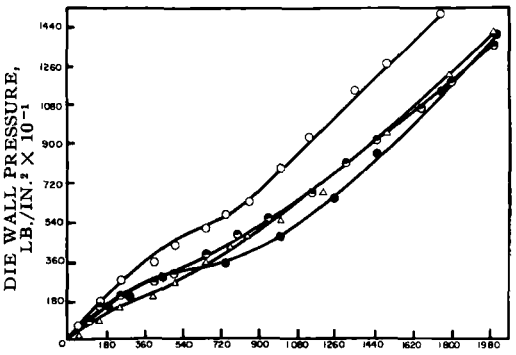

Fig. 13.—The effect of lubrication with magnesium stearate on the die wall–punch pressure response curve of potassium chloride. ●, Unlubricated KCl; O, KCl plus 0.25% magnesium stearate; ◓, KCl plus 0.50% magnesium stearate; Δ, KCl plus 1.00% magnesium stearate.

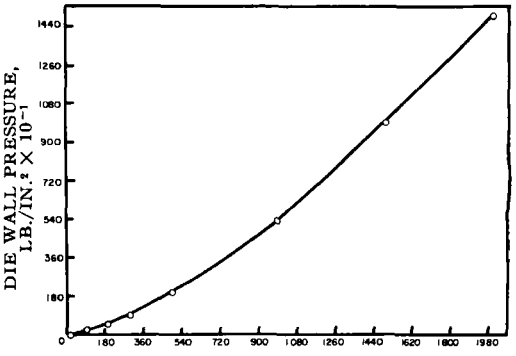

Fig. 14.—Die wall pressure response curve of magnesium stearate as a function of applied upper punch pressure. O, Magnesium stearate.

than with sulfathiazole; however, it presented the same trend at higher lubricant concentration that had been found with the sulfonamide.

The reason for the observed behavior may be found in the compressional characteristics of magnesium stearate. Figure 14 shows the curve obtained for the compression of pure magnesium stearate which is qualitatively similar to the curve shown for stearic acid in Fig. 11. The poor transmission behavior under lower pressure might give rise to the effect seen above, but this is not clearly established.

CONCLUSION

Although these studies have been largely preliminary, the results suggest that measurements of lateral pressure developed during formation of pharmaceutical tablets may provide a useful indication of compressional characteristics of various materials. As a broad and possibly too sweeping conclusion, it appears that materials which permit rather good conversion of normal pressure to lateral pressure tend to form good tablets. Substances expected to exhibit poor flow properties under pressure, such as those composed of thin, flat, leaf-like crystals, appear to be shown by this technique to behave in this manner.

The general method of study seems to be adaptable to pilot plant and commercial tablet machines with appropriate modifications. It is relatively simple and rapid. The rubber plug technique seems to provide a ready and quick means of calibration.

Sabadilla Alkaloids VIII

Isolation of Sabadillines I, II, and III

By GLENN R. SVOBODA†, HYMAN MITCHNER‡, and LLOYD M. PARKS§

The techniques of partition and adsorption chromatography as well as countercurrent distribution have been applied to alkaloidal concentrates from both sabadilla and veratrine. Whereas sabadilline previously was considered to consist of a single alkaloidal constituent, the present work has resulted in the isolation of three different materials which possess the characteristic ultraviolet absorption maximum at 238 mμ. These materials have been named sabadilline I, II, and III. Only sabadilline II was obtained in crystalline form. Attempts to establish a relationship between the three compounds were unsuccessful. Only sabadilline II yielded an alkaline isomerization product and this was not similar to either sabadillines I or III.

THE PRESENCE of an alkaloidal constituent of *Schoenocaulen officinale* (sabadilla) which exhibited an ultraviolet maximum at 238 mμ was first noted by Poetsch (1). This material was obtained from a commercial concentrate sold under the name "sabadilline." This was the name applied to the crystalline material, isolated by Hennig (2), which exhibited a similar ultraviolet spectrum. The work of Stuart (3) and Mitchner (4) confirmed the presence of a sabadilline-like material in both sabadilla and the commercial concentrate, veratrine, an alkaloidal extract of sabadilla.

A material which appeared to be similar to sabadilline was isolated by Auterhoff (5) and partially characterized by Vejdelek, Macek, and Kakac (6). To this material, which was named veragenine, was attributed an $\alpha\beta$-unsaturated ketone structure, unknown for any isolated sabadilla constituent other than sabadilline, for which an $\alpha\beta$-unsaturated ketone structure previously had been postulated by Stuart (3). The possibility of a similarity between the two compounds indicated the necessity of further investigation of the substance which exhibited

Sabadilla Alkaloids VIII

Isolation of Sabadillines I, II, and III

By GLENN R. SVOBODA†, HYMAN MITCHNER‡, and LLOYD M. PARKS§

The techniques of partition and adsorption chromatography as well as countercurrent distribution have been applied to alkaloidal concentrates from both sabadilla and veratrine. Whereas sabadilline previously was considered to consist of a single alkaloidal constituent, the present work has resulted in the isolation of three different materials which possess the characteristic ultraviolet absorption maximum at 238 mμ. These materials have been named sabadilline I, II, and III. Only sabadilline II was obtained in crystalline form. Attempts to establish a relationship between the three compounds were unsuccessful. Only sabadilline II yielded an alkaline isomerization product and this was not similar to either sabadillines I or III.

THE PRESENCE of an alkaloidal constituent of *Schoenocaulen officinale* (sabadilla) which exhibited an ultraviolet maximum at 238 mμ was first noted by Poetsch (1). This material was obtained from a commercial concentrate sold under the name "sabadilline." This was the name applied to the crystalline material, isolated by Hennig (2), which exhibited a similar ultraviolet spectrum. The work of Stuart (3) and Mitchner (4) confirmed the presence of a sabadilline-like material in both sabadilla and the commercial concentrate, veratrine, an alkaloidal extract of sabadilla.

A material which appeared to be similar to sabadilline was isolated by Auterhoff (5) and partially characterized by Vejdelek, Macek, and Kakac (6). To this material, which was named veragenine, was attributed an $\alpha\beta$-unsaturated ketone structure, unknown for any isolated sabadilla constituent other than sabadilline, for which an $\alpha\beta$-unsaturated ketone structure previously had been postulated by Stuart (3). The possibility of a similarity between the two compounds indicated the necessity of further investigation of the substance which exhibited

§ Present address: College of Pharmacy, Ohio State University, Columbus.

the ultraviolet maximum at 238 mμ first noticed by Poetsch (1). Before this could be done it was necessary to devise a more convenient separation procedure than the chromatographic separation devised by Hennig (2).

EXPERIMENTAL

Materials.—All chemicals except technical chloroform were of reagent quality. Ultraviolet spectra were obtained with a Cary model 11S automatic recording spectrophotometer. Infrared spectra were obtained with a Baird double-beam instrument. Buffers were standardized with a Beckman model H-2 pH meter. The Craig countercurrent distribution apparatus used was a 200 tube, robot driven instrument (manufactured by H. O. Post, Maspeth, N. Y.). Each tube was of 20-ml. capacity, adjusted for 10 ml. upper and lower phase. A 2-ml. microburet was used for the titrations. Samples were titrated in chloroform *versus* perchloric acid in glacial acetic acid using quinaldine red as the indicator. The veratrine used in this investigation was kindly supplied by S. B. Penick and Co.

Purification of Sabadilline Concentrates.—Available from the isolation of sabatine from Poetsch's Fraction D (1) by partition chromatography of successive samples on silicic acid at pH 8.00, were the peak materials eluted immediately prior to the sabatine peak. These corresponded to the material

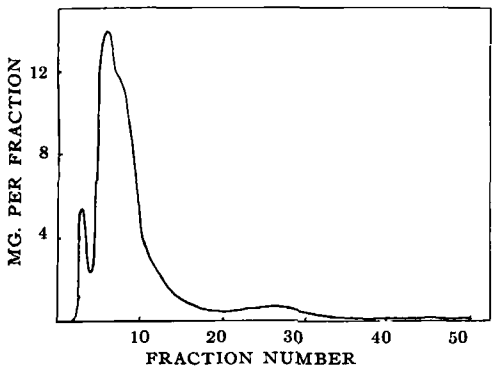

Fig. 1.—Partition chromatogram of a sabadilline concentrate on silicic acid with chloroform *vs.* pH 8.00 phosphate buffer.

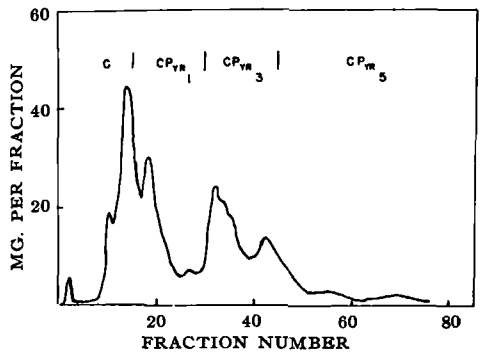

Fig. 2.—Partition chromatogram of a sabadilline concentrate on purified cellulose with chloroform and chloroform containing the designated increments (%) of pyridine *vs.* pH 6.50 phosphate buffer.

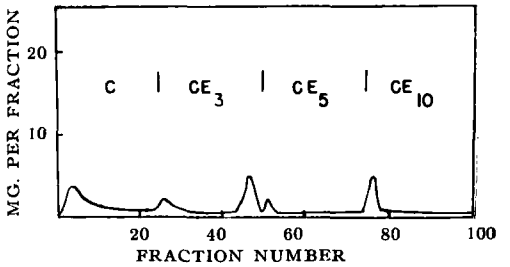

Fig. 3.—Adsorption chromatogram of a sabadilline concentrate on activated (basic) alumina with chloroform and chloroform containing the designated increments (%) of ethanol.

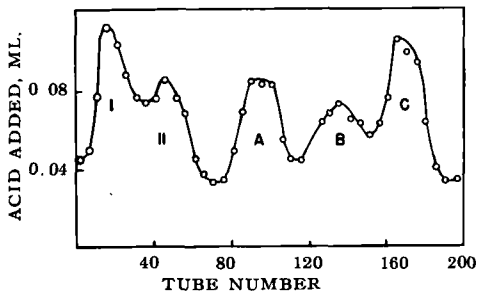

Fig. 4.—Countercurrent distribution of 1 Gm. of Fraction I at pH 6.35 for 406 transfers *vs.* chloroform.

from which Hennig (2) was able to isolate a few milligrams of sabadilline. Ultraviolet absorption analyses of these peak materials confirmed the presence of a maximum at 238 mμ. These sabadilline concentrates were purified by a modified countercurrent distribution using a chloroform–phosphate buffer (pH 7.25) system.

The sabadilline concentrates were dissolved in 50 ml. of chloroform and shaken with an equal volume of pH 7.25 phosphate buffer. The chloroform solution was transferred to the next separator containing fresh buffer at pH 7.25. The process was continued through six transfers. The buffer solutions were combined, made alkaline with ammonium hydroxide, and extracted with 10-ml. portions of chloroform until a negative Mayer's test was obtained. The chloroform extracts were filtered through anhydrous sodium sulfate and evaporated to dryness under reduced pressure. Successive peak materials were treated in a similar manner. Those materials which exhibited an ultraviolet maximum at 238 mμ were combined and used in chromatographic separations.

Partition Chromatography with Sabadilline Concentrates.—Silicic acid columns (30 Gm. silicic acid:30 ml. buffer) were prepared as described by Poetsch (1). A 15-to-1 ratio of length-to-width was maintained for all columns. Samples (about 500 mg.) were dissolved in a minimal volume of chloroform and placed on the column. Ultraviolet analyses of 10-ml. fractions showed that the sabadilline-like material was eluted from the negative slope of the main elution peak. Alkaloidal fractions which exhibited the ultraviolet absorption maximum at 238 mμ from several such columns were combined (125.6 mg.) and placed on a column which consisted of 6 Gm. of silicic acid and 6 ml. of pH 8.00 phosphate buffer. Ultraviolet analysis of the chloroform elu-

tion pattern obtained (Fig. 1) indicated the possibility of two independent materials which exhibited a sabadilline-like absorption spectrum based upon the extinction coefficients obtained.

Another supporting phase used for the partition chromatographic separation of sabadilline concentrates was Solka-Floc BW-200, a purified cellulose (obtained from the Brown Co., Boston, Mass.). A 1.0-Gm. sample of sabadilline concentrate was placed on a column which consisted of 40 Gm. of cellulose and 30 ml. of pH 6.50 phosphate buffer. Figure 2 shows the elution pattern of 10-ml. fractions obtained using chloroform and chloroform-containing increments of pyridine.

Ultraviolet analyses of the eluted fractions indicated the existence of three independent materials which exhibited the sabadilline maximum at 238 mμ. Fractions 13 to 20 were combined to give about 300 mg. of material which had an extinction coefficient ($k \times 100$ at 238 mμ) in excess of 1000. All attempts to crystallize this material were unsuccessful.

Adsorption Chromatography with Sabadilline Concentrates.—The adsorbents investigated in this study included silicic acid, acid-washed alumina, activated alumina, light and heavy magnesium oxides, Florisil, and Celite. Of these, only activated alumina gave results worth further consideration. Ultraviolet absorption analyses of the 10-ml. fractions obtained by the chromatographic separation of a 100-mg. sample of a sabadilline concentrate on 5.0 Gm. of activated alumina using chloroform and chloroform-containing increments of ethanol (Fig. 3) indicated the existence of three sabadilline materials.

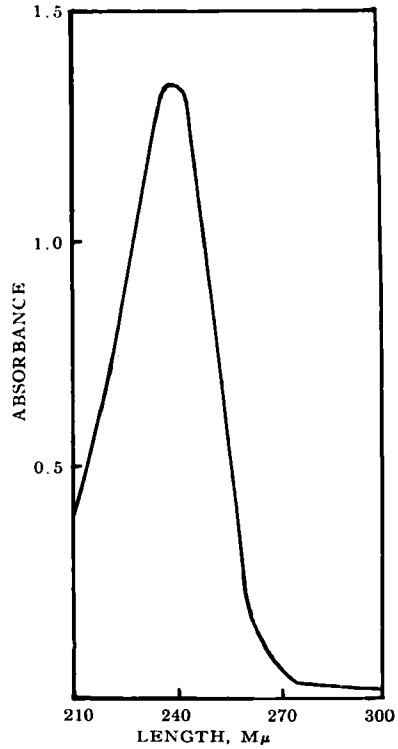

Fig. 7.—Ultraviolet spectrum of sabadilline II in absolute ethanol ($k \times 100 = 3004$).

The other adsorbents cited gave either too large a sample holdup or a lack of constituent resolution.

At this point it was deemed advisable to investigate other means of separation.

Countercurrent Distribution of Sabadillines Obtained from Veratrine.—Previous work (7) describing the quantitative determination of the known alkaloidal constituents of commercial veratrine described the isolation of the hydrophilic alkaloids in $P_{0.1.2}$. Successive 5-Gm. samples of $P_{0.1.2}$ were distributed for about 200 transfers at pH 7.00 *versus* chloroform. Five distribution peaks were obtained. Ultraviolet absorption analyses of the negative slopes of (*a*) Peak A, (*b*) Peak C, and (*c*) the positive slope of Peak E, indicated the presence of a maximum at 238 mμ. Alkaloidal material which was interposed between (*a*), (*b*), and (*c*) did not exhibit ultraviolet maxima at 238 mμ. Infrared absorption analyses confirmed the presence of an unsaturated band for (*a*), (*b*), and (*c*) and the absence of this band for the interposed material. The tubes which corresponded to these areas of the distributions were combined to give Fractions I to VI.

Successive portions of Fractions I, III, and V were subjected to countercurrent distribution until nearly identical theoretical and experimental curves were obtained or until the sample size prevented further purification; then attempts were made to crystallize the material. Distribution patterns were obtained as described previously (7).

Six portions of Fraction I (100 to 1100 mg.) were

distributed at pH values from 5.50 to 6.35 for 100 to 400 transfers. The best resolution of material was obtained with a 1.0-Gm. sample at pH 6.35 *versus* chloroform for 400 transfers. All alkaloidal material was found as shown in the first 200 tubes of Fig. 4. Peak B was the only material which exhibited an ultraviolet maximum at 238 mμ. All of the material of this peak was again distributed at pH 6.35 *versus* chloroform for 400 transfers. All of the alkaloidal material was found as shown in the first 200 tubes of Fig. 5. Although the distribution was symmetrical, there was no agreement between theoretical and experimental points. All attempts to crystallize the material obtained from Peak B, Fraction I were unsuccessful.

Amorphous sabadilline I (Peak B, Fraction I) softened from 126–133°, melted at 133–137°, and remelted from 133–140°. The material decomposed above 250°. Elemental analyses were inconclusive. The infrared spectrum of sabadilline I is shown in Fig. 8a. The alkaloidal spectrum (A.S.) value of sabadilline I was 6.05. The designation of alkaloidal constituents by A.S. value is helpful for unknown constituents. These constants are represented by that pH at which the partition coefficient of the constituent in chloroform *versus* aqueous buffer is unity (4). The A.S. values allow the accurate characterization of new components with respect to their A.S. values and give partition coefficient data for each unknown.

Sabadilline II was obtained from Fraction III in the following manner. Two samples of Fraction III (1.0 and 0.8 Gm.) were individually distributed for 210 transfers at pH 6.65 *versus* chloroform. The distribution pattern of the 1.0-Gm. sample is shown in Fig. 6. The distribution pattern was similar for the 0.8-Gm. sample. The materials found in Peaks A and B both exhibited an ultraviolet maximum at 238 mμ. The material in Peak A had an A.S. value of 6.72. However, the A.S. value of the material in Peak B (6.98) corresponded to the A.S. value of the material obtained by the aqueous alkaline treatment of Fraction III (*vide infra*). Therefore, Peak A was

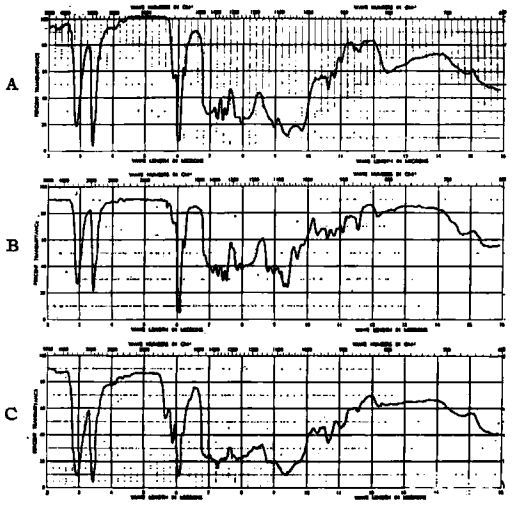

Fig. 8.—(A) Infrared spectrum of amorphous sabadilline I. (B) Infrared spectrum of crystalline sabadilline II. (C) Infrared spectrum of amorphous sabadilline III.

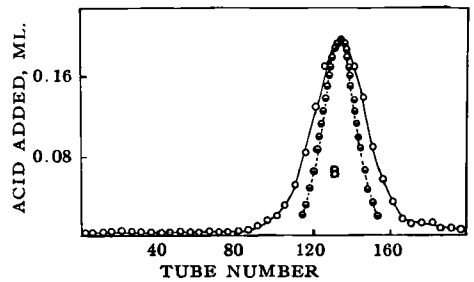

Fig. 9.—Countercurrent distribution of Peak B, Fraction V at pH 7.80 for 214 transfers *vs.* chloroform. Key: ○, experimental; ◒, theoretical.

considered to consist of naturally occurring sabadilline II. Crystalline sabadilline II was obtained from the combined Peak A materials of the two distributions. A total of 100 mg. of water-white, needle-shaped prisms was obtained by crystallization in ethanol-water. The crystals were dried at 100° (0.05 mm.) and exhibited the following melting characteristics: swelled and became opaque from 141–146°, decomposed slightly from 210–225° and melted from 235–252°. The ultraviolet spectrum of sabadilline II is shown in Fig. 7 and its infrared spectrum in Fig. 8b. Elemental analyses were inconclusive.

Sabadilline III was obtained from Fraction V. Five portions of Fraction V of from 100-1000 mg. were distributed at pH values of 7.90 to 8.00 *versus* chloroform for 200 transfers. Only Peak B of Fraction V exhibited an ultraviolet maximum at 238 mμ. The material which comprised Peak B from all of the distributions was combined and distributed for 214 transfers at pH 7.81 *versus* chloroform (Fig. 9). Sabadilline III had a calculated A.S. value of 7.83. There was no agreement between the theoretical and experimental distribution values. Attempts to crystallize sabadilline III were unsuccessful. Amorphous sabadilline III exhibited the following melting characteristics: swelled 126–136°, no true melt to 170°, reswelled from 123–140°, melted from 140 180°, and decomposed slowly above 210°. The infrared spectrum of sabadilline III is shown in Fig. 8c.

Attempts to Determine a Relationship Between Sabadillines I, II, and III.—Countercurrent distribution of the products of methanolysis (8) of Fraction III showed that the reaction conditions were too mild since only the original material appeared in the distribution pattern of the treated material. A similar analysis of the products of ethanolic potassium hydroxide treatment (8) of Fraction III indicated by their number that these reaction conditions were too severe. The conditions finally selected for the methanolic alkaline treatment of Peak B, Fraction III were as follows: A 59-mg. sample of Peak B, Fraction III was dissolved in a solution of 4 ml. of methanol and 1 ml. of 1 *N* potassium hydroxide. The solution was refluxed for 15 minutes, cooled, and made just acid with 1:1 hydrochloric acid. The methanol was removed under reduced pressure and the residue was extracted with four 25-ml. portions of chloroform after adding sufficient ammonium hydroxide to give a pH of 9.00. The combined chloroform extracts were dried by filtration through anhydrous sodium sulfate and evaporated to dryness under reduced pressure. The prod-

uct obtained was distributed for 106 transfers at a pH of 7.00 *versus* chloroform. The single distribution peak obtained was collected and distributed again at pH 7.50 *versus* chloroform. The single peak obtained from the latter distribution had a calculated A.S. value of 6.98 compared to 6.72 for sabadilline II. The material was considered to be an alkaline isomerization product of sabadilline II and was similar to the material obtained from Peak B, Fraction III which had a calculated A.S. value of 6.97.

Peak B, Fraction I and Peak B, Fraction III (sabadilline I and III) were treated in a similar manner. Infrared analysis of the materials obtained in the respective distribution peaks of the reaction products showed that they consisted of impure starting materials. Therefore, the results of the aqueous alkaline treatment of sabadillines I and III were inconclusive, in that they were not changed under the reaction conditions to which they were subjected. The small amount of material available precluded further investigation.

Pharmacological Evaluation of Sabadilline II.— In the dog under phenobarbital anesthesia, 1.0 mg./Kg. intravenously depressed respiration for approximately 10 minutes, depressed gut motility, and produced a slight transitory rise in blood pressure. The EKG record showed depression of the S-T segment with an increase in T-wave amplitude similar to that observed with increased blood potassium level. At 2.19 mg./Kg. intravenously it produced a fall in blood pressure for approximately 5 minutes and a temporary inhibition of respiration and gut motility. After 20 minutes, the heart rate slowed and the dog died. EKG changes were the same as with the 1-mg./Kg. dose.

Because of the amorphous nature of sabadilline I and III, their physiological activity as potential hypotensives was not checked.

DISCUSSION AND CONCLUSIONS

A prerequisite to the successful conclusion of this investigation was to devise separation and purification techniques for sabadilline concentrates. Early chromatographic studies were laborious and confusing, indicating the presence of several materials which possessed the sabadilline ultraviolet maximum at 238 mμ. Additionally, the elution of the possible single compound was discontinuous and the apparent presence of separate compounds of this nature was because of a change in elution solvent composition.

Countercurrent distribution analyses of commercial veratrine had shown that between 1.8 and 4.8% of sabadilline material (as unknown X_1) was present in the total alkaloids (7) This work involved the separation of veratrine into hydrophobic, hydrophilic, and intermediate solubility fractions. Further countercurrent distributions of the hydrophilic alkaloids indicated three of the six fractions contained material which exhibited the sabadilline ultraviolet absorption spectrum. Further separation of the sabadilline-like materials in these fractions utilized additional countercurrent separations as described in this work.

The first of these sabadilline-containing concentrates (Fraction I) was shown to consist of at least five different constituents. The first two peaks obtained (Fig. 4) were not homogeneous. The third peak, Peak A, was known to be cevacine. It was Peak B which yielded sabadilline I. Peak C was shown to be another previously unknown Sabadilla constituent and was obtained in crystalline form. Further description of this material will be the subject of a later publication.

Sabadilline II and a compound believed to be its alkaline isomerization product were isolated by the countercurrent distribution of Fraction III (Fig. 5). Peak A corresponded to sabadilline II; Peak B corresponded to a product obtained by the alkaline treatment of sabadilline II. Sabadilline II was the only sabadilline obtained in crystalline form. The infrared spectrum of sabadilline II suggests a structure which more closely resembles sabine (4) than veracevine (6), thus suggesting that the parent alkamine of sabadilline is structurally most like sabine.

The third of the sabadilline compounds was obtained by countercurrent distribution of Fraction V (Fig. 6). Peak B was shown to consist of amorphous sabadilline III.

There was no question of the independent nature of the three sabadillines. It was then of interest to determine if there was some simple relationship between these alkaloids. The fractions from which the sabadillines were isolated were subjected to aqueous alkaline treatment. Infrared spectra before and after such treatment showed no significant structural changes resulting from the conditions of such treatment. Herein is sufficient evidence that the $\alpha\beta$-unsaturated ketone structure attributed to the sabadillines does not arise from the isolation procedures inasmuch as these procedures are far more mild than the aqueous alkaline treatment.

Sabadilla Alkaloids IX

Isolation of Unreported Minor Constituents and Their Relationship to the Known Sabadilla Alkaloids

By GLENN R. SVOBODA†, HYMAN MITCHNER‡, and LLOYD M. PARKS§

Additional minor alkaloidal constituents of sabadilla have been isolated from veratrine. Four of these were obtained as symmetrical countercurrent distribution peaks. A fifth, sabadene, was obtained in crystalline form. Sabadene possessed no hypotensive properties. The investigation also notes the existence of extremely minor quantities of unresolved constituents. A review of the relationship of all reported sabadilla alkaloids is presented.

As INDICATED in previous reports (1, 2), additional unreported alkaloidal constituents of sabadilla have been isolated by countercurrent distribution of commercial veratrine. One of these, for which the name "sabadene" is proposed, was obtained in crystalline form. Sabadene was shown by infrared analysis to contain an isolated carbon-carbon double bond structure, previously unknown for any sabadilla alkaloid. In addition, four other amorphous alkaloidal materials were obtained as symmetrical distribution peaks and two additional distribution peaks were obviously of a heterogeneous nature.

Fortunately, the isolation procedure resulted in the isolation of previously known sabadilla constituents for which pH assignments have been made at which these constituents demonstrate a partition coefficient of unity in aqueous buffers *versus* chloroform. The constants represented by partition coefficients equal to one have been called alkaloidal spectra (A.S.) values (3). These values allowed the accurate characterization of the new components with respect to their relative A.S. values and gave partition coefficient data for each unknown.

None of the new alkaloidal constituents described herein exhibited a characteristic ultraviolet spectrum. However, vanilloyl veracevine which had been reported previously (4) did exhibit its characteristic ultraviolet spectrum. The description of the original isolation of vanilloyl veracevine did not cite its partition characteristics relative to the total sabadilla constituents as is done in the present work.

EXPERIMENTAL

Apparatus and Reagents.—These were the same as described previously (2). The isolation techniques and distribution determinations have been similarly described (2).

Constituents of Fraction I.—The distribution

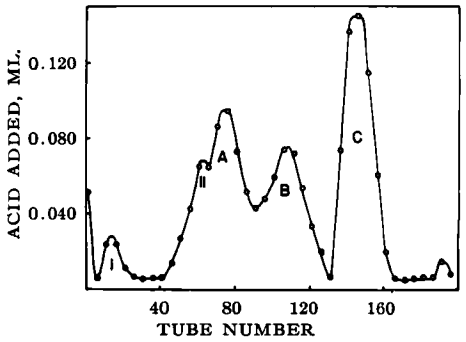

Fig. 1.—Countercurrent distribution of a 1.0-Gm. sample of Fraction I at pH 6.35 for 433 transfers *vs.* chloroform.

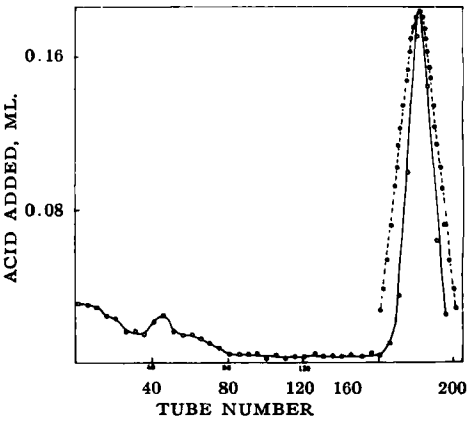

Fig. 2.—Countercurrent distribution of Peak I, Fraction I at pH 5.13 for 427 transfers *vs.* chloroform. Key: ○—experimental, ◒—theoretical.

conditions which resulted in the best resolution of the constituents of consecutive 1.0-Gm. samples of Fraction I were a pH of 6.35 and about 400 transfers *versus* chloroform. Figure 1 shows the results obtained, all of the alkaloidal constituents being present in the first 200 tubes. The alkaloidal material which constituted each of the individual peaks was collected and treated as follows.

Peak I, Fraction I, was collected and distributed at pH 5.13 for 427 transfers *versus* chloroform, all of the alkaloidal constituents being present in the first 200 tubes (Fig. 2). The calculated A.S. value of the single symmetrical peak was 5.00. Peak I, Fraction I, exhibited the following melting characteristics: melted at 123–131° and remelted at 153–158°.

The distribution of Peak II, Fraction I, at pH 5.47 for 403 transfers *versus* chloroform (Fig. 3) showed that the original peak was actually composed of at least three materials as well as a residual quantity of Peak I, Fraction I. In this distribution, all of the alkaloidal material was present in tubes 120 to 280. The identity of residual Peak I, Fraction I, as an unknown was confirmed by the calculated A.S. value (5.25) of Peak I (Fig. 3) compared to the value obtained for Peak I, Fraction I (5.20), of Fig. 2.

Peak A, Fraction I, was distributed at pH 5.88 for 464 transfers *versus* chloroform (Fig. 4). Peak A had a calculated A.S. value of 5.89 compared to 5.88 for cevacine and exhibited an infrared spectrum similar to that of authentic cevacine.

The treatment of Peak B, Fraction I, from which sabadilline I was isolated has been described previously (2).

The fractions which constituted Peak C (Fig. 1) were combined and yielded 159 mg. of crystalline

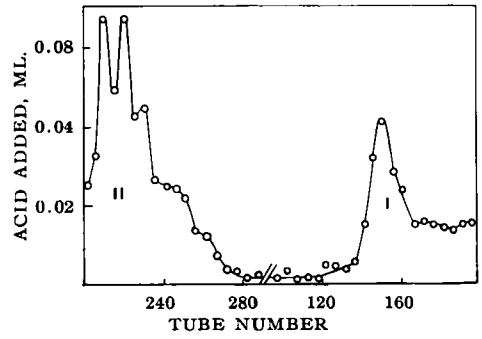

Fig. 3.—Countercurrent distribution of Peak II, Fraction I at pH 5.47 for 403 transfers *vs.* chloroform.

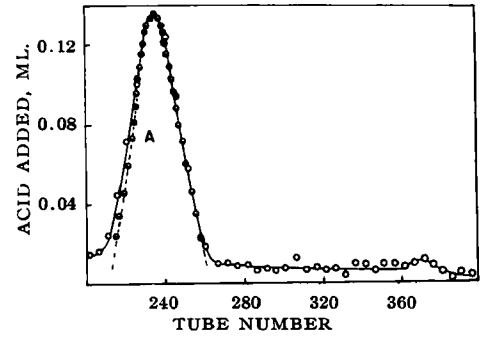

Fig. 4.—Countercurrent distribution of Peak A, Fraction I at pH 5.88 for 464 transfers *vs.* chloroform. Key: ○—experimental, ◒—theoretical.

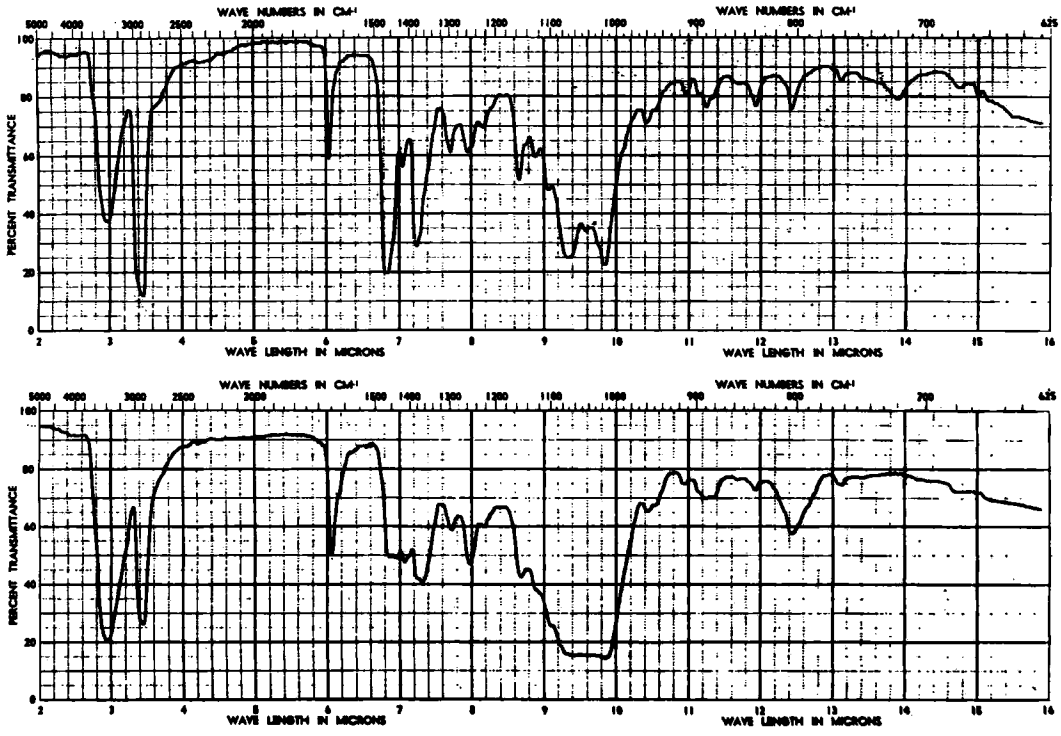

Fig. 5.—(*a*) Infrared spectrum of sabadene in Nujol. (*b*) Infrared spectrum of sabadene in a potassium bromide pellet.

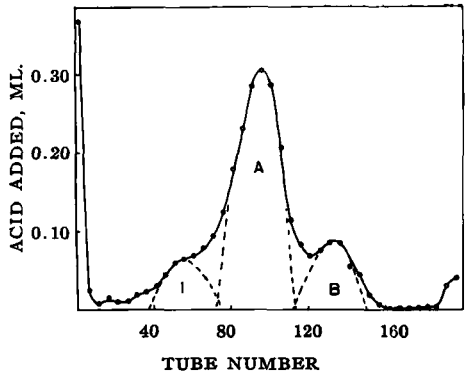

Fig. 6.—Countercurrent distribution of a 1-Gm. sample of Fraction II at pH 6.70 for 297 transfers *vs.* chloroform.

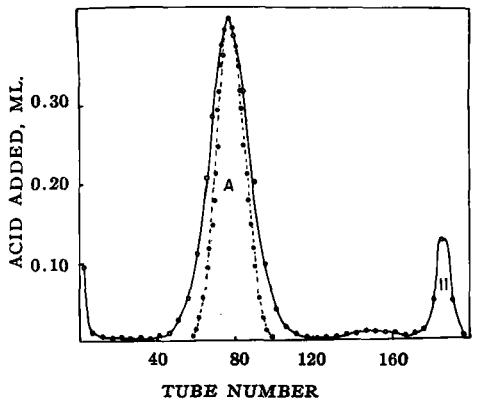

Fig. 7.—Countercurrent distribution of Peak A, Fraction II at pH 6.70 for 204 transfers *vs.* chloroform. Key: O—experimental, ⊖—theoretical.

sabadene from acetone-water. Crystalline sabadene melted from 218 to 219.5° after drying at 0.01 mm. for 24 hours. The silky mass of white needles lost their shiny appearance upon drying.

Elemental analyses best agreed with the formula $C_{28}H_{41-45}O_7N$. Insolubility of the material in chloroform required that the infrared spectrum be determined in Nujol (Fig. 5a) or as a potassium bromide pellet (Fig. 5b). Sabadene has a calculated A.S. value of 6.22.

Constituents of Fraction II.—Distribution of Fraction II (1-Gm. samples) at pH 6.70 for 200–300 transfers *versus* chloroform resulted in the resolution of three peaks (Fig. 6). Peak I, Fraction II, had a calculated A.S. value of 6.16 which suggested that it consisted of sabadene (6.22). Peak B, Fraction II, had a calculated A.S. value of 6.76 which suggested its identity as sabadilline II (6.72). Peak A, Fraction II (calculated A.S. value = 6.50), appeared to be another new alkaloidal constituent. The tube contents which constituted Peak A, Fraction II, were collected and distributed at a pH of 6.70 for 204 transfers *versus* chloroform (Fig. 7). Peak A, Fraction II, had a calculated A.S. value of 6.42 and Peak II, 7.64. The infrared spectrum of Peak II was identical to that of authentic veracevine although the A.S. values did not agree (7.64 *versus* 8.15). However, Peak II could only have resulted from the distribution conditions. This suggests that the alkamine of Peak A, Fraction II, is a veracevine type. The melting characteristics of amorphous Peak A, Fraction II, were as follows: swelled from 128–134°, melted 152–157°, remelted 152–157°, and decomposed slowly from 230–290°.

Constituents of Fraction III.—The distributions of Fraction III (1.0-Gm. samples) at pH 6.65 *versus* chloroform resulted in the isolation of sabadilline II from Peak A, Fraction III, and what appeared to be its alkaline isomerization product (Peak B, Fraction III) which has been discussed previously (2). In addition, three very minor distribution peaks were observed. Peak I, Fraction III (A.S. value 6.52), was probably identical to Peak A, Fraction II (A.S. value 6.50). Peak II, Fraction III (A.S. value 7.23), was probably identical to sabatine (A.S. value 7.33). Peak III, Fraction III (A.S. value 7.56), was probably identical to Peak A, Fraction V (A.S. value 7.51).

Constituents of Fraction IV.—The material which comprised Fraction IV had the same calculated A.S. value (7.33) as did sabatine. Crystalline sabatine

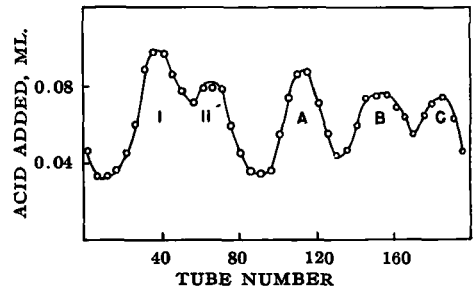

Fig. 8.—Countercurrent distribution of a 500-mg. sample of Fraction V at pH 7.80 for 210 transfers *vs.* chloroform.

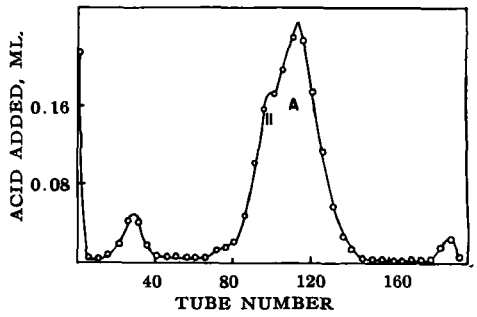

Fig. 9.—Countercurrent distribution of Peak A, Fraction V at pH 7.50 for 215 transfers *vs.* chloroform.

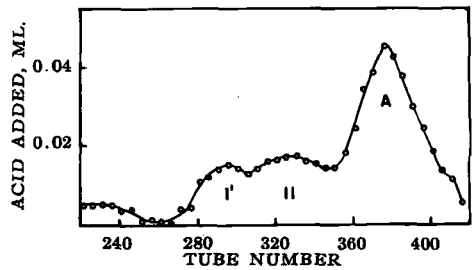

Fig. 10.—Countercurrent distribution of Peak A and Peak II, Fraction V at pH 7.50 for 697 transfers *vs.* chloroform.

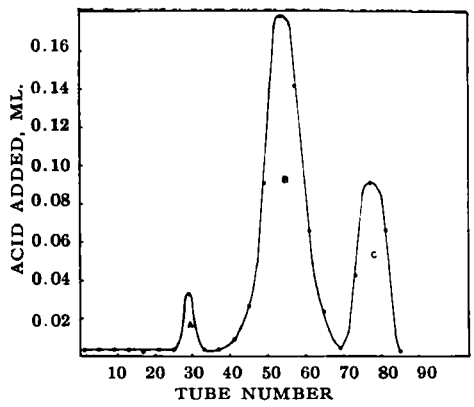

Fig. 11.—Countercurrent distribution of Fraction VI at pH 8.00 for 90 transfers *vs.* chloroform.

was isolated from this peak material. In addition, Fraction IV exhibited infrared absorption characteristics similar to sabatine.

Constituents of Fraction V.—The conditions which resulted in the best resolution of 0.5–1.0-Gm. samples of Fraction V were a pH of 7.80 and about 210 transfers *versus* chloroform. A typical distribution pattern obtained is shown in Fig. 8. Peak I, Fraction V, had an average calculated A.S. value of 6.77 which corresponded to the A.S. value of sabadilline II (6.72). Peak II, Fraction V, had an average A.S. value of 7.52. Peak A, Fraction V, appeared to be composed of at least two constituents in one distribution (not shown), but was generally obtained as a single symmetrical peak. The material which comprised Peak A and Peak II was collected and distributed at pH 7.50 for 215 transfers *versus* chloroform. As can be noted from Fig. 9, a poorly resolved peak of A.S. value 7.43 was obtained. This was believed to be similar to Peak II, Fraction V. The material which constituted Peak A was again collected and distributed at pH 7.50 for 697 transfers *versus* chloroform (Fig. 10). All of the alkaloidal material was contained in tubes 220 to 400. Again, material other than Peak A was observed. These minor peaks, I and II, were not further investigated. Amorphous Peak A (A.S. value 7.51) was collected and the following melting characteristics were obtained: swelled 105–115°, melted 140–150°, reswelled and became opaque from 222–229°, decomposed slowly above 310.

As noted previously (2), Peak B, Fraction V, was found to consist of sabadilline III.

Peak C, Fraction V, had an average calculated A.S. value of 8.12. This corresponded quite closely to the A.S. value of veracevine (8.15). All attempts to crystallize this material were unsuccessful. The infrared spectrum of Peak C was identical to that of authentic veracevine.

Constituents of Fraction VI.—A single distribution of Fraction VI (100-mg. sample) was made at pH 8.00 for 90 transfers *versus* chloroform. Three peaks were obtained (Fig. 11). Peak A had a calculated A.S. value of 7.68, but the small amount of material obtained precluded further study. Peak B had a calculated A.S. value of 8.15 and was undoubtedly veracevine (A.S. value 8.15). Peak C had a calculated A.S. value of 8.79, which is intermediate between the values for cevagenine (8.6) and sabine (8.9). Peak C was not further investigated.

TABLE I.—TOTAL KNOWN AND UNKNOWN ALKALOIDAL COMPOSITION OF SABADILLA

Compound	Source (1, 2)	A.S. Value
Veratridine	$P_{6,7,8}$	3.65

Pharmacological Evaluation of Sabadene.—In the dog under phenobarbital anesthesia doses up to 1 mg./Kg., intravenously, this had no significant effect on blood pressure, respiration, gut motility, or EKG.

SUMMARY AND CONCLUSIONS

In addition to the previously known sabadilla alkaloids, the three sabadillines and the aqueous isomerization product of sabadilline II, the six fractions of the hydrophilic sabadilla alkaloids have been shown to contain additional minor alkaloids. The total known and unknown alkaloidal composition of sabadilla is presented in Table I in increasing order of A.S. value.

It is possible that Peak C, Fraction VI, may consist of several materials which include cevagenine and sabine, although these materials were not directly noted in this study.

A procedure such as cited in our several papers on the countercurrent separation of the sabadilla alkaloids is to be recommended in the analysis of complex mixture of natural products which possess slightly different partition characteristics. Isolation of products in crystalline form or known chemical identity is not a prerequisite to identification of the constituents.

Dissolution Behavior of Crystalline Solvated and Nonsolvated Forms of Some Pharmaceuticals

By ELI SHEFTER† and TAKERU HIGUCHI

Relative rates of dissolution of several crystalline steroids, xanthines, and other solid drugs have been measured to determine the effect of solvate formation on this property. Equations have been derived relating the solubility products and diffusional constants to rates of solution of organic solvates. The results suggest that the tendency of many drugs to form such adducts provide pharmaceutical investigators a powerful tool in effecting rapid dissolution of highly insoluble substances.

MANY ORGANIC and inorganic compounds are capable of existing in more than one crystalline form having different physical properties. In some cases these states are the result of solvate formation; in others the molecular arrangement within the crystal lattice is responsible for the differences in the properties of crystal modifications. The pharmaceutical importance of variations in the thermodynamic properties associated with the differences in crystal forms have been recently pointed out. It has been suggested by Higuchi (1) that the differences in the free energy of polymorphs, for example, can be an extremely important factor in determining the stability and availability of certain pharmaceuticals. The present report is concerned with the results of theoretical and experimental studies conducted to determine the magnitude of the differences in the thermodynamic and dissolution properties arising from the formation of such crystalline variants of a drug.

Organic medicinal compounds appear to be particularly prone to both formation of polymorphs and solvates and to have large differences in energy associated with such crystalline modifications. This can be ascribed to the size and general complexity of molecules having medicinal value and to their polyfunctionality. Such structures do not usually favor rapid crystalline nucleation and growth. These forms which are favored from the rate of crystal growth viewpoint often turn out to be metastable compared to more difficultly produced polymorphs. It is apparent that the appropriate selection of the most suitable crystalline modification, whether arising from polymorphic differences or as a result of solvate complex formation, can often significantly increase the medicinal value of a given drug in a particular dosage form.

Specifically, this study was concerned with a theoretical and experimental investigation of the relative dissolution rates of some crystalline solvates and polymorphs in aqueous solutions. The thermodynamic properties of these crystal systems also have been experimentally determined in several instances.

The six crystalline systems whose dissolution behaviors were studied are cholesterol, forms N_1 and H_1; caffeine, forms N_1 and H_1; theophylline, forms N_1 and H_1; glutethimide, forms N_1 and H_1; succinyl sulfathiazole, forms N_1, H_1, H_2, and P_1; and 9α fluorohydrocortisone acetate (fludrocortisone acetate), forms N_1, N_2, P_1, and E_1, where N_1 represents a nonsolvated crystalline form and H_1, P_1, and E_1, represent a specific hydrate, pentanol solvate, and ethyl acetate solvate, respectively, for each compound. Polymorphic and additional variations are noted by appropriate subscripts. The thermodynamic differences between the various solvated and nonsolvated crystal forms of theophylline, glutethimide, fludrocortisone acetate, and succinyl sulfathiazole were evaluated. In addition, studies were undertaken to determine the effect of certain protective colloids on prolongation of a metastable phase.

PAST WORK ON CRYSTALLINE HYDRATES AND SOLVATES

Past studies on the physical chemical properties of crystalline hydrates appear to have been mainly limited to inorganic compounds. The phase solubility method was utilized, for example, by many workers to obtain the solution properties of inorganic hydrate systems in aqueous solutions. The investigation of Taylor and Henderson (2) on the various hydrates of calcium nitrate is a good example of the type of results obtained by this method.

Hill (3), in a similar type study on calcium sulfate, was able to determine accurately the transition temperature between an anhydrous form and a dihydrated form. Kuznetsov and co-workers (4) determined some of the factors involved in the con-

version of an anhydrous form of calcium sulfate to the dihydrate at 18°.

Eriksson (5) recently examined the apparent solubility of an anhydrous form and two hydrates of phenobarbital as a function of time in water. The concentration of drug in solution was measured on an hourly basis, assuming no immediate conversion of the metastable phases in the solution. In this investigation the solubility of the anhydrous form was greater than the two hydrates below 50°. No attempt was made to evaluate the thermodynamic properties or dissolution rates of these crystalline modifications. This study seems to be the only investigation reported in the literature which compares the solubilities of hydrated and anhydrous forms of organic compounds.

There are many references in the literature on the formation of crystalline solvates of organic compounds. These references are usually in connection with organic synthesis, a particular compound being reported as crystallizing from an organic solvent with molecules of the solvent attached. No previous investigations seem to have been reported on the properties of behavior of these types of solvates in aqueous media.

THEORETICAL CONSIDERATIONS

A general discussion of the theories basic to the equilibrium solubility (thermodynamic) and rates of solution for the various types of crystal systems studied is presented.

Thermodynamic Considerations

The equilibrium solubility of a nonsolvated form of a crystalline, nondissociating organic compound, A, in water may be represented by equilibrium 1 (Eq. 1) (6). This equilibrium is not only in-

$$A_{solid} \overset{Ks}{\rightleftharpoons} A_{aqueous} \qquad \text{(Eq. 1)}$$

fluenced by the parameters of temperature and pressure, but also by the crystalline state. Because organic compounds are able to exist in more than one crystalline state (polymorphism), it is necessary to identify the solid state in this equilibrium as a parameter.

The equilibrium constant, Ks, at a particular temperature and pressure may be defined as the solubility of a particular polymorph and is approximately proportional to the thermodynamic activity of the solid. An extensive treatment of the thermodynamic differences in the properties of polymorphs can be found in a recent report by Higuchi, *et al.* (7).

Equilibrium 2 (Eq. 2) represents the solid-solution

$$A:xH_2O_{solid} \overset{Ks}{\rightleftharpoons} A_{aqueous} + xH_2O \qquad \text{(Eq. 2)}$$

equilibrium for a hydrate in water. This system is analogous to the equilibrium for the nonsolvated form; consequently, the equilibrium constant, Ks, is essentially the solubility of the hydrate.

The hydration of an anhydrous crystal modification in water is represented by Eq. 3. The free

$$A_{solid} + xH_2O_{liquid} \rightleftharpoons A:xH_2O_{solid} \qquad \text{(Eq. 3)}$$

energy change for this process may be computed from Eq. 4

$$F_T = RT \ln \frac{(Ks) \text{ Hydrated form}}{(Ks) \text{ Anhydrous form}} \qquad \text{(Eq. 4)}$$

This energy difference can easily be obtained from solubility data for the two crystal forms at a particular temperature. Since the solubilities can be readily measured at several temperatures, the enthalpy and entropy changes corresponding to this process can also be determined. These thermodynamic data are of some theoretical interest relative to the information they provide concerning the molecular bonding of water in these solids.

An equilibrium model for the crystalline solvates of the type studied is shown in Eq. 5. This model assumes that in solution A and B exist as separate

$$A:nB_{solid} \overset{Ksp}{\rightleftharpoons} A_{aqueous} + nB_{aqueous} \qquad \text{(Eq. 5)}$$

species whose concentrations are determined by the solubility product, Ksp.

The free energy change corresponding to the process shown by Eq. 5 could be evaluated from the solubility of the solvated A in pure B, the solubility of unsolvated A in B, the solubility of the same unsolvated A in water, and the activity coefficient of B in water. It suffices to say at this point that for the solvates with which this study is concerned, Eq. 5 usually represents a far greater free energy difference than Eqs. 1 and 2.

Dissolution Rate (General Discussion)

Noyes and Whitney (8) have shown that the rate of dissolution of solids is directly proportional to the concentration gradient when the surface area of the dissolving material changes negligibly for systems yielding only a single species in solution.

In their equation, Eq. 6, Cs is the concentration of the saturated solution and Ct is the amount dis-

$$\frac{dC}{dt} = k(Cs - Ct) \qquad \text{(Eq. 6)}$$

solved at time t. The k in this equation has been shown to be dependent on many factors—on the surface area of exposed solid (9), the intensity of agitation (10), the temperature (11, 12), the size and shape of the particles (9), the apparatus, and the diffusion constant of the dissolved material. It is evident from the equation that for dissolution processes occurring in media where $Ct/Cs \ll 1$, such as may be found during the absorption of uncharged, nearly insoluble drugs *via* the oral route, the solubility term Cs is the major determining factor. This same relationship holds whether anhydrous forms or hydrates of drugs are being dissolved in water.

For systems which yield more than a single species in solution, such as the case with solvates of the type $A:nB$, the Noyes-Whitney equation cannot be used to predict their dissolution rate. The dissolution rate of a solvated organic solid in water seems never to have been treated mathematically. Since it appears that these crystalline addition complexes may possess such significantly high rates of solution as to be of pharmaceutical importance, equations relating some of the factors involved have been derived.

For a crystalline substance which dissociates as follows in water, and which follows the solubility

$$A{:}nB_{solid} \rightleftharpoons A_{aqueous} + nB_{aqueous}$$

product principle of the rate of dissolution under

$$[C_A]\ [C_B]^n = Ksp$$

constant stirring and geometric conditions may be written as

Rate of Dissolution =

$$G = \frac{dC_{A^*}}{dt} = kD_A\,(C_A - C_{A^*})$$

$$= \frac{1}{n}\frac{dC_{B^*}}{dt} = \frac{kD_B}{n}\,(C_B - C_{B^*}) \quad \text{(Eq. 7)}$$

C_{A^*} and C_{B^*} refer to the concentration of the two species in the bulk of the solution, C_A and C_B their respective concentrations at the immediate crystal surface, D_A and D_B the respective diffusitivity, and k the combined geometric and agitation factor. For our thinking, A can be considered to be the drug component (*e.g.*, steroid or sulfa drug) and B the organic solvent adduct (*e.g.*, amyl alcohol).

For the case $n = 1$ and $D_A = D_B$ the above relationships yield a very simple solution which is

$$G = \frac{dC_{A^*}}{dt} = kD_A(\sqrt{Ksp} - C_{A^*}) \quad \text{(Eq. 8)}$$

similar in form to Eq. 6. It is evident that C_{A^*} may be able to build well above the solubility of A itself in water.

Other simple relationships can be derived from the above equations when $n = 1$ but $D_A \neq D_B$. Thus from Eq. 7 and the solubility product, we have

$$G = kD_A\left(\frac{Ksp}{C_B} - C_{A^*}\right) \quad \text{(Eq. 9)}$$

And since $G = kD_B\,(C_B - C_{B^*})$

$$C_B = \frac{G}{kD_B} + C_{B_*} \quad \text{(Eq. 10)}$$

By substituting Eq. 10 into Eq. 9, the quadratic in Eq. 11 is obtained.

$$G^2 + G(kD_BC_{B^*} + kD_AC_{A^*}) - k^2D_BD_AKsp + k^2D_BD_AC_{B^*}C_{A^*} = 0 \quad \text{(Eq. 11)}$$

When $C_{A^*} = C_{B^*}$, the quadratic Eq. 11 is easily solved to yield Eq. 12

$$G = \frac{dC_{A^*}}{dt} = \frac{kC_{A^*}}{2}\times \left[\sqrt{(D_B - D_A)^2 + \frac{4KspD_AD_B}{(C_{A^*})^2}} - (D_A + D_B)\right] \quad \text{(Eq. 12)}$$

This equation leads to a zero rate only when $(C_{A^*})^2 = Ksp$ as expected and does not represent a first-order approach to saturation as is the case in both Eqs. 6 and 7.

If the concentration of C_{B^*} is increased much more than C_{A^*} by addition of the solvating solvent to the dissolution media, a binomial expansion can be used to simplify Eq. 11.

$$G = \frac{KD_AKsp - kD_AC_{A^*}}{C_{B^*}} \quad \text{(Eq. 13)}$$

which indicates that the dissolution rate for the solvate will decrease with an increase of B in solution.

Equations for solvates of higher order than one-to-one become more difficult to solve. In general the dissolution rates for these solvates are also dependent on their Ksp values.

EXPERIMENTAL

Apparatus

A glass-jacketed, 250-ml. Erlenmyer flask, constant temperature bath equipped with circulating pump,[1] magnetic stirrer, 1 1/2 in. flurocarbon-covered stirring bar, timer,[1] latex rubber tubes plugged with glass wool; Swinney hypodermic adaptor,[2] Millipore filters[2] (pore size 0.45 μ), Cary recording spectrophotometer (model 11 ms.), and Kofler melting-point apparatus[3] comprised the apparatus utilized.

Compounds

Cholesterol.—The hydrate (H_1) was obtained by crystallization of cholesterol (Eastman Kodak White Label) from an ethyl alcohol–water solution. Titration of these crystals with Karl Fisher reagent showed that 1.0 ± 0.2 molecule of water was bound to each cholesterol molecule.

Determination of the true melting point of this hydrate was not possible because of the rapid transformation of it to a nonsolvated form at elevated temperatures. This type of transformation also hindered the determination of the true melting behavior than the other crystalline forms of a compound and for the relatively stable nonsolvated forms.

The anhydrous form (N_1) (m.p. 149°) was formed by heating the hydrate above 80° for 48 hours.

Glutethimide.—The method of Neveu and Legagneur (13) was used to prepare the anhydrous and hydated forms of this compound. The hydrate (H_1) (m.p. 68°) was obtained by recrystallization of glutethimide (supplied by Ciba Pharmaceutical Co.) from water. The anhydrous crystals (N_1) (m.p. 83°) were prepared by recrystallization of the hydrate from anhydrous ethyl ether.

Theophylline.—The monohydrate (H_1) was obtained by using water to recrystallize theophylline (U.S.P. grade). The anhydrous form (N_1) (m.p. 272°) was prepared from the hydrate by heating it at 100° for 24 hours (14). Characteristic X-ray powder diffraction patterns (Debeye-Scherrer) for these two forms have been obtained.

Caffeine.—The monohydrate (H_1) and an anhydrous form (N_1) (m.p. 238°) of this compound were prepared in the same manner as that used for preparing the two forms of theophylline. Characteristic X-ray powder diffraction patterns (Debeye-Scherrer) of these two crystal forms have been obtained.

Fludrocortisone Acetate.—The crystalline pentanol solvate (P_1) and ethyl acetate solvate (E_1) of this compound were obtained by recrystallization of this steroid from the respective solvent. A nonsolvated crystal form (N_1, form 1) (m.p. 218–222°) was prepared by crystallization from a dilute ethyl alcohol solution.

The amount of solvent bound in each crystal form was determined by comparing the molar absorptivities of the different forms. The pentanol solvate

[1] Obtained from Precision Scientific Co., Chicago, Ill.
[2] Obtained from Millipore Corp., Bedford, Mass.
[3] Obtained from Arthur H. Thomas Co., Philadelphia, Pa.

contained 1.1 molecules of pentanol for each molecule of steroid. The ethyl acetate solvate was found to have 0.5 molecule of solvent bound to each molecule of fludrocortisone acetate.

A nonsolvated form (N_2, form 2) was isolated after the normal amyl alcohol solvate was agitated in an aqueous solvent for 24 hours and had the same molar absorptivity as form 1.

Characteristic X-ray powder patterns for each of these crystal forms have been obtained.

Succinyl Sulfathiazole.—A monohydrate (H_2, form 2) was obtained by recrystallization of succinyl sulfathiazole (obtained from National Biochemical Corp.) from a 25% ethyl alcohol–water solution. In the dissolution studies on this hydrate, another hydrate (H_1, form 1) was isolated. An anhydrous form (N_1) (m.p. 188°) of this compound was prepared by drying the crystals of form 2 to 100° *in vacuo* for 24 hours.

The pentanol solvate (P_1) (partial melting with subsequent resolidification between 127 and 136°, followed by complete melting at 191°) was obtained by recrystallization of the anhydrous form 1 from hot pentanol. By comparison of the molar absorptivity of this crystalline form with that of the nonsolvated form (N_1) it was found that 0.9 molecule of pentanol was bound to each molecule of the sulfa drug.

The distinctly different X-ray diffraction patterns for these four crystalline modifications have been obtained.

General Procedure in Dissolution Studies

The general procedure used to study the dissolution properties of all the crystal systems was similar. For each series of dissolution studies at a particular temperature for a drug, the same weight of each crystalline modification was used. The amount of the solid used was approximately in fourfold excess of that necessary to saturate the selected solvent with the most soluble form. The weighed sample was added rapidly to exactly 200 ml. of the solvent in a thermostated 250-ml. Erlenmyer flask subjected to agitation as described below. At measured time intervals small samples were withdrawn from the system and filtered. These samples were then analyzed for the concentration of drug present by an appropriate method.

Several of the specific procedures describing the individual steps in the above procedure are given in more detail in the following sections.

Agitation

The solution in the flask was agitated by a fluorocarbon-covered magnetic stirring bar rotating at a high speed. Although no serious attempt was made to maintain the intensity of agitation exactly constant in all the dissolution experiments, the simple procedure appeared to have given surprisingly good reproducibility of the dissolution curves for a given system.

Crystal Size

The size of the crystals in all the dissolution experiments was not controlled. Microscopic examination of many of the crystal samples showed that the initial particle size was well above 5 μ. Particles in this range should not show a solubility effect due to surface free energy (15).

Sampling

The samples from the dissolution system were withdrawn directly through a latex tube filled with glass wool. This produced a particle-free sample for analysis.

In the dissolution studies on fludrocortisone acetate and succinyl sulfathiazole, the crystal size of the various forms became smaller with prolonged agitation and were not able to be filtered by the above method. It was necessary to use a filter with a fine pore size to get good filtration. Millipore filters, pore size 0.45 μ, were used.

In the latter cases a syringe was used to withdraw the sample from the dissolution flask. A Swinney hypodermic adaptor with a Millipore filter inside was then placed on the syringe and the sample was pushed through the filter. The filtrate obtained in this manner was very clear.

Analytical Methods

The solutions of all the compounds except cholesterol were analyzed spectrophotometrically in the ultraviolet region. The concentration of cholesterol in solution was determined by a colorimetric assay (16), based on its color formation with iron in sulfuric acid.

Solvents Used

The dissolution experiments on the various crystalline modifications were generally performed in aqueous media. Since some of the compounds have a solubility in water too low to permit convenient determination of the solution concentration, ethyl alcohol–water solutions were used. In the case of cholesterol a glycerin–ethyl alcohol mixture containing approximately 5% water was used as the solvent.

In the dissolution studies on the various forms of succinyl sulfathiazole an acidic solution was used so that the ionization of this compound in water was held to a minimum.

Following is a list of the compounds studied with the solvents used, enclosed in the brackets: theophylline [water], caffeine [water], cholesterol [50% solution of glycerin in ethyl alcohol (contains approximately 5% water), fludrocortisone acetate [4.5% (v/v) ethyl alcohol in water and 15% (v/v) ethyl alcohol in water], glutethimide [13.4% (w/v) ethyl alchol in water], and succinyl sulfathiazole [~0.001 *N* sulfuric acid solution].

RESULTS AND DISCUSSION

The results of these investigations are considered in two parts. The first is concerned with the studies on the relative dissolution properties of hydrated and nonsolvated crystal systems. The second section presents the dissolution behaviors of crystalline solvates other than hydrates.

Comparison of Crystal Hydrates with Their Nonsolvated Forms

Dissolution Behavior.—The dissolution behaviors of hydrated and nonsolvated forms of cholesterol, theophylline, caffeine, glutethimide, and succinyl sulfathiazole are shown in Figs. 1–5, respectively. These figures show the concentration for each crystalline form attained in solution as a function of time

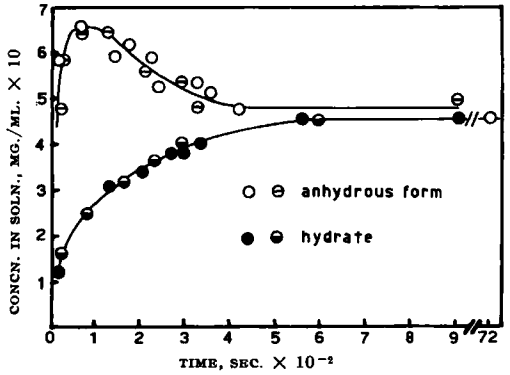

Fig. 1.—The dissolution curves for the anhydrous (N_1) and hydrated (H_1) crystalline forms of cholesterol in a 50% glycerin in ethanol solution at 25°C. The two different types of circles for each form represent successive experimental runs.

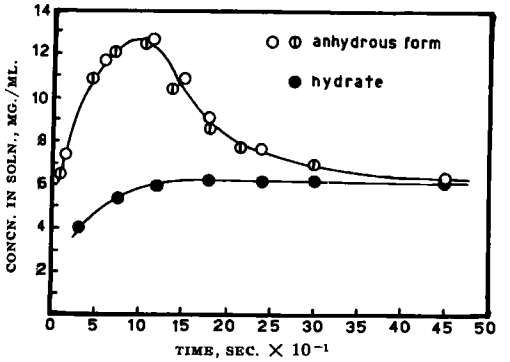

Fig. 2.—The dissolution curves for the anhydrous (N_1) and hydrated (H_1) crystalline forms of theophylline in water at 25°C. The two types of circles for the anhydrous form represent successive experimental runs.

in the presence of an excess of the solid phase and under essentially constant agitation. As indicated in some of these plots, each curve is drawn through points obtained during more than one run. Despite the relative simplicity of the dissolution technique employed, the results indicate that the procedure yielded a surprisingly reproducible rate value for each system.

It would be quite improper, of course, to attribute the apparently greater dissolution rates observed for the anhydrous forms entirely to the higher free energy contents of these species. In these as well as other dissolution experiments performed, no serious attempts were made to obtain samples possessing comparable specific surface areas, although gross microscopic examination showed no substantial differences in the size between the crystal systems of any one compound. It is evident from Eq. 6 that the ratio of the dissolution rates equals

$$\frac{\text{Dissolution Rate for Anhydrous form}}{\text{Dissolution Rate for Hydrate}} = \frac{k_A(Cs - Ct)_A}{k_H(Cs - Ct)_H}$$

where subscripts A and H represent the anhydrous and hydrated species of a particular compound. It is obvious from this ratio that some part of the observed enhancement may be due to contributions from the geometric factors k_A and k_H. It should be noted, however, that since the solubilities of the anhydrous forms in these particular instances were apparently substantially greater than those of the hydrates, the ratio of the dissolution rates of the two forms are always in the same direction as those predicted on solubility alone.

From a practical viewpoint it is evident that the rates of dissolution of a variety of crystalline drugs can be greatly influenced by the selection of the more energetic species. As seen in Figs. 1–5 the anhydrous samples dissolve much faster than the corresponding hydrates and in all cases yield concentrations substantially supersaturated with respect to the stable form. The maximal values observed in some instances may correspond to the solubility of the anhydrous crystalline phase; in others they probably represent a short-term steady-state phase situation involving equal rates of dissolution of the metastable form and crystallization of the stable hydrate.

From Fig. 1, for example, it would appear that the initial rate of dissolution of the anhydrous form, N_1, of cholesterol was very much greater than that for the hydrate, H_1, at 25°. The particular study was carried out in a 50% glycerin in ethyl alcohol solution containing approximately 5% water since cholesterol was extremely insoluble in water and because the high viscosity produced by glycerin reduced the initial dissolution rate sufficiently to permit its ready measurement. Although the maxi-

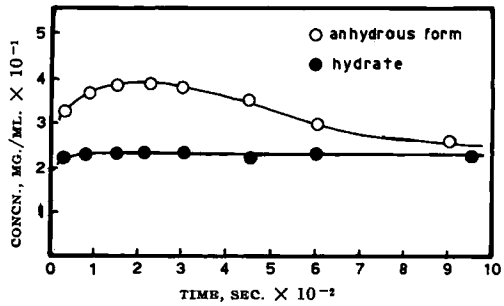

Fig. 3.—The dissolution curves for the anhydrous (N_1) and hydrated (H_1) crystalline forms of caffeine in water at 28°C.

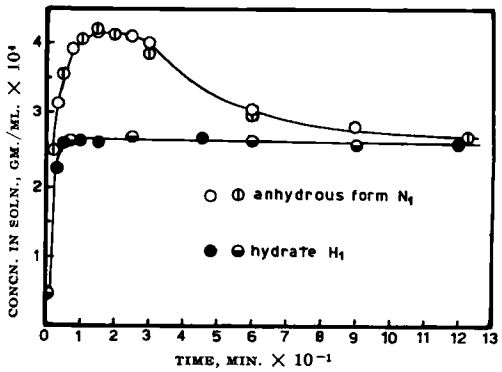

Fig. 4.—The dissolution of anhydrous and hydrated glutethimide in a 13.4% ethanol solution at 25°C. The different circles for each form represent successive experimental runs.

mum concentration reached with the nonsolvated form was only 1.4 times as great as the solubility of the hydrate, the initial rate appears to be at least three times that for the hydrate. The dissolution behavior of the anhydrous material suggests that nucleation and formation of the more stable hydrate prevented realization of the true solubility of the metastable form. It would appear that if this had not occurred, a markedly higher concentration would have been reached with the anhydrous crystals.

Qualitatively, both the dissolution and crystal growth phases appear from these diagrams to be kinetically controlled by the concentration gradient near the dissolving or growing crystalline surfaces. This is particularly evident for theophylline in Fig. 2. If the data shown are plotted as a first-order approach to equilibrium (concentration gradient controlled process) in the usual logarithmic fashion, a fairly respectable straight-line relationship is obtained. Apparently for this system the maximum exhibited by the anhydrous form, N_1, closely approaches the true solubility.

The apparent dissolution rate of anhydrous theophylline again appears to be much greater than that for the hydrate. The maximum concentration value attained with the nonsolvated crystals was twice the solubility of the hydrate at 25° in water. The higher thermodynamic activity associated with the anhydrous form apparently was the major contributing factor causing the initially greater dissolution rate observed for this modification. After the maximum concentration peak was reached with the anhydrous crystals, there is an apparent first-order decline in the amount of drug dissolved. The limiting value of this decrease was found to be the solubility of the hydrate, H_1.

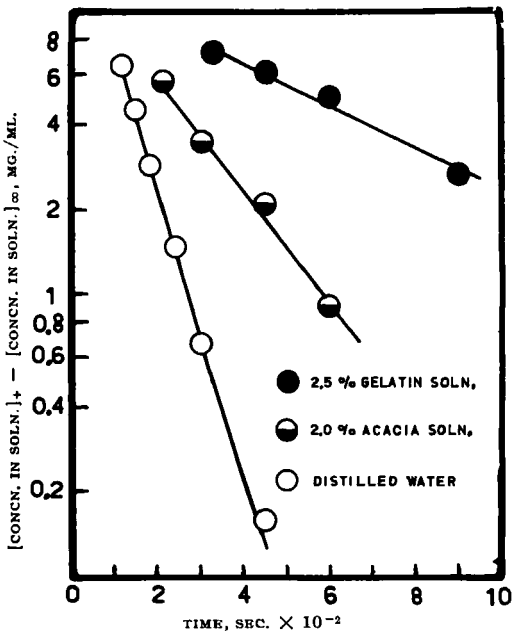

Fig. 8.—The influence of the acacia and gelatin solutions on the observed first-order transformation of anhydrous (N_1) theophylline to the hydrate (H_1) at 25°C.

Anhydrous caffeine, N_1, apparently also exhibits a greater initial dissolution rate than the hydrated form, H_1, in water. Figure 3 shows that the maximum concentration of caffeine achieved in solution with the nonsolvated form is 1.7 times the solubility

TABLE I.—INFLUENCE OF ADDITIVES ON RATE OF CRYSTALLIZATION OF THEOPHYLLINE HYDRATE

Solvent System	Transformation Rate, sec.$^{-1}$ (obtained from Fig. 9)	Water at 25°C.
Water	-5.3×10^{-3}	1.0
Acacia soln., 2.0%	-1.8×10^{-3}	1.6
Gelatin soln., 2.5%	-0.6×10^{-3}	2.5

of the hydrate at 28°. The higher concentration level reached with the anhydrous form was apparently sustained longer than that observed for many of the other metastable systems, suggesting an equilibrium saturation state over this interval.

The dissolution curves (Fig. 4) for the two crystalline forms of glutethimide also show that the initial dissolution rate of the nonsolvated form is greater than that for the hydrate. The dissolution study on this system was performed in a 13.4% (w/v) ethyl alcohol–water solution because glutethimide had a very limited solubility in pure water. The maximum concentration level attained with the anhydrous form, N_1 (1.6 times greater than the solubility of the hydrate at 25°) has a flatness similar to that observed for anhydrous caffeine. This suggests that the transformation process may occur in this system at a slower rate than, for example, cholesterol N_1. If this were the case, the plateau concentration level achieved with the anhydrous crystals might very well be its equilibrium solubility. This equilibrium effect is even more pronounced at higher temperatures as is evident in Fig. 6 for glutethimide at 40°. The observed increase in stability of the anhydrous material in solution is probably due to the reduction in the free energy difference between the two solid phases, as will be discussed later.

Succinyl sulfathiazole appears to form several hydrates and polymorphs (17). Results of the dissolution studies carried out on a few species of the sulfonamide are shown in Fig. 5. These measurements were performed in a ~0.001 *N* sulfuric acid solution to limit the ionization of the drug. The behavior of the drug in suspension strongly suggests formation of at least three hydrates. The lowest plot shows the dissolution behavior of hydrate H_2, (form 2) over a period of 15 minutes. Although an apparent equilibrium concentration is reached well within this time, storage of the suspension over several days, under the same conditions, results in a drop in the dissolved drug concentration of approximately 30% to another stable level corresponding to formation of a structurally different hydrate (H_1, form 1). The dissolution curve for the anhydrous form, N_1, shows that after the initial peak concentration value is reached, there is an apparent first-order decline in concentration to a lower constant value, but which is substantially higher than the solubility of the other two hydrates. After a few days, the

[a] Calculated for the conversion to the most stable hydrate, form 1.

concentration level of this system decreased until it reached the solubility value of form 1 hydrate.

The results obtained for the crystalline forms of succinyl sulfathiazole are interesting from a practical viewpoint, since the compound is particularly useful in medicine because its low solubility limits its absorption in the intestinal tract. In Fig. 5 it is evident that not only is the rate of dissolution of the anhydrous form much greater than that of the hydrate form 2, but also the maximum concentration value attained is 3.9 times higher than that of the solubility of the hydrate. This may be of some practical pharmaceutical importance if the least soluble form is desired.

Effect of Protective Colloids on the Nucleation Process.—Since protective colloids are known to retard various nucleation phenomena, their effect on the transformation occurring in the present systems was investigated. Studies were carried out with gelatin and acacia to determine their influence on the rate of transformation of anhydrous theophylline to the hydrate. The study was performed at 25° in the previously described manner using water, a 2.5% gelation solution, and a 2.0% acacia solution as solvents.

In Fig. 7 the overall dissolution process observed for the two forms of theophylline in water and in 2.5% gelatin solution are compared. It is apparent that the dissolution rates of both forms were slower in the gelatin solution than in water. The slightly higher solubility of theophylline observed in the presence of gelatin may be due to an interaction with the protein. The main point of interest in Fig. 7 is that the area under the curve for the anhydrous form dissolving in the gelatin solution was much greater than observed in water.

The relative rates of formation of the hydrate species in the several solution vehicles can be best compared by plotting the approach to equilibrium as a first-order process. In Fig. 8, the solution concentrations experimentally observed minus the concentration at infinite time have been plotted as logarithmic functions against time for the precipitation phases of these measurements in water, 2.0% acacia in water, and 2.5% aqueous gelatin solution. The slopes of these lines serve as convenient measures of the relative rates of nucleation and growth of the stable phase in the several vehicles. Although the reduction in the rate of solution depletion agrees qualitatively with the increase in viscosity as measured in a capillary viscometer, quantitative fit is rather poor as is evident from Table I. It is quite likely that the effect of the protective colloid arises as the result of nucleation inhibition of both the two and three dimensional variety.

Thermodynamic Analysis for the Hydrate Systems.—The dissolution behaviors of certain of the anhydrous crystalline forms in water suggested that the maximum values obtained were good approximations of the true solubility of these crystals. It is apparent that if this were the case, that measurements made at several temperatures would permit calculations of the thermodynamic quantities involved in the transitions of the anhydrous form to the hydrate.

Dissolution plots for theophylline, succinyl sulfathiazole, and, in particular, glutethimide seem to give fairly reliable approximations of the solubility of their respective anhydrous species. Measurements over the temperature range 20 to 50° when plotted in the classical van't Hoff fashion gave reasonably good linear relationships for the anhydrous species as shown in Figs. 9–11. Similar data for the stable hydrates are also given in the same figures. The values of the heat of solution for each crystalline form, calculated from the slopes of the latter plots, appear in Tables II and III.

Enthalpy of Hydration (18).—The change in heat content for the hydration of the anhydrous crystals in water (Eq. 17) was calculated from the enthalpy changes of the following reactions.

$$A_{solid} \rightleftharpoons A_{aqueous} \qquad \text{(Eq. 15)}$$

$$A:H_2O_{solid} \rightleftharpoons A_{aqueous} + H_2O_{liquid} \qquad \text{(Eq. 16)}$$

Equation 15 minus Eq. 16 gives Eq. 17

$$A_{solid} + H_2O_{liquid} \rightleftharpoons A:H_2O_{solid} \qquad \text{(Eq. 17)}$$

The heats of reactions of Eqs. 15 and 16 are obviously the heats of solution of the anhydrous and hydrated crystals of compound A. The enthalpy change for Eq. 17, $\Delta H_{A,H}$ is therefore the heat of solution of the anhydrous form minus the heat of solution for the hydrate. $\Delta H_{A,H}$ was utilized to calculate the entropy change involved in the hydration process of Eq. 17.

The values of $\Delta H_{A,H}$ for theophylline and glutethimide were found to be −3300 and −2000 cal./-

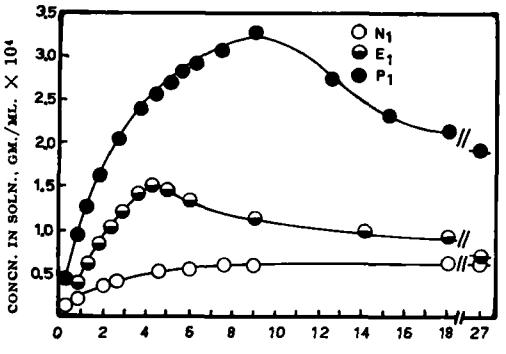

Fig. 12.—The dissolution behaviors of the nonsolvated form (N_1), pentanol solvate (P_1), and ethyl acetate solvate (E_1) of fludrocortisone acetate in an aqueous ethanol solution (15% v/v) at 20°C.

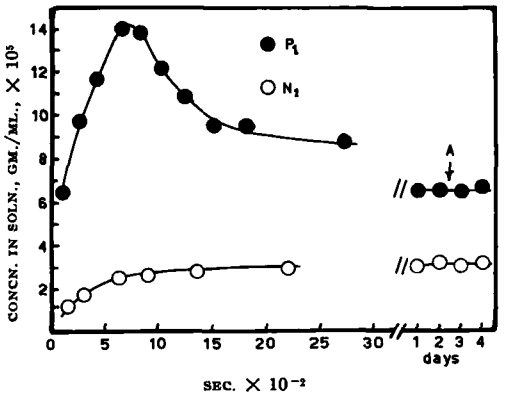

Fig. 13.—The dissolution behaviors of the pentanol solvate (P_1) and nonsolvated form (N_1) of fludrocortisone acetate in a 4.5% aqueous ethanol solution at 20°C. At the *A* concentration level, P_1 was found to be converted to a nonsolvated form (N_2).

mole, respectively. The $\Delta H_{A,H}$ value for the conversion of the anhydrous form of succinyl sulfathiazole to form 1 hydrate was −8600 cal./mole.

Free Energy of Hydration.—At constant temperature and pressure the free energy difference between the anhydrous and hydrated forms is determined by Eq. 18

$$\Delta F_T = RT \ln \frac{(Cs)\ \text{anhydrous}}{(Cs)\ \text{hydrate}} \quad \text{(Eq. 18)}$$

This equation relates the solubility, *Cs*, of the two forms at a particular temperature, *T*, to the free energy difference. This ΔF_T corresponds to the free energy change involved in Eq. 17, since the activity of water is approximately unity in the present systems. These values are listed in Tables II and III for glutethimide, theophylline, and succinyl sulfathiazole systems at 25°.

Entropy Change.—The entropy change for the hydration reaction in Eq. 17 can be calculated at a particular temperature, *T*, by Eq. 19

$$\Delta S_T = \frac{\Delta H_{A,H} - \Delta F_T}{T} \quad \text{(Eq. 19)}$$

The entropy changes for the hydration of the anhydrous crystals of glutethimide, theophylline, and succinyl sulfathiazole to their respective stable hydrate were computed by Eq. 19 at 25°. These values appear in Tables II and III.

The entropy change involved in the fusion of water at 25° is approximately −6 e.u. This decrease in entropy associated with the formation of ice is approximately the same entropy change obtained for the hydration of glutethimide and theophylline. It may be likely, therefore, that the energy involved in the transformation of the dehydrated form of these compounds to the hydrate is related mainly to the decrease in the entropy of water molecules in the hydrate structure.

The structure of theophylline hydrate was elucidated by Sutor (19). This structure analysis showed that the water molecules form a chain network throughout the lattice. One water molecule is hydrogen bonded to two other waters and to one theophylline molecule. This type of structure could be responsible for the larger decrease in entropy associated with the hydration of theophylline than with the fusion of pure water.

At the transition temperature of the anhydrous and hydrated crystalline forms, $\Delta F_{\text{Tran. } T}$ is equal to zero. Equation 19 then reduces to the simple form shown in Eq. 20. The entropy change calculated at

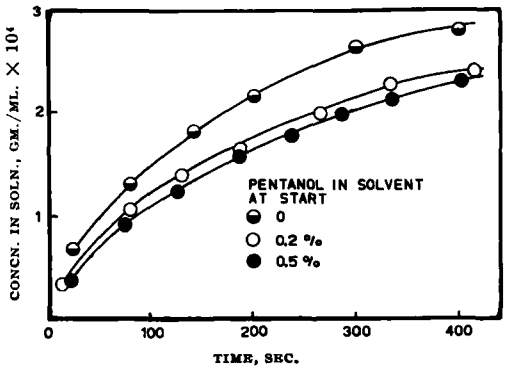

Fig. 14.—The influence of the addition of pentanol to the 15% aqueous ethanol solution on the dissolution of the pentanol solvate of fludrocortisone acetate at 20°C.

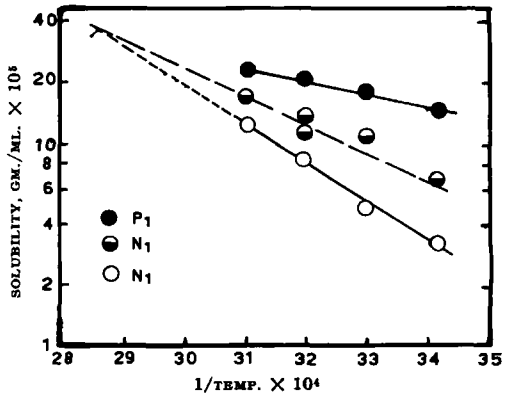

Fig. 15.—The van't Hoff-type plot for the nonsolvated forms N_1 and N_2 of fludrocortisone acetate in a 4.5% aqueous ethanol solution. The maximal concentration of steroid attained in solution with the pentanol solvate is also plotted in the same fashion.

$$\Delta S_{\text{Tran. } T} = \frac{\Delta H_{A,H}}{\text{Tran. } T} \qquad \text{(Eq. 20)}$$

the transition temperature for the theophylline and glutethimide systems are shown in Table II.

Transition Temperature.—The transition temperature for the hydrate-anhydrous crystal systems corresponds to that temperature at which the fugacity of the anhydrous form is equal to that of the hydrated form, *i.e.*, the temperature at which the solubility of the two forms are equal. The transition temperatures for the theophylline, glutethimide, and succinyl sulfathiazole systems were obtained directly from Figs. 9, 10, and 11 in that order.

Glutethimide hydrate was reported (13) by Legagneur and Neveu to decompose at 53° and melt at 68°. The transition temperature derived from the solubility data of the two crystal forms is 52°. This latter temperature could correspond to the "decomposition" temperature of the above workers.

Theophylline hydrate imbedded in paraffin and heated on a Kofler melting apparatus started to release bubbles at approximately 70°. These bubbles may indicate that water vapor is being given off by the crystals. Using the solubility of the anhydrous and hydrated forms of theophylline, a transition temperature of 73° was found.

In Table III the transition temperature for each hydrate of succinyl sulfathiazole is presented. Since form 1 hydrate seemed to be the most stable hydrate, it correspondingly had a lower transition temperature than form 2 hydrate.

Crystalline Solvate Systems

Dissolution Behavior.—The dissolution behaviors of the mono-amyl alcohol solvates of succinyl sulfathiazole and fludrocortisone acetate are recorded along with their stable modifications in Figs. 5 and 12, respectively. In the latter figure, the dissolution of the ethyl acetate solvate of fludrocortisone acetate also appears. The dissolution studies on the steroid were carried out in ethanol-water solutions because of the compounds' limited solubility in water.

These dissolution curves seemed to confirm the theoretical prediction that the concentration of drug attainable in solution with a solvate may be many times greater than that with a stable crystalline form. The pentanol solvates of the steroid and the sulfa drug produce drug concentrations five and ten times greater than the solubility of their respective stable crystalline forms. A similar measurement of the ethyl acetate adduct of fludrocortisone acetate showed that it was able to achieve more than twice the concentration in solution as did the stable form (form 1). It is apparent from the initial slopes of these dissolution curves that the solvates have, as expected, a much greater rate of solution than the stable forms.

The overall solution behavior of the pentanol solvate of the steroid is plotted in Fig. 13 at 20° in a 4.5% (v/v) ethyl alcohol–water solution. A decrease in the solubility was observed after the initially high concentration peak is reached with the solvate. This decrease corresponded to the conversion of the solvated crystals to a nonsolvated species, form 2. This was attested by X-ray analysis of the crystalline material within the dissolution flask. It appeared to have a solubility of more than twice that of form 1 at 20°. It also appears to be stable in solution at 20° for at least 5 days without subsequent transformation.

In Fig. 14, the effect on the dissolution rate of the pentanol solvate of fludrocortisone acetate by varying concentrations of pentanol is shown. The limited solubility of pentanol in the aqueous solvent allowed a maximum concentration of only 0.5% (v/v) to be used in this study. It is evident from Fig. 14 that the dissolution rate is retarded by the addition of pentanol, in qualitative agreement with Eq. 12. This equation for the generalized monosolvate indicates that the rate of solution decreases with the concentration of the solvating solvent in solution when it is present in greater concentration than the drug. An interesting result from this experiment that does not appear in Fig. 14 is that the maximum equilibrium concentration reached was the same for the three solvent systems, probably corresponding to the solubility of a nonsolvate, but was attained at different rates in the three systems. The maximum concentration peaks were attained in the following sequence: first the solvent without *n*-amyl alcohol present at 900 seconds, then the system with 0.2% (v/v) *n*-amyl alcohol at approximately 1250 seconds, and lastly the 0.5% (v/v) solution at 1800 seconds.

Temperature Dependence.—Although it was not possible to calculate the thermodynamic quantities of the solvate systems from the data obtained directly from the dissolution experiments, it is interesting to note the effect of temperature on the dissolution behaviors of the pentanol solvates. In Fig. 15, the solubility obtained for the nonsolvated polymorphs (forms 1 and 2) of fludrocortisone acetate along with the peak drug concentration attained in solution with the pentanol solvate (P_1) are shown as a function of temperature. A van't Hoff–type plot was used because it gave a relatively linear relationship for the different crystalline forms. The solubility of nonsolvate, form 2, was taken as the plateau concentration level reached after 24 hours of agitation of the pentanol solvate in solution. In Fig. 11, the maximum concentration attained with the pentanol solvate of succinyl sulfathiazole in solution is shown as a function of temperature together with the van't Hoff–type plots for the other forms of this compound that were studied.

GENERAL DISCUSSION

Experimental observations and the theoretical analysis presented above again strongly emphasize the importance of the role of the crystalline state of solid drugs. It is apparent that since the thermodynamic activity of these systems is often directly related to the physiological activity and availability, the choice of the proper crystalline form is of vital pharmaceutical concern.

We would like, in particular, to call attention to the possible broader utilization of organic solvates and complexes in dosage form development. Since the apparent free energy change associated with their dissolution in aqueous media can be vastly greater than that exhibited by an unstable polymorph relative to the stable form, much higher temporary solution concentrations and rates of solution

can be obtained by their use than from purely crystalline modification. This is because the system utilizes, in effect, the free energy of dilution of the complexing agent to raise the solubility of the drug. Since molecular complexes of this type are readily produced, particularly by relatively insoluble drugs, this approach may often provide the answer for those products which are poorly available because of slow rates of dissolution.

Drug Standards

Determination of Amphetamine in Dosage Forms by Partition Chromatography

By JOSEPH E. MOODY, JR.

A procedure is presented for the assay of preparations of amphetamine and several other sympathomimetic amines. The amine is isolated by extraction from the stationary aqueous phase of a partition column with a chloroform solution of triethylamine. The chloroform solution is then extracted with aqueous acid and the amine determined spectrophotometrically. Data obtained on several commercial samples of dextro-amphetamine sulfate tablets by three different assay procedures are reported, and the inapplicability of the U.S.P. XVI assay procedure to some of the commercial products is demonstrated. An analysis by the proposed column-ultraviolet procedure can be completed in about 1 hour.

MANY METHODS of analysis of sympathomimetic amines have been reported (1). They include direct titration of free bases, residual titration of free bases, extraction of bases combined in salts, distillation and titration of volatile bases, nonaqueous titration, gravimetric methods, ultraviolet absorption, and various chromatographic techniques. The widespread use of these preparations in medical practice and their extensive distribution in illegal channels creates a necessity for a simple and rapid method of assay.

Received March 1, 1963, from the Division of Pharmaceutical Chemistry, Bureau of Biological and Physical Sciences, Food and Drug Administration, U. S. Department of Health, Education, and Welfare, Washington, D. C.
Accepted for publication March 11, 1963.
This assay procedure was submitted to the Committee on Revision of the "United States Pharmacopeia" for consideration as a substitute for the currently official method. Subsequent to the preparation of this manuscript, the committee expressed a preference for the modification, using ammonium hydroxide rather than triethylamine as reagent. We have concurred that this modification is preferable for an official assay method.

The proposed procedure is designed to permit the assay of small samples, thus making it applicable to the analysis of a single dosage unit. In this procedure, the extraction of the amphetamine from the dosage form is achieved by elution from an immobile aqueous phase of a column with a solution of triethylamine in chloroform. The eluate is collected in a separator containing an accurately measured quantity of sulfuric acid solution (2 in 100) into which the amphetamine is then extracted. It is quantitatively determined by ultraviolet absorption of the acid solution.

In the development of the method, several other elution procedures were investigated. In a published report of an extraction procedure for alkaloids (2), *p*-toluenesulfonic acid and the alkaloid are incorporated in an aqueous solution as the stationary phase on a partition column. Ether is used to elute the acidic and neutral

can be obtained by their use than from purely crystalline modification. This is because the system utilizes, in effect, the free energy of dilution of the complexing agent to raise the solubility of the drug. Drug Standards

Determination of Amphetamine in Dosage Forms by Partition Chromatography

By JOSEPH E. MOODY, JR.

A procedure is presented for the assay of preparations of amphetamine and several other sympathomimetic amines. The amine is isolated by extraction from the stationary aqueous phase of a partition column with a chloroform solution of triethylamine. The chloroform solution is then extracted with aqueous acid and the amine determined spectrophotometrically. Data obtained on several commercial samples of dextro-amphetamine sulfate tablets by three different assay procedures are reported, and the inapplicability of the U.S.P. XVI assay procedure to some of the commercial products is demonstrated. An analysis by the proposed column-ultraviolet procedure can be completed in about 1 hour.

MANY METHODS of analysis of sympathomimetic amines have been reported (1). They include direct titration of free bases, residual titration of free bases, extraction of bases combined in salts, distillation and titration of volatile bases, nonaqueous titration, gravimetric methods, ultraviolet absorption, and various chromatographic techniques. The widespread use of these preparations in medical practice and their extensive distribution in illegal channels creates a necessity for a simple and rapid method of assay.

Received March 1, 1963, from the Division of Pharmaceutical Chemistry, Bureau of Biological and Physical Sciences, Food and Drug Administration, U. S. Department of Health, Education, and Welfare, Washington, D. C.
Accepted for publication March 11, 1963.
This assay procedure was submitted to the Committee on Revision of the "United States Pharmacopeia" for consideration as a substitute for the currently official method. Subsequent to the preparation of this manuscript, the committee expressed a preference for the modification, using ammonium hydroxide rather than triethylamine as reagent. We have concurred that this modification is preferable for an official assay method.

The proposed procedure is designed to permit the assay of small samples, thus making it applicable to the analysis of a single dosage unit. In this procedure, the extraction of the amphetamine from the dosage form is achieved by elution from an immobile aqueous phase of a column with a solution of triethylamine in chloroform. The eluate is collected in a separator containing an accurately measured quantity of sulfuric acid solution (2 in 100) into which the amphetamine is then extracted. It is quantitatively determined by ultraviolet absorption of the acid solution.

In the development of the method, several other elution procedures were investigated. In a published report of an extraction procedure for alkaloids (2), *p*-toluenesulfonic acid and the alkaloid are incorporated in an aqueous solution as the stationary phase on a partition column. Ether is used to elute the acidic and neutral

substances without removal of the alkaloid. The *p*-toluenesulfonic acid salt of the alkaloid is then eluted with chloroform, and the eluate is passed over an alkaline column which removes the *p*-toluenesulfonic acid moiety. Several variations of this procedure were tried for dextro-amphetamine sulfate, but quantitative recoveries were not achieved.

Another of the procedures investigated employed the addition of a layer of infusorial earth with concentrated ammonium hydroxide solution to an acidic column containing the amphetamine sample. When chloroform was passed through the column, it carried through a sufficient amount of the ammonia to neutralize the acid and allow the amphetamine to be eluted as the free base. The excess ammonia was then removed by warming on a steam bath under a stream of air. The chloroform was transferred to a separator containing sulfuric acid (2 in 100) and extracted as in the method given. Though this procedure gave quantitative results, it required two more steps than the method employing triethylamine. These are the mixing and packing of the ammoniacal infusorial earth onto the column and the removal of the large excess of ammonia which is needed to permit the elution of the amphetamine from the column.

PROCEDURE

Reagents

Triethylamine.—Prepare a 1 in 200 solution of triethylamine in water-saturated chloroform. Extract 20 ml. of this solution with 10 ml. of sulfuric acid solution (2 in 100). Determine the absorbance of the acid solution at 257 mμ, using the sulfuric acid solution as the blank. If the absorbance is 0.010 or greater, purify the amine as follows.

Reflux 100 ml. of triethylamine with 20 ml. of water and 2 Gm. of sodium hydrosulfite for about 6 hours. Wash the amine with water and dry it by refluxing through a Dean-Stark trap. Finally, distill, collecting the first 75 ml. of distillate, and store it over anhydrous sodium carbonate. Test the purified amine occasionally to determine if the absorbance is below the specified maximum.

Chloroform.—Saturate reagent grade chloroform with water.

Hydrochloric Acid.—Use 1 in 100 solution.

Sulfuric Acid.—Use a 2 in 100 chloroform saturated solution.

Infusorial Earth.—Use acid washed Celite.[1]

Preparation of the Sample

Weigh and finely powder a sufficient number of tablets to provide a representative sample. Weigh accurately a portion of the powder, equivalent to about 5 mg. of dextro-amphetamine sulfate, in a 100-ml. beaker. Add 2 ml. of hydrochloric acid solution and swirl gently to wet the powder thoroughly. Warm on a steam bath for about 1 minute with occasional gentle swirling and cool. Add 3 Gm. of infusorial earth to the beaker, and mix until a fluffy mixture is obtained.

Chromatographic Column

Pack a pledget of fine glass wool with the aid of a tamping rod in the base of a chromatographic tube made from approximately 5 cm. of 6–8 mm. tubing fused to a 25 × 300-mm. test tube. The tamping rod consists of a disk of stainless steel, aluminum, or glass, with a diameter about 1 mm. less than that of the column, attached to a rod approximately 18 in. long. To 2 Gm. of infusorial earth in a 100-ml. beaker, add 1 ml. of hydrochloric acid solution and mix thoroughly with a spatula. Transfer the mixture to the column and tamp lightly to compress the material into a uniform mass. Transfer the sample preparation to the column, "dry rinse" the beaker with about 1 Gm. of infusorial earth, and transfer it to the column. Add a pledget of fine glass wool and tamp as above. Wash the column with 100 ml. of water-saturated chloroform and discard the washings.

Assay

Place a 125-ml. separator containing 10.0 ml. of chloroform-saturated sulfuric acid solution under the column to receive the eluate. Pass 35 ml. of a 1 in 200 solution of triethylamine in water-saturated chloroform through the column. Complete the elution with 70 ml. of water-saturated chloroform. Shake the separator vigorously for 1 minute, allow the layers to separate, and discard the chloroform. Scan the spectra of the acid solution of the sample and of a standard solution, containing about 0.5 mg. of dextro-amphetamine sulfate per ml., from 350 to 250 mμ in 1-cm. cells with a suitable recording spectrophotometer using chloroform-saturated sulfuric acid as the blank. Determine the baseline-corrected absorbance of the

sample and standard solutions at the maximum at about 257 mμ by drawing the baseline as a continuation of the curve between 350 and 300 mμ.

Calculate the milligrams of dextro-amphetamine sulfate per tablet by the formula $10\ C\ (A_u/A_s)(W_t/W_u)$, in which C is the concentration of the standard solution in milligrams per milliliter, A_u is the absorbance of the sample solution, A_s is the absorbance of the standard solution, W_t is the average tablet weight, and W_u is the weight of the sample taken.

RESULTS AND DISCUSSION

A simulated dextro-amphetamine sulfate tablet mixture was prepared for use in standard recovery tests to check the accuracy of the method. Duplicate assays of the mixture gave recovery values of 100.0 and 100.2%.

Eleven samples of commercial 5-mg. dextro-amphetamine sulfate tablets, were assayed by three different methods: (*a*) the U.S.P. XVI procedure, (*b*) a distillation-ultraviolet absorption procedure, and (*c*) the method described herein. A sufficient number of tablets for all three procedures was weighed, finely powdered, and the appropriate aliquot taken for each method. All of the analyses were run in duplicate, the data from which are shown in Table I.

The distillation procedure was run on the 11 samples as a check on the accuracy of the proposed column procedure. A weighed sample, equivalent to about 15 mg. of dextro-amphetamine sulfate, was distilled from a strongly alkaline solution and collected in a solution of mineral acid. The acid solution was made alkaline and extracted with chloroform. The chloroform solution was then extracted and the amphetamine measured as it is in the column method.

Product K, one of the eleven commercial samples of compressed tablets, was distributed to other chemists of this laboratory for collaborative study. The resulting data are shown in Table II.

To investigate further the scope of the method, a timed release preparation of dextro-amphetamine sulfate, consisting of encapsulated pellets, was analyzed by the column procedure. The per cent of label claim found was 103.1, 102.0, and 102.8%. The method can also be used to analyze other sympathomimetic amines with similar physical and chemical properties. The results of the analyses of four such compounds are shown in Table III.

Amphetamine has a relatively low absorptivity. Using the Beckman spectrophotometer, a concentration of the order of 0.5 mg. per ml. is required to give an optimum absorbance value for quantitative determination. Since for single-dose-unit analysis a small sample is specified, the column eluate is concentrated by extraction into an acid solution. The small quantity of triethylamine employed is sufficient to neutralize the acid and release the amphetamine from the column. When quantities of triethylamine approaching 1 ml. were used, the assay results were consistently about 2% low. The excess triethylamine reacted with the sulfuric acid to form the water-soluble amine sulfate which increased the acid solution volume and caused the low results. Levine (3), in the determination of codeine in mixtures with antihistamines, used more than 1 ml. of triethylamine in the elution. The eluate was collected in a volumetric flask and diluted to volume with chloroform from which the absorbance was determined; therefore, no interference with the concentration was encountered.

The official method of assay of dextro-amphetamine sulfate tablets U.S.P. XVI (4) was shown to have several undesirable aspects. The data in Table I show that the results from the official assays are both low and are the least precise for most of the 11 samples. The results of the distillation-ultraviolet absorption and the column-ultraviolet absorption methods are practically the same. The longer time required to complete the official assay procedure and the low assay results make its use as a general method unsatisfactory. For the varied purposes of a compendium assay, a method suitable to all available products is necessary. The proposed method meets this criterion and at the same time provides a simpler and more rapid method of assay than does the official method.

Micro-Method for Intravenous Injection and Blood Sampling

By H. SALEM, M. H. GROSSMAN†, and D. L. J. BILBEY‡

The described methods have been found to be valuable in investigations into the body distribution and fate of pharmacological substances and are herein reported for the benefit of other workers in the field of pharmacology and toxicology.

IT HAS BEEN FOUND both expedient and practicable to combine two techniques in which substances are introduced directly into the bloodstream of small animals and recovered for determination in serial samples of blood.

The injection of prepared amounts of a substance in either solution or suspension (chemicals, drugs, bacteria, particulate matter ± radioactivity) are injected into the bloodstream of a mouse or other small experimental animal by the dorsal vein of the penis. For this purpose it has been found convenient to use a 1-ml. "tuberculin" syringe graduated into 100 divisions and fitted with a fine hypodermic needle (gauge 26–30). The animal is secured by an assistant who holds it by the loose skin behind the neck in the right hand and by either the tail or hind feet in the left in order to stretch the animal and hyperextend the vertebral column (Fig. 1). The operator then places gentle pressure over the lower abdomen and secures the tip of the penis between the thumb and forefinger of the left hand as shown in both Figs. 1 and 2. The dorsal vein of the penis is easily entered by a fine hypodermic needle and the contents of the syringe can be injected with ease. It should be noticed that in this maneuver the hands of the operator and his assistant are kept in close contact to prevent uncoordinated movements.

The advantage of this method is in its applicability to animals having no easily accessible site for intravenous injection. Although we have used the mouse to illustrate this technique, we have successfully employed it using guinea pigs and hamsters.

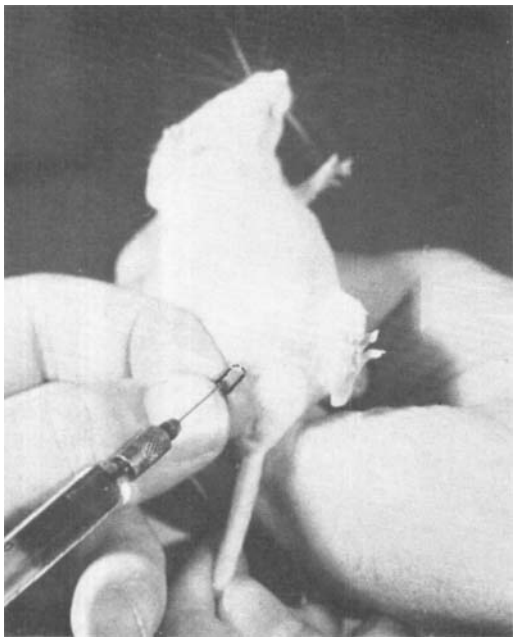

Fig. 1.—The method of holding the mouse, the retraction of the penis, and the insertion of the needle for injection into the dorsal vein.

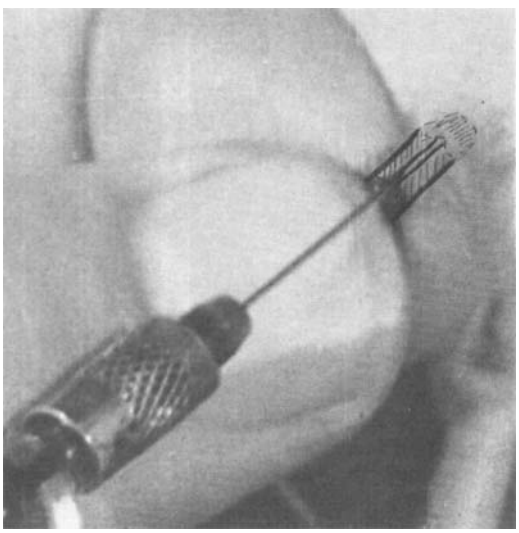

Fig. 2.—The method of insertion of the hypodermic needle into the dorsal vein of the penis. Note that the hands of the operator and assistant are in close contact to ensure stability during the injection.

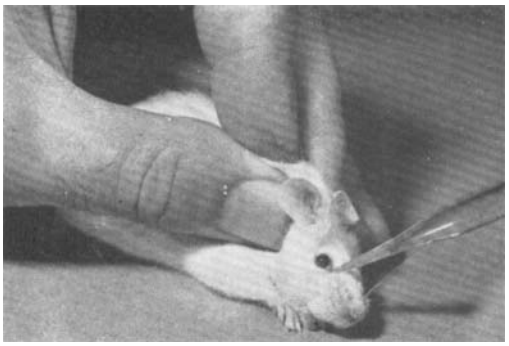

Fig. 3.—The angle at which the fine pipet should be placed at the medial canthus prior to the withdrawal of blood.

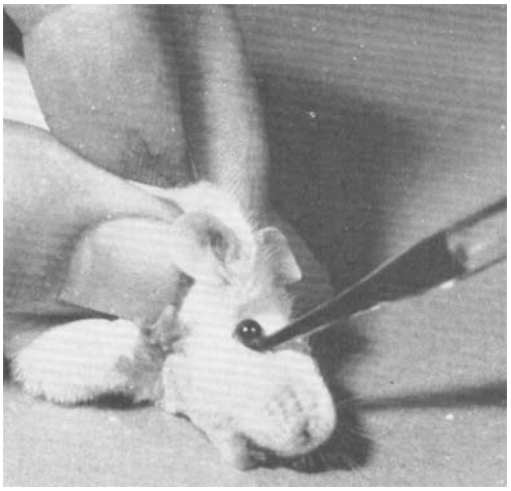

Fig. 4.—The removal of blood from the retro-orbital plexus and the positioning of the operator's thumb.

Small samples of blood are removed by the veins of the retro-orbital plexus (Fig. 5). This method has been described by Halpern and Pacaud (1) and later by Hans Nöller (2) and consists of the removal of a desired amount of the blood (usually 0.01 to 0.50 ml.) by a fine glass pipet which is inserted into the medial canthus of the orbit and which fills both by capillary action and venous pressure following the rupture of one or more of the fine branches of the orbital venous plexus. The manner of holding the animal and the angle at which the pipet is inserted is shown in Figs. 3 and 4. The middle and forefingers of

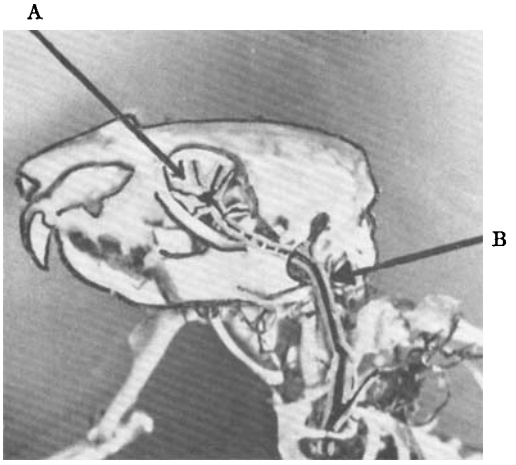

Fig. 5.—A rat skull prepared to show the veins of the head and neck in order to indicate the position of the drainage from the retro-orbital plexus of veins. *A*, indicates the orbit in which may be seen the main vessels of the plexus; *B*, shows the point at which the internal jugular vein leaves the skull and where pressure by the thumb serves to engorge the retro-orbital venous system with blood.

the left hand maintain the head of the animal in position. It is most important to press gently but firmly with the thumb just behind the angle of the jaw as shown in these illustrations. This last procedure causes a restriction of venous return by the internal jugular vein (Fig. 5) and consequent engorgement of the retro-orbital plexus. The longer the pressure is maintained, the greater volume of blood is withrawn. In order to prevent coagulation of the blood inside the pipet, the end of it is placed in a solution containing an anticoagulant before the taking of each sample. No damage to the actual eye is incurred in this procedure, and it is possible to remove up to as many as 30 serial samples from one animal. The blood that is withdrawn is available for various investigations and may be chemically, photometrically, or radioactively analyzed—cultured and plated for bacterial growth—or made into a film for observations under the microscope.

Stability of Pancreatic Deoxyribonuclease in the Presence of Proteases

By RICHARD E. MAXWELL, VIOLET S. NICKEL, and VERA LEWANDOWSKI

Bovine pancreatic deoxyribonuclease was found to be remarkably stable in the presence of relatively high concentrations of bovine plasmin, while comparable or much lower fibrinolytic levels of chymotrypsin, trypsin, or plant proteolytic enzymes gave rapid and extensive destruction of the nuclease activity. The results are considered to illustrate a sharp divergence in substrate preference between plasmin and the other proteases.

In the evaluation of a mixture of bovine pancreatic deoxyribonuclease and bovine plasmin[1] (hereafter referred to as DNase-P) for use as a debriding preparation, the possibility that the plasmin could inactivate the deoxyribonuclease was a matter of great concern since a number of proteins may serve as substrates for plasmin (1). As no pertinent information was available in the literature, it was necessary to design a study bearing on the question; the study included comparisons with other proteolytic enzymes, particularly chymotrypsin, which was considered as an alternative proteolytic constituent of the mixture. The results are worthy of note in illustrating unexpected degrees of substrate preferences by the two proteolytic enzymes.

MATERIALS AND METHODS

Enzymes.—Vials of DNase-P were obtained from production lots. Bovine plasmin was prepared as described by Loomis, *et al.* (2), and the deoxyribonuclease was the pharmaceutical grade material supplied by Worthington Biochemical Corporation. Pharmaceutical grade α-chymotrypsin and crystalline trypsin were also obtained from the latter source.[2] Bromelin concentrate was obtained from Takamine Laboratory, ficin concentrate from Merck and Co., and papain N.F. VIII from Difco Laboratories.

Enzyme Assays.—Previously described methods were used for the determination of fibrinolytic (3), caseinolytic (4), and deoxyribonuclease (5) activities. In the case of the latter activity, results are expressed for the present purposes as the numerical decrease of relative viscosity units in the 10-minute period from the initial relative viscosity of 4.0. All solutions and dilutions of the plant enzymes contained 0.025*M* cysteine except for the final dilutions for deoxyribonuclease assay. Exposure to cysteine alone was without effect on the deoxyribonuclease.

Stability Studies.—As indicated for clinical use, vials of DNase-P were reconstituted with 10 ml. of 0.9% NaCl. Corresponding mixtures were made with the same concentration of deoxyribonuclease, and the same or different concentrations of other proteolytic enzymes as established in each case by fibrinolytic assays. Solutions were prepared at 0° and then incubated in a 37° water bath. The pH of all solutions was adjusted to 7.0, which was that of the DNase-P. At intervals during incubation identical dilutions of the various mixtures were assayed for residual deoxyribonuclease and fibrinolytic activities.

RESULTS AND DISCUSSION

As shown in Table I the level of plasmin contained in DNase-P had no effect on the deoxyribonuclease in 4 hours; the same fall in viscosity was obtained if aliquots were assayed immediately after solution of the mixture at 0°. Significant destruction of the deoxyribonuclease activity was found only when the same level of deoxyribonuclease was incubated with 8× the DNase-P level of plasmin for 4 hours. In contrast, 0.1 as much fibrinolytic activity in the form of chymotrypsin completely destroyed the deoxyribonuclease in 1 hour; even the 0.01 level of chymotrypsin gave greater loss of deoxyribonuclease in 1 hour than the 8× level of plasmin did in 4 hours.

TABLE I.—PROTEASE EFFECT ON DEOXYRIBONUCLEASE

Enzyme[a]	Initial Fibrinolytic Level	Incubation, Hr.	Deoxyribonuclease Activity Δ Vr[b]
Plasmin (DNase-P)	1.0	1	2.8
"	"	2	2.7
"	"	4	2.8
Plasmin	3.0	2	2.7
"	"	4	2.6
Plasmin	8.0	2	2.3
"	"	4	2.0
Chymotrypsin	1.0	1	0
"	0.1	1	0
"	0.01	1	1.2
Trypsin	1.0	1	0
Ficin	1.0	3	0
Bromelin	1.0	3	0
Papain	1.0	3	1.6

[a] In terms of 280 mμ absorbance, concentrations at the 1.0 level were as follows: plasmin, 6.6; chymotrypsin, 0.087; trypsin, 0.067; ficin, 4.3; bromelin, 2.1; papain, 2.7. [b] Fall in relative viscosity units in 10 minutes from the initial value of 4.0.

Accepted for publication November 6, 1962.

[1] Marketed as Elase by Parke, Davis and Co.

[2] According to the manufacturer, pharmaceutical grade deoxyribonuclease has 70 to 90% of the activity of crystalline material. The pharmaceutical grade α-chymotrypsin has 90 to 100% of the activity of crystalline material, and trypsin contamination is "considerably" lower than one per cent.

Because plasmin is a more impure preparation than the chymotrypsin, the possibility was considered that inert proteins associated with the plasmin might protect the deoxyribonuclease from proteolytic attack. However, an equivalent amount of chymotrypsin added to the DNase-P mixture again completely destroyed the deoxyribonuclease in 1 hour. According to Feinstein and Hagen (6), ovalbumin had a remarkable effect in stabilizing deoxyribonuclease activity in crude pancreatic extracts; therefore, one per cent ovalbumin was added to a chymotrypsin-deoxyribonuclease mixture corresponding to the DNase-P formulation. The deoxyribonuclease was completely destroyed in 1 hour, indicating that the situation must be much different with the purified enzymes since this is even a higher level of inert protein than found in the DNase-P solution (about 0.6%). In this connection it might be noted that it is claimed in a recent patent (7) that solutions of crystalline deoxyribonuclease lost all activity in 3 hours at 31°. The deoxyribonuclease used in the present study showed no loss of potency in 4 hours at 37° in the presence or absence of plasmin, so that either the preparations or conditions used are not comparable in this respect. It is also now obvious that the possibility of chymotrypsin contamination must be ruled out in studies of the stability of any pancreatic deoxyribonuclease preparation.

By comparing the activities of bovine plasmin and chymotrypsin under optimum conditions of the fibrinolytic and caseinolytic assays, it was concluded that chymotrypsin "preferred" casein over fibrin as a substrate by a factor of about 3.5. In view of the above results it is apparent that the disparity may be orders of magnitude greater with respect to deoxyribonuclease (or perhaps some peptide bond related to its active center) as a substrate.

Under the conditions used for these stability studies plasmin was fairly unstable, presumably as a result of autodigestion in the absence of substrate. At the DNase-P level about 50% of the fibrinolytic activity remained after 1 hour and about 30% after 2 hours; in the case of chymotrypsin there was no significant decrease in this time. From the product processing point of view, therefore, it was possible to compensate for plasmin autodigestion by addition of excess plasmin without endangering the deoxyribonuclease activity; on the other hand, the amount of excess deoxyribonuclease required to compensate for its unexpectedly greater destruction by chymotrypsin eliminated consideration of such a mixture. The possibility of destruction of tissue deoxyribonuclease at the point of application by chymotrypsin and other proteolytic enzymes used in debriding preparations may have clinical implications, and it is hoped that information bearing on this question may be obtained in the future.

Variation of pKa'-Values of Tetracyclines in Dimethylformamide-Water Solvents

By EDWARD R. GARRETT

The variation of pKa'-values for several tetracycline antibiotics with per cent dimethylformamide (DMF) in per cent DMF-per cent H_2O solvents (v/v) is given. Quantitative expressions for the pKa' dependence on per cent DMF for the various functional groups have been obtained. This information is utilized in the assignment of pKa'-values to functional groups.

THE DISSOCIATION CONSTANTS or pKa'-values of many of the tetracycline antibiotics have been determined in various nonaqueous-water solvents because of the difficulties of solubilization and maintenance of homogeneous solutions over the entire titratable range for one solvent alone (1–4). A frequently used solvent mixture has been dimethylformamide-water.

In addition, a traditional routine procedure has been to titrate a substance in a nonaqueous-water solvent with an aqueous titrant giving an apparent pKa' at half-neutralization difficult to compare with the results from other routine titrations, since amounts of titer may vary and the relation of pKa' with per cent nonaqueous solvent has not been established.

This communication presents information on the variation of pKa'-values for several tetracycline antibiotics, presents quantitative expressions for their dependence on per cent dimethylformamide (DMF) in %DMF–%H_2O solvents, and attempts to demonstrate their potential usefulness in deducing pKa' assignments to functional groups.

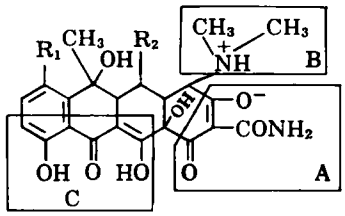
0.1000*N* HCl and 0.1*N* NaOH solutions. The titrations of desdimethylaminotetracycline and anhydrodesdimethylaminotetracycline plus added standard HCl were conducted on 10-mg. samples of the tetracyclines in 5 ml. %DMF–%H_2O solutions at 25° with 0.1000 *N* NaOH in a microburet.

The electrodes were glass-saturated calomel. The tetracycline derivatives were prepared by established methods (1–4) by Dr. Brian Bannister of the Upjohn Co.

The pKa'-values were estimated from the apparent pH values at half-neutralization of a functional group except for values *ca.* pKa' 4 and 10 where the Parke-Davis method was used (5, 6). The per cent DMF (v/v) at each pKa' was calculated from the known volume, the per cent of DMF (v/v) in the original solution and the known volume of aqueous titer added to achieve the apparent pH corresponding to that pKa'.

RESULTS AND DISCUSSION

The variation of pKa' for the various functional groups of tetracycline *Ic* as a function of the %DMF in %DMF–%H_2O (v/v) solvents is plotted in Fig. 1.



Ia, Oxytetracycline (Terramycin)
R_1 = H, R_2 = OH
Ib, Chlortetracycline (Aureomycin)
R_1 = Cl, R_2 = H
Ic, Tetracycline
R_1 = H, R_2 = H

The pKa'-assignments to the various labeled functional groups, A,B,C, of the tetracyclines *Ia*, *Ib*, *Ic* (1–4) are also designated by the lettered

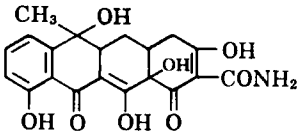
curves of Fig. 1.[1] Linear expressions[2] can be constructed to relate pKa' and %DMF for tetracycline *Ic* as

$$\text{Function A:}\quad pKa' = 0.021\,(\%DMF) + 3.30 \qquad \text{(Eq. 1a)}$$

$$\text{Function B:}\quad pKa' = 0.018\,(\%DMF) + 7.41 \qquad \text{(Eq. 1b)}$$

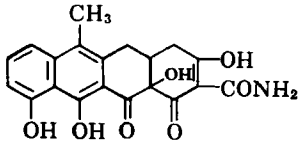
$$\text{Function C:}\quad pKa' = 0.007\,(\%DMF) + 9.62 \qquad \text{(Eq. 1c)}$$

The pKa'-assignments to the labeled functional groups of desdimethylaminotetracycline (hydrogen substituted for the dimethylamino group in *Ic*) are designated by the lettered curves of Fig. 2 (1-4).



II

Desdimethylaminotetracycline



III

Anhydrodesdimethylaminotetracycline

The linear expressions constructed to relate pKa' and %DMF for desdimethylaminotetracycline II are

[1] The assignments used are as published in literature (1–4). However, in light of recent interest in possible reassignment of pKa' values, it is interesting to note that the classical increase of apparent pKa' with decreasing dielectric constant for uncharged acids could argue for the interchange of the assignments of functions B and C. (See Fig. 1.)

[2] Due to a possible change in selective solvation of the dissociating molecule as 0% DMF is approached, the intercept of such expressions may vary slightly from the observed pKa' values in water.

Function A: $pKa' = 0.042\ (\%DMF) + 5.25$ (Eq. 2a)

Function C: $pKa' = 0.023\ (\%DMF) + 8.00$ (Eq. 2c)

Some of the literature data on pKa' (1–4) for the various tetracyclines in %DMF–$\%H_2O$ solutions are also plotted in Figs. 1 and 2 for comparison. It is apparent that the aureomycin and terramycin tetracyclines have lower pKa'-values but a similar relation with %DMF so that Eqs. 1 and 2 may be used as satisfactory estimates of pKa'-variation with %DMF—the same slopes but slightly lower intercepts.

A pKa' of 7.35 in 80%DMF–20%H_2O was observed for 10-benzenesulfonyltetracyclinonitrile. (The nitrile is substituted for the carboxamido group in *Ic*.) This value is consistent with the previously reported pKa' 6.9 at 50%DMF (2,4) for 10-benzenesulfonylterramycinonitrile which was assigned to the dimethylammonium ion. Addition of HCl to 10-benzenesulfonyltetracyclinonitrile showed no titratable group below pH 5 and above pH 2.0. This was consistent with the premise of highly increased acidity of the zwitterionic enolic system with nitril derivatives similar to but more acid than A in I(4).

The anhydrodesdimethylaminotetracycline, III, was observed to have two pKa'-values, pKa_1 = 8.06 (94%DMF), pKa_2 = 10.26 (91%DMF). This compound is analogous to anhydrodesdimethylaminoterramycin previously reported (2).

Now the pKa'-values of anhydroterramycin in water can be given (2) as 3.8 for A, 5.5 for C, and 7.2 for B, where the analogous functionalities are given in I. Since a 1,8-dihydroxybenzophthalide system has a pKa of 4.7 (2), the 5.5 pKa can possibly be assigned to the similar group C in anhydroterramycin; the 7.2 pKa' is consistent with the dimethylamine grouping B, zwitterionic with the carboxamide grouping A.

Removal of the dimethylamino group may consistently decrease the acidity of the carboxamido-enol complex A. It is noted that the pKa' 4.3 is elevated to 7.4, Δ pKa' = 3.1 in 50%DMF, and the pKa' 5.3 is elevated to 9.3, Δ pKa' = 4.0 in 95%DMF, for the change from tetracycline to desdimethylaminotetracycline (Figs. 1 and 2). Using these Δ pKa'-values, it can be predicted that on the insertion of a dimethylamino group into anhydrodesdimethylamino tetracycline III, the now zwitterionic carboxamide-enol complex could be assigned either the pKa'-values of 10.3 − 4.0 = 6.3, or 8.1 − 4.0 = 4.1 at 95%DMF. Because the derived pKa' of 6.3 for 95%DMF is the more consistent of these two possible values with the pKa' of the carboxamido-enol complex of tetracycline in 95%DMF, *i.e.*, 5.4 implies that the pKa_2 = 10.3 (94%DMF) is better assigned to the carboxamido grouping A in III, and the pKa_1 = 8.1 (94%DMF) can be assigned to the dihydroxynapthalene grouping C in III.

Effect of Zinc Oxide Catalyzed Peroxide on Sterols of Almond, Cottonseed, and Olive Oils

By M. WAFIK GOUDAH and EARL P. GUTH

The phytosterols of almond, cottonseed, and olive oils undergo changes in structure when the oils are irradiated in both ultraviolet and sunlight with zinc oxide. The changes in the phytosterol molecules of the oils indicate a probability that a similar change could occur in the sterols of the skin. These changes might produce a molecule with anti-inflammation activity, thus providing an explanation for the dermatological effect of zinc oxide external preparations.

THE CATALYTIC ACTIVITY of zinc oxide in the photochemical formation of hydrogen peroxide has been confirmed by many workers (1, 2). The pharmaceutical aspects of the phenomenon have also been investigated by Guth, Reese, Mathias, Minardi, Blubaugh, Young, and Lozada (3–8).

Lozada and Guth (8) showed that when zinc oxide-containing ointments were irradiated with ultraviolet light in the presence of water and air the measurable peroxide was less or nonexistant in systems that contained cholesterol or other sterols. This was particulary true when wool fat or hydrophilic petrolatum were components of the ointment base. This lack of peroxide was accounted for by the effect on the sterol molecule.

Infrared spectrographic studies showed that the β-hydroxyl group on cholesterol was oxidized to a carbonyl group. There was also evidence that the double bond shifted from the 5:6 position to the 4:5 position.

With this as a background, a study of the effect of zinc oxide catalyzed peroxide on the sterols in

Received September 18, 1962, from the College of Pharmacy, The Ohio State University, Columbus.

Function A: $pKa' = 0.042\ (\%DMF) + 5.25$ (Eq. 2a)

Function C: $pKa' = 0.023\ (\%DMF) + 8.00$ (Eq. 2c)

Some of the literature data on pKa' (1–4) for the various tetracyclines in %DMF–$\%H_2O$ solutions are also plotted in Figs. 1 and 2 for comparison. It is apparent that the aureomycin and terramycin tetracyclines have lower pKa'-values but a similar relation with %DMF so that Eqs. 1 and 2 may be used as satisfactory estimates of pKa'-variation with %DMF—the same slopes but slightly lower intercepts.

A pKa' of 7.35 in 80%DMF–20%H_2O was observed for 10-benzenesulfonyltetracyclinonitrile. (The nitrile is substituted for the carboxamido group in *Ic*.) This value is consistent with the previously reported pKa' 6.9 at 50%DMF (2,4) for 10-benzenesulfonylterramycinonitrile which was assigned to the dimethylammonium ion. Addition of HCl to 10-benzenesulfonyltetracyclinonitrile showed no titratable group below pH 5 and above pH 2.0. This was consistent with the premise of highly increased acidity of the zwitterionic enolic system with nitril derivatives similar to but more acid than A in I(4).

The anhydrodesdimethylaminotetracycline, III, was observed to have two pKa'-values, pKa_1 = 8.06 (94%DMF), pKa_2 = 10.26 (91%DMF). This compound is analogous to anhydrodesdimethylaminoterramycin previously reported (2).

Now the pKa'-values of anhydroterramycin in water can be given (2) as 3.8 for A, 5.5 for C, and 7.2 for B, where the analogous functionalities are given in I. Since a 1,8-dihydroxybenzophthalide system has a pKa of 4.7 (2), the 5.5 pKa can possibly be assigned to the similar group C in anhydroterramycin; the 7.2 pKa' is consistent with the dimethylamine grouping B, zwitterionic with the carboxamide grouping A.

Removal of the dimethylamino group may consistently decrease the acidity of the carboxamido-enol complex A. It is noted that the pKa' 4.3 is elevated to 7.4, Δ pKa' = 3.1 in 50%DMF, and the pKa' 5.3 is elevated to 9.3, Δ pKa' = 4.0 in 95%DMF, for the change from tetracycline to desdimethylaminotetracycline (Figs. 1 and 2). Using these Δ pKa'-values, it can be predicted that on the insertion of a dimethylamino group into anhydrodesdimethylamino tetracycline III, the now zwitterionic carboxamide-enol complex could be assigned either the pKa'-values of 10.3 − 4.0 = 6.3, or 8.1 − 4.0 = 4.1 at 95%DMF. Because the derived pKa' of 6.3 for 95%DMF is the more consistent of these two possible values with the pKa' of the carboxamido-enol complex of tetracycline in 95%DMF, *i.e.*, 5.4 implies that the pKa_2 = 10.3 (94%DMF) is better assigned to the carboxamido grouping A in III, and the pKa_1 = 8.1 (94%DMF) can be assigned to the dihydroxynapthalene grouping C in III.

Effect of Zinc Oxide Catalyzed Peroxide on Sterols of Almond, Cottonseed, and Olive Oils

By M. WAFIK GOUDAH and EARL P. GUTH

The phytosterols of almond, cottonseed, and olive oils undergo changes in structure when the oils are irradiated in both ultraviolet and sunlight with zinc oxide. The changes in the phytosterol molecules of the oils indicate a probability that a similar change could occur in the sterols of the skin. These changes might produce a molecule with anti-inflammation activity, thus providing an explanation for the dermatological effect of zinc oxide external preparations.

THE CATALYTIC ACTIVITY of zinc oxide in the photochemical formation of hydrogen peroxide has been confirmed by many workers (1, 2). The pharmaceutical aspects of the phenomenon have also been investigated by Guth, Reese, Mathias, Minardi, Blubaugh, Young, and Lozada (3–8).

Lozada and Guth (8) showed that when zinc oxide-containing ointments were irradiated with ultraviolet light in the presence of water and air the measurable peroxide was less or nonexistant in systems that contained cholesterol or other sterols. This was particulary true when wool fat or hydrophilic petrolatum were components of the ointment base. This lack of peroxide was accounted for by the effect on the sterol molecule.

Infrared spectrographic studies showed that the β-hydroxyl group on cholesterol was oxidized to a carbonyl group. There was also evidence that the double bond shifted from the 5:6 position to the 4:5 position.

olive oil, expressed almond oil, and cottonseed oil was undertaken.

EXPERIMENTAL

Calamine liniment, N.F. IX, was selected as the basic formula for the study. Zinc oxide "Baker" 3.2 Gm. was weighed into 1000-ml. Pyrex beakers, and 100 ml. of 0.2 *M* sodium formate solution was added. The contents were shaken by hand rotation. Ten milliliters of oil was added and the beakers (two at a time) were placed under a Dazor floating fixture ultraviolet lamp, model N. U-58 equipped with a General Electric VA-3 360 watt quartz photo chemical "Ulvirac" lamp.

Metal stirrers driven by Power-Stir model 58 motor, Eberbach Corporation, were used. The stirring was kept on the low speed indicated on the motor and was maintained through a 30-minute period of irradiation. The irradiation unit was completely enclosed within aluminum sheeting.

The phytosterols of each oil were isolated before and after each sample had been irradiated by the following method (9).

The sample of the oil was saponified with 2 *N* alcoholic potassium hydroxide under a reflux condenser. After saponification, most of the alcohol was removed by evaporation. The residual soap was dissolved in hot water and transferred to a separator. The flask was rinsed with hot water, and the rinsing was added to the funnel. After cooling, the unsaponifiable matter was extracted with three successive amounts of ethyl ether. The ethereal solutions were combined and washed with a small quantity of water to remove any residual soap. The ether was removed by distillation, and the residue was dried at 100°.

The unsaponifiable matter was dissolved in ethyl ether, and the solution was transferred to a small porcelain dish. The ether was allowed to evaporate spontaneously, the mass was dried on a water bath and dissolved (after cooling) in the smallest possible quantity of absolute alcohol. The phytosterols were allowed to crystallize from this solution.

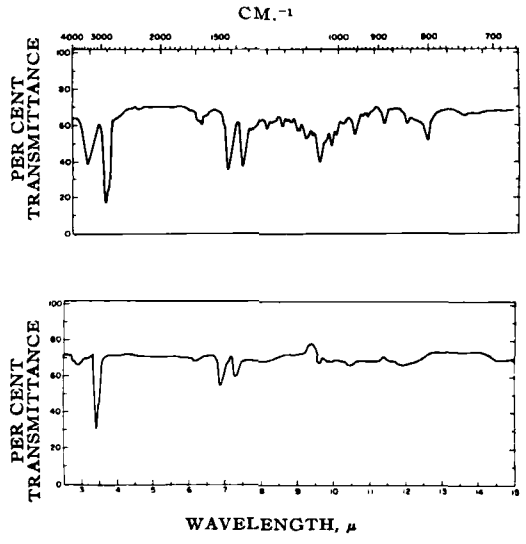

Fig. 1.—Infrared spectra of phytosterols in olive oil (top); in irradiated olive oil (bottom).

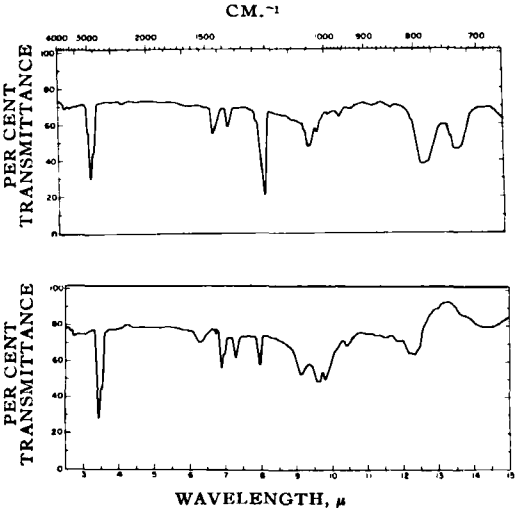

Fig. 2.—Infrared spectra of phytosterols in almond oil (top); in irradiated almond oil (bottom).

The sterols were dissolved in chloroform, and infrared spectrographs were determined in the Perkin–Elmer Infracord (Figs. 1–3). The phytosterols of cottonseed oil were also extracted after a mixture of zinc oxide and the oil had been exposed to the sunlight for 6 hours. The infrared spectra of the extracted phytosterols were determined and are shown in Fig. 3.

RESULTS AND DISCUSSION

The infrared spectra of the phytosterols of the oils isolated before irradiation showed a region from 4000 cm.$^{-1}$ (Figs. 1–3) which is characteristic of the functional groups in the molecule, while the "fingerprint" region is between 1350 cm.$^{-1}$ and 650 cm.$^{-1}$.

Absorption regions between 1055 cm.$^{-1}$ and 950 cm.$^{-1}$ are associated with the hydroxyl group in the sterol molecule. The absorption bands between 1464 cm.$^{-1}$ and 1375 cm.$^{-1}$ are characteristic of methylene group and angular methyl group. The 5:6 double bond gives bands at 840 cm.$^{-1}$ and 800 cm.$^{-1}$ (10). The region between 650 cm.$^{-1}$ and 800 cm.$^{-1}$ is also characteristic of all types of double bonds (11). All other absorption bands are "fingerprints" of the molecule.

The infrared spectra of the phytosterols of olive oil after it has been irradiated showed that variations occurred in the molecule. Bands due to the hydroxyl methyl group and the methylene group, although becoming reduced in intensity, are still present. The "fingerprint" bands showed a notable change. A very pronounced change is indicated by the disappearance of the double bond bands at 800 cm.$^{-1}$ and 840 cm.$^{-1}$.

The infrared spectra of the phytosterols of expressed almond oil after irradiation showed that certain groups disappeared and others shifted. The band at 1200 cm.$^{-1}$ was shifted to 1250 cm.$^{-1}$. As in the case of olive oil, the double bond region between 800 cm.$^{-1}$ and 650 cm.$^{-1}$ disappeared. Bands due to hydroxyl, methyl, and methylene groups were still present.

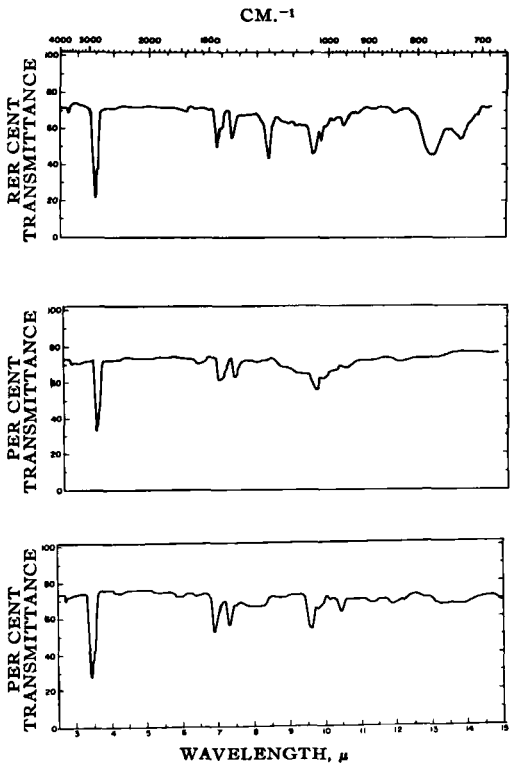

Fig. 3.—Infrared spectra of phytosterols in cottonseed oil (top); in irradiated cottonseed oil (middle); in 6 hour sunlight-exposed cottonseed oil (bottom).

Phytosterols of irradiated cottonseed oil still show bands of the hydroxyl, methyl, and methylene groups but of lessened intensity. The strong bands at 1200 cm.$^{-1}$ disappeared, and great changes in the "fingerprints" occurred. Also, (as with olive oil and almond oil) the double bond region between 800 cm.$^{-1}$ and 650 cm.$^{-1}$ disappeared.

When cottonseed oil, zinc oxide, sodium formate, and water were exposed to sunlight for 6 hours, changes also occurred in the phytosterol molecules. The changes are almost as identical as the changes in the oil irradiated under the ultraviolet lamp with the zinc oxide and sodium formate solution. The hydroxyl band was of greater intensity than when cottonseed oil was irradiated with ultraviolet light.

The disappearance of the double bond region from all the irradiated phytosterols, together with the other changes, indicates beyond doubt that the structure of the phytosterol molecule undergoes changes when exposed to the peroxides produced by zinc oxide and ultraviolet light. In the presence of oxygen–containing compounds such as water and air, Payot (12) found cholesterol susceptible to radiations and oxidizes on and about the 5,6 double bond. On the basis of the infrared spectrum and Payot's findings, it could be said that certain changes occurred in the molecule that might involve oxidation on and about the 5,6 double bond. Since hydrogen peroxide and ultraviolet irradiation energy are both present in this system, a reaction involving radical mechanism initiated by the energy of the ultraviolet very likely occurred in the phytosterol molecule.

When the sterols isolated from the sun-exposed cottonseed oil were tested pharmacologically they showed absence of anti-inflammatory activity. However, the changes which occurred in the molecule could possibly be a step in a chain of reactions which would yield a molecule that has anti-inflammatory effect. Since it has been shown that the production of hydrogen peroxide by zinc oxide and ultraviolet light as well as sunlight can cause structural changes in the sterols of natural lipids, it might be possible that changes could be caused in the sterols of the skin. If this were so, it would be a more rational explanation of the pharmacology of zinc oxide than the statements usually found in standard pharmacological references to zinc oxide action.

CONCLUSIONS

The infrared spectra of the phytosterols before and after irradiation proved that the phytosterols of the oils undergo changes in structure when the latter was irradiated in both ultraviolet and sunlight with zinc oxide. The double bond breakage in the sterol molecule was among the changes that occurred in the molecule.

Sunlight caused the same change in the sterol molecule as did ultraviolet light irradiations. Preliminary pharmacological tests showed that the sterols isolated from the sun-exposed cottonseed oil had no anti-inflammatory activity.

Colorimetric Determination of Phenylephrine Using 4-Aminoantipyrine

By K. THOMAS KOSHY and H. MITCHNER†

Two colorimetric methods are described for phenylephrine hydrochloride using potassium ferricyanide and 4-aminoantipyrine as reagents. Using 2 per cent sodium borate as the medium, a sufficiently stable color is obtained. This method is suitable for the analysis of phenylephrine in common tablet formulations without prior separation. A second procedure using tris(hydroxymethyl)aminomethane (Tham) buffer, pH 9, and isopropyl alcohol as medium gives a color stable for over 1 hour.

THE COLOR REACTION of 4-aminoantipyrine with phenols has been extensively investigated (1–11). Application of this reagent to the analysis of phenylephrine has been reported by Hiskey and Levin (12). Their procedure consisted of adding to the sample, solutions of potassium ferricyanide, 4-aminoantipyrine, and sodium bicarbonate in the above order and measuring the absorbance 15 minutes after addition of reagents. The waiting period was necessary to allow for the dissipation of an interfering color. The reagent blank had a high initial absorbance which dropped to about 0.06–0.07 (1 cm. cells) after 15 minutes. The color of the sample also faded rapidly during the first 15 minutes and at a less rapid rate thereafter.

Investigation of the reaction of 4-aminoantipyrine and phenylephrine was undertaken because of the specificity of the reaction and the possibility of application in complex mixtures. Critical factors found by literature review and investigation were pH, concentration of reagents, order of addition of reagents, and polarity.

A rapid and convenient procedure was developed utilizing a 2% buffer solution of sodium borate. The interfering red color reported by Hiskey and Levin (12) could be avoided by the addition of 4-aminoantipyrine after dilution of the phenylephrine-potassium ferricyanide reaction mixture with the buffer solution. An additional advantage of the revised procedure was that over a wide range neither the concentration nor the proportion of the two reagents were critical factors. The color obtained was fairly stable, and the absorbance due to the reagent blank was low (Fig. 1). Accurate and reproducible results were obtainable, and the color reaction was found to obey Beer's law in the range of 1–10 mcg./ml.

Studies relative to the increase of the stability of the color indicated that polarity of the medium was a factor. Water-miscible organic solvents were tried in combination with different buffer solutions to improve color stability. It was found that isopropyl alcohol when used with Tham buffer pH 9 had a stabilizing effect. The procedure consisted of the addition of the buffer solution and isopropyl alcohol to the mixture of phenylephrine and potassium ferricyanide, followed by 4-aminoantipyrine and more of the buffer solution to a definite volume. Again, the order of addition of reagents was important, as a more intense but less stable color was obtained if the 4-aminoantipyrine was added prior to the addition of isopropyl alcohol.

Received November 15, 1962, from the Pharmacy Research Laboratory, Miles Laboratories, Inc., Elkhart, Ind.
Accepted for publication November 27, 1962.
† Present address: Barnes-Hind Laboratories, Sunnyvale, Calif.

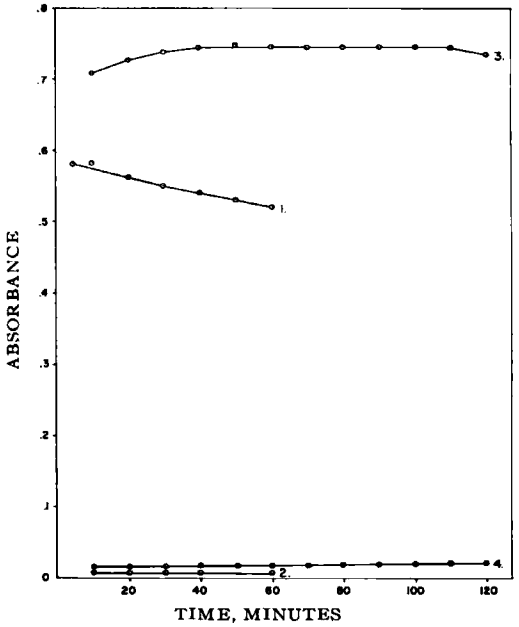

Fig. 1.—Phenylephrine–4-aminoantipyrine color reaction. 1, two per cent sodium borate medium; 2, blank for 1; 3, Tham buffer pH 9 —isopropyl alcohol medium; 4, blank for 3.

The color reaction was reproducible, obeyed Beer's law at concentrations down to 1 mcg./ml., and gave a low blank value. It was 25% more sensitive than the suggested procedure using borate buffer.

Application of the reactions in the two buffer media described was studied with a number of tablet formulations containing phenylephrine. Common tablet excipients and ingredients such as aspirin, ascorbic acid, phenacetin, caffeine, and chlortrimeton did not interfere in the borate buffer system when assaying a filtered aqueous extract of ground tablets for their phenylephrine content. When Tham buffer was utilized, cloudy solutions were frequently encountered on addition of isopropyl alcohol, and this system could not be used without prior separation of phenylephrine from interfering substances.

EXPERIMENTAL

Reagents and Equipment.—4-Aminoantipyrine, Eastman Organic Chemicals, 3% in water[1]; potassium ferricyanide, C.P., 4% in water[1]; sodium

[1] Solution stable for at least 1 week if stored in amber reagent bottle.

borate, $Na_2B_4O_7 \cdot 10H_2O$, A.C.S., Fisher Scientific Co., 2% in water; tris(hydroxymethyl)aminomethane (Tham), purified, Fisher Scientific Co., 50 ml. 0.1 *M* solution adjusted to pH 9 with 0.1 *M* HCl and diluted to 100 ml. with water; phenylephrine hydrochloride, Winthrop Laboratories; Beckman DU spectrophotometer; and 1-cm. Corex cells were utilized.

Procedure Using 2% Sodium Borate Solution.—Three milliliters of an aqueous solution containing 150–450 mcg. of phenylephrine hydrochloride was pipeted into a 50-ml. volumetric flask. One milliliter of potassium ferricyanide reagent was added, and the solution was diluted to about 48 ml. with sodium borate solution. One milliliter of 4-aminoantipyrine reagent was added, and the volume was made up with borate buffer and mixed. The absorbance of this solution was determined immediately at 490 mμ against a reagent blank. The concentration of the sample was calculated by comparison with the color developed simultaneously on a standard solution of phenylephrine hydrochloride.

Procedure Using Tham Buffer and Isopropyl Alcohol.—Three milliliters of an aqueous solution containing approximately 150–450 mcg. of phenylephrine was pipeted into a 50-ml. volumetric flask. One milliliter of potassium ferricyanide was added, followed by 15 ml. of the buffer, 15 ml. of isopropyl alcohol, 1 ml. of 4-aminoantipyrine, and more of the buffer to volume. The contents of the flask were mixed after the addition of each reagent. The absorbance of the solution was determined at 490 mμ against a reagent blank 30 minutes after the development of color. The color developed simultaneously on a standard solution of phenylephrine hydrochloride was used to calculate the concentration of the sample.

Acute Toxicity of Intravenous Sodium Lauryl Sulfate

By HELMUT F. CASCORBI, FRIEDA G. RUDO, and GORDON G. LU

Sodium lauryl sulfate (SLS) is an excellent emulsifying agent. An emulsion of methoxyflurane in oil, stable to autoclaving, and employing SLS as an emulsifier was prepared. The acute effects of intravenous SLS on red cells, electrocardiogram, vital organs of rabbits, dogs, and monkeys, and isolated hearts of rabbits and frogs were studied. The dose levels were 10 and 50 mg. per cent in 5 per cent glucose or in 3.5 per cent emulsion of methoxyflurane at administration rates of 6.2 ml./Kg./hr. intravenously. The hemolytic effects of SLS and its effect on the electrocardiogram are negligible. SLS evokes a precipitous transient depressor response in dogs. However, SLS has marked acute effect on lungs, kidneys, and especially liver. The hepatotoxicity of SLS seems to preclude its intravenous use in man.

SODIUM LAURYL SULFATE (SLS) has been used in dentifrices for years. Its pharmacologic and toxicologic properties have been studied by a number of investigators (1–5). Recently the Council on Drugs has directed attention to possible hepatosensitivity associated with erythromycin propionate lauryl sulfate (6).

The authors' work with intravenous anesthetic emulsions (7) prompted an investigation of the suitability of SLS as an emulsifier. SLS in concentrations of 2–5 mg. % proved to be an excellent emulsifier and produced a very stable emulsion that tolerated autoclaving for 19 minutes at 15 lb.

After we had established the usefulness of SLS as an emulsifier for emulsions of volatile anesthetics, we then proceeded to investigate its acute toxicity upon intravenous administration.

Received October 15, 1962, from the School of Medicine, Department of Pharmacology, University of Maryland, Baltimore.
Accepted for publication November 13, 1962.

The LD_{50} of SLS upon intravenous administration in rats and mice (kindly supplied to us by K. K. Chen) was found to be 118.2 ± 7.2 mg./Kg.

The properties that were of special interest to us were (*a*) lysis of the red cell membrane, (*b*) its influence on the electric activity of the heart, and (*c*) its acute toxic effects on liver, kidneys, and lungs.

METHODS

Hemolysis.—Two mongrel dogs were anesthetized with 25 mg./Kg. pentobarbital intravenously. The animals were then infused with a solution of 50 mg. % SLS in 5% glucose at a rate of 6.2 ml./Kg./hr. for 1 hour.

Prior to and after infusion, blood samples for hemolysis were taken. Samples were drawn through 17-gauge needles in plastic syringes, bubble free. Plastic centrifuge tubes and a well balanced centrifuge were used to avoid mechanical disrupture of the red cells.

borate, $Na_2B_4O_7 \cdot 10H_2O$, A.C.S., Fisher Scientific Co., 2% in water; tris(hydroxymethyl)aminomethane (Tham), purified, Fisher Scientific Co., 50 ml. 0.1 *M* solution adjusted to pH 9 with 0.1 *M* HCl and diluted to 100 ml. with water; phenylephrine hydrochloride, Winthrop Laboratories; Beckman DU spectrophotometer; and 1-cm. Corex cells were utilized.

Procedure Using 2% Sodium Borate Solution.—Three milliliters of an aqueous solution containing 150–450 mcg. of phenylephrine hydrochloride was pipeted into a 50-ml. volumetric flask. One milliliter of potassium ferricyanide reagent was added, and the solution was diluted to about 48 ml. with sodium borate solution. One milliliter of 4-aminoantipyrine reagent was added, and the volume was made up with borate buffer and mixed. The absorbance of this solution was determined immediately at 490 mμ against a reagent blank. The concentration of the sample was calculated by comparison with the color developed simultaneously on a standard solution of phenylephrine hydrochloride.

Procedure Using Tham Buffer and Isopropyl Alcohol.—Three milliliters of an aqueous solution containing approximately 150–450 mcg. of phenylephrine was pipeted into a 50-ml. volumetric flask. One milliliter of potassium ferricyanide was added, followed by 15 ml. of the buffer, 15 ml. of isopropyl alcohol, 1 ml. of 4-aminoantipyrine, and more of the buffer to volume. The contents of the flask were mixed after the addition of each reagent. The absorbance of the solution was determined at 490 mμ against a reagent blank 30 minutes after the development of color. The color developed simultaneously on a standard solution of phenylephrine hydrochloride was used to calculate the concentration of the sample.

Acute Toxicity of Intravenous Sodium Lauryl Sulfate

By HELMUT F. CASCORBI, FRIEDA G. RUDO, and GORDON G. LU

Sodium lauryl sulfate (SLS) is an excellent emulsifying agent. An emulsion of methoxyflurane in oil, stable to autoclaving, and employing SLS as an emulsifier was prepared. The acute effects of intravenous SLS on red cells, electrocardiogram, vital organs of rabbits, dogs, and monkeys, and isolated hearts of rabbits and frogs were studied. The dose levels were 10 and 50 mg. per cent in 5 per cent glucose or in 3.5 per cent emulsion of methoxyflurane at administration rates of 6.2 ml./Kg./hr. intravenously. The hemolytic effects of SLS and its effect on the electrocardiogram are negligible. SLS evokes a precipitous transient depressor response in dogs. However, SLS has marked acute effect on lungs, kidneys, and especially liver. The hepatotoxicity of SLS seems to preclude its intravenous use in man.

SODIUM LAURYL SULFATE (SLS) has been used in dentifrices for years. Its pharmacologic and toxicologic properties have been studied by a number of investigators (1–5). Recently the Council on Drugs has directed attention to possible hepatosensitivity associated with erythromycin propionate lauryl sulfate (6).

The authors' work with intravenous anesthetic emulsions (7) prompted an investigation of the suitability of SLS as an emulsifier. SLS in concentrations of 2–5 mg. % proved to be an excellent emulsifier and produced a very stable emulsion that tolerated autoclaving for 19 minutes at 15 lb.

After we had established the usefulness of SLS as an emulsifier for emulsions of volatile anesthetics, we then proceeded to investigate its acute toxicity upon intravenous administration.

Received October 15, 1962, from the School of Medicine, Department of Pharmacology, University of Maryland, Baltimore.
Accepted for publication November 13, 1962.

The LD_{50} of SLS upon intravenous administration in rats and mice (kindly supplied to us by K. K. Chen) was found to be 118.2 ± 7.2 mg./Kg.

The properties that were of special interest to us were (*a*) lysis of the red cell membrane, (*b*) its influence on the electric activity of the heart, and (*c*) its acute toxic effects on liver, kidneys, and lungs.

METHODS

Hemolysis.—Two mongrel dogs were anesthetized with 25 mg./Kg. pentobarbital intravenously. The animals were then infused with a solution of 50 mg. % SLS in 5% glucose at a rate of 6.2 ml./Kg./hr. for 1 hour.

Prior to and after infusion, blood samples for hemolysis were taken. Samples were drawn through 17-gauge needles in plastic syringes, bubble free. Plastic centrifuge tubes and a well balanced centrifuge were used to avoid mechanical disrupture of the red cells.

TABLE I.—EFFECT OF SLS ON VITAL ORGANS OF DOGS

Dog No.	SLS, 10 Mg. %	Diagnosis		
		Lungs	Kidneys	Liver
12	Emulsion	Atelectasis, mild	Cloudy swelling	Cloudy swelling
15	Emulsion	Atelectasis pneumonitis	Acute pyelonephritis	Subhepatic necrosis
16	Emulsion	Acute congestion	Normal	Acute congestion
17	Glucose, 5%	Moderate congestion	Mild cloudy swelling	Normal
18	Glucose, 5%	Normal	Moderate cloudy swelling	Severe cloudy swelling. Hemorrhage focal necrosis severe.
19	Glucose, 5%	Normal	Minimal cloudy swelling	Moderate cloudy swelling

TABLE II.—EFFECT OF SLS ON VITAL ORGANS OF RABBITS

Rabbit No.	Lungs	Kidneys	Liver	Bone Marrow	Diagnosis
1 3/1/62	Focal inflammatory reactions throughout specimen; some in bronchi. Much of lung is air containing.	Normal tubules. Cloudy swelling of tubules with moderate glomerular congestion.	Pericentral necrosis of liver cells involving 3/5 of each lobule. Bile ducts, vessels, and triads are normal.	30% reduction with normal ratio of cells. (30% depression of cellulloid.)	Hyperplasia, bone marrow. Necrosis, pericentral; liver severe. Cloudy swelling, kidneys. Globular pneumonia acute.
2 3/1/62	No lesions	Cloudy swelling of tubules. Normal glomeruli.	Mild pericentral necrosis in 3/5 lobule which appears to be reversible. Normal triads and bile ducts.	Normal	Cloudy swelling, kidneys. Fatty necrosis pericentral liver.
3 3/1/62	Collapse and congestion with early inflammation near bronchi; early. Abundant aeration is still present.	Very mild cloudy swelling only with normal glomeruli and tubules.	Considerable pericentral necrosis and congestion involving 50% of each lobule. Bile ducts, triads, and periportal cells not affected.	No Specimen	Necrosis, pericentral; liver severe. Pulmonary congestion. Pneumonia, lobular.

Two additional mongrel dogs were treated in a similar manner, employing a 10 mg. % SLS in 5% glucose solution for infusion.

Electrocardiogram and Blood Pressure of Dogs.—Nine mongrel dogs and two monkeys were anesthetized with pentobarbital sodium (25 mg./Kg. i.v.) and infused in the foregoing manner.

Two dogs were infused with a solution of 50 mg. % SLS in 5% glucose, and seven dogs were infused with a solution of 10 mg. % SLS in 5% glucose for 1 hour each. One monkey was infused with a solution of 15 mg. % SLS in 5% glucose, and another monkey was infused with 20 mg. % SLS in 5% glucose, each for 30 minutes with 6.2 ml./Kg./hr. Lead II of the electrocardiogram was monitored in all animals.

Three mongrel dogs under ether anesthesia were injected intravenously with varying amounts (3.5 mg./Kg. to 7.0 mg./Kg.) of SLS in a concentration of 70 mg. %, and the blood pressure was monitored from the carotid artery.

EKG recordings (Lead II) were obtained at the same time.

Acute Toxic Effects On Liver, Lungs, and Kidneys.—Three mongrel dogs were anesthetized with thiopental sodium, and a control liver biopsy was obtained through a midline incision. Anesthesia was then continued with an emulsion of methoxyflurane (3.5 ml. methoxyflurane, 3.0 ml. cottonseed oil, 1.0 ml. ethanol, 0.5 Gm. Pluronic F 68, 4.2 Gm. glucose and water *q.s. ad.* 100.00 ml.) to which 10 mg. % of SLS had been added after emulsification. The dogs were anesthetized with the emulsion for 3 hours. The dose was determined by the individual susceptibility of the animals to the anesthetic. The dose was 10.8, 9.1, and 6.6 ml./Kg./hr., respectively. After 3 hours of anesthesia, biopsies of liver, lungs, and kidneys were taken, and the animals were sacrificed.

Three more dogs were anesthetized with pentobarbital sodium (25 mg./Kg. i.v. with subsequent doses if necessary), a biopsy of the liver was obtained, and then an infusion of 10 mg. % SLS in 5% glucose administered at the rate of 6.2 ml./Kg./hr. for 3 hours. After this time another biopsy of the liver and biopsies of the lungs and kidneys were obtained, and the animals were sacrificed.

The organ specimens were fixated with 1% $CaCl_2$ in 10% formalin and sent to Dr. John A. Wagner of the Department of Neuropathology for the examination.

Five rabbits were anesthetized daily with 3.5%

emulsion of methoxyflurane by intravenous injection into the marginal ear vein. The emulsion contained 10 mg. % of SLS. Anesthesia was maintained for 30 minutes and repeated five times. The average dose was 16 ml./Kg./hr.

Isolated Rabbit's Heart.—The modified Langendorf procedure was used (8).

Perfused Frogs' Hearts *In Situ.*—The Greene frog-heart perfusion was used.

RESULTS

Hemolysis.—The plasma of three of the dogs was free of any visible hemolysis, whereas the plasma of one dog that received 10 mg. % SLS in 5% glucose showed a trace of hemolysis that was found to be below 30 mg. % hemoglobin.

Electrocardiograms.—The EKG tracings were remarkably devoid of significant findings. We observed peaking of *T* in two cases and an inversion of the *T*-wave in one case. The EKG of the monkeys was not changed.

Blood Pressures.—Dosage levels of SLS up to 3.5 mg./Kg. caused a fall in mean arterial pressure of 7–21% of the norm. Levels of 7 mg./Kg. evoked a 36–40% fall in blood pressure. Electrocardiographic changes were not significant.

Acute Toxic Effects On Liver, Lungs, and Kidneys.—The pathological diagnosis of the six dogs are shown in Table I. The table shows clearly that SLS causes cloudy swelling and congestion in lungs, kidneys, and liver with a preponderance on hepatic damage where even focal necrosis was observed.

Isolated Rabbit's Heart.—SLS dissolved in the perfusion fluid (60 mcg.) had no effect upon the amplitude of contraction of the rabbit's heart in two experiments. Levels of 120 and 240 mcg. caused a moderate depression of contractility.

Levels of 30 and 60 mcg. caused irregular transient coronary flow responses. Levels of 120 and 240 mcg. caused diminution of 35 and 80%, respectively.

Perfused Frogs' Hearts *In Situ.*—In three hearts 1 mg. % of SLS had no effect on the rate or amplitude of contraction. A level of 10 mg. % reduced the rate and amplitude of contraction in two hearts and in the third heart caused cardiac stoppage.

Rabbits.—The results of repeated administration of SLS in emulsion to rabbits are detailed in Table II. Two of the animals died before the study was completed.

DISCUSSION

We administered 10 mg. % SLS in 5% glucose solution to ascertain whether the hepatic toxicity that was found for 10 mg. % SLS in an emulsion could be ascribed to one of the constituents of the emulsion.

The recurrence of renal and especially hepatic changes compel us to ascribe these changes to the action of SLS. However, even at these levels hemolysis was not encountered. We believe that SLS should not be used intravenously in man.

Modification in Sample Preparation for the Microbiological Assay of Vitamin B_{12}

By ELKO M. STAPERT, HELEN CRAIN, and ROBERT NEEDHAM

A modification of the U.S.P. XVI method for the assay of vitamin B_{12} eliminates some negative bias encountered with some products and permits quantitative recovery of the vitamin. Soft-elastic and hard-filled capsules are blended in the buffered sodium metabisulfite solution before autoclaving. This procedure is particularly necessary to assay older capsules. Products containing reducing sugars are protected with potassium cyanide instead of sodium metabisulfite.

BLENDING WHOLE CAPSULES BEFORE ASSAY

THE MICROBIOLOGICAL METHOD for assaying products containing vitamin B_{12} is described in U.S.P. XVI (1). In this method the product is placed into a buffered solution of sodium metabisulfite and autoclaved for 10 minutes during which all convertible B_{12} is changed to the more stable sulfite form. In assaying many types of products, lower values were obtained with samples stored at room temperature for 18 and 24 months by U.S.P. XVI method than by the assay described in the U.S.P. XIV, third supplement (2).

When whole capsules are placed in the sodium metabisulfite solution, a period of time is required before the contents are in contact with the sodium metabisulfite. A modification in sample preparation described in this paper permits quantitative recovery of the vitamin in contrast to the U.S.P. method where some B_{12} may be destroyed.

Experimental Methods

Sample Preparation with KCN.—All operations and ingredients were as directed in the U.S.P. XVI assay method except the sample preparation.

Received November 13, 1962, from the Control Laboratories, The Upjohn Co., Kalamazoo, Mich.
Accepted for publication December 31, 1962.

[a] All volumes were 300 ml. Per cent recoveries are based on theoretical values.

TABLE II.—PER CENT RECOVERY OF VITAMIN B_{12} FROM SOFT-ELASTIC CAPSULES STORED AT ROOM TEMPERATURE[a]

KCN Method	U.S.P. Method		U.S.P. Method Modified
18 Mo.	18 Mo.	24 Mo.	24 Mo.
98	82	79.5	99.7
100.5	87.7	79	101.2
96	84	81	103.5
92	79	...	...

[a] All volumes were 300 ml. Per cent recoveries are based on theoretical values.

Capsules were blended for 2 minutes in 300 ml. of a buffer solution in which 100 mg. of potassium cyanide replaced the sodium metabisulfite. The samples were made to volume and diluted to the desired concentration immediately. The autoclaving step was eliminated.

U.S.P. Assay Method.—All operations were carried out as specified in the U.S.P.

Sample Preparation by U.S.P. Method Modified.—The U.S.P. procedure was carried out as specified except that capsules were blended 2 minutes in a Waring Blendor containing the required amount of sodium metabisulfite solution. Hard-filled capsules were opened and dropped into the sodium metabisulfite solution before autoclaving. This method is similar to the one published after our studies were initiated (3).

Results and Discussion

The assay results obtained with the three methods of sample preparations as applied to both soft-elastic and hard-filled capsules containing 2.2 or 5.5 mcg. vitamin B_{12} per capsule are shown in Tables I, II, and III. The tables include results with freshly made capsules as well as those stored at room temperature. Soft-elastic capsules which had been stored at room temperature for 18 or 24 months showed greater differences than freshly prepared capsules. This was probably due to the gradual conversion of cyanocobalamin to the hydroxo form by reducing substances present in the product. The hydroxo form is less stable to heat and may be destroyed during autoclaving before the capsules are dissolved. Full recoveries were obtained when the capsule fill was immediately in contact with the potassium cyanide or sodium metabisulfite.

Summary

It is apparent from results in the tables that total B_{12} potency can be measured in more products using the modification described than by the U.S.P. XVI method. It is suggested that all products be dissolved in the sodium metabisulfite solution prior to autoclaving.

INACTIVATION OF B_{12} BY REDUCING SUGARS

Results obtained by the U.S.P. microbiological assay for B_{12} have been compared with results using a Co^{60} radioactive trace method. Products containing reducing sugars gave lower values with the microbiological method than with the tracer method; this difference was great enough to interest us in investigating the cause for the lower values. Experiments were set up to determine the effect of various sugars on vitamin B_{12} and its protection by sodium metabisulfite and potassium cyanide in the U.S.P. assay procedure.

Experimental

Crystalline vitamin B_{12} was assayed according to the U.S.P. procedure in the presence of various reducing and nonreducing sugars. Intrinsic factor concentrate N.F. was treated in a similar manner.

Crystalline vitamin B_{12} plus lactose was prepared for assay according to the U.S.P. method, except that 100 mg. of potassium cyanide was added instead of the sodium metabisulfite. The KCN was added to the buffer solution used in preparing the sodium metabisulfite solution to keep the mixture at the proper pH value. Another modification was the elimination of the autoclaving step as a control for determining whether the sugars might have some toxic effect on the organism. Only reducing sugars were used in this modification.

Results and Discussion

The results recorded in Table IV show that the

[a] Samples made up without sodium metabisulfite and not autoclaved. [b] Per cent recoveries are based on theoretical values.

five reducing sugars affect the recovery of vitamin B_{12} to approximately the same amount. Full recovery of the B_{12} could be obtained in the presence of lactose when protected by potassium cyanide instead of sodium metabisulfite. Recoveries were complete in the presence of nonreducing sugars. It will also be noted that a sample of vitamin B_{12} protected by neither potassium cyanide nor sodium metabisulfite but autoclaved in the presence of water only gave a much higher value than the samples treated with reducing sugars and protected with sodium metabisulfite. This is further evidence that reducing sugars destroy vitamin B_{12} in the autoclaving step. The results indicating instability of vitamin B_{12} in the presence of reducing sugars confirm the report by Barr, Kohn, and Tice (4).

Table V shows the effect of increasing amounts of lactose in the assay of B_{12} and B_{12} with intrinsic factor concentrate. As indicated in the table, there is progressively more destruction of the vitamin with increasing amounts of lactose. This would probably be true with all reducing sugars. It appears that there may be some protection of the vitamin when B_{12} is combined with intrinsic factor concentrate, but the destruction is still progressive with increasing amounts of lactose.

Table VI shows the effect of reducing sugars when the samples are not subjected to the autoclaving step and not protected with sodium metabisulfite. This was a control to determine whether these sugars might have some affect on the growth of the test organism. As can be seen in the table, full recovery of the vitamin is obtained.

Some studies were made concerning the effect of dextrose in the medium during incubation of *Lactobacillus leichmanii* in the vitamin B_{12} assay. Since dextrose tends to reduce B_{12}, it should show its effect during the incubation period. In this experiment, which is shown in Fig. 1, a 15% greater growth was obtained with the sucrose medium. The authors' interpretation is that less vitamin is available to the test organism and therefore a depressed growth response is obtained. This may not affect assay precision since presumably all standard and test samples would be affected alike by the presence of dextrose in the medium.

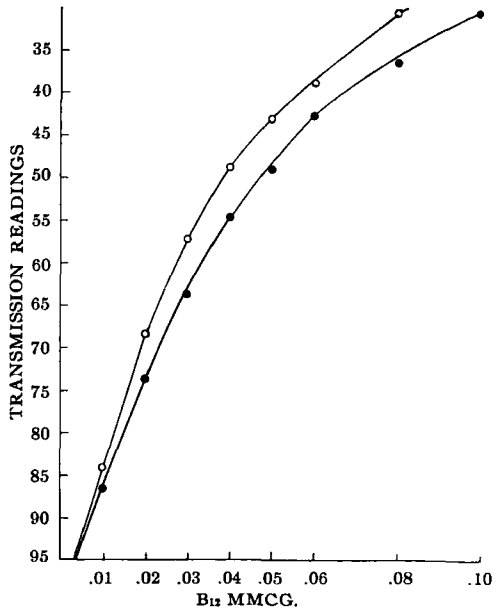

Fig. 1.—Effect of dextrose on vitamin B_{12} during incubation. ○, 40 Gm. sucrose per L. of medium; ●, 40 Gm. dextrose per L. of medium.

Summary

The U.S.P. XVI microbiological assay for vitamin B_{12} has been modified by replacing the sodium metabisulfite with potassium cyanide. This modification permits better recovery of vitamin B_{12} on products containing reducing sugars. The data indicate that potassium cyanide gives better protection in the presence of lactose during autoclaving than sodium metabisulfite.

Fluorometric Assay of Yohimbine

By H. C. CHIANG and W. F. CHEN

The fluorescence of solutions of yohimbine under ultraviolet light is increased by heating with hydrogen peroxide and is quantitatively related to its concentration. An assay procedure has been developed for pharmaceutical preparations containing yohimbine.

YOHIMBINE has been used medicinally as an aphrodisiac, but there is no convincing evidence for such an effect (1). However, in Formosa it is often illegally mixed in male hormone preparations. Consequently, there is an urgent need to find a suitable method for determining yohimbine in such preparations.

Previous analytical methods have been based on the color reactions of yohimbine with Reinecke salt (2), *p*-dimethylaminobenzaldehyde (3), vanillin (4), and xanthydrol (5). But the interference of hormones as well as vitamins make the above methods unsuitable for the determination of yohimbine in these combinations.

Yohimbine and other rauwolfia alkaloids have fluorescence under ultraviolet light, and this property has been used to determine their location on chromatograms (6–8).

We have found that the intensity of the fluorescence of yohimbine solutions heated with hydrogen peroxide is proportional to the concentration. This procedure has proved to be effective in determining yohimbine in preparations containing methyltestosterone, vitamin B_1, vitamin B_2, *dl*-methionine, and strychnine nitrate.

EXPERIMENTAL

Reagent.—Standard yohimbine solution containing 20 mcg. per ml. in 5 *N* acetic acid.

Apparatus.—Kotaki ultramicro fluorophotometer with 48 × 40 × 8 mm. cells.

Reaction.—It was found that a suitable fluorescence could be obtained by adding 1.0 ml. of 3% hydrogen peroxide to the solution and heating the tube in a boiling water bath for about 45 minutes. The fluorescence developed in this manner showed no change on standing 10 hours. Also the concentration of yohimbine to fluorometric reading follows a straight line relationship. The results of these experiments are summarized in Fig. 1.

Determination of Yohimbine in Hormone-Vitamin Preparations.—Transfer a portion of powder equivalent to 10 mg. of yohimbine-HCl to a 100-ml. volumetric flask. Add 2% tartaric acid solution to the mark, and shake the mixture occasionally during 2 hours; filter, if necessary, rejecting the first 20 ml. of filtrate. Pipet 20 ml. of filtrate into a separator. Then add ammonia T. S. to distinct alkalinity, and extract yohimbine with 20, 20, 10, 10, and 10-ml. quantities of ether. Wash the combined ether extracts with two 10-ml. portions of water. Extract the washings with 10 ml. of ether; add this ether to the combined ether extracts and evaporate the ether on a steam bath to dryness. Dissolve the residue in 100 ml. of 5 *N* acetic acid to make a solution of concentration of 20 mcg./ml.

Received October 3, 1962, from the Taiwan Provincial Hygienic Laboratory, No. 4, Tsing-Tao East Road, Taipei, Taiwan.

Accepted for publication December 28, 1962.

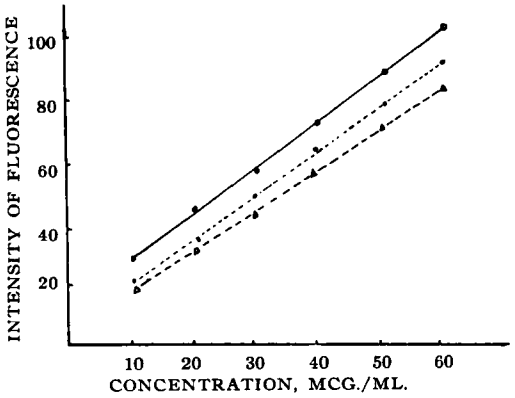

Fig. 1.—Relationship between heating time, concentration, and intensity of fluorescence. Key: O——O——O, 45–60 minutes of heating time; ● . . . . . ● . . . . . ●, 15 minutes of heating time; △ – – – △ – – – △, 5 minutes of heating time.

TABLE I.—SAMPLE PRESCRIPTIONS AND RESULTS OF EXPERIMENTS

Description	Capsule 1, mg.	Capsule 2, mg.	Capsule 3, mg.	Mixture 1, mg.
Methyltestosterone	10	10	10	10
Vitamin B_1	5	10	10	10
Vitamin B_2	2.5	...	...	2.5
dl-Methionine	35	...	...	30
Strychnine nitrate	...	1	...	1
Amino ethane sulfonic acid	...	...	30	30
Calcium glycerophosphate	...	...	200	200
Yohimbine-HCl	2	2	2	0
Av. recovery, %	100.1 ± 1.8	101.6 ± 1.4	99.4 ± 0.2	0

Accurately pipet 2.0 ml. of this solution and standard solution respectively into a 10-ml. volumetric flask. Add 1 ml. of 3% hydrogen peroxide to each, dilute to exact volume with 5 *N* acetic acid, and mix well. Heat in boiling water for 45 minutes. Then cool to room temperature and measure the fluorescence. The concentration of yohimbine hydrochloride in the sample solution is calculated

$$\frac{\text{Galvanometer reading of sample}}{\text{Galvanometer reading of standard}} \times \text{mcg. of yohimbine HCl in standard solution} = \text{mcg. of yohimbine HCl in sample solution.}$$

RESULTS AND DISCUSSION

The proposed method of assay is applied to the mixtures of known yohimbine content. Sample prescriptions and results of experiments are presented in Table I. The results have been shown to be free of interference from most of the vitamins and substances frequently associated with yohimbine.

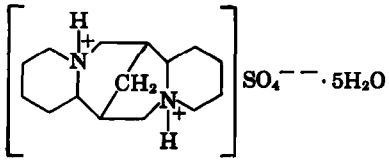
Quantitative Determination of Sparteine Sulfate

By PAUL TURI and DAN GROSSMAN

Official compendia fail to include assay methods for pharmaceutical preparations of sparteine sulfate. A direct acidimetric titration method for sparteine sulfate and an indirect titration of the sparteine base, obtained by distillation from a solution of sparteine sulfate, were investigated in a comparative study. The accuracy and applicability of both methods are evaluated.

SPARTEINE, an alkaloid of *Cytisus scoparius* L. (syn. *Sarothamnus scoparius*, Koch), *Lupinus luteus* L. and other plants of the *Leguminosae*, has been known as a medicinal agent for more than 70 years (1).



Sparteine had been formerly recommended in tachycardia, functional palpitation of the heart, and as a diuretic agent.

"The National Formulary," 8th ed., 1946, monograph (2) for sparteine sulfate (the last official U. S. compendium to list this drug) fails to include a method of assay. Recent interest in sparteine sulfate as an adjunct in induction of labor (3) prompted an evaluation of the known quantitative assay procedures.

In a survey of several suggested methods Higuchi and Bodin (4) list four methods for the determination of sparteine sulfate: (*a*) a colorimetric assay through the Reineckate salt, (*b*) an acid dye procedure (assaying colorimetrically a chloroform extract of the compound formed with acid methyl orange), (*c*) a polarographic method, and (*d*) a gravimetric determination through the silicotungstate salt.

The official method in the "Pharmacopoea Helvetica V" (5) for sparteine sulfate assay is a direct acidimetric titration. This procedure is based on the principle that mineral acid salts of very weak nitrogen bases in aqueous solution can be titrated directly with strong alkaline titrants to the phenolphthalein red end point, since the liberated weak base does not interfere with the indicator (6).

Our objective was to select a simple and rapid method with satisfactory accuracy. The direct titration method requires only a single step; therefore its advantages are obvious. To increase the specificity of the analysis, we adapted another titration technique which included a separation step. The principle of distillation of the alkaloid base and back titration of volatile alkaloids was utilized.

The scope of this study is a comparison between the two acidimetric titration methods: *method I*, sparteine sulfate is titrated directly with 0.1 *N* sodium hydroxide solution; and *method II*, sparteine sulfate salt is converted to the base, distilled with steam into a measured volume of acid, and the excess acid is back-titrated.

$$r = 0.6745 \sqrt{\frac{\Sigma d a^2}{n - 1}}$$ (n = number of assays)

TABLE III.—ASSAY RESULTS FOR PEROXIDE-TREATED SPARTEINE SULFATE SOLUTIONS

Sample No.	Sample Type	Method I, %	Method II, %
1	C	100.14	90.08
2	C	98.66	89.05

phenolphthalein T.S. was added, and the solution was titrated with 0.1 *N* NaOH to the appearance of the red color. 1 ml. 0.1 *N* NaOH = 42.253 mg. $C_{15}H_{26}N_2 \cdot H_2SO_4 \cdot 5H_2O$.

Method II: 5.0 ml. of the stock solution was transferred into a 300-ml. Kjeldahl flask. A few glass beads, 75 ml. water, and 2 ml. of 50% NaOH were added, and the flask was connected immediately to a condenser fitted with a delivery tube extending below the surface of 15.0 ml. 0.1 *N* HCl in a receiver. Two drops of methyl orange T.S. was added to the receiver as the indicator.[1] About 65 ml. of the distillate was collected in the receiver, followed by a residual titration of the excess acid with 0.1 *N* NaOH. Each ml. of 0.1 *N* HCl is equivalent to 21.1265 mg. $C_{15}H_{26}N_2 \cdot H_2SO_4 \cdot 5H_2O$.

Sample B.—An ampul solution of sparteine sulfate (containing 150 mg. of $C_{15}H_{26}N_2 \cdot H_2SO_4 \cdot 5H_2O$ and 4.5 mg. sodium chloride in 1.0 ml. of water) has been assayed by the two methods in a similar manner to that described above. Experimental results are summarized in Tables I and II.

Degradation Studies

To investigate the effects of degradation products on the two titration methods, the following experiment was performed.

Sample C.—4.0 Gm. sparteine sulfate was dissolved in about 80 ml. of distilled water. Seven milliliters of hydrogen peroxide T.S. and exactly 3.0 ml. of 0.1 *N* H_2SO_4 were added, and this colorless mixture was boiled for 1 hour. The solution was cooled to room temperature. A definite yellow coloration indicated presence of degradation products. Following the addition of exactly 3.0 ml. of 0.1 *N* NaOH, the solution was quantitatively transferred into a 100-ml. volumetric flask and brought up with water to volume (at 20°).[2] Five-milliliter aliquots of the peroxide-treated sparteine sulfate solution was assayed by both methods described above. Assay results are reported in Table III.

RESULTS AND DISCUSSION

The assay series performed on sparteine sulfate solutions (*Samples A* and *B*) facilitated an evaluation of the reproducibility and accuracy of the investigated methods.

As shown in Tables I and II, the averages of nine parallel determinations are very close; the difference of the average percentages is only 0.02%. The probable error is less than 1% for both methods, and only 0.5% for the direct titration procedure (*method I.*)

Solutions of sparteine sulfate exposed to high temperatures (100–160°) for a prolonged period showed insignificant degradation or no degradation. Earlier reported experiments (8) indicate a number of different oxidation products which could be formed by treating sparteine with a variety of oxidizing agents. Our results, reported in Table III, indicate that under the described experimental conditions degradation products develop which do not affect the direct titration method. By the distillation technique (*method II*), an anticipated decrease in alkaloid content appears.

CONCLUSIONS

Our experimental data led us to conclude that the method of choice for pure sparteine sulfate substance or for pharmaceutical preparations containing no interferring ingredients is the direct titration method. In the presence of interferring substances (incorporated in the pharmaceutical formula or developed by degradation), the distillation technique offers the advantage of separating the sparteine base from the nonvolatile ingredients and can be used for quantitative determinations with satisfactory accuracy.

[1] More recent work indicates that a sharper end point can be obtained by using four drops of bromocresol green-methyl orange mixed indicator (0.2% BCG + 0.02% MO) to the appearance of a light green color.

[2] A 5-ml. aliquot of this solution was acidified with 1 ml. of diluted sulfuric acid, and one drop of 0.1 *N* $KMnO_4$ solution added. A slight pink color indicated absence of hydrogen peroxide.

Modified Automated Apparatus for Determination of Dissolution Rates of Capsules and Tablets

By LOUIS C. SCHROETER and WILLIAM E. HAMLIN

Intermittent filtration and sampling of the dissolution fluid permits the routine use of short light path (1 mm.) spectrophotometer flow cells in the monitoring of the *in vitro* dissolution process of tablets and capsules by an automated method.

CONTINUOUS MONITORING of the dissolution process of a tablet or capsule may be accomplished most easily by cycling a sample of dissolution fluid through a spectrophotometer flow cell and recording the change in absorbance as a function of time (1). Spectrophotometer flow cells of minimum volume ($\leq$ 5 ml.) with light paths from 10–100 mm. may be used to extend the useful range of the continuous cycling method to those dosage forms which contain small amounts of drug(s) with low molar absorptivities. Determination of the dissolution characteristics of tablets containing large amounts of drug(s) with high molar absorptivities through the use of short light path ($\leq$ 5 mm.) flow cells has in the past involved many operational difficulties: particles of insoluble tablet additives tend to collect in the flow cells and continuous filtration of the sample stream results in rapid and progressive diminution of flow rate as filters become clogged with insoluble materials.

This brief report describes a modification of the continuous cycling procedure for automated dissolution rate studies (1) which greatly extends the utility of the method by employing a 1-mm. light-path flow cell. A three-way solenoid valve is used to shunt the circulating sample stream away from the filter, except during the time actual recording of the dissolution process is underway.

EXPERIMENTAL

Equipment.—The arrangement of components for modified continuous cycling with intermittent filtration and sampling is shown in Fig. 1. The U.S.P. disintegration apparatus and basket rack assembly (2) were used to provide reproducible agitation; disks were *not* used. Sampling lines were of shortest possible length and of minimum internal diameter consistent with sampling-line flow rates of 1 to 1.5 ml. per second. Typical lengths of connecting tubing and volumes of components shown in Fig. 1 were as follows: *A*, 70 cm.; *B*, 50 cm.; *C*, 20 cm.; *D*, 10 cm.; *E*, 30 cm.; *F*, 85 cm.; valve (sample port open), 1 ml.; filter, 4.6 ml.; 1 mm. flow cell,[1] 1.0 ml. Configuration of the glass filtering device and the solenoid valve is shown in Fig. 2. An electronic repeat cycle timer[2] was used to actuate the solenoid valve to divert the rapidly circulating sample fluid through the filtering device and flow cell every 1 or 2 minutes for a period of 15–20 seconds. A more detailed description of the automated dissolution rate apparatus and its design requirements has been reported (1).

Procedure.—Operationally, the dissolution rate determination of tablets or capsules by the intermittent filtration-sampling method is the same as that used with the previously reported continuous monitoring process (1). Recorder response was adjusted to read 100 units or 100% drug in solution when a filtered sample stream from the beaker containing drug from one tablet wholly dissolved (100% drug in solution) was pumped through the flow cell. The sampling system was flushed with fresh buffer and connected with a new beaker containing 750 ml. of fresh buffer maintained at 37°. One tablet was placed into the U.S.P. disintegration basket assembly (no disks), immersed into the buffer solution, and agitated at the prescribed rate of 30 cycles per minute. Introduction of the tablet into the buffer marked zero time for the process. The timer was adjusted to divert the sample stream through the filter and flow cell every minute for a period of 15 seconds.

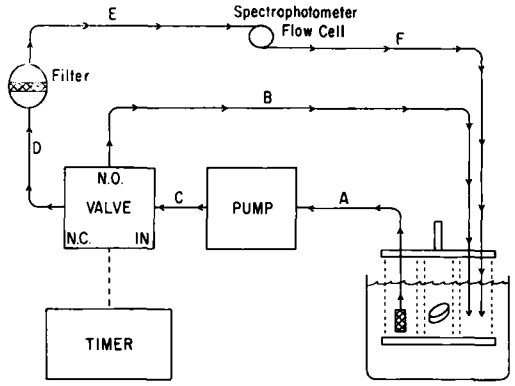

Fig. 1.—Arrangement of components for modified continuous cycling with intermittent filtration and sampling.

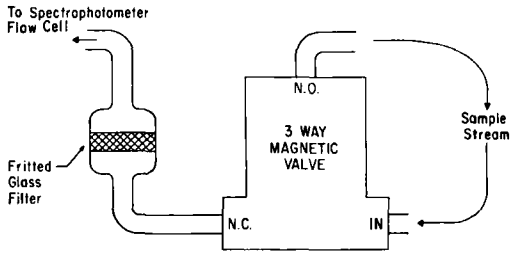

Fig. 2.—Configuration of filter and three-way solenoid valve for intermittent filtration and sampling. The abbreviations "N.O." and "N.C." designate the normally open and normally closed valve parts.

Received November 23, 1962, from the Pharmacy Research Section, Product Research and Development, The Upjohn Co., Kalamazoo, Mich.

Accepted for publication December 20, 1962.

The excellent technical assistance of N. K. Hine is gratefully acknowledged.

[1] Suprasil flow cell, No. L134FT, 1-mm. light path, Lux Scientific Instrument Corp., New York 13, N. Y.

[2] Repeat cycle timer, model 1, G. C. Wilson and Co., Huntington, W. Va.

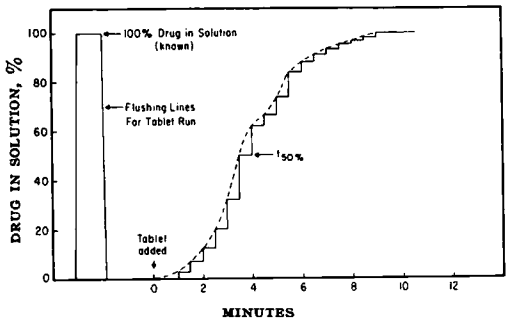

Fig. 3.—Idealized recorder curve obtained with modified continuous cycling method. Actual curves recorded at sufficiently fast chart speeds will show the vertical lines to be more nearly sigmoidal, due to the time lag involved in the establishment of optical density equilibrium. Dashed line indicates dissolution profile; vertical line indicates flow cell open; horizontal line indicates flow cell closed.

RESULTS AND DISCUSSION

Vertical lines shown in the idealized recorder tracing in Fig. 3 represent the rapid change in recorder response which occurs when the sample stream is diverted through the flow cell at 1-minute intervals. Shortly after establishment of equilibrium in the lines, the rapidly flowing sample stream is once again shunted away from the filter and flow cell. During this time no sample flows through the cell; hence a horizontal trace is made by the pen until the valve once again opens to divert the sample stream through the filter and flow cell. Intersection of the horizontal and vertical lines represents a concentration of drug in solution at that time; the dissolution profile of the dosage form is shown by a dashed line joining these intersections or concentration-time values.

Accuracy and reliability of the modified continuous cycling method has been determined by simultaneous independent assays of the dissolution fluid during the dissolution process of various tablets. The dissolution profile of a sulfonylurea tablet in pH 7.2 buffer at 37° was determined in a series of studies conducted on different days by different investigators using the modified method described above and by simultaneous independent spectrophotometric assays of the dissolution fluid. Figure 4 is typical of the excellent agreement which exists between the automated and manual methods.

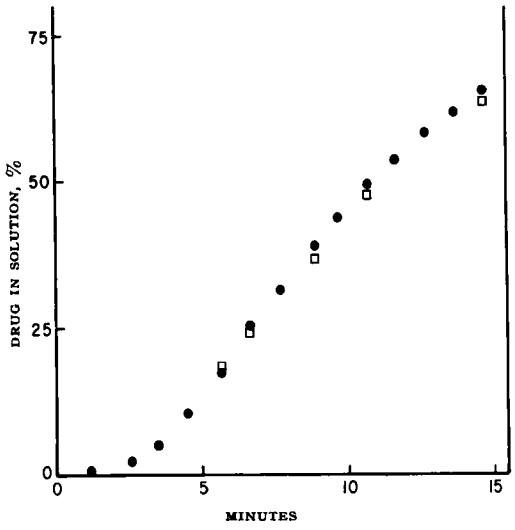

Fig. 4.—Dissolution profile of a sulfonylurea tablet obtained by the automated procedure and by simultaneous independent assay: ●, automated; □, independent assay.

Ferguson Principle and the Critical Micelle Concentration

By BERNARD ECANOW and FREDERICK P. SIEGEL

The thermodynamic activity values of a series of quaternary ammonium salts were calculated through the use of critical micelle concentrations. The correlation of these thermodynamic activities to the published values of their bactericidal activities is shown through application of the Ferguson principle. The value of the Ferguson principle in helping to point out the possible presence of different mechanisms of activity within a series of similar compounds has been suggested.

FERGUSON (1) has suggested that the toxicities of physically toxic substances should not be compared by the values of the toxic concentrations in the external solution but by the chemical potentials in this phase, which must be identical with the chemical potential at the site of activity. Ferguson used the activity function of G.N. Lewis as the chemical potential. From a review of published data, he showed that "though diverse chemical compounds exert the same toxic effect on a given organism at widely different concentrations, the activities corresponding to these concentrations lie within a relatively narrow range. The differences in activity within this range are ascribed to the effect of chemical constitution."

It has been shown (1, 2) that when the toxic agent is applied as a vapor, the activity is given with "useful" accuracy by the ratio of the partial pressure of the agent over that of the saturated vapor pressure of the substance at the temperature

The value of the Ferguson principle in helping to point out the possible presence of different mechanisms of activity within a series of similar compounds has been suggested.

FERGUSON (1) has suggested that the toxicities of physically toxic substances should not be compared by the values of the toxic concentrations in the external solution but by the chemical potentials in this phase, which must be identical with the chemical potential at the site of activity. Ferguson used the activity function of G.N. Lewis as the chemical potential. From a review of published data, he showed that "though diverse chemical compounds exert the same toxic effect on a given organism at widely different concentrations, the activities corresponding to these concentrations lie within a relatively narrow range. The differences in activity within this range are ascribed to the effect of chemical constitution."

It has been shown (1, 2) that when the toxic agent is applied as a vapor, the activity is given with "useful" accuracy by the ratio of the partial pressure of the agent over that of the saturated vapor pressure of the substance at the temperature

[a] Time required for 99.99% kill.

of the experiment. When the toxic agent is applied in solution and is a substance of limited solubility, the activity at the toxic concentration can be obtained (with sufficient accuracy for judicious use) by using the ratio of the toxic concentration of the substance over its solubility.

It is the purpose of this paper to show that the Ferguson principle can be extended to the relationship of bactericidal activity of quaternary ammonium salts and the critical micelle concentration (CMC) of the salts.

DISCUSSION

J. A. Cella, *et al.* (3), have reported that bactericidal activity generally appears to increase with decreased CMC within a series of quaternary ammonium salts that were tested. The data shown in Table I are from their work.

Previous investigators (1, 2, 4) have preceded with the selection of the pure substances as the standard free state and on the basis that solutions in equilibrium with excess solid have the same thermodynamic activity. An extension of this concept should apply to the equilibrium of solutions with micelles. The thermodynamic activity and, therefore, the biological activity should be equal to a constant per cent of the CMC of the active constituent.

The activities in Table I are calculated by obtaining the ratio of the test concentration divided by CMC. The variation between activity coefficients shown in Table I is very small (with one exception), showing a two- or three-fold difference as against the 200- to 300-fold variation in the extremes of CMC. As the Ferguson principle holds here, it tends to substantiate the view that the bactericidal activity is the result of some physical activity (presumably surface effects) rather than chemical activity.

In reviewing Table I without the columns of activity indices, one would have a difficult time discerning a striking difference in the activity of any compound. However, with the inclusion of the activities it becomes apparent that compound 8 has a unique value. Therefore, this would indicate that the compound may act through a different mechanism.

SUMMARY

The thermodynamic activity values of a series of quaternary ammonium salts were calculated through the use of CMC. The correlation of these thermodynamic activities to the published values of their bactericidal activities is shown through application of the Ferguson principle.

The value of the Ferguson principle in helping to point out the possible presence of different mechanisms of activity within a series of similar compounds has been suggested.

Pharmaceutical Investigation of Selected Alberta Bentonites III. Cation Exchange Determination

By ARTHUR J. ANDERSON† and ELMER M. PLEIN

Previously reported data established that anomolous behavior of Alberta bentonites could not be explained on the basis of official limit tests. Results of a cation exchange study of these clays are discussed.

To EVALUATE the acceptability of Alberta bentonites as pharmaceutical agents, a study of the various known deposits of the material was undertaken. Details regarding identification procedures and limit tests were reported earlier (1, 2).

Since the anomolous behavior of the clays could not be explained on the basis of the data obtained from the official limit tests, it was felt that a knowledge of the cation exchange capacities of the respective clays might provide a better basis for explaining the apparent lack of uniform quality found among the samples collected.

Clay minerals possess to a varying degree the ability to adsorb cations and to retain these in an exchangeable state (3–5). This ability is claimed to be the result of unbalanced lattices and is expressed in milliequivalents (meq.) of cation per 100 Gm. of clay. Increasing valency of the cation and decreasing hydration of the particle facilitates this exchange.

Various methods for determining the cation-exchange capacity of soils have been reported (5–12). The continued search for a satisfactory method served only to emphasize the difficulties inherent in such a determination. Even less accuracy has been found in the determination of the specific exchangeable cations (13).

EXPERIMENTAL

The procedure employed in this study was taken from the "Methods Book, Soils Survey Laboratories," University of Alberta (14), and was essentially a modified version of the ammonium acetate method of Schollenberger and Simon (12). In general, neutral ammonium acetate solution was used to displace the original adsorbed cations from the clays by a process of leaching. The leachates were retained for determination of the specific cations removed in the leaching process. The capacity of the clays to adsorb ammonium ions under controlled conditions was then determined by a Kjeldahl technique employing titration of 4% boric acid solution with standard sulfuric acid. Values obtained are presented in Table I.

In considering the ammonium acetate leachates obtained from the cation exchange procedure, it appeared that analytical procedures designed to yield quantitative values for sodium, potassium, calcium, and magnesium should be sufficient for the purposes of this study. The four cations mentioned were considered to exert the most significant effects on hydration properties of bentonites. Advantage was taken of the flame photometer analytical method for all four of the cations mentioned (Table II).

A Beckman spectrophotometer, model DU, with an acetylene and oxygen burner was employed in the determination of these exchanged cations. Sensitivity of the flame signal response was enhanced through use of a model 9200 photomultiplier unit. Interference effects were lessened by means of a flooding technique as employed by the Alberta Soils Survey Laboratories (14, 15).

RESULTS

Per cent transmittance of sodium, potassium, calcium, and magnesium was read at 589 mμ, 769 mμ, 422.5 mμ, and 285.2 mμ, respectively. The values for each ion were referred to a standard curve for that ion and translated into meq./L. This latter value was then converted into meq. per 100 Gm. of oven-dry clay through

$$\text{meq./100 Gm. oven-dry clay} = \frac{F(\text{meq./L.-blank})\ 25}{W}$$

where F = dilution factor for the leachate necessary to bring transmittance values within the range covered by the standard curve, and W = weight of oven-dry sample.

Ideally, the sum of the exchanged cations should equal the cation exchange capacity for each clay studied. However, due to a number of factors, such as errors inherent in the procedures employed plus the presence of soluble salts extracted during the leaching process, such an agreement is rarely obtained. In Table III such differences are attributed to the presence of soluble salts only.

On this basis, the clays from the Rosalind beds (Samples 1A, 3, 21, and 28) showed very little soluble salt content, with exchangeable potassium also very low. Sample 32, while also a product of

[a] All values are presented as meq. per 100 Gm. of oven-dry clay. [b] From Table I. [c] Control: Volclay B. C. grade, received from the American Colloid Co., Merchandise Mart Plaza, Chicago 54, Ill. [d] Within the limits of error for these determinations this value may be considered as zero.

the Rosalind beds (1), had been collected from the stack at the plant in an effort to procure an air-floated commercial product free of "grit." As shown in the table, significant changes in cation values were found when compared with the "regular" Rosalind clays. A notable increase in calcium ion was found in the leachate, while a reduced cation exchange capacity was observed. On the other hand, Sample 9 with a lower swelling power and much lower gelling power than Sample 32 (2) was shown to possess a higher cation exchange capacity than the latter clay (Table III). Similar observations could be made for other samples presented, indicating that the information shown, while of interest to the clay investigation generally, was not in itself sufficient to account for the observed behavior of the clay samples studied.

This conclusion is in agreement with the findings of Foster (16) who reported that the degree of swelling of sodium montmorillonites was not correlated with cation-exchange capacity or with charge on the tetrahedral layers.

Gas Chromatographic Data for Some Antihistamines

By ALEXANDER MACDONALD, JR., and RONALD T. PFLAUM

METHYL SILICONE POLYMER SE-30 (General Electric Co.) has been used effectively as the stationary phase in gas-liquid chromatography for the separation of alkaloids (3), sympathomimetic amines (2), barbiturates (1), and steroids (4). The separation applied to small samples uses a low liquid-to-solid packing ratio of the silicone polymer in a column operated at relatively low temperatures.

The gas-liquid chromatographic separation characteristics of 16 antihistamines have been determined using a 6-ft. column packed with 100–120-mesh Gas Chrom-P. A 1% loading factor of SE-30 was employed for the column operated at 173°.

EXPERIMENTAL

A Barber-Colman model 10 gas chromatograph equipped with an argon β-ray ionization detector and a 6-ft. packed glass column was used in this work. The column packing was prepared by the addition of a 1% benzene solution of SE-30 to a known amount of 100–120-mesh Gas Chrom-P contained in a round bottom flask. Benzene was removed under vacuum with a rotary evaporator The column was filled by the slow addition of dry packing with continuous vibration (5). The column was conditioned at a temperature of 200° for 24 hours. An argon flow of 20 ml. per minute was maintained throughout the conditioning period.

Samples of the antihistamines were prepared as 10% solutions of the free bases in chloroform. Chloroform solutions of 0.4 μl. were injected into the chromatograph with a Hamilton microliter syringe.

RESULTS

The retention times for the antihistamines studied in this investigation are presented in Table I. The data indicate that the column and operational parameters are suitable for the identification of most of the compounds listed.

The response curves obtained from the chromatograph showed sharp peaks with sharp leading edges. Tailing was a prevalent feature, becoming more pronounced with increasing retention time. Decomposition of some antihistamines was indicated by the occurrence of double peaks.

Work is in progress to overcome the tailing and decomposition problems. Other gas chromatographic procedures for antihistamines are also being investigated.

A "Go, No-Go" Assay Procedure for Residual Amounts of Acetone in Film-Coated Tablets

By WALTER W. HOLL, THEODORE P. MICHAELS, and L. PAUL SINOTTE

The iodoform reaction has been adapted as a quantitative method for the determination of residual amounts of acetone in film-coated tablets. The procedure makes use of a "Go, No-Go" principle in order to provide a rapid means of determining whether the acetone is within established limits.

TABLETS THAT are enteric coated with an acetone solution of cellulose acetate phthalate, even after considerable drying, retain residual amounts of the solvent. This residual acetone, if present in high enough concentration, results in an objectionable odor in the packaged product.

It was necessary to develop a method for the rapid determination of residual acetone and to set a limit at which no odor would be detectable. At first a colorimetric method involving formation of the 2,4-dinitrophenylhydrazone was used, and a limit of 300 mcg. per tablet established. The method, however, was time consuming (it took several hours) as it required extraction of the color from the reaction mixture before measurement (1).

For in-process control and feed-back information, a procedure that could be performed in the production area by a person with little or no technical training was desired. Instead of determining the exact quantity of residual acetone, this procedure would determine compliance with the specification limit and hence be called a "Go, No-Go" method.

The volumetric procedure that best fitted these requirements was patterned after the methods of Messinger (2) and Romijn (3). The method makes use of the familiar haloform reaction

$$CH_3-\overset{\overset{O}{\|}}{C}-CH_3 + 3I_2 + 4OH^- \rightarrow CHI_3 + CH_3COO^- + 3I^- + 3H_2O$$

Since 1 mole of acetone reacts with six equivalents of iodine, the method is suitable for measuring small amounts of acetone accurately. The determination is carried out as a back titration of excess iodine. The accuracy of this procedure has been previously reported by Goltz and Glew (4).

TABLE I.—TESTS ON STANDARD ACETONE SOLUTIONS

Solution	Acetone Equivalent, mcg./tablet	"Go, No-Go" Result
A	297	Go
B	298	Go
C	299	Go
D	300	Go
E	301	No-Go
F	302	No-Go

EXPERIMENTAL

Reagents.—Approximately 0.1 *N* sodium hydroxide solution; concentrated hydrochloric acid; starch indicator suspension U.S.P.; standardized 0.051 *N* iodine solution; standardized 0.040 *N* sodium thiosulfate solution were the reagents utilized.

The procedure and the normalities of the iodine and thiosulfate solutions are specific for a "Go, No-Go" limit of 300 mcg. of acetone per tablet, or 0.310 meq. in the sample taken (ten tablets). The exact normalities are not critical; however, the difference (0.310 meq.) must be maintained. For other "Go, No-Go" limit concentrations of acetone, the number of meq. must be calculated and this difference maintained between the normalities of the iodine and thiosulfate solutions.

Equipment.—Automatic Palo pipets[1] of 50 ml., 10 ml., and 5 ml. delivery and standard laboratory glassware were employed.

Procedure.—Place a sample of 10 tablets in a glass-stoppered 125-ml. flask. Using Palo pipets, add 50 ml. of approximately 0.1 *N* sodium hydroxide solution and 10 ml. of the standardized 0.051 *N* iodine solution. Shake this mixture occasionally for 10 minutes or until the tablets are completely disintegrated. Add 1 ml. of concentrated hydrochloric acid. Immediately add, by means of a Palo pipet, 5 ml. of the standardized 0.040 *N* sodium thiosulfate solution.

A dark brown mixture indicates the presence of unreacted iodine and that the residual acetone in the sample is well below the limit—the sample passes (Go). If the mixture is white or pale yellow (CHI_3), the sample is above or close to the limit. In this case, add 1 ml. of starch indicator suspension. If the mixture is now blue, unreacted iodine is present and the sample passes (Go). However, if the mixture remains white or pale yellow, there is no unreacted iodine present; the acetone concentration is above the limit and the sample fails (No-Go).

18	279	Go
11	283	Go
10	295	Go
4	308	No-Go
6	321	No-Go
16	324	No-Go
17	327	No-Go
14	332	No-Go
15	332	No-Go
9	443	No-Go
13	443	No-Go
8	775	No-Go

RESULTS AND DISCUSSION

The results in Table I obtained by the "Go, No-Go" test on several standard acetone-water solutions show the accuracy of the procedure to be better than ±0.5%.

Table II lists a number of tests on actual tablets and shows the correlation between the quantitative 2,4-dinitrophenylhydrazine assay and the "Go, No-Go" procedure.

These results show the test to be reliable and free from bias caused by the reaction of iodine with the tablet ingredients.

The method fulfills the original requirements which were: (*a*) it can be performed quickly (less than 15 minutes); (*b*) it can be performed by nontechnical personnel; (*c*) it can be done in the immediate production area.

This results in considerable time saving since samples do not have to be submitted to a control laboratory, and there is no waiting period for results. Also tests can be performed during drying operations and the tablets removed from the dryer as soon as they are below the limit. This frees the dryers for other work since it minimizes oven-drying time per lot.

This "Go, No-Go" concept, commonly used in other industries, appears to have many applications in pharmaceutical quality control when applied to the chemical checking for tolerance limits only.

SUMMARY

A general chemical procedure has been presented for rapidly determining whether a product is within a specified tolerance, *i.e.*, a "Go, No-Go" procedure. As an example the procedure is applied to the control of residual acetone in film-coated tablets. This principle could easily be extended to other product ingredients and a "Go, No-Go" test performed at both the maximum and the minimum tolerances.

Book Notices

Basic Facts of Pharmacology. By STEWART M. BROOKS. W. B. Saunder Co., Hampton Rd., P. O. Box 850, Camden, N. J. ix + 354 pp. 15 × 21 cm. Price $5.

Written by a pharmacist and instructor of pharmacology, a reasonably concise text for the use of clinical students is presented in this work. Stress is placed on vitamins, hormones, and electrolytes because of their vital value to all segments of therapeutic practice. After a few preliminary chapters of basic knowledge, a class by class discussion of clinical applications of drugs is presented.

Infrared Spectra of Inorganic and Coordination Compounds. By KAZUO NAKAMOTO. John Wiley & Sons, Inc., 400 Park Ave. South, New York 16, N. Y. xii + 328 pp. 15 × 23 cm. Price $9.50.

A discussion and explanation of the fundamental theory of molecular vibration and the method of normal coordinate analysis is presented along with a review of the literature on infrared spectra of inorganic compounds. Compounds are classified according to molecular structure and the observed fundamental frequencies are tabulated for each group.

Problems of Psychiatry and Neurology. Vol. III. Edited by I. F. SLUCHEVSKII. Pergammon Press, Inc., 122 East 55th St., New York 22, N. Y. viii + 376 pp. 15 × 23 cm. Price £ 5.

The transactions of the Leningrad Scientific Society of Neurologists and Psychiatrists are reported. Forty papers in the usual research style are included as well as four papers dealing with clinical observations. Among topics discussed are: problem of psychic disturbances in bronchial asthma; cerebral tumors developing with symptoms of vascular diseases; application of pharmacological loads for investigation of sugar curves in disorders of the central nervous system; and treatment of epilepsy.

SELECTION OF ADVISORS FOR FDA

Considerable support has come from various quarters to the recommendation embodied in the 1962 Citizens Advisory Committee report on the federal Food and Drug Administration which suggested that the agency should have the benefit of outside advisory committees. Such panels of experts would provide counsel to FDA on the highly complex scientific questions which arise from time to time in the course of administering its responsibilities as defined under pertinent sections of the Federal Food, Drug, and Cosmetic Act, its amendments and regulations.

We endorse and support this view and urge its early and wide implementation. However, we have noted with some concern that most, if not all, discussion and consideration of this recommendation have been solely in terms of completely medically-oriented advisory bodies which would consider medical questions and problems. Our concern is that—as in the case of the *Commission on Drug Safety* about which we commented in the August issue of THIS JOURNAL—the FDA may overlook the fact that many of the problems which it now faces and will be facing in the immediate future, have pharmaceutical ramifications of major significance.

Consequently, we feel that adequate recognition of this situation is also necessary on the part of FDA officials in order that knowledgeable pharmaceutical scientists might be appointed to the committees considering medical questions. Furthermore, it is our opinion that separate committees, composed *primarily* of scientists from various appropriate disciplines, should be established to study and advise specifically on those medically-related problems about which such panels would most properly be concerned. *The fact must be recognized that many of the present complex questions concerning the safety, efficacy, and quality of drugs are basically concerned with the pharmaceutical sciences, and are only indirectly or incidentally of a medical nature.*

Review Article

Synergism

With Special Reference to Central Nervous System Depressants

By G. VICTOR ROSSI

EXAMINATION OF THE *Papyrus Ebers* translation (126) suggests that therapists have long been intrigued by the interaction of drugs in combination. Traditionally, drugs have been prescribed in mixtures in attempts to surpass the effects of the separate components. Formulation of mixtures of active agents remained almost exclusively on an empirical basis for centuries. Indeed, the rational use of drug combinations remains a challenge to the present day medical practitioner (192).

Green (93) has aptly stated that "drug action must ultimately be explicable on a molecular basis, but owing to the complexity of living processes it is rarely possible to attribute a pharmacologic action, even qualitatively, to any precise chemical or biochemical reaction." Analyses of specific parameters are further complicated by superimposition of the action of one drug upon that of another. Nevertheless, advances are being made toward elucidation of the physicochemical bases of drug action and the fundamental mechanisms of drug interaction.

A seemingly infinite number of research publications embody, in title or text, the terms *synergism* or *potentiation*. On the assumption that certain general principles and problems relating to these phenomena might be illustrated by consideration of a selected group of pharmacologic agents, this review has been restricted primarily to central nervous system depressants. To facilitate presentation, these have been arbitrarily subdivided into three categories: analgesics, anesthetics, and hypnotics.

Nomenclature.—The ambiguity of nomenclature relative to the phenomena of drug interaction is clearly evident upon perusal of the introductory chapters of modern textbooks of pharmacology. Semantic confusion has impeded progress in various disciplines. The International Committee for the Nomenclature of Blood Clotting Factors was established with the primary objective of clarifying the chaotic terminology in this field (41). Although the problems are not comparable in scope, a need to define precisely and establish a common meaning for terms applicable to the mutual modification of drugs in combination exists.

In his classical analysis of the subject, Veldstra (207) stated that the term potentiation means "to endow with power." It was further noted that the individual components of drug combinations possess an intrinsic "power" (*i.e.*, specific activity). Therefore, in synergic combinations, "power" is not conferred, but the effectiveness of the "power" originally present may be enhanced. Inasmuch as there is no evidence of potentiation, according to the proposed definition, Veldstra recommended that use of the term in this connection be discontinued. A plethora of scientific articles published subsequent to this indictment attests to the undiminished popularity of the de-

Received from the Department of Pharmacology, Philadelphia College of Pharmacy and Science, Philadelphia 4, Pa.

scriptive term "potentiation." In defense of this choice it may be noted that a more liberal definition is provided by another authority: potentiate—"to make potent or more effective" (210).

It is this reviewer's impression that the term "potentiation," as employed in the majority of cases, is intended to connote "that situation wherein one agent shows no appreciable effect on the biological system but exaggerates the response of the system to another substance" (213). However, the enhancement of response effected by a combination of an active and an inactive compound has also been designated as "sensitization" (169). Other investigators (78) have noted that a potentiator may exert its effect by impeding the metabolic transformation of the active drug or by sensitizing the organism to the drug. These authors have recommended that a compound of the first type be classified as a prolonging agent; the second, as a true potentiator.

The heuristic merit of the word "potentiation" is perhaps as acceptable as any other. Because of the diversity of current interpretations, however, the term will be meaningless unless the individual author clearly delineates the concepts implied by its use.

In this review the general term "synergism" will be used in reference to all situations wherein facilitation of a pharmacologic response is obtained by the combined action of two or more compounds. Although some authors have defined synergism in a more restricted sense, the term (Gk. *synergos*) literally means "working together" (210), cooperation. For clarity of expression, the concept of synergism as translated into molecular terms by Veldstra (207) warrants repetition: "the combination effects a certain response with a smaller number of molecules than that required for the most active compound separately, or in the range of suboptimal concentrations, the effect of a certain number of molecules of this compound is enhanced in the mixture."

ANALGESICS

The ideal of a potent nontoxic and nonaddictive analgesic awaits realization. New molecules have not evidenced satisfactory dissociation of the seemingly obligatory relationship between analgesia and toxicity (159). Thus, other means of compensating for the deficiencies inherent in currently available compounds have been explored.

Narcotic Antagonists.—One approach to the optimal utilization of analgesics has been directed toward the concomitant administration of a narcotic and a narcotic antagonist. In one sense, narcotic antagonists may be considered as "selective synergists." Nalorphine and levallorphan inhibit many (but not all) of the pharmacodynamic effects of morphine and other narcotic analgesics (150). Their remarkable antidotal effect on narcotic-induced respiratory depression suggested the possible clinical utility of narcotic: antagonist mixtures in the alleviation of severe pain. Despite early favorable reports, the use of morphine: nalorphine combinations has not gained wide acceptance. In controlled studies involving postoperative patients and healthy volunteers, a combination of 2 mg. of nalorphine and 10 mg. of morphine was found to produce analgesia and side-effects indistinguishable from those achieved by 10 mg. of morphine (10, 124). Houde and Wallenstein (99) observed that the incidence of side-effects increased in direct proportion to the relative concentration of nalorphine in morphine : nalorphine mixtures administered to hospitalized cancer patients. Analgesic: levallorphan combinations have been viewed with somewhat greater favor. Cullen and Santos (50) used a premixed solution of levorphan tartrate and levallorphan tartrate in an 8:1 or 10:1 ratio for the relief of chronic severe pain. The analgesic effectiveness of the combination was considered essentially equivalent to levorphan, whereas the respiratory depression was significantly less than that produced by the narcotic alone. Foldes, *et al.* (75), reported that levallorphan effectively blocked the respiratory depressant action of alphaprodine when these compounds were injected simultaneously for the purpose of obstetrical analgesia. Comparable results were obtained with oxymorphone: levallorphan mixtures (76).

The numerous clinical studies involving combinations of narcotics and narcotic antagonists have been critically reviewed by Eckenhoff and Oech (66). These authors hold that narcotic depression of respiration may be minimized by prior or simultaneous administration of a specific antagonist in the alleviation of acute painful conditions. In their opinion, however, such mixtures are not applicable to the treatment of chronic pain. This limited therapeutic efficacy of narcotic: antagonist combinations is not conceded by Telford and Keats (201).

Synergists.—Another approach to the goal of improving the efficacy of existing analgesic drugs has involved their use in combination with a variety of essentially unrelated compounds found, largely by "trial and error," to augment

analgesic activity. Both adrenergic (89, 102) and cholinergic (111, 112, 178) drugs have been reported to enhance the effectiveness of morphine. Veldstra (207) has documented the extensive literature relating to enhancement of the analgesic activity of narcotics by such diverse agents as suramin, sparteine, antispasmodic agents, and several methonium compounds. Recent studies have demonstrated that the activity of narcotic analgesics in experimental animals may also be augmented by captodiamine (113), carbetidine (143), chlortetracycline (145), mephenesin (170), mephenoxalone (92), methylquizolone (14), pentolinium (94), phenetamine (131), quinine (157), reserpine (51), tryptamine, 5-hydroxytryptamine, amphetamine and mescaline (187), and SU-8629 (2-amino-indane HCl) (216). Data supporting the clinical efficacy of these combinations is lacking, however.

SKF 525-A.—With the exception of a hypocholesterolemic effect demonstrated in several animal species (56), SKF 525-A (β-diethylaminoethyl-diphenylpropylacetate HCl) possesses minimal direct pharmacologic activity (23). Primary interest in this compound has centered on its intriguing ability to act synergistically with drugs of diverse chemical structure and pharmacodynamic properties. Among the different types of drugs whose characteristic activities have been shown to be augmented by SKF 525-A are included: barbiturates and nonbarbiturate hypnotics (44), analgesics (45), antiepileptic drugs (195), spinal cord depressants and central nervous system stimulants (136), skeletal muscle relaxants (153), antihypertensive agents (90), and certain antibacterial and antiprotozoal drugs (202).

The key to the practicality of synergistic drug combinations is selectivity. Nonselective enhancement of the entire pharmacodynamic spectrum of a given drug provides a doubtful therapeutic advantage. Optimally, an augmentation of the therapeutically useful properties of the active component, accompanied by suppression of undesirable effects, is achieved. Exploration of the mechanisms of selective synergy remains to be exploited as a possible avenue to the objective of improved pharmacotherapy.

Cook, *et al.* (45, 46), showed that SKF 525-A enhanced the analgesic effect of various narcotics in rats without influencing either the LD_{50} (of morphine or meperidine) or the respiratory suppressant action (of morphine) in the same animals. This clearly demonstrated that different facets of the narcotic spectrum could be influenced selectively. Although the synergistic agent in this case (SKF 525-A) has proven an extremely useful tool in the investigation of pathways of drug metabolism, it remains restricted to experimental use.

It may be of interest that chronic administration of SKF 525-A is associated with hepatotoxicity in rats (204) and dogs (56). Holmes and Bentz (96) have postulated that interference with an important electron transfer coenzyme (coenzyme Q) may account for SKF 525-A-induced accumulation of lipid material in the livers of animals.

Phenothiazines (Animal Studies).—In the initial report on the subject Courvoisier and her associates (49) noted that chlorpromazine, although devoid of intrinsic analgesic activity, increased the intensity and prolonged the duration of action of morphine in mice. Subsequently, several investigators, using a variety of analgesimetric techniques, obtained comparable results in experimental animals with chlorpromazine and other phenothiazine derivatives (51, 55, 81, 152, 154, 162, 180, 205). The statement that the phenothiazines are not effective pain-relieving drugs, but that they potentiate the activity of specific analgesics, reflects the current consensus. Both of these views represent oversimplifications based largely on the original studies with promethazine and chlorpromazine.

Carter and David (38) reported that preinjection of chlorpromazine, thioperazine, and prochlorperazine effectively augmented the analgesic activity of morphine, meperidine, phenazocine, and raceoramide (SKF 5137) in rats. Of these three phenothiazine derivatives, chlorpromazine and thioperazine were found to diminish the degree of tolerance, but not necessarily the rate at which tolerance developed, when the narcotics were administered once daily during a 9-week period. Comparable enhancement by chlorpromazine of the analgesic activity of morphine in rats was observed by Mazurkiewicz and Lu (140). However, these investigators noted that chlorpromazine did not retard the development of tolerance in rats given a single daily injection of the narcotic during a period of 7 weeks.

Weiss and Rossi (212) reported that preinjection of a trifluorinated phenothiazine derivative (NDR-3680) enhanced the analgesic activity of codeine, dihydrocodeine, and morphine (d'-Amour-Smith analgesimetric method), and inhibited the constipating and respiratory depressant effect of codeine and morphine, but not dihydrocodeine, in rats. These investigators also found that phenothiazine pretreatment increased the extent and duration of protection provided by codeine, dihydrocodeine, and morphine against phenylquinone-induced writhing, reduced the

acute toxicity of codeine and dihydrocodeine, but increased the toxicity of morphine in mice.

Although there have been many differences in magnitude and a few differences in direction of the response, investigations performed with experimental animals have provided more consistent evidence of a synergistic relationship between the phenothiazines and the analgesic activity of narcotics than those studies performed in man.

Phenothiazines (Human Studies).—Numerous publications have appeared which describe the effects of phenothiazines, alone and in conjunction with barbiturates or analgesics, in surgical and obstetrical situations (82, 114, 137, 188, 191, 211), and in chronic pain of diverse origin (132, 174, 208). The lack of uniformity of rating systems, the paucity of control series, and the failure to provide statistical validation of the significance of the difference between treatments, mitigates against acceptance of facile claims of phenothiazine "potentiation" characteristic of many reports in this category. This reviewer is cognizant of the inordinate difficulties encountered in the evaluation of drugs intended for the amelioration of subjective phenomena in humans. However, these difficulties cannot always be accepted as an adequate excuse for poor experimental design. Controlled studies often reveal astonishing gaps between clinical impressions, theoretical assumptions, and established facts. Beecher (9), Wolf (217), and Modell and Houde (147) hold that there are no compelling reasons why quantitative methods cannot be utilized in the evaluation of subjective responses in humans.

Boulton (16) reported that the administration of chlorpromazine (25 mg. orally), prior to and following anesthesia, reduced the postoperative requirements of meperidine by 23% in females and by 6 to 7% in males who had undergone thoracic surgery. Dyrberg and Johansen (64) found no difference in the postoperative requirements for analgesic drugs among patients premedicated with 10 mg. of morphine or 50 mg. of chlorpromazine. Addition of 5 mg. of perphenazine to the standard premedication was found by Phillips, *et al.* (161), to reduce the incidence of requirements of analgesic drugs in the postoperative period by approximately 50%. Comparable results were obtained by Lear, *et al.* (128), with triflupromazine. The variables involved in such clinical situations make it extremely difficult to dissociate the effects of phenothiazines *per se* on anxiety reactions, and the possible enhancement of the analgesic activity of narcotics as distinct from prolongation of the action of general anesthetics.

Sadove, *et al.* (174), reported that narcotics and sedatives, which had previously proven ineffective in 22 of 28 patients with malignant lesions, provided satisfactory relief of pain when given in conjunction with chlorpromazine. Wallis (208) concluded that chlorpromazine effectively augmented the action of narcotics in the majority of patients suffering chronic pain of diverse origin. Light, *et al.* (132), noted that promethazine enhanced and prolonged the effectiveness of meperidine and morphine in two patients suffering the pain of inoperable malignancy. In a controlled crossover study, Houde and Wallenstein (98) found that single doses of 25 mg. of chlorpromazine alone exhibited no significant analgesic effect in 34 hospitalized patients with chronic severe pain. Furthermore, the relief obtained with a combination of morphine sulfate (10 mg.) and chlorpromazine (25 mg.) was essentially the same as that provided by the narcotic alone in these patients.

Respiratory and Circulatory Effects.—In a discussion of combination therapy, Sollmann (189) stated that "synergism is utilized to secure the summation of the desirable effects of several drugs, while the side actions are not increased in proportion, or may even be neutralized." Several experimental animal studies noted in this review have demonstrated that the simultaneous use of two drugs may result in a selective reinforcement of certain pharmacodynamic properties with a resultant increase in the therapeutic index. However, few clinical data substantiate that such a fortuitous situation applies to the combined use of phenothiazines and narcotics in humans.

Divergent clinical reports indicate that phenothiazines suppress (127, 166), intensify (122), or do not significantly alter (68, 80, 108) the effects of narcotics on respiration. Obviously, the influence of phenothiazine derivatives on narcotic-induced respiratory depression in humans remains equivocal. Data provided in support of phenothiazine antagonism of the respiratory effects of narcotics are not particularly convincing, however.

The alterations of circulatory homeostasis by phenothiazine derivatives and by narcotic analgesics, separately, is well documented. Reduction of systemic arterial pressure by the phenothiazines is apparently due to a combination of factors, including depression of the vasomotor regulatory centers (198), adrenergic blockade (88), and direct relaxation of arterial smooth muscle (73). The hypotensive activity of narcotic analgesics may also be attributed to multiple mechanisms, which include inhibition of the vasomotor centers (70), and peripheral vasodilation

due to a direct effect on the blood vessels (179), or mediated *via* histamine liberation (72). Variations are considerable among the different members of each series; however, the phenothiazines generally manifest greater vasodepressor potency than the narcotics. The theoretical assumption was made by Burgi (207) that "in combining drugs with the same end effect, the resulting activity is additive when the sites of action of the components are identical and superadditive if they are different." Although this generalization is not universally applicable, the complex of mechanisms associated with the hypotensive effect of the phenothiazines and the narcotics would appear to provide an ample basis for synergistic activity. Data supporting this contention are lacking; however, Eckenhoff and Oech (66) consider that the combination of a narcotic with a phenothiazine derivative theoretically imposes a greater threat to the circulation than it does to the respiration.

Qualitative Differences.—The "drug explosion" (146) has added impetus to a pre-existing tendency to group structurally and/or pharmacodynamically related chemicals into a common category. The phenothiazines represent a case in point. Exaggerated emphasis has been placed on the phenothiazine nucleus as a determinant of biodynamic activity; the majority of published reports foster the impression that the various substitutions largely influence the properties of the molecule in a quantitative rather than a qualitative sense. Increasing sophistication has resulted in dissatisfaction with such generalizations.

The property of synergy has become identified indiscriminately with the phenothiazines as a group, although this association does not hold necessarily for all members of the series. Possible explanations for selectivity in regard to the enhancement of analgesic activity may be discerned in those studies which have demonstrated that the phenothiazines cannot be considered as a homogenous group with respect to their effect on pain.

Analgesic versus Antianalgesic Activity.—Hougs and Skouby (100), using the Hardy, Wolff, and Goodell radiant heat analgesimetric method, noted that chlorinated phenothiazine derivatives exerted a mild analgesic action which was not demonstrable with the nonchlorinated compounds. Boreus and Sandberg (15), who also employed a thermal technique for inducing pain in healthy human volunteers, concluded that although chlorpromazine and acetylpromazine reduced somewhat the sensitivity to noxious stimulation, neither significantly increased the analgesic action of methadone. Mepazine, which evidenced no analgesic action when administered alone, antagonized the pain-relieving effect of methadone.

Methotrimeprazine was found to be equivalent (on a milligram basis) to morphine in providing relief of pain in postoperative and postpartum patients (125). Promazine, chlorpromazine, and trimeprazine evidenced modest effectiveness against experimentally induced pain in humans, whereas other phenothiazine derivatives manifested "slight" (prochlorperazine, perphenazine, trifluoperazine, triflupromazine) or "marked" (promethazine, mepazine) antianalgesic activity (149). Methdilazine, despite a marked sedative propensity, significantly increased the amount of meperidine required for the control of postoperative pain (200). Thus, contrasted to other investigators (133) who reported an augmentation of the activity of morphine and meperidine by methdilazine (radiant heat analgesimetric method in rats), Taylor, *et al.* (200), concluded that this phenothiazine derivative manifested a definite analgesic antagonism. It is possible that these apparently divergent conclusions are both valid, but that one is encountering the classical question of the relationship between the perceptual and psychic components of the pain phenomenon in man and the reflex reaction patterns to noxious stimuli in laboratory animals (109).

This dichotomous effect on patient sensitivity to pain may be reflected in the degree to which the action of the central nervous system depressants can be influenced by premedication with different phenothiazine derivatives. Dundee and Moore (62) found that, with the exception of those derivatives which evidenced a marked antianalgesic action, the phenothiazines under consideration significantly reduced the total dosage of barbiturate (methohexitone) required during the performance of a standard surgical procedure. The increased need for supplementary doses of barbiturate following premedication with promethazine and mepazine suggested the possibility of an antagonism between the antianalgesic phenothiazines and the anesthetic state.

Other evidence suggests that categorization of the various phenothiazine derivatives on the basis of an "analgesic" or "antianalgesic" effect may be artefactual. Clinical studies have indicated that barbiturates may have a diphasic effect on sensitivity to pain in man (4). Relatively high concentrations induce an anesthetic state *per se* or augment the analgesic or anesthetic activity of other agents. In contrast, a reduced threshold to pain may be experienced in the

presence of low levels of barbiturate in the central nervous system. A comparable diphasic action in regard to analgesia may be characteristic of other central depressants, *viz.*, phenothiazines (63). It is within the realm of possibility that, depending on dosage and/or time parameters, a particular phenothiazine might manifest either a synergistic or an antianalgesic effect.

ANESTHETICS

Using mice as the test subjects, Carson and Domino (37) found that relatively large doses of chlorpromazine (15 mg./Kg., intraperitoneally) significantly reduced the mean time required for loss of the righting reflex during exposure to ethyl ether, chloroform, or halothane. However, an equal dose of promethazine did not alter the time required for onset of anesthesia with these volatile agents. Brunaud, *et al.* (28), showed that propiomazine was considerably more effective than promethazine in its ability to prolong ether anesthesia in mice. Perhaps because of the technical difficulties associated with the quantitative administration of volatile anesthetics to small animals, most of the experimental animal studies in this field relate to effects obtained with fixed anesthetics (*i.e.*, barbiturates). Although the division is arbitrary, these reports will be considered in the section on *Hypnotics*.

Awareness of the potential application of phenothiazines in surgical anesthesia stemmed largely from the publications of Laborit and his coworkers (115, 116, 118–120), particularly in regard to promethazine and chlorpromazine. The role of this group in the development of the concept of "potentiated anesthesia" has been detailed by Laborit (117).

The versatility of phenothiazines in surgery is characterized by the reports of Sadove (173) and Dobkin (58), who describe the use of promethazine as a sedative preoperatively, as a supplement to anesthetics in producing the lighter planes of anesthesia and the hypothermic state, and as a means of combating emesis and hiccups. Taylor, *et al.* (199), observed that premedication with chlorpromazine alone permitted surgical anesthesia to be obtained with significantly lower concentrations of ethyl ether than with atropine alone. Carroll and Moir (35), and Adelman, *et al.* (1), reported that premedication with promethazine facilitated the induction and maintenance of general anesthesia and appeared to reduce the requirements of anesthetic agents in surgical and obstetrical cases. Stone (193) found that trifluprom azine facilitated the action of general anesthetics in doses which did not usually depress circulation. Thiopental anesthesia in man has been found to be augmented by a variety of central nervous system depressants, including antiemetics, antihistamines, and phenothiazine and nonphenothiazine ataraxics (60).

HYPNOTICS

Drowsiness associated with the clinical use of many antihistaminic drugs has been observed repeatedly. In experimental animals, however, it is ordinarily not possible to demonstrate sedation by the antihistamines when administered alone. In 1948, Winter (214), proceeding on the assumption that a simultaneous central excitatory action might mask a covert sedative effect, found that where antihistamines *per se* did not grossly manifest central depressant activity, they significantly prolonged the hypnotic action of hexobarbital in mice and guinea pigs. Although the basic technique had been previously employed by other investigators (34), Winter's report (214) catalyzed a surge of interest, which continues unabated in the potentialities of this tool.

Determination of the ability of a compound to prolong the duration of the loss of the righting reflex induced by a hypnotic dose of a barbiturate (generally hexobarbital) in laboratory animals (generally mice) remains a procedure widely used on the assumption that it provides a means of detecting subtle components of central nervous system depressant activity. The most frequently employed modification of this procedure is based on determination of the ability of a compound to convert a subhypnotic dose of a barbiturate to one which will induce a loss of the righting reflex (168, 206, 218).

There are few substances whose activity, based on either one or both of these criteria, has escaped examination.[1] Early studies relating to prolongation of barbiturate hypnosis, with particular reference to the antihistamines, disulfiram, carbohydrate metabolites, SKF 525-A, and alpha-tocopherol phosphate, have been previously reviewed (207). Within the past several years a representative grouping of compounds of diverse structure which have been reported to enhance the action of barbiturates and other hypnotics, includes: chlorpromazine, promazine, and their metabolites or "model" metabolites, monomethylchlorpromazine, chlorpromazine-N-oxide, 2-hydroxypromazine and 4-hydroxypromazine (163), other phenothiazine derivatives

[1] Only selected reports concerning hypnotic drug synergism are cited in this review. A separate bibliography relative to the subject and containing in excess of 100 references is available on request.

(28, 133, 196), reserpine and other rauwolfia alkaloids (27), urethan (83), chloral hydrate (71), diphenylhydantoin and other anticonvulsant drugs (74), captodiamine (113), amphenidone, hydroxyzine and meprobamate (167), phenaglycodol and metaglycodol (209), emylcamate (141), metaxolone, carisoprodol, and benactyzine (36, 97), various thiaxanthene derivatives, including chlorprothixene (148), meperidine (139), morphine and other analgesics (54), and many other compounds evidencing overt central nervous system depressant activity. To this list of drugs, which would be expected to add to the depressant effect of barbiturates or other hypnotics, may be appended a heterogeneous group of compounds, all of which have been reported to augment sleeping time: N-acetyl-*p*-aminophenol (19), aminopyrine and phenylbutazone (67), octamethylpyrophosphoramide and other anticholinesterase agents (72), quinine (157), atropine and scopolamine (142), colchicine (8), chlortetracycline (145) and chloramphenicol (57), thyroxin (43), epinephrine, norepinephrine, ephedrine, and other adrenergic amines (144), nikethamide (168), and the antidepressant compounds, imipramine and amitriptyline (95), iproniazid and other amine oxidase inhibitors (69, 123).

Methods.—Assays based on (*A*) prolongation of sleeping time, and (*B*) conversion of a subthreshold dose of a hypnotic to one which will result in loss of the righting reflex, have previously been cited as those most commonly employed (with kaleidoscopic nuances) in studies of hypnotic drug synergism. Another perspective may be gained by a third procedure based on (*C*) reinduction of hypnosis after spontaneous arousal from anesthesia. The latter technique is used less frequently; therefore, relatively little data are available on which to base comparisons among the three methods.

The heterogeneity of molecules which have been found to extend the duration of barbiturate-induced sleep underscores the grossly nonspecific nature of this assay. Although it is of limited utility in attempts to discern qualitative differences, it is of value when used conjointly in the establishment of pharmacodynamic profiles, and it may be considered a versatile investigative tool. One ponders, nevertheless—to what extent has the magnificent simplicity of this "data machine" (major components: mouse, stopwatch) contributed to its ascendancy?

Interest in the ability of a compound to prolong the sleeping time induced by a hypnotic dose of a barbiturate (method *A*) resided initially on the supposition that the assay provided a rapid means of detecting elusive central depressant activity, *e.g.*, in the evaluation of potential sedative or ataractic drugs. In a large number of cases the mechanism involves primarily (*a*) a summation of the central depressant effects of the drugs in question. It is apparent, however, that other factors, acting independently or conjointly, may also be responsible for the effect observed; these include: (*b*) increased rate of penetration into the central nervous system, (*c*) decreased binding to plasma or tissue components, *i.e.*, loss at "silent receptors," (*d*) reduced rate of biotransformation or (*e*) excretion, (*f*) contribution of the postictal depressant component of central stimulants, (*g*) "sensitization" to central depressant drugs as a consequence of alterations in acid-base balance or brain electrolyte patterns, etc. In the absence of other types of supporting data, it is obviously difficult to discern which of these factors (or conceivably other mechanisms not cited) are operative.

Some investigators (11) have used induction time of barbiturate hypnosis (*i.e.*, interval between injection and loss of righting reflex) as the criterion for alteration in the permeability of the "blood brain barrier." While this parameter may serve as a tentative indication of permeability changes, Child, *et al.* (39, 40), have shown that a decrease in induction time does not necessarily imply an increase in the rate of penetration of barbiturates into the brain.

Methods *B* and *C* are fundamentally related in that they both involve the ability of a compound to induce a loss of the righting reflex in the presence of a subhypnotic concentration of a barbiturate (or other hypnotic) in the blood. Method *C* constitutes the most rigorous challenge inasmuch as the second agent is not administered until after the brain concentration of barbiturate has receded below the anesthetic threshold, as evidenced by spontaneous arousal. Enhancement of barbiturate activity in all three situations depends not only on the inherent properties of the synergist but also on the dose administered, route of administration, and latency of action. These latter considerations are more critical in method *B* than in method *A*, and are most critical in method *C*, particularly in the presence of a hypnotic having a short biological half-life (*e.g.*, hexobarbital). Dismissal of these factors from consideration could conceivably lead to the adoption of erroneous conclusions regarding probable mechanisms of synergy.

The isobolometric studies of Loewe (134) provided discrete evidence of the dissociability of intensity of effect and duration of effect regarding barbiturate synergism. He found that the

HD_{50} (median hypnotic dose) of pentobarbital was essentially unchanged by any dose of strychnine, whereas the HD_{50} of butallylonal was diminished by approximately 50% by a wide range of strychnine doses in mice. Irrespective of the alteration of hypnotic threshold, strychnine prolonged the duration of sleeping time with both barbiturates.

Shagass (184) developed the concept of sedation threshold, a determination of the amount of barbiturate required to produce certain quantitative changes in the electroencephalogram, as a possible index of emotional tension in humans. In a related study of thiopental thresholds in rabbits, using "head drop" as the behavioral end point, Shagass, *et al.* (185), noted that chlorpromazine significantly diminished the amount of thiopental required to elicit the characteristic response. This procedure should be explored as a possibly sensitive and quantitative approach to the evaluation of barbiturate-synergist interactions.

Lessin (129) proposed a battery of three pharmacologic assays in mice to estimate inhibition of drug oxidation based on the assumption that a "nonspecific" liver oxidase system serves as the common denominator in: (*a*) prolongation of pentobarbital hypnosis, (*b*) intensification of chlorpromazine-induced hypothermia, and (*c*) reduction in the acute toxicity of octamethylpyrophosphoramide. Qualitatively similar results were obtained with isoniazid, iproniazid, and SKF 525-A in these three assays. It is an interesting approach; the validity of the hypothesis should be supported by examination of a larger series of compounds.

Variations in Response.—The many quantitative and occasional qualitative variations in response as they relate to species, sex, and age differences in the metabolism of drugs have been recently reviewed by Bousquet (17) and Brodie (22). Particularly relevant to this subject are the studies of Quinn, *et al.* (164), who demonstrated a striking relationship between hexobarbital sleeping time and the biological half-life of this barbiturate in several species. These investigators noted, however, that following administration of hexobarbital, mice, rats, and rabbits recovered the righting reflex at plasma levels of approximately 60 mcg. of barbiturate per ml., whereas hypnosis in dogs and man persisted until the level had declined to about 20 mcg. per ml. These data suggested that, in addition to differences in rates of drug metabolism, variations in the sensitivity of the central nervous system play a major role in species differences in response to depressant drugs. Other factors germane to the interpretation of barbiturate synergism studies are the possible effects of hypothermia and hydration.

Hypothermia.—Studies conducted with a series of antihistamines demonstrated the absence of a relationship between histamine antagonism and synergic activity with barbiturates (2, 3). This conclusion was corroborated by the finding that histamine also prolonged barbiturate sleeping time. Although distinct quantitative differences were evident, Packman, *et al.* (158), found that histamine and each of 15 different antihistaminic compounds evaluated reduced the body temperature of mice. Subsequently, other investigators (71, 130, 218) reported that many drugs which prolong the action of hypnotics also lower body temperature. Conversely, β-tetrahydronaphthylamine, a potent pyretic agent, inhibited the prolonging action of 5-hydroxytryptamine on hexobarbital sleeping time in mice (160). There is little evidence of a strict causal relationship; nevertheless, the influence of a drug on body temperature is frequently a determinant of its effect on barbiturate hypnosis. Examination of the literature relative to barbiturate synergism suggests that not all investigators are aware of the importance of ambient temperature and the possible hypo- or hyperthermic effects of the compounds being studied on the response to hypnotic drugs.

Hydration and Dehydration.—Bhide (13) reported that hydration (intraperitoneal injection of water or 5% glucose solution) significantly increased hexobarbital sleeping time in mice. This finding was confirmed by Ramwell and Lester (165), who also observed that dehydration (resulting from deprivation of water or injection of various diuretics) markedly reduced the duration of hexobarbital hypnosis. The effect of water loading on the brain electrolyte pattern and electroshock seizure threshold has been detailed by Swinyard (195), for the experimental evaluation of anticonvulsant drugs. However, relatively little attention has been accorded the possible influence of alterations in the extracellular sodium concentration on the duration of barbiturate hypnosis. It is reasonable to speculate that changes in the electrolyte balance may constitute a critical factor in the observed effect of corticotropin and corticosteroids on sleeping time (215). The susceptibility of mice to dehydration should also be considered in the design of sleeping time experiments.

Dose and Time Factors.—Most investigators are cognizant of the limited value of data which relate the biological effect of a compound to a single dose evaluated at an arbitrarily selected

time interval after administration. Construction of dose-time-effect relationships requires serial determinations of response repeated in temporal sequence at various levels in the range from the minimum to the maximum effective concentration. However, practical considerations frequently restrict the completeness with which three-dimensional analyses are performed with individual compounds. Considering the additional complexities inherent in the pharmacologic evaluation of drug mixtures, it is not surprising that most studies in this area lack adequate perspective.

The observation of Shore, *et al.* (186), that relatively large doses (10 mg./Kg.) of lysergic acid diethylamide (LSD) antagonized a central action of 5-hydroxytryptamine (5-HT) in the intact animal, provided a basis for speculation as to the role of this amine in normal and disturbed mental processes and the mechanisms of action of psychosomimetic and psychosoplegic drugs. It is not within the scope of this review to consider the controversies in these areas; however, it is relevant to note certain apparently dose-related inconsistencies which have necessitated a re-evaluation of earlier concepts. LSD and 2-brom-*d*-lysergic acid diethylamide (BOL), in doses (2 to 5 mcg./Kg.) which did not alter the duration of hexobarbital hypnosis in mice, were found to enhance further the prolonging effect of 5-HT (but not reserpine) on hexobarbital sleeping time (175). Larger doses (2.5 to 80 mg./Kg.) of LSD, which have been claimed both to prolong (33, 219) and have no effect (27) on barbiturate hypnosis, and larger doses of BOL, having no effect (33) in this regard, blocked the prolongation of sleeping time induced by either 5-HT or reserpine (176) but not iproniazid (27).

In certain cases, either a synergistic or an antagonistic relationship may be effected, depending upon the time interval separating administration of two drugs. Prolongation of barbiturate-induced hypnosis by chlorpromazine, administered simultaneously or several hours prior to the hypnotic, is well documented. In contrast, Kato (105) showed that sleeping time was significantly reduced when pentobarbital or hexobarbital was administered 48 hours after chlorpromazine (15 mg./Kg., intraperitoneally) in rats. A comparable diphasic effect on the duration of hexobarbital action has been reported to occur with urethan (83), SKF 525-A, N-ethyl-3-piperidylbenzilate HCl, nikethamide, and iproniazid (183). Other studies have demonstrated a marked reduction in the duration of action of pentobarbital, hexobarbital, meprobamate, and zoxazolamine in rats injected 24 hours or more in advance with a variety of drugs and chemical carcinogens (17, 20, 42). The decreased sensitivity is explained by an accelerated *in vivo* biotransformation, subsequent to the increased activity of hepatic microsomal drug-metabolizing enzymes induced by a host of foreign compounds (85).

Recent evidence suggests that SKF 525-A and Lilly 18947 (2,4-dichloro-6-phenylphenoxyethyl diethylamine HBr) may have an "immediate" inhibitory and a "late" inducing effect on the same enzyme systems (106, 107). The interesting hypothesis has been formulated that the initial inhibitory action may be the factor responsible for stimulating the compensatory increase in *de novo* biosynthesis of microsomal drug-metabolizing enzymes (107). Further studies are needed on the relationships between the inhibitory action and enzyme-inducing action of other compounds; in some cases, synergism and antagonism may be different sides of the same coin.

MECHANISMS

The number of different types of drug combinations for which a synergistic relationship has been claimed greatly exceeds the plausible explanations of the mechanisms involved. At present no unifying concept appears adequate to account for all the diverse forms of molecular interaction encompassed by the term "synergism." Veldstra (207) suggested that a large proportion of the cases may be explained on the basis of a competition between the active compound and the synergist at various "sites of loss" for the former. These sites of loss have been identified as loci of nonspecific adsorption (*i.e.*, storage at "silent receptors"), as enzyme surfaces functioning in the metabolism or detoxication of the active compound, or as excretion mechanisms. Although this pregnant concept provides a valuable frame of reference, it is obvious that detailed analyses are required to elucidate specific mechanisms of synergic activity.

Structure-Activity Relationships (Phenothiazines).—Adequate data are not available to establish clear relationships between chemical structure and synergic activity of the various phenothiazines, although some efforts in this direction have been reported. Dobkin (59) evaluated several phenothiazines on the basis of their ability to prolong thiopental anesthesia in the dog. Quantitative relationships could not be derived inasmuch as different doses of the various derivatives were used. Nevertheless, in the doses employed, promazine and propiomazine were most effective in prolonging the anesthetic

effect of thiopental; levomepromazine and methdilazine were somewhat less active, whereas mepazine, prochlorperazine, and trifluoperazine did not influence the duration of thiopental anesthesia.

A comparative study of seven phenothiazine derivatives revealed the lack of a definite relationship based on their ability to prolong barbiturate hypnosis in mice, and impair locomotor activity in rats, and climbing dexterity in mice (177). The outstanding exception in this case, perphenazine, exhibited the greatest activity in all three assays. Jindal, *et al.* (103), compared the effects of uniform doses (on a milligram basis) of a series of phenothiazine derivatives on the duration of pentobarbital-induced hypnosis in mice. The interesting aspect of this study is that compounds which prolonged sleeping time also evidenced antidiuretic effects in saline-loaded rats, whereas those compounds which either reduced or did not alter the duration of pentobarbital hypnosis had a diuretic effect in such rats. The authors suggested that a parallelism may exist between these two phenomena. Domino (61) stated that it is unlikely that antidiuretic hormone release is the only factor involved in the enhancement of pentobarbital anesthesia by phenothiazines, but it may be contributory.

Biochemical Mechanisms (Phenothiazines).—Bain and Mayer (7), and Laborit, *et al.* (121), have prepared comprehensive analyses of researches relating to the effects of chlorpromazine and certain other phenothiazines on various enzyme systems. There is a progressively increasing literature documenting the action of phenothiazines as relatively nonspecific inhibitors of many biochemical reactions *in vitro*. However, inferences are frequently drawn from *in vitro* experiments regarding the effects of drugs on enzymatic activity, with little consideration given to the influence of normal cellular architecture on biochemical processes *in vivo*. At present it is difficult to relate the pharmacodynamic actions of the phenothiazines to their currently established biochemical effects. Despite the relatively low potency evidenced in many of the *in vitro* systems, it is nevertheless tempting to speculate that inhibition of drug metabolism constitutes at least one aspect of the mechanism of phenothiazine synergy.

Decsi (53) compared a variety of central nervous system depressants, including eight phenothiazine derivatives, on the basis of their ability to inhibit a conditioned avoidance response in the rat, augment the hypnotic action of hexobarbital in the mouse, and inhibit oxidative phosphorylation and adenosine triphosphatase activity in rat brain homogenates. The investigator concluded that there exists a quantitative relationship among the biochemical and pharmacologic effects described, thus enabling prediction of the *in vivo* potency of a drug solely on the basis of its *in vitro* activity. Inspection of the data failed to reveal adequate justification for this confidence.

Chlorpromazine was found, in healthy humans (194) and in rabbits (203), to elevate the blood alcohol concentration significantly above the levels detected in control series after adminstration of a standardized dose of ethanol. Although the study of Zirkle, *et al.* (220), did not substantiate the effect of chlorpromazine on the blood alcohol level, it demonstrated that chlorpromazine markedly increased the impairment of neuromuscular coordination following a standard dose of ethanol in man. This apparent discrepancy may be related to the indirect estimation of blood alcohol volume by means of a "Breathalyzer" in the latter study. Tipton, *et al.* (203), concluded that the elevation of the blood alcohol level by chlorpromazine was not due to an increase in the rate of absorption, but that it may be attributable to an inhibition of ethanol metabolism. In support of this premise, Khouw, *et al.* (110), have demonstrated that relatively low concentrations of chlorpromazine inhibit the activity of rabbit liver alcohol dehydrogenase.

Kaplan, *et al.* (104), demonstrated that large doses of nicotinamide markedly increased the levels of diphosphopyridine nucleotide (DPN) in mouse liver. These transiently elevated DPN levels were maintained for a prolonged period when chlorpromazine was administered prior to the injection of nicotinamide (31). Burton, *et al.* (30), observed that nicotinamide, in concentrations which did not influence the duration of pentobarbital-induced hypnosis in mice, significantly extended the effect of chlorpromazine on pentobarbital sleeping time. In a subsequent study, Burton, *et al.* (32), found that "nontranquillizing" derivatives of phenothiazine (*e.g.*, thioperazine) were ineffective in maintaining elevated DPN levels. It would be interesting to determine whether a relationship exists between the synergistic activity of various phenothiazine derivatives and their ability to maintain nicotinamide-induced levels of DPN.

Inhibition of drug inactivating mechanisms is not held accountable for phenothiazine synergy by all investigators. Martin, *et al.* (138), observed that chlorpromazine and chlorpromazine sulfoxide enhanced the magnitude and prolonged the duration of the chronotropic action of epinephrine and norepinephrine in the spinal vagotomized cat. Although the factors in this phe-

nomenon were not elucidated, it was emphasized that chlorpromazine did not alter the metabolism of these catecholamines by either blood or liver.

Brodie, *et al.* (25) observed that mice which had just recovered from hypnosis induced by hexobarbital, reverted immediately to the hypnotic state when injected with chlorpromazine. In contrast, mice were not visibly affected by SKF 525-A or amine oxidase inhibitors of the hydrazine type administered after return of the righting reflex (123). These researchers concluded that SKF 525-A and the amine oxidase inhibitors prolong anesthesia by interferring with hexobarbital metabolism, whereas chlorpromazine increases the sensitivity of the central nervous system to depressant drugs. The precise nature of this "sensitization" remains to be elucidated; the extent to which it may involve the central adrenergic blocking activity of chlorpromazine (26) or the postulated alteration of the "trophotropic-ergotropic" equilibrium (24) has not received attention.

Several types of evidence have been cited in support of the concept that a reduction or stabilization of the permeability of certain biological membranes may constitute the primary action of chlorpromazine. Spirtes and Guth (190) observed that concentrations of chlorpromazine less than required to influence oxidative phosphorylation diminished the water imbibition of mitochondria induced by thyroxin and other swelling agents. Gey and Pletscher (87) have summarized other findings in support of this view and have suggested that a reduction of membrane permeability *in vivo* may account for their observation of interference by chlorpromazine with the metabolism of aromatic amino acids in rat brain. In a report on the influence of chlorpromazine on the activity of monoamine oxidase inhibitors and monoamine releasers in rat brain Schwartz, *et al.* (181), similarly concluded that the phenothiazine probably interferes with the permeation of monoamines or their precursors through brain membranes. There are no data which relate this concept to the possible mechanisms of phenothiazine synergy; nevertheless, it is conceivable that biotransformation processes may be impeded by reduced accessibility to intracellular sites of metabolism in the absence of direct inhibition of the enzymes involved.

Biochemical Mechanisms (SKF 525-A and Other Synergists).—The polyvalent nature of the synergistic activity of SKF 525-A has been attributed largely to an interference with the biotransformation of active drugs. This hypothesis is supported generally by the many reports which have established the prolongation of the action of various drugs by SKF 525-A, and specifically by those studies which have elucidated the effects of SKF 525-A on discrete metabolic pathways (17, 21, 42, 207).

SKF 525-A has been shown to inhibit the conversion of mephenesin to *o*-toloxylactic acid (135), the side-chain oxidation of hexobarbital, pentobarbital, and secobarbital (6, 48), the deamination of amphetamine, the formation of morphine glucosiduronide, the O-dealkylation of codeine (5, 48), the N-demethylation of aminopyrine, meperidine (48, 86), and the opiates (197), and the oxidation of phenylbutazone (29). Fouts and Brodie concluded that inhibition of drug-metabolizing enzyme systems present in liver microsomes (77) and in the soluble fraction of the liver cell (79) constituted a major factor in the synergistic activity of SKF 525-A.

The activity and/or toxicity of certain compounds is antagonized, rather than synergized, by SKF 525-A. This paradoxical effect has been explained on the basis of inhibition of enzyme systems required for the formation of active metabolites of the parent compound. For example, SKF 525-A diminished the prophylactic action of mepacrine against equine encephalomyelitis in mice (101, 202). This observation suggests, but does not prove, that SKF 525-A retards the conversion of mepacrine to an active antiviral metabolite. Organophosphates of the phosphorodiamidate and phosphorothionate classes are not toxic directly, but are converted to potent cholinesterase inhibitors by an oxidative reaction which, in mammals, is accomplished almost exclusively by liver microsomes (52). When added to mammalian liver preparations *in vitro*, SKF 525-A blocks the "activation" of schradan (tetramethylphosphordiamide anhydride), Guthion (dimethoxy ester of benzotriazine dithiophosphoric acid), and parathion (diethyl *p*-nitrophenyl phosphorothionate) (52, 151). SKF 525-A has been shown to be an effective antagonist of poisoning by schradan and Guthion, but not parathion in mice (155, 156). Presumably parathion possesses a greater affinity than the other organophosphates for the activating system *in vivo*, and therefore is not significantly altered by the presence of SKF 525-A (156). In summary, there have been cited multifaceted evidences that SKF 525-A influences enzymatic pathways involved in the detoxication of various drugs, and the conversion of certain latent species to biologically active molecules.

Interference with drug metabolism has been proposed as the basis for the synergistic activity

demonstrated with many compounds other than SKF 525-A. In the case of Lilly 18947 (77), iproniazid (78), JB 516 (123), captodiamine (65), chloramphenicol (57), and thyroxin (43), prolongation of hexobarbital sleeping time has been correlated with elevation of whole body concentrations of barbiturate and reduction of the rate of hexobarbital oxidation in an *in vitro* system. In studies of JB 516, N-ethyl-3-piperidyl benzilate and N-methyl-3-piperidyl diphenylcarbamate, Fujimoto, *et al.* (84), and Serrone and Fujimoto (182) related extension of hexobarbital hypnosis to whole body concentrations of the hypnotic, rates of disappearance from an isolated liver perfusion system, alteration of bromsulfalein retention, and inhibition of hexobarbital metabolism *in vitro*. Robison and Schueler (171) performed comparable studies with α-benzoylamine-β-(4-pyridyl)acrylic acid piperidide. Results of these investigations provided objective support of the proposed mechanism of action of the compounds in question. Such multidimensional analyses designed to elucidate fundamental synergic mechanisms are, unfortunately, the exception rather than the rule.

Data reported by several investigators suggest that the mechanism of action of SKF 525-A and certain other compounds which manifest synergic activity cannot be explained solely on the basis of retardation of drug metabolism. Several phenomena indicate that additional factors, not fully revealed at present, may also be operative. The phenomena include: (*a*) discriminative enhancement of certain properties of a drug, (*b*) reinstitution of a characteristic response by administration of the synergist after initial response to the active drug had terminated, (*c*) manifestation of a response by administration of a subthreshold dose of an active drug in combination with a synergist.

Corresponding specific observations involving SKF 525-A which do not conform totally to the "drug metabolism hypothesis," may be cited: (*a*) SKF 525-A prolonged hexobarbital-induced hypnosis without significantly altering the LD_{50} of the barbiturate (47) and enhanced the analgesic activity but not the respiratory depressant effect or LD_{50} of morphine (45). Similarly, the anticonvulsant activity and neurotoxicity of several central nervous system depressants were not uniformly increased by SKF 525-A (195). (*b*) Injection of SKF 525-A in the sciatic nerve-gastrocnemius muscle preparation of the chloralosed dog, after the muscle relaxant action of succinylcholine has ceased, resulted in a renewed and substantially increased curarizing effect (12, 18). These investigators proposed that the synergist displaced the muscle relaxant compound fixed in an inactive form at nonspecific receptor sites. A renewed and sharply defined depressor response was elicited by the administration of SKF 525-A after the blood pressure reducing effect of several different hypotensive drugs had largely dissipated in unanesthetized rats and dogs (90, 91). (*c*) These authors also observed that subthreshold doses of the hypotensive drugs evoked a significant decrease in blood pressure when injected after the administration of nondepressor doses of SKF 525-A. Such experiments lend support, albeit indirectly, to the concept of displacement of the active molecule from loci of nonspecific adsorption by the synergic agent.

Attention directed toward the role of biotransformation mechanisms in synergic phenomena, while most revealing, has tended to subjugate consideration of other basic aspects of the drug activity spectrum, *i.e.*, absorption, binding, cellular and subcellular distribution and localization, and elimination. A perspective of the kinetics of drug synergy must await investigations comparable to those reviewed in this section performed in conjunction with analyses of factors other than drug biotransformation which may influence the pharmacologic response. Parallel studies, utilizing both biodynamic and biochemical parameters, may clarify mechanisms of synergy in relationship to the total metabolic sojourn of the active drug.

Chemical Identification of Defective Thyroid Preparations

By ALBERT D. WILLIAMS, LESTER MEISTER, and WARNER H. FLORSHEIM

A modification of the Leland and Foster method for estimation of the thyroxine-like fraction in thyroid materials is described. This chemical method can be used to identify commercial thyroid preparations which are defective by clinical evaluation or by biological assay. In contrast, no difference in the content of the thyroxine-like fraction of effective and defective thyroid samples could be shown by our use of Blau's method.

RECENTLY we have found that certain batches and brands of thyroid tablets were relatively ineffective in the treatment of hypothyroidism in agreement with other recent reports (1, 2). Except for a British Pharmacopoeia preparation, all material clinically studied had been standardized in accordance with U.S.P. requirements. Unusually large daily amounts of these defective preparations were needed by patients who nevertheless responded at least as well to the customary small daily doses of other lot numbers or brands of thyroid. Since it was apparent that the defective thyroid tablets contained excessive amounts of nonhormonal iodinated compounds, quantitation of the hormonally active fraction might be useful in the identification of "ineffective" thyroid preparations.

Leland and Foster (3) described a method for the determination of the thyroxine content in an alkaline hydrolysate of large quantities (1 Gm.) of desiccated thyroid. We have modified the Leland and Foster method by using the sealed-tube alkaline hydrolysis procedure of Kennedy (4) for which only small amounts (1/4 to 2 grains) of thyroid material are required. The iodinated compounds in the hydrolysate are extracted into *n*-butanol and a small portion of the butanol extract, after backwashing with alkali, is analyzed directly for iodine content using a procedure modified from Bodansky, *et al.* (5). The iodide-catalyzed decolorization of ceric ion by arsenite is stopped after a predetermined time by adding brucine sulfate as suggested by Grossman and Grossman (6) which produces a stable color for photometric measurement.

Received November 18, 1962, from the Radioisotope and Medical Services, Veterans Administration Hospital, Long Beach, Calif., and University of California Medical School, Los Angeles.

Accepted for publication January 9, 1963.

Supported in part by Research Grant A-4455 from the U. S. Public Health Service.

We wish to thank Dr. Lloyd C. Miller of the United States Pharmacopeia for helpful discussions during the course of this investigation and Miss Audrey Kam for technical assistance in performing many of the iodine analyses. We are indebted to the many individuals and pharmaceutical companies who provided thyroid materials or biological assays. The names of these sources are available from the authors.

PROCEDURE

Reagents.—Reagents 1–5 were prepared exactly as described by Bodansky, *et al.* (5); all were prepared in glass-distilled water. The reagents used were 1, sodium chromate (0.5%); 2, chloric acid (28%); 3, arsenious acid; 4, ceric ammonium sulfate; 5, potassium iodate standards; 6, brucine sulfate (1%) in water; 7, thiourea (0.2%) in water; 8, 2 *N* sodium hydroxide; and 9, 4 *N* sodium hydroxide saturated with *n*-butanol.

Total Thyroid Iodine.—A single thyroid tablet (1/4 to 2 grains)[1] or a 15 to 60-mg. sample of desiccated thyroid powder in a 25 × 150-mm. Pyrex tube was digested with 0.2 ml. of sodium chromate and 6 ml. of chloric acid. We modified the procedure of Bodansky, *et al.* (5), and digested the sample at 130° for 2 hours in an aluminum heating block with holes 4 cm. deep to accommodate the tubes. Different manufacturers formulate thyroid tablets with various and varying amounts of binders and diluents creating some problems in this first digestion step. Organic diluents in the larger tablets may reduce the chromate resulting in a potential loss of iodine. Additional chloric acid may be required for the complete digestion of such preparations. Certain inorganic binders will form an insoluble residue after digestion but this does not appear to interfere with subsequent steps in the procedure. The digested thyroid sample is quantitatively transferred to a volumetric flask (100 to 500 ml.) and diluted to volume with glass-distilled water. A small aliquot of the diluted sample (0.2 to 1.0 ml.) containing between 0.01 to 0.05 mcg. of iodide is pipetted in duplicate into 25 × 150-mm. test tubes. One milliliter of glass-distilled water (for reagent blanks)

[1] A 1-grain tablet is considered to contain 60 mg. of desiccated thyroid although we are aware that not all 1-grain thyroid tablets contain exactly this amount of thyroid powder.

and 1 ml. of each of the five working standards (0.01 to 0.06 mcg. of iodine per ml.) is pipetted in duplicate into similar tubes. Chloric acid (6 ml.) and sodium chromate (0.2 ml.) are added to the unknown samples, reagent blanks, and standards for digestion at 130° for 2 hours in the aluminum heating block. Glass-distilled water (10 ml.) and arsenious acid (2 ml.) are added to the tubes after digestion as described by Bodansky, *et al.* (5), and the tubes are placed in a 28° water bath. After temperature equilibration, 0.5 ml. of ceric ammonium sulfate is added in sequence at 30-second intervals to each tube, the tube contents rapidly mixed by swirling, and the tubes returned to the water bath. Exactly 25 minutes later, 0.5 ml. of brucine sulfate is added at 30-second intervals to each sample in sequence and mixed. Thus, the iodide-catalyzed ceric ammonium sulfate decolorization reaction is allowed to proceed for exactly 25 minutes in each tube before the reaction is stopped with brucine. The color intensity of each unknown sample, reagent blank, and standard is measured in a Klett photoelectric colorimeter using a No. 42 filter. The instrument is set to zero with water; the reagent blank readings are usually about 300 Klett units. The average reading of each unknown sample, and of each standard, is divided by the average blank reading. Since a linear relationship exists between the logarithm of each standard ratio and its concentration, a standard curve can be plotted on semilogarithmic paper as described by Kontaxis and Pickering (7). The iodide content of each unknown, determined from the standard curve, is multiplied by the appropriate dilution factor to obtain the iodine content in the original digested thyroid sample.

"Thyronine" Iodine.—Although Kennedy (4) used evacuated, sealed reaction tubes for the alkaline hydrolysis of thyroid, we have found it more convenient to place a single thyroid tablet (1/4 to 2 grains) or a 15 to 60-mg. sample of thyroid powder in a 20 × 185-mm. Thunberg tube. After adding 0.1 ml. (0.2 mg.) of thiourea and 12 ml. of 2 *N* sodium hydroxide to the sample, the tube is evacuated at the water pump and sealed (while pumping) by turning the lightly greased stopper. It is heated at 100° for 16 hours in an aluminum heating block. The lower 4 cm. of the Thunberg tube is heated directly by the block while the upper 14 cm. acts as an air-cooled reflux condensor. After hydrolysis, the tubes are cooled and the hydrolysate, with any insoluble residue, is transferred by pipet to 25 × 150-mm. screwcap Pyrex tubes. The Thunberg tube is rinsed with 12 ml. of *n*-butanol which is transferred to the alkaline hydrolysate in the screwcap tube. The tubes are tightly sealed with a small square of Parafilm under the screwcap and vigorously shaken for 1 minute. After phase separation by centrifugation, the butanol layer is removed to a volumetric flask and the aqueous phase is extracted a second time with an equal volume of *n*-butanol. After centrifugation, the second butanol extract is pooled with the first in the volumetric flask and diluted to volume with butanol. The diluted solution should contain about 0.1 to 0.2 mcg. of iodine per ml. Iodotyrosines are removed from a small portion of the diluted butanol extract by shaking with an equal volume of 4 *N* sodium hydroxide saturated with butanol and separating the phases by centrifugation. Aliquots of the alkali backwashed butanol extract (0.1 to 0.3 ml.), reagent blanks and iodide standards are pipetted into 25 × 150-mm. tubes for digestion with sodium chromate and chloric acid as described previously for the determination of total thyroid iodine. It is important to digest no more than 0.3 ml. of the butanol extract with the chloric acid reagent: *larger amounts of butanol react explosively when heated with chloric acid.* After digestion, iodine analysis is done as described previously for total thyroid iodine determination to obtain the butanol-extractable iodine content ("thyronine" iodine) in the alkaline hydrolysate of the thyroid preparation.

Clinical Evaluation and Bioassay of Thyroid Materials.—Many of the thyroid preparations mentioned in this report have been assayed for biological potency.[2] Methods used for bioassay, as well as the clinical evaluation of patient response to these thyroid preparations will be fully described in a forthcoming publication. The methods used for clinical assay purposes included most of the commonly accepted metameters such as the determination of the serum PBI and cholesterol levels, general clinical criteria (including body weight changes and subjective responses), and, in a few instances, the BMR. Primary emphasis was placed on the serum PBI values. Dosage levels were multiple whenever possible for both the standard and unknown thyroid preparations, the latter being given at both high and customary dosages.

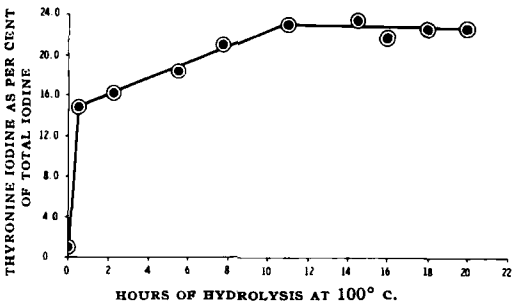

Fig. 1.—"Thyronine" iodine recovery from thyroid tablets subjected to varying periods of sealed tube alkaline hydrolysis. Points on the curve represent the average "thyronine" iodine as per cent of total iodine content for pairs of thyroid samples hydrolyzed for the indicated times.

RESULTS AND DISCUSSION

Identification of Samples.—With reference to the results to be discussed in this report, the thyroid tablets and powders are coded by number as they are received in the laboratory. Each code number refers to the lot number as received by us. A protocol has been filed with Dr. Lloyd C. Miller of the U.S.P. relating each code number to the brand and lot number of the material studied. In some cases, we have tested different lots of tablets or desiccated thyroid powders from the same pharmaceutical company.

Definition of "Thyronine" Iodine.—The term

[2] We wish to acknowledge with appreciation the cooperation of Wilson Laboratories, Chicago, Ill., and Armour Pharmaceutical Co., Kankakee, Ill., for bioassays of a number of thyroid preparations.

TABLE I.—"THYRONINE" IODINE RECOVERY

Sample	"Thyronine" Iodine, %	Total Iodine, %	"Thyronine" Iodine as % of Total Iodine
L-3,5-Diiodotyrosine	0.25	53.8	0.46
L-3,5-Diiodothyronine	21.8	47.8	45.6
L-3,3',5-Triiodothyronine	41.8	50.2	83.3
Sodium L-thyroxine powder	53.0	59.6	88.9
Sodium L-thyroxine powder	55.6	62.8	88.5
Sodium L-thyroxine tablets	43.8	50.0	87.6
Sodium L-thyroxine tablets	54.0	64.0	84.4
Sodium L-thyroxine tablets	44.7	48.0	93.1
Sodium L-thyroxine-I^{131}	9110 c/m[a]	10,240 c/m[b]	89.0
Sodium L-thyroxine-I^{131}	9580 c/m	10,590 c/m	90.5

[a] Total counts per minute recovered in the "Thyronine" iodine fraction. [b] Total counts per minute in the original sample corrected for 3% inorganic iodide-I^{131} counts as judged by filter paper chromatography.

"thyronine" iodine used in this report has special meaning. After alkaline hydrolysis of the thyroid material, the *n*-butanol soluble portion of the hydrolysate is backwashed with 4 *N* sodium hydroxide saturated with *n*-butanol to remove inorganic iodide and iodotyrosines. The alkali backwashed *n*-butanol extract of the hydrolysate contains chiefly thyroxine and triiodothyronine. The iodine content of this *n*-butanol fraction is referred to as "thyronine" iodine in this report although we recognize that this fraction may contain small amounts of other iodinated compounds.

Expression of "Thyronine" and Total Iodine Values.—"Thyronine" iodine and total iodine values are reported as per cent by weight of the material studied. In the case of thyroid tablets, it is assumed that a 1-grain thyroid tablet contains 60 mg. of desiccated thyroid material[1] and this weight is used to calculate per cent "thyronine" iodine or total iodine. In some of the tables, "thyronine" iodine is expressed as per cent of the total iodine content of the material studied. All values reported represent the mean of four or more individual determinations.

Optimal Time for Alkaline Hydrolysis.—The optimal time for alkaline hydrolysis was established by preparing a number of single 1 grain tablets of the same lot number for hydrolysis in sealed tubes. Pairs of tubes were removed at intervals from the heating block for "thyronine" iodine determinations. Points on the curve in Fig. 1 are the average of duplicates and represent "thyronine" iodine as per cent of the total iodine content of the tablet. The "thyronine" iodine recovery curve plateaus after 11 hours of hydrolysis with little change to 20 hours and resembles that reported by Leland and Foster (3). An overnight hydrolysis is convenient and all "thyronine" iodine values in this report are based on a 16 hour hydrolysis period.

Total Iodine Recovery Studies.—To evaluate our method for total iodine analysis of desiccated thyroid powders, thyroglobulin extracts, iodinated casein and L-sodium thyroxine, we compared our total iodine values with the manufacturer's reported total iodine content in 21 different samples. The mean recovery by our method was 98.5 ± 3.3 (s.d.) % of the manufacturer's indicated total iodine value (range 92.3 to 107.7%).

Thyroxine Iodine Recovery Studies.—Sodium L-thyroxine powder and sodium L-thyroxine tablets were analyzed for total and "thyronine" iodine by our method. Theoretically "thyronine" iodine represents thyroxine iodine in these samples and should correspond to the total iodine content. Results are listed in Table I for "thyronine" and total iodine content of thyroxine and other iodinated compounds. Also included in Table I are radioactive thyroxine recovery studies. Mixtures of thyroxine-I^{131} and non-radioactive thyroxine were hydrolyzed in sealed tubes and extracted with *n*-butanol for radioactivity measurement. The total counts per minute in the original thyroxine-I^{131} samples in Table I were corrected for a 3% contamination by inorganic-I^{131} as judged by paper chromatography.

The mean recovery of iodine in the "thyronine" fraction in seven thyroxine samples (Table I) is 88.9 ± 2.7 (s.d.)% of the total iodine content found. This recovery is somewhat better than that reported by Leland and Foster (3) who observed a 25% loss of pure thyroxine in their alkaline hydrolysis method. Blau (8), in a study of the alkaline hydrolysis of thyroid, recovered 97 and 90% of thyroxine iodine when pure samples of thyroxine were boiled in barium hydroxide or in sodium hydroxide, respectively. Kroc, *et al.* (9), in control studies with pure thyroxine, recovered 88 to 90% of the theoretical iodine using Blau's method. In contrast to the recoveries of Leland and Foster, our more satisfactory recoveries may be due to the use of partially evacuated sealed tubes and to the protective effect of the thiourea used during alkaline hydrolysis.

Recovery of iodine in the "thyronine" iodine fraction from samples of diiodotyrosine, diiodothyronine, and triiodothyronine was determined by sealed tube alkaline hydrolysis and *n*-butanol extraction. It is evident from the results in Table I that only a very small fraction of diiodotyrosine iodine remains in the backwashed *n*-butanol extract but about 45% of any diiodothyronine iodine, if present, will be

found in this fraction. Recovery of triiodothyronine iodine (83%) is similar to that reported by Kroc, *et al.* (9).

Reproducibility of the Method.—The "thyronine" and total iodine content of one of our samples, a 1 grain thyroid tablet of known clinical potency, has been determined on many individual tablets in a number of different experiments during the past year. A summary of these results (Table II) shows good reproducibility of the method considering that some individual variation in both total and "thyronine" iodine content in the tablets of this particular lot number may exist. Included in Table II are results for the total and "thyronine" iodine content in fourteen 20-mg. samples of an undiluted thyroid powder analyzed in a single experiment which also show good reproducibility.

Effect of Lactose on "Thyronine" Iodine Recovery.—Lactose, used as a diluent in some desiccated thyroid preparations to reduce the total organic iodine content to U.S.P. or B.P. specifications, was shown by Doery (10) to interfere with the analysis of thyroxine in thyroid. Addition of lactose to desiccated thyroid powder increased the thyroxine iodine value when measured by the 1936 Addendum to the B.P. (1932) method for thyroid. Johnson and Smith (11) using the B.P. (1958) method for thyroid assay confirmed Doery's observations. Doery (10) pointed out that the sodium hydroxide was partially neutralized by organic acids formed from lactose during hydrolysis. Under these less effective hydrolytic conditions, incompletely digested protein (containing non-thyroxine iodine) was adsorbed to the flocculent precipitate which formed after acdification resulting in increased thyroxine iodine values. Doery (10) also measured the recovery of thyroxine from thyroid by the butanol extraction method of Leland and Foster (3) and observed a significant (18 to 29%) loss of thyroxine when thyroid powder was hydrolyzed with sodium hydroxide in the presence of added lactose.

The results of Doery prompted us to study the influence of added lactose on "thyronine" iodine recovery by our method from thyroid powders and from sodium L-thyroxine. The results of our experiments are shown in Table III. In this table, samples 16, 17, and 23 are undiluted, desiccated thyroid powders containing from 0.65 to 0.80% total iodine. Sample 28 is sodium L-thyroxine. The samples were hydrolyzed in the absence of and also in the presence of 20 and 60 mg. of added lactose. The butanol extracts were then analyzed for "thyronine" iodine. The reduction in the "thyronine" iodine value by lactose is relatively small, and the differences we find in the "thyronine" iodine content of effective and defective thyroid preparations cannot be ascribed to the presence of lactose in the defective material. In our procedure, the ratio of sodium hydroxide to thyroid material is greater than that used by Leland and Foster (3). The increased sodium hydroxide content and the use of thiourea in the alkaline hydrolysis step of our procedure may decrease the lactose effect described by others (10, 11).

Evaluation of Blau's Method for Thyroxine Iodine in Thyroid.—Blau (8) described a method for the determination of thyroxine in thyroid materials in which barium hydroxide hydrolysates were acidified prior to extraction of thyroxine into butanol. After backwashing with Blau's reagent, the butanol solu-

tion was analyzed for iodine. Blau stated that results by his method agreed with those obtained by the B.P. acid precipitation method for samples of commercial thyroid powder although neither his nor the B.P. method gave consistent results with thyroid tablets. He felt that the discrepancies observed in the analysis of thyroid tablets could be attributed to adsorption of iodinated compounds to the excipients used in formulating the tablets. Doery (10) suggested that acidification of a mixture of soluble and insoluble products in the alkaline hydrolysate favored adsorption of non-thyroxine iodine to the thyroxine precipitate.

We determined the "thyronine" iodine content in a number of commercial thyroid powders and tablets using the method of Blau (8) and these results are compared in Table IV with results obtained on the same preparations by our method. The first seven samples in Table IV were defective, and the last eight samples were effective preparations when tested biologically or clinically.

The data in Table IV clearly indicate that, by our method, the results for "thyronine" iodine (calculated as per cent of total iodine) sharply discriminate between effective and ineffective thyroid preparations. In contrast, using Blau's method for the measurement of "thyronine" iodine content of thyroid materials, we were unable to detect any significant difference between the effective and ineffective preparations. It is of particular interest that the "thyronine" iodine content of the effective preparations is comparable by both methods. The ineffective preparations, however, have "thyronine" iodine values by the Blau method which, on the average, exceed by a factor of 1.7 the corresponding results by our method.

Since all preparations in Table IV complied with or exceeded U.S.P. specifications, the high values by Blau's method for "thyronine" iodine in ineffective material are due to nonhormonal iodinated residues in the alkaline hydrolysate, possibly as incompletely hydrolyzed polypeptides. Such residues may be more readily soluble in butanol after acidification of the hydrolysate and are inefficiently removed when the butanol extract is backwashed with sodium hydroxide. The iodine content of the resulting

[a] In the case of thyroid tablets, this per cent is based on an assumed weight of 60 mg. of desiccated thyroid powder per 1-grain tablet. (See footnote 1 in text.)

butanol extract, therefore, is due not only to "thyronine" iodine but to an excess of nonhormonal iodinated materials. It is possible that the longer period of sodium hydroxide hydrolysis used in our method and the direct butanol extraction of the alkaline hydrolysate results in an extract which, after backwashing with alkali, has an iodine content more nearly reflecting the true hormonal iodine content of the thyroid material. The effective thyroid materials containing less non-thyroxine iodinated substances would be expected to yield "thyronine" iodine values by Blau's method which are comparable to or only slightly higher than the results by our method.

Results with Present Method.—*Effective Thyroid.* The analytical results, by our method, for all thyroid tablets and desiccated thyroid or thyroglobulin powders which we studied and consider to be effective are presented in Table V. Of the 44 samples in this table, 26 are known to be clinically or biologically effective. The remaining 18 samples in this group, while not tested directly by us, were submitted to our laboratory as "good" thyroid and no unsatisfactory biological or clinical results with any of these preparations have been reported to us. In Table V, the per cent of total and "thyronine" iodine content of each sample identified by our code number is listed. Additionally, a value for the "thyronine" iodine as per cent of the total iodine content of the sample is given along with an indication of which materials studied were clinically or biologically adequate. The mean "thyronine" iodine as per cent of the total iodine content of the effective thyroid preparations in Table V is 24.2 ± 2.35 (s.d.).

Defective Thyroid.—The analytical values for "thyronine" and total iodine in a group of defective thyroid preparations are given in Table VI. Fourteen of the samples in this table have been shown to be either clinically or biologically defective. The remaining four samples, not tested clinically or biologically, are considered as unsatisfactory preparations since "thyronine" iodine expressed as per cent of total iodine content of these samples falls within the range of known defective thyroid material. One of these samples, No. 62, is known to have been formulated with desiccated thyroid powder from the same source used for four other samples in Table VI which were shown to be clinically or biologically defective. The thyroid tablets in Table VI were sold as U.S.P. thyroid and all except one, No. 39 (which had a slight excess of total iodine), met the requirements of the U.S.P. in terms of total organic iodine content. The mean "thyronine" iodine as per cent of total iodine in the defective thyroid group is 14.1 ± 1.55 (s.d.).

SUMMARY AND CONCLUSIONS

A summary of all thyroid preparations studied is given in Table VII. A highly significant difference ($p = < 0.001$) exists between the mean "thyronine"

TABLE VII.—SUMMARY OF ALL THYROID SAMPLES STUDIED

	Effective Samples	Defective Samples
"Thyronine" iodine as per cent of total iodine (Mean):	24.2	14.1
Standard error	±0.35	±0.37
Number of samples tested chemically	44	18
Range of values	21.0–29.6	11.4–16.8
Number of samples tested clinically or biologically or both	26	14
Number effective by clinical testing	19	0
Number effective by biological testing	15	0
Number defective by clinical testing	0	10
Number defective by biological testing	0	10

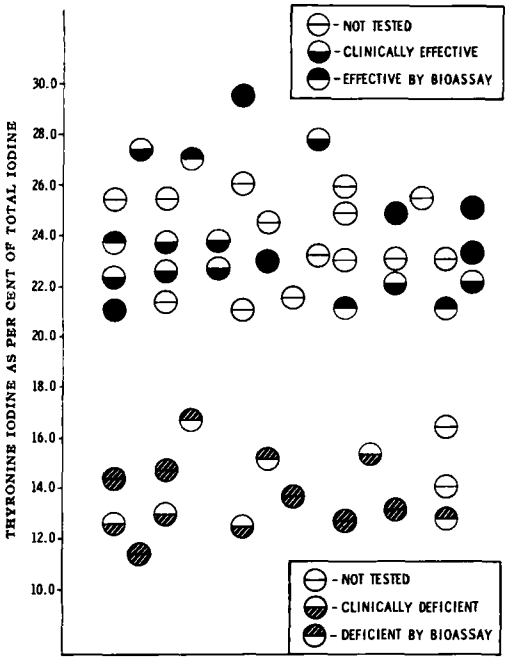

Fig. 2.—Scattergram of the "thyronine" iodine content as per cent of total iodine for individual thyroid preparations. Each point on the graph represents a different thyroid preparation and the symbols used indicate the thyroid preparations which tested clinically or biologically effective or deficient.

iodine per cent of total iodine in the effective and the defective samples with no overlapping of values between the two groups. Twenty-six of the effective and 14 of the defective preparations were biologically or clinically evaluated; some samples in each group were tested by both methods. In the effective group, 19 samples were clinically effective, 15 were biologically effective, and none were defective. In contrast, the defective group contained 10 samples which were clinically and 10 which were biologically defective, but none that were biologically or clinically effective.

In Fig. 2, the results of our chemical evaluation of some of the thyroid preparations studied are presented graphically together with an indication of those particular samples which were examined by clinical or bioassay methods.

In conclusion, we have described a method for the chemical analysis of the "thyronine" iodine content of commercial thyroid material. The "thyronine" iodine content expressed as per cent of the total iodine content of the thyroid samples correlates well with clinical or biological evaluation of the thyroid preparations.

ADDENDUM

The thyroid preparations listed in the table below have been examined for their content of triiodothyronine and thyroxine iodine in the laboratories of the Physiology and Hormones Section of the Canadian Food and Drug Directorate through the kind collaboration of Dr. N. R. Stephenson and Mr. W. F. Devlin using methods previously published by these authors [*J. Pharm. Pharmacol.*, **14**, 597 (1962)]. In the table, the values obtained by Devlin and Stephenson are compared with our "thyronine" iodine values expressed as per cent of total iodine, revealing a substantial degree of correlation.

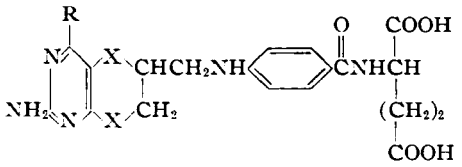
Analogs of Tetrahydrofolic Acid VII

Synthesis of N-[1-(2-Amino-4-hydroxy-6-methyl-5-pyrimidyl)-3-propyl]-*p*-aminobenzoyl-L-glutamic Acid, An Inhibitor of Folic Reductase

By B. R. BAKER and C. E. MORREAL

The title compound (XI) has been synthesized in a six-step sequence using ethyl acetoacetate, acrolein, guanidine, and *p*-aminobenzoyl-L-glutamic acid. This compound inhibits folic reductase and binds to the enzyme better than the substrate, folic acid. It also inhibits dihydrofolic reductase.

FIFTEEN ENZYMES UTILIZING folic acid, tetrahydrofolic acid (I), or derivatives of tetrahydrofolic acid are known (2–4). A number of these enzymes are inhibited (5–8) by aminopterin (4-amino-4-deoxyfolic acid), but nearly as many are not (7, 9–11). In contrast, 5,6,7,8-tetrahydroaminopterin (II) can inhibit some of the enzymes not inhibited by aminopterin (11, 12). 5,8-Dideaza-5,6,7,8-tetrahydroaminopterin (IV) has been recently synthesized (13) and found to have inhibitory properties similar to tetrahydroaminopterin (13, 14). In addition, 5,8-dideaza-5,6,7,8-tetrahydrofolic acid (III) (15) has been found to bind to folic reductase eight times stronger than the substrate, folic acid (16).



I. R = OH, X = —NH—
II. R = NH_2, X = —NH—
III. R = OH, X = —CH_2—
IV. R = NH_2, X = —CH_2—

The folic cofactor area should be a prime target for utilization of recent developments in nonclassical antimetabolite theory (17–19), since larger differential effects on inhibition of these enzymes might be obtained by the bulk principle of specificity (17), the exo-alkylating irreversible inhibition phenomenon (18), and the bridge principle of specificity (19). In order to use these three corollaries of nonclassical antimetabolite theory, it would be advisable to have an inhibitor that can be made by a relatively short sequence and the sequence should be one that lends itself to the placing of substituents in a variety of positions. Synthesis of compound XI, which satisfies both the inhibitor and synthetic requirements, is the subject of this paper.

Although the synthesis of ethyl 2-acetylglutaraldehydate (V) by Michael addition of ethyl acetoacetate to acrolein has been described by Moe and Warner (20), but no yield recorded, their procedure gave 5–20% yields in this laboratory. After considerable experimentation, consistent yields were obtained when it was finally realized that the reaction of ethyl acetoacetate with acrolein was so rapid that a 2:1 adduct between acrolein and the keto ester was being obtained before an individual drop could be adequately mixed. By addition of an ethanolic solution of acrolein to the vortex of a stirred ethanol solution of a 30% excess of ethyl acetoacetate containing a trace of sodium ethoxide, consistent yields of about 47% of V were obtained. The aldehyde function of V was then selectively converted to a diethyl acetal (VI)[1] in 56% of yield by reaction of V with boiling ethanol containing ammonium chloride, under which conditions the ketone function was not converted to an enol ether.

Reaction of VI with guanidine hydrochloride and sodium methoxide in boiling absolute ethanol gave the crystalline pyrimidine VII in 76% yield; guanidine carbonate was equally effective. In order to complete the synthesis of XI *via* the anil X, it was considered necessary to block the 2-amino group of VII, before the aldehyde function was unblocked in order to avoid polymerization of the amino aldehyde (13, 15, 21). Acetylation of VII with hot acetic anhydride (13, 15, 21) gave small and variable yields of the crystalline acetamido acetal, VIII; the oily by-products appeared to contain *O*-acetate bands in the infrared, suggesting that some acetolysis of the acetal function was taking place in the mildly acidic medium. As a result of this apparent side reaction, acetylation was run with acetic anhydride in pyridine at 85° when consistent yields of crystalline VIII in the order of 57% were obtained.

Received September 27, 1962, from the Department of Medicinal Chemistry, School of Pharmacy, State University of New York at Buffalo, Buffalo 14.
Accepted for publication October 26, 1962.

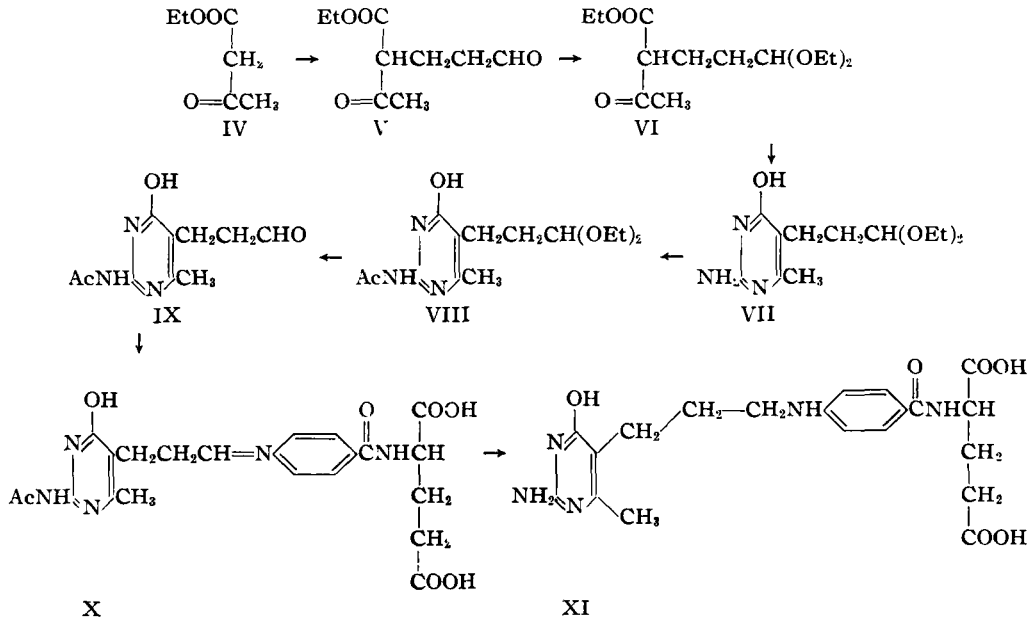
[1] Attempts to prepare VI by condensation of ethyl acetoacetate with β-chloropropionaldehyde diethyl acetal in absolute ethanolic sodium ethoxide with or without the presence of sodium iodide were unsuccessful. The reaction was slow, the products boiled over a wide range and examination of various fractions by analysis and infrared spectra did not give data compatible with structure VI.



Hydrolysis of the acetal function of VIII with 90% formic acid (13, 15, 21) gave variable yields of the crystalline aldehyde IX; unfortunately, the best yields were obtained on quantities of less than 1 Gm. of VIII. However, short boiling in water was sufficient to hydrolyze the acetal group of VIII to IX which was readily purified in consistent yields of 45–50%.

When a solution of the aldehyde IX and *p*-aminobenzoyl-L-glutamic acid in ethanol was refluxed for 1 hour, an amorphous precipitate separated from solution that resisted purification and gave poor analytical values for the supposed anil, X. In addition, the maximum amount of *p*-aminobenzoyl-L-glutamic acid, as determined quantitatively by the Bratton-Marshall reaction (22), that could be obtained on mild acid hydrolysis was 37–44 mole%; the analytical figures and the Bratton-Marshall values indicated that some de-N-acetylation of IX or X or both had occurred in the absolute alcohol, followed by the formation of higher condensation products. Although the anil was highly impure, this material did serve for working out suitable conditions for reduction and de-N-acetylation of X to the desired folic acid analog, XI.

The reduction of crude X with sodium borohydride was followed by a combination of change in ultraviolet spectrum at pH 1 and the amount of Bratton-Marshall dye obtained after short acid hydrolysis. The reduced product XI, had a peak at 222 mμ[2] that was absent in the anil, X, but present in *p*-aminobenzoyl-L-glutamic acid at 224 mμ with lower extinction coefficient; thus the reaction could be followed by the increase in extinction. The reduction of X in aqueous sodium bicarbonate with a large excess of sodium borohydride was complete in 1 hour at room temperature; the reaction was followed by periodic removal of aliquots, short hydrolysis in 1.5 *N* acid to remove the N-acetyl group, then measurement of the extinction coefficient at 222 mμ in 0.1 *N* acid. In this way the first sample of pure XI was obtained in about 15% yield.

Since the formation of the anil X in absolute ethanol led to side-reactions involving alcoholysis of the N-acetyl group, the anil was prepared *in situ* by reaction of IX with *p*-aminobenzoyl-L-glutamic acid in dimethylformamide; without isolation, the anil was reduced with sodium borohydride after the addition of methanol. In this way, XI was prepared in 44% yield (based on IX) containing about 5% of Bratton-Marshall positive material. Final purification afforded 21% of XI (based on IX) of pure product giving a negative Bratton-Marshall test.

The folic acid analog, XI, inhibited folic reductase (16) and had a $K_i = 2 \times 10^{-6}$, which is one-fifth the K_m value of folic acid. This compound also inhibited the dihydrofolic reductase from amethopterin-resistant Ehrlich ascites; an 0.2 m*M* concentration of XI gave a 66% inhibition of the enzymatic reaction run in the presence of 0.02 m*M* dihydrofolic acid (23). Since this compound is constructed from ethyl acetoacetate, acrolein, guanidine, *p*-aminobenzoic acid, and L-glutamic acid, it is obvious that a variety of substituted derivatives of XI can be made by modifying the five components or by transformations of VII; in this way, compounds could be obtained that—by use of non-classical antimetabolite theory (17–19)—might selectively inhibit some of the 15 enzymes in the folic acid cofactor area. In addition, considerable information could be obtained about the relative binding and conformational requirements of these substrates when complexed to their respective enzymes (14). Such a program is continuing in these laboratories.

EXPERIMENTAL[3]

Ethyl 2-Acetylglutaraldehydate (V).—To a vigor-

[2] It could be anticipated that the ultraviolet spectrum of XI and III (15) would be similar, since their chromophores are identical.

[3] Melting points were determined on a Kofler Heizbank and are corrected. Ultraviolet spectra were obtained on a Cary 11 recording spectrophotometer and infrared spectra on a Perkin-Elmer 137B recording spectrophotometer.

ously stirred solution of 130 Gm. (1 mole) of ethyl acetoacetate and 0.1 Gm. of sodium methoxide in 350 ml. of absolute ethanol was added dropwise to the vortex, a solution of 46.4 Gm. (0.83 mole) of acrolein in 100 ml. of absolute ethanol; the addition time was 70 minutes, the temperature was maintained at 10–13° by adequate cooling, and the solutions were protected from moisture. After standing for an additional 30 minutes without cooling, the solution was neutralized with acetic acid, then spin-evaporated to a syrup *in vacuo*. A solution of the syrup in 300 ml. of chloroform was washed with water, dried with magnesium sulfate and evaporated *in vacuo*. Distillation of the residue gave 66.2 Gm. (47%) of a colorless oil, b.p. 89–101° (0.5 mm.), that was suitable for the next step. Redistillation of a similar preparation gave pure material, b.p. 99–101° (0.5 mm.); $\lambda_{max.}^{film}$ 3.68 (aldehyde CH); 5.79 (aldehyde and ester C=O); 5.88 (ketone C=O); 6.12 (weak enolic C=C); 8.09, 8.20 μ (ester C—O—C).

Ethyl 2-Acetylglutaraldehydate Diethyl Acetal (VI).—To a solution of 66.2 Gm. (0.36 mole) of V in 450 ml. of absolute ethanol was added 2 Gm. of ammonium chloride. After being refluxed for 2 hours, the mixture was spin-evaporated to a syrup *in vacuo*. The residue was partitioned between 300 ml. of methylene chloride and 50 ml. of water. Washed again with 50 ml. of water and dried with magnesium sulfate, the organic solution was evaporated *in vacuo* and the residue distilled. After a forerun of 7.7 Gm. of unchanged V, the product distilled as a colorless oil, b.p. 107–124° (0.3 mm.) that was suitable for the next step; yield, 46.3 Gm. (50%). Redistillation gave the pure product, b.p. 110–112° (0.2 mm.); $\lambda_{max.}^{film}$ 5.77 (ester C=O); 5.84 (ketone C=O); 6.12 (weak enolic C=C); 8.09 (ester C—O—C); 9.45 μ (ether C—O—C). When the reaction was run for 4.5 hours, the yield was increased to 56%.

Anal.—Calcd. for $C_{13}H_{24}O_5$: C, 60.1; H, 9.64. Found: C, 60.0; H, 9.70.

β-(2-Amino-4-hydroxy-6-methyl-5-pyrimidyl)-propionaldehyde Diethyl Acetal (VII).—To a mixture of 1.52 Gm. (0.016 mole) of guanidine hydrochloride and 0.86 Gm. (0.016 mole) of sodium methoxide in 40 ml. of absolute ethanol was added 4.16 Gm. (0.016 mole) of VI. After being refluxed for 19 hours, the solvent was spin-evaporated *in vacuo*. The residue was partitioned between 50 ml. of chloroform and 30 ml. of water. The separated chloroform layer was dried with magnesium sulfate, then evaporated to dryness *in vacuo*. Recrystallization of the residue from ethyl acetate gave 3.1 Gm. (76%) of product, m.p. 176–177°, that was suitable for the next step. Further recrystallization from ethyl acetate afforded white crystals, m.p. 179–180°; $\lambda_{max.}^{KBr}$ 2.93, 3.14 (OH, NH); 6.10, 6.29 (NH, pyrimidine ring); 9.45 μ (ether C—O—C).

Anal.—Calcd for $C_{12}H_{21}N_3O_3$: C, 56.6; H, 8.31; N, 16.5. Found: C, 56.5; H, 8.10; N, 16.7.

β-(2-Acetamido-4-hydroxy-6-methyl-5-pyrimidyl)propionaldehyde Diethyl Acetal (VIII).—A solution of 15 Gm. of VII in 60 ml. of reagent pyridine and 40 ml. of acetic anhydride was heated in a bath at 80–90° for 1 hour protected from moisture. The solution was spin-evaporated to a syrup *in vacuo;* the evaporation was then repeated after the addition of 60 ml. of toluene. Recrystallization of the residue from ethyl acetate gave 10 Gm. (57%) of product, m.p. 148–150°. Further recrystallization from ethyl acetate afforded white crystals, m.p. 150°; $\lambda_{max.}^{KBr}$ 3.15 (NH); 6.05 (amide I); 6.28, 6.38 (NH and pyrimidine ring); 9.44, 9.66 μ (ether C—O—C).

Anal.—Calcd. for $C_{14}H_{23}N_3O_4$: C, 56.6; H, 7.81; N, 14.1. Found: C, 56.8; H, 7.94; N, 14.3.

β-(2-Acetamido-4-hydroxy-6-methyl-5-pyrimidyl)propionaldehyde (IX).—A solution of 1.00 Gm. (4.5 mmoles) of VIII in 50 ml. of water was refluxed for 1 hour, then spin-evaporated to dryness *in vacuo*. Two recrystallizations from ethyl acetate gave 0.34 Gm. (45%) of pure IX, m.p. 158–160°; $\lambda_{max.}^{pH\ 1}$ 228 (ϵ 8880), 270 mμ (ϵ 8270); $\lambda_{max.}^{pH\ 8.4}$ 270 mμ (ϵ 5350); $\lambda_{max.}^{pH\ 13}$ 278 mμ (ϵ 10,500); $\lambda_{max.}^{KBr}$ 3.16 (OH, NH); 3.65 (aldehyde CH); 5.87 (aldehyde C=O); 6.16 (amide I and pyrimidine ring); 6.74 (NH and pyrimidine ring); no ether C—O—C near 9.5 μ.

Anal.—Calcd. for $C_{10}H_{13}N_3O_3$: C, 53.8; H, 5.87; N, 18.8. Found C, 53.6; H, 5.95; N, 18.6.

N-[1-(2-Amino-4-hydroxy-6-methyl-5-pyrimidyl)-3-propyl]-p-aminobenzoyl-L-glutamic Acid (XI).—A solution of 100 mg. (0.5 mmoles) of IX and 120 mg. (0.5 mmoles) of *p*-aminobenzoyl-L-glutamic acid in 2 ml. of dimethylformamide was allowed to stand for 10 minutes, then diluted with 15 ml. of reagent methanol. The solution was then treated with 0.20 Gm. of sodium borohydride portionwise with stirring over a period of 30 minutes, then stirred overnight at room temperature. After the addition of 5 ml. of 0.1 *N* sodium hydroxide, the solution was spin-evaporated *in vacuo* to 5 ml., then acidified to pH 5 with 3 *N* hydrochloric acid. After being chilled for several hours, the mixture was centrifuged and the white solid washed successively with water (2 × 5 ml.), absolute alcohol (2 × 5 ml.) and dry ether (5 ml.); yield, 84 mg. (44%) that contained 5% of Bratton-Marshall positive material calculated as the anil (X). Recrystallization from dimethylformamide by addition of water gave 40 mg. (21%), m.p. >250°, of pure material, as determined by its ultraviolet spectra and negative Bratton-Marshall test. A similar preparation was analyzed and had $\lambda_{max.}^{pH\ 1}$ 222 (ϵ 27,800), 270 (ϵ 19,200), and 303 mμ (ϵ 11,400); $\lambda_{max.}^{pH\ 8.4}$ 295 mμ (ϵ 15,100); $\lambda_{max.}^{pH\ 13}$ 284 mμ (ϵ 20,500).

Anal.—Calcd. for $C_{20}H_{23}N_5O_6$: C, 55.8; H, 5.85; N, 16.2. Found: C, 56.2; H, 5.66; N, 16.5.

The Bratton-Marshall test was performed in the following way. A 1-ml. aliquot in 5% aqueous sodium bicarbonate, estimated to contain 0.2 to 0.5 mg. of XI, was diluted with 1 ml. of 3 *N* hydrochloric acid, then heated on a steam-bath for 15 minutes to hydrolyze any anil (X) to *p*-aminobenzoyl-L-glutamic acid. This solution was then cooled, diazotized and coupled with N-(1-naphthyl)-ethylenediamine as described by Bratton and Marshall (22). The amount of dye was determined by its extinction at 560 mμ using *p*-aminobenzoyl-L-glutamic acid as a standard.

Nonaqueous Titrimetric Analysis of Aminophylline

By THOMAS MEDWICK and FREDERICK SCHIESSWOHL

A nonaqueous potentiometric titration is described by which ethylenediamine and theophylline, the components of aminophylline, are titrated differentially as a mixture of bases. Acetic acid is used as the solvent for the ethylenediamine neutralization after which acetic anhydride is added to the system to allow titration of the theophylline, a very weak base. This method was applied to the analysis of aminophylline powder, tablets, ampuls, and suppositories. When compared with the U.S.P. XVI analyses, the nonaqueous approach is simpler since no elaborate sample treatment is needed. The precision of the one titration, nonaqueous procedure is about the same as the U.S.P. XVI analyses which require two titrations to obtain the same data. An alternative approach is suggested for cases, for example, some tablets, where the nonaqueous method is not successful.

VARIOUS APPROACHES to the analysis of aminophylline, a mixture of theophylline and ethylenediamine, have been reported. In the majority, these procedures measure the theophylline which is present and (by appropriate calculation) express the result as aminophylline. Connors (1) discussed the argentometric, ultraviolet spectrophotometric, and other methods which have been used. In the U.S.P. XVI (2–5) the theophylline content of aminophylline in its various forms is determined by an argentometric titration procedure involving several preliminary steps. In aminophylline powder and ampuls only (2, 3) in addition to the theophylline analysis, an ethylenediamine assay is specified.

The xanthines, theophylline, theobromine, and caffeine possess analytically useful acid-base properties. All three xanthines have been found to be very weakly basic, pKb's (aqueous) > 13 (6), and, in addition, theophylline and theobromine are weakly acidic, pKa (aqueous) = 8.6, pKa (aqueous) = 10, respectively. Acetic anhydride has been used as a solvent component in the titration of these compounds as bases. The titrant used exclusively was acetous perchloric acid. Theophylline has been titrated in a 4:1 nitromethane-acetic anhydride solvent (7) and theobromine, dihydroxypropyltheophylline, and caffeine were titrated in mixed solvents containing acetic anhydride and nitromethane, benzene, toluene, or dioxane (8, 9). Similarly, Anastasi, Gallo, and Novacic (10) reported the satisfactory titration of caffeine in an acetic anhydride–acetic acid solvent. Recent work by Ellert, Jasinski, and Pawelczak (11) showed that, although theophylline did not titrate as a base in propionic acid, a propionic acid–propionic anhydride solvent permitted satisfactory titration as a base. Employing the acidic behavior of theophylline, McEniry (12) was able to determine the theophylline content of aminophylline by titrating a sample in dimethylformamide with sodium methoxide titrant.

Although nonaqueous titrimetric methods have been applied to theophylline determination, no work appears to have been done in regard to measuring both the theophylline and ethylenediamine by this means. Since ethylenediamine

is a distinctly basic compound, pKb (aqueous) = 4.07 (13), it should be readily titratable. This communication deals with the selection and analytical use of a nonaqueous solvent system in which ethylenediamine and theophylline, the components of aminophylline, can be determined differentially as bases by a single titration.

EXPERIMENTAL

Pharmaceuticals, Chemicals, and Reagents Used

Aminophylline powder U.S.P., Merck and Co., Inc., Rahway, N. J.; aminophylline tablets, 100 and 200 mg., containing at least 80% anhydrous theophylline; aminophylline injection, 500 mg. in 2 ml., containing at least 80% anhydrous theophylline and benzyl alcohol, 2% v/v; aminophylline suppositories, 0.5 Gm., (cocoa-butter base with paraffin) were employed.

All chemicals were reagent grade. Acetous perchloric acid, *ca.* 0.1 *N*, was prepared according to Fritz (14) and standardized against triphenylguanidine with α-naphtholbenzein indicator. The indicator was a 0.2% w/v solution in glacial acetic acid.

Selection of a Solvent System

The properties of ethylenediamine and theophylline complicate the selection of a suitable titration medium. Although acetic acid (a valuable solvent for the titration of bases) would permit satisfactory determination of the stronger base, ethylenediamine, theophylline is too weakly basic to be determined in this solvent. Theophylline has been successfully determined in an acetic anhydride–containing solvent (7). However, if the anhydride were used here, reaction with ethylenediamine in the sample would destroy the desired basic properties of the amine unless the amine was already titrated or the titration was carried out at a low temperature (15). As a result of these considerations the following approach was developed.

After the aminophylline sample is dissolved in glacial acetic acid, it is potentiometrically titrated with acetous perchloric acid in the presence of an indicator which shows the completion of the ethylenediamine neutralization without the necessity of a preliminary potential (mv.) *versus* titrant added (ml.) plot. A small additional volume of titrant is added, followed by a volume of acetic anhydride. The titration is continued in this new medium until complete. This basic procedure is varied as needed in cases of specific dosage form analysis.

Procedures

The potentiometric titrations were conducted using a Beckman model N pH meter equipped with a glass electrode (Beckman No. 41263) and a sleeve-type calomel electrode (Beckman No. 40463) in which the aqueous saturated potassium chloride solution was replaced with 0.2 *M* acetous lithium chloride. A 10-ml. teflon stopcock Koch microburet was employed.

Aminophylline Powder.—About 0.135 Gm. of aminophylline is accurately weighed and dissolved in 30 ml. of glacial acetic acid in a beaker. After six drops of α-naphtholbenzein indicator solution are added, the solution is potentiometrically titrated with *ca.* 0.1 *N* acetous perchloric acid using the electrode system previously described. When the solution exhibits a green tinge, the volume is recorded and a total of 2 ml. of the titrant is added in two increments. Ten milliliters of acetic anhydride is introduced into the solution; the titration is continued until complete. A plot of the data, mv. observed *versus* ml. of titrant, is constructed and the end points graphically determined (16).

Aminophylline Tablets.—A sample of 20 tablets is accurately weighed, ground to a fine powder, and a sample of the powder equivalent to *ca.* 0.135 Gm. of aminophylline is then accurately weighed into a beaker. Thirty milliliters of glacial acetic acid are added and the analysis is carried out as described above under *Aminophylline Powder* by following the procedure from "After six drops of α-naphtholbenzein . . ."

Aminophylline Injection.—A volume of the injection equivalent to 500 mg. of aminophylline is accurately measured and transferred into a 100-ml. volumetric flask. Acetic acid is used to bring the solution to the mark. A sample of exactly

Curve D–Titration of a sample of aminophylline injection 500 mg./2 ml. in glacial acetic acid with the addition of acetic anhydride after the first inflection point. Curve E–Titration of a sample of 0.5-Gm. aminophylline suppositories in chloroform-acetic acid with the addition of acetic anhydride after the first inflection point.

25 ml. is transferred to a beaker which contains 5 ml. of glacial acetic acid. The analysis is carried out as described above under *Aminophylline Powder* by following the procedure from "After six drops of α-naphtholbenzein ..." being certain to note the following conditions.

When the injection taken for analysis contains 500 mg. in 2 ml., then 10 ml. of acetic anhydride is used as directed under *Aminophylline Powder*. However, when the injection to be analyzed contains 500 mg. in 20 ml., then 40 ml. of acetic anhydride is added, the remainder of the procedure continuing unchanged.

Aminophylline Suppositories.—A small beaker and glass rod are tared after which five suppositories are placed into the beaker and accurately weighed. The beaker is heated until the suppositories are melted; the melt is allowed to cool without mixing. When solid, an amount of sample equivalent to about 0.5 Gm. of aminophylline is weighed and placed into a beaker. Chloroform, 60 ml., and acetic acid, 40 ml., are added alternately in small quantities and mixed with the sample until solution is completed. The sample solution is transferred quantitatively to a 100-ml. volumetric flask and brought to volume with any chloroform and acetic acid remaining. Chloroform–acetic acid, 3:2 v/v, may be used, if needed, to complete the dilution. A sample of exactly 25 ml. is transferred to a beaker containing 15 ml. of glacial acetic acid. The analysis is carried out as described above under *Aminophylline Powder* by following the procedure from "After six drops of α-naphtholbenzein ..."

U.S.P. Analyses.—Each sample was analyzed by the official U.S.P. XVI methods (2–5).

Calculation for the Nonaqueous Procedures.—

$$\text{Ethylenediamine, \%} = \frac{\text{ml. (first end point)} \times N_{HClO_4} \times 0.03005}{\text{Gm. aminophylline in sample}}$$

$$\text{Theophylline, \%} = \frac{\text{ml. (second end point} - \text{first end point)} \times N_{HClO_4} \times 0.1802}{\text{Gm. aminophylline in sample}}$$

$$\text{Aminophylline dihydrate, \%} = \frac{\text{ml. (second end point)} \times N_{HClO_4} \times 0.1141}{\text{Gm. aminophylline dihydrate in sample}}$$

RESULTS AND DISCUSSION

The titrimetric behavior of aminophylline as a mixture of two bases was observed as expected according to the aqueous pKb values. Although the pKb difference (*ca.* 10 units) is sufficient to permit the bases to be differentiated in glacial acetic acid solvent (Fig. 1, Curve A), it is noted that only the first inflection, representing the neutralization of the stronger base, ethylenediamine, is analytically useful. The second inflection point, assignable to theophylline neutralization, is not satisfactory.

Acetic anhydride has been found to be a valuable solvent for the titration of very weak bases (15, 17). More than simply producing an anhydrous medium by reacting with water (a weak base), this ability has been related to the presence in acetic anhydride of a species more acidic than the solvated proton in acetous perchloric acid (18). Figure 1, curve B, represents the titrimetric behavior of a sample of aminophylline powder in acetic acid solution to which acetic anhydride was added after the first (ethylenediamine) neutralization was completed. It is noted that the character of the second or theophylline neutralization is improved. Both inflections are now analytically suitable.

The nature of Fig. 1, curves B, C, D, and E indicates that satisfactory titrimetric behavior was experienced when aminophylline analyses were carried out on the powder, tablets, injection, and suppositories, respectively. Graphical determination of the end point was possible without difficulty.

The analytical results are summarized in Table I. Each of the samples were analyzed by the official analytical procedures as well as by the nonaqueous titration technique. All of the aminophylline monographs (except for the powder) require the argentometric result (theophylline determination) to be expressed as aminophylline dihydrate. Where possible, the nonaqueous data are presented in the same form as the official analytical results. The nonaqueous calculation is made using the total volume of acid consumed, *i.e.*, the volume needed to neutralize both the ethylenediamine and theophylline. Because of the differential nature of the nonaqueous titration, the percentage of ethylenediamine is calculated from the first end point volume obtained from the same curve.

It is noted that the ethylenediamine content of the

TABLE I.—SUMMARY OF AMINOPHYLLINE ANALYSES[a]

	Nonaqueous			U.S.P. XVI[b]		
	n[d]	Ethylenediamine, %	Xanthine, %	n[d]	Ethylenediamine, %	Xanthine, %
Aminophylline powder U.S.P.	8	12.9 ± 0.2	83.2 ± 1.2 (as theophylline)	3	13.1 ± 0.1 (12.8–14.1)	82.5 ± 0.8 (78 to 83.5) (as theophylline)
Aminophylline tablets, 200 mg.	4	12.6 ± 0.1	98.8 ± 0.1 (as aminophylline dihydrate)	4	...[c]	102.0 ± 0.6 (93–107) (as aminophylline dihydrate)
Aminophylline injection, 500 mg./2 ml.	3	19.4 ± 0.1	81.3 ± 0.4 (as theophylline)	3	19.0 ± 0.1 (18.8–20.1)	102.1 ± 1.3 (93–107) (as aminophylline dihydrate)
Aminophylline suppositories, 500 mg.	4	12.0 ± 0.2	101.7 ± 0.9 (as aminophylline dihydrate)	4	...[c]	102.9 ± 0.2 (90–110) (as aminophylline dihydrate)

[a] Values are means and their standard deviation. [b] Values in parentheses indicate acceptable U.S.P. range. [c] No official analysis specified in this case. [d] Number of determinations is n.

injection is higher than in the other dosage forms when determined by either method. The U.S.P. provides for the addition of excess ethylenediamine to assure a clear solution (3). Thus, when the nonaqueous analysis is carried out, the total volume of acid consumed does not represent aminophylline only but includes the additional ethylenediamine. The calculation reported in Table I, in this instance, is made from the volume of acid used to neutralize the theophylline present and is expressed as percentage of theophylline. The percentage of ethylenediamine is reported also.

When the procedure for the analysis of aminophylline injection is examined, it is noted that the amount of acetic anhydride to be added is variable. Since injections of different concentration are available, the amount of acetic anhydride added must be altered to react with all the water introduced in sampling the aqueous injection solution. In addition to creating a water-free solution, enough excess anhydride remains to be consistent with the 15–20% (by volume) anhydride–acetic acid composition employed in the other dosage form procedures.

Inspection of the data presented in Table I indicate reasonable agreement between the nonaqueous and official methods. The largest deviation exists in the case of the 200-mg. tablets where the nonaqueous value is about 3% lower than the official result. The precision of both methods is found to be about 0.1 to 0.2% for ethylenediamine and about 0.7% for the xanthine (as theophylline or aminophylline dihydrate).

This nonaqueous method was not applicable in the case of some tablets. Although satisfactory results were achieved with 200-mg. tablets, very high results were noted in the analysis of 100-mg. tablets. From the appearance of the titration curves, it was apparent that some tablet constituent other than ethylenediamine and theophylline was acting as a base and contributing to the high results. This behavior was not unexpected and was attributed to the presence of sodium sulfate in the formulation. The interference of various tablet components in acetic acid–nonaqueous titrimetric procedures has been reported (19, 20) and should be anticipated.

Since the nonaqueous method was not successful in the analysis of some tablets, an alternative means of analysis was sought. The official approach to the measurement of ethylenediamine in aminophylline powder and injection employs titration of a sample in water to a methyl orange end point. This simple aqueous titration was found to work well for the determination of ethylenediamine in aminophylline tablets. However, in the present work, better end point detection was achieved by the use of bromcresol green indicator (21). Thus, when the nonaqueous method is unsuccessful, the argentometric or ultraviolet spectrophotometric methods for theophylline determination (1) may be combined with the aqueous titration of ethylenediamine for complete aminophylline analysis.

The nonaqueous procedure offers certain advantages when compared with the official analytical approach. The nonaqueous method is capable of measuring both components of aminophylline in a single titration without elaborate sample treatment. There are fewer reagents needed and the time-consuming heating, cooling, and filtration of the official argentometric assay are eliminated. The simplified procedure is of particular note in the case of the official suppository analysis which involves liquid-liquid extraction as well.

SUMMARY

A time saving, nonaqueous titrimetric procedure has been developed whereby the components of aminophylline, ethylenediamine, and theophylline are titrated differentially as bases during a single titration.

The precision of the described method is similar to the official analysis which requires elaborate sample treatment as well as two titrations to obtain the same data.

The nonaqueous method was not successful in the analysis of certain aminophylline tablets because of the presence of basic tablet components. An alternative approach has been suggested.

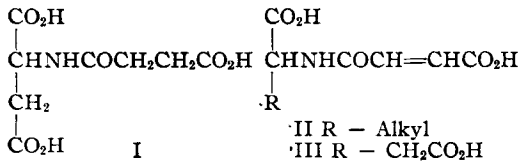
Some Derivatives of Aspartic and Glutamic Acids

By AJAY K. BOSE† and RICHARD E. STRUBE

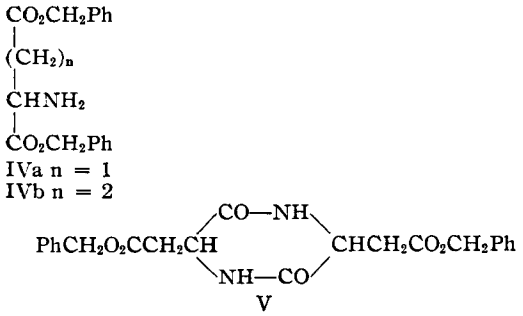
N-Acylation of L-glutamic and L-aspartic acids was carried out under mild conditions *via* their benzyl esters. Anomalous racemization was observed with some aspartic acid derivatives.

In connection with some research on the biogenesis of diaminopimelic acid (1) a sample of N-(β-carboxypropionyl)-L-aspartic acid (I) was required. It has been reported (2) that amino acids in aqueous solution react with maleic anhydride in benzene solution to give the N-acylated derivative II in good yield

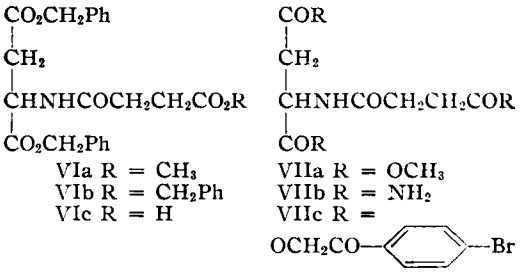


We attempted the preparation of N-(β-carboxyacroyl)-L-aspartic acid (III) by this method with the aim of hydrogenating it to the desired aspartic acid derivative, I; however, neither L-aspartic acid nor its disodium salt reacted with maleic anhydride or succinic anhydride (3). β-Carbomethoxypropionyl chloride and disodium aspartate (4) also failed to lead to the desired product.

In the hope that acylation might be more successful in a homogeneous reaction mixture, it was decided to use dibenzyl L-aspartate (IVa) which is soluble in organic solvents. This ester was obtained as a viscous oil which on long standing deposited a crystalline solid. The diketopiperazine structure V has been assigned to this on the basis of elemental analyses, molecular weight, and infrared spectrum



Dibenzyl L-aspartate (IVa) reacted readily with β-carbomethoxypropionyl chloride and β-carbobenzyloxypropionyl chloride to give the N-acylated products VIa and VIb, respectively. Hydrogenolysis of VIb gave an amorphous product whose infrared spectrum showed the presence of the amide and carboxyl functions expected of I. It was found that IVa condensed with succinic anhydride to give the N-acylated compound VIc in excellent yield. Hydrogenolysis of VIc afforded I as an amorphous material



On treatment of I with diazomethane an oily trimethyl ester (VIIa) was obtained; this gave a crystalline amide (VIIb) by reaction with alcoholic ammonia. Compound I was further characterized by the preparation of a crystalline *p*-bromophenacyl ester (VIIc).

N-Phthaloyl amino acids are of importance in peptide synthesis. Some amino acids, such as L-aspartic and L-glutamic acids, undergo racemization during phthaloylation by the fusion method. Alternative multi-step procedures have been described for the preparation of N-phthaloyl derivatives of L-aspartic and L-glutamic acids (5–10). The availability of dibenzyl L-aspartate made it possible to explore yet another mild method of phthaloylation that has been described recently (11, 12). This method, which involves phthaloylation in toluene solution in presence of triethylamine, was also applied to esters of L-glutamic acid.

EXPERIMENTAL[1]

Benzyl esters of amino acids were prepared as their *p*-toluene-sulfonate salts by using the method of Cipera and Nicholls (13). The free esters, obtained in high yield on shaking the salts with cold sodium bicarbonate solution, were optically active and could

The authors extend their thanks to Dr. D. T. Warner for a sample of γ-benzyl L-glutamate, to Mr. W. A. Struck and his associates for analytical and spectroscopic data, and to Mr. A. R. Hanze for his interest in this work.

† Present address: Department of Chemistry and Chemical Engineering, Stevens Institute of Technology, Hoboken, N. J.

[1] All melting points are uncorrected.

be used for acylation without further purification. β-Benzyl L-aspartate was prepared by using the procedure described for γ-benzyl L-glutamate (14).

Dibenzyl L-Aspartate *p*-Toluenesulfonate.—*p*-Toluenesulfonic acid monohydrate (60.0 Gm., 0.32 mole), L-aspartic acid (40.0 Gm., 0.30 mole), and benzyl alcohol (100 ml., 104 Gm., 0.96 mole) were placed in a 1-L. flask provided with a mechanical stirrer and a Dean-Stark water separator with condenser. The mixture was heated for 18 hours under vigorous reflux. Fifteen milliliters of water was collected during this period. The clear solution was cooled in ice and the precipitate removed by filtration. The crude product (131 Gm., yield 74%), recrystallized twice from water containing 5% of ethanol, yielded 82 Gm. (41%); m.p. 157–158°, $[\alpha]_D^{25}$ + 1° (95% EtOH).

Anal.—Calcd. for $C_{25}H_{27}NO_7S$: C, 61.85; H, 5.61; S, 6.59. Found: C, 61.44; H, 5.69; S, 6.61.

The preparation of dibenzyl DL-aspartate *p*-toluenesulfonate by a similar procedure has been described (15).

Dibenzyl L-Aspartate (IVa).—One hundred grams (0.206 mole) of dibenzyl L-aspartate *p*-toluenesulfonate was added to a cold mixture of 500 ml. of ether and 100 ml. of water in a separator and shaken. A cold, nearly saturated solution of 45.0 Gm. (0.363 mole) of sodium carbonate monohydrate was then added and the mixture shaken vigorously for a few minutes. The ether layer was separated and the aqueous layer was extracted several times with ether. The combined ether extracts were dried over anhydrous sodium sulfate. On removing the solvent under reduced pressure at room temperature, 57.4 Gm. (88%) of a slightly yellow oil (IVa) was obtained. Purification of this product by distillation under reduced pressure could not be accomplished because the compound decomposed at about 90° with the formation of succinic anhydride, m.p. 119°.

For identification, 3.0 Gm. of the oil IVa was converted to its hydrochloride (2.6 Gm., 60%) which was recrystallized from methanol-ether, m.p. 129.5 to 130° [lit. (16) m.p., 124–125°], $[\alpha]_D^{25}$ + 1 (95% ethyl alcohol).

Anal.—Calcd. for $C_{18}H_{20}ClNO_4$: C, 61.79; H, 5.76; Cl, 10.14; N, 4.01. Found: C, 61.70; H, 6.02; Cl, 9.93; N, 4.03.

After standing for several weeks at room temperature, the compound IVa deposited crystals which were removed by filtration. Compound V melted at 157–158° after washing with acetone and recrystallization from ethanol.

Anal.—Calcd. for $C_{22}H_{22}N_2O_6$: C, 64.38; H, 5.40; N, 6.83; mol. wt., 410. Found: C, 64.32; H, 5.57; N, 6.95; mol. wt., 434.

$\nu_{max.}^{Nujol}$ in cm.$^{-1}$: 3290, 3150 (N—H); 1735 (SH), 1730 (ester CO); 1688, 1655 (amide CO).

Hydrogenolysis of Dibenzyl L-Aspartate.—The ester IVa (3.13 Gm.) was dissolved in 25 ml. of absolute methanol and hydrogenated at an initial pressure of 20 lbs./sq. in. in the presence of 1.5 Gm. of 10% palladium-on-charcoal. The catalyst and the precipitate were removed by filtration and then extracted with 500 ml. of hot water. The clear aqueous solution was lyophilized. The rotation and infrared spectrum of the product were identical with that of L-aspartic acid.

β-Benzyl L-Aspartate.—Fifty milliliters of concentrated sulfuric acid followed by 500 ml. of benzyl alcohol were added carefully to 500 ml. of ether. The ether was removed under reduced pressure and 66.5 Gm. (0.50 mole) of L-aspartic acid was added. The solution was kept at room temperature for 20 hours, then cooled to 0°, and a mixture of 250 ml. of pyridine in 1000 ml. of ethanol (96%) was added under vigorous stirring. The precipitate (71 Gm., 63%) was removed by filtration and washed with ether after standing overnight in the refrigerator. Recrystallization from 1000 ml. of water containing 10 ml. of pyridine gave 37 Gm. (33%) of pure XI: m.p. 211.5 to 212.5° dec.; $[\alpha]_D^{25}$ + 27° (1 *N* HCl).

Anal.—Calcd. for $C_{11}H_{13}NO_4$: C, 59.18; H, 5.87; N, 6.28. Found: C, 58.86; H, 6.01; N, 6.33.

Benzyl Esters of L-Glutamic Acid.—Under conditions similar to those described above for L-aspartic acid, the reaction of 33.0 Gm. (0.224 mole) of L-glutamic acid, 75 ml. (0.723 mole) of benzyl alcohol, and 45.0 Gm. (0.238 mole) of *p*-toluenesulfonic acid monohydrate in benzene for 13 hours afforded 98 Gm. (88%) of dibenzyl L-glutamate *p*-toluenesulfonate, m.p. 122.5 to 128.5°. On recrystallization from hot water, the m.p. was raised to 139.5 to 141.5°.

Anal.—Calcd. for $C_{26}H_{29}NO_7S$: C, 62.71; H, 5.87; N, 2.80; S, 6.41. Found: C, 62.47; H, 5.76; N, 3.05; S, 6.66.

When 14.7 Gm. (0.100 mole) of L-glutamic acid, 30 ml. of benzyl alcohol, 19.2 Gm. (0.110 mole) of *p*-toluenesulfonic acid monohydrate, and 75 ml. of benzene were allowed to react for only 4 hours, the product amounted to 43.5 Gm. of a white solid. On recrystallization from ethanol-ether, 33 Gm. of a solid, m.p. 147–153°, was obtained. A solution of 2.00 Gm. of this material in 20 ml. of 95% alcohol was stirred; 5 ml. of pyridine was added dropwise. After storage overnight in an icebox, the solid was filtered, washed with cold alcohol, and dried to give 0.68 Gm. (43%) of γ-benzyl L-glutamate (IXc), m.p. 162–164°, $[\alpha]_D^{25}$ + 19° (c = 2.62 in acetic acid). A sample of this ester prepared by following the method of Guttmann and Boissonnas (14) showed m.p. 168° and $[\alpha]_D^{25}$ + 18.6° (c = 5.855 in acetic acid).

Using the same method as for preparing IVa, 54.0 Gm. of dibenzyl L-glutamate *p*-toluenesulfonate was converted into 34.4 Gm. (97%) of the free diester IVb. This ester was characterized by its conversion in a nearly quantitative yield to its hydrochloride, m.p. 99–100°, $[\alpha]_D^{25}$ + 9° (0.1 *N* HCl) [lit. (17) m.p., 100–102°, $[\alpha]_D^{25}$ + 9.4°].

Anal.—Calcd. for $C_{19}H_{22}ClNO_4$: C, 62.71; H, 6.09; Cl, 9.74. Found: C, 62.77; H, 6.25; Cl, 9.67.

L-Leucine Benzyl Ester *p*-Toluenesulfonate.—This compound was prepared from L-leucine (26.2 Gm., 0.200 mole), benzyl alcohol (35 Gm., 0.32 mole), and *p*-toluene sulfonic acid monohydrate (40.0 Gm., 0.230 mole) by the esterification procedure described above. The yield of the crude product was 50 Gm. (62%). After recrystallization from water, the m.p. was 211.5 to 212.5° dec.

Anal.—Calcd. for $C_{20}H_{27}NO_5S$: C, 61.04; H, 6.92; N, 3.56; S, 8.15. Found: C, 61.21; H, 7.05; N, 3.84; S, 8.22.

N-(β-Carbomethoxyprepionyl)-L-aspartic Acid,

Dibenzyl Ester (VIa).—A solution of 1.9 Gm. (0.015 mole) of sodium carbonate monohydrate in 4.5 ml. of water was added to a solution of 9.4 Gm. of freshly prepared IVa in 50 ml. of ether. A solution of 3-carbomethoxypropionyl chloride (18) in 50 ml. of ether was added dropwise to this mixture in the course of 30 minutes at 15–17°. After stirring for another 30 minutes the ether layer was separated, dried over anhydrous sodium sulfate, and the solvent removed under reduced pressure. The residual oil (11.7 Gm., 91%) solidified after standing for 2 days under reduced pressure over concentrated sulfuric acid. Recrystallization from petroleum ether gave 9.1 Gm. (71%) of VIa, m.p. 57–58°.

Anal.—Calcd. for $C_{23}H_{25}NO_7$: C, 64.62; H, 5.89; N, 3.28. Found: C, 64.73; H, 5.99; N, 3.19.

β-Carbobenzyloxypropionyl Chloride.—A mixture of benzyl hydrogen succinate (19) (6.24 Gm., 0.040 mole) and thionyl chloride (9.5 Gm., 0.080 mole) was heated in a bath at 35–40° for 100 minutes. The excess thionyl chloride was removed under reduced pressure at room temperature. The colorless oil could not be purified by distillation under reduced pressure and was, therefore, used directly for the preparation of VIb.

N-(β-Carbobenzyloxypropionyl)-L-aspartic Acid, Dibenzyl Ester (VIb).—A solution of 2.0 Gm. (0.016 mole) of sodium carbonate monohydrate in 4.5 ml. of water was added to a solution of 9.4 Gm. of freshly prepared IVa in 50 ml. of methylene chloride. A methylene chloride solution of 3-carbobenzoxypropionyl chloride (prepared freshly from 6.24 Gm. (0.040 mole) of the corresponding acid) was added dropwise to this mixture in the course of 30 minutes at 10–15°. Proceeding in a similar manner as described above for compound VIa, 13.6 Gm. (90%) of VIb, m.p. 70 to 71.5°, was obtained.

Anal.—Calcd. for $C_{29}H_{29}NO_7$: C, 69.17; H, 5.81; N, 2.78. Found: C, 69.08; H, 5.49; N, 2.74.

N-(β-Carboxypropionyl)-L-aspartic Acid, Dibenzyl Ester (VIc).—A solution of 28.8 Gm. of freshly prepared IVa and 9.0 Gm. (0.090 mole) of succinic anhydride in 300 ml. chloroform was heated under reflux for 30 minutes. After removing the solvent by distillation, an oil (36.6 Gm.) was obtained which crystallized on scratching with a glass rod and adding some petroleum ether. Recrystallization from carbon tetrachloride gave 34.9 Gm. (96%) of a white solid, m.p. 97–98°.

Anal.—Calcd. for $C_{22}H_{23}NO_7$: C, 63.91; H, 5.61; N, 3.39. Found: C, 63.76; H, 5.63; N, 3.36.

N-(β-Carboxypropionyl)-L-aspartic Acid (I).—(*a*) Compound VIb (0.5 Gm., 0.001 mole), dissolved in 150 ml. of absolute methanol, was catalytically hydrogenated in the presence of 2.0 Gm. of 10% palladium-on-charcoal and at an initial pressure of 50 lbs./sq. in. The hydrogenation was complete in 5–10 minutes. The catalyst was removed by filtration and the solvent was distilled under reduced pressure over phosphorus pentoxide. Attempts to crystallize the oil were unsuccessful even after several months of storage.

Anal.—Calcd. for $C_8H_{11}NO_7$: C, 41.20; H, 4.76; N, 6.01. Found: C, 41.70; H, 4.91; N, 5.67.

(*b*) Compound VIa was hydrogenated as described above and the product was isolated as an amorphous solid.

Anal.—Calcd. for $C_8H_{11}NO_7$: C, 41.20; H, 4.76; N, 6.01. Found: C, 41.40; H, 5.12; N, 5.53.

N-(β-Carboxypropionyl)-L-aspartic Acid, Trimethyl Ester (VIIa).—Compound VIc (1.0 Gm.) was hydrogenated as described above; to the methanol solution of the product (*ca.* 3 ml.) was added dropwise with stirring at 0–5° a cold solution of diazomethane in ether until a yellow color remained. After standing for 10 minutes, dilute 1:4 hydrochloric acid was added until the yellow color of the excess diazomethane had disappeared. The ether layer was washed with water and dried over anhydrous sodium sulfate. After removing the solvent by distillation a colorless oil was obtained, the infrared spectrum of which indicated that no free carboxyl group was present. The product was used directly for preparing compound VIIb.

N-(β-Carboxypropionyl)-L-aspartic Acid, Triamide (VIIb).—Compound VIIa was dissolved in 3 ml. of absolute ethanol and 10 ml. of ethanol saturated with ammonia was added. The flask was stoppered and left at room temperature for 1 week. The precipitate formed was removed by filtration, washed with absolute ethanol, and recrystallized from water. The yield was 0.47 Gm. (82% based on compound VIc), m.p. 220.5 to 221.0° dec.

Anal.—Calcd. for $C_8H_{14}N_4O_4$: C, 41.73; H, 6.13. Found: C, 41.55; H, 6.05.

N-(β-Carboxypropionyl)-L-aspartic Acid, Tri-(*p*-bromophenacyl) Ester (VIIc).—Compound VIb (1.0 Gm.) was hydrogenated as mentioned before; after removing the solvent, the acid was neutralized with 0.1 *N* sodium hydroxide and then lyophilized. Water (10 ml.) and a solution of 2.98 Gm. (0.01 mole) of *p*-bromophenacylbromide in 100 ml. of absolute ethanol were added. The solution was heated on the steam bath for 3 hours, filtered, and cooled in the refrigerator for several hours. The crystalline product formed was recrystallized from absolute ethanol, m.p. 138–139° dec.

Anal.—Calcd. for $C_{32}H_{26}Br_3NO_{10}$: C, 46.62; H, 3.68; Br, 29.08; N, 1.69. Found: C, 46.58; H, 3.50; Br, 29.40; N, 1.78.

N-Phthaloyl-L-aspartic Acid.—(*a*) A mixture of 4.85 Gm. of dibenzyl L-aspartate (IVa), 2.3 Gm. (0.015 mole) of phthalic anhydride, 0.5 ml. of triethylamine, and 100 ml. of toluene was heated under reflux for 3.5 hours in a flask fitted with a Dean-Stark water separator. On working up the reaction product as described in (*b*), 6.3 Gm. of an oil was obtained which on hydrogenation gave 3.7 Gm. of a solid. Crystallization from hot water following decolorization with Darco charcoal gave a solid, m.p. 223–226°, $[\alpha]_D^{25} - 39°$ (c = 0.639 in ethanol) [lit. (10) m.p., 197°, $[\alpha]_D^{25} - 58°$ (methanol)]. The infrared spectrum of this material was identical with that of phthaloyl aspartic acid.

(*b*) Finely powdered phthalic anhydride (1.48 Gm., 0.0100 mole) was dissolved with shaking in a mixture of 250 ml. of toluene and 10 ml. of triethylamine. A 4.85-Gm. (0.0100 mole) quantity of dibenzyl L-aspartate *p*-toluenesulfonate, was added to this solution; the mixture was heated under reflux for 2.5 hours in a flask fitted with a Dean-Stark water separator. Within a few minutes of heating all suspended solid dissolved. At the end

of the reaction a small second layer of liquid below the toluene layer dissolved in water.

The upper toluene layer was washed, dried, and evaporated to give 3.9 Gm. of a viscous, yellow oil which had a satisfactory infrared spectrum [$\nu_{max.}^{Nujol}$ in cm.$^{-1}$ 1780, 1730 (phthalimido carbonyls); 1710 (ester carbonyl)]. On hydrogenation of this oil in methanol solution in the presence of 0.8 Gm. of 10% palladium-on-charcoal catalyst, nearly two moles of hydrogen were absorbed. After filtration the reaction mixture was evaporated and 2.5 Gm. of a white solid was obtained. After one crystallization from hot water, the m.p. of this product was 221–223° (softens at 180°) and $[\alpha]_D^{25}$ − 40°.

After two more recrystallizations from hot water the melting point changed to 228 to 229.5° and $[\alpha]_D^{25}$ became −9° (c = 0.627 in 95% ethyl alcohol).

Evidently DL-phthaloylaspartic acid is less soluble in water than L-phthaloylaspartic acid and recrystallization from water has resulted in the enrichment of the proportion of the DL-acid. This is in keeping with the findings of Schilling and Strong (20) concerning the comparative solubility of DL- and L-phthaloylglutamic acids.

Anal.—Calcd. for $C_{12}H_9NO_6$: C, 54.76; H, 3.45; N, 5.32. Found: C, 54.81; H, 3.71; N, 5.19.

In a second experiment starting with 10 Gm. of dibenzyl L-aspartate *p*-toluenesulfonate, 3.7 Gm. (67%) of phthaloylaspartic acid, m.p. 223–225°, $[\alpha]_D^{25} \backsim 0°$, was obtained.

(*c*) A mixture of 3.87 Gm. of dibenzyl L-aspartate (IVa), 1.75 Gm. (0.0118 mole) of phthalic anhydride, and 50 ml. of N,N-dimethylformamide was heated to boiling for 45 minutes and then poured on cracked ice. This mixture was extracted with methylene chloride. On evaporating the methylene chloride, a dark material was extracted with ether. The ether solution was thoroughly washed with water, dried, and evaporated to give 4.4 Gm. of a yellow viscous oil which was hydrogenated. The product (2.65 Gm.), m.p. 223–225°, was optically inactive.

(*d*) A mixture of 4.63 Gm. of dibenzyl L-aspartate (IVa), 3.00 Gm. (0.0203 mole) of phthalic anhydride, and 30 ml. of acetic acid was heated under reflux for 8 hours and then poured into 250 ml. of water. The mixture was extracted with methylene chloride and the extract washed with dilute sodium bicarbonate solution and then with water, dried, and evaporated to give 5.5 Gm. of a colorless, viscous oil. On hydrogenation, 3.0 Gm. of a solid, m.p. 225–227°, $[\alpha]_D^{25} \sim 0°$, was obtained.

Diethyl N-Phthaloyl-L-aspartate.—A suspension of 11.3 Gm. (0.050 mole) of diethyl L-aspartate hydrochloride and 7.5 Gm. (0.051 mole) of phthalic anhydride in 150 ml. of toluene and 10 ml. of triethylamine was refluxed for 2.5 hours in a flask fitted with a water separator. Nearly the calculated amount of water separated. The reaction mixture was filtered and the solid so obtained was washed with benzene and dried to give 6.5 Gm. (95%) of triethylamine hydrochloride. The filtrate was washed with dilute hydrochloric acid and with water, dried over anhydrous magnesium sulfate, and evaporated to give 14.0 Gm. (92.5%) of a slightly yellow, heavy oil. On distillation a colorless oil was obtained (nearly quantitative recovery) which had a satisfactory infrared spectrum and $[\alpha]_D^{25}$ −45° (c = 0.7 in ethanol, [lit. (10), $[\alpha]_D^{?}$ −40° (ethanol)].

N-Phthaloyl-L-glutamic Acid.—(*a*) Using the general procedure described above, L-glutamic acid *γ*-benzyl ester (IIc) was converted to an oily phthaloylation product which on hydrogenation gave a colorless oil. This oil was dissolved in hot water; on seeding, a white solid (68.5% overall yield), m.p. 156–159°, was obtained. On evaporation the mother liquor gave an oil that refused to crystallize. The solid after recrystallization from hot water had a m.p. 158–160° and $[\alpha]_D^{25}$ − 45° (c = 0.773 in ethanol) [lit. (8), m.p. 160–161°; $[\alpha]_D$ − 43° (95% ethyl alcohol)].

Anal.—Calcd. for $C_{13}H_{11}NO_6$: C, 56.32; H, 4.00; N, 5.05. Found: C, 56.56; H, 4.18; N, 4.85.

$\nu_{max.}$ in cm.$^{-1}$: 3200–2500 (bonded hydroxy), 1771 (CO), and 1742 (SH) (carbonyl).

(*b*) To the clear solution obtained on shaking 1.48 Gm. (0.0100 mole) of phthalic anhydride with 150 ml. of toluene and 5 ml. of triethylamine, 5.13 Gm. (0.0103 mole) of dibenzyl L-glutamate *p*-toluenesulfonate was added. After heating for a few minutes all solid disappeared and a two-phase liquid mixture was obtained; this was heated under reflux for 3 hours in a flask fitted with a Dean-Stark water separator. After cooling, the reaction mixture was successively washed with water, dilute hydrochloric acid and water, dried, and evaporated. A 3.5 Gm. quantity of a colorless viscous oil with the infrared spectrum expected for N-phthaloyl-glutamic acid dibenzyl ester (VIIId) was obtained. This oil was hydrogenated in methanol solution in the presence of 0.5 Gm. of 10% palladium-on-charcoal catalyst and the product was purified by crystallization from hot water. The yield of N-phthaloyl L-glutamic acid (VIIIc), m.p. 158–160°, $[\alpha]_D^{25}$ − 44° (c = 0.833 in ethanol), was 1.4 Gm. (50%). The infrared spectrum of the product was satisfactory.

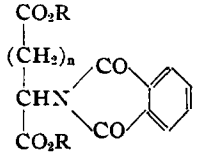
N-Phthaloyl-L-leucine.—Using the one-step phthaloylation method described above, L-leucine benzyl ester *p*-toluenesulfonate was converted to the oily N-phthaloyl-L-leucine benzyl ester which was used without purification for hydrogenation. After crystallization from aqueous methanol, the product, m.p. 119–121°, $[\alpha]_D^{25}$ − 24° (c = 0.5 in ethanol) [lit. (21) m.p., 118.5 to 119.5°, $[\alpha]_D^{26.5}$ − 24°], was obtained in 38% overall yield.

DISCUSSION

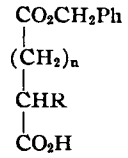
Sachs and Brand (22) have described a procedure for the preparation of dibenzyl L-glutamate hydro chloride. In our hands this method led only to the hydrochloride of L-glutamic acid. The *p*-toluenesulfonate of dibenzyl L-glutamate, which is easily prepared in good yield, can be converted into the hydrochloride or directly used in place of the hydrochloride.

The reaction of dibenzyl L-glutamate *p*-toluenesulfonate (IVb) [or *γ*-benzyl L-glutamate (IXc)] with an acid anhydride followed by hydrogenolysis appears to be a convenient synthesis of optically active pure N-acyl L-glutamic acid. It is noteworthy, however, that the same sequence of reactions with dibenzyl L-aspartate *p*-toluenesulfonate led to a racemized product. When the *β*-benzyl ester of L-aspartic acid was employed as the starting material, the extent of racemization was much reduced. It is interesting to note that when diethyl L-aspartate

hydrochloride was substituted for the dibenzyl ester, the N-phthaloylaspartic acid diethyl ester (VIIIc) was formed without any racemization



VIIIa n = 1, R = CH_2Ph
VIIIb n = 1, R = H
VIIIc n = 1, R = C_2H_5
VIIId n = 2, R = CH_2Ph
VIIIe n = 2, R = H



IXa n = 1, R = NH_2

IXb n = 1, R = 
IXc n = 2, R = NH_2

IXd n = 2, R = 
To examine the possibility that benzyl esters of amino acids may be prone to racemization, the *p*-toluenesulfonate of L-leucine benzyl ester was phthaloylated using the procedure of Bose, Greer, and Price (11) and the product hydrogenated. The N-phthaloyl-L-leucine so obtained was optically pure.

In the light of the results with benzyl esters of L-leucine and L-glutamic acid, the behavior of the benzyl esters of L-aspartic acid during phthaloylation is anomalous. In particular, it is difficult to see why β-benzyl L-aspartate should racemize to a limited extent during the phthaloylation and hydrogenation sequence.

After the completion of this work the preparation of N-phthaloyl L-glutamic acid (23) and N-phthaloyl L-aspartic acid (24) has been reported using a new method (25).

SUMMARY

L-Aspartic acid failed to condense with succinic or maleic anhydride, but the desired N-(β-carboxypropionyl)-aspartic acid could be prepared by the reaction of succinic anhydride with dibenzyl L-aspartate, followed by hydrogenolysis of the ester group.

The preparation of mono and dibenzyl esters of L-aspartic and L-glutamic acids and the benzyl esters of L-leucine is described. N-Phthaloyl derivatives of glutamic acid and aspartic acid were prepared under mild conditions *via* their benzyl esters. Optically pure N-phthaloyl L-glutamic acid was obtained this way, but anomalous racemization was observed with some aspartic acid derivatives.

Rates of Hydrolysis of Carbamate and Carbonate Esters in Alkaline Solution

By LEWIS W. DITTERT† and TAKERU HIGUCHI

The rate of the alkaline hydrolysis of several aliphatic and aromatic carbamate and and carbonate esters was studied at various temperatures. The reactions were found to be first order with respect to both hydroxyl ion and the ester. The data seemed to indicate two mechanisms for the hydrolysis of the carbamates: that initiated by an hydroxyl ion attachment on the central carbon atom followed by a carbamate ion intermediate, and that involving direct ionization of an amide hydrogen followed by formation of an isocyanate intermediate. Since the latter mechanism appears to proceed with much greater ease for carbamates of strongly electrophilic alcohols, the N-unsubstituted and N-monosubstituted carbamates of these compounds undergo cleavage at rates several orders of magnitude greater than those of the corresponding disubstituted carbamates.

ALTHOUGH several drugs are marketed which contain the carbamate ester linkage, *e.g.*, physostigmine, neostigmine, carbachol, etc., no exhaustive kinetic or mechanistic study on the general stability of this linkage toward alkaline hydrolysis appears to have been carried out. The specific stability of physostigmine in solution has, however, been the object of many qualitative investigations (1–6). Ellis and his co-workers (7) in a quantitative study showed that the destruction of physostigmine in aqueous solution was first order in hydroxyl ions and first order in physostigmine. A physostigmine analog, neostigmine methylsulfate (8), was reported by Morch (9) to be hydrolyzed in very dilute alkaline solutions under autoclave conditions, but Chaiken (10) was unable to find any decomposition of an analogous compound (a dimethylcarbamate) in pH 7.4 phosphate buffer at 38°. The results of these studies indicate that the dimethylcarbamate esters are much more stable toward alkaline hydrolysis than are the N-methylcarbamate esters.

More recently, because of their potent anticholinesterase activity, carbamates have been employed as insecticides, *e.g.*, Sevin,[1] Isolan,[2] Pyrolan,[2] Pyramat,[2] etc. Casida and his coworkers (11) have studied the alkaline hydrolysis of these and similar compounds and have also found the dimethylcarbamate esters to be more stable than the N-methylcarbamate esters.

It has been known for many years that carbamate esters in alkaline solution hydrolyze according to

$$R{-}O{-}\overset{\displaystyle O}{\overset{\|}{C}}{-}NR'_2 + 2OH^- = ROH + CO_3^= + HNR'_2$$

Although Werner (12), in 1918, proposed a mechanism for the destruction of urethane in aqueous alkali at 100°, no exhaustive kinetic or mechanistic study on urethane appears to have been carried out since that time.

It was the purpose of the present investigation to explore the general kinetics and mechanisms of the alkaline hydrolysis of urethane, ethyl N-methylcarbamate, ethyl dimethylcarbamate, phenyl carbamate, phenyl N-methylcarbamate, phenyl dimethylcarbamate, *p*-nitrophenyl carbamate, *p*-nitrophenyl N-methylcarbamate, *p*-nitrophenyl dimethylcarbamate, phenyl ethyl carbonate, and *p*-nitrophenyl ethyl carbonate, and to determine the effect of temperature and structure on the hydrolytic reaction.

EXPERIMENTAL

Materials

Ethyl N-Methylcarbamate and Ethyl Dimethylcarbamate.—The compounds were synthesized by the method of Schreiner (13) and purified by fractional distillation through a 30-cm. Vigreaux column. The following fractions were collected: ethyl N-methylcarbamate 167–168° (lit. 170° (13)), ethyl dimethylcarbamate 142–144° (lit. 139–140 (13)).

Phenyl N-Methylcarbamate.—The compound was synthesized by the method of Schreiner (13) and purified by repeated crystallization from 5% benzene in petroleum ether, m.p. 85–87°.

Phenyl Dimethylcarbamate and p-Nitrophenyl Dimethylcarbamate.—The compounds were synthesized by reacting dimethyl carbamyl chloride with the appropriate phenol in pyridine solution. Phenyl dimethylcarbamate was recrystallized repeatedly from petroleum ether, m.p. 44 to 45.5° (lit. 44–45° (14)). *p*-Nitrophenyl dimethylcarbamate was recrystallized repeatedly from ethanol, m.p. 107–109°.

Phenyl Ethyl Carbonate and p-Nitrophenyl Ethyl Carbonate.—The compounds were prepared

Received June 6, 1962, from the School of Pharmacy, The University of Wisconsin, Madison.
Accepted for publication February 26, 1963.
Based on a thesis submitted by Lewis W. Dittert to the Graduate School, The University of Wisconsin, in partial fulfillment of Doctor of Philosophy degree requirements.

by reacting ethyl chloroformate with the appropriate phenol in pyridine solution. Phenyl ethyl carbonate was purified by fractional distillation through a 30-cm. Vigreaux column, b.p. 226–228° (lit. 227–230° (15)). *p*-Nitrophenyl ethyl carbonate was recrystallized repeatedly from ethanol, m.p. 64–66° (lit. 67–68° (16)).

p-Nitrophenyl Carbamate and p-Nitrophenyl N-Methylcarbamate.—The compounds were prepared by nitration of the corresponding phenyl esters after the method of Ransom (16). *p*-Nitrophenyl carbamate was recrystallized repeatedly from ethanol, m.p. 110–140° (lit. 161° (17)). *p*-Nitrophenyl N-methylcarbamate was recrystallized repeatedly from ether-acetone solution, m.p. 105–109°.

Procedures

1. The Rate of Disappearance of Urethane from Strongly Basic Solutions at 30°.—The reaction mixture was prepared by dissolving urethane in sodium hydroxide–barium hydroxide solution of the desired normality. Periodically, 5 to 20-ml. portions of this solution containing about 15 mg. of urethane were neutralized by dropwise addition of 60% perchloric acid and distributed in 1 Gm. of silicic acid per ml. of urethane solution. The silicic acid was slurried with chloroform, quantitatively transferred to a chromatography column, packed down, and developed with 300 to 500 ml. of chloroform. The eluate was boiled down to a small volume, and 10 ml. of 0.1 *N* perchloric acid in glacial acetic acid and 25 ml. of chlorobenzene were added. The mixture was boiled until the temperature of the solution reached 104°. The solution was refluxed for 2 hours at 104°, cooled, and titrated with 0.05 *N* sodium acetate in glacial acetic acid to the α-naphthol benzein end point. The amount of perchloric acid consumed represented the amount of urethane present in the aliquot.

2. Rate of Appearance of Carbonate Ions in Strongly Basic Solutions of Urethane at 30°.—The reaction mixture was prepared as described in the preceding paragraph, and 20-ml. aliquots of the solution were filled into 8-dr. vials with a hypodermic syringe. The vials were sealed with rubber stoppers and placed in a 30° thermostat. Periodically, the vials were removed from the thermostat; sufficient barium chloride solution was added to precipitate all the carbonate ion which had formed. The contents of the vials were then filtered through Pyrex glass medium porosity fritted disk Buchner funnels. The barium carbonate precipitate was washed well and dissolved in standard hydrochloric acid. This solution was washed through the funnel and the excess acid titrated with standard carbonate-free sodium hydroxide solution to the bromcresol green end point.

3. Rate of Alkaline Hydrolysis of Urethane, Ethyl N-Methylcarbamate, and Ethyl Dimethylcarbamate in Strongly Basic Solutions at Various Temperatures.—The reaction mixture was prepared by dissolving the ester in sodium hydroxide–barium hydroxide solution so that the concentration of hydroxyl ions was twice the concentration of the ester. Five-milliliter aliquots of this solution were filled into 5-ml. ampuls with a hypodermic syringe, and the ampuls were sealed and placed in a thermostat at the desired temperature. At zero time, and periodically thereafter, the ampuls were removed from the bath and crushed under standard hydrochloric acid. The excess acid was titrated with standard carbonate-free sodium hydroxide solution to the bromcresol green end point.

4. Rate of Alkaline Hydrolysis of Various Aromatic Carbamates and Carbonates at Various Temperatures in Buffered and Strongly Basic Solutions.—The reactions were followed spectrally by measuring

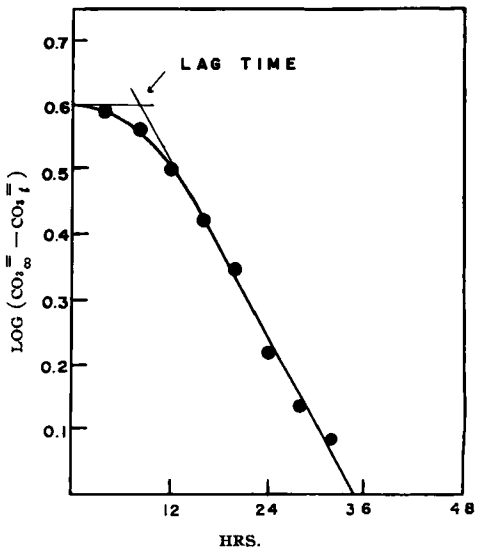

Fig.1.—Plot showing the rate of appearance of carbonate ions in a 0.4 *N* OH^- solution of urethane at 30°C.

the absorbance due to the phenate ion (at 235 mμ wavelength) or the *p*-nitrophenate ion (at 400 mμ wavelength) using a model 11 MS Cary recording spectrophotometer. The reactions were allowed to proceed until no further change in the absorbance could be detected. Pseudo first-order rate constants were determined from the slopes of plots of log ($A_\infty - A_t$) *versus* time. Borate and phosphate buffers and sodium hydroxide–barium hydroxide solutions were employed and several pH's or hydroxyl ion concentrations were studied for each compound. All buffer results were extrapolated to infinite dilution.

RESULTS AND DISCUSSION

Experimental studies on the hydrolytic rate of urethane and various substituted carbamates strongly suggest that, as would be expected, the initial cleavage occurred at the CO—O bond.

Urethane.—The pseudo first-order rate constants ($k_{\text{urethane}} \cdot [OH^-]$) for the rate of disappearance of urethane from strongly basic solutions at 30° and the dependency of this reaction on the base concentration are shown in Table I. These data were procured by *Procedure 1*. A plot of pseudo first-order rate constant *versus* hydroxyl ion concentration yielded a straight line through the origin with a slope of unity, showing that the reaction was first order with respect to hydroxyl ions. The second-order rate constant (k_{urethane}) for this reaction at 30° is also shown in Table I. This rate constant corresponds to the rate of the initial attack on the urethane molecule.

A typical plot showing the rate of appearance of carbonate ions in strongly basic solutions of urethane at 30° is shown in Fig. 1. These data were procured by *Procedure 2*. The reactions were allowed to proceed until no further change in the amount of barium carbonate could be detected. The plot of log

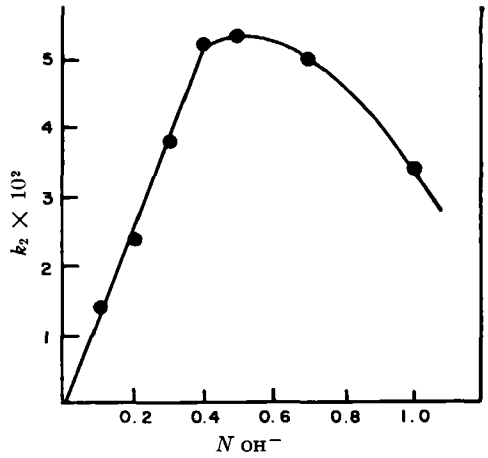

Fig. 2.—Plot showing the relationship between pseudo first-order rate constants for the rate of appearance of carbonate ions in strongly basic solutions of urethane at 30°C. and hydroxyl ion concentration.

($CO_{3\infty}^{=} - CO_{3t}^{=}$) *versus* time, shown in Fig. 1, goes through a lag period, then a straight line portion. The dependency of the slopes of the straight line portions, calculated as pseudo first-order rate constants, on the base concentration is shown in Table I and Fig. 2. The dependency of the lag time on the base concentration is also shown in Table I.

Faurholt (18) pointed out that in solutions of pH above 12.5, the rate of conversion of carbamate ions into carbonate ions and ammonia decreases as the pH increases. This is shown in Table I as an increase in the lag time with increasing hydroxyl ion concentration. The effect is also shown in Fig. 2 as a decrease in $k_{\text{carbonate}}$ with increasing hydroxyl ion concentration above 0.5 N OH$^-$. The fact that k_{urethane} equals $k_{\text{carbonate}}$ between 0.1 and 0.4 N OH$^-$ shows that the rate of rupture of the CO—O bond in the ester linkage is the rate-determining step in the appearance of carbonate ions at these OH$^-$ concentrations. The decrease in $k_{\text{carbonate}}$ with increasing hydroxyl ion concentration beyond 0.5 N OH$^-$ indicates that at these OH$^-$ concentrations the conversion of carbamate ions into carbonate ions is the rate-determining step in the appearance of carbonate ions.

Werner (12) stated that in refluxing sodium hydroxide solution the major intermediate in the hydrolysis of urethane was alkali cyanate. When a solution of urethane in 0.5 N OH$^-$, which had stood at room temperature until the precipitate of barium carbonate was in evidence, was tested for cyanate ions by Werner's method (19), the test was so faint that it could hardly be distinguished from the blank. According to Jensen (20), the decomposition of cyanate ion in such strongly basic solutions is extreme-

TABLE III.—SECOND-ORDER RATE CONSTANTS FOR THE ALKALINE HYDROLYSIS OF AROMATIC CARBAMATE ESTERS

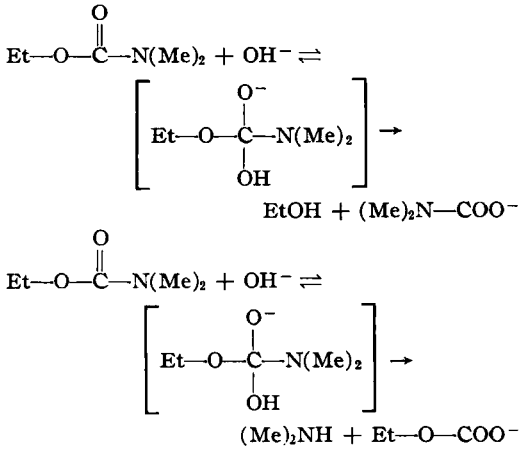
Ester	k(L.·Mole^{-1}·Min.$^{-1}$) 34°C.	25°C.	Apparent ΔHa (Kcal./Mole)
p-Nitrophenyl dimethylcarbamate	5.5×10^{-2}	2.4×10^{-2}	17
p-Nitrophenyl N-methylcarbamate	3.9×10^{4}	3.5×10^{4}	2
p-Nitrophenyl carbamate	1.5×10^{7}	1.5×10^{7}	2
Phenyl dimethylcarbamate	6.0×10^{-3}	2.8×10^{-3}	16
Phenyl N-methylcarbamate	1.9×10^{2}	1.2×10^{2}	8
Phenyl carbamate	2.2×10^{4}	1.6×10^{4}	7

ly slow. If cyanate ion had been the true intermediate in the hydrolysis of urethane at 30°, carbonate ions probably never would have been detected.

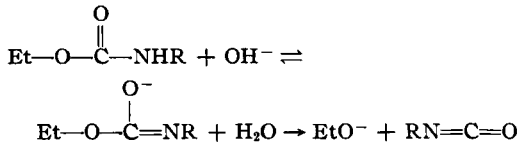
Effect of Temperature on the Rate of Alkaline Hydrolysis of Urethane, Ethyl N-Methylcarbamate, and Ethyl Dimethylcarbamate in Strongly Basic Solutions.—The second-order rate constants for the alkaline hydrolysis of the three aliphatic carbamate esters at several temperatures are shown in Table II. These data were procured by *Procedure 3*.

This method for following the aliphatic carbamates was considered completely reliable for studies at any hydroxyl ion concentration, even though appreciable quantities of carbamate ions may have been present in the reaction mixture. The aliquots to be analyzed were first placed in strong acid solution which, according to Faurholt (18), would instantaneously decompose any carbamate ions into ammonia and carbon dioxide and include them in the titer. According to Jensen (20), any cyanate ion present would also have been rapidly converted into ammonia and carbon dioxide under these conditions, although the change would not have been instantaneous. The decomposition of urethane itself was studied by *Procedure 3* at 30°, and the resulting k was exactly the same as the value previously determined by following the disappearance of the ester.

Methylation of the amide nitrogen of urethane produced significant changes in the hydrolytic rate, but the changes were not sufficient to indicate major changes in the basic mechanism. In the case of ethyl dimethylcarbamate, the only mechanism possible is a direct hydroxyl ion attack on the carbonyl carbon atom followed by either a dimethylcarbamate ion or a monoethylcarbonate ion intermediate



Faurholt (18) has shown that the dimethylcarbamate ion does not exist in solution under any conditions and (21) that the monoethylcarbonate ion is rapidly converted into carbamate ions and ethyl alcohol under the conditions of these experiments. Thus, the initial hydroxyl ion attack on the ethyl dimethylcarbamate ester is probably followed by complete disintegration of the molecule. In the urethane and ethyl N-methylcarbamate cases the formation of an isocyanate intermediate is possible



but the rate constants for these compounds were so close to that for ethyl dimethylcarbamate that this possibility seems remote. The apparent heats of activation for the three compounds are essentially equal, suggesting no major difference in mechanism between them. The small differences in rates which were observed are probably because of the inductive and steric effect of the methyl groups.

Rate of Alkaline Hydrolysis of Various Aromatic Carbamates.—The second-order rate constants obtained for several aromatic carbamates are shown in Table III. These data were procured by following the appearance of the phenate or p-nitrophenate ions spectrally and therefore correspond to the rate of cleavage of only the CO—O bond.

Unlike the case of urethane, methylation of the amide nitrogen of phenyl carbamate and p-nitrophenylcarbamate has a very marked effect on the hydrolytic rate. The second-order k for phenyl carbamate is nearly 10^7 times that for phenyl dimethylcarbamate. The second-order k for p-nitrophenyl carbamate is nearly 10^9 times that for p-nitrophenyl dimethylcarbamate. The apparent heats of activation for the hydrolysis of these two types of carbamates are also very different. These facts strongly suggest some shift in the mechanism of the hydrolysis. It has already been pointed out in the case of ethyl dimethylcarbamate, that the hydrolysis of the dimethylcarbamates can only occur by direct hydroxyl ion attack on the carbonyl carbon, probably followed by complete disintegration of the molecule. It therefore seems likely that the alternative mechanism, *i.e.*, the formation of an isocyanate intermediate, may be responsible for the great increase in the hydrolytic rate seen with the aromatic N-unsubstituted and N-monosubstituted carbamate esters. If the hydrolysis proceeds according to

TABLE IV.—SECOND-ORDER RATE CONSTANTS FOR THE ALKALINE HYDROLYSIS OF CARBONATE ESTERS

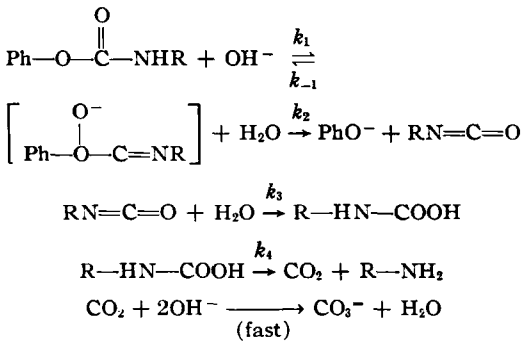
Ester	k(L.·Mole^{-1}·Min.$^{-1}$) 34°C.	25°C.	Apparent ΔHa (Kcal./Mole)
p-Nitrophenyl ethyl carbonate	400	320	5
Phenyl ethyl carbonate	37	24	9
Diethyl carbonate[a]	5.5(35°C.)	2.8	13

[a] After Miller and Case (22).

TABLE V.—INFLUENCE OF THE ELECTROPHILICITY OF THE ALCOHOLIC OR PHENOLIC GROUPS ON THE STABILITY OF ETHYL CARBONATE AND ACETATE ESTERS TOWARD HYDROXYL ION ATTACK

Ester	pKa of ROH	k(L.·Mole^{-1}·Min.$^{-1}$) (25°C.)
p-Nitrophenyl ethyl carbonate	~6	320
Phenyl ethyl carbonate	~10	24
Diethyl carbonate[a]	~16	2.8
p-Nitrophenyl acetate[b]	~6	1600 (22°C.)
Phenyl acetate	~10	...
Ethyl acetate[c]	~16	5.6 (21°C.)

[a] Miller and Case (22). [b] Casida, *et al.* (11). [c] Warder (23).



it is possible that the initial ionization of the carbamate ester has a negative temperature coefficient, since the apparent heat of activation of the overall hydrolysis reaction is rather small. The relative closeness of the rates and apparent heats of activation for phenyl carbamate and phenyl N-methylcarbamate and for *p*-nitrophenyl carbamate and *p*-nitrophenyl N-methylcarbamate suggests that the isocyanate mechanism is dominant in these cases.

Rate of Alkaline Hydrolysis of Various Aromatic Carbonates.—The pseudo first-order rate constants and second-order rate constants obtained for two aromatic ethyl carbonates are shown in Table IV. These data were procured by following the appearance of the phenate or *p*-nitrophenate ions spectrally and therefore correspond to the rate of rupture of only the CO—O bond vicinal to the phenol group.

Miller and Case (22) studied the rate of alkaline hydrolysis of diethyl carbonate and determined a value of 2.8 L. · mole^{-1} · minute^{-1} for the second-order rate constant for the initial cleavage at 25° and an apparent heat of activation of 13 Kcal./mole for this reaction. The differences in rates of hydrolysis of the various carbonate esters seem to parallel the electrophilicity of the alcoholic or phenolic moieties. This

Phenyl ethyl carbonate	~10	24
Diethyl carbonate	~16	2.8

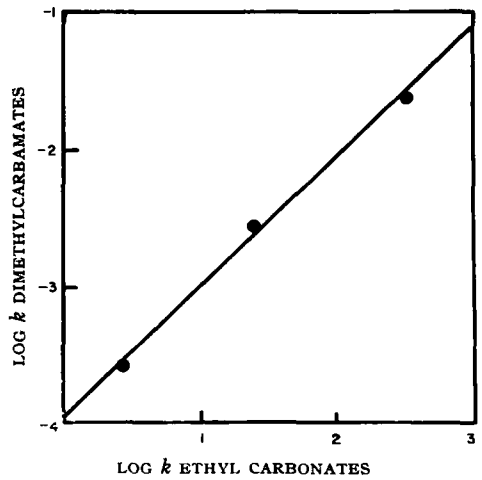

Fig. 3.—Plot showing the proportionality of effect of R—O— groups on the rate of hydrolysis of dimethylcarbamate and ethyl carbonate esters.

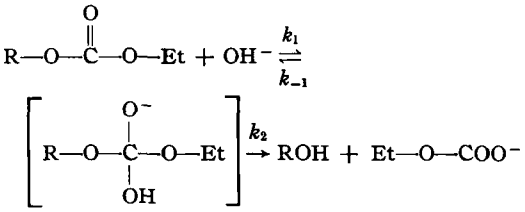
effect is illustrated in Table V. It can be seen that the effect of the alcoholic or phenolic groups on the stability of the ethyl carbonate esters and the acetate esters toward hydroxyl ion attack is essentially the same. This suggests that the increased hydrolytic rate in each case is because of an increased polarization of the carbonyl carbon atom which facilitates the initial hydroxyl ion attack. In the carbonate case, this initial attack is followed by a monoalkylcarbonate ion intermediate, probably monoethylcarbonate ion

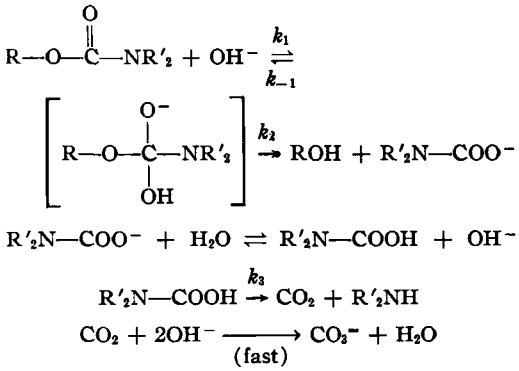


and the effect of the R group suggests that the rate-determining step in this mechanism is probably k_1. Faurholt (21) has already shown that the resulting monoethylcarbonate ion is rapidly converted to carbonate ions and ethyl alcohol in the solutions employed in our studies. Thus, the carbonate esters can be considered to be completely destroyed after the initial cleavage.

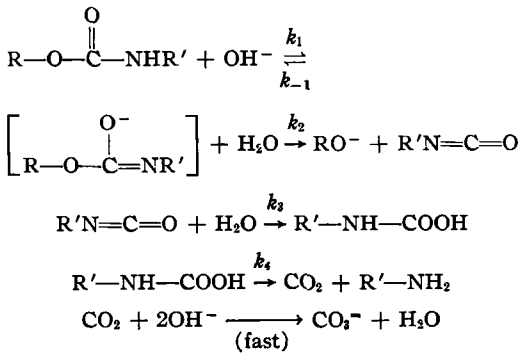
Comparison with the Work of Casida, et al.—Casida and his co-workers (11) have studied the hydrolysis of some of the compounds listed in Tables III and IV in 0.05 *M* phosphate buffer at pH 7.8 and 22°. Their results are shown in Table VI. The rate constants in Table VI are somewhat higher than might be expected from the data of Tables III and IV. This is probably because of buffer catalytic effects.

CONCLUSIONS

On the basis of the data presented above, two mechanisms appear to be responsible for the alkaline hydrolysis of the carbamate esters: (*a*) hydroxyl ion attack followed by a carbamate ion intermediate



(b) hydroxyl ion attack followed by an isocyanate intermediate



The second mechanism appears to predominate in the extremely fast reactions of the N-unsubstituted and N-monosubstituted aromatic carbamates, whereas the first mechanism appears to be the only one possible in the slower reactions of the dimethylcarbamates. The data seem to indicate that mechanism (a) predominates in the hydrolysis of all the aliphatic carbamates. The apparent heats of activation for the compounds which proceed *via* mechanism (a) are of the same order of magnitude as those which might be expected for ordinary hydrolytic reactions. The extremely low apparent heats of activation for the compounds which proceed *via* mechanism (b) seem to indicate that some step in this mechanism has a negative temperature coefficient. That step is very likely the initial ionization of the carbamate ester, since in this step a molecule of water is formed releasing 13 Kcal. of energy.

The electrophilicity of the alcoholic or phenolic moiety appears to exert considerable influence on the stability of the dimethylcarbamate and ethyl carbonate esters toward hydroxyl ion attack. This effect is illustrated in Table VII and Fig. 3 and is probably the result of an increased polarization of the carbonyl carbon atom, since more electrophilic R—O— groups cause greater polarization of the carbonyl group. The Hammett-type plot of log k for a dimethylcarbamate ester *versus* log k for the corresponding ethyl carbonate ester, shown in Fig. 3, is a straight line with a slope very nearly unity, showing that the effect of the alcoholic or phenolic group follows a linear free-energy relationship (24). Since the polarity of the carbonyl group seems largely to determine the rate, k_1 is probably the rate-determining step in mechanism (a).

TABLE VIII.—INFLUENCE OF THE ELECTROPHILICITY OF THE ALCOHOLIC OR PHENOLIC GROUPS ON THE STABILITY OF CARBAMATE AND N-METHYLCARBAMATE ESTERS TOWARD HYDROXYL ION ATTACK

Ester	pKa of ROH	k(L. · Mole^{-1} · Min.$^{-1}$) (25°C.)
p-Nitrophenyl N-methylcarbamate	~6	3.5×10^{4}
Phenyl N-methylcarbamate	~10	1.2×10^{2}
Ethyl N-methylcarbamate	~16	3.4×10^{-4}
p-Nitrophenyl carbamate	~6	1.5×10^{7}
Phenyl carbamate	~10	1.6×10^{4}
Ethyl carbamate (urethane)	~16	1.2×10^{-3}

The effect of the R—O— group is even more marked in the case of intermediate isocyanate formation, *i.e.*, mechanism (b). This is illustrated in Table VIII. The greater effect in this case is probably because this mechanism requires the loss of the R—O$^-$ ion, and *p*-nitrophenate ion is a better leaving group than phenate ion. This suggests that k_2 is probably the rate-determining step in mechanism (b). The two aliphatic compounds are included in Table VIII to show that they do not fit this theory. This is further evidence that the N-unsubstituted and N-monosubstituted aliphatic compounds probably hydrolyze *via* the carbamate ion intermediate, *i.e.*, mechanism (a), at ordinary temperatures. It should be noted that the k's for the aliphatic compounds at 25° are practically equal. The small differences are probably because of the inductive and steric effects of the methyl groups. Even the apparent heats of activation for all the aliphatic compounds are essentially the same and correspond most closely to those values determined for the compounds which can only hydrolyze *via* mechanism (a).

Chelatometric Determination of Ferrous Iron with 2-Pyridinealdoxime as an Indicator

By SANFORD BOLTON

Ferrous iron may be quantitatively determined by titration into a known EDTA solution containing 2-pyridinealdoxime as an indicator. The principal advantages of this method over oxidation-reduction procedures are that the reagents are more stable and reducing substances, in general, do not interfere.

CLASSIC METHODS for the quantitative determination of ferrous iron have usually involved oxidation-reduction titrations. In these procedures, reducing substances tend to interfere, and the titrating solutions are often unstable, requiring frequent standardizations. A spectrophotometric approach, utilizing the 2-pyridine ketoxime-ferrous chelate, has been proposed by Banerjea and Tripathi (1); however, this type of assay has the disadvantages of being cumbersome and/or requiring special equipment. Because of the advantages of convenience, rapidity, and specificity claimed for chelatometric titrations, much recent work has been reported on this approach to the analysis of metallic ions (2). Notably lacking in the literature, however, is a simple titrimetric chelatometric procedure for determining ferrous iron. The present report describes a titrimetric assay for ferrous iron with 2-pyridinealdoxime (2-PA) as an indicator.

Solutions of ferrous iron form a deep red-colored chelate with 2-PA (3) which is easily detected at low concentrations. A solution of unknown concentration of iron is titrated into a solution of known concentration of EDTA containing 2-PA. The iron first combines stoichiometrically with the EDTA, and the subsequent formation of the red color of the Fe^{++}-2-PA chelate denotes the end point.

This assay method was applied to several official and commercial preparations containing ferrous salts and the results compared favorably with the official assays and/or label-stated quantities.

METHOD

Reagents.—2-Pyridinealdoxime, m.p. 111–113°; indicator solution consisting of a 0.1% solution of 2-PA; EDTA, analytical reagent grade were employed. The known solution of EDTA was prepared by dissolving 4.380 Gm. of EDTA with the aid of three equivalents of NaOH per equivalent of EDTA in enough distilled water to make 500 ml., to yield a solution of approximately 0.03 *M* (disodium EDTA also may be used). This solution was standardized against a known ferrous solution prepared from analytical grade iron wire; 0.50 *M*, pH 5 acetate buffer; salicylic acid, citric acid, and ascorbic acid, all U.S.P. grade; iron wire, analytical reagent grade. All other salts were analytical reagent grade.

Received January 10, 1963, from the University of Rhode Island, College of Pharmacy, Kingston.
Accepted for publication February 13, 1963.

TABLE I.—ASSAY OF FERROUS AMMONIUM SULFATE SOLUTIONS

Assay with Ceric Nitrate, Molar Ferrous	Assay with EDTA and 2-PA, Molar Ferrous	Recovery, %
0.0150	0.0151	100.7
0.00750	0.0076	101.3

0.0600	0.5975	99.6

TABLE II.—TEMPERATURE EFFECTS ON THE ASSAY OF FERROUS AMMONIUM SULFATE SOLUTIONS

Approximate Temp., °C.	Ferrous Theoretical, *M*	Ferrous Observed, *M*	Recovery, %
25	0.0300	0.0310	103.3
35	0.0300	0.0306	102
50	0.0300	0.0301	100.3
65	0.0300	0.0300	100
70	0.0300	0.0300	100
85	0.0300	0.0297	99

Procedure.—An appropriate sample of the ferrous salt or the ferrous containing dosage form was dissolved in distilled water, filtered if necessary, and made to volume in a volumetric flask. For best results the final concentration of iron was found to be approximately 0.03 *M*. This solution was the titrant. Five milliliters of pH 5 acetate buffer were added to a mixture of 1 ml. of 2-PA indicator solution and 2–4 ml. of the known EDTA solution. This mixture was heated to approximately 50–70° and titrated immediately with the iron solution. The solution turned from a pale yellow-green to pink at the end point. The reaction was stoichiometric; the iron consumed was equivalent to the EDTA

$$\text{ml.}_{\text{EDTA}} \times M_{\text{EDTA}} = \text{ml.}_{\text{iron}} \times M_{\text{iron}}$$

The results of this method were compared to results obtained by titration with ceric nitrate and are shown in Table I. These and subsequently reported values are an average of at least three determinations.

Temperature Effect.—The results of the effect of temperature on the appearance of the end point are shown in Table II. Below 50° the end point appeared prematurely, probably because the Fe^{++}-2-PA chelate once formed is not easily dissociated

TABLE III.—VOLUME EFFECTS ON THE ASSAY OF FERROUS ION

Approx. Total Soln. Vol. at End Pt.	Indicator Vol.	Ferrous Theoretical, *M*	Ferrous Observed, *M*
12	2	0.0150	0.0153

17	1	0.0300	0.0299
22	1	0.0300	0.0294
22	2	0.0300	0.0298
32	2	0.0300	0.0296
32	1	0.0300	gradual end pt.

at the pH of the assay. It was extremely difficult to eliminate the red color of the chelate, even in the presence of EDTA. The application of heat apparently hastened the equilibrium between the iron and the chelating agents.

pH Effect.—At a pH of 4.5 or below, the end point was gradual and indistinct. At pH's greater than 6, the avidity of the ferrous ion for 2-PA was great enough to produce its characteristic color before the theoretical end point. A satisfactory end point was produced in the range of approximately pH 4.5 to 5.5.

Volume Effect.—Known amounts of distilled water were added to the titration vessel to determine the effect of increased volume on the end point. The results shown in Table III indicate that the end point was slightly delayed at large solution volumes. This observation suggests that the pink color produced at the end point cannot be immediately detected in dilute solutions. In titrations where the total volume of solution at the end point was 22 ml. or more, the addition of an extra milliliter of indicator yielded good results. The effect of indicator volume on the titration was similar to the dilution effect (see Table III). Too little indicator delayed detection of the end point, while too much favored production of the Fe^{++}-2-PA complex with a resultant premature end point.

INTERFERING SUBSTANCES

Metal Ion Interference.—Metal ions which have high chelate stability constants with EDTA interfered with the assay by preferentially binding the EDTA. The following ions interfered: Mn^{++}, Zn^{++}, Cd^{++}, Ni^{++}, Cu^{++}, Co^{++}, and Fe^{3+} (see below). In the presence of 0.03 *M* Fe^{++}, Ca^{++} interfered above 0.05 *M*. Two molar KNO_3, 3 *M* NaCl, and 1 *M* $MgSO_4$ did not interfere.

Calcium Interference.—Since calcium salts are often ingredients in iron-containing dosage forms, an effort was made to analyze ferrous ion in the presence of calcium. An excess of Na_2SO_4 was added to a known Fe^{++}-Ca^{++} solution; the solution was filtered and made up to volume. Analysis showed that this procedure yielded accurate results for 0.03 *M* Fe^{++} solutions in the presence of at least 0.80 *M* Ca^{++}.

Ferric Interference.—Although Fe^{3+} interfered, the assay gave accurate results of total iron present up to at least a 3:2 ratio of Fe^{3+} to Fe^{++}. A chelatometric procedure based on that suggested by Cheng, *et al.* (4), in combination with the present assay, could be used to determine Fe^{++} in the presence of Fe^{3+}. Two to four milliliters of an approxi-

[c] These tablets were at least 5 years old.

mately 0.03 *M* iron solution in 0.01 *N* HCl is titrated with EDTA using salicylic acid as an indicator. The disappearance of the red-violet (Fe^{3+}-salicylic acid chelate) color denotes the end point. At this low pH, Fe^{++} combines to a very slight degree with EDTA and the assay gives only Fe^{3+} concentration. The concentration of total iron present and of Fe^{3+} can be used to determine ferrous ion by difference. If the unknown solution has a color of its own, this method fails because the end point in the Fe^{3+} titration cannot be accurately observed. Results of this method are shown in Table IV.

Chelating Agent Interference.—Two chelating agents often found in iron preparations, which might interfere with the assay by binding ferrous ion, are citric acid and ascorbic acid. In known samples containing 0.03 *M* Fe^{++}, citric acid interfered when present in concentrations greater than 0.03 *M*. Ascorbic acid did not affect the assay in concentrations up to at least 0.50 *M*.

ASSAY OF COMMERCIAL PREPARATIONS

Several U.S.P. and commercially available products were assayed for iron content to test the applicability of the method to more complex preparations. Liquid dosage forms were appropriately diluted so that the final concentration of iron was approximately 0.03 *M*. Solid dose forms were prepared by filtering an aqueous suspension of pulverized tablets or capsule contents through a sintered-glass funnel and making up to volume in a volumetric flask. If calcium was present, sodium sulfate was added prior to filtration, as previously described.

Since no other assay method could be conveniently used, the analysis of commercial preparations by this method could only be compared to the labeled amount of iron. Therefore, a mixture was prepared from vitamin capsules and folic acid tablets to contain a known quantity of ferrous sulfate; the assay showed good recovery for ferrous ion (see Table V).

Whenever possible, known assay methods were used to verify the results of the chelatometric titration. Although the commercial liquid iron preparations tested contained only a single active ingredient, titration with ceric nitrate failed, perhaps because of interfering additives. Also the presence of ascorbic acid in other preparations precluded the use of ceric nitrate.

Although some of the diluted iron solutions were colored, the end point of the 2-PA titration was readily distinguishable. However, ferric ion could not be determined in these same preparations because the end point with salicylic acid at pH 2 is not sharp enough to be observed when interfering colors are present.

Results of these assays are shown in Table V.

SUMMARY

When compared to oxidation-reduction and other official methods for the determination of ferrous ion the titrimetric chelatometric assay described in this report presents a more advantageous method under certain conditions: (*a*) Reducing substances, which interfere in oxidation-reduction methods, usually become innocuous in the chelatometric titration. These include such substances as ascorbic acid and possibly certain fillers and flavors in dosage forms. In the case of ferrous iodide syrup N.F., this assay gave accurate results, which compared favorably to the N.F. method and which obviated much of the tedium associated with the official assay. (*b*) The solutions used in the chelatometric titration are extremely stable. In addition, EDTA can be purchased in a virtually 100% pure state; standardized EDTA solutions corresponded very closely to the amount of EDTA used to prepare these solutions. (*c*) Total iron content may be determined even in the presence of large amounts of ferric ion.

Oxidation-reduction methods are more efficacious when ferrous is to be determined in the presence of ferric ion. Also, certain chelating metals and chelating agents interfere with the chelatometric titration. In these cases, oxidation-reduction assay methods can be used to advantage.

Under certain conditions, the procedure for ferrous determination described in this report is advantageous compared to established methods and presents an approach which may be utilized where other methods fail.

Preparation of Tritio-Cholecalciferol

(Tritiated Vitamin D_3)

By C. T. PENG

Cholecalciferol was tritiated by exposure to tritium gas at −198° (liquid nitrogen). Pure tritiated vitamin D_3 with a specific activity of 216 μc./mg. was obtained following equilibration with solvents and purification by successive recrystallization from acetone at −80° and column chromatography on Florisil until a constant specific activity was achieved. The formation of radiation decomposition products was minimal because of using low temperature during tritiation. A possible explanation for this low temperature effect is given.

BIOLOGICALLY important compounds have frequently been randomly labeled with tritium by the Wilzbach gas exposure method (1). This method, however, has not been widely used with unsaturated compounds because tritium atoms add across the —C=C— bond giving rise to saturated products of extremely high specific activity (2) which are difficult to remove.

The addition reaction of tritium was first observed by Jones, *et al.* (2), with methyl oleate which, on tritiation, yielded methyl tritio-stearate as the only radioactive product. However, in other unsaturated compounds such as cholesterol, isobutylene (3), 1-hexene, 1,5-hexadiene (4), methyl linolenate (5), etc., substitution as well as addition of tritium occurred during the labeling process. While the mechanism of tritiation by Wilzbach method has been studied in homogeneous systems of methane-tritium (6), ethylene-tritium (7), and propane-tritium (8) and found to involve decay- and β-labeling, the mechanism of tritiation in heterogeneous systems remains obscure (9). Moreover, no systematic investigation has been made of the mechanism of hydrogenation of the —C=C— bond by exposure to tritium gas and the effect of changing the reaction parameters, *viz.*, tritium pressure, temperature coefficient, etc.

In this laboratory, tritio-cholecalciferol was prepared by exposure to tritium gas at −198°. This low temperature, as discussed later, minimizes molecular decomposition by radiation because of an enhancement of the "cage" effect and reduces the formation of radioactive impurities. Purification of the tritiated vitamin D_3 was effected by extraction, column chromatography, and recrystallization.

Received December 19, 1962, from the Radioactivity Research Center, School of Pharmacy, University of California Medical Center, San Francisco.

Accepted for publication February 26, 1963.

This investigation was supported in part by a grant-in-aid from the U. S. Public Health Service (C-3630), Cancer Research Funds of the University of California, and research funds of the Academic Senate of the University of California, San Francisco.

MATERIALS

All solvents used were reagent grade and were redistilled. Peroxide in ethyl ether was removed by passage through a column of basic alumina. Silica gel G, prepared for thin-layer chromatography according to Stahl (10), was obtained from E. Merck Co. Florisil, activated at 260°, was purchased from Floridin Co., Tallahassee, Fla.

EXPERIMENTAL

All manipulations involving tritiated vitamin D were carried out in an atmosphere of nitrogen and in low actinic glassware, or in glassware protected from light by wrapping in aluminum foil to minimize oxidation and photodecomposition.

Tritiation.—Approximately 500 mg. of vitamin D_3 (Mann Research Laboratories, New York, N. Y.) was exposed to 50 curies of tritium gas at a pressure of 130 mm. Hg at −198° (liquid nitrogen) for 39 days. The vitamin sample was introduced into the tritiation chamber shown in Fig. 1 through the open end *A* which was subsequently sealed. The sample-filled chamber was then attached at *T* to the pumping arm of a Toepler pump in a high vacuum line and evacuated to a pressure of 10^{-6} mm. Hg (11). Tritium gas, obtained from the Oak Ridge National Laboratory, was admitted without further purification into the tritiation chamber. After filling with the gas, the chamber was detached from the vacuum line by sealing off the capillary constriction at *D*.

The sealed tritiation chamber containing vitamin D_3 and tritium gas was immersed in liquid nitrogen (−198°) in a dewar flask and kept there for the duration of the exposure time.

To terminate the labeling process, the tritium gas, together with any radioactive gaseous products formed by radiation decomposition during exposure, was removed by breaking seal *B* of the tritiation chamber in the high vacuum line system.

Purification.—Purification of the tritiated vitamin D_3 consists of removing labile tritium activity and then eliminating radioactive impurities. Complete recovery at each step of purification was not attempted because it was more important that trace impurities of high specific activity be completely separated from the parent compound rather than high yields be obtained.

The unpurified tritiated vitamin D_3 was repeatedly dissolved in dry acetone and evaporated to dryness to remove labile tritium activities. The

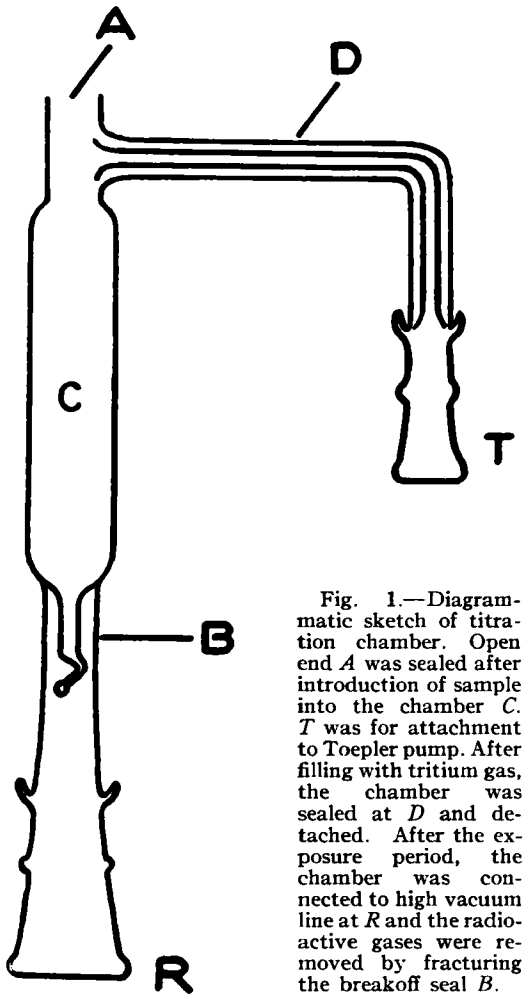

Fig. 1.—Diagrammatic sketch of titration chamber. Open end *A* was sealed after introduction of sample into the chamber *C*. *T* was for attachment to Toepler pump. After filling with tritium gas, the chamber was sealed at *D* and detached. After the exposure period, the chamber was connected to high vacuum line at *R* and the radioactive gases were removed by fracturing the breakoff seal *B*.

residue was recrystallized[1] from dry acetone at −80° to eliminate acetone soluble radioactive impurities. The recrystallized tritio-cholecalciferol (approximately 100 mg.) was dissolved in 150 ml. of peroxide-free ethyl ether and the ether solution was washed successively with three 50-ml. portions of ice-cold water to remove any hydroxylic protium exchangeable activities. The solution was dried with anhydrous sodium sulfate, filtered, and taken to dryness at room temperature in a rotatory evaporator. Whenever the residue was not completely clear, it was azeotropically dried by repeated evaporation with 20 ml. of a mixture of equal volumes of benzene and absolute ethanol. The clear residue was then taken up in 50 ml. of *n*-hexane for purification by column chromatography.

Approximately 10 to 15 mg. of the partially purified tritio-cholecalciferol in *n*-hexane was applied to a chromatographic column, 1.2 cm. in diameter and 15 cm. in height, prepared by pouring a slurry of 12 Gm. of 60 to 80-mesh Florisil in *n*-hexane into the chromatographic tube containing the same solvent. The column was kept at 15° by a water jacket to prevent solvent evaporation and thus eliminate formation of bubbles along the adsorbent bed. After loading, the column was rinsed with 100 ml. of *n*-hexane followed by elution with 400 ml. of 10% ethyl ether in *n*-hexane. The flow rate of the eluent was adjusted to 2 to 3 ml. per minute with a Teflon plugged stopcock at the lower end of the column. The eluent was collected in 10-ml. fractions. Concentration of tritio-cholecalciferol in the eluent was measured with Nield's reagent (12) against a known standard.

Purity of the tritiated cholecalciferol was ascertained by thin-layer chromatography on 250 μ-thick silica gel plates using a mixture of chloroform: methanol:water (10:50:10 by volume) as solvent. Color development was effected by spraying the plates with 20% antimony pentachloride in chloroform (13). Appearance of a pink color changing to dark brown indicated the presence of vitamin D_3.

The processes of recrystallization from acetone at −80° and column chromatography on Florisil were repeated until a constant specific activity was achieved.

Radioactivity Measurement.—Radioactivity of all samples was measured in a liquid scintillation spectrometer using 10 ml. of 0.3% diphenyloxazole in toluene as scintillator as previously reported (14). For samples in aqueous solution a scintillator consisted of 5 ml. of the above solution plus 5 ml. of a dioxane solution containing 7 Gm. diphenyloxazole, 50 mg. POPOP (2,2′-*p*-phenylenebis (5-phenyloxazole)), and 50 Gm. of naphthalene to 1 L. of purified dioxane.

The amount of the label in thin-layer chromatograms of tritio-cholecalciferol was determined by transferring the silica gel in narrow sections from the chromatogram into counting vials and assaying the radioactivity by liquid scintillation counting.

Absorption Spectrum.—The infrared spectra of unpurified tritio-cholecalciferol, nonradioactive vitamin D_3, and an unidentified decomposition product were obtained with a Beckman IR-5 infrared spectrophotometer using the KBr disk method. The ultraviolet spectra of these compounds were deter-

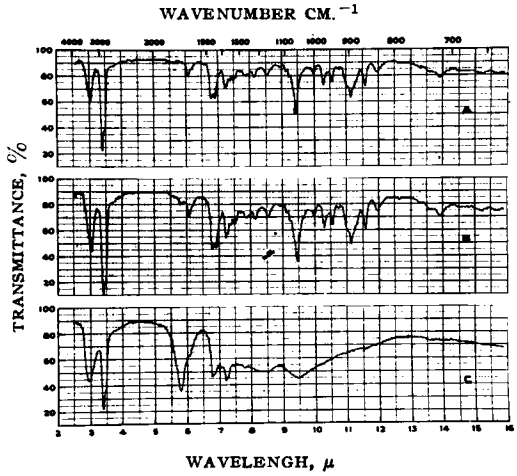

Fig. 2.—Infrared absorption spectra of cholecalciferol (*A*), unpurified tritio-cholecalciferol (*B*), and an unidentified decomposition product (*C*).

mined with a Cary model 11 recording spectrophotometer, using an ethanolic solution of 2 mg.% concentration.[2]

RESULTS AND DISCUSSION

The average β energy of tritium is 5.5 kev with a half-thickness value of 0.031 mg./cm.[2] in hydrogen (15) and a maximum range of 6 μ in water (16). At the prevailing pressure in the tritiation chamber, complete dissipation of the decay energy of tritium within the container is certain. The radiation dose to the cholecalciferol crystals, which occupied only a fraction of the total volume of the chamber, was estimated to be a minimum of approximately 2.4×10^7 rads. Apparently at $-198°$, this dose level did not cause excessive radiation damage as indicated by the identity of the infrared spectrum of the unpurified tritio-cholecalciferol (*B*) and that of an authentic nonradioactive standard (*A*) (Fig. 2). It should be noted, however, that the former contains a small absorption band at 5.8 μ, characteristic of carbonyl groups.

The purity of the tritio-cholecalciferol was ascertained by thin-layer chromatography on silica gel. The R_f value and the contour of the vitamin D_3 spot after solvent irrigation varied not only with the quantity of vitamin D_3 but also with the polarity of the solvent used for spotting. For instance, the spot obtained from a solution of vitamin D_3 in *n*-hexane or in petroleum ether (b.p. 40–60°) was more compact in shape and faster in movement as shown by an increased R_f value than that obtained from a solution in acetone, probably because of differences in ease of evaporation of the solvents and in the intrinsic solubility of vitamin D_3 in them. The R_f value of vitamin D_3 also varied inversely with the quantity of material being chromatographed on the thin-layer silica gel plate in the region of 5 to 40 mcg. regardless of the spotting solvent. In this concentration range, the vitamin D_3 spot tended to migrate nearer to the solvent front. At high concentrations ranging from 60 to 200 mcg., migration of the spot remained practically constant (R_f value: 0.651 ± 0.017 (S.D.) for hexane; 0.791 ± 0.012 (S.D.) for acetone). For routine assay, this uncertainty of the R_f value may be overcome by chromatographing spots of graded material concentration or by comparison with spots co-chromatographed with a known standard.

Distribution of tritium label in the unpurified tritio-cholecalciferol was studied on a 10-mg. sample. The results are shown in Table I. The labile tritium activity exchangeable with protium atoms on equilibration with acetone, water, and ether amounted to 73% of the initial activity. Purification by recrystallization from acetone at $-80°$ which was carried out with the bulk tritiated vitamin D_3 was neglected in this case because it would entail an excessive loss of material. Recovery of radioactivity from column chromatography on Florisil was about 71% although material recovery using a nonradioactive standard was 92%. Apparently the adsorbent at the top of the chromatographic column retained some radiation decomposition products as a yellowish band; this band was intensely radioactive and could not be eluted by acetone.

Radioactivity eluted by acetone represented approximately 53% of the label initially applied to the column. This acetone eluable fraction was found by means of thin-layer chromatography to coincide with a fast running spot which frequently appeared after long storage of known solutions of nonradioactive vitamin D_3 and which had a R_f value of approximately 1. The infrared spectrum of this compound was shown as *C* in Fig. 2. Loss of fine structure in the region of 7 to 14 μ and the presence of carbonyl stretching band at 5.8 μ, together with the minimal absorption in ultraviolet region of an ethanolic solution (2 mg.%) serve to indicate the absence of the tri-ene conjugation in the molecule. However, no attempt was made to identify this compound.

Tritio-cholecalciferol was eluted with 10% ether in *n*-hexane. The specific activity of the eluent fractions along the ascending and descending limbs of the band was found to be practically identical within experimental error, thus indicating the absence of radioactive congeners of high specific activity as possible contaminants. However, to insure a high degree of radiopurity, only the peak fractions of the tritio-cholecalciferol band were pooled for further purification. In this manner, by successive purification processes, including one recrystallization from acetone at $-80°$ and three chromatographic passages on Florisil column, a preparation of pure tritiated vitamin D_3 with a specific activity of 216 μc./mg. was obtained. The adequacy of this compound as a tracer was verified by biological studies (17) which yielded results similar to those found for nonradioactive vitamin D_3.

Condition of the adsorbant for column chromatography was found to be essential for successful separation of the tritio-cholecalciferol from its contaminants. Florisil activated at 260° was found to give better results than that deactivated with 6% water or neutral alumina (Brockmann activity III). The latter two adsorbants yielded vitamin D_3 fractions contaminated with trace of the fast-moving impurity described above, possibly due to artifact of decomposition on column. Purification of tritio-cholecalciferol by preparative thin-layer chromatography on silica gel is also feasible, provided that oxidation and photodecomposition are avoided.

TABLE I.—TRITIUM INCORPORATION AND DISTRIBUTION IN UNPURIFIED TRITIO-CHOLECALCIFEROL

		Tritium Activity
I.	Incorporation after exposure of 1.95×10^3 curie-days	2.7 mc./mg.
II.	Loss after equilibration with (%)	
	Acetone	66.6
	Water	5.6
	Ethyl ether	<1.0
III.	Distribution in chromatographic eluents (%)	
	n-Hexane	2.3
	10% Ether in *n*-hexane	15.3
	Acetone	53.4
	Activity remained on column (by subtraction)	29.0

[2] The measurement was performed by M. K. Hrenoff of the Spectrographic Laboratory, School of Pharmacy, University of California, San Francisco.

When a sample of vitamin D_3 was exposed to tritium gas at room temperature, no useful product was isolated, indicating that the use of low temperature (−198°) for labeling by exposure to tritium gas is of marked advantage since the formation of radioactive impurities is decreased. Because β labeling is due to formation of excited and ionized molecular species (18) which require energy of activation for subsequent chemical reactions, it is reasonable to postulate that at −198°, the small RT value in the Boltzmann factor reduces the probability of reaction. In addition, recombination of molecular ions is facilitated because their diffusion in solids is restricted as a result of an enhancement of the reaction cage effect at −198°.

The validity of the latter factor is supported by the work of Wenzel, *et al.* (19), who noted an increase in specific activity as well as fewer radioactive impurities after gas exposure labeling of charcoal-adsorbed compounds compared to the nonadsorbed control compounds. It is probable that either charcoal adsorption or low temperature (−198°) brings about a common effect, *i.e.*, a passive rigidity of molecular configuration and a restricted diffusion of molecular ions; both of these effects tend to diminish radiation decomposition and to increase substitution by tritium during exposure.

Kinetics of the Metabolism of Acetaminophen by Humans

By EINO NELSON and TADASHI MORIOKA

The kinetics of the metabolism of acetaminophen to its sulfuric and glucuronic acid conjugates has been studied in normal adult humans. In post-absorptive and post-equilibrative times the elimination process was found to be first order with a mean half-life of 1.95 hours with a range of 1.62 to 2.83 hours in nine tests using a five-subject test panel. Previously published data on pain threshold elevation resulting from ingestion of acetaminophen were examined during times following maximum elevation. Decay of pain threshold elevation was shown to be an apparent first-order process with a half-life of 0.42 hours. This half-life was less than one-fourth the half-life for metabolism, indicating that poor correlation exists between pharmacological activity and body level of acetaminophen, even though a kinetic relationship may exist between these quantities.

THE ANALGESIC DRUG, acetaminophen (4′-hydroxyacetanilide), is known to be metabolized nearly completely after administration to humans. Information on the metabolic fate of this drug in humans has been summarized by Williams (1). About 3% of an oral dose is excreted unchanged in the urine, and most of the balance of a dose can be found in the urine conjugated with sulfuric and glucuronic acids, with the latter conjugate predominating. The conjugates are formed at the 4′-hydroxy position on the molecule. Apparently the kinetics of the metabolism of this substance have not been studied previously. This communication reports the results of a pharmacokinetic study of the metabolism and excretion of acetaminophen and discusses the results obtained in terms of the physiological and pharmacological factors involved.

EXPERIMENTAL

Subject and Test Procedure.—One-gram doses of drug grade acetaminophen (finely powdered by

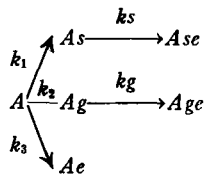
grinding in a mortar with a pestle and filled in hard gelatin capsules) were ingested in the morning on overnight-fasted stomachs by adult humans apparently in normal health. No food was taken until at least 1 hour after ingestion of the drug. The designation, sex, age, weight in kilograms, and body surface in sq. m. of the test subjects, respectively, were E-M-43-77-2.50, V-M-22-68-1.84, T-M-29-60-1.60, G-M-28-59-1.70, and S-F-37-57-1.62. Body surface areas were obtained from a nonogram (2) relating this quantity to height and weight. For determining blank excretion, urine specimens over a timed interval were obtained immediately prior to ingestion of the doses. Following ingestion of the doses, collection of urine at appropriate times was quantitative during the active course of the experiments. Nine experiments were made using the five-subject test panel.

Analytical Method.—The urines were assayed in triplicate for free acetaminophen by the method of Brodie and Axelrod (3) and in triplicate for total acetaminophen by a modification of the method described in the same publication. For determination of total acetaminophen, hydrolysis was effected by making suitably diluted urine 6 *N* in titer with hydrochloric acid and heating for 1.5 hours at 100°. One complete set of urines was assayed by both the modified and original method. Cumulative excretion of total drug was 942 mg. by the original method and 975 mg. by the modified method. The precision of the modified method was of the same order as the original method. The acetaminophen used to construct the standard curves was from the same lot used in the *in vivo* experiments.

RESULTS AND DISCUSSION

Cumulative free and conjugated drug excretions are listed in Table I.

Excretion Kinetics.—It was assumed that Scheme I described the kinetics of the metabolism and excretion of acetaminophen and its metabolites after absorption of a dose and attainment of apparent equilibrium between drug in blood and drug in other fluids of distribution



Scheme I

In Scheme I, A is the amount of acetaminophen in the body at any time; As and Ag are the amounts of acetaminophen in the form of its sulfuric and glucuronic acid conjugates, respectively, in the body at any time; Ase and Age are the amounts of acetaminophen sulfate and glucuronide ethers excreted in the urine in any time; and Ae is the amount of unchanged acetaminophen excreted in any time. The k's with number or letter subscripts are first-order rate constants with the dimensions of reciprocal time for the processes indicated. First-order processes for metabolism and urinary excretion are assumed since it has been found that this type of process describes within experimental error (in post-absorptive and post-equilibrative times) the metabolism and disposition of many drugs and foreign substances (4–15).

A preliminary examination of urinary excretion data indicated that apparent first-order excretion was being followed 2 or 3 hours after ingestion of doses. For mathematical treatment of data, a zero time shift (13, 14) of these values of time was made and cumulative amounts of drug excreted corrected to agree with the new time base by subtraction of the amount excreted in the time equal to the time shift.

[a] All data expressed as mg. of free drug. [b] Between 12 and 24 hours depending on a given subjects' sampling schedule.

TABLE II.—RATE CONSTANTS AND HALF-LIVES FOUND FOR THE METABOLISM AND EXCRETION OF ACETAMINOPHEN BY HUMANS[a]

Test Subjects	E-1	E-2	E-3	E-4	E-5
Rate constant (K), $hr.^{-1}$	0.400 (2.69×10^{-2})	0.385 (3.77×10^{-2})	0.394 (3.83×10^{-2})	0.427 (4.36×10^{-2})	0.275 (8.37×10^{-3})
Half-life, hr.	1.73 (1.14×10^{-1})	1.80 (1.79×10^{-1})	1.76 (1.85×10^{-1})	1.62 (1.60×10^{-1})	2.52 (3.60×10^{-2})
Test Subjects	**V**	**G**	**T**	**S**	**Mean**
Rate constant (K), $hr.^{-1}$	0.385 (4.58×10^{-2})	0.391 (1.90×10^{-2})	0.245 (1.28×10^{-2})	0.408 (3.73×10^{-2})	0.368 (5.60×10^{-2})
Half-life, hr.	1.85 (2.44×10^{-1})	1.77 (8.37×10^{-2})	2.83 (1.61×10^{-1})	1.70 (1.57×10^{-1})	1.95 (2.26×10^{-1})

[a] Standard deviations shown in parentheses.

In the model above it was further assumed that excretion of the metabolites of acetaminophen would be rate limited by the formation steps ($k_e \gg k_1$ and $k_g \gg k_2$).

On the basis of the considerations discussed in the preceding paragraphs, the following differential equations describe the several processes shown in the model

$$\frac{dA}{dE} = -KA \qquad \text{(Eq. 1)}$$

$$\frac{dAse}{dt} = k_1A \qquad \text{(Eq. 2)}$$

$$\frac{dAge}{dt} = k_2A \qquad \text{(Eq. 3)}$$

$$\frac{dAe}{dt} = k_3A \qquad \text{(Eq. 4)}$$

In Eq. 1 $K = k_1 + k_2 + k_3$. Equation 1 when integrated with constant of integration evaluated at zero time, where A° is the amount of acetaminophen in the body at zero time gives

$$A = A^\circ \, exp\,[-Kt] \qquad \text{(Eq. 5)}$$

Substitution in Eq. 2 of the value for A given in Eq. 5, and integration of the resulting expression with constant of integration evaluated at zero time under the condition that no metabolite was excreted gives

$$Ase = \frac{k_1A^\circ}{K}(1 - exp\,[-Kt]) \qquad \text{(Eq. 6)}$$

By a procedure identical with the immediately preceding one, Eq. 3 becomes

$$Age = \frac{k_2A^\circ}{K}(1 - exp\,[-Kt]) \qquad \text{(Eq. 7)}$$

and Eq. 4 becomes

$$Ae = \frac{k_3A^\circ}{K}(1 - exp\,[-Kt]) \qquad \text{(Eq. 8)}$$

In the experimental procedure adopted for following excretion of sulfuric and glucuronic acid ethers of acetaminophen, both substances were determined and the relative amounts of each form were unknown. Therefore, the combined excretion should be given by the sum of Eqs. 6 and 7

$$Am = \frac{k_1A^\circ}{K}(1 - exp\,[-Kt]) + \frac{k_2A^\circ}{K}(1 - exp\,[-Kt]) \qquad \text{(Eq. 9)}$$

In Eq. 9 Am is the amount of the sulfuric and glucuronic acid conjugates of acetaminophen excreted in the urine at any time. After a sufficiently long time corresponding to the time that only negligible excretion of metabolites occurs, where Am° is total amount of metabolites excreted after zero time, Eq. 9 reduces to

$$Am^\circ = \frac{k_1A^\circ}{K} + \frac{k_2A^\circ}{K} \qquad \text{(Eq. 10)}$$

If the value of the constants on the right-hand side of Eq. 10 are substituted in Eq. 9, the latter equation becomes

$$Am = Am^\circ(1 - exp\,[-Kt]) \qquad \text{(Eq. 11)}$$

Thus a relatively simple expression describes excretion of the metabolites of acetaminophen. Equation 11 was used in the form

$$\log_e(1 - Am/Am^\circ) = -Kt \qquad \text{(Eq. 12)}$$

After the shifts in zero time, at each of the data point times except the last ones, values of K were calculated, using the experimental data and Eq. 12. The values were then averaged to give a mean value of this quantity for a given experiment. These values were then divided into 0.693 to give the rate of the processes in terms of a half-life ($t^1/_2$). Because K represents the sum of all rate constants determining the rate of removal of acetaminophen

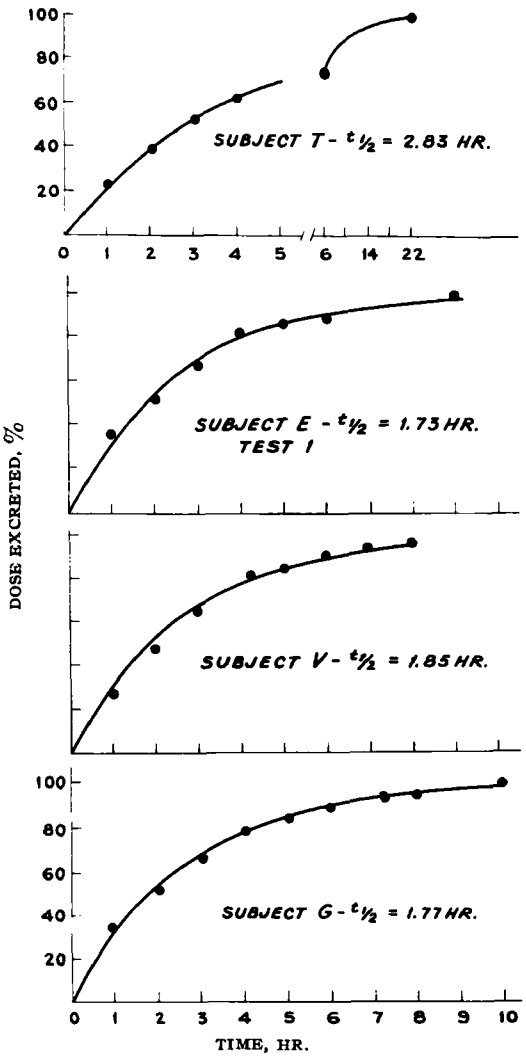

Fig. 1.—Cumulative excretion curves of acetaminophen's metabolites following oral ingestion of 1-Gm. doses of acetaminophen. Curves shown are theoretical for excretion after the time taken as zero time. Plotted points are experimentally observed values of cumulative excretion at the same times. Each curve is labeled with the test subject's designation and half-life for disposal of the drug from the body in a given experiment.

TABLE III.—RATE CONSTANTS AND HALF-LIVES FOUND FOR THE URINARY EXCRETION OF FREE ACETAMINOPHEN BY HUMANS

Test Subject	E-1	E-2	E-3	E-4	E-5	V	G	T	S	Mean
Rate constant, (k_3), hr.$^{-1}$ × 10^3	9.12	11.1	14.2	18.5	13.7	17.3	8.29	9.11	11.3	12.5
Half-life, hr.	76.0	62.4	48.8	37.4	50.6	40.0	83.6	76.1	61.3	59.6

from the body, the half-life so found represents the half-life for acetaminophen's disposal by the body.

Values of the rate constants, K, and half-lives found in all the experiments are given in Table II. To show that Eq. 12 did describe the excretion of acetaminophen's metabolites within experimental error, the mean values of K were substituted into Eq. 12 and theoretical excretion curves calculated. Some of these are shown in Fig. 1. The experimental points are included on the same plots, and it is shown that there is good agreement between theoretically predicted and experimentally observed cumulative acetaminophen metabolite excretion.

Free drug excretion was in such small amounts that it was not considered practical to fit the data to Eq. 8. The rate constant k_3 is deducible, however, from other information obtained in the experiments. At the time which corresponds to the end of the active course of experiments, Eq. 8 reduces to

$$Ae^\circ = \frac{k_3 A^\circ}{K} \qquad \text{(Eq. 13)}$$

where Ae° is the total amount of drug excreted as unchanged material. At this time Eq. 10 also holds which may be rearranged to give

$$A^\circ = \frac{KAm^\circ}{k_1 + k_2} \qquad \text{(Eq. 14)}$$

or

$$A^\circ = \frac{KAm^\circ}{K - k_3} \qquad \text{(Eq. 15)}$$

since $K = k_1 + k_2 + k_3$. If Eq. 13 is solved for A°, equated to Eq. 15, and the resulting expression rearranged, the value of the rate constant for excretion of free acetaminophen is

$$k_3 = \frac{Ae^\circ K}{Ae^\circ + Am^\circ} \qquad \text{(Eq. 16)}$$

All quantities on the righthand side of Eq. 16 are known; hence the value of k_3 may be obtained. In the present experiments the mean value was found to be 12.5×10^{-3} hr.$^{-1}$ The individual values of these constants are listed in Table III. If the relative amounts of drug conjugated with sulfuric and glucuronic acids are known, it is easy to show that the rate constants k_1 and k_2 would be, respectively

$$k_1 = \frac{Ase^\circ K}{Ae^\circ + Am^\circ} \qquad \text{(Eq. 17)}$$

and

$$k_2 = \frac{Age^\circ K}{Ae^\circ + Am^\circ} \qquad \text{(Eq. 18)}$$

where Ase° and Age° are the total amounts of drug found conjugated with sulfuric acid and glucuronic acids, respectively.

Pain Threshold Elevation and Kinetics of Metabolism.—It is of interest to compare the results of the present kinetic study with the kinetics of the analgesic effect of acetaminophen. Elevation of pain threshold following oral administration of 0.325-Gm. doses of drug to adult humans has been studied (16). After the maximum elevation in pain threshold, which occurred about 2.5 hours after administration of the doses, a rapid decay in elevation occurred. When values of elevation after the maximum were plotted as a function of time using semilogarithmic paper, a straight line resulted which indicated an apparent first-order process for decline in activity. This is shown in Fig. 2. Other instances of apparent first-order decay in pharmacological effects have been discussed by Swintosky (17). It is shown from Fig. 2 that the half-life for acetaminophen's activity is about 0.42 hours. In the paper where the data used to constant Fig. 2 were reported (16), it was stated that pain threshold elevation paralleled acetaminophen serum levels observed in another study (18). Examination of these data (which were limited) indicated that that decay in free acetaminophen levels in the post-absorptive phases had a half-life of approximately 1.9 hours. This half-life is more than four times as long as that which described decay in pain threshold elevation. The serum half-life of 1.9 hours compares favorably in magnitude to the mean half-life found in the

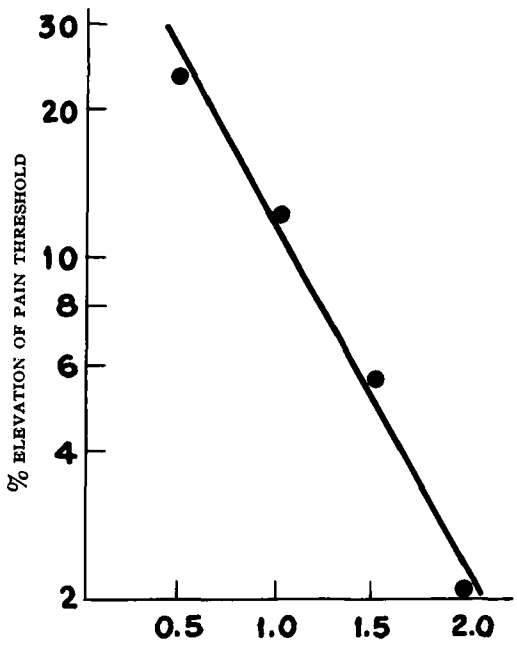

Fig. 2.—Illustrating first-order decay in pain threshold elevation after maximum observed elevation in threshold after oral ingestion of acetaminophen. Data for graph are taken from Flinn and Brodie (16).

present study of 1.95 hours. It would appear that disappearance of acetaminophen's pharmacologic effects bears little relationship to the rate with which this drug is metabolized and excreted, even though a kinetic relationship may exist between these quantities.

Biological Variations and Body Surface Area of Test Subjects.—Expected biological variation was found in the individual values of either the half-life or rate constant for disposal of acetaminophen. Since the rates of other physiological processes are sometimes related to body surface area, it was of interest to examine the present results to determine whether these were factors in causing the variation observed. There was no evidence of a relationship between surface area and rate constant when these quantities were plotted.

Aryl Indolizines I

Synthesis and Properties of Some Phenylindolizines

By VINCENT S. VENTURELLA†

Several aromatically substituted indolizines were prepared for possible psychotropic activity utilizing the Tschitschibabin method, and the susceptibility of the nucleophilic position toward benzoyl chloride was established. The properties of the prepared compounds indicated that those with an aromatic halide are not susceptible to nucleophilic attack such as the formation of alkoxy derivatives and also that those compounds containing the *p*-nitrophenyl group could be reduced to the corresponding amino compounds only under drastic conditions not normally expected of such compounds.

THE PHYSIOLOGICAL ACTIVITY of serotonin analogs (1) and reserpine (2) suggests that the structurally similar diphenylindolizines may possess psychotropic activity. In addition, it has been reported (3) that several alkylindolizines have a convulsant activity which would tend to indicate a profound effect on the central nervous system. It is hoped that the use of aryl substituents will moderate this activity thus producing compounds having the desired effect.

It is possible to prepare substituted indolizines by methods developed by Tschitschibabin (4), Barrett (5), or Scholtz (6), the former being most desirable because of ease of formation, good yields, and availability of starting materials. A modification of the method of Moser and Bradsher (7) permitted easy quaternization of the corresponding aryl pyridine with a substituted phenacyl halide to produce a solid product (Table I) in the absence of solvent followed by cyclization according to the scheme shown in Eq. 1.

When 2-parachlorobenzylpyridine was employed, the conditions necessary for the quaternization forced a spontaneous cyclization to occur, thus making it difficult to isolate these intermediates. Considerable decomposition of the tar base, which was always present in excess, was evident in the quaternization step either with 2-benzylpyridine or the *p*-chloro analog. The indolizines prepared are summarized in Table II.

The resonating system of the indolizines in the active state results in an alternating system of electron density (8) which causes nucleophile activity at position 1 or at position 3 if the former is substituted, leading to facile attack by electrophilic reagents. Thus treat-

[a] Based on pyridinium salt. [b] Based on starting substituted acetophenone.

ment with benzoyl chloride gave fair to good yields of the corresponding benzoyl derivatives by a modification of the procedure of Holland (9). The benzoyl compounds are peculiar in their lack of reactivity toward carbonyl reagents, but are said to form 2,4-dinitrophenylhydrazones readily (10). However, the compounds prepared in the present study formed these derivatives in poor yields and only after several hours of heating. In addition, the prepared benzoyl compounds have an infrared spectrum which would tend to preclude the presence of the carbonyl group. The effect of adjacent aromatic groups on the wavelength of absorption (11) coupled with reports that alkyl formyl derivatives (12) absorb at 6.1 μ tends to substantiate the fact that the carbonyl compounds of the present study had an absorption at 6.3 to 6.4 μ.

Anomolus behavior of the aryl indolizines prepared was found to exist in two instances. First, a fair degree of basicity should be evident because many of literature compounds form salts with mineral acid (10). In all cases of the present study, the compounds could be dissolved in concentrated mineral acid, but quantitatively precipitated upon dilution with even minute amounts of water. This anomoly is most logically attributed to the presence of multiple resonating systems which inactivate the available electrons on the tertiary nitrogen. Although a report (13) indicates that the presence of an aryl nitro group retards hydrolysis of 1-acyl groups, it was found that if a *p*-nitrophenyl group and a *p*-chlorophenyl group were at positions 2 and 3, respectively, the benzoyl derivative could not be isolated. The evidence discounts the possibility that hydrolysis occurs during reaction or processing. The only other explanation for this result is that the presence of a *p*-chlorophenyl group in the 3-position increases the neighboring group neutralizing effect of the resonance form of the *p*-nitrophenyl group, thereby preventing a nucleophilic center from being established.

Preliminary studies on the reactivity of the *p*-chlorophenyl group indicated that it has a low order of reactivity because it failed to undergo nucleophilic substitution in refluxing methanolic sodium methoxide.

EXPERIMENTAL[1]

The first two parts of the Experimental are general procedures, the details of which are presented in Tables I and II.

2-Benzylpyridinium Acetophenone Bromides.—The appropriate bromoacetophenone was mixed with 3 equiv. of 2-benzylpyridine and warmed to the required temperature on a water bath with constant agitation until solidification occurred. The resulting product was refrigerated for 2 days. The solid was then fragmented, leached, removed by filtration, and recrystallized.

Cyclodehydration of the Pyridinium Salts.—The pyridinium salt was placed in a three-neck flask equipped with a stirrer and water condenser and treated with a saturated solution of sodium bicarbonate (20 Gm./500 ml.) and 10 ml. of ethanol. The mixture was refluxed with constant stirring for the required period of time. The resulting slurry was filtered hot, the solid washed several times with hot water, dried by suction, and recrystallized.

Quaternization with 2-*p*-Chlorobenzylpyridine.—In each case, the substituted pyridine was mixed with the bromoacetophenone and heated as described for the 2-benzylpyridinium salt. The temperature, time of condensation, and the leaching solvent for the *p*-chloro analogs of compounds *IA*, *IB*, and *IC*, respectively, were as follows: 50° for 10 minutes, stand at room temperature for 3 days; ethanol: 60° until reddish brown and syrupy, shake until solid, and refrigerate 3 days; methanol: steam bath until dark brown and syrupy, shake until solid, immediately cool in an

ice bath, and refrigerate overnight; warm methanol.

1-Benzoyl-2-(*p*-bromophenyl)-3-phenylindolizine.—Ten milliliters of benzoyl chloride and 4.5 Gm. (0.013 mole) of II*A* were mixed in a 100-ml. three-neck flask equipped with a stirrer and water condenser, and stirred at 40° for 30 minutes. The resulting viscous suspension was diluted with 50 ml. of benzene, allowed to stand at room temperature for 60 hours, then placed in a boiling water bath for 1 hour while stirring. The dark green solution was then cooled to room temperature and treated slowly with 60 ml. of a 40% sodium hydroxide solution. The benzene layer was removed, washed with 60 ml. of water, and the combined aqueous layers washed with benzene until the benzene washings were colorless. The benzene layers were then dried over anhydrous sodium sulfate and evaporated under reduced pressure to a thick green syrup. The addition of 50 ml. of petroleum ether (30–60°) to the syrup caused precipitation of a greenish brown solid. The solid was removed by filtration, washed with two 50-ml. portions of petroleum ether, and suction dried to give 4.0 Gm. (68%) of a bright green powder. It crystallized from boiling ethanol as needles, m.p. 196–198°.

Anal.—Calcd. for $C_{27}H_{18}BrNO$: C, 71.68; H, 3.98; N, 3.10. Found: C, 71.48; H, 3.98; N 3.10.

2,4-Dinitrophenylhydrazone.—Red-brown scales (95% ethanol), m.p. 140–142°.

Anal.—Calcd. for $C_{33}H_{22}BrN_5O_4$: N, 11.07. Found: N, 11.52.

1-Benzoyl-2-(*p*-bromophenyl)-3-(*p*-chlorophenyl)indolizine.—Five grams (0.013 mole) of the corresponding indolizine was mixed at 60° (water bath) with 12.5 ml. of benzoyl chloride, stirred for 1 hour, diluted with 25 ml. of benzene, and kept at this temperature for 2 additional hours. After standing for 48 hours at room temperature, the green solution was diluted with 50 ml. benzene, made basic with a 40% solution of sodium hydroxide, and the liquids were separated. Processing as previously described gave a green solid which was washed twice with ice-cold acetone and suction dried to give 4.5 Gm. (70%) of a crystalline solid. Recrystallization from hot acetone gave yellowish-green flakes, m.p. 235–237°.

Anal.—Calcd. for $C_{27}H_{17}BrClNO$: C, 66.81; H, 3.51; N, 2.88. Found: C, 66.78; H, 3.76; N, 2.22.

2,4-Dinitrophenylhydrazone.—Orange-red needles (70% ethanol), m.p. 185–187°.

Anal.—Calcd. for $C_{33}H_{21}BrClN_5O_4$: N, 10.55. Found: N, 10.99.

1-Benzoyl-2-(*p*-nitrophenyl)-3-phenylindolizine.—Five grams (0.016 mole) of II*B* was mixed with 12.3 ml. of benzoyl chloride and heated on a water bath at 60° for 30 minutes, giving a dark greenish-brown syrup. Ten milliliters of benzene was added, followed by refluxing for 1 hour. The mixture was stirred at room temperature for 20 hours and allowed to stand for 3 days. Processing followed by the addition of petroleum ether (30–60°) gave a dark oil which crystallized when triturated with cold ethyl acetate. Filtration and washing with petroleum ether gave 3.5 Gm. (53%) of a green solid which recrystallized as plates from boiling ethanol, m.p. 253–257°.

Anal.—Calcd. for $C_{27}H_{18}N_2O_3$: C, 77.52; H, 4.31; N, 6.69. Found: C, 77.53; H, 4.30; N, 6.77.

2,4-Dinitrophenylhydrazone.—Orange-brown granules(ethanol), m.p. 198–201°, dec.

Anal.—Calcd. for $C_{33}H_{22}N_6O_6$: N, 14.10. Found: N, 14.79.

2 - (*p* - Aminophenyl) - 3 - phenylindolizine.—Ten grams (0.031 moles) of II*B* was placed in a 250-ml. three-neck flask equipped with a stirrer and water condenser and mixed with 9 equiv. of concentrated hydrochloric acid (28 Gm.), stirred, and diluted with water to 80 ml. The stirred suspension was then heated to 60° while 0.124 moles of granular tin was added portionwise over 1.5 hours. At the end of 5 hours of heating, the suspension was cooled, allowed to stand overnight at room temperature, and filtered. The filtrate was made alkaline with 10 *N* sodium hydroxide solution. Stirring for 1 hour, followed by filtration and water washing gave 7.2 Gm. (71%) of a tan microcrystalline material. The solid was recrystallized from hot aqueous acetone and dried at 100°, m.p. 153 to 154.5°.

Anal.—Calcd. for $C_{20}H_{16}N_2$: C, 84.51; H, 5.63; N, 9.86. Found: C, 84.59; H, 5.76; N, 9.74.

2 - (*p* - Aminophenyl) - 3 - (*p* - chlorophenyl)indolizine.—Ten grams of II*E* was reduced in the same manner as II*B* to give 4.5 Gm. (49%) of product, m.p. 165–167° after recrystallization from ethanol-water.

Anal.—Calcd. for $C_{20}H_{15}ClN_2$: C, 75.47; H, 4.72; N, 8.80; Cl, 11.01. Found: C, 74.97; H, 4.67; N, 8.57; Cl, 10.94.

Critical *In Vitro* Factors in Evaluation of Gastric Antacids I

Polypeptide Inhibition

By SAURABH DESAI, MILO GIBALDI, and JOSEPH L. KANIG

In vitro **investigation of a wide range of antacid materials contained in various commercially available dosage forms has indicated demonstrable differences in both the degree and rate of neutralization and in buffering capacities. Results obtained by using pH-titration curves reveal that the type of dosage form exerts an influence on the antacid properties of the same chemical compound. Inhibition of antacid activity of some compounds was observed when polypeptides were added to the artificial gastric fluid. It is thus conceivable that antacid activity could be completely curtailed if similar conditions are encountered in the human system.**

ANTACIDS are the object of considerable interest in therapeutics and in pharmacological and pharmaceutical research. Because of their widespread use in the treatment of peptic ulcers, hyperacidity, and gastric distress, numerous *in vitro* investigations have been instituted to evaluate antacid activity (1–11).

The increasing popularity of antacid therapy has led to the marketing of a large number of products which are based on the principle of neutralization of excess gastric acid. These commercially available products may be broadly divided into systemic and nonsystemic preparations. According to Fuchs (12) systemic antacids are defined as those which react with hydrochloric acid in the stomach to form by-products which are readily absorbed and, in turn, induce a systemic alkalosis by shifting the buffer balance of the blood. Nonsystemic antacids are said to form by-products which are insoluble in body fluids and therefore will not induce an alkalosis.

In vivo excretion data obtained from another study currently being conducted in our laboratories offer evidence that the supposed nonsystemic antacids may induce a mild but nevertheless measurable systemic alkalosis. Furthermore, almost all of the products in this category will react with HCl to form water soluble by-products such as magnesium chloride, calcium chloride, and aluminum chloride which are equally soluble in body fluids.

Since the possibility exists that the so-called nonsystemic antacids might induce systemic effects and to avoid conceptual misunderstandings because of erroneous terminology, antacids have been classified in this investigation on an entirely different basis. A study of the currently marketed antacids indicated that all products could be divided into two major product types—effervescent and noneffervescent.

Although a number of comparative studies in recent years have been reported (1–3, 7–10, 13) regarding antacid efficiency, a lack of information still exists on comparisons between (*a*) effervescent and noneffervescent antacids, (*b*) antacid products using doses recommended by manufacturers rather than equal weights of similar products or other arbitrary levels, (*c*) the different dosage forms of the same products at the recommended dosage levels for each.

Since it has the greatest effect on results, one of the most critical *in vitro* factors is the composition of the test fluid. Almost invariably a dif-

Critical *In Vitro* Factors in Evaluation of Gastric Antacids I

Polypeptide Inhibition

By SAURABH DESAI, MILO GIBALDI, and JOSEPH L. KANIG

In vitro **investigation of a wide range of antacid materials contained in various commercially available dosage forms has indicated demonstrable differences in both the degree and rate of neutralization and in buffering capacities. Results obtained by using pH-titration curves reveal that the type of dosage form exerts an influence on the antacid properties of the same chemical compound. Inhibition of antacid activity of some compounds was observed when polypeptides were added to the artificial gastric fluid. It is thus conceivable that antacid activity could be completely curtailed if similar conditions are encountered in the human system.**

ANTACIDS are the object of considerable interest in therapeutics and in pharmacological and pharmaceutical research. Because of their widespread use in the treatment of peptic ulcers, hyperacidity, and gastric distress, numerous *in vitro* investigations have been instituted to evaluate antacid activity (1–11).

The increasing popularity of antacid therapy has led to the marketing of a large number of products which are based on the principle of neutralization of excess gastric acid. These commercially available products may be broadly divided into systemic and nonsystemic preparations. According to Fuchs (12) systemic antacids are defined as those which react with hydrochloric acid in the stomach to form by-products which are readily absorbed and, in turn, induce a systemic alkalosis by shifting the buffer balance of the blood. Nonsystemic antacids are said to form by-products which are insoluble in body fluids and therefore will not induce an alkalosis.

In vivo excretion data obtained from another study currently being conducted in our laboratories offer evidence that the supposed nonsystemic antacids may induce a mild but nevertheless measurable systemic alkalosis. Furthermore, almost all of the products in this category will react with HCl to form water soluble by-products such as magnesium chloride, calcium chloride, and aluminum chloride which are equally soluble in body fluids.

Since the possibility exists that the so-called nonsystemic antacids might induce systemic effects and to avoid conceptual misunderstandings because of erroneous terminology, antacids have been classified in this investigation on an entirely different basis. A study of the currently marketed antacids indicated that all products could be divided into two major product types—effervescent and noneffervescent.

Although a number of comparative studies in recent years have been reported (1–3, 7–10, 13) regarding antacid efficiency, a lack of information still exists on comparisons between (*a*) effervescent and noneffervescent antacids, (*b*) antacid products using doses recommended by manufacturers rather than equal weights of similar products or other arbitrary levels, (*c*) the different dosage forms of the same products at the recommended dosage levels for each.

TABLE I.—ANTACID PRODUCTS AND INGREDIENTS EVALUATED

Code Designation	Dosage Form	Recommended Dose[a] Min.	Max.	Composition
A	Effervescent tablet	1	2	Sodium bicarbonate, citric acid, monocalcium phosphate
B	Effervescent powder	1	...	Sodium bicarbonate, sodium potassium tartrate, tartaric acid
C	Effervescent granules	1	2	Sodium bicarbonate, potassium bicarbonate, citric acid, tartaric acid, calcium lactate, sodium phosphate, magnesium sulfate
D	Tablet	2	4	Aluminum hydroxide, magnesium hydroxide
D-L	Liquid	2	4	1 teaspoonful of D-L = 1 tablet of D
E	Tablet	2	4	Magnesium hydroxide, aluminum hydroxide
E-L	Liquid	2	4	1 teaspoonful of E-L = 1 tablet of E
F	Tablet	1/2	1	Aluminum hydroxide
F-L	Liquid	1	2	1 teaspoonful of F-L = 1/2 tablet of F
G	Tablet	1	2	Aluminum hydroxide, magnesium hydroxide
G-L	Liquid	1	2	1 teaspoonful of G-L = 1 tablet of G
H	Tablet	2	4	Magnesium trisilicate, aluminum hydroxide
H-L	Liquid	1	4	1 teaspoonful of H-L = 1 tablet of H
I	Tablet	2	4	Magnesium hydroxide
I-L	Liquid	1	3	Magnesium hydroxide[b]
J	Tablet	1	2	Calcium carbonate, glycine
J-L	Liquid	1	...	Calcium carbonate, glycine[b]
K	Tablet	2	3	Sodium bicarbonate, calcium carbonate, bismuth subcarbonate, magnesium carbonate, magnesium oxide, papain
L	Tablet	6	...	Sodium bicarbonate, charcoal, ginger, capsicum.
M	Tablet	1	2	Dihydroxy aluminum-sodium carbonate
N	Tablet	1	4	Calcium carbonate, magnesium carbonate, magnesium trisilicate
O	Tablet	1	4	Aluminum hydroxide, magnesium oxide, sodium lauryl sulfate
P	Tablet	1	2	Aluminum hydroxide, calcium carbonate, magnesium peroxide

[a] Expressed as number of tablets in the case of tablets; number of teaspoonfuls (5 ml.) for liquids or granules. [b] No equivalency between whole dosage units of liquid and tablet forms is available.

ferent test fluid has been proposed for each of the evaluative procedures reported in the literature (6). In 1953, Brindle (5) found that the results obtained from *in vitro* evaluations of antacids depended upon the presence or absence of pepsin and peptone in the test fluid. Others have stated (14, 15) that such materials have little effect on the results. Recently, Beekman (16) and Newey (17) have confirmed Brindle's observations and have shown that pepsin and peptone exhibit a marked inhibitory effect on the *in vitro* activity of dried aluminum hydroxide gel. The effect of polypeptides has not, however, been evaluated with other antacids which are formulated with calcium or magnesium compounds or with effervescent antacids. Furthermore, the mechanism of such an inhibition has never been elucidated.

The objectives of this study were therefore (*a*) to compare the evaluation of the basic types of marketed antacids and the different dosage forms of individual antacid preparations, and (*b*) to investigate the role of polypeptides on *in vitro* antacid activity.

EXPERIMENTAL

Volume of Test Fluid.—According to Fuchs (12) the human stomach contains the equivalent of approximately 50 ml. of free 0.1 *N* HCl shortly after a meal. He also concludes that an additional 240 ml. of 0.1 *N* HCl is secreted within 2 hours thereafter. Based on these observations it was decided to employ 50 ml. of 0.1 *N* HCl as the starting volume in all neutralization determinations. When buffering capacities of an antacid were evaluated, 0.1 *N* HCl was added to this volume at the rate of 2 ml./minute.

TABLE II.—INDIVIDUAL ANTACID COMPONENTS EVALUATED

Code Designation	Material	Quantity Evaluated
Q	Sodium bicarbonate U.S.P.	1 Gm.
R	Sodium citrate U.S.P.	1 Gm.
S	Dried aluminum hydroxide gel U.S.P.	1 Gm.
S-L	Aluminum hydroxide gel, 10%	10 ml.
T	Magnesium trisilicate U.S.P.	1 Gm.
T-L	Magnesium trisilicate gel, 10%	10 ml.
U	Calcium carbonate U.S.P.	1 Gm.
U-L	Calcium carbonate gel, 10%	10 ml.
V	Magnesium oxide U.S.P.	1 Gm.
W	Magnesium carbonate U.S.P.	1 Gm.

TABLE III.—RATES OF NEUTRALIZATION AND MAXIMUM pH ATTAINED BY MINIMUM RECOMMENDED DOSAGES OF COMMERCIAL ANTACIDS

Code Designation	Minutes Required to Attain pH 4	Max. pH Reached
A	< 0.5	6.7
B	< 0.5	5.3
C	< 0.5	9.1
D	2 (<1)[a]	6.4
D-L	< 0.5	4.9
E	2 (1)	7.7

M	...	3.8
N	22 (4)	7.8
O	25 (3)	5.2
P	4 (4)	7.4

[a] Figures in parentheses indicate values for crushed tablets.

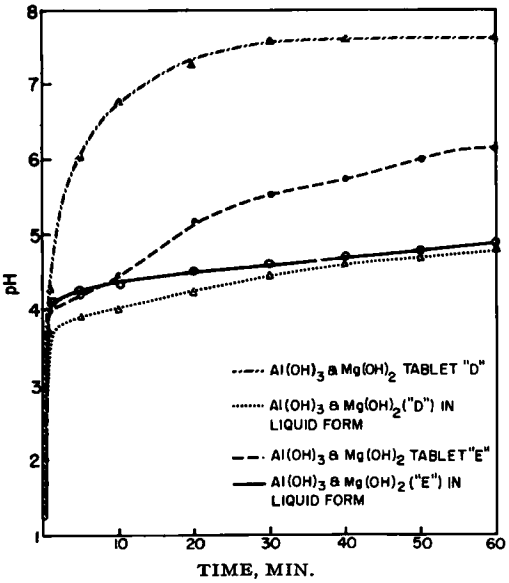

Fig. 1.—Rate of neutralization and maximum pH attained with minimum equivalent doses of two dosage forms of two commercial antacids in 50 ml. 0.1*N* HCl.

Range of Antacid Activity.—Lack of agreement exists regarding the pH range required for antacid effect. These have been reported as ranges of 2 or above, 3 or above, and from 4 to 5.5. Dale and Booth (13) have stated, "despite this apparent disagreement it is likely that all are correct since for certain clinical purposes a final pH range of from 4 to 6 may be desirable while for others a pH of 2 to 3 may suffice." These authors have advocated that antacids could be considered as being effective as long as the pH of the stomach contents remains above that of normal gastric fluid which is considered to be about 1.5 to 2. In view of these considerations, a return to a pH of 2 was considered as the end point of all buffering capacity determinations.

Selection of Antacids.—The commercial antacid products and the antacid components utilized in this study are tabulated and coded in Tables I and II. These were selected as being representative of the various types of antacids and the variety of mixtures of antacid materials currently employed.

Procedures

A. Rate of Neutralization.—The recommended minimum dose of a commercial antacid was added to a 400-ml. beaker containing 50 ml. of 0.1 *N* HCl. When the dosage form tested was a tablet, it was evaluated in both crushed and uncrushed form. The test mixture was maintained at a constant temperature of 37 ± 0.5° by immersing the beaker in a constant temperature water bath. Stirring was effected by an overhead stirrer. Stirring was maintained at a constant rate throughout the investigation and provided sufficient agitation to preclude the sedimentation of insoluble material during each evaluation.

The pH changes were recorded with respect to time utilizing a Beckman zeromatic pH meter with an accuracy of ±0.05 pH unit. Readings were taken at regular intervals until the pH remained constant for a period of 15 minutes. This procedure, although not indicative of *in vivo* conditions, nevertheless presents data on neutralization rates of the antacids and gives a clear picture of the speed of neutralization and maximum pH achieved.

B. Buffering Capacity.—Each commercially avail-

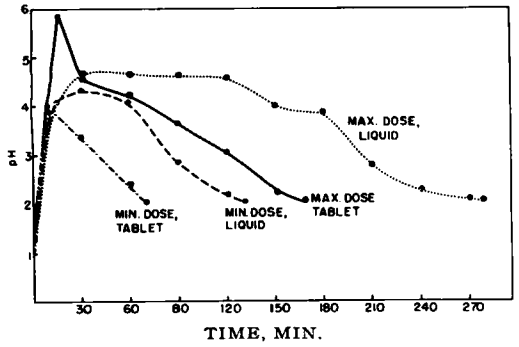

Fig. 4.—Differences in buffering capacities of minimum and maximum equivalent doses of two dosage forms of a commercial antacid containing magnesium and aluminum hydroxide, "E."

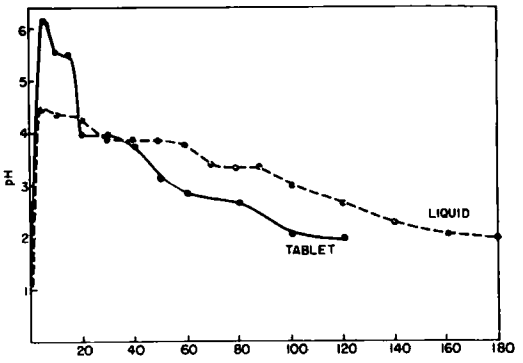

Fig. 5.—Difference in buffering capacity of the maximum equivalent doses of two dosage forms of a commercial antacid containing magnesium and aluminum hydroxide, "H."

able antacid product was evaluated as described in *Procedure A* by adding either the minimum or the maximum dose recommended by the manufacturer. Immediately after adding the dose, additional 0.1 *N* HCl was added to the reaction mixture at the rate of 2 ml. per minute until the pH returned to a base value of 2. This procedure indicated the total amount of acid consumed by the antacid under consideration as well as the time-pH relationship. An additional aspect of this phase of the study was the evaluation of the individual component chemicals currently utilized in antacid preparations.

C. Effect of Test Fluid Composition on Antacid Activity.—Commercially available antacids and antacid component chemicals were evaluated as described in *Procedure B* except that the test fluid used was modified as follows:

Test Solution 1.—Pepsin 0.32% and sodium chloride 0.2% dissolved in 0.1 *N* HCl was used. This is U.S.P. XVI artificial gastric fluid.

Test Solution 2.—Pepsin 0.32%, sodium chloride 0.2%, and peptone[1] 0.15% dissolved in 0.1 *N* HCl was used. The concentration of peptone approximates the amount of this material found in human gastric fluid (5).

These solutions were used in additional modified procedures which were designed to study the effect of polypeptides on rate of neutralization. The method outlined in *Procedure A* was employed but *Test Solution 2* was used instead of 0.1 *N* HCl.

[1] Bacto-Peptone, Difco Laboratories, Detroit, Mich.

RESULTS AND DISCUSSION

The onset of action of an antacid is a critical feature of its efficiency. This action is demonstrated by the rate of neutralization manifested by the product. The results listed in Table III indicate that in almost all cases antacid effect is observed within 5 minutes. For comparison, the time required to reach a level of pH 4 for each antacid is reported. It is evident from the data presented in Table III that there is little difference in onset of action between the liquid form of an antacid product compared to a chewable tablet.

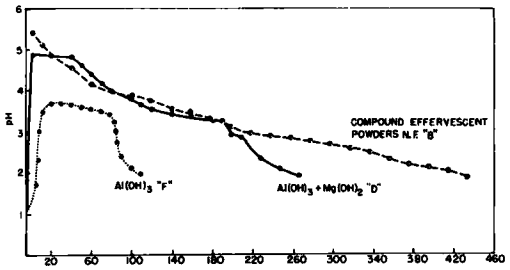

Fig. 6.—Buffering capacities of representatives of three different types of antacid preparations.

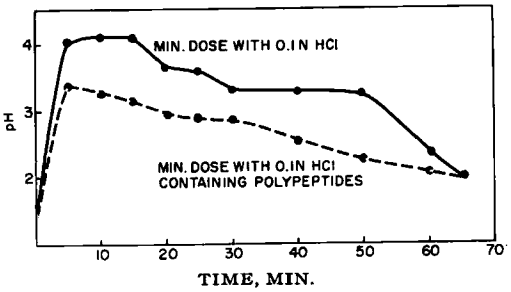

Fig. 7.—Polypeptide inhibition on buffering activity of a commercial antacid tablet containing aluminum and magnesium hydroxide, "E."

Moreover, the liquid forms of products D and E seem to be less basic than the equivalent amounts of the same components in tablet form. Figure 1 indicates that in both products D and E a lower maximum pH is attained with the liquid form. This may be attributable to the nonactive components of the suspension or the tablet which may combine with the antacid material to yield a compound of lower alkalinity upon neutralization or which may physically impede the availability of the active components. Viscosity increasing agents used to stabilize suspensions or binding agents used in tablets may possibly demonstrate this effect. This phenomenon is more clearly observed in Figs. 2 and 3 which indicate buffering capacity of antacids D and F. In each case the tablets consume a significantly greater quantity of acid compared to the liquid form.

In Fig. 3, even though the minimum dose of the liquid preparation is a superior antacid (as indicated by the area under the curve to a base line at pH 2), the equivalent dose in tablet form neutralizes

a greater amount of acid. If the assumption is made that a similar picture exists *in vivo*, then it is conceivable that the tablet form would be severely limited in treatment of peptic ulcer where inactivation of gastric pepsin activity due to elevated pH is desired. In such cases, the liquid form would manifest a greater degree of therapeutic activity.

On the other hand, when products E and H and their liquid equivalents, E-L and H-L, were evaluated under identical conditions, quite the opposite effects were noted. These results are depicted in Figs. 4 and 5 and indicate that the liquid showed a considerably greater neutralizing capacity compared to the equivalent dose in tablet form.

It is significant that products D and F contain aluminum hydroxide as the predominent component, while product E contains equivalent amounts of magnesium and aluminum hydroxides and product H contains magnesium trisilicate in a ratio of 2–1 to aluminum hydroxide. Auxiliary investigations are currently underway to discover whether these divergent results are due to individual product properties or the antacid components generally.

A comparison of the different types of products revealed that all the effervescent antacids tested possess a much greater buffering capacity than the noneffervescent antacids. These results are contained in Tables IV and V. Figure 6 indicates that compound effervescent powder N.F. (product B) neutralized almost twice the volume of 0.1 *N* HCl as product D. Product D is the most efficient noneffervescent compound with respect to neutralizing capacity. Of greater significance is that effervescent product B neutralizes almost four times the amount of 0.1 *N* HCl as does product F which contains aluminum hydroxide as the sole active component.

Effect of Polypeptides.—It has been demonstrated (16, 17) that polypeptides such as would be found in the stomach contents following ingestion of a meal have a decided inhibitory effect on antacid activity of aluminum hydroxide. To ascertain whether polypeptides such as pepsin and peptone exhibit a similar inhibitory effect on other antacid materials, the buffering capacities of a number of marketed antacid preparations of varying composition were evaluated in the presence of polypeptides. Figures 7–9 represent the results of these tests. These figures indicate that the inhibitory effect of polypeptides is not limited to aluminum hydroxide exclusively but is seen to occur with the other products tested which contain magnesium or calcium compounds.

Polypeptide inhibition was not observed in the

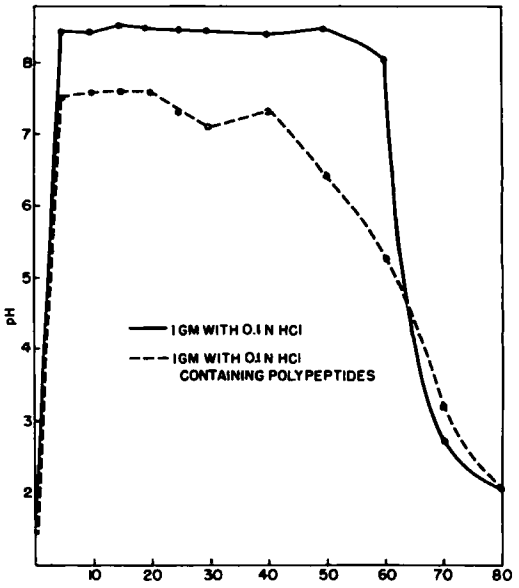

Fig. 13.—Polypeptide inhibition of buffering activity of magnesium carbonate.

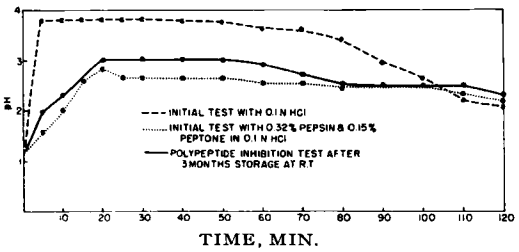

Fig. 14.—Effect of aging on polypeptide inhibition of the buffering capacity of a 10% w/v aluminum hydroxide aqueous suspension.

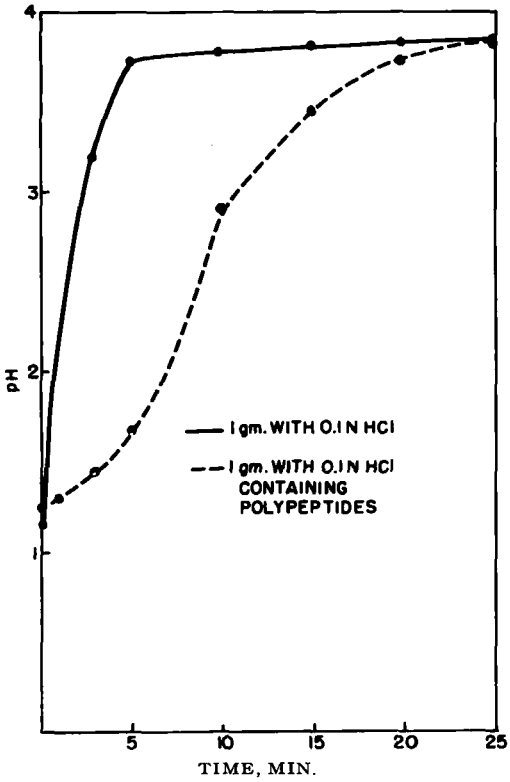

Fig. 15.—Polypeptide induced neutralization lag with dried aluminum hydroxide gel U.S.P.

liquid products tested regardless of composition. In addition, it was not demonstrated with the effervescent products tested. Increases in concentration of pepsin and peptone in the test solutions failed to cause deviations in the neutralization or buffering capacity curves of the effervescent antacids. This resistance to inhibition would seem to offer a marked advantage to the use of either the liquid form of an antacid or an effervescent antacid.

To complete the study of the inhibitory effect, a number of powdered antacid chemicals were selected and tested for buffering capacity in the presence of pepsin and peptones. Figures 10–13 demonstrate the pronounced depression in the curves for aluminum, magnesium, and calcium compounds.

Although there is a marked depression in the pH attained by an antacid in the presence of polypeptides, an important observation which has not been reported in the literature to date is that the total volume of HCl neutralized remains the same. In all cases the volume of hydrochloric acid required to return the pH to a level of 2 was the same regardless of whether pepsin and peptone were present. This indicates that the inhibition will be of little significance when considering maximum doses of calcium and magnesium compounds. Since both compounds elevate the pH well above 5 at these dosage levels, a slight decrease of 1 to 1.5 pH units will have little effect on their activity, considering that the same amount of hydrochloric acid is neutralized.

The inhibition effect, however, does become significant when considering the lower doses of these materials as well as dry aluminum compounds. It is therefore plausible to consider the possibility that the *in vivo* activity of these antacids in the presence of polypeptides will be markedly reduced or limited.

Mechanism of Inhibitory Effect.—Figure 14 depicts the results obtained when a 10% dispersion of dried aluminum hydroxide gel in distilled water was allowed to hydrate for a period of 3 months. The aging period served to decrease the polypeptide effect; these results are in agreement with those obtained with commercial liquid antacid products.

The neutralization lag was studied by subjecting 1 Gm. of dried aluminum hydroxide gel to *Test Solution 2*. Figure 15 indicates that the maximum pH level of the lower curve is the same as the upper curve. This fact together with those observed in all buffer capacity experiments, which showed the same amount of HCl neutralized with or without polypeptides, indicates that a kinetic involvement underlies these phenomena rather than some irreversible complex formation. Additional work is being conducted which will lead to a more complete elucidation of the mechanism involved.

SUMMARY

1. A comparative *in vitro* evaluation was conducted on effervescent and noneffervescent products and on liquid and solid dosage forms of the same product. It was demonstrated that the effervescent antacids were superior in buffering capacity to the noneffervescent types. Differences in efficiency were observed between solid and liquid dosage forms on an equivalent dosage basis.

2. The role of polypeptide inhibition in *in vitro* procedures was studied and produced data which indicate that a positive inhibitory effect may be observed with all solid noneffervescent antacids but not with liquid or effervescent forms.

3. The pronounced effect of polypeptides on many antacid preparations illustrates the vital role they exercise in *in vitro* evaluations and the necessity for their inclusion in all artificial test fluids.

Tachyphylaxis III

Ephedrine

By F. F. COWAN, T. KOPPANYI, and G. D. MAENGWYN-DAVIES

Tachyphylaxis to ephedrine was studied in anesthetized cats by the following parameters: pressor responses (height and duration), heart rate, nictitating membrane contractions, and tone. *Levo* or *dl*-norepinephrine infusions, in contrast to epinephrine or phenylephrine infusions, given after the initial development of tachyphylaxis, produced a partial return of responses to ephedrine. Ephedrine tachyphylaxis and its specific reversal by norepinephrine are discussed.

OUR STUDIES on the reversal of neuro-sympathomimetic amine tachyphylaxis (1, 2) were continued with *l*-ephedrine sulfate, which is a well known tachyphylactogenic agent (3, 4). Its action has been postulated to be of a mixed nature (5–7), *i.e.*, it appears to act directly on smooth muscle as well as indirectly by release of norepinephrine from endogenous stores. Thus, it was of particular interest to ascertain whether the replacement of the partially depleted neurohumor, *l*-norepinephrine, would alter the development of tachyphylaxis to this sympathomimetic amine of dual action.

METHODS

l-Ephedrine sulfate was injected intravenously once every hour at a dose of 1.5 mg./Kg. or 0.75 mg./Kg. *l*-Norepinephrine bitartrate monohydrate (*l*-NOR) or *dl*-norepinephrine hydrochloride (*dl*-NOR) were dissolved in physiological salt solution to a concentration of 60 mcg./ml. and administered intravenously by continuous infusion at the rate of 2.3 mcg./minute, regardless of the weight of the animal. The infusions started 15 minutes after the second, third, or fourth ephedrine injection when tachyphylaxis was developed. In view of the differences in molecular weights between the two norepinephrine salts and of the well known lesser potency of *d*-norepinephrine, this infusion rate was arbitrarily chosen.

To ascertain the specificity of norepinephrine, phenylephrine hydrochloride (diluted to 300 mcg./ml. with physiological salt solution) was infused starting 15 minutes after the second hourly ephedrine injection at a rate of 11.6 mcg./minute, as was *l*-epinephrine hydrochloride at a rate of 4.6 mcg./minute. Dichloroisoproterenol hydrochloride (DCI), the β-receptor blocking agent (9), was administered intravenously at a dose of 3 mg./Kg. 15 minutes before the first hourly injection of ephedrine to determine the influence of β-receptors (8).

Male cats, weighing 3–4 Kg., were anesthetized with α-chloralose (80.0 mg./Kg. intraperitoneally) and pretreated with atropine sulfate (2.0 mg./Kg. intravenously). Polygalacturonic acid glycoside (PAG) was employed as an anticoagulant. The parameters measured and reported in this paper were (*a*) mean arterial blood pressure, (*b*) heart rate, (*c*) tonus, and (*d*) contractions of the nictitating membrane. Blood pressure from the left carotid artery was recorded by a Sanborn transducer (No. 267-B) on a four channel Sanborn polygraph. The changes in blood pressure responses are reported in mm. Hg and their duration in minutes. The contractions and tone of the right nictitating membrane in animals were recorded with a Grass transducer (No. FTO3) with the crystalline lens removed. The weight on the nictitating membrane was 3.2 Gm. The attenuator (Carrier preamplifier, Sanborn No. 150-1100AS) was set at $\times 5$; the responses of the nictitating membrane are reported in millimeters and read directly from the paper. Changes in heart rate were counted from the blood pressure recording with the paper speed set at 5 mm./second. The right femoral vein was cannulated for single injections and the left femoral vein for continuous drug infusions. Tracheotomy was routinely performed in all animals, although it was not necessary to use artificial respiration in any of the animals.

The first ephedrine injection was given 15 minutes after completion of surgery and pretreatment with atropine and PAG.

The data were evaluated statistically and the control animals were compared with the infused cats by the "t" test for paired experiments (10).

MATERIALS

The following drugs were used in these experiments: *l*-ephedrine sulfate,[1] *l*-norpinephrine bitartrate monohydrate,[2] *dl*-norepinephrine hydrochloride,[3] phenylephrine hydrochloride,[4] *l*-epinephrine hydrochloride,[5] dichloroisoproterenol hydrochloride,[6] α-chloralose,[7] atropine sulfate,[8] and polygalacturonic acid glycoside.[9] All doses are expressed as the weight of the respective salts.

RESULTS

Ephedrine Sulfate, 0.75 mg./Kg.

For the following reported experiments, only

those cats were chosen which showed clear-cut tachyphylaxis after the third hourly injection. This group of animals was comprised of 13 cats, five of which were used as controls and eight of which were infused with norepinephrine.

A dose of 0.75 mg./Kg. of ephedrine caused invariably reduced pressor responses to the second hourly injection when compared with the first, but in many animals the responses thereafter showed very little (if any) additional decrease. In some cats this dose of ephedrine caused continued tachyphylaxis on blood pressure as could be judged from the substantial diminution of the pressor response to the injections thereafter. The duration of the responses also decreased with the repeated injections of ephedrine, from an average of 6 minutes to an average of 2 minutes.

Infusion With *l*-Norepinephrine (*l*-NOR).—With the infusion rate of *l*-NOR employed, the initial mean arterial blood pressure was little changed but decreased slightly toward the end of the experiments.

The duration of the blood pressure responses to ephedrine was not altered by the infusion of *l*-NOR when compared with the controls.

In Table I, the differences in the blood pressure responses and changes in heart rate from the fourth through seventh hourly injections of ephedrine in the absence and presence of *l*-NOR are compared with the third hourly responses. Five cats received only hourly ephedrine injections (controls), whereas four cats were continuously infused intravenously with *l*-NOR starting after the third hourly injection of ephedrine.

As can be seen from Table I, the decrease in the blood pressure responses to ephedrine in the control animals became progressively more significant with time, except for the fifth hour. The differences between the responses in the *l*-NOR-treated animals were not significant throughout this period of time, showing that *l*-norepinephrine prevented the further development of ephedrine tachyphylaxis. Also the heart-rate changes in the control animals were significantly reduced and *l*-NOR infusion counteracted this reduction.

The nictitating membrane contractions induced by ephedrine did not show such a clear-cut effect of *l*-NOR. In all of the control animals the contractions were progressively and significantly reduced. When compared with the third hourly response, *l*-NOR showed its reversing effect only at the fourth and sixth hours. In the control animals the nictitating membrane tone increased significantly in the fourth and fifth hours and thereafter remained essentially the same. In the *l*-NOR treated animals, the nictitating membrane tone plateaued after the fourth hourly injection of ephedrine.

Infusion with *dl*-Norepinephrine (*dl*-NOR).—The infusion of *dl*-NOR in doses already referred to did not alter the initial mean arterial blood pressure significantly. The duration of the blood pressure responses to ephedrine was essentially unaltered by the infusion of *dl*-NOR.

The effect of infusion of *dl*-NOR on the changes in blood pressure response, the changes in heart rate, and the nictitating membrane tone to ephedrine was identical with that described previously for *l*-NOR. The effect of *dl*-NOR on the nictitating membrane contractions to ephedrine is summarized in Table II.

As can be clearly seen, the nictitating membrane contractions to ephedrine show significant reductions upon the progressive hourly administration of ephedrine in the control cats and *dl*-NOR prevents this reduction. This shows that *dl*-NOR, in contrast to *l*-NOR, is capable of counteracting ephedrine tachyphylaxis on this organ.

Ephedrine Sulfate, 1.5 mg./Kg.

A dose of 1.5 mg./Kg. of ephedrine caused significant reductions of the mean arterial blood pressure and heart-rate responses upon repeated hourly injections in all control animals.

TABLE II.—DIFFERENCES OF NICTITATING MEMBRANE CONTRACTIONS (MM.) TO 0.75 MG./KG. OF EPHEDRINE INJECTED INTRAVENOUSLY ONCE EVERY HOUR

Treatment	$\bar{d} \pm s\bar{d}$, 3rd to 4th	*P*, 3,4	$\bar{d} \pm s\bar{d}$, 3rd to 5th	*P*, 3,5	$\bar{d} \pm s\bar{d}$, 3rd to 6th	*P*, 3,6	$\bar{d} \pm s\bar{d}$, 3rd to 7th	*P*, 3,7

With *dl*-NOR[b,d]	$+1.5 \pm 1.2$	<0.3	$+0.9 \pm 1.5$	<0.6	$+0.5 \pm 1.2$	<0.7	-0.8 ± 0.9	<0.5

[a] Number of cats, 5; weight, 3.0 to 4.5 Kg. [b] Number of cats, 4; weight, 3.0 to 4.0 Kg. [c] Indicates statistical significance. [d] *dl*-Norepinephrine (*dl*-NOR) was continuously infused intravenously starting 15 minutes after the third hourly and ending 30 minutes after the seventh hourly ephedrine injection at the rate of 2.3 mcg./min.

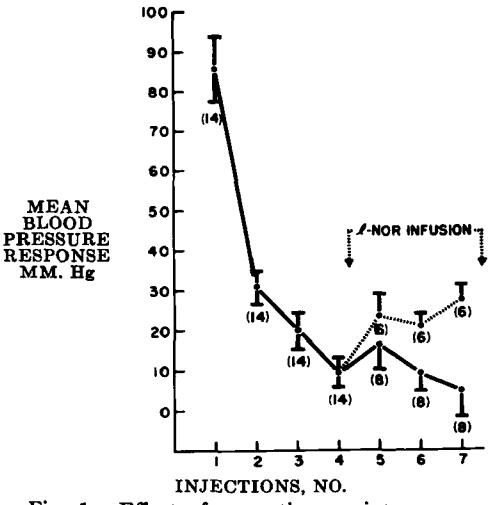

Fig. 1.—Effect of a continuous intravenous infusion of *l*-norepinephrine (*l*-NOR, 2.3 mcg./minute) upon the mean arterial blood pressure responses to ephedrine (1.5 mg./Kg.) injected intravenously once every hour. The *l*-norepinephrine infusion was started 15 minutes after the fourth and ended 30 minutes following the seventh hourly ephedrine injection in six of 14 cats. The remaining eight animals were given only the hourly injections of ephedrine (controls). The pressor responses to ephedrine of the control and *l*-NOR-infused groups of cats were pooled for the first four hourly injections.

With this dose of ephedrine the initial mean arterial blood pressure increased slightly during the course of the experiments in all control cats (average, +28 mm. Hg).

The duration of the blood pressure responses to this dose of ephedrine showed a greater reduction than that observed, following the repeated hourly administration of the lower dose (0.75 mg./Kg.), *i.e.*, from an average of 8 minutes to an average of less than 1 minute.

Infusion with *l*-Norepinephrine (*l*-NOR).—The rate of infusion of *l*-norepinephrine, 2.3 mcg./minute, was determined in pilot studies and was used in these experiments. When infusion rates of *l*-NOR *smaller* than 2.3 mcg./minute were employed in six cats, complete tachyphylaxis to the pressor effects of ephedrine developed. When a *higher* infusion rate of *l*-NOR was used in six cats, the initial pressor responses to ephedrine following *l*-norepinephrine infusions were considerably augmented. However, *l*-norepinephrine at these *higher* infusion rates did not prevent the terminal development of tachyphylaxis. *l*-NOR infusion at the rate of 2.3 mcg./minute increased the initial mean arterial blood pressure by an average of +25 mm. Hg, which remained essentially constant throughout the experiments.

The duration of the blood pressure responses to ephedrine in the presence of *l*-NOR was less reduced than in the control animals (from an average of 8 minutes to an average of 2 minutes).

Figure 1 summarizes the pooled mean arterial blood pressure changes for all 14 animals regarding the first four hourly injections of ephedrine. Eight of these 14 animals served as the ephedrine controls. In the remaining six animals *l*-NOR infusion (2.3 mcg./minute) was started 15 minutes after the fourth injection and continued to the end of the experiment. It can be clearly seen that the infusion *l*-NOR *at this rate* will reverse tachyphylaxis to the level of the second hourly injection of ephedrine but not fully. Thus, the reversal of tachyphylaxis in this experiment is partial but not complete. The "protective" effect of *l*-NOR on the pressor responses to ephedrine (fifth to the seventh hour) is statistically significant (P = <0.02 to <0.01). In summary, we may say that an infusion rate of *l*-NOR of 2.3 mcg./minute was effective in reversing the development of tachyphylaxis of the ephedrine pressor responses, but that infusion rates *higher* or *lower* than 2.3 mcg./minute were not effective.

The data for the changes of heart rate in these same animals are summarized in Fig. 2. The changes in heart rate to ephedrine become progressively less reduced to repeated injections of the amine after the second hour.

Between the first and second injections of ephedrine the heart rate is elevated and remains rapid throughout the experiment.

The continuous infusion of *l*-NOR partially reverses the ever decreasing heart-rate response to ephedrine, although this reversal is statistically significant only at the seventh injection of ephedrine (P = <0.02).

A summary of the nictitating membrane tone and contractions of these same animals is given in Table III.

The nictitating membrane responses to ephedrine of all 14 animals were pooled for the first 4 hours, and the responses of the eight control animals and the six *l*-NOR-infused animals are shown separately for the fifth through the seventh hour. As can be seen, the sums of the nictitating membrane contraction and tone are nearly constant throughout the experimental period, both in the presence and absence of *l*-NOR.

From the fifth to the seventh hour the eight control cats show a progressive decrease of the nictitat-

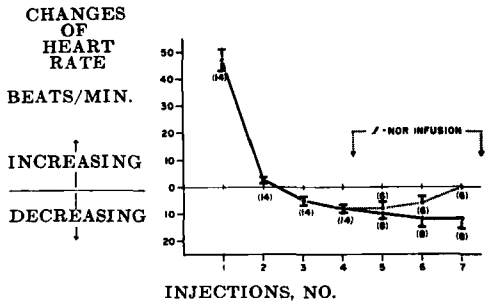

Fig. 2.—Effect of a continuous intravenous infusion of *l*-norepinephrine (*l*-NOR, 2.3 mcg./minute) upon the ephedrine-induced (1.5 mg./Kg. intravenously) mean changes in heart rate. The ephedrine was injected once every hour. The *l*-norepinephrine infusion was started 15 minutes after the fourth and ended 30 minutes following the seventh hourly ephedrine injection in six of 14 cats. The remaining eight animals were given only the hourly injections of ephedrine (controls). The ephedrine-induced changes in heart rate observed in the control and *l*-NOR-infused groups of cats were pooled for the first four hourly injections.

6. Sum of 4 + 5	...	...	...	...	22.8	23.0	22.6

[a] The responses of all 14 cats were pooled for the first four hourly ephedrine injections. [b] *l*-Norepinephrine (*l*-NOR) was continuously infused intravenously starting 15 minutes after the fourth and ending 30 minutes after the seventh hourly ephedrine injection at the rate of 2.3 mcg./min.

ing membrane contractions and a simultaneous increase in tone. The nictitating membrane tone of the *l*-NOR-treated cats is higher than that of the control animals, and the contractions are lower. Nevertheless, *l*-NOR might exert a slight "protective" effect since a further decrease in contractions from the fifth to the seventh hour is absent. The "protective" effect of *l*-NOR on these nictitating membrane contractions to ephedrine cannot be demonstrated by statistical methods.

We questioned whether repeated hourly injections of 1.5 mg./Kg. of ephedrine would depress the responses to single doses of *l*-NOR.

Ephedrine tachyphylaxis was permitted to develop through the fourth injection. Single repeated (three times) injections of a geometric series of *l*-NOR (0.25 to 1.0 mcg./Kg.) were administered intravenously before the first and after the fourth ephedrine injections. The pressor responses to the single injections of *l*-NOR were biphasic and ranged *initially* from +77 to −3 mm. Hg to the low dose, to +103 to −19 mm. Hg to the high dose of *l*-NOR. After the fourth ephedrine injection, the responses to the low dsse of *l*-NOR were +73 to −12 mm. Hg and to the high dose +86 to −9 mm. Hg. Thus, in the presence of ephedrine tachyphylaxis only insignificant reductions of the pressor responses to the single injections of *l*-NOR could be observed.

Infusion with *dl*-Norepinephrine (*dl*-NOR).—In addition to *l*-NOR, *dl*-NOR was also employed to study its effect on the development of ephedrine tachyphylaxis. The infusion of *dl*-NOR essentially failed to alter the initial mean arterial blood pressure at the rates administered.

dl-NOR was infused (2.3 mcg./minute) starting 15 minutes after the fourth hourly injection of ephedrine, and this catecholamine infusion was continued to the end of each experiment. It is obvious that *dl*-NOR is less potent than *l*-NOR; nevertheless, the results observed on the pressor responses to ephedrine are similar, though the heart rate responses appear to be less marked. Furthermore, *dl*-NOR caused only an insignificant increase in the duration of the blood pressure responses to ephedrine when compared with control animals. (Average first response, 10 minutes; average seventh response, 1.1 minutes.)

It may be observed in Table IV that in cats infused with *dl*-NOR the ephedrine-induced contractions of the nictitating membrane are significantly higher than those of the control animals. The increase in nictitating membrane tone is considerably less pronounced in the animals infused with *dl*-NOR compared with that observed in the cats infused with *l*-NOR.

Infusion with Other Sympathomimetic Amines.—To ascertain the specificity of norepinephrine in partially counteracting ephedrine tachyphylaxis, five cats were infused with *l*-epinephrine and three cats with phenylephrine (see *Materials* and *Methods*).

TABLE IV.—DIFFERENCES IN RESPONSES TO HOURLY INTRAVENOUS INJECTIONS OF 1.5 MG./KG. OF EPHEDRINE WITH[a] AND WITHOUT[b] CONTINUOUS INTRAVENOUS INFUSION OF *dl*-NOREPINEPHRINE (*dl*-NOR) STARTING 15 MINUTES AFTER THE FOURTH HOURLY EPHEDRINE INJECTION

None of the four parameters measured was influenced by the infusion of these two sympathomimetic amines when compared with the controls.

Effect of Dichloroisoproterenol (DCI) upon Development of Ephedrine Tachyphylaxis

Since DCI was shown to antagonize the effects of ephedrine on the heart (11), it was of interest to test the influence of this β-receptor blocking agent on ephedrine tachyphylaxis and its reversal by norepinephrine. These experiments were carried out for the duration of six hourly ephedrine (1.5 mg./Kg.) injections, and DCI (3 mg./Kg.) was administered intravenously 15 minutes before the first ephedrine injection. Four cats were tested with DCI and ephedrine alone. In contrast to the cats not pretreated with DCI, which showed a slight increase in the initial mean arterial blood pressure throughout the experiments, these DCI-treated cats showed a slight decrease (average, −29 mm. Hg). No change in heart-rate response to ephedrine was observed throughout the experimental period, although the duration of action of DCI at this dose was reported to be considerably shorter than 6 hours (11). In two cats the initial heart rate remained unchanged; however, in the other two animals the initial heart rate increased somewhat after the third hour without further increase following the fourth, fifth, and sixth ephedrine injections. Nevertheless, tachyphylaxis development to ephedrine-induced blood pressure responses, nictitating membrane contractions, and the increase in nictitating membrane tone paralleled the effects of ephedrine in animals without DCI administration. However, the duration of the blood pressure responses to ephedrine was considerably prolonged (average of 40 minutes to the first injection and an average of 25 minutes to the sixth ephedrine injection). It should be emphasized that the considerable variations of the pressor effects to the first injection of ephedrine were largely eliminated in cats pretreated with DCI. This also resulted in lower pressor effects upon the first ephedrine injection.

Three other cats received DCI (3 mg./Kg.) 15 minutes before the first injection of ephedrine and were infused with *l*-NOR starting 15 minutes after the second ephedrine injection. This catecholamine was infused continuously to the end of the experiment. The initial mean arterial blood pressure in these animals was not significantly altered, and the duration of the pressor responses to ephedrine were essentially the same as those observed in the control animals. Under these experimental conditions *l*-NOR did not reverse the ephedrine-induced tachyphylaxis on the blood pressure. In these three cats the heart rate did not increase to ephedrine administration; therefore, even during the infusion of *l*-NOR, ephedrine failed to accelerate the heart. However, *l*-NOR itself produced a slight increase in the heart rate throughout the experiment.

The only parameter measured which showed statistically significant reversal of ephedrine tachyphylaxis by *l*-NOR infusion in the DCI-pretreated animals were the contractions of the nictitating membrane.

DISCUSSION

The above experiments demonstrating the tachyphylaxis of sympathomimetic amines were designed in accordance with the original method of Tainter (12).

For the present studies we arrived at a dose of ephedrine (1.5 mg./Kg.) to which tachyphylaxis of all parameters measured was observed in all experimental animals. We also employed a borderline tachyphylactic dose (0.75 mg./Kg.).

In ephedrine (1.5 or 2.5 mg./Kg.) tachyphylaxis (1), the main differences in the blood pressure responses to this drug occur between the first and second hourly injections and those to the heart rate between the first and third hourly administrations (first phase of tachyphylaxis). The reductions in these responses thereafter become progressively less pronounced (second phase of tachyphylaxis). The separation of the two phases of ephedrine tachyphylaxis becomes considerably less distinct with the 0.75 mg./Kg. dosage. There is little or no disagreement that norepinephrine release is involved in the indirect action of the sympathomimetic amines such as ephedrine. However, the direct action of these amines may be attributed to a reversible combination with α-adrenergic receptors (action abolished or greatly diminished by α-adrenergic blocking agents) and/or to a similar reversible combination with other unknown receptors in the smooth and cardiac muscle. Blockade of the cardiac β-receptors by DCI reduces the first blood pressure response to ephedrine and thereby makes the first phase of tachyphylaxis less pronounced without essentially altering the prolonged second phase.

With the infusion of *l*-NOR or *dl*-NOR we were able to overcome the second phase of tachyphylaxis. DCI, in the presence of which the first phase of tachyphylaxis is greatly reduced, prevented this reversing effect of norepinephrine on blood pressure. Thus, we must attribute a crucial role to the heart in this return of responses; however, the heart alone cannot fully account for the partial reversal by norepinephrine of the ephedrine tachyphylaxis because the contractions of the nictitating membrane were also partially re-established. Since by the infusion of norepinephrine we were unable to reverse the first phase of tachyphylaxis to ephedrine at 1.5 mg./Kg., and could not reverse either phase of tachyphylaxis to 2.5 mg./Kg., as previously reported (2), we must assume a partly irreversible direct, possibly toxic, action of ephedrine on the heart and smooth muscle, which becomes apparent immediately upon the first injection of the amine. It was observed in our laboratory that ephedrine in high concentration increased the permeability of the vessels of the rat-*meso*-appendix (13). Since ephedrine is a drug of prolonged duration of action, its toxicity or irreversible effect might also be due to such an alteration of vascular, *i.e.*, smooth muscle permeability. Another possibility is a depression by ephedrine of the secretion of adrenocorticoids which, according to Ramey and Goldstein (14), maintain the integrity and responsiveness of tissues in the process of reacting to norepinephrine.

The effects of the drugs on the smooth muscle of the nictitating membrane are difficult to evaluate unequivocally because the tone of this organ never returns to control levels after the first injection of ephedrine. Nevertheless, the contractions of the

nictitating membrane were partially re-established in the absence and presence of DCI. These results should make it obvious that we cannot expect all parameters made tachyphylactic by ephedrine to be simultaneously reversed (partially or completely) by an infusion of norepinephrine.

The observations made on blood pressure responses to single norepinephrine injections preceding and following ephedrine tachyphylaxis development exclude adrenergic contractile receptor saturation as an explanation for ephedrine tachyphylaxis. This is further corroborated by the fact that norepinephrine can be infused in amounts too large to prevent reversal which represents true "receptor saturation." This is not in complete agreement with the suggestions of Winder (15) and of Horita, West, and Dille (16) that "receptor saturation" is the true explanation for tachyphylaxis to sympathomimetic amines.

In view of the above considerations, full reversal of both phases of ephedrine tachyphylaxis with norepinephrine could not be expected. Nevertheless, our original postulate (that the loss of norepinephrine from critical sites as an important etiological factor in the development of sympathomimetic amine tachyphylaxis) was fully substantiated.

Norepinephrine shows a unique specificity since epinephrine cannot be substituted in its place as a reversing agent. The precursors of norepinephrine may be effective in reversing ephedrine tachyphylaxis if the synthesis of norepinephrine is not influenced by the presence of large concentrations of ephedrine. To evaluate fully the nature of ephedrine tachyphylaxis on smooth muscle, the nictitating membrane might constitute a very reliable test organ *in situ* if studied under more favorable conditions, such as by close-arterial injections. We agree with the findings of Trendelenburg, *et al.* (17), that ephedrine is neither a purely directly acting nor purely indirectly acting sympathomimetic amine, and this fact may be responsible for only the partial reversal of ephedrine tachyphylaxis by norepinephrine infusions.

In view of the dual nature of ephedrine, which is further substantiated by our observations, it is realized that this amine is not the best drug to demonstrate fully the phenomenon of tachyphylaxis reversal. We are investigating, therefore, tachyphylaxis reversal by norepinephrine of sympathomimetic amines reported to have a greater indirect effect than ephedrine (5–7, 17), *e.g.*, tyramine and amphetamine. These results have been reported in part and will be published in the near future.

Studies of Preservatives of Poliomyelitis (Salk) Vaccine I

Benzethonium Chloride

By HILLIARD PIVNICK, J. M. TRACY, and D. G. GLASS

Several antimicrobial materials may be present in killed Salk poliomyelitis vaccine. They are (*a*) antibiotics which are added to the tissue culture to inhibit growth of bacterial contaminants without inhibiting growth of the poliomyelitis virus, (*b*) formaldehyde added to kill the virus, and (*c*) preservatives such as benzethonium chloride added to the finished vaccine to prevent the growth of bacterial and fungal contaminants. The stable antibiotics contribute considerable antibacterial activity; the formaldehyde, if not neutralized by bisulfite, is an effective, stable antibacterial agent with some antifungal activity. Benzethonium chloride adds little, if any, antibacterial activity to that obtained either by antibiotics or formaldehyde but does furnish some antifungal activity.

PRESERVATIVES for killed poliomyelitis (Salk) vaccine must be chosen with special care because the antigenic potency of the vaccine is easily destroyed. Benzethonium chloride (BEC) has been used as a preservative for poliomyelitis vaccine and has been found to cause no destruction of the virus antigen when used in concentrations of about 25 p.p.m. (1). This concentration

Studies of Preservatives of Poliomyelitis (Salk) Vaccine I

Benzethonium Chloride

By HILLIARD PIVNICK, J. M. TRACY, and D. G. GLASS

Several antimicrobial materials may be present in killed Salk poliomyelitis vaccine. They are (*a*) antibiotics which are added to the tissue culture to inhibit growth of bacterial contaminants without inhibiting growth of the poliomyelitis virus, (*b*) formaldehyde added to kill the virus, and (*c*) preservatives such as benzethonium chloride added to the finished vaccine to prevent the growth of bacterial and fungal contaminants. The stable antibiotics contribute considerable antibacterial activity; the formaldehyde, if not neutralized by bisulfite, is an effective, stable antibacterial agent with some antifungal activity. Benzethonium chloride adds little, if any, antibacterial activity to that obtained either by antibiotics or formaldehyde but does furnish some antifungal activity.

PRESERVATIVES for killed poliomyelitis (Salk) vaccine must be chosen with special care because the antigenic potency of the vaccine is easily destroyed. Benzethonium chloride (BEC) has been used as a preservative for poliomyelitis vaccine and has been found to cause no destruction of the virus antigen when used in concentrations of about 25 p.p.m. (1). This concentration

of BEC is a good preservative against fungi and some G-positive bacteria but has little or no effect against many G-negative species, especially members of the genus *Pseudomonas* (2–4).

Besides the preservatives which are added to poliomyelitis vaccine at the end of the manufacturing process, other antimicrobial materials are added during the manufacture of the vaccine. Antibiotics such as streptomycin, neomycin, and polymyxin B are added to the tissue culture fluid to control bacterial contaminants. Some of these antibiotics, depending on their stability, will be present in the finished vaccine. In addition, formaldehyde is added to kill the virus and, unless neutralized, about three-quarters of the original amount of this compound will still be present in the finished vaccine. Thus poliomyelitis vaccine may possess considerable preservative activity without the addition of extra preservatives.

Unfortunately, despite the numerous antimicrobial compounds, contaminants do grow in poliomyelitis vaccine.

During a 3-year period, 13 partially used multiple-dose vials of poliomyelitis vaccine or poliomyelitis vaccine combined with other antigens were returned to this laboratory because of apparent contamination. All of these vials had been preserved by the addition of 25 p.p.m. of BEC; all contained some residue of the antibiotics added to the tissue culture medium. None of them, however, contained residual formaldehyde as it had been neutralized by sodium bisulfite. Two of the vials were contaminated with molds. The remainder yielded species of the genus *Pseudomonas* and two of these contained *Pseudomonas aeruginosa*. This species may cause fatal septicemia (5, 6).

All the vials had been entered and part of the contents withdrawn. Three of them, each from a different lot of poliomyelitis vaccine, were returned by a single physician, and each yielded the same species of *Pseudomonas*, but this species was not encountered in the other contaminated vials. No unused vials have shown contamination. Obviously, the entry of nonsterile needles had introduced microorganisms which had grown despite the presence of BEC. Apparently BEC was inadequate as a preservative; this report attempts to explain the reasons for the inadequacy.

EXPERIMENTAL

Vaccines and Other Preserved Media

During this investigation many preparations, described below, were preserved and challenged.

HB597 Medium.—This is a nutrient solution used in tissue culture for the growth of poliomyelitis virus. It differs from medium 199 of Morgan, *et al.* (7), in that it contains no purines, pyrimidines, ribose, deoxyribose, or adenosinetriphosphate. In addition, Hanks' balanced salt solution is used instead of Earle's solution.

Killed Poliomyelitis (Salk) Vaccine.—This consists of HB597 medium with antibiotics, virus of the three types of poliomyelitis, soluble residue from the monkey kidney cell tissue culture, formaldehyde which may or may not be neutralized by sodium bisulfite, and a preservative. During these experiments, as discussed later, the antibiotics, preservatives, and formaldehyde have been varied.

Diphtheria - Pertussis - Tetanus - Poliomyelitis (DPT Polio) Vaccine.—This is a mixture of diphtheria and tetanus toxoids, pertussis vaccine, and Salk vaccine. The poliomyelitis component of this mixture is 96% of the total volume.

Preservatives

BEC, at a concentration of 0.5% in Hanks'

4	23	9

balanced salt solution, was added with constant mixing to obtain the desired concentration in the medium or vaccine. Analysis of BEC was by a modification (8) of the method of Auerbach (9). Antibiotics were determined quantitatively in the vaccine by usual methods (10). When more than one antibiotic was present, assay organisms were used which were resistant to all antibiotics except the one being measured. Formaldehyde was determined by the method of Nash (11) and by a modification of the Nash method (12).

Bacteria

All bacterial cultures (see Table I) were stored in the lyophilized state or on nutrient agar slopes at −20°. To obtain cells for challenging preserved vaccines, Difco[1] nutrient broth was inoculated and incubated 2 days at 30°. During the second day of incubation the culture was aerated on a reciprocating shaker. The broth culture was then sedimented by centrifugation and resuspended to one-fifth of the original volume in Difco tryptose (0.1%)-saline (0.5%). Counts of viable cells in these suspensions were made on numerous occasions and found to vary from 0.5 to 5.0 × 10^9 cells per ml.

Yeasts and Molds

These cultures (see Table I) were stored at 4° on Difco Sabouraud agar. To obtain material for challenging samples they were grown for 5 days at 30° on Sabouraud agar slopes, washed off with tryptose-saline, and shaken vigorously to break up clumps. Several determinations indicated viable populations of 10^7 and 10^8 cells per ml.

Challenge of Preserved Systems

Medium or vaccines were dispensed, 4 ml. per screw-capped test tube, and challenged with 0.1 ml. of the suspended culture undiluted, diluted 1 × 10^{-3} and 1 × 10^{-6}.

All tubes were incubated at room temperature (20 ± 4°) and examined after 4, 11, and 30 or 60 days for macroscopic growth and/or acid production. Tubes in some experiments were incubated at 4°. When there was doubt concerning growth, media challenged with bacteria were subcultured to Difco nutrient broth or a neutralizing broth (13), and fungi were subcultured to Sabouraud agar. If positive, the medium was considered to have macroscopic evidence of growth. Tubes which showed no obvious signs of bacterial growth (no color change of phenol red indicator or no increase in turbidity above that contributed by the inoculum) were recorded as negative. In many experiments, all tubes which showed no macroscopic evidence of growth were subcultured 11 or 30 days after challenge. The objectives of this investigation were, however, concerned mainly with inhibition of growth, regardless of whether inhibition was due to bacteriostasis or to death of the challenge cultures.

Most results were obvious after 11 days of incubation, but occasionally some tubes which appeared negative at 11 days contained visible growth after 30 days at room temperature.

TABLE V.—ADSORPTION OF BEC BY PERTUSSIS VACCINE

Vaccine	BEC, p.p.m. Added	BEC, p.p.m. Found
Tetanus toxoid	25	18
Tetanus toxoid with polio vaccine	25	19
Diphtheria toxoid with polio vaccine	25	19.5
Tetanus toxoid, diphtheria toxoid, and pertussis vaccine with polio vaccine (DPT Polio)	25	7
Pertussis vaccine	50	15

RESULTS

Benzethonium Chloride Content of Vaccines.—Table II shows the BEC content found in several commercially produced vaccines.

Table III shows that if BEC is added to poliomyelitis vaccine only about 80% can be found upon analysis when the vaccine is dispensed in 10-ml. amounts in multiple-dose vials and even less is found in 1-ml. ampuls. The reason for less than complete recovery of the BEC is probably adsorption on the glass as found by Fogh, *et al.*, with cetylpyridinium chloride (14). The smaller containers would have a larger *surface of glass/volume of liquid* ratio than the 10-ml. vials.

Table IV shows that BEC also disappears when poliomyelitis vaccine is converted to a multivalent vaccine (DPT Polio) by the addition of four volumes of combined diphtheria toxoid, tetanus toxoid, and pertussis vaccine to 100 volumes of poliomyelitis vaccine. The three additives had been preserved by the addition of at least 25 p.p.m. of BEC, so dilution of the BEC in the poliomyelitis vaccine was not a factor in producing the low levels found.

Apparently either the toxoids or pertussis cells adsorb or otherwise change benzethonium chloride. Table V shows that the presence of pertussis cells is a cause of failure to recover all of the added

TABLE VI.—PRESERVATIVE ACTIVITY OF BEC IN HB597 MEDIUM

benzethonium chloride. The toxoids do not remove appreciable amounts of BEC.

Preservative Activity of BEC.—To test the antimicrobial activity of BEC in systems uncomplicated by the presence of antibiotics normally found in poliomyelitis vaccine, BEC was added to antibiotic-free HB597 medium and the 4 ml. of medium was challenged with 0.1 ml. of the challenge cultures previously described. Table VI shows that 24 p.p.m. of BEC has little antibacterial activity but has some antifungal activity against the lower concentrations of fungal cells. The two bacterial cultures inhibited by the BEC were *Staphylococcus aureus*.

As stated previously, BEC is not the only preservative in poliomyelitis vaccine. In production of vaccine the HB597 medium used in the tissue culture had added to it 200 units of streptomycin, 20 units of polymyxin, and 10 units of neomycin per ml. Table VII shows that the polymyxin is completely destroyed during the production of vaccine but that the neomycin and streptomycin are stable.

As a check on the preservative power of the residual antibiotics in poliomyelitis vaccine, 50 strains of *Staphylococcus aureus* were obtained from a clinical laboratory. It was assumed (but not checked) that from such a source many of the organisms would be resistant to antibiotics. Fifty test tubes were charged with poliomyelitis vaccine in which the formaldehyde had been neutralized and to which no preservative had been added. Each tube was inoculated with about 10^8 cells of a different strain of *S. aureus*. No growth was observed in any of the tubes. The residual antibiotics were evidently effective preservatives against most strains of *S. aureus*.

Table VIII shows that the antibiotics remaining in finished poliomyelitis vaccine possess some activity against the test organisms and that this activity is not increased appreciably by BEC.

Experiments similar to those depicted in Table VIII but with tubes incubated at 4° showed that many of the G-negative bacteria were able to grow at refrigerator temperature if the incubation period was extended to 2 months.

To test the effect of the addition of polymyxin to finished poliomyelitis vaccine which contained BEC, a vaccine which contained only streptomycin (200 mcg. per ml.) was used. Three separate experiments were run. The aggregated results (Table IX) show that polymyxin and neomycin do not increase the preservative activity obtained by streptomycin alone.

Table IX, like Table VIII, shows that the addition of BEC to vaccine which contains only streptomycin gives a slight increase in preservative activity. However, when polymyxin and neomycin as well as BEC were added to the vaccine containing streptomycin there was a definite increase in preservative activity. Apparently there is some synergistic or additive effect between polymyxin and BEC. (Compare with Table VIII.)

It appeared desirable to increase the preservative activity in poliomyelitis vaccine, either by increasing the concentration of BEC or by adding polymyxin to the inactivated vaccine just before packaging. Unfortunately, increasing the concentration of BEC to 33 p.p.m. caused a precipitate in the vaccine and as shown in Table X, polymyxin is unstable even at 4° and would be valueless in vaccines stored for several months.

The above results indicated that BEC added little antibacterial activity to that obtained from the residual antibiotics in Salk vaccine. It did, however, confer some antimycotic activity (Table VI).

In contrast to the inadequate antibacterial activity of BEC it was found that formaldehyde was an excellent preservative in poliomyelitis vaccine. Table XI shows that the neutralization of formaldehyde by bisulfite decreases markedly both the antibacterial and antimycotic activity in poliomyelitis vaccine.

The addition of BEC to poliomyelitis vaccine containing residual formaldehyde does not materially increase the antibacterial effect on the test organisms used but, as Table XII shows, the BEC increases the antifungal activity of the preservatives in the poliomyelitis vaccine.

DISCUSSION

The objective of this research was to determine the reason for growth of bacterial and fungal contaminants in poliomyelitis vaccine preserved by the addition of 25 p.p.m. of BEC. McLean (1), Schuchardt, *et al.* (15), and Schuchardt (16) have shown that this compound, added as a preservative to poliomyelitis vaccine, did not significantly damage the antigenicity of the vaccine. They stated that it should be used preferably in vaccines to which bisulfite had not been added, but they failed to present data concerning its efficacy as a preservative with or without neutralization of formaldehyde.

The work described in this report furnishes two reasons for the failure of BEC to give adequate preservation to poliomyelitis vaccine and DPT Polio vaccine. The most important reason is that BEC at 25 p.p.m. or less is not a very effective inhibitor of G-negative bacteria. Other workers have reported this deficiency (2, 3). The other apparent reason is the loss of BEC, probably because of adsorption on glass or bacterial cells. The phenomenon of adsorption on glass has been reported for other quaternary ammonium compounds by Fogh, *et al.* (14).

The challenge dose used in these experiments was, in our opinion, severe. Not only were large numbers of organisms used (up to 10^8 viable cells), but also many of the cultures were isolated from contaminated vaccines. The necessity of using a severe challenge is evident; the desirability of using contaminants from biologicals has been emphasized by Pittman and Feeley (17). The use of less severe challenge doses (Table VI) shows clearly the lack of ability of BEC to inhibit even small numbers (10^2 to 10^5 cells) of G-negative bacteria.

There is little or no need for BEC as an inhibitor of G-positive bacteria in poliomyelitis vaccine and (as stated above) its ability to inhibit many G-negative bacteria is questionable. As an antifungal agent it does serve some purpose. Therefore, a preservative which has the antifungal activity of BEC and the antibacterial activity of formaldehyde is still needed in poliomyelitis vaccine, especially if the formaldehyde has been inactivated by bisulfite. Such a compound has been found and its effectiveness will be the subject of a later report.

SUMMARY

Benzethonium chloride (BEC) is adsorbed on glass and on bacterial cells.

BEC alone does not inhibit the growth of sev-

eral G-negative bacteria but does inhibit the growth of G-positive bacteria, yeasts, and molds.

BEC adds little antibacterial effect to the residual antibiotics present in poliomyelitis vaccine but does contribute antimycotic activity.

Formaldehyde, if not neutralized by bisulfite, is highly antibacterial and exhibits some antimycotic activity.

Oxidation of Sulfurous Acid Salts in Pharmaceutical Systems

By LOUIS C. SCHROETER

Many aqueous, oxygen-labile pharmaceutical systems may be effectively protected by the antioxidant activity of sulfurous acid salts. The sulfite system is inordinately sensitive to trace amounts of heavy metal catalysts and a wide variety of organic compounds which act as oxidation inhibitors. Mechanism of sulfite oxidation in the presence of known inhibitors at levels normally encountered in pharmaceutical formulations appears to involve heavy metal catalysts. At the concentration (p.p.m.) of heavy metals normally present in formulations, the rate of oxidation and antioxidant activity is directly dependent upon the heavy metal concentration. However, a slow but measurable rate of sulfite oxidation occurs in systems especially purified to remove metal ions. The copper-catalyzed oxidation of sulfurous acid salts in buffered systems containing ethanol as an inhibitor may be described by first-order kinetics. The pH profile of the absolute initial rate of the copper-catalyzed oxidation has been experimentally determined and found to be in reasonable agreement with a theoretically derived curve.

ORGANIC COMPOUNDS in very low concentrations (10^{-6} M) appear to inhibit the rate of oxidation of aqueous solutions of sulfurous acid salts (1). This inhibitory action has been demonstrated by many compounds representing diverse structural features and functional groupings—typical drug molecules may be expected to retard the rate of sulfite oxidation (2). This fact may at first seem paradoxical since it is well known that sulfurous acid salts are employed as pharmaceutical antioxidants (3). Pharmaceutical systems generally contain much more drug than antioxidant: the molar concentration of drug may be as much as two orders of magnitude greater than that of the antioxidant.

Effectiveness of sulfurous acid salts as pharmaceutical antioxidants in most aqueous systems appears to depend on their avidity for free radicals such as OH or simply on the ease with which they are oxidized in comparison with most autoxidizable drugs (3). However, this reveals little about the mechanism of sulfite oxidation in the presence of known inhibitors.

Inhibition of the rate of sulfite oxidation may be described by an equation (1–3)

$$-\frac{d(S_t)}{dt} = \frac{k_1(S_t)A}{B + M} \qquad \text{(Eq. 1)}$$

where S_t is the concentration of total sulfurous acid species, k_1 is the specific rate constant for the uninhibited reaction, M is the molar concentration of additive, and A and B are constants generally of the magnitude 10^{-5}. The specific rate constant, k_1, for the air oxidation (atmospheric pressure, 25°) of pure aqueous sulfite is 2.9×10^{-3} seconds^{-1} under conditions such that the diffusion or dissolution rate of oxygen is not rate limiting; the copper-catalyzed (10^{-6} M Cu^{2+}) reaction yields an apparent rate constant of 5.1×10^{-3} seconds^{-1}. Inhibition of sulfite oxidation by a variety of compounds over

Oxidation of Sulfurous Acid Salts in Pharmaceutical Systems

By LOUIS C. SCHROETER

Many aqueous, oxygen-labile pharmaceutical systems may be effectively protected by the antioxidant activity of sulfurous acid salts. The sulfite system is inordinately sensitive to trace amounts of heavy metal catalysts and a wide variety of organic compounds which act as oxidation inhibitors. Mechanism of sulfite oxidation in the presence of known inhibitors at levels normally encountered in pharmaceutical formulations appears to involve heavy metal catalysts. At the concentration (p.p.m.) of heavy metals normally present in formulations, the rate of oxidation and antioxidant activity is directly dependent upon the heavy metal concentration. However, a slow but measurable rate of sulfite oxidation occurs in systems especially purified to remove metal ions. The copper-catalyzed oxidation of sulfurous acid salts in buffered systems containing ethanol as an inhibitor may be described by first-order kinetics. The pH profile of the absolute initial rate of the copper-catalyzed oxidation has been experimentally determined and found to be in reasonable agreement with a theoretically derived curve.

ORGANIC COMPOUNDS in very low concentrations (10^{-6} M) appear to inhibit the rate of oxidation of aqueous solutions of sulfurous acid salts (1). This inhibitory action has been demonstrated by many compounds representing diverse structural features and functional groupings—typical drug molecules may be expected to retard the rate of sulfite oxidation (2). This fact may at first seem paradoxical since it is well known that sulfurous acid salts are employed as pharmaceutical antioxidants (3). Pharmaceutical systems generally contain much more drug than antioxidant: the molar concentration of drug may be as much as two orders of magnitude greater than that of the antioxidant.

Effectiveness of sulfurous acid salts as pharmaceutical antioxidants in most aqueous systems appears to depend on their avidity for free radicals such as OH or simply on the ease with which they are oxidized in comparison with most autoxidizable drugs (3). However, this reveals little about the mechanism of sulfite oxidation in the presence of known inhibitors.

Inhibition of the rate of sulfite oxidation may be described by an equation (1–3)

$$-\frac{d(S_t)}{dt} = \frac{k_1(S_t)A}{B + M} \qquad \text{(Eq. 1)}$$

where S_t is the concentration of total sulfurous acid species, k_1 is the specific rate constant for the uninhibited reaction, M is the molar concentration of additive, and A and B are constants generally of the magnitude 10^{-5}. The specific rate constant, k_1, for the air oxidation (atmospheric pressure, 25°) of pure aqueous sulfite is 2.9×10^{-3} seconds^{-1} under conditions such that the diffusion or dissolution rate of oxygen is not rate limiting; the copper-catalyzed (10^{-6} M Cu^{2+}) reaction yields an apparent rate constant of 5.1×10^{-3} seconds^{-1}. Inhibition of sulfite oxidation by a variety of compounds over

a wide range (10^{-3} to 10^{-7} M) of inhibitor concentration has been satisfactorily described by Eq. 1 or others of similar form (1–4). Activity of inhibitors in breaking sulfite radical chains appears to be proportional to the inhibitor concentration in dilute ($\leq 10^{-3}$ M) solutions of inhibitor and independent of the primary chain activation. The thermal (dark) and photo-induced reactions of sulfite in the presence of inhibitors both proceed by a radical process and may be described by an equation in which the rate is inversely proportional to the sum of a constant and the molar concentration of inhibitor, *i.e.*, Eq. 1, holds for dilute (10^{-3} to 10^{-7} M) solutions of the inhibitor (5). Chain termination of the sulfite radical in the presence of an inhibitor has been shown (6) to yield traces of oxidized inhibitor. For example, oxidation of sulfite in the presence of benzyl alcohol or isopropyl alcohol yields small quantities of benzaldehyde and acetone, respectively. The inhibitor apparently provides an alternate reaction pathway to the chain propagation process (7) and is itself oxidized to a noncarrier product. This would correspond to a bimolecular reaction with a first-order dependence on inhibitor concentration and first-order dependence on the radical chain carrier. The oxidation of inhibitors through their interaction with radicals generated in systems such as sulfite corresponds to Jorissen's "Induced Oxidation" (8).

Reliable data on the rate of oxidation of sulfite in the presence of high concentrations ($>10^{-2}$ M) of inhibitors are not available. Jorissen (8) reports values for sodium sulfite oxidation in the presence of relatively high concentrations (0.25 M) of inhibitors in pure oxygen. The times required for essentially complete oxidation of sulfite in the presence of 0.25 M mannitol and 0.25 M *n*-propanol were 13 days and 18 days, respectively. The

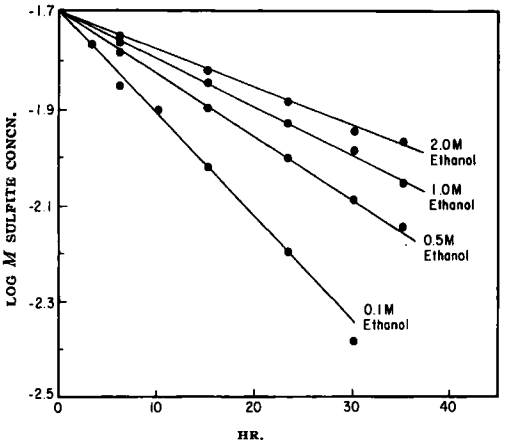

Fig. 1.—Air oxidation of 0.02 M sodium sulfite in the presence of Cu (II) (1×10^{-6} M) and ethanol at 25°C.

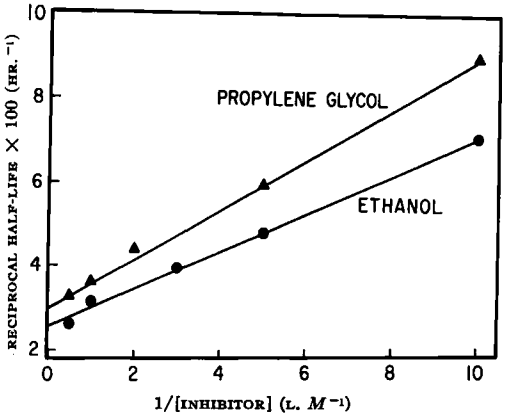

Fig. 2.—Reciprocal half-life for the cupric ion (1×10^{-6} M) catalyzed air oxidation of sodium sulfite (0.02 M) as a function of reciprocal inhibitor concentration at 25°C.

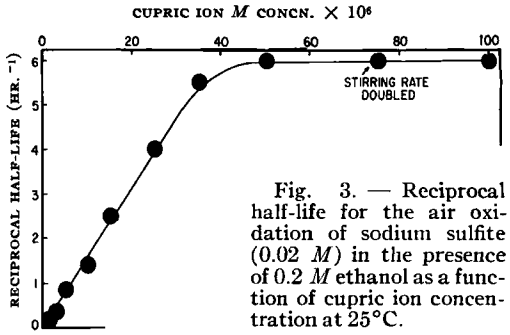

Fig. 3. — Reciprocal half-life for the air oxidation of sodium sulfite (0.02 M) in the presence of 0.2 M ethanol as a function of cupric ion concentration at 25°C.

theoretical value for the time required for 95% ($t_{95\%}$) oxidation of sulfite in the presence of 0.25 M inhibitor may be approximated with

$$t_{95\%} = \frac{2.303}{k_1} \log \frac{100}{5} = \frac{2.99}{k_1} \quad \text{(Eq. 2)}$$

where k_1 is the specific rate constant for the oxidation in pure oxygen in the presence of 0.25 M inhibitor calculated with Eq. 1 using Fuller and Crist's (9) value (1.3×10^{-2} seconds^{-1}) for the noninhibited rate.

$$k_1 = \left(\frac{10^{-5}}{10^{-5} + 0.25}\right) 1.3 \times 10^{-2} \text{ sec.}^{-1} = 5.2 \times 10^{-7} \text{ sec.}^{-1}$$

These approximate calculations yield a value of about 67 days or almost 2 months for the time required for 95% of sulfite to oxidize ($t_{95\%}$) in the presence of 0.25 M inhibitor and pure oxygen. The predicted value, $t_{95\%}$, obtained with Eq. 1 is about five times greater than that found experimentally (13–18 days).

Failure of Eq. 1 to describe the effect of inhibitors

under conditions described above is not wholly unexpected nor without precedent in radical reactions. The form of Eq. 1 is determined by the nature of the chain-breaking process and not by the initiation process (10). The presence of inhibitors generally alters only the rate of chain propagation and not the rate of radical initiation. Thus, the observed decrease in total sulfite which occurs in oxidizing systems containing inhibitors may be accounted for if radial initiation or some fraction thereof leads to oxidized product (sulfate); the radical initiating process becomes the rate-determining step in the overall oxidation scheme when the rate of chain propagation is decreased or, in equivalent terms, when the chain length is reduced. Existence of a measurable reaction rate in radical mediated processes in the presence of overwhelming amounts of inhibitor has been described as the "completely inhibited" rate (10). In the case of nitric oxide inhibition of alkyl free radical gas reactions, the completely inhibited or residual reaction rate has been interpreted in terms of an alternate nonradical mechanism (11); however, there is some evidence of free radicals in these systems (12). Heavy metal catalysis of sulfite oxidation allows another possible mechanism for radical initiation; this pathway for radical initiation may be important in systems containing inhibitors. The catalytic effect of copper ions on sulfite oxidation may be detected in concentrations as low as 10^{-6} M. This is within the permissible range of parts per million of heavy metal contaminants for many compounds of pharmaceutical interest (13); it is a reasonable assumption to consider that most complex pharmaceutical formulations contain catalytic (1 p.p.m.) amounts of heavy metals. It is the

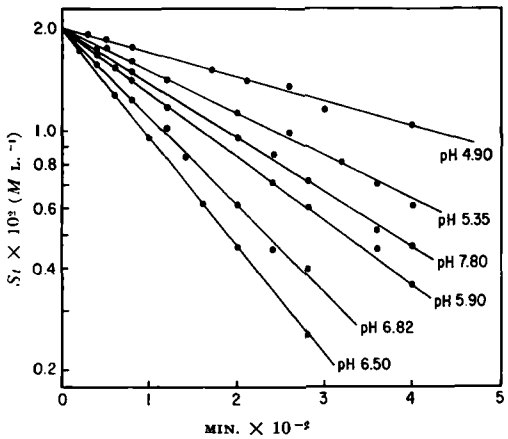

Fig. 5.—Cupric ion (5×10^{-5} M) catalyzed air oxidation of sulfurous acid specie ($S_t = 0.02$ M) in the presence of 0.2 M ethanol at constant pH (McIlvaine buffers 0.3 M; total ionic strength adjusted to 1.0 with KCl).

purpose of this study to describe some of the kinetic and mechanistic aspects of sulfite oxidation in the presence of a known inhibitor (ethanol) and in systems containing both inhibitor and catalyst.

EXPERIMENTAL

Water used in these studies was distilled twice from a Pyrex apparatus and stored not longer than 6 hours under nitrogen atmosphere prior to use. Reagent grade sodium sulfite was recrystallized twice from water. Ethanol was distilled twice from a Pyrex apparatus. All other materials were of reagent grade and used without further purification unless otherwise specified. Rapid ($t^1/_2 \leq 5$ minutes) oxidations were carried out in a vessel described in a prior communication (1). Slower reactions were studied by vigorously agitating the solution in a flask: 25 ml. of solution contained in a 500-ml. Erlenmeyer flask was shaken at a constant rate with a Burrell wrist action shaker[1] in a thermostatted room in which temperature was controlled at 25 ± 1°. Total sulfurous acid content of solutions was determined iodometrically. The pH of each solution was measured at 25 ± 0.05° with a Beckman GS pH meter.

RESULTS AND DISCUSSION

The copper-catalyzed air oxidation of aqueous-ethanol solutions of sodium sulfite exhibits an apparent first-order dependency on total sulfurous acid species as shown in Fig. 1. The apparent first-order rate constant decreases with increasing concentrations of ethanol: 0.1 M ethanol, k = 0.050 hours^{-1}; 0.5 M ethanol, k = 0.030 hours^{-1}; 1.0 M ethanol, k = 0.023 hours^{-1}; 2.0 M ethanol, k = 0.018 hours^{-1}.

Selection of ethanol as the chain propagation inhibitor was made on the basis of its importance in pharmaceutical formulations and the ease with which it can be distilled free from heavy metal contaminants. Cupric ion ($1 \times 10^{-6} M$) catalyst, which was added to each system immediately prior to oxidation, corresponded to less than 0.1 p.p.m. as Cu(II). Total heavy metal content of the oxidation system was not directly determined; however, kinetic oxidative studies with varying concentrations of sodium sulfite in water-ethanol indicated the presence of less than 10 p.p.b. copper ion.

[b] pH of solutions determined at 25° prior, during, and after oxidation (three half-lives) with Beckman GS pH meter did not vary more than 0.05 pH unit from value shown. [c] Experimentally determined apparent second ionization constant for sulfurous acid, $K_s' = 2.55 \times 10^{-7}$ (25°, $\mu = 1.0$).

Dependence of the copper-catalyzed (1×10^{-6} M) oxidation rate of sodium sulfite on inhibitor concentration is shown in Fig. 2. The linear relationship between the reciprocal half-life for the copper-catalyzed reaction and the reciprocal of the concentration of added inhibitor clearly demonstrates that significant oxidation of the thio compound takes place in the presence of overwhelming amounts of inhibitor when copper is present. The inhibitor appears to have little or no effect on radical initiation; it appears to function primarily by decreasing chain length. The heavy metal catalyzed oxidation of sulfurous acid salts in the presence of high concentrations of inhibitor is especially significant since this simulates pharmaceutical systems in which the compounds are utilized as antioxidants.

The rate of oxidation of sodium sulfite in the presence of 0.2 M ethanol appears to be directly proportional to the concentration of added cupric ion over the concentration range 0 to 30×10^{-6} M Cu(II) as shown in Fig. 3. However, a slow but measurable rate of oxidation of sodium sulfite takes place in the presence of an inhibitor even in the absence of added copper ion. This uncatalyzed rate of sulfite oxidation in the presence of an inhibitor may be approximated with Eq. 1 assuming $A = B = 10^{-5}$ and using the specific rate constant for the oxidation of sodium sulfite in air, $k = 2.8 \times 10^{-3}$ seconds^{-1}. For a sodium sulfite solution containing 0.2 M ethanol as an inhibitor, Eq. 1 predicts an approximate first-order rate constant for the inhibited oxidation: $k_1 = 5 \times 10^{-4}$ hours^{-1}; in terms of half-life, $t^1/_2 \cong 1400$ hours. This theoretical value agrees reasonably well with the experimentally determined half-life (1525 hours) for sulfite oxidation in the presence of 0.2 M ethanol and 1×10^{-3} M sodium cyanide as shown in Table I. Since the uncatalyzed reaction rate is four orders of magnitude less than the maximum copper-catalyzed rate, it is not detected as an intercept value on a rate plot such as Fig. 3. At higher concentrations ($> 40 \times 10^{-5}$ M) of the metal

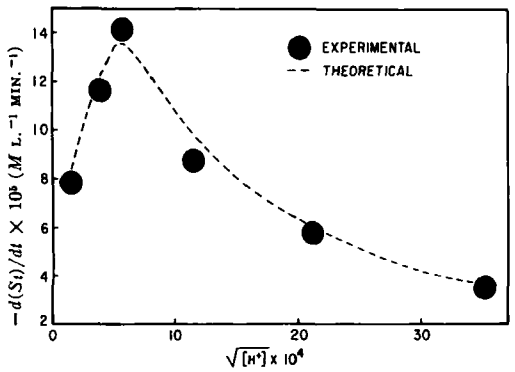

Fig. 6.—Initial rate of loss of total sulfurous acid species ($-d(S_t)/dt$) as a function of square root of the hydrogen ion concentration at 25°C. Initial solution composition: 0.02 M total sulfurous acid species, 0.2 M ethanol, 5×10^{-5} M Cu (II) in 0.3 M buffers. Ionic strength unity ($\mu = 1.0$). Theoretical line calculated with Eq. 4.

ion, the reaction appears to reach a limiting rate corresponding to a half-life for the oxidation of about 10 minutes. Doubling the stirring rate to increase the dissolution of oxygen does not apparently affect the limiting rate under these experimental conditions. This rate-limiting step may be related to the rate of reduction of Cu(II) or its regeneration.

Effect of initial solution pH on the copper-catalyzed oxidation of sulfurous acid salts in aqueous-ethanol solution is shown in Fig. 4. The initial pH of each of these solutions was adjusted to the indicated values with appropriate amounts of standard sodium hydroxide solution; the test solutions contained no other buffer species. Rapid initial oxidation occurred in all solutions at initial pH values from 5.9 to 8.3. The oxidation rates appeared to reach a plateau region in which little or no change occurred during the time of observation. The oxidation of bisulfite proceeds with the production of the more acidic sulfate species and an increase in the hydrogen ion concentration. The apparent effect is to decrease the total sulfurous acid species (HSO_3^- and SO_3^{2-}) wholly at the expense of sulfite as shown in Table II. This phenomenon has been discussed in a previous publication (1). The increase in hydrogen ion concentration in unbuffered oxidizing systems decreases the rate of oxidation in accordance with

$$-\frac{d(S_t)}{dt} = g\frac{(HSO_3^-)}{\sqrt{(H^+)}} \qquad \text{(Eq. 3)}$$

Oxidation of sulfurous acid salts in pharmaceutical systems usually takes place under conditions of constant pH since these compounds are added in small amounts and rarely represent the major buffer species. Oxidation of sulfurous acid salts in strongly buffered systems follows apparent first-order kinetics as shown in Fig. 5. The oxidation was studied in duplicate over about 90% of the reaction course (three half-lives). The relationship between the pH and the slopes of the lines representing the specific first-order rate constants suggests the presence of a maximum in the pH-rate constant profile. Table III indicates that the rate constants increase up to pH 6.5 and decrease at higher pH values. This unique dependency of the oxidation rate on hydrogen ion concentration may be satisfactorily explained by a modified form of Eq. 3. The concentration of hydrogen sulfite may be described in terms of total sulfurous acid specie added to the system, S_t

$$[HSO_3^-] = \frac{S_t(H^+)}{K_s' + (H^+)} \qquad \text{(Eq. 4)}$$

Substituting Eq. 4 into Eq. 3 gives

$$-\frac{d(S_t)}{dt} = g\frac{\frac{S_t(H^+)}{K_s' + (H^+)}}{\sqrt{(H^+)}} = g \cdot S_t \frac{\sqrt{(H^+)}}{K_s' + (H^+)} \qquad \text{(Eq. 5)}$$

The relationship shown above predicts a maximum oxidation rate when $[H^+] = K_s'$ since the terms $(\sqrt{(H^+)}/K_s' + (H^+))$ is maximal at this hydrogen ion concentration.

This further supports Abel's theoretical predictions (14) which were found to describe limited experimental data derived from unbuffered oxidizing sulfite systems. The rather good agreement between experimentally determined absolute initial rate of oxidation in buffered sulfite systems and the theoretical curve from Eq. 5 is shown in Fig. 6. The experimental maximum rate occurs at a hydrogen ion concentration of 3.16×10^{-7} which shows reasonable agreement with the theoretical value 2.55×10^{-7}. The latter value represents the experimentally determined apparent second ionization constant of sulfurous acid at 25° in buffer of total ionic strength equal to unity.

Binding of Organic Electrolytes by a Nonionic Surface-Active Agent

By ARTHUR R. HURWITZ†, PATRICK P. DELUCA‡, and H. B. KOSTENBAUDER

Although possible consequences of combining ionic pharmaceuticals with surface-active agents of opposite charge are generally recognized, there has been little or no consideration of possible interactions between drug ions and nonionic surface-active agents. In the present study, cations such as chlorpromazine, promethazine, tetracaine, methylrosaniline, and dodecylpyridinium, and anions such as naphthalenesulfonate and methyl orange were bound to the nonionic surface-active agent polysorbate 80. The degree of interaction in some cases is sufficient to suggest that polysorbate 80 might have considerable influence on the stability and availability of ionic drugs in pharmaceutical formulations.

THE USE OF nonionic surface-active agents in the formulation of various pharmaceutical dosage forms is often a routine procedure. Their presence in pharmaceuticals sometimes results in incompatibilities—notably, the inactivation of some antimicrobial agents which are commonly used in pharmaceuticals for their preservative activity (1–16). In the majority of examples of incompatibility which have previously been described, the agent which is bound to the surfactant is primarily in molecular or nonionized form; interaction with the surfactant has generally been explained on the basis of either the formation of specific molecular complexes or the preferential solubility in the surfactant micelle. Persons engaged in pharmaceutical formulation are generally cognizant of possible incompatibilities of this nature.

Although textbooks devote considerable discussion to incompatibilities which might arise from the combination of an ionic surfactant with a drug or germicide of opposite charge, there is usually no suggestion of possible incompatibility or inactivation which might arise from the combination of an ionic drug or germicide with a nonionic surfactant. Recent observations in these laboratories indicated that organic ions, such as quaternary ammonium germicides, can be strongly bound by nonionic surfactants (16). These observations suggest that such generally unrecognized incompatibilities might exist in many pharmaceutical systems and might markedly influence the release of a drug from a dosage form or might alter the stability of a drug. The present study was designed to investigate the possible association of various cations and anions with a typical nonionic surface-active agent, polysorbate 80.[1] The existence of a significant degree of interaction between ionic drugs and nonionic surfactants might require a re-evaluation of the routine use of nonionic surface-active agents in pharmaceutical formulation.

EXPERIMENTAL

Reagents.—Ephedrine hydrochloride N.F.; sulfathiazole sodium N.F.; methylrosaniline chloride U.S.P.; promethazine hydrochloride U.S.P.[2]; methapyriline hydrochloride N.F.[3]; diphenhydramine hydrochloride U.S.P.[4]; chlorpromazine hydrochloride U.S.P.[5]; tetracaine hydrochloride U.S.P.[6]; cetylpyridinium chloride U.S.P.[7]; polysorbate 80, a commercial sample; sodium salt of 2-naphthalene sulfonic acid, recrystallized from water; dodecylpyridinium bromide, laboratory prepared; were used. All other chemicals were reagent grade.

Method for Detecting Interaction.—Equilibrium dialysis was employed to detect possible drug–nonionic surface-active agent interaction. The technique was similar to that described previously by Patel and Kostenbauder (17) in their study of the interaction of methyl and propyl *p*-hydroxybenzoate with polysorbate 80. This method involves equilibration of two solutions across a semipermeable membrane, one solution containing the surface-active agent and the other solution containing only the drug. Nylon membranes were used in this study, these membranes being selected to permit the drug to come to equilibrium in both solutions but to prevent passage of the nonionic surface-active agent.

The nylon membranes were cut to give bags which held 20 ml. of solution. The bags, when filled with the solution of the ionic agent being studied, were tied and placed in wide mouth,

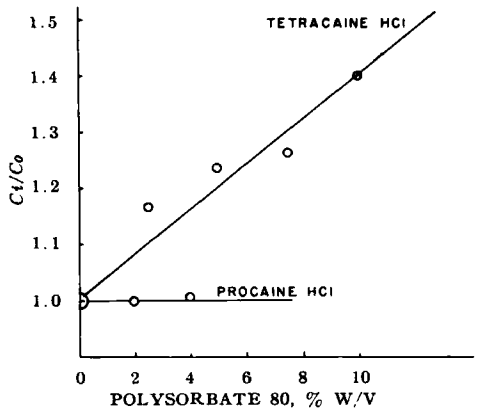

Fig. 1.—Binding of tetracaine hydrochloride by polysorbate 80 at 30°.

screw-cap, glass bottles containing 60 ml. of a polysorbate 80 solution with a concentration of ionic agent equal to that in the internal phase. By starting with equal concentrations of drug in both phases, the equilibration or agitation time could be greatly reduced. Also, shorter agitation time decreased the possibility of membrane breakage. The bottles were then tightly closed, using a piece of polyethylene film between the cap and the bottle top to prevent leakage. The bottles were agitated in a constant temperature water bath at 30° for 2 to 6 days. Aliquot portions were then taken from both the internal and external phases and assayed spectrophotometrically for the ionic agent, using a Beckman DU spectrophotometer and an appropriate blank solution in each case. A few agents were studied in the presence of potassium chloride to determine the effect of salt on the interaction, and sodium bisulfite was added to solutions of promethazine and chlorpromazine to retard oxidation. The spectrophotometric assays of methyl orange and methylrosaniline chloride were performed on the Beckman model B spectrophotometer. The addition of polysorbate 80 (2% w/v) caused a shift in the absorption maximum of methyl orange from 465 mμ to 425 mμ, and the maximum for methylrosaniline chloride was shifted from 595 mμ to 600 mμ. The polysorbate-containing solutions of these agents were always assayed by adjusting the final polysorbate concentration to 2%, then determining the absorbance at the shifted maximum.

The extent of binding is represented as C_i/C_o, where C_i represents the total concentration of organic electrolyte on the polymer-containing side of the membrane, and C_o is the concentration on the nonpolymer-containing side. For calculation of the apparent degree of binding, the ratio total/free is taken as equal to the ratio C_i/C_o. Actually, as a result of a Donnan effect, the free concentration on the polymer-containing side of the membrane is less than C_o and the actual ratio total/free $> C_i/C_o$. The complexity of the systems prevents calculation of the Donnan correction for most of the examples of binding considered in this report but, if applied, such a correction would indicate even greater binding than the apparent ratios reported here.

RESULTS

Tetracaine Hydrochloride and Procaine Hydrochloride.—The relative affinity of tetracaine hydrochloride and procaine hydrochloride for polysorbate 80 is shown in Fig. 1. At a concentration of 5% polysorbate 80, approximately 20% of the total tetracaine is bound to the surfactant; at a concentration of 10% polysorbate 80, approximately 30% of the tetracaine is bound. The procaine ion does not appear to interact significantly with the polysorbate under the conditions of this study.

Chlorpromazine Hydrochloride.—Figure 2 illustrates interaction of chlorpromazine hydrochloride with polysorbate 80 in aqueous solution. The addition of electrolyte appears to enhance the interaction considerably. In an aqueous solution of 2% polysorbate 80, approximately 50% of the total chlorpromazine present is bound to the surfactant; when 0.1% $NaHSO_3$ is present in this system (to retard oxidation), approximately 75% of the chlorpromazine is bound; when the system consists of 2% polysorbate 80, 0.1% $NaHSO_3$, and 0.5 *M* KCl, approximately 90% of the chlorpromazine is bound to the surfactant.

Promethazine Hydrochloride.—The interaction of promethazine hydrochloride with polysorbate 80 is illustrated in Fig. 3. At a concentration of 2% polysorbate 80 and in the presence of 0.1% $NaHSO_3$ (to retard oxidation of the promethazine), approximately 38% of the total promethazine is bound to the surfactant; when KCl is added to this system to establish a total ionic strength of approximately 0.6, approximately 70% of the promethazine is bound to the polysorbate 80.

Dodecylpyridinium Chloride and Cetylpyridinium Chloride.—DeLuca and Kostenbauder previously presented data to illustrate the high degree of

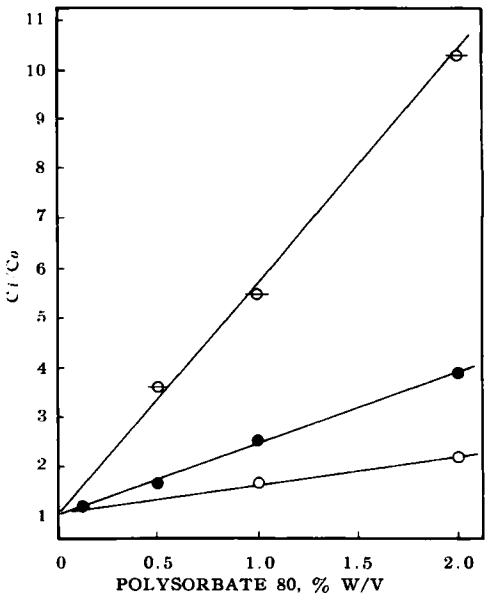

Fig. 2.—Influence of electrolyte on binding of chloropromazine hydrochloride by polysorbate 80 at 30°. Sodium bisulfite added as antoxidant. Key: O, in polysorbate 80; ●, in polysorbate 80 plus 0.1% $NaHSO_3$; ⊖, in polysorbate 80 plus 0.1% $NaHSO_3$ and 0.5*M* KCl.

interaction between cetylpyridinium chloride and polysorbate 80 (16). These data are reproduced in Fig. 4 to permit comparison with the interaction between dodecylpyridinium ion and polysorbate 80. At a concentration of 2% polysorbate 80 approximately 40% of the dodecylpyridinium ion is bound to the polysorbate; while at this concentration of polysorbate 80, approximately 97% of the cetylpyridinium ion is bound.

Methylrosaniline Chloride.—Figure 5 illustrates the interaction of the cationic dye methylrosaniline chloride with polysorbate 80. These adsorption isotherms indicate that the nature of the binding may change markedly with concentration of free methylrosaniline ion, and it is not possible to apply the relatively simple description of the binding used previously; *i.e.*, it is not sufficient to describe the binding in terms of a definite percentage of the methylrosaniline chloride bound to the polysorbate at any specific polysorbate concentration. For example, at a concentration of 0.25% polysorbate 80, the percentage of dye bound to the surfactant varied from approximately 70% at the lower dye concentrations to 40% at the higher dye concentrations. At a concentration of 5% polysorbate 80, approximately 90% of the dye was bound throughout the concentration range studied.

Sodium Naphthalene Sulfonate.—Sodium naphthalene sulfonate was included in this study to demonstrate that anionic as well as cationic agents might be bound to nonionic surface-active agents. The interaction of the naphthalene sulfonate anion with polysorbate 80 is illustrated in Fig. 6. In the presence of a 2% aqueous solution of polysorbate 80, approximately 7% of the total naphthalene sulfonate ion is bound to the polysorbate; however, when 0.1 *M* KCl was added to this system, approximately 17% of the naphthalene sulfonate was bound to the polysorbate. The naphthalene sulfonate ion was selected for study because of the absence of functional groups, other than sulfonate, which might permit hydrogen bonding to the polyether portion of the polysorbate, and because this ion is essentially in the completely dissociated form in aqueous solution, thereby eliminating the possibility of an interaction being attributed to binding of undissociated molecules to the polysorbate.

Methyl Orange.—The interaction of the anionic dye methyl orange with polysorbate 80 is shown in Fig. 7. As with methylrosaniline chloride, the fraction of dye bound to the surfactant at any polysorbate concentration changes markedly with the concentration of unbound dye; in the presence of 5% polysorbate 80, the percentage of bound dye ranged from 96% at low dye concentrations to 83% at higher dye concentrations.

Drug Ions Not Bound to Polysorbate 80.—No significant interaction was observed for the following drug ions in the presence of aqueous solutions of polysorbate 80: ephedrine hydrochloride, sulfathiazole sodium, methapyrilene hydrochloride, and diphenhydramine hydrochloride.

DISCUSSION

Nature of Interaction with Polysorbate 80.—The interaction of drug ions with polysorbate 80 appears to be similar to the interaction of cetylpyridinium ion with polysorbate 80 as described by DeLuca and Kostenbauder (16). It appears that ions having a large hydrophobic group can undergo association with the polysorbate micelle to form a type of mixed-micelle. Binding of ions such as dodecylpyridinium and naphthalene sulfonate, which exist entirely in dissociated form in aqueous solution and have no other functional groups which might be expected to hydrogen bond to the ethylene oxide portion of the polysorbate, indicates that the necessary structural feature for an organic ion to interact with a nonionic surface-active agent is that of a relatively large hydrophobic portion.

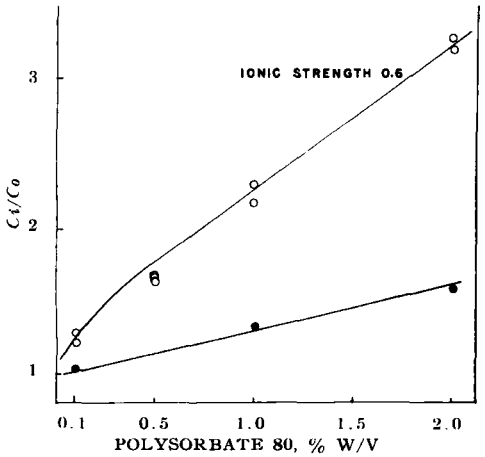

Fig. 3.—Binding of promethazine hydrochloride by polysorbate 80 at 30°. Solid symbols correspond to systems containing 0.1% $NaHSO_3$ as antoxidant; open symbols represent systems containing 0.1% $NaHSO_3$ plus sufficient KCl to produce an ionic strength of 0.6.

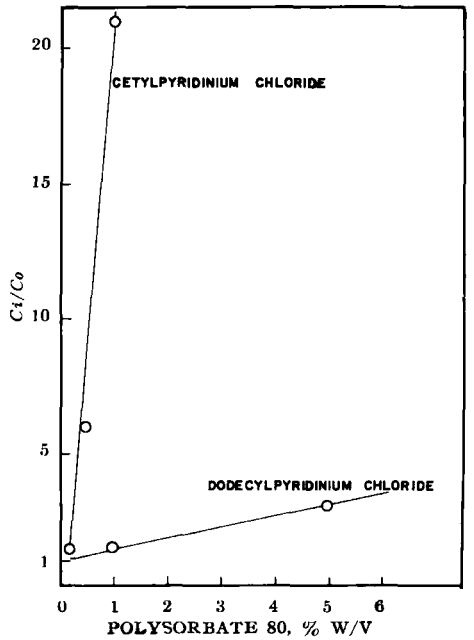

Fig. 4.—Relative binding by polysorbate 80 of dodecylpyridinium chloride and cetylpyridinium chloride at 30°. Binding data for cetylpyridinium chloride reproduced from DeLuca and Kostenbauder (16).

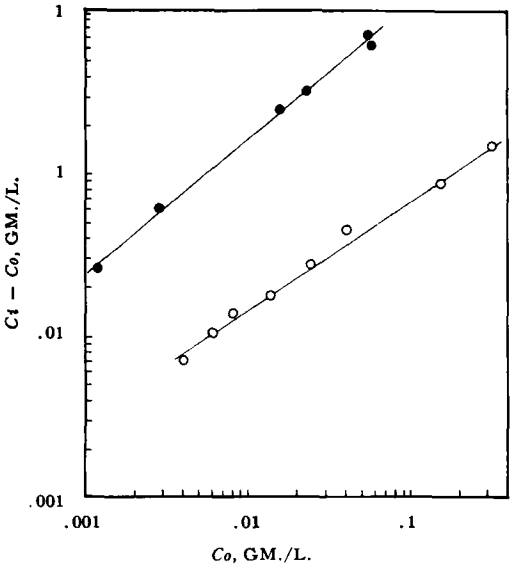

Fig. 5.—Binding of methylrosaniline chloride by polysorbate 80 at 30°. Open symbols represent solutions containing 0.25% polysorbate 80; solid symbols represent 5% polysorbate 80.

Ions such as ephedrine, sulfathiazole, methapyrilene, diphenhydramine, and procaine apparently are not sufficiently hydrophobic to associate with polysorbate 80 micelles. The presence of the *n*-butyl substituent on the *p*-amino group of tetracaine apparently confers sufficient hydrophobic character for this ion to associate with the polysorbate. The importance of the hydrophobic character of the ion is further illustrated in the comparative binding of cetylpyridinium ion and dodecylpyridinium ion.

Salt Effects.—For a weakly bound electrolyte such as sodium naphthalene sulfonate, enhanced binding to polysorbate 80 in the presence of added electrolyte might be accounted for on the basis of swamping of a Donnan effect. Adsorption of hydrophobic ions would, in effect, cause the polysorbate 80 to act as an ionic polymer and necessitate a Donnan correction for the binding studies. If the adsorbed hydrophobic ion binds few counter ions, and if it is assumed that the hydrophobic ion under study does not form micelles at the concentrations considered, then a Donnan correction can be applied in the following manner

Let

C_o = concentration of hydrophobic ion in the outside or nonpolymer containing compartment.

C_i = concentration of total hydrophobic ion in the inside compartment and consists of bound plus free.

$C_{i,\,free}$ = concentration of free hydrophobic ion in inside compartment.

Donnan equilibrium:

$$(C_o)^2 = C_i \times C_{i,\,free}$$

$C_{i,\,free}$ is therefore less than C_o and actual ratios of total/free drug are greater than the observed ratio C_i/C_o.

This Donnan correction was applied to the naphthalene sulfonate–polysorbate 80 data. As

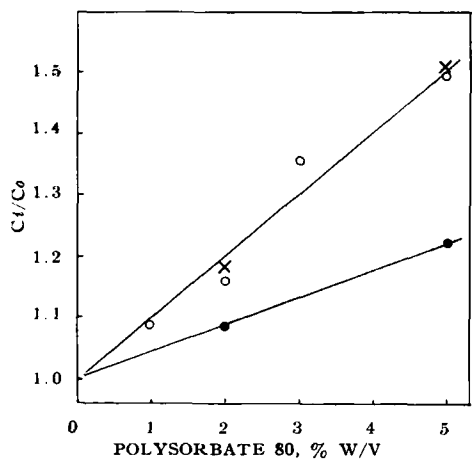

Fig. 6.—Binding of sodium naphthalene sulfonate by polysorbate 80 at 30°. Key: O, with 0.1 *M* KCl; ●, without KCl; ×, points obtained by applying a Donnan correction to the binding data obtained in absence of KCl.

shown in Fig. 7, the binding data in absence of salt, when corrected for the Donnan effect, are in excellent agreement with the degree of binding observed in the presence of 0.1 *M* swamping electrolyte. The effect of electrolyte on the apparent degree of binding of naphthalene sulfonate to polysorbate 80 can therefore be attributed almost entirely to elimination of the Donnan effect.

Other systems studied are not amenable to correction for this Donnan effect. Where there is a high degree of interaction with the polysorbate 80, it is almost a certainty that there is considerable counter-ion retention, just as there would be in micelles of ionic surfactants. While it is not feasible to apply a Donnan correction, it can be predicted that any correction for a Donnan effect could only lead to an even greater degree of interaction than that indicated by the ratio C_i/C_o; therefore, total/free $\geqq C_i/C_o$ in all cases.

Where there is considerable counter-ion retention by bound hydrophobic ions, added electrolyte may have a further effect as indicated by application of the law of mass action to micelle formation. Where A^+ represents the hydrophobic ion and B^- the counter-ion, the interaction with polysorbate may be represented as

$$aA^+ + bB^- + Tw \rightleftarrows (A_a^+ B_b^- \, Tw) \qquad a > b$$

$$K = \frac{(A_a^+ B_b^- \, Tw)}{(A^+)^a \, (B^-)^b \, Tw}$$

The concentration of bound hydrophobic ion, (A^+), is

$$\frac{K \, (A^+)^a \, (B^-)^b \, (Tw)}{a}$$

and an increase in the concentration of the counter-ion (B^-), on addition of an electrolyte such as KCl, would be expected to increase markedly the binding of the hydrophobic ion, A^+.

For a strongly bound electrolyte such as chlorpromazine hydrochloride, the effect of added electrolyte on the observed ratio C_i/C_o might therefore be attributed in part to swamping of the Donnan

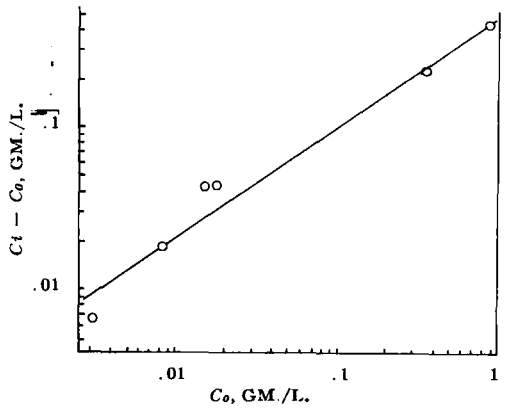

Fig. 7.—Binding of methyl orange by 5% polysorbate 80 at 30°.

effect and in part to the effect of increasing concentration of counter-ion on the equilibrium as predicted by the law of mass action.

Pharmaceutical Significance of These Interactions.—Perhaps the most obvious consequence of interactions such as those described in this paper is the influence of the binding on the release of a drug from a formulation containing a nonionic surfactant or the availability or activity of a germicidal agent in such a formulation. Interactions in which a large percentage of the drug is bound to a component in the formulation would be expected to modify greatly the release of the drug and subsequent absorption or access to the site of action. This might be particularly true in topical formulations where nonionic surface-active agents may be employed in concentrations of 5% or more in the aqueous phase. Of course absorption of drugs or release of drugs from formulations is an extremely complex process, and binding of drug to surfactant is only one aspect of the problem; it may well be that other factors to be considered make it highly desirable that the surfactant be employed in a large concentration in spite of possible interactions with the drug. Nevertheless, it is important to recognize that nonionic surfactants can interact with ionic drugs and that this interaction might be expected to exert considerable influence on the release of some drug ions from such systems.

The very pronounced effect of interaction between nonionic surfactants and quaternary ammonium compounds on the availability and antimicrobial activity of the quaternary ammonium compounds has been demonstrated previously (16). Such interactions between nonionic agents and quaternary ammonium compounds, or other materials having antimicrobial activity, are not always undesirable; the inactivation of quaternary ammonium compounds by addition of a nonionic agent is a common procedure in carrying out sterility tests where there normally would be interference from the antimicrobial agent present in the formulation.

A second important consequence of drug-surfactant interactions is the effect of such interaction on the stability of the drug. Although no data can be cited for systems discussed in this paper, Riegelman (18) has demonstrated the very significant effects on drug stability which might arise from association of drugs with surfactant micelles. Riegelman (18), Nogami, *et al.* (19, 20), and Nakajima (21) have shown that a number of drugs with labile ester linkages can be significantly stabilized against ester hydrolysis when solubilized in aqueous solutions of micellar nonionic surface-active agents. On the other hand, Motsavage and Kostenbauder (22) have recently demonstrated that binding of alkyl sulfates to nonionic micelle-forming agents may increase the rate of the hydronium ion catalyzed hydrolysis of the sulfate ester as much as 60-fold. Whether a drug is more or less stable when associated with the nonionic surfactant micelle will depend on the positioning of the labile group in or on the micelle and on the nature of the decomposition to which it is subject.

SUMMARY

Data have been presented to show that drug ions can interact in aqueous solution with a nonionic surface-active agent to an extent which might markedly influence the stability of the drug or the release of the drug from a formulation.

Only those drug ions having a relatively large hydrophobic group were found to interact with polysorbate 80. The mechanism of the interaction appears to be similar to the mixed micelle formation which occurs on interaction of cetylpyridinium ion with polysorbate 80. Addition of electrolyte appears to enhance the interaction considerably.

The following ions were found to bind to polysorbate 80 in aqueous solution: cetylpyridinium, methylrosaniline, methyl orange, chlorpromazine, dodecylpyridinium, promethazine, tetracaine, and naphthalene sulfonate.

The following ions did not appear to interact with polysorbate 80 to a significant extent: ephedrine, sulfathiazole, diphenhydramine, methapyriline, and procaine.

Thiaindanones

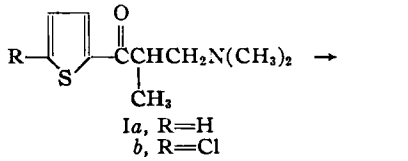
Thiophene Isosteres of Indanone

By JOSEPH SAM and ALONZO C. THOMPSON

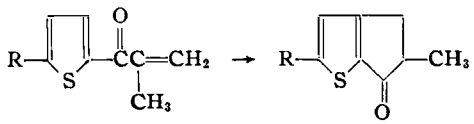
The preparation of substituted 4- and 6-thiaindanones[1] (thiophene isosteres of indanone) *via* intramolecular acylation of β-(2- and 3-thienyl)propanoic acids is described. The Wolff-Kishner and sodium borohydride reductions provided the corresponding thiaindan and thiaindanol (thiophene isosteres of indan and indanol), respectively.

THE IMPORTANCE of molecular size and shape in determining biological properties has been recognized for many years. The chemical, physical, and biological properties of isosteres have been studied extensively (2), since they possess steric similarities. Interest in the synthesis and in the biological properties of isosteres is kindled in the hope that useful medicinal agents and essential clues to the mechanism of drug action may be obtained.

Burckhalter and Sam (1) prepared the thiophene isostere (III*a*) of 2-methyl-1-indanone (IV) but did not report biological activity. Since the thiaindanones (III) represented a ring system that had not been investigated extensively, we were interested in the preparation of other thiophene isosteres of indanone and in ascertaining their biological properties. Moreover, since the presence of the sulfur atom gives rise to an unsymmetrical molecule, we were also interested in the preparation of the isomeric thiophene isosteres (V). During the course of our work Poirier (3) described the preparation of some closely related derivatives of this ring system.

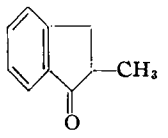


I*a*, R=H
b, R=Cl

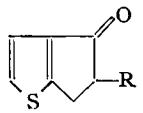


II*a*, R=H
b, R=Cl

III*a*, R=H
b, R=Cl

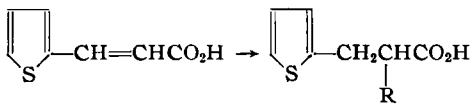


IV

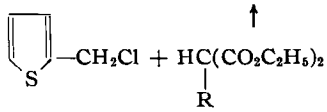


V

The method (I→III) reported by Burckhalter and Sam (1) for the preparation of III*a* is not generally applicable to other substituted thiaindanones. Except for the preparation of the chloro derivative (III*b*) we made use of the intramolecular acylation of substituted β-thienylpropanoic acids. The substituted β-(2-thienyl) propanoic acids (VII) were prepared by the condensation of 2-thenyl chloride with substituted malonates according to the procedure described by Levy (4) and modified by Sam and Plampin (5) for the preparation of substituted hydrocinnamic acids. The unsubstituted acid (VII, R=H) was obtained from the reduction of the corresponding acrylic acid (VI)



VI VII



The reduction of VI was accomplished either with 10% sodium-lead alloy in water at room temperature or catalytically at 3–4 Atm. with 10% palladium-on-charcoal catalyst. Contrary to expected results, we obtained a good yield in the catalytic reduction of VI to VII (R=H).

The substituted β-(3-thienyl)propanoic acids (VIII) were prepared from 3-thenyl bromide *via* condensation with substituted malonates (6)

Received January 29, 1963, from the School of Pharmacy, University of Mississippi, University.
Accepted for publication March 29, 1963.
The authors are grateful to Bristol Laboratories for financial support of this project.
Abstracted in part from a thesis submitted by Alonzo C. Thompson to the Graduate School, University of Mississippi, in partial fulfillment of Doctor of Philosophy degree requirements.
Presented to the Scientific Section, A.PH.A., Miami meeting, May 1963.

[1] Because of the cumbersome chemical name originally assigned (1) to III*a*, *i.e.*, 4,5-dihydro-5-methyl-6H-cyclopenta-(b)thiophen-6-one, we propose the name thiaindan for the thiophene isostere (i) of indan (ii), and the names thiaindanone and thiaindanol for the corresponding isosteres of indanone and indanol, respectively.

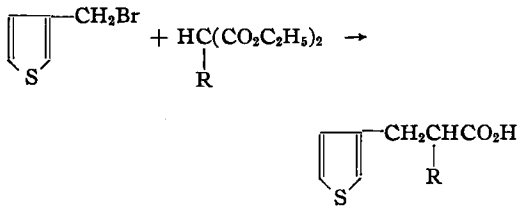
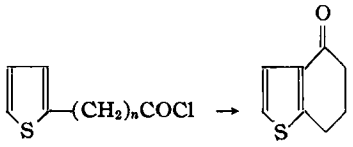
[a] Polyphosphoric acid. [b] Eight separate experiments varying the temperature and duration. [c] Acid chloride.



VIII

Intramolecular acylation studies of the substituted β-(2 and 3-thienyl)propanoic acids are summarized in Tables I and II. Our studies (Table I) with α-methyl-β-(2-thienyl)propanoic acid revealed that a solution of the organic acid in chlorobenzene when added to polyphosphoric acid (PPA) at an elevated temperature (preferably 130°) over a short period of time gave the best results. The use of other dehydrating agents such as sulfuric acid and liquid hydrogen fluoride gave negligible results. In contrast to the good results obtained by Fieser and Kennelly (7) with the cyclization of γ-(2-thienyl)butanoyl chloride (IX, $n=3$) to X, we were unable to cyclize β-(2-thienyl)propanoyl chloride (IX, $n=2$) to V (R=H) utilizing the same conditions. Aluminum chloride also was ineffective in the cyclization of the acid chloride

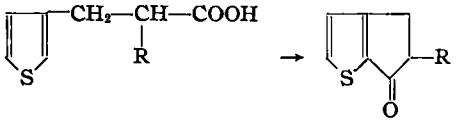


IX X

The intramolecular acylation of substituted β-(3-thienyl)propanoic acids (VIII) to the corresponding substituted 6-thiaindanones (XI, Table II) was accomplished without difficulty and in moderate yields with either PPA or liquid hydrogen fluoride. In contrast to the sluggish cyclization of the isomeric 2-thienyl acids (VII), the ease with which this cyclization was accomplished is explained on the basis of the differences in the reactivity of the 2 and 3 positions of thiophene.

The 5-methyl-6-thiaindanone, III*a*, undergoes

TABLE II.—THIAINDAN-6-ONES



VIII XI

R	Solvent for VIII	Reaction Temp., °C.	Reaction Time	Yield, %	Cyclization Agent
H	C_6H_5Cl	75	5 min.	10.4	PPA
H	...	30	12 hr.	43.9	HF
ϕ	C_6H_5Cl	130	15 min.	21.7	PPA
ϕ	...	30	48 hr.	71.9	HF

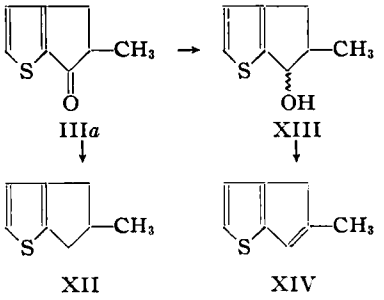
CH_3	...	70	1 hr.	0.0	PPA

the typical Wolff-Kishner reduction (8) to give the thiophene isostere (XII) of 2-methylindan; sodium borohydride reduction (9) of III*a* yielded a thiophene isostere (XIII) of 2-methyl-1-indanol. Preliminary attempts to obtain the isomeric alcohol have been unsuccessful. Since analogous reductions of 2-methyl-1-indanone to 2-methyl-1-indanol with sodium borohydride have provided exclusively the *cis*-2-methyl-1-indanol, we believe the reduction of III*a* likewise gives the *cis* isomer.



The dehydration of 5-methyl-6-thiaindanol occurred on heating and resulted in a product (XIV?) which gave the characteristic tests for unsaturation. However, this material rapidly deteriorated and was not fully characterized.

Preliminary pharmacological studies in mice demonstrated that the semicarbazones of III*a* and V (R = CH_3) exhibit weak anticonvulsant activity. The acid, VIII (R = CH_3), and the ketone, XI (R = H), also exhibited weak anticonvulsant activity. The semicarbazone of III*a* produced a weak antihypertensive response in both rats and dogs.

EXPERIMENTAL[2]

β-(2-Thienyl)propanoic Acid.—*Method A.*—A 9.6% lead-sodium alloy (100 Gm.) was added to a stirred solution of 15.4 Gm. (0.1 mole) of β-(2-thienyl)acrylic acid in 200 ml. of 10% sodium hydroxide solution over a period of 2 hours. The mixture was filtered and the basic filtrate neutralized with concentrated hydrochloric acid. The precipitate was removed by filtration, air dried, and recrystallized from petroleum ether (b.p. 30–60°) to give 10 Gm. (64%) of product, m.p. 48–49° (lit. (10) m.p. 46–48°).

Method B.—A solution of 15.4 Gm. (0.1 mole) of β-(2-thienyl)acrylic acid in 200 ml. of methanol was treated with 2 Gm. of 10% palladium-carbon catalyst and hydrogenated at 42 p.s.i. Hydrogenation was complete at the end of 1 hour; no further hydrogen uptake occurred during an additional hour. The catalyst was removed by filtration and the solvent was distilled *in vacuo* leaving 12.6 Gm. (80%) of product, m.p. 48–49°. The infrared spectra of samples from *Methods A* and *B* were identical. Mixed melting points showed no depression.

[2] All melting points were taken on a Fisher-Johns apparatus and are corrected; boiling points are uncorrected. Infrared spectra were determined on a Perkin-Elmer model 137 infracord spectrophotometer.

α-(Methyl-β-(3-thienyl)propanoic Acid.—To a solution of 234.6 Gm. (1.4 moles) of diethyl methylmalonate in ethanolic sodium ethoxide (made from 29.7 Gm. (1.3 Gm. At.) of sodium and 600 ml. of ethanol) was added through a dropping funnel 230 Gm. (1.3 moles) of 3-thenyl bromide and the mixture heated at reflux for 7 hours. A solution of 300 Gm. (5.36 moles) of potassium hydroxide in 300 ml. of water was added to the ethanol solution and the mixture refluxed for 24 hours. The mixture was concentrated *in vacuo* to about 400 ml. The residual mixture was treated with 500 ml. of water, cooled in an ice bath, neutralized with concentrated hydrochloric acid, and extracted with ether. Evaporation of the ether and distillation of the residual oil gave 151 Gm. of product (68%), b.p. 141–145° (5 mm.) n_D^{28} 1.5225.

Anal.—Calcd. for $C_8H_{10}O_2S$: C, 56.5; H, 5.9. Found: C, 56.4; H, 6.2.

The amide was prepared in the usual manner and recrystallized from an ethanol-water mixture and water, respectively, m.p. 121–122°.

Anal.—Calcd. for $C_8H_{11}NOS$: C, 56.8; H, 6.5. Found: C, 57.0; H, 6.8.

α-Phenyl-β-(3-thienyl)propanoic Acid.—The procedure for the synthesis of α-methyl-β-(3-thienyl)-propanoic acid was employed using 177 Gm. (1.0 mole) of 3-thenyl bromide and 238 Gm. (1.0 mole) of diethyl phenylmalonate. Ninety-seven grams (42%) of product were obtained, b.p. 194° (2.5 mm.); m.p. 87–89°.

The amide was prepared in the usual manner and recrystallized from an ethanol-water mixture, m.p. 130–132°.

Anal.—Calcd. for $C_{13}H_{13}NOS$: C, 67.5; H, 5.6; N, 6.1. Found: C, 67.6; H, 5.5; N, 6.0.

Cyclization of β-(2- and 3-Thienyl)propanoic Acids to Thiaindanones (Tables I, II). *Polyphosphoric Acid Method.*—The appropriate β-(2- and 3-thienyl)propanoic acid *per se* or dissolved in 100 ml. of solvent was added with stirring to 200 Gm. of polyphosphoric acid, preheated to the desired temperature. The dry acid was added essentially in one lot, whereas the solution of the acid in the solvent was added over a 15-minute period. Thereafter, the mixture was poured with stirring into 200 ml. of ice water. The mixture was extracted with either ethyl acetate or ether. The combined extracts were washed with water, 10% sodium bicarbonate solution, and dried over anhydrous sodium sulfate. Evaporation of the solvent and distillation or recrystallization of the residue provided the desired product (Table III). Infrared spectra in carbon tetrachloride showed strong carbonyl absorption at 1625–1740 $cm.^{-1}$

Hydrogen Fluoride Method.—The procedure was adapted from that of Heinzelmann and co-workers (11) for the cyclization of substituted phenylpropanoic acids. A 250-ml. copper retort containing 0.1 mole of the appropriate thienylpropanoic acid per 150 Gm. of liquid hydrogen fluoride was allowed to remain overnight in a fume hood. The contents of the retort were poured into a copper beaker and the remaining hydrogen fluoride evaporated. An ethereal solution of the residual material was washed with water and 10% sodium bicarbonate solution, respectively. The product was isolated as described above.

[a] Recrystallized from an ethanol-ethyl acetate mixtures. [b] 2,4-Dinitrophenylhydrazone. [c] Recrystallized from ethanol. [d] Oxime. [e] Calcd. for S, 18.6. Found: S, 18.9. [f] Semicarbazone. [g] Reference 2. [h] Calcd. for S, 15.0. Found: S, 15.1. [i] 2-Chloro derivative.

5-Chloro-2-(α-methylacrylo)thiophene.—The procedure described by Burckhalter and Sam (1) for the preparation of 2-(α-methylacrylo)thiophene was followed. From 145 Gm. (0.83 mole) of 5-chloro-2-propionylthiophene, 66.5 Gm. (0.83 mole) of dimethylamine hydrochloride, 24.9 Gm. (0.83 mole) of formaldehyde, there was obtained 49 Gm. (26%) of product, b.p. 130° (6 mm.); n_D^{25} 1.5576.

Anal.—Calcd. for C_8H_7ClOS: C, 51.5; H, 3.8. Found: C, 51.7; H, 4.0.

2-Chloro-5-methylthiaindan-6-one.—The procedure described by Burckhalter and Sam (1) for the preparation of 5-methylthiaindan-6-one was followed. From 48.7 Gm. (0.26 mole) of 5-chloro-2-(α-methylacrylo)thiophene there was obtained 20 Gm. (50%) of product, b.p. 91° (0.8 mm.); n_D^{25} 1.5887.

The 2,4-dinitrophenylhydrazone was prepared in the usual manner and recrystallized eight times from an ethanol–ethyl acetate mixture, m.p. 218–219°.

5-Methylthiaindan.—In a 500-ml. three-necked flask were placed 45.6 Gm. (0.3 mole) of 5-methylthiaindan-6-one, 30 ml. of 85% hydrazine hydrate, 40 Gm. (0.71 mole) of potassium hydroxide, and 300 ml. of diethylene glycol. The general method (7) for the Wolff-Kishner reaction was followed. The flask was heated on a steam bath until most of the potassium hydroxide had dissolved, then heated at reflux for 1 hour. The solution was partially distilled until the internal temperature of the flask reached 200°. The resulting solution was heated at 200° for 3 hours, cooled to 90°, and treated with 100 ml. of water. The reaction mixture was distilled until the internal temperature reached 200°. The oil from the aqueous distillate was separated, dried over calcium chloride, and distilled. Distillation was difficult because of foaming under reduced pressure. After distillation, 20 Gm. (50%) of product was obtained, b.p. 69–73° (17 mm.); n_D^{25} 1.5306. The infrared spectrum did not show carbonyl absorption between 1600 and 1700 cm.$^{-1}$

5-Methylthiaindan-6-ol.—In a 500-ml. three-necked flask fitted with a condenser, magnetic stirrer, and a dropping funnel a solution of 40 Gm. (0.265 mole) of 5-methylthiaindan-6-one in 200 ml. of methanol was placed. Through the dropping funnel 7.6 Gm. (0.2 mole) of sodium borohydride in 100 ml. of methanol was added with stirring. The addition of the sodium borohydride solution was regulated to keep the solution refluxing. After the addition of sodium borohydride, the reaction mixture was refluxed for 1 hour. The methanol was distilled *in vacuo;* the white solid was treated with 165 ml. of 20% sodium hydroxide solution and extracted three times with 100-ml. portions of ether. The combined ether extracts were dried over anhydrous magnesium sulfate. The ethereal solution was distilled to give 30 Gm. (75%) of product, b.p. 114° (6 mm.), m.p. 51–52°. The infrared spectrum in carbon tetrachloride showed characteristic hydroxyl absorption at 3550 cm.$^{-1}$, whereas carbonyl absorption was absent.

cis-2-Methyl-1-indanol.—The above procedure was followed using 12 Gm. (0.08 mole) of 2-methyl-1-indanone, 3.5 Gm. (0.1 mole) of sodium borohydride, and 200 ml. of methanol. Twelve grams (100%) of *cis*-2-methyl-1-indanol was obtained, m.p. 43–46° (lit. (12) m.p. 50–51°).

Synthesis of Amides of Diphenic Acid as Potential Antispasmodic Agents

By GLENN L. JENKINS, CHARLES S. DAVIS, ADELBERT M. KNEVEL, and DAVID S. YODER†

Twenty-six new amides of diphenic acid have been synthesized as potential antispasmodics. All of the described compounds were screened for pharmacological activity; none of the new structures demonstrated significant antispasmodic activity to warrant further investigation. Details of the pharmacological screening will be reported by G. K. W. Yim in another paper.

It is well documented that many compounds containing the ester group have demonstrated pharmacological activity as antispasmodics and local anesthetics. Since the amide group is quite similar to the ester both chemically and pharmacologically, it might be expected that the amides of diphenic acid would produce "active" compounds (1, 2). In some instances in which the ester group has been substituted by an amide group (as in the case of procainamide) the pharmacological action has been prolonged and the toxicity reduced. The prolonged activity has been attributed to the slow rate of hydrolysis of the amide as compared to the ester (3).

Diphenic acid as an inert nontoxic substance (4) has properties which may make it desirable as a carrier of pharmacologically active groups. Demers and Jenkins (5) prepared a number of derivatives of diphenic acid which were found to possess spasmolytic activity about equal to that of atropine (6).

EXPERIMENTAL

Diphenic acid was prepared by the method of Atkinson and Lawler (7) with the modification of Demers and Jenkins (5). Diphenic anhydride was prepared by the general procedure of Roberts and Johnson (8). Diphenic acid, diphenimide, and the monoethyl ester of diphenic acid were prepared by the methods of Underwood and Kochmann (9). Potassium diphenimide was prepared by reacting equimolar quantities of potassium ethoxide in anhydrous ethanol with diphenimide; ethyl diphenoyl chloride by the procedure described by Demers and Jenkins (5). The amines used for this investigation were supplied through the courtesy of Union Carbide and Carbon; β-diethylaminoethyl chloride HCl and β-dimethylaminoethyl chloride HCl were supplied through the generosity of the Michigan Chemical Corp. The dialkylaminoalkyl chlorides not commercially available were synthesized by the method of Mason and Block (10) and according to Adams and Whitmore (11). Liberation of the "free" chloro-base compounds from the hydrochloride salts was accomplished by the procedure of Burtner (12).

It is interesting to note that in the attempted preparations of diphenimide derivatives the imide ring opened to produce an ester and an amide. The product formed was identical to that prepared from the ester-acid chloride reaction.

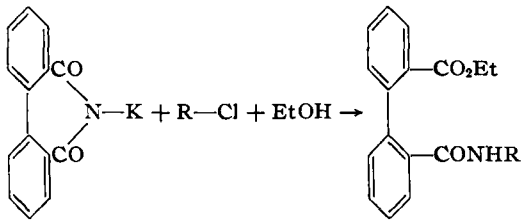

Table I lists the amide derivatives synthesized by one of the following procedures.

Procedure A

Ethyl N-(Dialkylaminoalkyl)-diphenamate.—To 100 ml. of anhydrous ethyl alcohol was added 43 m*M* of metallic potassium with cooling. A 43-m*M* quantity of diphenimide was added to the potassium ethoxide solution. After the diphenimide had dissolved, 43 m*M* of the appropriate dialkylaminoalkyl chloride was added and the mixture was refluxed for 12–14 hours. At the conclusion of the reflux period, a white precipitate formed which was removed by filtration. The filtrate was concentrated under vacuum and the residue taken up in anhydrous ether. Dry hydrogen chloride was passed into the etheral extract; a white precipitate formed, which crystallized upon standing. The crystals were collected, dried, and recrystallized.

Procedure B

Ethyl N-(Dialkylaminoalkyl)-diphenamate.—To 25 m*M* of ethyl diphenoyl chloride in 20 ml. of dry benzene was added slowly 25 m*M* of the appropriate dialkylaminoalkylamine in 10 ml. of dry benzene with stirring and cooling in an ice bath. After completion of the reaction, the mixture was cooled overnight in a refrigerator. If the product did not crystallize, the syrupy residue was treated with fresh portions of cold dry ether until a precipitate was formed. The crystals were collected, dried, and recrystallized.

Procedure C

Ethyl N-Alkyldiphenamate.—A 25-m*M* quantity of ethyl diphenoyl chloride was added with stirring and cooling to 50 m*M* of alkylamine in 10 ml. of dry benzene or chloroform. After the mixture was allowed to stand overnight in a refrigerator, the

[a] All melting points are corrected.

precipitate of alkylamine hydrochloride was filtered. The filtrate was partially evaporated and the amide was induced to crystallize by the addition of petroleum ether. The crystals were collected, dried, and recrystallized.

Procedure D

Ethyl N,N-Diphenyldiphenamate.—To a solution of 22 m*M* of ethyl diphenoyl chloride in 25 ml. of dry benzene was added 80 m*M* of dipnenylamine dissolved in 25 ml. of dry benzene. The mixture was refluxed for 10 hours; then the benzene solvent was removed under vacuum. The resulting residue was cooled overnight and then washed with cold methyl alcohol. The gummy solid was recrystallized from an aqueous methanol mixture to produce white crystals.

Procedure E

N,N-Dialkyldiphenamic Acid.—One-hundred millimoles of N,N-dialkylamine was added slowly with rapid stirring to 22 m*M* of diphenic anhydride. Heat was evolved and the mixture turned a brown color. Upon cooling, the reaction mixture was washed with ether to remove the excess amine. The residue was then dissolved in water and filtered. The filtrate was diluted with 150 ml. of water and then acidified with 10% hydrochloric acid. Upon standing, a precipitate was formed which could be further purified by recrystallizing from ethyl alcohol and water.

Comparison of Extractive Procedures for Digitalis

By BERNARD R. LETASSY† and C. LEE HUYCK‡

The shearing action of the Premier colloid mill and the Eppenbach Homo-Mixer was applied to a mixture of digitalis powder and its extracting liquid in order to determine whether these pieces of equipment might be superior to the percolator for extraction of the active principles. The official method was used as the control procedure and simple agitation as an intermediate procedure. Data presented show order of effectiveness.

A MORE efficient extraction of the active principles of digitalis has been the target of numerous investigators. Bay and Gisvold (1) destroyed the enzymes in fresh digitalis leaves by heating the ground leaves to 70° before attempting extraction. In a later investigation Hopponen and Gisvold (2) found that quick freezing of the freshly harvested digitalis leaves retarded enzyme action and kept the glycoside content at a maximum until extracted. In an extension of this work (3) a maximum yield was obtained when the aqueous extraction represented two per cent of the drug on a dry leaf weight basis. Eighty-seven per cent of the activity could be extracted in this way. Aqueous extraction possesses several disadvantages, however. One disadvantage is hydrolysis of the active principle with a subsequent lower yield of glycosides. Another disadvantage is the glycosides are less soluble in water than they are in alcohol.

Kušević (4) made a comparative study of maceration, percolation, agitation, and digestion in an attempt to determine whether a more effective method for extraction of digitalis could be found. The digestion method with dilute alcohol at 60° gave the best results of the methods tested.

A somewhat different approach to the problem of extraction was taken by Dean, *et al.* (5), who demonstrated that it is possible to prepare tinctures in a few minutes, whereas the conventional methods require several days. This was accomplished by passing a suspension of the powdered drug in menstruum through a colloid mill. Using belladonna leaf, a 5-minute maceration yielded 37.2 per cent of the desired components. The percentage of yield increased to 99.5 per cent when the mixture of leaf and menstruum was circulated in a colloid mill continuously for 5 minutes.

EXPERIMENTAL

Using the milling method described by Dean, *et al.* (5), as a guide an attempt was made to increase the yield obtained by the official method for extraction of digitalis glycosides. In addition to the colloid mill, three other pieces of equipment were utilized: the Eppenbach Homo-Mixer, simple agitation in a screw-top jar; and the percolator (by the U.S.P. method which served as a control). Agitation in a jar provided an intermediate method to determine whether simple agitation had any effect on improving the extraction of the macerated leaf.

Procedure.—Four 100-gram portions of 80-mesh *Digitalis purpurea* powder were made evenly and distinctly damp with the menstruum (4 volumes alcohol and 1 volume water) and allowed to stand for 15 minutes. The control portion was packed in a cylindrical percolator. All four portions were allowed to macerate for 24 hours with additional menstruum.

At the end of the maceration period a suspension of the first portion was passed through the Premier colloid mill, type U-B7, using a setting of 0.005 inch between rotor and stator. The suspension was filtered and the marc was washed with menstruum until the filtrate measured 1,000 ml. A suspension of the second portion was subjected to the Eppenbach Homo-Mixer, type CS, for 5 minutes at maximum speed without loss of liquid and filtered through paper. The marc was washed with menstruum to volume. The third portion was shaken vigorously for 5 minutes in a one-gallon screw-top jar and filtered through paper. Likewise the marc was washed with menstruum to volume.

In order to insure accuracy, the entire process was repeated with another four 100-Gm. portions of the same batch of powder. The resulting tinctures were assayed by the chemical method of Bell and Krantz (6).

TABLE I.—PERCENTAGE STRENGTH OF TINCTURES PREPARED BY THE VARIOUS METHODS OF EXTRACTION IN TERMS OF U.S.P. REFERENCE STANDARD TINCTURE

Method	1st	2nd	Average
U.S.P. XV	88.5	89.7	89.1
Eppenbach Homo-Mixer	78.8	65.0	71.9
Premier colloid mill	73.5	69.0	71.2
Simple agitation	63.4	64.0	63.7

Table I reveals that percolation of the macerated digitalis leaf is superior to the other extraction methods. Probably the most important factor in favor of the percolation method is the fact that fresh menstruum is continually passing around the particles of the drug. Although this factor also took place in the modified methods where the marc was continually washed on the filter paper, it took place less efficiently. Table I also reveals the order in which the glycosides were extracted when percolation was not a factor. The Homo-Mixer gave approximately the same results as the colloid mill, and both were better than simple agitation.

SUMMARY

An attempt to increase the yield of digitalis glycosides by applying high speed shearing to a mixture of powdered drug and menstruum in place of percolation by the U.S.P. method was made. Shearing was obtained by two pieces of equipment

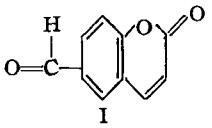
Antitubercular Activity of Some Aromatic Aldehyde and Ketone Derivatives

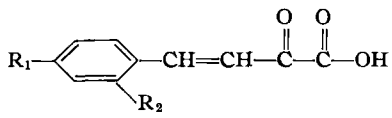
By AJIT K. DATTA† and T. C. DANIELS

The semicarbazones, para-nitrobenzoyl hydrazones and isonicotinyl hydrazones of the unsubstituted and three substituted 4-phenyl-2-oxo-3-butenoic acid and 6-formyl-1,2-benzpyrone were prepared and the toxicities and *in vitro* antitubercular activities measured. Three isonicotinyl hydrazones show the same order of antitubercular activity as isonicotinic acid hydrazide.

THE WELL KNOWN antitubercular activity of thiosemicarbazones, *p*-nitrobenzoyl hydrazones, and isonicotinyl hydrazones of a number of substituted and α,β-unsaturated aromatic aldehydes (1, 6) and ketones (2) made it of interest to prepare the corresponding derivatives of 6-formyl-1,2-benzpyrone (I) and of 4-phenyl-2-oxo-3-butenoic acid (II; R_1, R_2 = H), the latter possessing the additional advantage of affording water-soluble salts.



I



II

In view of the interesting antitubercular activity of the isonicotinyl hydrazone of II, the corresponding *o*-chloro, *o*-methoxy, and *p*-methoxy substituted derivatives of II were prepared for comparison and are described in Table I.

In vitro antitubercular activity was determined against *Mycobacterium tuberculosis* var. *hominus* strain H 37 RV by the serial dilution technique, using the modified Dubos medium (3). The results are shown in Table II.

Acute toxicity of the compounds was determined using intraperitoneal injections of suspensions in 6% acacia in Webster strain mice of both sexes (average weight 20 Gm.). The results are given in Table III.

EXPERIMENTAL[1]

6-Formyl-1,2-benzpyrone.—Prepared by the method of Sen and Chakravarti (4), the compound melted at 189° (lit. m.p. 187–189°) (4).

6-Formyl-1,2-benzpyrone Thiosemicarbazone.—A mixture of 0.8 Gm. of 6-formyl-1,2-benzpyrone in 35 ml. of 80% ethanol, 0.45 Gm. of thiosemicarbazide, and 1 Gm. of sodium acetate was refluxed on a steam cone for 1 hour. The reaction product was recrystallized from dilute alcohol. One gram (85% yield) of a cream-colored crystalline product was obtained. The compound sublimes without melting at 300°.

Anal.—Calcd. for $C_{11}H_9N_3O_2S$: N, 17.0. Found: N, 16.79.

6-Formyl-1,2-benzpyrone *p*-Nitrobenzoyl Hydrazone.—A mixture of 0.9 Gm. of 6-formyl-1,2-benzpyrone in 35 ml. of 80% ethanol and 0.9 Gm. of *p*-nitrobenzoyl hydrazide in 20 ml. of ethanol was refluxed for 1.5 hours on a steam bath. The reaction product was recrystallized from 30% alcohol from which 1.5 Gm. (90% yield) of lemon-yellow crystals was obtained, m.p. 314–315°.

Anal.—Calcd. for $C_{17}H_{11}N_3O_5$: N, 12.46. Found: 12.7.

6-Formyl-1,2-benzpyrone Isonicotinyl Hydrazone.—A 0.7-Gm. quantity of isonicotinic acid hydrazide in 10 ml. of distilled water was added to a solution of 0.9 Gm. of 6-formyl-1,2-benzpyrone in 35 ml. of 80% ethanol. The mixture was heated on a steam bath; white crystals started separating immediately. The crude product was recrystallized from water. The product weighed 1.4 Gm. (92% yield) and melted at 284–285°.

Anal.—Calcd. for $C_{16}H_{10}N_3O$: N, 14.33. Found: N, 14.53.

Light—An Essential Factor in the Trihydroxyindole-Spectrophotofluorometric Assay of Norepinephrine

By LINCOLN CHIN, ALBERT L. PICCHIONI, and RICHARD F. CHILDS

When iodine is used as the oxidant in the spectrophotofluorometric assay of norepinephrine, conversion of the oxidation product (noradrenochrome) to the fluorophore (noradrenolutine) requires the presence of adequate light. At a light intensity of 105 foot-candles, a period of 30 minutes is required for maximal development of fluorescence. With the use of intense light (sun light: 8400 foot-candles), maximal development of fluorescence was obtained in 2 minutes. At a light intensity of 40 foot-candles or less, the development of fluorescence was incomplete even when the conversion reaction was allowed the prescribed time of 45 minutes. It is apparent that light is an important factor in the conversion of noradrenochrome to noradrenolutine. Consistent and reproducible results are obtained only when this part of the assay is carried out under an adequate intensity of light for a suitable length of time.

THE SPECTROPHOTOFLUOROMETRIC method for the assay of norepinephrine described by Shore and Olin (1) involves initial oxidation of the amine to noradrenochrome by iodine at a weakly acidic pH. Noradrenochrome is then rearranged to a highly fluorescent trihydroxyindole (THI) derivative, noradrenolutine, by an alkaline ascorbate solution. Forty-five minutes are allowed for maximal development of fluorescence; the solution is then placed in a spectrophotofluorometer and activated at 400 mμ and the resulting fluorescence read at 520 mμ.

During the course of some early norepinephrine assays in this laboratory, it was observed that fluctuation of daylight in the room, assay at different times of day, and shielding of test tubes from light during the THI reaction yielded erratic results. In the case of samples that were exposed to strong light, development of fluorescence was complete, as suggested by a rapid excursion of the galvanometer indicator-needle to the peak reading. However, in the case of samples that were exposed to weak light or were shielded from bright light, development of fluorescence was incomplete, as suggested by an initial rapid sweep of the indicator to an intermediate point on the galvanometer scale which was then followed by a slower increase in the reading. When a continuous reading was made of these latter solutions, the indicator drifted slowly and reached a peak reading only after approximately 30 minutes, during which time the sample in the spectrophotofluorometer was continuously irradiated by the activating lamp. These early observations suggest that light has a definite effect on this assay. Because there is a paucity of information in the literature regarding the influence of light on this analysis for norepinephrine, studies were undertaken to investigate further the role of light in the procedure.

EXPERIMENTAL

Norepinephrine,[1] 0.1 mcg./ml. in 0.01 *N* HCl, was used throughout this investigation. The chemical reactions were carried out in the manner described by Shore and Olin (1). In one study, following addition of alkaline ascorbate, test tubes of the sample were exposed to varying intensities of light for a standard period of 45 minutes. In another study, test tubes of the sample were exposed to a standard light intensity for various periods of time. In addition, other test tubes of sample were exposed to direct sunlight (*ca.* 8400 foot-candles) to determine the effect of an intense light on the THI reaction. Measurements of fluorescence were made with the Aminco-Bowman spectrophotofluorometer.[2]

RESULTS

As illustrated in Fig. 1, completion of noradrenochrome rearrangement requires an adequate light intensity. When the reaction was allowed to take place in the dark for 45 minutes, a negligible amount of fluorescence developed. However, when the reaction was permitted to take place in graded intensities of light, relatively greater degrees of fluorescence developed up to a maximal level. Light intensity of 105 foot-candles was sufficient for producing maximal fluorescence in 45 minutes of exposure; a greater intensity yielded no additional increase in fluorescence. Figure 2 shows that with a light intensity of 105 foot-candles, adequate time is required for completion of the THI reaction. Within the initial 15 minutes, following addition of alkaline ascorbate, there was a rapid development of fluorescence. By 20 minutes the rate of reaction had diminished appreciably and by 30 minutes fluorescence had essentially reached its peak. Readings made after longer intervals of exposure were not significantly different from those obtained at the 30-minute period. In the study which utilized an intense light source, samples that were exposed to direct sunlight showed maximal fluorescence after 2 minutes of exposure. When the samples that had been kept in the dark or exposed to dim light were subsequently exposed to sunlight for 2 minutes, they developed a degree of fluorescence comparable to that seen in the samples exposed for 45 minutes to artificial light of 105 foot-candles. On the other hand, samples that had been allowed

[1] Norepinephrine bitartrate, supplied by Winthrop Laboratories, was used to prepare the norepinephrine solution. The concentration is calculated and expressed as norepinephrine base.

[2] The galvanometer readings of samples, in which development of fluorescence was incomplete, were made at the end of the initial rapid sweep of the indicator before the onset of its slow drift to a peak value.

to react for 45 minutes in artificial light of 105 foot-candles developed no additional fluorescence upon further exposure to direct sunlight for 2 minutes.

DISCUSSION

Lund (2), who employed manganese dioxide as the oxidizing agent in the formation of noradrenochrome, indicates that rearrangement of this aminochrome to noradrenolutine occurs almost instantaneously following addition of alkali. Maynert and Klingman (3) report that if potassium ferricyanide is substituted for iodine in the assay of catecholamines, fluorescence may be measured 5–10 minutes after addition of alkali. Udenfriend (4) also indicates that when potassium ferricyanide is used as the oxidizing agent, the conversion of aminochromes to fluorophores is completed very rapidly, 1–2 minutes after addition of alkali. On the other hand, as indicated by the above investigators (3, 4) iodine-oxidized norepinephrine requires a longer period for conversion from noradrenochrome to noradrenolutine. In view of the apparent difference in the rate of rearrangement associated with the use of various oxidizing agents and of the observations made in this laboratory, it is postulated that rapid conversion of noradrenochrome to the fluorophore requires either a metal catalyst or radiant energy. When manganese dioxide or potassium ferricyanide is used as the oxidizing agent, it is conceivable that metallic ions may act as catalysts during the THI reaction. Whereas, when iodine is used as the oxidizing agent, light may supply the energy for accelerating the formation of noradrenolutine; if the intensity of light is exceptionally great (*e.g.*, sunlight), rearrangement may occur at a rate comparable to that of the assay in which one of the metallic salts is used.

It is of interest that reports on the effect of light on the ethylenediamine procedure for the estimation of norepinephrine (5, 6) indicate that daylight causes a *loss* of fluorescence. On the basis of this finding it would appear logical to shield the test tubes from light during the THI reaction in the assay procedure of Shore and Olin (1). However, the present observations demonstrate that when iodine is employed as the oxidant an adequate light intensity is imperative during the THI reaction. Insufficient light during this phase would result in erratic readings; this may account for some of the dissatisfaction voiced by some investigators for the THI-spectrophotofluorometric assay of norepinephrine. On the other hand, one group of investigators (7), who employed iodine as the oxidizing agent, reports 20 minutes (rather than 45 minutes) as adequate for completion of the THI reaction. The shorter time period used by these workers could be explained on the basis of a relatively bright illumination in the laboratory.

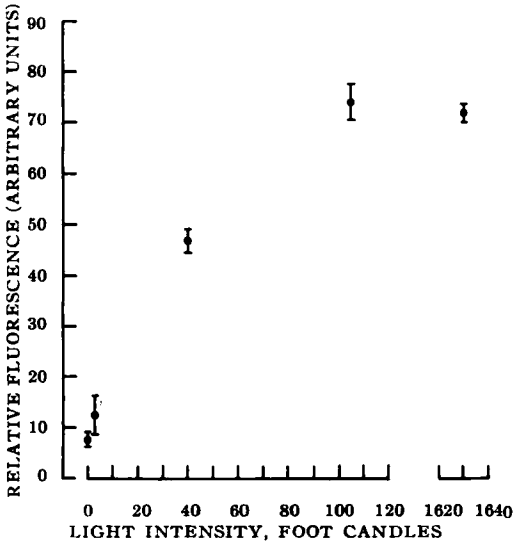

Fig. 1.—Relative fluorescence of norepinephrine samples following oxidation, addition of alkaline ascorbate, and exposure to graded intensities of light for 45 min. Four or more samples were used for each determination. Vertical bracketed lines indicate 95% confidence limits. The reaction at 1630 foot-candles was carried out under sunlight partially shaded with layers of cotton gauze to produce this light intensity; other reactions were carried out in darkness or artificial light (fluorescent light).

CONCLUSION

The data reported herein show that when iodine is employed as the oxidizing agent in the spectrophotofluorometric assay of norepinephrine, light is essential for the conversion of noradrenochrome to noradrenolutine. This finding supports the warning recently advanced by Udenfriend (4) (with respect to the THI reaction) that when iodine is used as the oxidizing agent shielding the samples from light will produce erratic results. It is obvious that consistent and reproducible results can not be obtained unless the THI reaction is allowed to take place under an adequate intensity of light for a suitable period of time.

ADDENDUM

Subsequent to completion of the present studies, Sloan and co-workers (8) reported that following the

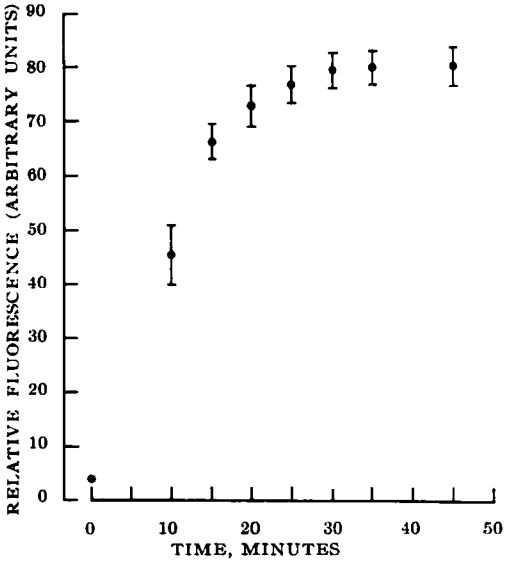

Fig. 2. –Relative fluorescence of norepinephrine samples following oxidation, addition of alkaline ascorbate, and exposure to a standard light intensity of 105 foot-candles (fluorescent light) for various time intervals. Four samples were used for each determination except that one sample was employed for the zero-time determination. Vertical bracketed lines indicate 95% confidence limits.

addition of alkaline ascorbate solution the reaction is extremely photosensitive. These investigators avoided erratic results by placing the tubes of samples inside a box which contains two General Electric 20-watt ultraviolet black light bulbs. They found that rigid control of the lighting conditions enhanced the intensity of fluorescence and improved reproducibility. This finding further supports the contention that light is an essential component in the spectrophotofluorometric assay of norepinephrine during the THI reaction.

Cyclized Substituted Thioureas III

1-Substituted-tetrazolines-5-thiones

By RONALD E. ORTH

A convenient synthesis and purification of some 1-substituted-tetrazoline-5-thiones is accomplished. Decreased per cent yields with increased chain length lends some credence to the probability that steric hindrance occurs in the ring closing step. The infrared studies show identifying bands for —N=C=S, C=S, cyclic —N—N=N—, and the tetrazole ring. Low toxicity for these compounds is indicated.

QUALIFIED success with propylthiouracil (1) and methimazole (2) during hyperthyroid therapy has led to the synthesis of chemically related compounds and to their subsequent *in vitro* and *in vivo* trials. Countless antibacterial and tuberculostatic screening programs have also been carried out using compounds which embody the thiourea moiety.

Some 1-alkyltetrazoline-5-thiones were prepared by synthesizing the methyl ester of *N*-alkyldithiocarbamic acid and refluxing it with sodium azide (3). A more convenient method consists of preparing the sodium *N*-alkyl dithiocarbamate from carbon disulfide, the corresponding amine, and sodium hydroxide. Ethyl chloroformate and the dithiocarbamate give ethyl *N*-alkyldithiocarbamate, which upon decomposition yields carbonyl sulfide, ethanol, and the desired alkyl isothiocyanate (R—N=C=S). The 1-substituted-tetrazoline-5-thiones were isolated following reflux of the isothiocyanate with sodium azide and acidification. The lower yields with increased chain length suggests that there is a steric effect since it has been demonstrated that 1-aryl substituents increases the yields appreciably (4).

Tetrazole and its substitution products usually show only a small amount of end absorption in the ultraviolet region of the spectrum (240–250 mμ) (5). Otting found that tetrazole gave large peaks at 1520, 1270, 1160, 1100, 1020, 915, and 670 cm.$^{-1}$ and a number of characteristic small peaks (6). Lieber, *et al.*, found some 5-substituted tetrazoles to give results interpreted as tetrazole ring absorption bands in the 8.9 to 10 μ region (7). In later work with 1-aryl-tetrazoline-5-thiones more definite tetrazole skeletal assignments were demonstrated. The bands were found at approximately 1100, 1080, 1045, 1020, and 990 cm.$^{-1}$ Frequencies were also assigned for N—C=S, C=S, and cyclic —N—N=N— linkages (8). The spectra for the 1-substituted-tetrazoline-5-thiones summarized in Table I closely approximate the Lieber assigned values and support his hypothesis showing the presence of sulfur in the thione form. Characteristic sulfhydryl bands were not seen for any of the compounds tested from this series. The results of this investigation emphasize the uniformity of the data obtained using 1-aryl and 1-alkyl substituents in the tetrazoline-5-thione system.

LD_{50}'s of 207 ± 27 mg./Kg. and 215 ± 23 mg./Kg. body weight were obtained for 1-methyl- and 1-isopropyltetrazoline-5-thiones, respectively, using five groups per compound, each group having 20 young male white mice.

EXPERIMENTAL

1-Substituted-Tetrazoline-5-thiones.—Three-tenths mole (19.5 Gm.) of sodium azide is dissolved in 300 ml. of water and filtered into a 500 ml. round-bottom flask and two-tenths mole of an isothiocyanate is added, followed by refluxing. Cease the operation and remove any unreacted isothiocyanate by ether extraction when the green reaction mixture turns colorless. Acidify the aqueous solution to a pH of 3 with HCl, filter, and extract the filtrate with ether. Wash the ether solution with small portions of ice water, dry over anhydrous sodium sulfate, and decolorize with activated charcoal. The dried acidic ether extract is evaporated to a yellow-brown oil, which in turn forms pale yellow crystals, using the Rinco rotary evaporator and steam bath. These crystals are blotted dry on filter paper, and recrystallized from 100–115° petroleum ether.

Determination of Ergotamine and Ergotaminine in Pharmaceutical Preparations

By THOMAS G. ALEXANDER

Ergotamine and its diastereoisomer, ergotaminine, are separated from each other and from other ingredients by column chromatography. The isolated fractions are then assayed by the classical van Urk method. Identity and purity of the fractions are confirmed by paper chromatography. A number of commercial products were analyzed successfully.

ERGOTAMINE in solution forms an equilibrium mixture of the diastereoisomers, ergotamine, and ergotaminine. This study was undertaken to develop a practical quantitative method for the assay of both ergotamine and ergotaminine in injection solutions. Of the different techniques that have been described for this purpose, column chromatography appeared to be the best suited. Larger amounts of alkaloid can be recovered more efficiently on a column than with methods involving the extraction of spots from paper or thin-layer chromatograms (1–3). Yet large samples are not required as with the polarimetric methods (4). Also a column chromatographic technique does not require the use of as much time and specialized glassware as would one involving countercurrent extraction (5).

Received November 8, 1962, from the Division of Pharmaceutical Chemistry, Bureau of Biological and Physical Sciences, Food and Drug Administration, U. S. Department of Health, Education, and Welfare, Washington 25, D. C.

Accepted for publication January 29, 1963.

The author thanks the following persons for their cooperative assistance: J. Kottemann, Division of Pharmaceutical Chemistry, and A. Major, Jr., Bureau of Field Administration, both of the Food and Drug Administration.

The method presented involves partition chromatography using a column prepared by adsorbing 1:4 citric acid solution on siliceous earth. This column extracts ergotamine from a chloroform solution containing both ergotamine and ergotaminine. The latter passes through in the effluent and is assayed. Ergotamine is recovered by chloroform extraction of the extruded column. This procedure was submitted to the Committee on Revision of the "United States Pharmacopeia" and it has been incorporated into the Monograph for Ergotamine Tartrate Injection. The procedural details are contained in this revised monograph (6).

To analyze ergotamine salts and simple tablet mixtures, weighed portions are dissolved in or triturated with 1:100 tartaric acid solution; the sample is then analyzed in the manner described in the revised monograph for injections.

EXPERIMENTAL AND DISCUSSION

In following the methods described by Berg (7) and van de Langerijt (8) involving the use of benzene as eluent, both ergotamine and ergotaminine rapidly epimerized and deteriorated. Carless (9)

[a] These results were obtained on individual whole tablets. [b] This ergotamine tartrate was unusually impure. The fact that only about 90% of the sample used was received would indicate that either part of the material was retained by the first column or if it came through in either the ergotamine or ergotaminine fractions, it did not respond to the color reaction. In either case, it could not be closely related to ergotamine. Infrared data indicated that the material in the *dextro* fraction was not ergotamine but might have been of the ergotoxine group or one of the "aci-ergot" alkaloids (13). [c] The author is grateful to E. F. Drew and Co. for supplying this hydrogenated vegetable oil suppository base.

recovered only 80% of the ergotamine in pyridine-ether effluents from columns of cellulose treated with McIlvaine citrate-phosphate buffer. In attempting to improve upon Carless' method, it was learned that both phosphate salts and pyridine have detrimental effects on ergotamine.

The sharpness with which citric acid columns will resolve mixtures of ergotamine and ergotaminine in chloroform varies with the strength of the acid. Columns prepared with strong 1:3 citric acid solution will sharply separate the diastereoisomers, but an excessive volume of effluent is required to elute completely the ergotaminine. With columns using weaker acid solution, 1:5, the ergotamine and ergotaminine fractions overlap. The column developed (9 Gm. siliceous earth plus 7 ml. of 1:4 citric acid solution) retains ergotamine, while about 97.5% of the ergotaminine appeared in the first 100 ml. and another 1 or 1.5% was obtained in the next 100 ml. Recoveries of 97 or 98% of the ergotamine were obtained by extraction of the extruded and alkalized column. The completeness of these separations was also checked by paper chromatography, using a modified version (10) of Stoll and Rüegger's reversed-phased method (11). After aliquots of the two chloroform extracts were removed for assay, the remaining portions were evaporated to a concentration suitable for spotting on paper chromatograms. Ergotamine was not detected in the ergotaminine fractions tested. Occasionally, trace amounts of ergotaminine were detected in the ergotamine fraction.

To check further the validity of the method, four simulated injection solutions were prepared, using ergotamine bitartrate freshly recrystallized from methanol and ergotaminine prepared by Stoll's method (12). These solutions were then assayed promptly. The results are presented in Table I.

ADAPTATION TO COMPLEX MIXTURES

For the analysis of ergotamine tartrate tablets and suppositories containing caffeine, acetophenetidin, barbiturates, and belladona alkaloids[1] it is necessary that the ergot alkaloids first be separated from the other ingredients prior to the isolation of ergotamine from ergotaminine. For this purpose, a previously published method was found to be suitable (10), whereby ergotamine and ergotaminine are obtained together in chloroform solution isolated from the other nitrogenous bases. This chloroform solution is then passed onto the citric acid column and the analysis continued as with the simple formulations.

RESULTS

Several mixtures were prepared to simulate commercial products. These and several commercial preparations were analyzed. The assay results are

[1] This method is not applicable to preparations containing cyclizine.

presented in Table II. Identity and purity checks by paper chromatography showed that (except as noted) no ergot alkaloids other than ergotamine or ergotaminine were detected in the products. In some older samples with low assay values, brown spots appeared at $R_f = 0$ on the paper chromatogram of the ergotaminine fraction. These probably represent ergotamine that has oxidized or otherwise deteriorated.

Determination of Zinc in Insulin Preparations

By BENNIE ZAK and JERRY S. COHEN

A description of an accurate absorptiometric technique for the determination of zinc in insulin is presented. It involves differential demasking of zinc in the presence of contaminating interferences such as copper and iron, followed by a reaction with the color reagent, zincon. It appears to be a simple yet useful process for quality control.

AN IMPORTANT analytical phase for the pharmaceutical industry involves quality control of products (1). The determination of zinc in insulin preparations for quality control purposes is an assay which presents some difficulty. Included among the procedural techniques for this element are processes employing spectrophotometry (2, 3), polarography (4, 5), and chelatometric titrations (6, 7). The first two types of procedure involve selective dithizone extractions followed by colorimetric measurement and retrograde extraction followed by polarographic measurement. The titrimetric procedure with a complexone titrant becomes more difficult and subjective as the concentration of zinc decreases. One milliliter of 0.001 *N* ethylenediamine tetraacetic acid corresponds to 65.4 mcg. of zinc (8); some insulin preparations, such as the unmodified variety, contain only 6 mcg. of zinc per ml. A visual titration involving a two-color indicator, such as Eriochrome black T, is subject to serious shortcomings when the titrant becomes very dilute, and the indicator color-change represents a slow transition from one form to the other (9).

The procedure for insulin zinc analyses to be discussed here involves an absorptiometric technique without extraction. It is capable of achieving an accurate determination for zinc yielding high absorbance data on samples which are never greater than 1 ml., even for those preparations containing the smallest amounts of zinc (10, 11). In the case of zinc-insulin solutions, the required amount of material is a micro quantity.

EXPERIMENTAL

Reagents.—Borate buffer, pH 9.0: dissolve 31 Gm. of boric acid in metal-free distilled water, add 53 ml. of 4 *N* NaOH, and dilute the solution to a liter with any necessary adjustment of pH. Zincon color reagent: dissolve 130 mg. of zincon in 2 ml. of the detergent, acationox, and dilute the solution to 100 ml. with metal-free distilled water. Stock standard zinc solution (100 mg./L.): dissolve 100 mg. of zinc in a minimum amount of HCl and dilute the solution to a liter with metal-free distilled water. This stock is diluted with water so that 0–18 mcg. per aliquot was used as a working standard.

Procedure.—An aliquot containing approximately 6–18 mcg. of zinc was pipeted into a centrifuge tube and diluted to 3.0 ml. with metal-free distilled water. This aliquot ranged from 0.05 ml. for an 80-unit globin-zinc-insulin preparation to 1.0 ml. for a 40-unit unmodified insulin preparation. To the diluted insulin solution, 1.5 ml. of 1 *N* HCl was added to liberate the zinc from its protein binding site. Ten per cent trichloracetic acid (1.5 ml.) was then mixed in to precipitate the proteins. Trichloracetic acid may be capable of performing both functions, but the stronger acid ensures that the zinc will become unbound. After a 5-minute stand, the mixture was centrifuged, and a 4.0-ml. aliquot was transferred to a Coleman 19 mm. O.D.

presented in Table II. Identity and purity checks by paper chromatography showed that (except as noted) no ergot alkaloids other than ergotamine or ergotaminine were detected in the products. In some older samples with low assay values, brown spots appeared at $R_f = 0$ on the paper chromatogram of the ergotaminine fraction. These probably represent ergotamine that has oxidized or otherwise deteriorated.

cell. A quantity of 4.0 *N* NaOH was added to neutralize the acidity so the capacity of the buffer would not be exceeded (0.4 ml. was used in the described procedure). One milliliter of pH 9 buffer was added followed by 0.1 ml. of 3% NaCN solution to form complexes with the zinc and any contaminating copper and iron present in the sample (12) or in the reagents used. Zincon color reagent (0.6 ml.) was then added. Because the cyano complexes are too tightly bound to release the metals for reaction with zincon, each tube can be used as its own blank. The instrument was zeroed at 630 mμ with the tube, then 0.2 ml. of 60% chloral hydrate solution was quickly mixed into each tube of standard or sample to demask the zinc differentially. Within 1 minute after the final addition, the absorbance of each tube was obtained again at 630 mμ. Since the zinc cyanide complex breaks down first, contaminating trace metals do not interfere in the process.

DISCUSSION AND RESULTS

The self-blanking described under procedure was quite convenient and yielded accurate results. Slight variations in different blanks were not significant because the absorbance difference before and after demasking could be obtained precisely. Background color characteristics of samples did not appear to affect the answers and this was decidedly advantageous. Copper and iron are ubiquitous trace contaminants of reagents. It was felt therefore that masking them in a system wherein demasking occurred much later than for the desired zinc would ensure accurate determinations.

A precision and accuracy study was carried out using replication on several absolute concentrations of zinc. The findings are shown in Table I. The values obtained were quantitatively in accord with those values known to be present in every instance. Conclusions concerning the precision as well as the accuracy of the determinations were therefore obvious in this experiment.

Twenty lots of different types of insulin unknowns were analyzed for their zinc content by the described procedure. The preparations varied from approximately 6 mcg. of zinc per ml. to 240 mcg. per ml. The results of this blind spectrophotometric study were compared to an ethylenediamine tetraacetate titration technique carried out in another laboratory where neither laboratory knew the results obtained by the other in advance. The comparative values are shown in Table II. The values obtained for the spectrophotometric procedure compare well enough to the EDTA titration since visual titrations of low concentration constituents with two-color indicators such as the Eriochrome black T used here are difficult (13) even if screening is employed as a visual aid (14).

Different quantities of zinc were added to aliquots of each of several lots of insulin. Zinc determinations were carried out on the insulins where a prior analysis of the materials established the base values. Because the zinc contents for different types of insulin are of such divergent composition (6–240 mcg./ml.), it was necessary to vary the size of the starting sample to conform to the best spectrophotometric characteristics of the system. The values found for base plus addition were quantitative and these results make up Table III.

Globin	0.05	122	9.0	15.1	15.4

SUMMARY

A procedure has been described for the spectrophotometric determination of the zinc content of various lots of insulin. This technique for quality control involves differential demasking as a means of precluding the effect of contaminating trace metals such as copper and iron. The process is simple, accurate, and capable of rapid analysis for large numbers of samples. It should be useful in the pharmaceutical industry for this important determination.

Nonclassical Antimetabolites XVI. The Bridge Principle of Specificity with Active Site-Directed Irreversible Inhibitors, VII. Detection of Differences in Specificity of Enzymic Nucleophilic Sites by the Maleamyl Group

Sir:

The concept of (1) a new class of irreversible inhibitors that operate by active site-direction (exo-alkylation)[1] has been supported by strong experimental evidence (2); a properly designed inhibitor such as 4-(iodoacetamido)salicylic acid (I) can reversibly complex with the active site of an enzyme such as GDH,[2] then become irreversibly bound to the enzyme adjacent to the complexing site by an anchimerically assisted type of alkylation. Four other laboratories have subsequently and independently made related observations pertinent to this type of irreversible inhibition in the field of esterases (3–5) and in the field of immunochemistry (6). Our detailed version of the experimental evidence for active site-directed irreversible inhibition (7) led to the proposal of the bridge hypothesis of specificity:

Compared to a reversible inhibitor, the active site-directed type of irreversible inhibitor can have an extra dimension of specificity; this extra specificity is dependent upon the ability of the reversibly-bound inhibitor to bridge to and covalently link to a nucleophilic group on the enzyme surface and upon the nucleophilicity of the enzymic group being attacked.

Experimental evidence for the first corollary of the bridge hypothesis of specificity, namely, the difference in ability of certain reversibly bound inhibitors to bridge to and alkylate on enzymic nucleophilic site has been presented (8, 9). More recently experimental evidence for the second corollary, the difference in nucleophilicity of the enzymic groups being covalently linked, was demonstrated with compounds related to 5-(carbophenoxyamino)salicylic acid, whereby GDH was irreversibly inhibited, but LDH was not (10). In fact, the substrate-

[1] The term "active site-directed irreversible inhibition" is preferable to the term "exo-alkylation" used in previous papers since, first, the term is more self-explanatory and, second, some of the irreversible inhibitors operate by acylation or Michael addition and not by alkylation.

[2] Abbreviations: LDH, lactic dehydrogenase from rabbit skeletal muscle; GDH, glutamic dehydrogenase from mammalian liver.

identical enzyme, LDH, from two different tissues could be irreversibly inhibited selectively by use of both corollaries (11, 12).

The fact that 4-(iodoacetamido)salicylic acid (I) could irreversibly inhibit both GDH and LDH was attributed to the low functional specificity of the iodoacetamido group. In contrast, 5-(carbophenoxyamino)salicylic acid irreversibly inhibited GDH, but not LDH; this selectivity was attributed to the specificity of the carbophenoxy group for reaction with a primary amino group which apparently was properly juxtapositioned in GDH to the carbophenoxy function for reaction, but was not in LDH. This paper describes a cross-over of functional specificity with 4-(maleamyl)salicylic acid (II).

In Table I is listed a comparison[3] of both reversible and irreversible inhibition of GDH

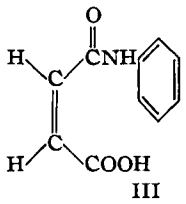
II



III

and LDH by compounds I–III. Although 4-(maleamyl)salicylic acid (II) could reversibly bind to both enzymes, *only LDH was irreversibly* inhibited. Maleanilic acid (III) showed relatively weak reversible binding to LDH,[4] *but showed no irreversible inhibition.* The irreversible inhibition of LDH shown by II and not III is strong evidence that a properly oriented complex with the active site is an obligatory intermediate for irreversible inhibition; if II had inactivated LDH by random bimolecular reaction, then maleanilic acid (III) should have inactivated LDH even more rapidly than II, since II would protect the active site against bimolecular reaction (12). Bimolecular inactivation of enzymes by N-ethylmaleimide is a well known phenomenon, and maleanic acid also inactivates enzymes but at a much slower rate (14); since III does not inactivate LDH, the inactivation of LDH by II definitely operates by a different mechanism, presumably by active site-directed irreversible inhibition.

The α,β-unsaturated carbonyl system of II, maleimides, and maleamic acids react in general most rapidly with SH groups, much slower with amino groups, and extremely slowly with hydroxyl groups. Thus, it is probable that LDH has a properly juxtapositioned SH group within the LDH–II complex that allows for an anchimerically assisted Michael addition reaction, whereas GDH does not; in contrast, GDH is irreversibly inhibited by active site-directed acylation with the amine reagent 5-(carbophenoxyamino)salicylic acid, but LDH is not irreversibly inhibited by this reagent (10).

Further search for groups on a reversible inhibitor that can specifically bridge to and covalently link other enzymic functional groups is continuing; such group specific active site-directed irreversible inhibitors would be of use in both chemotherapy and protein structure studies.

School of Pharmacy
State University of New York at Buffalo
Buffalo 14, N. Y.

Received June 25, 1963.
Accepted for publication July 11, 1963.
This work was generously supported by Grant CY-5867 of the National Cancer Institute, U. S. Public Health Service.

[3] The technical assistance of Dorothy Ackerman and Maureen Vince in making these measurements is acknowledged.

[4] III probably binds reversibly *via* the carboxylate in the fashion of benzoate and cinnamate (13), thus giving a conformationally different complex than I and II.

Book Notices

Pharmaceutical Calculations. By WILLIS T. BRADLEY, CARROLL B. GUSTAFSON, and MITCHELL J. STOKLOSA. Lea & Febiger, Inc., 600 S. Washington Square, Philadelphia 6, Pa., 1963. 357 pp. $14^1/_2 \times 23$ cm. Price $5.

The revised fourth edition of this student text on pharmaceutical calculations contains several areas of study which have become more prominent in the intervening years since the last edition. The text covers the usual fundamentals of calculations quite adequately in the tradition of prior editions. Several appendices are worthy of note, particularly those dealing with the HLB system, H-ion concentration, and basic statistical concepts. The authors note that the book is concerned exclusively with the arithmetic of today's applied pharmacy and this emphasis is apparent throughout.

Advances in Enzymology. Vol. 25. Edited by F. F. NORD. John Wiley & Sons, Inc., 605 Third Ave., New York 16, N. Y., 1963. v + 564 pp. $14^1/_2 \times 22^1/_2$ cm. Price $15.

The more significant developments in enzymology are presented in this annual review. Subjects covered include elementary steps in enzyme reactions as studied by relaxation spectrometry; energetics and related topics of photosynthesis; chemistry of light emission; prevalence and significance of product inhibition enzymes; biological methylation; recent developments in the biochemistry of amino sugars, as well as other topics. Cummulative subject and author indexes for volumes 1 through 25 are appended.

Pharmacological Approach to the Brain. By W. FELDBERG. Williams & Wilkins Co., 428 East Preston St., Baltimore 2, Md., 1963. 128 pp. $13 \times 21^1/_2$ cm. Price $4.50.

The first lecture in the Evarts A. Graham Memorial Lecture series at the Washington University School of Medicine is presented. The lectures discuss studies by the author on the action of drugs reaching the brain from the cerebral cavities and from the subarachnoid space. Intraventricular injections and perfusion of the cerebral ventricles, penetration of substances into the brain from its inner and outer surface, absorption into the blood stream, and symptomatology are the major areas around which the presentation is organized.

Analytical Chemistry. Edited by PHILIP W. WEST. American Elsevier Publishing Co., Inc., 52 Vanderbilt Ave., New York 17, N. Y., 1962. x + 411 pp. 16 × 24 cm. Price $16.

The proceedings of the Feigl Anniversary Symposium held in England in April 1962 are reported in this volume. All but two papers are published in English. Nearly 60 papers were presented and deal with spot tests and qualitative analysis, semiquantitative spot test methods, organic reagents and their applications, separation processes, and electrochemical, radiochemical, optical, and titrimetric analyses. The volume is indexed for ready reference.

Index-Handbook of Cardiovascular Agents. Vol. I. By ISAAC D. WELT. McGraw-Hill Book Co., Inc., 330 West 42nd St., New York 36, N. Y., 1963. xxvi + 2067 pp. $22^1/_2 \times 27^1/_2$ cm. Price $32.50.

Over 18,000 scientific communications have been analyzed and annotated with reference to experimental and clinical data on the effects of chemical agents upon anatomy, physiology, and pathology of the cardiovascular system and presented in this work. The format permits rapid searches for both the effects of a specific compound or group of compounds and the effects on a specific cardiovascular entity. This volume covers the literature published during 1930–1950. Literature reports of particular interest to any subsequent worker can be pinpointed with a high degree of precision.

Industrial Hygiene and Toxicology. Vol. II. 2nd rev. ed. FRANK A. PATTY, Editor. John Wiley & Sons, Inc., 605 Third Ave., New York 16, N. Y., 1963. xxxi + 1546 pp. $15^1/_2 \times 24$ cm. Price $40.00.

For people responsible for the industrial health of others, a comprehensive treatment of industrial chemicals along with reference to toxicological data and industrial literature is presented. Included in the volume are discussions of the source, uses, industrial exposures, physical and chemical properties, determination in the atmosphere, physiological response, odor and warning properties, flammability, and hygienic standards of permissible exposure regarding industrial chemicals.

Concise Chemical and Technical Dictionary. Edited by H. BENNETT. Chemical Publishing Co., Inc., 212 Fifth Ave., New York, N. Y., 1962. xxxix + 1039 pp. $12^1/_2 \times 22^1/_2$ cm. Price $15.00.

The editor has added a separate 119-page section covering about 5000 definitions of new trademarked products, chemicals, drugs, and terms to this second and enlarged dictionary of over 50,000 entries. The format of the original edition has been retained. General sections on the nomenclature of organic chemistry, names and formulas of organic radicals, pronunciations, Greek symbols, important organic ring systems, and tabular data of general usefulness has also been included.

Antimicrobial Agents and Chemotherapy. Edited by J. C. SYLVESTER. American Society for Microbiology, 115 Huron View Blvd., Ann Arbor, Mich., 1963. xiv + 884 pp. $14^1/_2 \times 22^1/_2$ cm. Price $12.00.

The scientific reports presented at the Second Interscience Conference on Antimicrobial Agents and Chemotherapy are presented in this second volume of an annual series. The composition, activity, and production of new antibiotics; synergistic effects of antimicrobial agents; control of microbial resistance to antibiotics; effects of physical state of drugs on their activity; chemotherapy of infectious diseases; and clinical evaluation of chemotherapeutic substances are among some of the more prominent subjects included.

Antimicrobial Agents and Chemotherapy. Edited by J. C. SYLVESTER. American Society for Microbiology, 115 Huron View Blvd., Ann Arbor, Mich., 1963. xiv + 884 pp. $14^1/_2 \times 22^1/_2$ cm. Price $12.00.

The scientific reports presented at the Second Interscience Conference on Antimicrobial Agents and Chemotherapy are presented in this second volume of an annual series. The composition, activity, and production of new antibiotics; synergistic effects of antimicrobial agents; control of microbial resistance to antibiotics; effects of physical state of drugs on their activity; chemotherapy of infectious diseases; and clinical evaluation of chemotherapeutic substances are among some of the more prominent subjects included.

Book Notices

Pharmaceutical Calculations. By WILLIS T. BRADLEY, CARROLL B. GUSTAFSON, and MITCHELL J. STOKLOSA. Lea & Febiger, Inc., 600 S. Washington Square, Philadelphia 6, Pa., 1963. 357 pp. $14^1/_2 \times 23$ cm. Price $5.

The revised fourth edition of this student text on pharmaceutical calculations contains several areas of study which have become more prominent in the intervening years since the last edition. The text covers the usual fundamentals of calculations quite adequately in the tradition of prior editions. Several appendices are worthy of note, particularly those dealing with the HLB system, H-ion concentration, and basic statistical concepts. The authors note that the book is concerned exclusively with the arithmetic of today's applied pharmacy and this emphasis is apparent throughout.

Advances in Enzymology. Vol. 25. Edited by F. F. NORD. John Wiley & Sons, Inc., 605 Third Ave., New York 16, N. Y., 1963. v + 564 pp. $14^1/_2 \times 22^1/_2$ cm. Price $15.

The more significant developments in enzymology are presented in this annual review. Subjects covered include elementary steps in enzyme reactions as studied by relaxation spectrometry; energetics and related topics of photosynthesis; chemistry of light emission; prevalence and significance of product inhibition enzymes; biological methylation; recent developments in the biochemistry of amino sugars, as well as other topics. Cummulative subject and author indexes for volumes 1 through 25 are appended.

Pharmacological Approach to the Brain. By W. FELDBERG. Williams & Wilkins Co., 428 East Preston St., Baltimore 2, Md., 1963. 128 pp. $13 \times 21^1/_2$ cm. Price $4.50.

The first lecture in the Evarts A. Graham Memorial Lecture series at the Washington University School of Medicine is presented. The lectures discuss studies by the author on the action of drugs reaching the brain from the cerebral cavities and from the subarachnoid space. Intraventricular injections and perfusion of the cerebral ventricles, penetration of substances into the brain from its inner and outer surface, absorption into the blood stream, and symptomatology are the major areas around which the presentation is organized.

Analytical Chemistry. Edited by PHILIP W. WEST. American Elsevier Publishing Co., Inc., 52 Vanderbilt Ave., New York 17, N. Y., 1962. x + 411 pp. 16 × 24 cm. Price $16.

The proceedings of the Feigl Anniversary Symposium held in England in April 1962 are reported in this volume. All but two papers are published in English. Nearly 60 papers were presented and deal with spot tests and qualitative analysis, semiquantitative spot test methods, organic reagents and their applications, separation processes, and electrochemical, radiochemical, optical, and titrimetric analyses. The volume is indexed for ready reference.

Index-Handbook of Cardiovascular Agents. Vol. I. By ISAAC D. WELT. McGraw-Hill Book Co., Inc., 330 West 42nd St., New York 36, N. Y., 1963. xxvi + 2067 pp. $22^1/_2 \times 27^1/_2$ cm. Price $32.50.

Over 18,000 scientific communications have been analyzed and annotated with reference to experimental and clinical data on the effects of chemical agents upon anatomy, physiology, and pathology of the cardiovascular system and presented in this work. The format permits rapid searches for both the effects of a specific compound or group of compounds and the effects on a specific cardiovascular entity. This volume covers the literature published during 1930–1950. Literature reports of particular interest to any subsequent worker can be pinpointed with a high degree of precision.

Industrial Hygiene and Toxicology. Vol. II. 2nd rev. ed. FRANK A. PATTY, Editor. John Wiley & Sons, Inc., 605 Third Ave., New York 16, N. Y., 1963. xxxi + 1546 pp. $15^1/_2 \times 24$ cm. Price $40.00.

For people responsible for the industrial health of others, a comprehensive treatment of industrial chemicals along with reference to toxicological data and industrial literature is presented. Included in the volume are discussions of the source, uses, industrial exposures, physical and chemical properties, determination in the atmosphere, physiological response, odor and warning properties, flammability, and hygienic standards of permissible exposure regarding industrial chemicals.

Concise Chemical and Technical Dictionary. Edited by H. BENNETT. Chemical Publishing Co., Inc., 212 Fifth Ave., New York, N. Y., 1962. xxxix + 1039 pp. $12^1/_2 \times 22^1/_2$ cm. Price $15.00.

The editor has added a separate 119-page section covering about 5000 definitions of new trademarked products, chemicals, drugs, and terms to this second and enlarged dictionary of over 50,000 entries. The format of the original edition has been retained. General sections on the nomenclature of organic chemistry, names and formulas of organic radicals, pronunciations, Greek symbols, important organic ring systems, and tabular data of general usefulness has also been included.

Antimicrobial Agents and Chemotherapy. Edited by J. C. SYLVESTER. American Society for Microbiology, 115 Huron View Blvd., Ann Arbor, Mich., 1963. xiv + 884 pp. $14^1/_2 \times 22^1/_2$ cm. Price $12.00.

IN THE PUBLIC SERVICE

This year marks the diamond anniversary of a program which has become one of the most significant contributions of organized professional pharmacy to the public health and welfare. Seventy-five years ago, in 1888, the first edition of the *National Formulary* was published as part of the American Pharmaceutical Association's effort to standardize the composition and purity of drug preparations then on the market. This project represented the major part of a broad effort by the Association to eliminate the adulteration of drugs, which was an extremely serious problem during the latter half of the 19th century. Indeed, the problem was of such great proportions, and of such serious concern to pharmacists of that era, that it was listed in the A.PH.A. Constitution as the first reason for the Association's establishment about 30 years earlier.

However, the pharmaceutical and medical professions responded to this challenge so well that by 1906, when the first Federal Food and Drugs Act was passed, Congress took note of the vital importance of the *National Formulary* and designated it, along with the *U. S. Pharmacopeia*, as an "official compendium" under pertinent sections of the law.

The role played by the *National Formulary* today in combating drug adulteration is fully as important as at any time during its 75-year history. Furthermore, the N.F. has assumed an increasingly active role in the standardization of drug potency, and in elevating the overall quality and purity of drugs marketed in this country. Therefore, the contribution of the N.F. to the public health and well-being continues to be of great importance. This fact, coupled with the very unique position accorded to the compendium by our federal and state legislative bodies, serves to place an awesome responsibility of public service in the hands of the profession of pharmacy.

It is somewhat of an unfortunate anomaly, however, that many American pharmacists—including some of the profession's leaders and elected officials—seem to have less recognition of this sacred trust than many non-pharmacists in closely related fields of the health-sciences complex.

Review Article

Use of Nonaqueous Solvents in Parenteral Products

By A. J. SPIEGEL and M. M. NOSEWORTHY

THE PRACTICE OF incorporating naturally occurring nonaqueous solvents such as fixed oils and glycerin in pharmaceuticals has been common for many years. Water is always the solvent of choice. However, when it is not possible for physical or chemical reasons (such as limited solubility and hydrolytic reactions) to use a wholly aqueous system, nonaqueous solvents aid the formulator in developing stable, convenient parenteral dosage forms. A parenteral solution avoids the disadvantages inherent in suspensions, such as nonuniform dosage, caking, and possible slow release of the medicament when it is not desired.

A formulator encounters many problems once he determines that an aqueous system is unsatisfactory. The chosen solvent must be nontoxic, nonirritating, and nonsensitizing. It also must exert no pharmacologic activity of its own, nor adversely affect the action of the medicament. There are reported instances in which a solvent potentiated the activity of the medicament necessitating a change of dosage level. This will be discussed in greater detail later in this review.

In addition to being pharmacologically acceptable, the chemical and physical properties of the solvent must be taken into account. Thus, the ideal solvent should not be affected by acids or alkalies and it should be generally stable under normal conditions of pharmaceutical use. The viscosity must be such as to allow for ease of injection, and the solvent must remain fluid over a fairly wide temperature range. It is advantageous if the solvent has a sufficiently high boiling point to allow heat sterilization. Additional considerations are water and body fluid miscibility, the degree of flammability, availability, source of supply, and constant purity.

Obviously, no such individual solvent presently exists. Thus, the selection of a nonaqueous solvent for a parenteral vehicle is a compromise among the many influencing factors. The advent of modern chemical technology has produced many new synthetic solvents in addition to the naturally occurring ones.

This review presents the toxicity, chemical and physical properties, and applications of some of the more commonly used nonaqueous solvents, as well as some specialized and rarely used solvents in pharmaceutical formulations.

FIXED OILS

The U.S.P. (1) recognizes the use of fixed oils as parenteral vehicles. Fixed oils are mainly mixtures of esters of unsaturated fatty acids which are fluid at 20°. The fluidity is generally due to the presence of the oleic acid esters of glycerin. The most commonly used fixed oils are corn oil, cottonseed oil, peanut oil, and sesame oil (2). Castor oil and olive oil have been used occasionally. While the toxicities of vegetable oils are relatively low, some patients exhibit allergic reactions to specific vegetable oils. Therefore, when such oils are used as vehicles, the label must state the specific oil contained in the product. Fixed oils have been known to cause undesirable

Received from the Pharmaceutical Research and Development Department, Chas. Pfizer & Co., Inc., Brooklyn, N. Y.
Presented in part at the Fourth Annual National Industrial Pharmaceutical Research Conference, Land O'Lakes, Wis., June 1962.

local tissue reactions, such as cysts, foreign-body granulomas and, occasionally, nerve injury.

The requirements for fixed oils to be used in parenteral products are specified in the U.S.P. (1). The use of fixed oils is limited because of the low solubility of most drugs in these solvents. Since these oils are not miscible with water, dissolved drugs may exhibit a sustained-release effect with a possible diminution of absorption. Aqueous insolubility also precludes the use of fixed oils in unemulsified intravenous products.

Cottonseed oil has been used in intravenous fat emulsions administered to surgical patients as reported by Lehr and co-workers (3) and a commerical product is available.

Drugs which are incorporated in oils are mainly the steroid hormones, dimercaprol, calciferol, and menadione. Since fixed oils contain unsaturated fatty acids, oxidative changes take place which may necessitate the use of oil soluble antioxidants such as propyl gallate, butylated hydroxyanisole, butylated hydroxytoluene, and tocopherols.

A list of the official U.S.P. (1) and N.F. (4) parenteral solutions using fixed oils as solvents is given in Table I.

TABLE I.—OFFICIAL INJECTIONS IN OIL

Desoxycorticosterone acetate U.S.P.
Dimercaprol U.S.P.
Estradiol benzoate U.S.P.
Estradiol cyclopentylpropionate N.F.
Estradiol dipropionate U.S.P.
Estrone U.S.P.
Progesterone U.S.P.
Testosterone propionate U.S.P.
Diethylstilbestrol dipropionate N.F.
Menadione N.F.

A typical intramuscular formula for a testosterone propionate oil solution, 50 mg./ml., is (5)

	Gm./1000 ml.
Testosterone propionate	50.0
Benzyl alcohol	21.0
Sesame oil	869.0

Since sesame oil becomes turbid on cooling, a "winterized" or treated oil should be used, so that the oil remains clear when cooled to 5°.

ETHYL OLEATE

The "British Pharmacopoeia" (6) recognizes ethyl oleate as an alternative vehicle in injections of deoxycortone acetate, estradiol monobenzoate, progesterone, and testosterone propionate.

It is a yellowish oily liquid which is insoluble in water and miscible with alcohol, ether, and fixed oils. It has properties similar to fixed oils, except that it is less viscous, is a superior solvent, and is more rapidly absorbed by the tissues (7). Unlike untreated sesame oil, ethyl oleate remains clear at 5°, but it has the disadvantage of discoloring on standing.

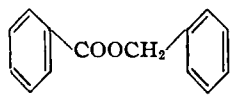
There are indications of increased hormone activity when ethyl oleate is used in place of sesame oil as a parenteral hormone vehicle. Studies by Dekanski and Chapman (8) demonstrated improved intensity and duration of action of testosterone phenylpropionate and testosterone propionate in ethyl oleate over that of the same androgens in sesame oil.

ISOPROPYL MYRISTATE

The use of isopropyl myristate as a vehicle for parenteral injections has been reported by Platcow and Voss (9). It is an oil miscible, water immiscible, chemically stable substance, not susceptible to rancidity and having a specific gravity of 0.852 (10). It consists mainly of isopropyl myristate and a small amount of isopropyl esters of other saturated fatty acids. Acute toxicity studies indicate a very low order of toxicity, but attempts to establish an LD_{50} in mice failed when dosages equivalent to 100 ml./Kg. did not affect the test animals. Isopropyl myristate shows a very low degree of irritability and exhibits no sensitizing properties in rabbits and guinea pigs following topical and parenteral administration. In experiments on ovariectomized rats it compared favorably with sesame oil as a repository vehicle for estrogens (9). The external pharmaceutical use has been evaluated by Donovan, *et al.* (11), who found it a useful intermediate solvent for the incorporation of phenol, cocaine, resorcinol, and salicylic acid into liquid petrolatum.

BENZYL BENZOATE

Benzyl benzoate (12) is a colorless, oily liquid with a pleasant aromatic odor. It has a specific gravity of 1.118, boils at 323°, and is insoluble in water or glycerin, but is miscible with alcohol, chloroform, ether, and fixed oils. Its structural formula is

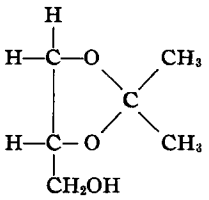


Benzyl benzoate has found some use as a cosolvent in oleaginous injectables such as dimercaprol injection, and in commercial preparations of hydroxyprogesterone benzoate where it is present in concentrations of 30% for the 125-mg. product in sesame oil, and 46% for the 250-mg.

product in castor oil. The formula for the injection of dimercaprol B.P. (1958) is dimercaprol 5.0 Gm., benzyl benzoate 9.6 ml., and peanut oil, to make 100 ml.

DIOXOLANES

The dioxolanes represent a new and interesting group of synthetic solvents for pharmacists. These substances are the reaction products of glycerin with ketones in the presence of a dehydrating agent (13). The least toxic member of the group is 2,2-dimethyl-1,3-dioxolane-4-methanol (14). This structural formula is



This compound [also known as Solketal, isopropylidene glycerol, and glycerol dimethylketal (15)] is reported to be a nontoxic, nonirritating solvent, miscible with water, alcohol, esters, aliphatic and aromatic hydrocarbons, and virtually all other organic solvents. It is a water-white, practically odorless liquid of medium viscosity, stable on storage, and unaffected by alkalies. Its boiling point is 82–83°, and has a specific gravity of 1.064. It is, however, hydrolyzed by strong aqueous acid solutions to acetone and glycerin (15–19).

Berger (14) reported the dioxolanes (as a class) produce transient muscular relaxation and paralysis. These effects were due to a depressant action on the central nervous system and not to a peripheral curare-like action. The mean paralyzing dose, ED_{50}, and the mean lethal dose, LD_{50}, for 2,2-dimethyl-1,3-dioxolane-4-methanol after intraperitoneal administration in mice was reported to be greater than 2.112 Gm./Kg. (16.0 mM/Kg.).

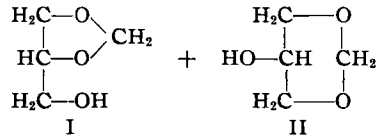
Teuber (20, 21) reported that the oral LD_{50} in mice is 4.0 to 7.2 Gm./Kg. (30–55 mM/Kg.). Dermatologic tests on rabbits produced no untoward reactions after 3 weeks of application.

Guinea pigs exposed to aerosol sprays for 1 hour a day for 3 days exhibited no inflammation of mucous membranes. Huber (22) reported on the use of antibiotic aerosol sprays utilizing this solvent as a carrier for penicillin and oxytetracycline.

In this country, 2,2-dimethyl-1,3-dioxolane-4-methanol has been reported in the patent literature as a water-miscible solvent in gelatin capsules (23) and as a parenteral vehicle for a tetracycline preparation (24).

GLYCEROL FORMAL

Glycerol formal is a condensation product of glycerol and formaldehyde consisting of 3-hydroxymethyl-1,3-dioxolane (I) (25%) and 5-hydroxy-dioxane (II) (75%). The structural formulas are

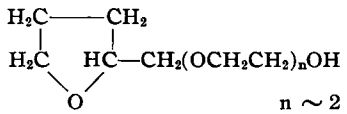


I II

It is a chemically stable, colorless, odorless liquid of low viscosity and is miscible with water in all proportions. Sanderson (25) reported that the LD_{100} for rats by intraperitoneal administration was 3000 mg./Kg. and that the maximum symptomless dose was 1500 mg./Kg. The use of glycerol formal as a nontoxic solvent in toxicity testing has been suggested. It has been used as an industrial solvent and no toxic effects have been reported (25).

GLYCOFUROL

Glycofurol is a Hoffmann-LaRoche trade name for a tetrahydrofurfuryl alcohol polyethylene glycol ether containing an average of two ethylene glycol units per molecule. It is a colorless liquid, miscible with water in all proportions and soluble in methanol, ethanol, *n*-propanol, and glycerin. It has a boiling point of 80–155° and a specific gravity of 1.078. The structure is (26)

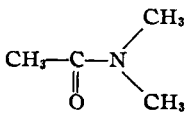


Spiegelberg and co-workers (26) extensively studied the pharmacology of this material and reported on its use as a parenteral solvent. Irritating when administered undiluted, it is nontoxic and nonirritating when diluted with water. The intravenous LD_{50} in the mouse is 3.78 Gm. (3.5 ml.)/Kg., and its tolerability equals that of propylene glycol. Acetylcholine chloride is reported to be stable in glycofurol solutions, while it is not stable in propylene glycol.

DIMETHYLACETAMIDE

Dimethylacetamide (DMA), also known as acetic acid dimethylamide and acetyldimethylamine, is an interesting solvent which warrants some discussion. It is a clear neutral liquid

having a boiling point of 165.5°, a specific gravity of 0.943, and a molecular weight of 87.12. The structural formula is



This solvent is miscible in all proportions with water and alcohol and very soluble in organic solvents and mineral oil (27).

Davis and Jenner (28) studied the acute toxicities of dimethylacetamide, dimethylformamide (DMF), and propylene glycol after single doses were administered intraperitoneally to mice. A 50% solution of DMA was used; however, the toxicity results are for the DMA content of the solution. The DMF and propylene glycol were administered undiluted. These results are as follows: the LD_{50} for DMF was 1122 mg./Kg., for DMA 3236 mg./Kg., and for propylene glycol 11,400 mg./Kg. The LD_{100} for DMA is 5012 mg./Kg.

Horn (29) investigated the chronic toxicity of DMA by dermal application in dogs at dosage levels of 0.1 to 4.0 mg./Kg. and by exposing both rats and dogs to an atmosphere containing DMA at concentrations of 40.0, 64.4, 102, and 195 p.p.m. All experiments were of 6-month duration unless obvious toxicity occurred. Liver damage occurred at all levels greater than 0.1 ml./Kg. dermally and 40 p.p.m. by inhalation.

The patent literature mentions the use of a 50% DMA solution as a vehicle for a preconstituted oxytetracycline (30) solution and as a solvent in soft and hard gelatin capsules (31). Its use as an anti-inflammatory agent in topical formulations is also reported (32).

Hammer, *et al.* (33), reported on a preconstituted intramuscular solution of oxytetracycline which consisted of a solution of an ethanolammonium magnesium salt of oxytetracycline in 50% N,N-dimethylacetamide. After testing in animals and humans, this formulation was found to be well tolerated and produced effective antibiotic serum levels. The stability was satisfactory for 2 years at room temperature.

A 50% solution of DMA is used as a solvent for a 250-mg./ml. chloramphenicol intravenous formulation, but it must be diluted with normal saline or 5% dextrose before administration.

A commercially available reserpine intramuscular product contains 10% DMA as a cosolvent (34).

DMA, when used as a drug solvent and administered to 15 patients with advanced malignancies produced hallucinations when given at levels above 400 mg./Kg. of body weight per day for 3 days or more (35). However, the normal parenteral level for DMA is equivalent to 30 mg./Kg. per day. Thus, in normal use this hallucinagenic effect would not be expected.

An oxytetracycline 50-mg./ml. formula (30) was reported to have been composed of oxytetracycline, 50 mg.; magnesium chloride, hexahydrate 1.7%; ethanolamine, 20% aqueous 1.5%; sodium formaldehyde sulfoxylate 0.2%; lidocaine 2%; and N,N-dimethylacetamide 50%, to make 1.00 ml.

N-(β-HYDROXYETHYL)-LACTAMIDE

N - (β - Hydroxyethyl) - lactamide (36), also known as lactic acid carboxamide, is a clear, colorless, syrupy liquid which is water miscible. The specific gravity of the pure compound is 1.192. It is used as a 50% solution and has the following formula: $CH_3CHOHCONHCH_2CH_2OH$. This compound is the reaction product of methyl acetate and 2-aminoethanol. The acute subcutaneous, LD_{50}, toxicity (37) for a 50% w/v N-(β-hydroxyethyl)-lactamide solution is 15.8 Gm. lactamide/Kg. in mice and 16.1 Gm. lactamide/Kg. in rats. This compound has been used in Europe as a solvent for a preconstituted oxytetracycline solution. Neumann (37) reported that this product was stable for several years and showed improved tissue tolerability.

Dimmling (38) has also reported on the use of N-(β-hydroxyethyl)-lactamide as a solvent for oxytetracycline. After 24 hours, a detectable serum level was found after a single dose of 250 mg. in ten healthy persons. Following a second injection of 250 mg. after an interval of 24 hours, the levels showed a cumulative increase. Further studies (39) on the serum concentrations confirmed the previous findings.

The results of Seeliger's (40) investigation with oxytetracycline intramuscular in N-(β-hydroxyethyl)-lactamide solution in patients have confirmed the previous values obtained in healthy individuals. A single injection of 250 mg. gave an effective serum concentration for over 24 hours. Following repeated injections on consecutive days, marked cumulative effects were observed. The clinical effect was in accordance with blood level determinations. Survey of local tolerability showed practically no pain in 93.7% of the 380 injections performed; slight and tolerable local reactions, which in no case persisted for more than 2 or 3 hours, were found in 6.3%.

Hupe (41) reported that in 90 major surgical cases 250 mg. of oxytetracycline intramuscular in this solvent, once a day, was effective and well tolerated.

The patent literature also refers to the use of N-(β-hydroxyethyl)-lactamide as a solvent for oxytetracycline injectables (30, 42). The use of other alkylol amides such as the amides of β-hydroxybutyric acid, succinic acid, adipic acid, tartaric acid, glycolic acid, and salicylic acid, was also mentioned (42). A typical formula for a 250 mg./3 ml. oxtyetracycline product is

	Gm./100 ml.
Oxytetracycline hydrochloride	9.62
Magnesium chloride-hexahydrate	4.00
Sodium formaldehyde sulfoxylate	0.20
Water, pyrogen-free	44.20
N-(β-hydroxyethyl)-lactamide	50.00
Monoethanolamine	2.30

ETHYL LACTATE

Ethyl lactate, ethyl α-hydroxypropionate, $CH_3CH(OH)COOCH_2CH_3$, is a colorless liquid with a specific gravity of 1.042 which is miscible with water and has a characteristic odor. In aqueous solution some decomposition takes place (43).

Latven and Molitor (44) determined the acute toxicity of ethyl lactate in mice by subcutaneous and intravenous administration, and their results are shown in Table II.

TABLE II.—ACUTE TOXICITY OF ETHYL LACTATE

	LD_0	LD_{50}	LD_{100}	Minimum Sympt. Dose	Maximum Nonsympt. Dose
Subcutaneous, ml./Kg.	2.0	2.5	3.0	1.0	0.8
Intravenous, ml./Kg.	0.2	0.6	1.0	0.3	0.2

Ethyl lactate was irritating on intradermal injection in guinea pigs and on application to the eyes of rabbits.

Ethyl lactate (10–100%) solubilizes an esterone injection in castor oil to a concentration of 3.5 to 6.5 mg./ml. (45). This product is stable at room temperature (46). It has been used as an industrial solvent and no toxic effects from its use have been recorded (47).

ETHYL CARBONATE

Ethyl carbonate, diethyl carbonate, $CH_3CH_2OCOOCH_2CH_3$, has also been used as a solvent for erythromycin, but there is a paucity of literature on its use and toxicity. It is a liquid immiscible with water but miscible with alcohol and ether and has a specific gravity of 0.975 and a boiling point of 126° (48). This compound has also been used as an industrial solvent with no reported toxic effects (49).

POLYETHYLENE GLYCOLS

The polyethylene glycols (PEGs), as the name implies, are polymers of ethylene oxide (50) with the general formula: $HOCH_2(CH_2OCH_2)_nCH_2OH$, where n represents the average number of ethylene oxide groups. These polymeric products are designated by a number which represents the average molecular weight (51). Polyethylene glycol 200, 300, 400, and 600 are moderately viscous, colorless, somewhat hygroscopic liquids. They are less volatile than glycerin and do not hydrolyze or deteriorate (52). They dissolve in water in all proportions to form clear solutions (51). Polyethylene glycol 1000, 1540, 4000, and 6000 are white waxy solids (Table III).

For the purpose of this discussion, we will confine our comments to the liquid polyethylene glycols which are more likely to be used in parenteral products. The literature abounds with papers discussing and describing measurements of the toxicity of the various PEGs by oral or topical routes (50–58). However, there is a scarcity of material on the parenteral administration. PEG 300 and 400 are better described than the other two members of the liquid PEG series. Only the parenteral LD_{50}'s (as shown in Table IV) were found by the authors. Oral and dermal toxicity data are given in Tables V and VI.

Subcutaneous dosages of PEG 400 up to 10 ml. (ten times the human dose) in rats caused no permanent damage. The reactions were described as "blanching of the skin and scab formation in 48 hours." The test results were reported to be the same as with propylene glycol. PEG 300 and 400 do not elicit a foreign body reaction in animals (52). In dogs, the removal of PEG

TABLE III.—PHYSICAL PROPERTIES OF POLYETHYLENE GLYCOLS (51)

PEG	Av. Mol. Wt.	Sp. Gr., 20° C.	Freezing or Melting Range, ° C.	Viscosity, Cps. at 210° F.	Comparative Hygroscopicity Glycerol = 100
200	190–210	1.125	Super Cools	4.3	70
300	285–315	1.125	−15 to −8	5.8	60

200	38.3	30.0	6.5	55
600	47.0	16.0	8.0	60

TABLE VI.—ORAL TOXICITY OF POLYETHYLENE GLYCOLS IN RATS (51)

Polyethylene Glycol	Single Oral LD_{50} Rats Gm./Kg.	No-Effect Dose with Repeated Feedings, Rats Gm./Kg./Day
200	28.9 ml. (32.51 Gm.)	0.88 (2 yr.)
300	31.7 ml. (35.66 Gm.)	5.4 (90 days)
400	43.6 ml. (49.05 Gm.)	0.96 (2 yr.)
600	38.1 ml. (42.86 Gm.)	2.42 (90 days)

from the site of injection is rapid, since the material diffuses freely into surrounding tissue.

When PEG 400 was injected intravenously into humans, 77% was recovered in the first 12 hours. Intramuscular injections in rats of five to ten times the expected human dosage levels of PEG 300 produced ischemic necrosis of the muscle fibers when the dose infiltrated a muscle bundle. The tissue response was one of mild chemical inflammation (50).

Lee and Anderson (61) determined the toxicity of vancomycin in 50% PEG 200 and of PEG 200 alone. Their results indicated that PEG 200 produced no apparent toxic effects when given to dogs at 1.0 ml./Kg. per day for 80 days intramuscularly, or of 0.5, 1.0, 2.5, and 5.0 ml./Kg. as single intravenous doses. Venous carbon dioxide content, blood nonprotein-nitrogen, and blood alkaline phosphatase were normal, no gross or microscopic abnormality was found in the kidneys, circulatory system, or other organs.

A dosage form for intravenous use containing nitrofurantoin was marketed some years ago containing PEG 300. In a study by McCabe, *et al.* (62), it was found that daily administration of 240 mg. of nitrofurantoin in PEG 300 to 30 patients caused severe metabolic acidosis and nephropathy in seven resulting in two deaths. These damaging effects were attributed to the PEG rather than nitrofurantoin and that dosage form was withdrawn from the market.

It should be noted that drugs dissolved in the PEGs may well present a toxicity and drug level much different from those reported in aqueous solutions or suspensions (51).

Swanson and co-workers (63) investigated the effect on the activity and toxicity of sodium amobarbital and sodium secobarbital by the addition of 60 and 70%, respectively, of polyethylene glycol 200. Their findings indicated that the addition of PEG 200 showed approximately the same potency and toxicity as aqueous solutions of these barbiturates. The median anesthetic dose (AD_{50}) by vein in rats was 75.0 ±3.5 mg./Kg. for sodium amobarbital and 39.0 ±1.2 mg./Kg. for sodium secobarbital. The median lethal doses (LD_{50}) were approximately twice as large as the AD_{50}'s. This ratio of nearly 2:1 is common to most barbiturates in use. It was also reported that subacute toxicity experiments show that both barbiturates in PEG 200 produced no obvious pathological changes. When injected intramuscularly in rabbits the aqueous solutions of the two barbiturates produced more irritation in tissues than solutions in PEG 200.

Bodin and Taub (64) investigated the stability of sodium pentobarbital in aqueous solutions containing 0 to 60% of polyethylene glycol 400. Their results indicated that the pH influences the concentration of polyethylene glycol 400 required for optimum stability. At a concentration of 30% and at a pH of 10, aseptic formulation of a stable product is possible. The addition of 10% ethanol permits sterilization by autoclaving without discoloration. It is also possible to prepare formulations containing 60% of the glycol and 10% ethanol at a pH as low as 8. These solutions are also stable to autoclaving.

Linde (65) studied the extent to which a number of sodium salts of 5,5-disubstituted barbiturates such as phenobarbital, barbital, aprobarbital, amobarbital, and pentobarbital could be stabilized by propylene glycol, polyethylene glycol 400, glycerin, and alcohol. Both the glycols, as well as alcohol, showed the same stabilizing activity. Glycerin had considerably lower stabilizing properties. With glycols as stabilizers, the various barbiturate derivatives studied displayed great differences in stability. The concentration of the solvent added to the solution was found to be the factor governing the stabilizing effect. The stability increased as the concentration was increased. A concentration of

50% was the highest used. The author (65) also established that stability of barbiturates dissolved in pure propylene glycol and polyethylene glycol 400 was very good, and that a lowering of pH in alcohol solutions decreases the rate of deterioration.

The use of 10% polyethylene glycol 300 as a solubilizing agent for a 2.5 mg./ml. injection of reserpine has been reported by Leyden, *et al.* (66). Commercial reserpine products containing 10–30% PEG 300, as well as 25% PEG 400, are available.

Higuchi and Lach (67) reported that although pentobarbital and barbital have little or no tendency to complex with polyethylene glycols, phenobarbital forms stable and stoichiometric molecular compounds with these macromolecular substances. Analysis indicates that one phenobarbital molecule is bound by two ethylene oxide units of the polyether chain. They have also shown that phenolic compounds are bound by the polyethers in the same manner, the higher molecular weight polymers exhibiting greater complexing tendency than those of lower degrees of polymerization. Several organic acids, such as salicylic acid and *p*-hydroxybenzoic acid, are only weakly bound.

An erythromycin ethyl succinate intramuscular product in a PEG vehicle is available, as is a secobarbital parenteral product in a 50% PEG vehicle. The specific PEG used was not indicated in either case.

GLYCERIN

Glycerin (68) is a clear, viscous, high-boiling liquid, which is miscible with water and alcohol and is a good solvent for many compounds. It is hygroscopic and will absorb several times its weight of water under conditions of high humidity. Glycerin tends to supercool rather than crystallize at lower temperature; its aqueous solutions resist freezing.

The toxicity (69) is low with oral administration. No deleterious effects were observed in man with 110 Gm. of glycerin per day for 50 days. Normal growth and reproduction occurred in rats with 41% of glycerin added to the food for 40 weeks, and in dogs with 35% added for 50 weeks. Drill (70) reports the oral LD_{50} in rats for undiluted glycerin to be 25 Gm./Kg. and the intravenous LD_{50} is 5 to 6 Gm./Kg.

There appears to be some controversy regarding the use of glycerin in parenterals, as indicated by reports that its administration to animals has caused hemoglobinurea (71, 72), hypotension (73, 74) and central nervous disturbances (74), and weight loss (75). Hanke (76) has given an excellent review of the physiologic action of glycerin.

There are, however, references to its use in human parenteral therapy. No toxic effects were noted after the administration of very small amounts of glycerin by intra-arterial administration in the treatment of elephantiasis (77).

Sloviter (78, 79) reported that the intravenous administration of solutions containing 5% glycerin to experimental animals and to man caused no toxic or other undesirable effects. Humans were given intravenously 50 Gm. of glycerin in a liter of solution which also contained 50 Gm. of glucose and 9.0 Gm. of sodium chloride. No disturbances of cardiorespiratory or central nervous system function occurred, and no significant hemolytic effects occurred. Sloviter (78, 79) further stated that the previously reported toxic effects of parenterally administered glycerin were not observed, and that there were indications that these toxic effects were due to the osmotic disturbances produced by the injection of solutions of high glycerin concentrations. In the dog, the rapid injection of a concentrated solution produced a transient drop in blood pressure which the author believed to be due to a peripheral vasodilating effect. It was also suggested that intravenously administered glycerol may be useful as a nutritional agent as well as for a solvent in preparations of drugs for intravenous administration (79).

Large parenteral doses cause convulsant and paralytic symptoms through direct action on the central nervous system. The blood corpuscles are also laked, probably caused by an osmotic effect as previously mentioned. The glycerin remains for a time, unabsorbed, and in high concentration at the site of injection, and the corpuscles are probably laked during their passage through this area (69).

Lachaux (80) states that aqueous solutions of up to 30% glycerin are well tolerated intramuscularly. Absorption is good and there is rapid dilution by the body fluids.

Latven and Molitor (44) determined the intravenous and subcutaneous toxicity in white mice. Their results are shown in Table VII.

TABLE VII.—ACUTE TOXICITY OF GLYCERIN

	LD_0	LD_{50}	LD_{100}	Min. Sympt. Dose	Max. Non-Sympt. Dose
Subcutaneous, ml./Kg.	8.0	10.0	12.0	8.0	7.0
Intravenous, ml./Kg.	5.0	6.0	7.0	3.0	2.0

Krause and Cross (81) have found that the solubility of phenobarbital in alcohol was enhanced by the addition of glycerin. The maximum solubility of phenobarbital in alcohol–glycerin mixtures was reached at a level of 80% alcohol and 20% glycerin.

Linde (65), in his work on sodium salts of barbiturates, found that glycerin has considerably lower stabilizing properties than propylene glycol, polyethylene glycol, and alcohol.

Husa and Jatul (82) found that after heating a sodium phenobarbital solution in 50% glycerin for 30 minutes at 115°, deterioration was 8% compared to 9% in pure water solution.

The U.S.P. (1) allows the use of glycerin in injections of deslanoside and digitoxin. A commercial product of deslanoside contains 15% glycerin.

ETHANOL

Ethanol (alcohol), ethyl alcohol, finds occasional use in parenteral products, particularly the digitalis glycosides. A commercial digitoxin preparation for intramuscular or intravenous use contains 49% alcohol. This produces pain on intramuscular administration. The U.S.P. (1) states that such a product can contain 5–50% alcohol. A digoxin preparation containing 10% alcohol, as allowed by the U.S.P., may be used for intramuscular or intravenous administration. A deslanoside product containing 7.4% alcohol is also available.

Alcohol injected subcutaneously causes considerable pain followed by anesthesia. If injection is made close to nerves, neuritis and nerve degeneration may occur. Injection in or near nerves is deliberately used to cause anesthesia in the treatment of severe pain. The intravenous anesthetic dose is 2–3 ml. of 95% alcohol/Kg. (83).

Latven and Molitor (44) have reported the LD_{50} in mice to be 1973 mg./Kg. intravenously, and 8285 mg./Kg. subcutaneously.

A commercial hydrocortisone intravenous product contains 50% alcohol. Mephensin injection B.P. (1958) contains 25% alcohol, its formula is mephenesin 10 Gm.; alcohol (95%) 25 ml.; propylene glycol 15 ml.; and water, pyrogen-free, to make 100 ml.

The formula for digoxin injection B.P. (1960 Supplement) is digoxin 25 mg.; alcohol (80%) 12.5 ml.; propylene glycol 40 ml.; citric acid 75 mg.; sodium phosphate 0.45 Gm.; and water, pyrogen-free to make 100 ml.

PROPYLENE GLYCOL

Seidenfeld and Hanzlik (84) in 1932 stated that propylene glycol, which was first described in 1895, has commanded little or no interest in chemistry or medicine even though it is available commercially. Today, it is one of the most widely used nonaqueous solvents.

Propylene glycol, 1,2-propanediol, is a viscous hygroscopic liquid with a specific gravity of 1.036. It freezes at −59° and boils at 188° and is miscible with water, acetone, and chloroform, but is immiscible with fixed oils. Under ordinary conditions it is very stable but at high temperatures it is oxidized to propionaldehyde, lactic acid, pyruvic acid, and acetic acid (85, 86).

The toxicity of propylene glycol has been extensively studied (44, 84, 87–91). Seidenfeld and Hanzlik (84) reported the intravenous minimum fatal dose for white rats to be 1.68 Gm./Kg. and for rabbits, 5.25 Gm./Kg. The intramuscular minimum fatal dose was 14.7 Gm./Kg. for rats and 7.5 Gm./Kg. for rabbits. Mice are more sensitive to propylene glycol (92) and have a lower toleration for this solvent. The LD_{50} for mice by intraperitoneal injection was found to be 9.7 Gm./Kg. (92). The subcutaneous and intravenous LD_{50} for mice was reported to be 18.5 Gm./Kg. and 8.0 mg./Kg., respectively (44). The action of propylene glycol on the central nervous system in dogs is similar to that of ethyl alcohol; however, its activity is about one-third that of ethyl alcohol (93).

Brittain and D'Arcy (94) reported that intravenous injections of propylene glycol in saline solution up to 50% in rabbits had no effect on the red blood cell count, packed cell volume, hemoglobin, or total white blood cell count. There was, however, an increase in the number of circulating polymorphs and a decrease in the lymphocytes. Blood clotting time was markedly decreased.

Heine, *et al.* (95), have given several formulas illustrating the use of propylene glycol in the preparation of barbiturate solutions for intramuscular or intravenous use

Sterile Solution of Sodium Pentobarbital 0.150 Gm./ml.	
Sodium pentobarbital	15.0 Gm.
Benzyl alcohol	2.0 ml.
Propylene glycol	60.0 ml.
Water for injection, to make	100.0 ml.

Sterile Solution of Sodium Amobarbital 0.250 Gm./ml.	
Sodium amobarbital	25.0 Gm.
Benzyl alcohol	2.0 ml.
Propylene glycol	60.0 ml.
Water for injection, to make	100.0 ml.

Sterile Solution of Sodium Phenobarbital 0.150 Gm./ml.	
Sodium phenobarbital	15.0 Gm.
Benzyl alcohol	2.0 ml.
Propylene glycol	60.0 ml.
Water for injection, to make	100.0 ml.

Brass (96) prepared a quinidine formulation for intramuscular use composed of 10.0 Gm. of quinidine hydrochloride and 75.0 ml. of propylene glycol. This solution showed no signs of discoloration or crystallization over a period of 6 months. When injected in man, the evidence of the action of quinidine is detectable in 15 minutes and persists for approximately 2 hours.

Gluck, *et al.* (97), tested a 20% solution of quinidine sulfate in propylene glycol for its local irritant effects by intramuscular injection and for its action on the auricle in auricular fibrillation and flutter. The results indicated negligible local reaction and a dose response similar to that obtained with oral administration—peak effect being reached in an average of about 3 hours, about half of the effect wearing off in about 8 hours, and the effect disappearing completely in 24 hours or less.

The use of propylene glycol as a vehicle for the intravenous administration of desoxycorticosterone acetate in a concentration of 10 mg./ml. has been discussed by McGavack and Vogel (98). Since this compound crystallizes out when diluted with water, a technique is reported whereby the preparation is injected slowly, not to exceed a rate of 2.5 ml. per minute. This assures its rapid dilution and prevents the formation of any acicular precipitate.

Ganz and co-workers (99) have studied the intramuscular administration of digoxin in 40% propylene glycol and 10% ethanol in patients with auricular fibrillation and reported satisfactory results.

The comprehensive use of propylene glycol is reviewed in articles by Parisi (100), Gialdi and Baruffini (101), Brown (102), and Heine, *et al.* (95).

Gershenfeld and Witlin (103) investigated the use of propylene glycol as a solvent for iodine and suggested that iodine 2% and sodium iodide 2.4% in distilled water containing 25 to 50% propylene glycol would be a suitable formula.

Linde (65) reported that the stability of barbiturates dissolved in pure or diluted propylene glycol was satisfactory.

Peterson and Hopponen (104) determined the solubility of phenobarbital in propylene glycol–alcohol-water systems. The solubility reached a maximum at a 50% mixture of propylene glycol and alcohol. Propylene glycol, 100%, dissolves more phenobarbital than 100% alcohol. Upon addition of water to the solvents, the solubility falls off more quickly with propylene glycol than with alcohol.

Propylene glycol was found to potentiate the preservative action of the parabens (105). Mehta and Drommond (106) determined the stability of various medicaments in propylene glycol after storage at 25°.

Marcus and Taraszka (107) reported that the specific hydrogen ion–catalyzed degradation of chloramphenicol in solutions containing up to 50% (v/v) of propylene glycol was qualitatively similar to degradation in purely aqueous systems. The reactions remain pseudo-first order with respect to chloramphenicol and the direct dependence of the rate upon acid concentration is maintained. Their results show that it is unwise to assume that replacement of all or a portion of the water in a vehicle will always enhance the stability of the active ingredient.

Huttenrauch (108) has shown that propylene glycol enhances the stability of L-ascorbic acid in tests run for 120 weeks at room temperature.

Weinstein, *et al.* (109), reported that oxytetracycline intramuscular solution in propylene glycol was well tolerated and produced prompt, prolonged, satisfactory blood levels. A 250 mg./-2 ml. oxytetracycline intramuscular formula would be

Oxytetracycline	250 mg.
Lidocaine	2%
Magnesium chloride, hexahydrate	6%
Sodium formaldehyde sulfoxylate	0.5%
Ethanolamine	4.2%
Propylene glycol	67%
Water	16.8%

This formula is stable for 2 years at room temperature. Without the use of propylene glycol, the stability is of 2-day duration only.

Hanson (110) compared the amount of tissue reaction produced by subcutaneous and intramuscular injections of a number of parenteral preparations of broad-spectrum antibiotics. The smallest amount of tissue reaction was produced by propylene glycol solutions of oxytetracycline.

1,3-BUTYLENE GLYCOL

1,3-Butylene glycol, 1,3-butanediol, is a colorless, viscous liquid having a specific gravity of 1.005, a boiling point of 204°, and is soluble in water and alcohol (111). It is possible to modify the effect of drugs by choosing the proper solubilizing agent. In this manner, we can cause an increase or decrease in the effect of a drug. Bornmann, *et al.* (112), demonstrated that 1,3-butylene glycol can prevent the toxic reactions of pentamethylenetetrazol. It was also shown that the action of morphine hydrochloride, meperidine hydrochloride, and methadone hydrochloride in 1,3-butylene glycol, as compared to aqueous solutions, gave stronger and more prolonged effects

in a shorter time. Thus, by the use of this solvent, the dose may be lowered and undesirable side effects eliminated.

Bornmann and Loeser (113) reported on the use of propylene glycol and 1,3-butylene glycol as solvents for meprobamate. The 1,3-butylene glycol preparation was found to be slightly more toxic than the propylene glycol product, but both were suitable as solvents for the drug.

Bornmann (114–116) in his review of glycol toxicity, stated that 1,3-butylene glycol had a slight acute as well as a slight chronic toxicity. The LD_{50} subcutaneously in mice is 16.51 ml./-Kg. and in rats is 20.06 ml./Kg.

SUMMARY

A large number of organic solvents are currently available to the pharmaceutical formulator The three most commonly used nonaqueous solvents are fixed oils, propylene glycol, and the polyethylene glycols. The remaining solvents discussed are of minor importance and are used only in specific instances.

The use of nonaqueous solvents in parenteral products offers greater latitude in the formulation of new dosage forms. Such solvents, however, should be used only if a definite need is established. It must be recognized that any formulation containing a nonaqueous solvent is potentially a new entity and must be adequately tested.

Nonclassical Antimetabolites XII

Bridge Principle of Specificity with Exo-Alkylating Irreversible Inhibitors V. Differences in Specificity of Enzymic Nucleophilic Sites as Detected by the Carbophenoxy Group

By B. R. BAKER and R. P. PATEL

Investigation of four carbophenoxyamino derivatives of salicylic acid and oxanilic acid has shown that all four reversibly bind to lactic dehydrogenase (LDH) and glutamic dehydrogenase (GDH). Three of these compounds showed irreversible inhibition of GDH with no irreversible effect on LDH. Since 4-(iodoacetamido)-salicylic acid had previously been shown to inhibit both enzymes irreversibly, the specificity shown by the carbophenoxyamino group is attributed to its specificity for reaction only with a primary amino group in the nucleophilic site of an enzyme.

RELATIVELY LARGE molecules—compared to the substrate—have been found that can inhibit an enzyme and have accordingly been called nonclassical antimetabolites (3, 4), in contrast to classical antimetabolites that have only a small change in structure compared to the substrate. Based on the nonclassical antimetabolite theory, it was possible to propose the concept of irreversible inhibition by an exo-alkylation mechanism (3); a properly designed inhibitor such as 4-(iodoacetamido)salicylic acid can reversibly complex with glutamic dehydrogenase (GDH),[1] then become irreversibly bound within the complex by alkylation of the enzyme adjacent to the active site. Strong experimental evidence to support this exo-alkylation phenomenon has been presented (5, 6).

Experimental observations pertinent to the exo-alkylation phenomenon were subsequently

and independently made in two other laboratories. Lawson and Schramm (7) observed that the *p*-nitrophenyl ester of N-bromoacetyl-L-α-aminobutyric acid rapidly released *p*-nitrophenol when allowed to react with chymotrypsin; the resultant bromoacetyl-L-α-aminobutyryl derivative of chymotrypsin (presumably bound by an ester link to a serine residue) underwent intramolecular alkylation between the bromoacetyl group and one of the two methionine residues in chymotrypsin. Wofsy, Metzger, and Singer (8) have made related observations in the area of hapten immunochemistry.

In our detailed version of the experimental evidence for the exo-alkylation phenomenon (6), the bridge hypothesis of specificity was proposed. Compared to a reversible inhibitor, "the exo-alkylating type of irreversible inhibitor can have an extra dimension of specificity; this extra specificity is dependent upon the ability of the reversibly bound inhibitor to bridge to and alkylate a nucleophilic group on the enzyme surface and upon the nucleophilicity of the enzymic group being alkylated."

Recently we presented experimental evidence (9, 10) for the first corollary of the bridge hypothesis of specificity; that is, the difference in ability of certain inhibitors to bridge to and alkylate an enzymic nucleophilic site which merited raising the status of the hypothesis to principle. Evidence has now been found to support the second corollary of the bridge hypothesis —namely, the difference in nucleophilicity of the enzymic group being alkylated; this evidence is the subject of this paper.

MATERIALS AND METHODS

Reagents.—Sodium pyruvate, α-ketoglutaric acid, DPNH, LDH, and GDH were purchased from Nutritional Biochemical Corporation and from Sigma Chemical Co.; LDH was the crystalline enzyme isolated from rabbit muscle and GDH the crystalline enzyme isolated from mammalian liver.

Reversible Binding of Inhibitors to Enzymes (I_{50}).—The I_{50} is defined as the millimolar concentration of inhibitor necessary to give 50% inhibition in the presence of 1 m*M* concentration of the substrate (4). The procedure employed for LDH was the same as previously described, except that Tris buffer (pH 7.4) and 1 m*M* pyruvate were employed; the I_{50} values for GDH were determined in the same fashion as for LDH using cell concentrations of 1 m*M* α-ketoglutarate and 75 m*M* ammonium sulfate in Tris buffer (pH 7.4).

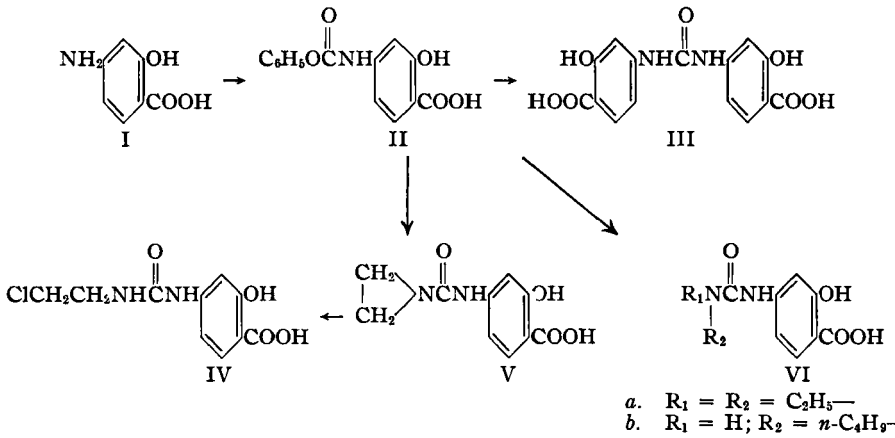
Enzyme Inactivation Procedure.—The LDH inactivation procedure (6), as later modified (10) was employed. The GDH incubations were run as previously described (6). In all incubations for determination of irreversible inhibition, three incubation solutions were run simultaneously and were made from the same master enzyme-DPNH solution (6): (*a*) a 2 m*M* concentration of test compound, (*b*) a standard with 2 m*M* 4-ISA, and (*c*) an enzyme control with no inhibitor. All runs were duplicated at least twice. An occasional bad run was readily eliminated if the control or standard did not behave properly.

The rate saturation experiments were run similarly, except that (*b*) was either a 1 m*M* solution or a 4 m*M* solution of the test compound depending upon the extent of reversible binding of inhibitor by the enzyme, that is, the I_{50}. Considerable care must be taken in making up solutions of the carbophenoxy compounds (Table II) so that the base labile phenyl ester group did not hydrolyze. Usually, 6 m*M* master solutions were made by stirring in Tris buffer at 0° with the gradual addition of 1 *N* sodium hydroxide to keep the pH at 7.4, but care was taken that the pH did not rise above 7.4; several hours were usually required to obtain complete solution. A 12.2 m*M* solution of the standard, 4-ISA, in pH 7.4 Tris buffer was stable for several weeks at 2–5°, as determined by the thiosulfate titration of covalently bound iodine (6). However, the carbophenoxy compounds as 6 m*M* solutions in Tris buffer (pH 7.4) were 25–30% hydrolyzed after 24 hours at 5° (determined spectrophotometrically) and thus were prepared fresh for each incubation.

CHEMISTRY

The synthesis of phenylurethanes and their further reaction with amines to give mixed ureas has been described by Crosby and Niemann (11). When 4-aminosalicylic acid (I) in aqueous sodium bicarbonate was treated under the usual conditions used for reaction with acid chlorides (12), 4-(carbophenoxyamino)salicylic acid (II) was obtained in low and variable yields and considerable amounts of the symmetrical urea (III) were formed.

The usual conditions (12) of dropwise addition of the acid chloride to a solution of I in aqueous sodium bicarbonate at near 0° were unsatisfactory because the initially formed product (II) in the alkaline solution could further react with as yet unreacted 4-aminosalicylic acid (I) to give the symmetrical urea (III). With amines soluble in an organic solvent, Crosby and Niemann (11) avoided this difficulty by reverse addition of the amine to the acid chloride; since the chloro group is more reactive than the phenoxy group, good yields of O-phenylurethanes could be obtained. Such a method would be incompatible with the aqueous alkaline method, since the acid chloride would merely undergo hydrolysis if insufficient amine were present. This enigma was resolved by adding the phenyl chloroformate all at once to the cold solution of I in aqueous sodium bicarbonate; this was possible since the chloroformate reacted slowly enough that the temperature was capable of being controlled. However, it is essential to have sufficiently vigorous stirring in this reaction to emulsify the acid chloride; magnetic stirring was insufficient and allowed the product (II) in solution to compete favorably for the 4-aminosalicylic acid (I), resulting in large amounts of the urea III being formed. The presence of the carbophenoxy group in II was readily determined by its distinctive "active ester" carbonyl at 1720 cm.$^{-1}$ in the in-



a. $R_1 = R_2 = C_2H_5$—
b. $R_1 = H$; $R_2 = n\text{-}C_4H_9$—

frared. The urea III, of course, did not show carbonyl absorption at higher frequency than that of the carboxyl at 1640 cm.$^{-1}$ Mixtures of II and III obtained in the earlier runs were readily separated by the high solubility of II, but relative insolubility of the urea III, in ethanol.

All other compounds could be prepared by this method, except 4-(carbophenoxyglycylamino)salicylic acid. In the latter case, sodium bicarbonate was not strong enough to remove the proton from the zwitterion structure of 4-(glycylamino)salicylic acid and it was necessary to use aqueous sodium hydroxide. If too much base was employed, the carbophenoxy group suffered cleavage, thus leading to unchanged amino acid; in addition, a shortened contact time with the aqueous base was advantageous.

To study carbophenoxy compounds such as II as potential irreversible inhibitors of LDH or GDH it was necessary to determine the stability of II in Tris buffer at pH 7.4 and 37°. Two possible reactions could take place, leading to one of three products. First, the phenoxy group might be displaced by the tris-(hydroxymethyl)aminomethane to give a mixed urea of type VI. Second, hydrolysis to *p*-aminosalicylic acid (I) might occur; the latter then might react with unchanged II to give the symmetrical urea III. To follow the course of this decomposition reaction, a model compound (VI*b*) was prepared in excellent yield by reaction of the carbophenoxy salicylic acid (II) with excess *n*-butylamine in dimethylformamide by short heating on a steam bath.

Table I lists the ultraviolet absorption spectra of the compounds involved in the decomposition of the carbophenoxy group of II. Although there was little difference in the position of the two peaks, the ϵ ratio of these two peaks was considerably higher in compound II than in the others; thus by following the change in the ϵ ratios it was possible to check the stability of II.

TABLE I.—RELATIVE ULTRAVIOLET PEAK RATIOS OF SUBSTITUTED 4-AMINOSALICYLIC ACIDS IN TRIS BUFFER (pH 7.4)

Compd.	Peak I, mμ (ϵ)	Peak II, mμ (ϵ)	ϵ Ratio of Peak I to Peak II
I	267 (13,000)	300 (8600)	1.51
II	264 (20,000)	300 (7750)	2.60
VI*b*	268 (20,800)	300 (10,000)	2.08

In 1% aqueous sodium bicarbonate (pH 8.4) at 37°, the ϵ ratio rapidly dropped from 2.60 to 1.75 in 15 minutes and 1.57 in 45 minutes; after 24 hours at 37°, the ϵ ratio was 1.50, the same as *p*-aminosalicylic acid (I). It is highly probable that at the high dilution this experiment is run (0.55 m*M*), hydrolysis to I occurs rather than urea III formation.

In Tris buffer (pH 7.4) at 37°, II was considerably more stable. In 1 hour, the ϵ ratio dropped from 2.60 to 2.42; after 24 hours at 37°, the ϵ ratio was 2.01. The latter number is probably within experimental error for formation of a mixed urea such as VI with the Tris; it is unlikely that hydrolysis to I (ratio of 1.51) took place since a greater change in ϵ ratio from 1 hour to 24 hours should have taken place. In either case, it is clear that the maximum decomposition that could occur in 1 hour in the Tris buffer (the length of the enzyme incubation period) was about 34% if the mixed urea VI with Tris was formed and less if I was formed.

The ease with which the phenoxy (II) could be converted to a mixed N-*n*-butyl-urea (VI*b*) with *n*-butylamine suggested that the synthesis of the mixed urea V with aziridine be attempted, since V could be a potentially useful irreversible inhibitor. When II was reacted with 3–4 equivalents of aziridine in dimethylformamide at about 90°, these conditions employed for preparation of VI*b* led to polymeric materials. That diethylamine could react smoothly with II to give a mixed urea (VI*a*) showed that a secondary amine could be used for this reaction. When a solution of II in dimethylformamide containing two equivalents of triethylamine was allowed to react with one equivalent of aziridine at room temperature, then the reaction mixture poured into dilute hydrochloric acid, slow separation of the chloroethyl urea IV took place over several days. That IV could be isolated certainly indicated the aziridinyl urea V had been formed. However, attempts to isolate V directly when the reaction was run or worked up under a variety of conditions proved to be fruitless, even though mixed ureas of aziridine have been previously prepared by the carbophenoxy route (13).

4-(Carbophenoxyamino)salicylic Acid (II).—A solution of 5.0 Gm. (32.6 mmoles) of 4-aminosalicylic acid in 130 ml. of water containing 11 Gm. of sodium bicarbonate was cooled to 3° in an ice bath. Then 7.55 Gm. (48 mmoles) of phenyl chloroformate

was added in one portion; the mixture was vigorously stirred with a mechanical paddle stirrer for 3 hours. During this time, the temperature stayed between 3–8°; some of the sodium salt of the product separated from solution. The solid sodium salt was collected on a filter and the filtrate was acidified to about pH 2 with 3 *N* hydrochloric acid. The product was collected on a filter, washed with water, and dried.

The insoluble sodium salt was quickly dissolved in 200 ml. of water preheated to about 75°, then filtered. The filtrate was immediately acidified with 3 *N* hydrochloric acid. The separated product was combined with the first fraction and recrystallized from aqueous ethanol; yield, 7.9 Gm. (89%) of pure material, m.p. 215–217°; $\nu_{max.}^{KBr}$ 3340 (NH); 1720 (urethane C=O); 1637 cm.$^{-1}$ (carboxyl C=O); $\lambda_{max.}^{EtOH}$ 264 (ϵ 25,000), 302 mμ (ϵ 9,800).

Anal.—Calcd. for $C_{14}H_{11}NO_5$: C, 61.5; H, 4.02; N, 5.12. Found: C, 61.3; H, 4.06; N, 5.26.

5-(Carbophenoxyamino)salicylic Acid.—This compound was prepared from 5-aminosalicylic acid hydrochloride in the same manner as described for II. Recrystallization from alcohol-water gave 7.0 Gm. (97%) of product as nearly white crystals, m.p. 264–275° dec.; $\lambda_{max.}^{EtOH}$ 221 (ϵ 41,200), 246 (ϵ 16,900), 325 mμ (ϵ 3,800); $\nu_{max.}^{KBr}$ 3310(NH); 1705 (urethane C=O); 1620 cm.$^{-1}$ (carboxyl C=O).

Anal.—Calcd. for $C_{14}H_{11}NO_5$: C, 61.5; H, 4.02; N, 5.12. Found: C, 61.3; H, 3.78; N, 5.31.

m-(Carbophenoxyamino)oxanilic Acid.—From 5 Gm. of *m*-aminooxanilic acid (14) and 5.9 Gm. of phenyl chloroformate, as described for the preparation of II, a 4.5-Gm. (59%) quantity of product was obtained. Recrystallization from chloroform afforded white crystals, m.p. 182–183°; $\lambda_{max.}^{EtOH}$ 237 mμ (ϵ 35,900); $\nu_{max.}^{KBr}$ 3310 (NH); 1760 (urethane C=O); 1710 (carboxyl C=O); 1680 cm.$^{-1}$ (amide C=O).

Anal.—Calcd. for $C_{15}H_{12}N_2O_5$: C, 60.0; H, 4.00; N, 9.33. Found: C, 59.9; H, 4.16; N, 9.29.

4-(Carbophenoxyglycylamino)salicylic Acid.—A solution of 1.00 Gm. (4.76 mmoles) of 4-(glycylamino)salicylic acid (12, 15) in 40 ml. of 0.25 *N* sodium hydroxide was cooled in an ice bath. When the temperature reached 3°, 1.14 Gm. (7.14 mmoles) of phenyl chloroformate was added in one portion. The mixture was rapidly mixed in with a mechanical paddle stirrer with continued ice bath cooling for 90 minutes. The cold solution was filtered through a Celite pad and the filtrate immediately acidified with 3 *N* hydrochloric acid. The product was collected on a filter and washed with water; yield, 0.70 Gm. (45%), m.p. 236–238°. Recrystallization from ethyl acetate gave white crystals, m.p. 242–243°; $\nu_{max.}^{KBr}$ 3400 (NH); 1720 (sh.) (urethane C=O); 1640 (carboxyl C=O); 1680 (amide C=O); 732, 690 cm.$^{-1}$ (monosubstituted phenyl). Longer reaction times or more base gave lower yields.

Anal.—Calcd. for $C_{16}H_{14}N_2O_6$: C, 58.2; H, 4.24; N, 8.48. Found: C, 58.1; H, 4.44; N, 8.29.

N - n - Butyl - N′ - (3 - hydroxy - 4 - carboxyphenyl)urea (VI*b*).—To a solution of 1.00 Gm. (3.66 mmoles) of 4-(carbophenoxyamino)salicylic acid (II) in 10 ml. of dimethylformamide was added 0.80 Gm. (11 mmoles) of *n*-butylamine. After being heated on a steam bath for 1 hour protected from moisture, the solution was diluted with 40 ml. of water and acidified to about pH 3 with 3 *N* hydrochloric acid. The product was collected on a filter and washed with water. Recrystallization from dilute alcohol gave 0.80 Gm. (95%) of white crystals, m.p. 205–206°; $\nu_{max.}^{KBr}$ 3325 (NH), 1650 (urea and carboxyl C=O); and no urethane C=O near 1720 cm.$^{-1}$; $\lambda_{max.}^{EtOH}$ 274 (19,800), 302 mμ (ϵ 12,300).

Anal.—Calcd. for $C_{12}H_{16}N_2O_4$: C, 57.1; H, 6.34; N, 11.1. Found: C, 57.5; H, 6.57; N, 11.3.

N,N - Diethyl - N′ - (3 - hydroxy - 4 - carboxyphenyl)urea (VI*a*).—This was prepared in the same manner as described for VI*b* using diethylamine; yield, 0.90 Gm. (98%). Recrystallization from dilute alcohol gave white crystals, m.p. 161–162°; $\nu_{max.}^{KBr}$ 3450 (NH); 1640 (urea and carboxyl C=O); and no urethane C=O near 1720 cm.$^{-1}$; $\lambda_{max.}^{EtOH}$ 273 (ϵ 19,400), 304 mμ (ϵ 23,500).

Anal.—Calcd. for $C_{12}H_{16}N_2O_4$: C, 57.1; H, 6.34; N, 11.1. Found: C, 57.1; H, 6.35; N, 10.8.

N - (2 - Chloroethyl) - N′ - (3 - hydroxy - 4 - carboxyphenyl)urea (IV).—To a solution of 1.00 Gm. (3.66 mmoles) of 4-(carbophenoxyamino)salicylic acid (II) and 1.02 ml. (7.32 mmoles) of triethylamine in 10 ml. of dimethylformamide a 0.188-ml.

RESULTS

Comparisons of the reversible and irreversible inhibition of LDH and GDH by the four carbophenoxy derivatives are listed in Table II. All four compounds were good to excellent reversible inhibitors of both enzymes. Three of the four compounds, 5-(carbophenoxyamino)salicylic acid (VII), 4-(carbophenoxyglycylamino)salicylic acid (VIII), and *m*-(carbophenoxyamino)oxanilic acid (IX) inactivated GDH even more rapidly than the standard compound, 4-(iodoacetamido)salicylic acid; in contrast, none of these three compounds showed inactivation of LDH. These three compounds also showed a rate saturation in inactivation of GDH.

The theoretical rate saturations values can be calculated in the following manner if the rate of inactivation is dependent upon the concentration of reversible complex, *EI*, formed in Eq. 1.

$$E + I \longleftrightarrow EI \qquad \text{(Eq. 1)}$$

where E is the free enzyme concentration, I is the inhibitor concentration and EI is the concentration of enzyme-inhibitor reversible complex.

$$K_I = \frac{[E]\,[I]}{[EI]} \qquad \text{(Eq. 2)}$$

$$E_t = [E] + [EI] \qquad \text{(Eq. 3)}$$

where E_t = the total enzyme concentration excluding that portion of the enzyme that has become inactivated.

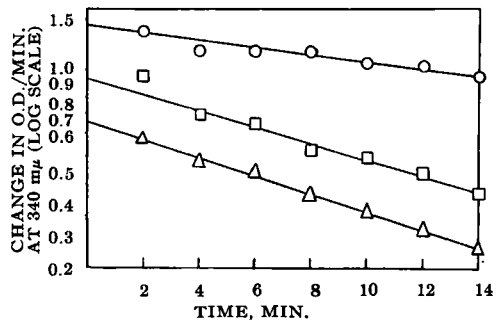

Fig. 3.—Rate saturation effect during inactivation of GDH·DPNH by 5-(carbophenoxyamino)salicylic acid (VII). Key: O, GDH·DPNH control; □, 1 m*M* VII; △, 2 m*M* VII.

Substituting Eq. 3 in Eq. 2 gives Eq. 4

$$[EI] = \frac{[E_t]}{\frac{K_I}{[I]} + 1} \qquad \text{(Eq. 4)}$$

Similarly, Eq. 5 can be derived (16) where S = the substrate concentration and ES = the concentration of enzyme-substrate complex and Km = the substrate-enzyme dissociation constant

$$[ES] = \frac{E_t}{\frac{Km}{[S]} + 1} \qquad \text{(Eq. 5)}$$

When $[ES] = [EI]$, 50% inhibition will be obtained, the I_{50}. Thus, equating Eqs. 4 and 5 gives Eq. 6

$$K_I = \frac{Km[I]}{[S]} = Km \times I_{50} \qquad \text{(Eq. 6)}$$

Since $Km = 2.5 \times 10^{-4}$ for α-oxoglutarate on GDH has previously been determined (6), the K_I for any of the compounds in Table II can be calculated. Thus, from Eq. 6 and an I_{50} of 1.6, 5-(carbophenoxyamino)salicylic acid (VII) has $K_I = 4 \times 10^{-4}$. Then when $[I] = 2$, Eq. 4 gives $[EI] = 0.83\,[E_t]$ and when $[I] = 1$, $EI = 0.71\,[E_t]$. An increase in $[I]$ from 1 m*M* to 2 m*M* should increase $[EI]$ by 0.83/0.71 or 1.17-fold. Therefore, the ratio of rates of inactivation should be 1.17 if the inactivation is

dependent upon initial reversible complex at the active site (exo-alkylation) and should be 2.0 if the inactivation were due to a random bimolecular collision between inhibitor and enzyme (tail-alkylation).

Other rate saturation ratios calculated similarly are listed in Table II. In the case of compound VIII, where the I_{50} value is greater than five it is better to use a 4/2 ratio to show rate saturation, rather than the standard 2/1 ratio. It is clear that compounds VII, VIII, and IX (Table II) inactivate GDH with rate saturation in agreement with the prediction for the exo-alkylation mechanism.

Not all carbophenoxy compounds showed inactivation of GDH, as the bridge principle would predict. Thus, 4-(carbophenoxyamino)salicylic acid (II) showed no irreversible inhibition of GDH in four runs. Irreversible inhibition of LDH at a slightly slower rate than the standard 4-ISA was shown by II; since II did not show a rate saturation effect, this irreversible inactivation of LDH by II is by some mechanism different than the exo-alkylation mechanism. (See *Discussion*.)

To conserve space, only three of the many inactivation runs listed in Table II are shown. Figure 1 shows the inactivation of GDH by 5-(carbophenoxyamino)salicylic acid (VII) and Fig. 2 shows the lack of inactivation of LDH by VII. A rate saturation effect in the inactivation of GDH by VII is shown in Fig. 3.

DISCUSSION

In seeking evidence for the exo-alkylation phenomenon (3), we deliberately chose the experimental design of an alkylating group with low specificity; in this way, the chances were increased that the alkylating group could covalently link with some enzymic nucleophilic site adjacent to the active site after a reversible complex had been formed at the active site. A group with the desired low specificity was the iodoacetyl group; strong experimental evidence was obtained (5, 6) that 4-(iodoacetamido)-salicylic acid inactivated both LDH and GDH by the exo-alkylation mechanism. It was then proposed (6) that the ability of the alkylating group to bind covalently with an enzymic nucleophilic site was dependent both on the ability of the bound inhibitor to bridge to the nucleophilic group and upon the nucleophilicity of the enzymic site being alkylated. Such an hypothesis, if true, could give an extra magnitude of specificity not possible with reversible inhibitors.

Specificity with the iodoacetyl group was obtained by influencing the bridging (9, 10), even though the iodoacetyl group has little functional specificity. Of some 15 amino acids in proteins containing a third functional group, about one-half have the nucleophilic capacity to react with the iodoacetyl group to form a covalent bond. In contrast, the carbophenoxy group of a molecule such as 5-(carbophenoxyamino)salicylic acid (VII), has complete functional specificity; that is, it will react only with a primary amino group on a protein; neither the indole-NH of tryptophane or the imidazole-NH of histidine will react with phenyl esters (17). Although no information concerning the reaction of phenyl esters with the guanidino group of arginine could be found, the guanidino group is not a probable site since it would be fully protonated at pH 7.4. Thus, the most likely nucleophilic site of a protein that could bind covalently with the carbophenoxy group by exo-alkylation would be the ϵ-amino group of a lysine and, less likely, a terminal α-amino group.[2]

All four carbophenoxy compounds listed in Table II were good to excellent reversible inhibitors of LDH and GDH. Of these, three (VII–IX) irreversibly inactivated GDH but had no inactivation effect on LDH; it is highly probable that these three compounds inactivated GDH by the exo-alkylation mechanism since all three showed the rate saturation effect indicating that a reversible complex between GDH and the inhibitor was an obligatory intermediate to inactivation. Although it would appear that the inactivity of II is because of the inability of the urethane group of 4-(carbophenoxyamino)salicylic acid (II) to reach the enzymic amino group for covalent bond formation, it is also possible that the enzyme hinders the relatively large phenyl group from assuming the transition state necessary for covalent bond formation.

The fact that GDH is attacked by either the carbophenoxy group of VII–IX or by the iodoacetyl group of 4- or 5-(iodoacetamido)salicylic acid (6) indicates that within the reversible enzyme-inhibitor complex an amino group on the enzyme can be bridged for covalent bond formation; however, it cannot necessarily be concluded that the amino group on GDH covalently bound by VII–IX is the same group that is covalently bound by the (iodoacetamido)salicylic acids, even though it is possible for these two nucleophilic groups to be one and the same.

Conversely, it can be concluded that VII, VIII, and IX cannot bridge to an available amino group on LDH. It might have been expected that 4-(carbophenoxyglycylamino)salicylic acid (VIII), with its relatively long bridging ability, should have been able to form a covalent bond with an amino group on LDH; however, it is also possible that hindrance interaction between the enzyme and the phenyl group prevented the formation of the proper transition state. If a carbophenoxy compound is ultimately found that can irreversibly inhibit two enzymes, it would be of interest to see if specificity could be achieved by placing bulky groups on the phenoxy radical for selective hindrance of the transitional state.

Although 4-(carbophenoxyamino)salicylic acid (II) inactivated LDH almost as rapidly as the standard, 4-ISA, it is clear that this inactivation did not proceed by the exo-alkylation mechanism since no rate saturation effect was obtained. Several obvious explanations are readily eliminated: (*a*) the inactivation is not by the tail-alkylation mechanism, or VII, VIII, and IX should also have inactivated LDH by this bimolecular process; (*b*) it is highly unlikely that some extraneous impurity caused this effect, since two different samples prepared at 6-month intervals showed the same effect.

---

[2] As pointed out by a referee, the carbophenoxy group is an acylating group and not an alkylating group. At the time that the first evidence for the exo-alkylation phenomenon was presented (5), an acylation reaction of this type was unforeseen. We have used "exo-alkylation" as equivalent to "covalent bond formation—adjacent to the binding site—within the enzyme-inhibitor reversible complex." It is apparent that the latter general expression was intended and that perhaps the word "exo-alkylation" should be literally limited to covalent bond formation by alkylation.

A possible explanation is that 4-(carbophenoxyamino)salicylic acid (II) can bind weakly to some site other than the active site, then form a covalent link that makes the active site inaccessible to the substrate; such reversible binding to an extraneous site would have to have a dissociation constant larger than 10^{-2} to show the lack of a rate saturation effect within experimental error. The fact that one compound does not show a rate saturation effect actually strengthens the interpretation that those compounds showing a rate saturation effect might operate by the exo-alkylation mechanism.

Although no compound in Table II inactivated LDH selectively by the exo-alkylation mechanism, it is probable that such a compound could be found by further investigation.

Of importance to chemotherapy is the irreversible specificity noted with the phenyl esters (VII–IX), this specificity being because of the difference in the nucleophilic character of the enzymic groups being covalently bound on LDH and GDH. Groups on a reversible inhibitor that can bridge to and specifically bind other enzymic functional groups would be of use in both chemotherapy and protein structure studies; such a study is continuing in these laboratories.

Nonclassical Antimetabolites XIII

Simulation of the 5′-Phosphoribosyl Moiety of 5′-Adenylic Acid at the Enzyme Level by ω-Carboxyalkyl and Aralkyl Groups Attached to Adenine

By B. R. BAKER and H. S. SACHDEV

5′-Adenylic acid can inhibit both lactic dehydrogenase and glutamic dehydrogenase; since both the phosphate and adenine moieties are necessary for good inhibition, the 5′-adenylic acid presumably competes with DPN. This inhibition by 5′-adenylic acid can be duplicated by 9-(4′-carboxybutyl)-adenine (XVIII) on both enzymes, indicating that the ω-valeric acid side chain can simulate the binding of the 5-phosphoribosyl group when the latter is attached to adenine. 9-(*para*-Carboxybenzyl)-adenine (XVI), a compound with a conformation-fixed side chain, can simulate the binding of 5′-adenylic acid to glutamic dehydrogenase but not lactic dehydrogenase; this difference has been attributed to the difference in conformation of 5′-adenylic acid (and DPN) when bound to the two enzymes.

MANY IMPORTANT ENZYMES have substrates bearing the 5-phosphoribosyl moiety such as the ribotides involved in nucleic acid biosynthesis. A number of purines and pyrimidines useful in cancer chemotherapy operate by enzymic blockade at the nucleotide level (2). For example, 5-fluorouracil is converted intracellularly to 5-fluorouracil deoxyribotide; the latter inhibits cell growth by blockade of thymidylate synthetase (3, 4). Similarly, in the cell 6-mercaptopurine (I) is converted by inosinic pyrophosphorylase to 6-mercaptopurine ribotide (II) (5, 6). The latter compound is a potent inhibitor for inosinic dehydrogenase, the enzyme converting inosinic acid (IV) to xanthylic acid (V); at a somewhat higher concentration, II also inhibits adenylosuccinate synthetase, the enzyme forming adenylosuccinate (III) from inosinic acid (IV) (7, 8).

Simulation of the 5′-Phosphoribosyl Moiety of 5′-Adenylic Acid at the Enzyme Level by ω-Carboxyalkyl and Aralkyl Groups Attached to Adenine

By B. R. BAKER and H. S. SACHDEV

5′-Adenylic acid can inhibit both lactic dehydrogenase and glutamic dehydrogenase; since both the phosphate and adenine moieties are necessary for good inhibition, the 5′-adenylic acid presumably competes with DPN. This inhibition by 5′-adenylic acid can be duplicated by 9-(4′-carboxybutyl)-adenine (XVIII) on both enzymes, indicating that the ω-valeric acid side chain can simulate the binding of the 5-phosphoribosyl group when the latter is attached to adenine. 9-(*para*-Carboxybenzyl)-adenine (XVI), a compound with a conformation-fixed side chain, can simulate the binding of 5′-adenylic acid to glutamic dehydrogenase but not lactic dehydrogenase; this difference has been attributed to the difference in conformation of 5′-adenylic acid (and DPN) when bound to the two enzymes.

MANY IMPORTANT ENZYMES have substrates bearing the 5-phosphoribosyl moiety such as the ribotides involved in nucleic acid biosynthesis. A number of purines and pyrimidines useful in cancer chemotherapy operate by enzymic blockade at the nucleotide level (2). For example, 5-fluorouracil is converted intracellularly to 5-fluorouracil deoxyribotide; the latter inhibits cell growth by blockade of thymidylate synthetase (3, 4). Similarly, in the cell 6-mercaptopurine (I) is converted by inosinic pyrophosphorylase to 6-mercaptopurine ribotide (II) (5, 6). The latter compound is a potent inhibitor for inosinic dehydrogenase, the enzyme converting inosinic acid (IV) to xanthylic acid (V); at a somewhat higher concentration, II also inhibits adenylosuccinate synthetase, the enzyme forming adenylosuccinate (III) from inosinic acid (IV) (7, 8).

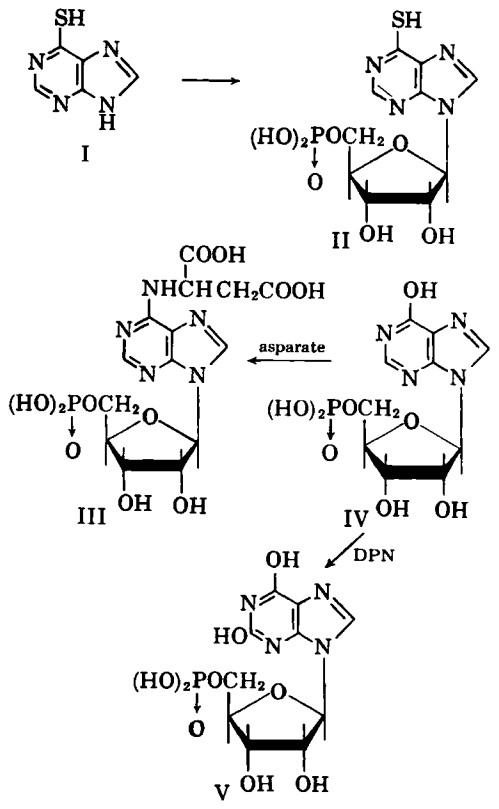
The authors are grateful to Dorothy Ackerman and Maureen Vince for their excellent technical assistance. We also thank the Cancer Chemotherapy National Service Center, National Cancer Institute, and Starks Associates, Inc., for synthesis of additional quantities of inhibitors mediated by Contract No. SA-43-ph-4346.

Unfortunately, cancer cells all too soon become resistant to the effects of 6-mercaptopurine (I) because of the mutational loss of the inosinic pyrophosphorylase that converts I and hypoxanthine to their ribonucleotides, II and IV (5, 8). Although 6-mercaptopurine ribotide (II) is still effective as an inhibitor of the enzymes utilizing inosinic acid (IV) in a cell-free extract of resistant cell lines (7), II has little effect on the intact resistant cells (7, 9, 10). This lack of activity probably is because 6-mercaptopurine ribonucleotide (II), like natural nucleotides (11), suffers enzymic cleavage back to the corresponding base (I) during entrance into the cell by active transport.

One approach to the solution of the enigma of this resistance problem has been to block completely the phosphate group of II as a triester (12); the latter type could presumably enter the cell by passive transport, then be reconverted intracellularly to the free nucleotide (II) by a nonspecific phosphoesterase. This approach has been partially successful (13).

A second approach would be to utilize a 9-substituted derivative of 6-mercaptopurine wherein this 9-substituent could simulate the binding of the ribotide moiety of II to the enzymes utilizing inosinic acid (IV) as a substrate but still have the ability to penetrate a cell wall and not suffer enzymic cleavage to the base. Since a major portion of the binding of the ribose phosphate moiety can certainly be attributed to the binding of the ionized phosphate to an enzymic cationic site, other anionic groups such as sulfates, phosphonates, or carboxylates should be able to replace the phosphate group in binding. In addition, since the ribose part of this moiety probably contributes much less than half of the total binding of this moiety, the ribose fragment should be replaceable by any group that is smaller than β-D-ribofuranose, providing that this group can properly juxtaposition the anionic binding group and the purine moiety. This juxtapositioning will be dependent upon the conformation of the nucleotide as it binds to a given enzyme. For reasons to be presented in the *Discussion*, the *p*-carboxybenzyl and the 4-carboxybutyl groups attached to the 9-position of some purines were selected for initial investigation.



Although crude preparations of inosinic dehydrogenase (14, 15) and adenylosuccinate synthetase (16) (two enzymes utilizing inosinic acid (IV)) have been described, we considered it expedient to use commercially available crystalline enzymes to determine—as a first approximation—if the binding of a nucleotide to one of these enzymes could be simulated by replacement of the ribose phosphate moiety with a suitable group. Since LDH and GDH[1] have been used extensively in these laboratories for other inhibitor studies (1, 17, 18), and since both enzymes use the dinucleotide, DPN, as a cofactor, these two enzymes were selected for initial studies of the relative binding of AMP, 9-(*p*-carboxybenzyl)adenine (XVI), and 9-(4′-carboxybutyl)-hypoxanthine (XVIII). The synthesis and evaluation of the latter two compounds as DPN inhibitors of LDH and GDH is the subject of this paper.

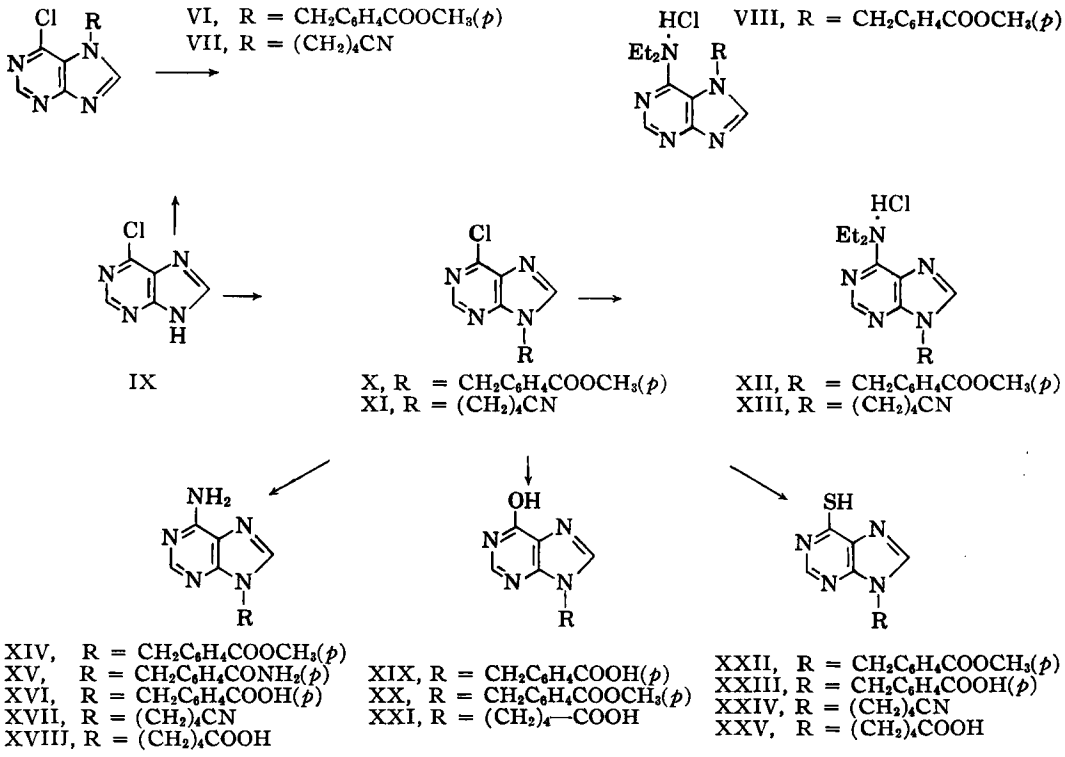
EXPERIMENTAL

Enzyme Measurements

Reagents.—DL-Lactate, L-glutamate, DPN, and adenosine were purchased from Nutritional Biochemicals Corp. AMP, IMP, and AMP-2′(3′) were purchased from Pabst Laboratories. Crystalline LDH (isolated from rabbit skeletal muscle) and crystalline GDH (isolated from mammalian liver) were purchased from the Sigma Chemical Co.

Methods of Assay.—The enzymatic rates for LDH and GDH were determined by the rate of formation of DPNH as measured by the rate of

[1] Abbreviations used: LDH, lactic dehydrogenase; GDH, glutamic dehydrogenase; DPN, diphosphopyridine nucleotide; AMP, 5′-adenylic acid; IMP, 5′-inosinic acid; AMP-2′(3′), a 1:1 mixture of 2′- and 3′-adenylic acid; Ad, adenine; Hx, hypoxanthine; ADP, adenosine 5′-diphosphate.



appearance of DPNH at 340 mμ in a Cary 11 spectrophotometer. All reactions were run in 0.05 *M* Tris buffer (pH 8.4).

For LDH, the cell contained 3.2 m*M* DPN, 8 m*M* DL-lactate, and the inhibitor when necessary in a total volume of 3.0 ml. The reaction was initiated by the addition of the appropriate amount of enzyme in 100 λ of buffer. Sufficient enzyme was used to give an initial rate of formation of DPNH of 0.4–0.6 optical density units per minute (17, 19).

The GDH assays were run similarly using 3.2 m*M* DPN, 2 m*M* L-glutamate and the inhibitor when necessary. Sufficient enzyme was used to give an initial rate of 0.9–1.2 optical density units per minute (17, 20).

Chemistry

Methods.—Although some purines can be alkylated directly to 9-alkylpurines–for example, 2-methylthio-6-dimethylaminopurine (21) and purine (22)–other purines react poorly or even fail to react properly (23). More often mixtures of 7- and 9-alkyl derivatives are obtained which must be separated (21, 24). The elegant methods developed by Montgomery and Temple (24, 25) for synthesis of 9-alkylpurines *via* 9-alkyl-6-chloropurine are particularly suitable if one wishes to have several different substituents at the 6-position. Their first route for 9-alkyl-6-chloropurines *via* 5-amino-4,6-dichloropyrimidine and an appropriate amine is favored if the necessary alkylamine is readily available, since only a 9-substituted purine can be obtained after ring closure with ethyl orthoformate-acetic anhydride (25–28). The second route involving the reaction of 6-chloropurine with an alkyl halide is useful when an alkyl halide is more available than the amine; dimethylformamide or dimethylsulfoxide as the solvent and potassium carbonate as the acid acceptor were the keys to the success of this reaction (24, 29). In most cases a mixture of 7- and 9-alkyl-6-chloropurines were obtained with the 9-isomer predominating as is usually the case in such alkylations (21). Once the separation has been completed, the chloro group can then be displaced by a large variety of nucleophiles (24, 25, 29) in a direct manner that gives no further isomer problems.

The second route of Montgomery and Temple was chosen for our syntheses of carboxyalkyl and aralkyl purines since bromo esters give considerably less difficulty in nucleophilic reactions than amino esters; the latter cause complications by polymerization. Condensation of methyl α-bromo-*p*-toluate (30) with 6-chloropurine (IX) proceeded smoothly. The 9-substituted purine (X) was obtained in 65% yield and was readily separated from the 7-isomer (VI) formed in 4% yield; the latter is readily soluble in hot methanol and X is insoluble. That the major isomer was the 9-isomer (X) was readily shown by conversion of X and VI to the corresponding 6-diethylaminopurines (XII and VIII) by the use of diethylamine in boiling methanol. The two 6-diethylaminopurines were readily distinguished by the large difference in their ultraviolet absorption maxima; XII showed a peak at 276 mμ in ethanol, whereas VIII showed a maximum at 298 mμ, in agreement with other 7- and 9-alkyl-6-dimethylaminopurines (21). The use of diethylamine is simpler than the use of dimethylamine for these structure proofs (24), since dimethylamine requires a sealed vessel for reaction.

Reaction of 9-(*p*-carbomethoxybenzyl)-6-chloropurine (X) with methanolic ammonia at 105° for 75 minutes gave the corresponding adenine derivative (XIV) in 85% yield. However, longer reaction

times and higher temperatures (115°) or both led to the additional ammonolysis of the ester function with formation of appreciable quantities of the amide (XV). Saponification of XIV with hot 1 *N* sodium hydroxide afforded the desired 9-(*p*-carboxybenzyl)-adenine (XVI) in 80% yield.

When the chloropurine, X, was refluxed with concentrated hydrochloric acid for 2 hours, hydrolysis of the 6-chloro and ester groups occurred with formation of 9-(*p*-carboxybenzyl)-hypoxanthine (XIX) in 89% yield. The use of hot 0.1 *N* hydrochloric acid gave only hydrolysis of the 6-chloro group; the resultant hypoxanthine ester (XX) was isolated in 74% yield.

The chloropurine X also reacted smoothly with thiourea in boiling methanol to give the 6-mercaptopurine ester XXII in 90% yield. Further saponification of XXII with hot 1 *N* sodium hydroxide afforded 9-(*p*-carboxybenzyl)-6-mercaptopurine (XXIII) in 70% yield.

Alkylation of 6-chloropurine (IX) with 5-bromovaleronitrile in dimethylformamide proceeded smoothly. Apparently considerable amounts of 7-isomer were present which made purification somewhat difficult and the yield of usable 9-isomer (XI) was 27%. That the crystalline isomer obtained was indeed the 9-isomer was shown by conversion of XI to the 6-diethylaminopurine derivative (XIII), isolated as the crystalline hydrochloride; the latter showed an ultraviolet maximum at 276 mμ in ethanol, as expected for a 9-isomer (21). Conversion of XI to 9-(4′-carboxybutyl)-hypoxanthine (XXI), 9-(4′-cyanobutyl)-6-mercaptopurine (XXIV) and 9-(4′-cyanobutyl)-adenine (XVII) proceeded smoothly as described for the *p*-carboxybenzyl series. However, conversion of XXIV and XVII to the corresponding 9-(4′-carboxybutyl)-6-mercaptopurine (XXV) and 9-(4′-carboxybutyl)-adenine (XVIII), respectively, was more expediently done with hot concentrated hydrochloric acid than with the alkaline hydrolysis used in the *p*-carboxybenzyl series.

Synthesis.[2]—*9-(p-Carbomethoxybenzyl)-6-chloropurine (X).*—To a solution of 6.87 Gm. (0.03 mole) of methyl α-bromo-*p*-toluate (30) in 50 ml. of dimethylformamide was added 4.4 Gm. (0.032 mole) of anhydrous potassium carbonate followed by 4.63 Gm. (0.03 mole) of 6-chloropurine. The mixture was stirred for 2 hours protected from moisture during which time a buff-colored solid separated. The mixture was poured into 150 ml. of ice water. The solid was collected on a filter and washed with 50 ml. of water. The dry filter cake weighed 8.2 Gm., m.p. 165–190°. The dry solid was heated to boiling with 125 ml. of methanol and filtered hot. The undissolved product melted at 196–201°; yield, 5.9 Gm. (65%). Recrystallization from benzene gave analytically pure material; yield 4.2 Gm. (46%), m.p. 200–201°; $\nu_{max.}^{KBr}$ 1715 (ester); 1600, 1560, 1510 cm.$^{-1}$ (C=C, C=N).

Anal.—Calcd. for $C_{14}H_{11}ClN_4O_2$: C, 55.5; H, 3.70; N, 18.5. Found: C, 55.6; H, 3.83; N, 18.5.

The hot methanol mother liquor was evaporated to residue *in vacuo*. Two recrystallizations from methanol gave 0.40 Gm. (4%) of 7-(*p*-carbomethoxybenzyl-6-chloropurine (VI), m.p. 174°.

Anal.—Calcd. for $C_{14}H_{11}ClN_4O_2$: C, 55.5; H, 3.70; N, 18.5. Found: C, 55.6; H, 3.62; N, 18.4.

9-(4′-Cyanobutyl)-6-chloropurine (XI).—A mixture of 6.18 Gm. (0.04 mole) of 6-chloropurine (IX), 7.24 Gm. (0.044 mole) of 5-bromovaleronitrile, 5.52 Gm. (0.04 mole) of anhydrous potassium carbonate, and 60 ml. of dimethylformamide was stirred at room temperature for 8 hours. After dilution with 180 ml. of ice cold water, the mixture was extracted with chloroform (4 × 50 ml.). The combined extracts were dried with anhydrous magnesium sulfate and the solvent was spin-evaporated *in vacuo;* the last traces with dimethylformamide were removed at oil pump pressure. The oily residue solidified after standing overnight. Two recrystallizations from benzene-petroleum ether gave 2.5 Gm. (27%) of product, m.p. 87–89°, that was suitable for further transformations. Repeated recrystallization afforded the analytical sample, m.p. 90–91°; $\nu_{max.}^{KBr}$ 2250 (C≡N); 1590, 1550, 1490 cm.$^{-1}$ (C=C, C=N).

Anal.—Calcd. for $C_{10}H_{10}ClN_5$: C, 51.0; H, 4.28; N, 29.7. Found: C, 51.1; H, 4.31; N, 29.5.

9-(p-Carbomethoxybenzyl)-6-diethylaminopurine Hydrochloride (XII).—A 160-mg. (2.2 mmoles) quantity of diethylamine was added to a solution of 302 mg. (1 mmole) of X in 25 ml. of reagent grade methanol. After being refluxed for 2 hours, the solution was spin-evaporated to a syrup *in vacuo*. The residual gum was triturated with 15 ml. of 1:1 reagent acetone-dry ether; the diethylamine hydrochloride was removed by filtration and washed with 1:1 acetone-ether. With cooling, dry hydrogen chloride was passed into the filtrate until precipitation was complete; the product rapidly separated. It was collected on a filter and washed with ether. The solid was dissolved in reagent acetone and dry ether was added to turbidity. On standing at 3°, the pure product separated as white crystals; yield, 170 mg. (45%), m.p. 183–184°; $\lambda_{max.}^{EtOH}$ 276 mμ (ε 19,500).

Anal.—Calcd. for $C_{18}H_{22}ClN_5O_2$: C, 57.5; H, 5.91; N, 18.6. Found: C, 57.7; H, 6.05; N, 18.9.

No attempt was made to obtain a second crop.

9-(4′-Cyanobutyl)-6-diethylaminopurine Hydrochloride (XIII).—This was prepared in a similar way and recrystallized from 1:1 ethyl acetate–acetone; yield of pure material 52%, m.p. 120–123°; $\lambda_{max.}^{EtOH}$ 277 mμ (ε 20,000).

Anal.—Calcd. for $C_{14}H_{21}ClN_6$: C, 54.5; H, 6.86; N, 27.3. Found: C, 54.3; H, 6.96; N, 27.2.

7-(p-Carbomethoxybenzyl)-6-diethylaminopurine Hydrochloride (VIII).—This was also prepared as described for XII. Recrystallization from acetone–ether gave a 64% yield of pure product, m.p. 193–195°; $\lambda_{max.}^{EtOH}$ 298 mμ (ε 15,900).

Anal.—Calcd. for $C_{18}H_{22}ClN_5O_2$: C, 57.5; H, 5.91; N, 18.6. Found: C, 57.4; H, 6.01; N, 18.4.

9-(p-Carbomethoxybenzyl)-adenine (XIV).—A 1.00-Gm. (3.3 mmoles) quantity of X was added to 75 ml. of methanol saturated with ammonia gas at 0° and placed in a steel bomb. The bomb was heated at 105–106° for 75 minutes, then cooled in cold water. A white solid separated out on the walls of

[2] Melting points were taken on a Mel-temp. apparatus in capillary tubes and are uncorrected. Infrared spectra were determined in KBr disk with a Perkin-Elmer recording spectrophotometer 137B. Ultraviolet spectra were determined with a Cary 11 recording spectrophotometer.

the bomb. The product was collected on a filter and washed with a little cold methanol; yield, 0.80 Gm. (85%), m.p. 228–229°, that was sufficiently pure for further transformations. An analytical sample was obtained by recrystallization from methanol as white crystals, m.p. 230–231°; $\nu_{max.}^{KBr}$ 3300 (NH); 1730 (ester C=O); 1675, 1610, 1570 cm.$^{-1}$ (NH, C=C, C=N).

Anal.—Calcd. for $C_{14}H_{13}N_5O_2$: C, 59.4; H, 4.62; N, 24.7. Found: C, 59.2; H, 4.56; N, 24.6.

9-(4'-Cyanobutyl)-adenine (XVII).—This was prepared as described for XIV. Recrystallization from chloroform with the aid of decolorizing carbon gave 54% of white needles, m.p. 156–157°; $\nu_{max.}^{KBr}$ 3300 (NH); 2240 (C≡N); 1670, 1600, 1575 cm.$^{-1}$ (NH, C=C, C=N).

Anal.—Calcd. for $C_{10}H_{12}N_6$: C, 55.5; H, 5.62; N, 38.9. Found: C, 55.3; H, 5.52; N, 38.9.

9 - (p - Carbomethoxybenzyl) - 6 - mercaptopurine (XXII).—A mixture of 0.302 Gm. (1 mmole) of X, 15 ml. of methanol, and 0.076 Gm. (1 mmole) of thiourea was refluxed with stirring for 2 hours. During this time the solid nearly dissolved, then the product separated. The cooled mixture was filtered and the product washed with 20 ml. of cold water; yield, 270 mg. (90%), m.p. 289–290°, that was suitable for further transformation. Recrystallization from 2-methoxyethanol gave 200 mg. (67%) of pure product as pale-buff crystals, m.p. 290–291°; $\nu_{max.}^{KBr}$ 1710 (ester C=O); 1600, 1575, 1530 (C=C, C=N); 1275 cm.$^{-1}$ (ester C—O—C).

Anal.—Calcd. for $C_{14}H_{12}N_4O_2S$: C, 56.0; H, 4.03; N, 18.7. Found: C, 56.2; H, 4.16; N, 18.5.

9-(4'-Cyanobutyl)-6-mercaptopurine (XXIV).—This was prepared as described for XXII; yield, 200 mg. (86%), m.p. 284–285°. Recrystallization from ethanol gave pale-colored needles, m.p. 286–287°; $\nu_{max.}^{KBr}$ 2255 (C≡N); 1600, 1540 cm.$^{-1}$ (C=N, C=C).

Anal.—Calcd. for $C_{10}H_{11}N_5S$: C, 51.5; H, 4.77; N, 30.0. Found: C, 51.7; H, 4.90; N, 30.0.

9-(p-Carboxybenzyl)-adenine (XVI) Hydrochloride.—A mixture of 150 mg. (0.53 mmole) of XIV and 15 ml. of 1 *N* aqueous sodium hydroxide was refluxed for 45 minutes; the ester rapidly dissolved. The cooled solution was acidified to pH 2 with 6 *N* hydrochloric acid. The white solid was collected on a filter, washed with water, and dried at 100°; yield, 130 mg. (80%), m.p. 348–349°. Recrystallization from absolute ethanol gave analytically pure material, m.p. 350°; $\nu_{max.}^{KBr}$ 3450 (NH); 1700 (acid C=O, C=NH$^+$); 1600, 1510 cm.$^{-1}$ (NH, C=C, C=N).

Anal.—Calcd. for $C_{13}H_{12}ClN_5O_2$: C, 51.1; H, 3.97; N, 22.8. Found: C, 51.3; H, 4.15; N, 22.8.

9-(p-Carboxybenzyl)-6-mercaptopurine (XXIII).—From 150 mg. (0.50 mmole) of XXII, as described for the preparation of XVI, was obtained after recrystallization from 2-methoxyethanol 100 mg. (70%) of product, m.p. 318–320°; $\nu_{max.}^{KBr}$ 1685 (carboxyl C=O); 1595, 1570, 1525 cm.$^{-1}$ (C=N, C=C).

Anal.—Calcd. for $C_{13}H_{10}N_4O_2S$: C, 54.5; H, 3.57; N, 19.6. Found: C, 54.5; H, 3.70; N, 19.7.

9-(p-Carbomethoxybenzyl)-hypoxanthine (XX).—A solution of 500 mg. (1.65 mmoles) of X in 50 ml. of methanol and 5 ml. of 1 *N* aqueous hydrochloric acid was refluxed for 3.5 hours. Most of the solvent was spin evaporated *in vacuo*, then 25 ml. of water was added. The product was collected on a filter and recrystallized from methanol; yield, 350 mg. (75%) of white crystals, m.p. 288°; $\nu_{max.}^{KBr}$ 1715 (ester C=O); 1600, 1555 (C=O, C=N, C=C); 1280 cm.$^{-1}$ (ester C—O—C).

Anal.—Calcd. for $C_{14}H_{12}N_4O_3$: C, 59.1; H, 4.27; N, 19.7. Found: C, 58.9; H, 4.06; N, 19.5.

9-(p-Carboxybenzyl)-hypoxanthine (XIX).—A solution of 151 mg. (0.50 mmole) of X in 7 ml. of concentrated hydrochloric acid was refluxed for 2.5 hours with magnetic stirring during which time the product separated. The mixture was diluted with 15 ml. of water and cooled. The product was collected on a filter and washed with water; yield, 120 mg. (89%), m.p. 324–327°. Recrystallization from 2-methoxyethanol gave white crystals, m.p. 330–331°; $\nu_{max.}^{KBr}$ 1670 (carboxyl C=O); 1600, 1580 cm.$^{-1}$ (C=O, C=C, C=N).

Anal.—Calcd. for $C_{13}H_{10}N_4O_3$: C, 57.8; H, 3.77; N, 20.7. Found: C, 57.5; H, 3.91; N, 20.9.

9-(4'-Carboxybutyl)-hypoxanthine (XXI).—Hydrolysis of 235 mg. (1 mmole) of XI, as described for the preparation of XIX gave, after recrystallization from 2-methoxyethanol, 150 mg. (64%) of product, m.p. 260–261°; $\nu_{max.}^{KBr}$ 1690 (carboxyl C=O); 1650, 1600 (C=C, C=N, C=O).

Anal.—Calcd. for $C_{10}H_{12}N_4O_3$: C, 50.9; H, 5.14; N, 23.8. Found: C, 50.9; H, 5.22; N, 23.9.

9-(4'-Carboxybutyl)-adenine (XVIII).—Hydrolysis of 216 mg. (1 mmole) of XVII with concentrated hydrochloric acid for 3 hours, as described for the preparation of XIX, gave 190 mg. (81%) of product, m.p. 267–270°. Recrystallization from 2-methoxyethanol gave 140 mg. (60%) of white crystals, m.p. 272–273°.

Anal.—Calcd. for $C_{10}H_{13}N_5O_2$: C, 51.1; H, 5.58; N, 29.8. Found: C, 51.0; H, 5.63; N, 30.0.

9-(4'-Carboxybutyl)-6-mercaptopurine (XXV).—A mixture of 233 mg. (1 mmole) of XXIV and 10 ml. of concentrated hydrochloric acid was refluxed for 6 hours, then cooled and diluted with 25 ml. of ice water. The crude product was collected on a filter and washed with water, then dissolved in excess 5% aqueous sodium bicarbonate. Acidification gave 90 mg. (36%) of tan crystals, m.p. 257–258°. Recrystallization from 2-methoxyethanol gave an analytical sample, m.p. 258–259°; $\nu_{max.}^{KBr}$ 1710 (carboxyl C=O); 1600, 1575, 1545 cm.$^{-1}$ (C=C, C=N).

Anal.—Calcd. for $C_{10}H_{12}N_4O_2S$: C, 47.7; H, 4.82; N, 22.2. Found: C, 47.7; H, 4.90; N, 22.1.

Results

By plotting Vo/V against I for four or more concentrations of I, the concentration of I necessary to give 50% inhibition ($Vo/V_I = 2$) was readily determined, where Vo = velocity of the enzymic reaction with no inhibitor, V_I = velocity of reaction in the presence of inhibitor, and I = concentration of inhibitor (17). At least two of the points should be in the 30–70% inhibition range where the least error occurs. In a few cases where a saturated solution gave only 35–49% inhibition, such as with compound XX, the plot was extended to Vo/V = 2 to determine the concentration of I that would

TABLE I.—50% INHIBITION OF LDH AND GDH BY NUCLEOTIDE ANALOGS

Group	Compound[a]	mM Concentration for 50% Inhibition LDH	GDH

	Carboxybutyl-Hx (XXI)	82	D[c]
	Valerate	340	210
D	Benzoate	27	95
	p-Toluate	24	
	{Adenosine / Benzoate}[b]	17	B[c]

[a] For abbreviations see *Footnote 1*. [b] Equal concentrations of both compounds. [c] Compound not sufficiently soluble to determine 50% inhibition. See this group in Table II for partial inhibition data.

give 50% inhibition. These 50% inhibition values for LDH and GDH are listed in Table I.

In cases where a compound gave less than 35% inhibition with a saturated solution, a group run was made for simultaneous comparison of two to four compounds at the same concentration (Table II); if one of the compounds in the group did give a normal 50% inhibition plot, the inhibition at lower concentration was taken from Vo/V_I *versus* I plot–for example compound XVIII in Table II, group C.

DISCUSSION

Both riboflavin-5′-sulfate and adenosine-5′-sulfate have been observed to be flavin-adenine dinucleotide inhibitors in the D-amino acid oxidase system (31, 32). In addition, AMP, IMP, and adenosine have been found to be inhibitors in alcohol dehydrogenase systems, whereas nicotinamide mononucleotide was not (33, 34). ADP-ribose, an hydrolysis product of DPN is a strong competitive inhibitor of LDH (35) and alcohol dehydrogenase (36). Therefore it was not unreasonable to expect that AMP would be an inhibitor in the LDH and GDH systems.

That AMP was an inhibitor in both the LDH and GDH systems is shown in Table I. Attempts to show that AMP was a "competitive" DPN inhibitor by Lineweaver-Burk plots were not conclusive since results varied between "competitive" and "partially competitive" (20, 37). Therefore, we chose to rely on molecular changes in inhibitor structure to determine whether the synthetic compounds were binding to the enzymes in the same manner as AMP, an approach which Reiner (38) considers to be more definitive and with which we concur (17). Thus, both the LDH and GDH systems could be used to search for chemical groupings that simulate the 5′-phosphoribosyl moiety of AMP as an inhibitor.

To check on the mode of binding of AMP to LDH and GDH, IMP and adenosine were measured as inhibitors. IMP inhibited both LDH and GDH, but considerably higher concentrations than AMP were needed for 50% inhibition (Table I). It can be concluded that the adenine moiety is necessary for binding to both enzymes, and the hypoxanthine moiety binds less effectively, probably because it is less basic. Adenosine was not sufficiently soluble to determine the concentration necessary for 50% inhibition. However, 7 mM adenosine gave no measurable inhibition of LDH, contrasted to AMP at 6.7 mM which gave 50% inhibition (Table I). Similarly, 15 mM adenosine gave only 7% inhibition of GDH, whereas AMP at 15 mM gave 29% inhibition (Table II, group C). Therefore it can be concluded that the phosphate group of AMP is necessary for binding to LDH and GDH when AMP acts as an inhibitor.

In the AMP structure, the purine ring has a rigid structure and the furanose ring can vary only slightly in conformation because of its slight pucker. The main possible changes in conformation of binding of AMP to an enzyme is because of the free rotation of the 1′-9 bond and all of the bonds of the phosphomethylene group. Examination of Leybold

TABLE II.—PARTIAL INHIBITION OF LDH AND GDH BY NUCLEOTIDE ANALOGS

Group	Enzyme	Compound[a]	mM Concn.	Vo/V_I	Inhibition, %
A	LDH	Valerate	18	1.15	13

models shows that there are two conformations of AMP with extremes in the distance of the P–O$^{\ominus}$ from the 6-amino group of AMP[3], 13.0 Å. (XXIX) and 3.0 Å. (XXVII). Another way of measuring the relative conformation is the distance between the P–O$^{\ominus}$ and the 9-nitrogen; in the case of XXIX, this distance[3] is 9.0 Å. Another type of extreme conformation is XXVI. In this case the P–O$^{\ominus}$ is tucked in towards the 9-nitrogen and the two atoms can almost touch. The latter conformation for enzyme binding is highly improbable because of the crowding of these ionic binding groups and probable steric hindrance to ionic binding to the enzyme. However, if the P–O$^{\ominus}$ and 9-nitrogen were separated about 3 Å., this type of conformation would be possible. One of the many possible intermediate conformations is shown by structure XXVIII.

Two side chains were selected for investigation to determine whether the 5′-phosphoribose moiety of AMP could be simulated in the binding of AMP to GDH or LDH or both. 9-(*p*-Carboxybenzyl)-adenine (XVI) has a fixed relationship between the 9-nitrogen of the adenine moiety and the charge of the $\begin{matrix} O \\ \diagdown \\ \diagup \\ O \end{matrix}\ominus$ of 8.6°. This distance compares favorably to that of 9.0 Å. between the O$^{\ominus}$ and 9-N of AMP[3] for the most extended conformation of AMP (XXIX). Slight rotation of the phosphate of XXIX group can bring this distance down to 8.6 Å. The most extended conformation of AMP and XVI both have a distance between the nitrogen of the 6-amino group[3] and the anionic group of 13 Å. All of the *p*-carboxybenzyl group except one hydrogen fits within the space occupied by the 5′-phosphoribosyl group. Thus XVI has the binding potential of the most extended conformation of AMP.

The second compound chosen was (4′-carboxybutyl)-adenine (XVIII). This compound has a flexible side chain which can vary in conformation from nearly the most extended conformation of AMP (XXIX) to nearly the least extended (XXVII) and include other conformations such as XXVI and XXVIII. In most (if not all cases) the bulk of the carboxybutyl side chain fits within the space occupied by the ribose-5′-phosphate moiety.

To determine whether 9-(*p*-carboxybenzyl)-adenine (XVI) and 9-(4′-carboxybutyl)-adenine (XVIII) simulate the inhibitor properties of AMP for LDH and GDH, three criteria must be met:

1. The compound should inhibit the same magnitude as AMP.
2. The hypoxanthine analog must inhibit less effectively than the adenine analog.
3. A given concentration of a compound such as XVI with two ionic points of attachment should show considerably greater inhibition than a solution of equal concentration of both of its moieties with one ionic point of attachment, such as benzoate and adenine. Actually adenosine and AMP-2′(3′) were used in place of adenine since the latter was not sufficiently soluble and has an undesirable acidic NH.

9-(*p*-Carboxybenzyl)-adenine (XVI) was an inhibitor of both LDH and GDH (Table I, group B) but inhibited in different ways. In the case of GDH, all three criteria for simulating AMP were met. First, XVI inhibited GDH slightly better than AMP. Second, 9-(*p*-carboxybenzyl)hypoxanthine (XIX) was required at 2.4 times the concentration of XVI to give 50% inhibition (Table I, group B); IMP was required in 1.9 times the concentration of AMP to give 50% inhibition, a favorable comparison. Third, 30 m*M* each of benzoate and AMP-2′(3′) in the same solution gave only 16% inhibition, whereas 30 m*M* of XVI gave 67% inhibition. The simulation of the inhibition of AMP by XVI is evidence that AMP has the fully extended conformation of the 5′-phosphoribosyl moiety when AMP binds to GDH, as discussed earlier.

With LDH, the criteria for simulating AMP were not met by 9-(*p*-carboxybenzyl)-adenine (XVI). First, the compound inhibited LDH half as well as did AMP (Table I). However, at only 1.5 times the concentration of XVI, 9-(*p*-carboxybenzyl)-hypoxanthine (XIX) gave 50% inhibition; this was far too inhibitory since there is a tenfold difference in concentration between AMP and IMP necessary for 50% inhibition. The reason for the high inhibition of XIX is apparent when one notes that 24 m*M* *p*-toluate gives 50% inhibition and benzoate at 27 m*M* (Table I); apparently XIX binds primarily as a derivative of benzoate and XIX has no second ionic binding point as required in the simulation of AMP. In addition, the third criterion was not met, since 17 m*M* concentrations of benzoate and adenosine in the same solution gave the same inhibition as 15 m*M* of XVI (Table I, group D). Apparently, XVI does not bind in a two ionic point attachment to LDH, but the adenine moiety of one molecule and the carboxybenzyl moiety of another molecule bind to one enzymic active site. Since the binding of AMP to LDH cannot be simulated by XVI, it can be concluded that AMP most probably does not have the most extended conformation of its ribose phosphate moiety when bound to LDH.

9-(4′-Carboxybutyl)-adenine (XVIII) was an

[3] Distances measured from the center of the O$^{\ominus}$ and N atoms.

inhibitor for both enzymes (Table I), and in both cases XVIII met the three criteria for simulating AMP. With GDH, XVIII gave 50% inhibition at only a slightly higher concentration than that required for AMP. The hypoxanthine analog (XXI) was not sufficiently soluble to determine the 50% inhibition point; therefore the equal concentration comparison listed in Table II, group D was made. At the highest obtainable concentration (52 m*M*), the hypoxanthine analog (XXI) gave 19% inhibition, whereas 9-(4′-carboxybutyl)-adenine (XVIII) gave 67% inhibition at 52 m*M*, thus meeting the second criterion. Third, in Table II, group C, 15 m*M* each of a mixture of valerate and adenosine gave only 11% inhibition, whereas 15 m*M* 9-(4′-carboxybutyl)-adenine (XVIII) gave 26% inhibition and 15 m*M* AMP gave 29% inhibition.

With LDH, a 30 m*M* concentration of the adenine analog (XVIII) was needed to give 50% inhibition, compared to 6.7 m*M* AMP. The other two criteria for simulation of AMP by XVIII were also met. As shown in Table I, group C, the AMP analog (XVIII) showed 50% inhibition at about one-third the concentration of the IMP analog (XXI). XVIII and XXI do not show the tenfold spread in concentration shown by AMP and IMP, for 50% inhibition of LDH is apparently due to appreciable one ionic-point attachment of the valerate side chain at the high concentration (82 m*M*) necessary for 50% inhibition. As shown in Table II, group A, 9-(4′-carboxybutyl)-adenine (XVIII) shows considerably higher inhibition than a solution of equal concentrations of valerate and adenosine.

In view of the reference material at the beginning of the *Discussion*, the data obtained in this paper, and the similarity in structure between AMP and half of the DPN molecule, it is probable that AMP binds to LDH and GDH in the same part of the active site as the AMP half of DPN. It follows that DPN probably has two different conformations when bound to LDH and GDH. The evidence is strong that 9-(4′-carboxybutyl)-adenine (XVIII) can simulate either conformation that AMP assumes when bound to these two different enzymes; it is probable that most of the conformations that AMP can assume when bound to other enzymes can be simulated by XVIII.

Side chains in addition to the *p*-carboxybenzyl group with a fixed conformation—or a limited locus of conformations—should be more specific as inhibitors when they simulate AMP. Of course these arguments can also apply to nucleotide substrates of purine and pyrimidine bases. One could even speculate that substrate-identical enzymes from different tissues might be expected to have different conformational requirements for the substrate.

In our opinion, this pilot study on simulation of the inhibitor properties of AMP against LDH and GDH by adenine derivatives substituted with an anionic side chain has been sufficiently definitive to warrant further study of these compounds including the mercaptopurines (XXIII, XXV) as inhibitors of enzymes interconverting nucleotides. By blocking the carboxylate group, a variety of possibilities for potentiation are possible to aid transport and membrane permeability *in vivo*, if necessary.

The search for other anionic side chains, particularly with a limited locus of conformational possibilities, attached to purines and pyrimidines that may inhibit biosynthesis of nucleic acid precursors is also warranted.

Solution Phase Interaction of Nicotinamide with Ascorbic Acid

By DAVID E. GUTTMAN and DANA BROOKE†

A study was made of what appears to be a charge-transfer interaction that is responsible for the instantaneous generation of a yellow color in aqueous solutions containing nicotinamide and ascorbic acid. Spectral studies were utilized to elucidate some of the factors that influence the interaction. Analysis, by the method of continuous variation, showed that a 1:1 complex was formed. The extent of association was pH dependent and exhibited a maximum at a pH of approximately 3.8. The pH dependency was compared with that of the 3-carbamyl-1-methyl-pyridinium chloride–ascorbic acid system and indicated that the interactants were protonated nicotinamide and ascorbate anion. Association constants, at a number of different temperatures, were determined by using the Benesi-Hildebrand treatment of spectral data. The standard enthalpy change that resulted from association was estimated to be −1,500 cal.

COMPLEX OR ADDITION compound formation in systems containing ascorbic acid and nicotinamide was first reported in 1944 by Milhorat (1). Since that time a limited number of publications have appeared which have described in greater or lesser detail some of the properties of this combination. Bailey, Bright, and Jasper (2), for example, constructed temperature-composition diagrams for nicotinamide-ascorbic acid and nicotinic acid–ascorbic acid systems and demonstrated in this way that the reaction products had 1:1 stoichiometric compositions. Molecular weight determinations revealed that a high degree of dissociation occurred in aqueous and alcoholic solutions. Wenner (3) also studied the reaction and observed that it proceeded at a perceptible rate. His observation contrasts with those of others who reported that an almost instantaneous formation occurred upon mixing the interactants. Najer and Guépet (4), on the basis of studies in the U.V. and I.R. regions, concluded that the isolatable product was essentially the ascorbate of nicotinamide, but that some interaction occurred between the amide grouping and a secondary hydroxyl group of the acid. Investigations of the antiscorbutic properties of the complex were conducted and reported by Chalopin (5) and Nigeon-Dureuil (6). In addition, at least two patents were issued covering the product (7, 8).

The present investigation was undertaken to provide more definitive information about the nature of the interaction between the two vitamins, the extent of their association in aqueous solution, and the factors that influence such an occurrence. As will be seen, finite concentrations of a 1:1 complex were formed when the vitamins were combined in solution. The interaction was markedly dependent on the pH of the solution and appeared to be because of a charge-transfer interaction between protonated nicotinamide and ascorbate ion.

EXPERIMENTAL

Reagents.—Nicotinamide and ascorbic acid were U.S.P. grade. 3-Carbamyl-1-methyl-pyridinium chloride was synthesized by the method of Huff and Perlzweig (9), m.p. 237–239° (uncorrected). All solutions were freshly prepared in double-distilled, deionized water that had been thoroughly flushed with nitrogen. Disodium ethylenediaminetetraacetic acid (0.1%) was added to all solutions. Precautions were taken in all mixing procedures to prevent the

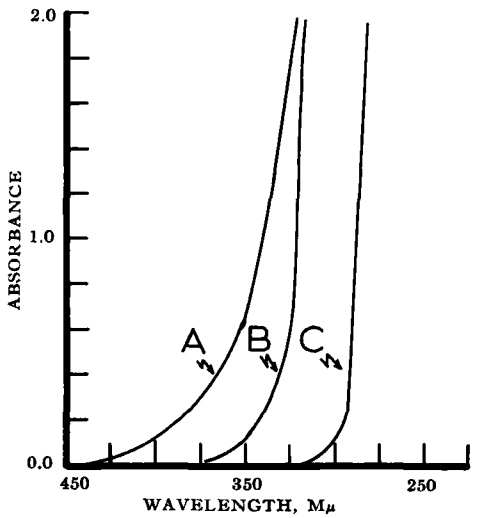

Fig. 1.—A plot showing the spectral characteristics of nicotinamide, ascorbic acid, and a mixture of the two. Curve A is the spectrum of a solution that was 0.02 *M* with respect to nicotinamide and 1.8 *M* with respect to ascorbic acid. Curve B is the spectrum of a 1.8 *M* solution of ascorbic acid. Curve C is the spectrum of a 0.02 *M* solution of nicotinamide.

introduction of air. Such precautions were necessary to preclude rapid autoxidation of ascorbic acid.

Methods.—Spectral studies were based on the fact that the addition of ascorbic acid to solutions of nicotinamide or its N^1-methyl derivative resulted in the instantaneous generation of a faint yellow color. Spectrophotometric examination, which is illustrated in Fig. 1, revealed the appearance of a new band as a long tail to the longer wavelength side of the ascorbic acid spectrum. Absorbance values of solutions were determined at two arbitrarily chosen wavelengths—345 and 365 mμ—and these served as quantitative indications of the concentration of complex in solution. The absorbance of each sample containing ascorbic acid and nicotinamide was corrected for the absorbance contribution of ascorbic acid by using as a solvent blank an ascorbic acid solution having the same concentration as the sample. This contribution was found to be small at lower pH values but became increasingly significant as the pH was increased. All spectrophotometric determinations were made with a Beckman model DU spectrophotometer, which was equipped with thermostatic plates, through which constant-temperature water was circulated to maintain the cell compartment at the desired temperature. Prior to absorbance measurements, the solutions were cooled or heated in an external bath to a temperature close to that of the compartment.

Analysis by Continuous Variation.—Equimolar solutions (0.4 *M*) of ascorbic acid and nicotinamide were prepared. Aliquots of the two solutions were mixed in various proportions to yield mixtures having a total volume of 25 ml. The absorbance at 365 mμ was determined for each solution using an appropriate solvent blank.

Influence of pH.—One-milliliter aliquots of a stock solution of nicotinamide or its N^1-methyl derivative were placed in a series of 25-ml. volumetric flasks. A 20-ml. volume of a 1.25 *M* solution of ascorbic acid was added to each flask. Volumes of concentrated aqueous sodium hydroxide were added; each flask was made up to volume with water. Absorbance values were determined at 365 mμ using solutions prepared in the same manner as solvent blanks, but which did not contain the amide. The pH of each solution was determined with a Beckman model G pH meter immediately after spectrophotometric examination.

Association Constant Determination.—One milliliter of a stock solution of nicotinamide was placed in each of a series of 10-ml. volumetric flasks. A volume of a 1.8 *M* solution of ascorbic acid, which had previously been adjusted to a pH of 4.0 by the addition of aqueous sodium hydroxide, was placed in each flask. Solutions were then made up to volume by the addition of water. An appropriate blank was formulated for each sample. Absorbances at 365 and 345 mμ were determined for each solution. Initially, the pH of each solution was measured. Repeated trials showed that dilution did not markedly change the pH from that of the original stock solution.

RESULTS

The analyses by continuous variation experiments are summarized in Fig. 2. The maximum absorbance appeared to correspond to a solution that was approximately equimolar with respect to the two vitamins and thus indicated the reversible formation of a complex of 1:1 stoichiometry. The high degree of dissociation of the complex was suggested by the absence of a well defined maximum in Fig. 2.

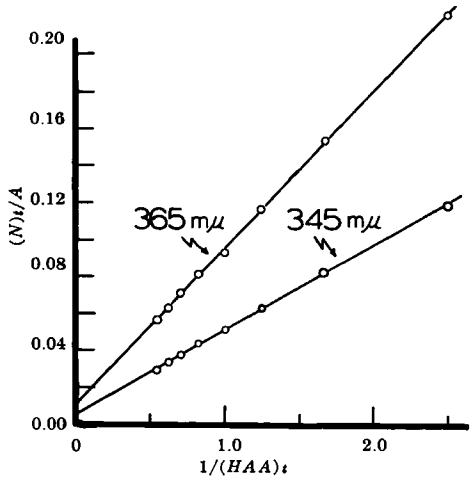

Fig 3.—A plot illustrating the Benesi Hildebrand treatment used to investigate the interaction between ascorbic acid and nicotinamide at 25°C. and at a pH of 4.0. The nicotinamide concentration was 0.04 *M*.

The stoichiometry was substantially confirmed by the plots shown in Fig. 3, where the effect of ascorbic acid concentration on the absorbances of solutions containing the two vitamins at constant pH was summarized. The treatment illustrated by the figure is analogous to that first proposed by Benesi and Hildebrand (10) and which is commonly used to determine complex association constants from spectral data. Here it was assumed that nicotinamide and ascorbic acid reversibly interacted to form a 1:1 complex, that the interaction obeyed the law of mass action, that the absorbance at the chosen wavelength was entirely due to the complex and followed Beer's law, and that the concentration of complex was insignificantly small compared to that of ascorbic acid. With these assumptions, it can be shown that

$$(N)_t/A = 1/a_c + 1/a_cK(HAA)_t \quad \text{(Eq. 1)}$$

where $(N)_t$ = analytical concentration of nicotinamide, A = absorbance at a particular wavelength, a_c = molar absorptivity of the complex at that wavelength, K = apparent association constant, and $(HAA)_t$ = analytical concentration of ascorbic acid.

Equation 1 predicts a linear relationship between $(N)_t/A$ and $1/(HAA)_t$ with a slope value of $1/a_cK$ and an intercept value of $1/a_c$. Excellent linearity of the curves of Fig. 3, over a wide range of ascorbic acid concentrations and at two different wavelengths, served to confirm the assumptions that were basic to the derivation of Eq. 1. Similar linearity was observed at three other temperatures.

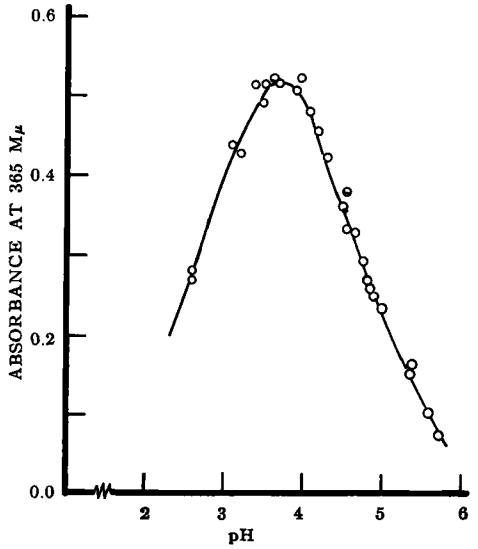

Fig. 4.—A plot illustrating the effect of pH variation on the interaction between ascorbic acid and nicotinamide at room temperature. Each solution was 0.05 M with respect to nicotinamide and 1.0 M with respect to ascorbic acid.

The influence of pH on the system and on a similar system containing 3-carbamyl-1-methyl-pyridinium chloride is depicted in Figs. 4 and 5. Here absorbance values of solutions of identical composition, except for hydronium-ion concentration, were plotted as a function of pH. The ascorbic acid–nicotinamide system exhibited the maximum degree of interaction at a pH of approximately 3.8. In the case of the N^1-methyl derivative, the degree of interaction increased with an increase in pH in a manner that is characteristic of the degree of ionization behavior of a weak acid. It will be seen that these results could be reasonably interpreted to mean that the species that underwent association to form the complex were ascorbate anion and the quaternary form of the pyridine derivative.

DISCUSSION

In the pH region which was investigated in the study illustrated by Fig. 4, nicotinamide existed in solution as the free base (N) and/or as the protonated base (NH^+). Similarly, ascorbic acid was present as the free acid (HAA) and/or as ascorbate ion (AA^-). The relative distribution of species in a particular solution would, of course, be dependent on the pH of that solution. This consideration leads to the possibility that one or more of four equilibria were operative and responsible for the formation of a colored 1:1 complex. These include

$$NH^+ + HAA = NH^+{:}HAA \quad \text{(Eq. 2)}$$

$$NH^+ + AA^- = NH^+{:}AA^- \quad \text{(Eq. 3)}$$

$$N + HAA = N{:}HAA \quad \text{(Eq. 4)}$$

$$N + AA^- = N{:}AA^- \quad \text{(Eq. 5)}$$

The pH profile of the interaction, as illustrated in Fig. 4, indicated, however, that equilibria of Eqs. 2 and 5 were not significantly responsible for the formation of a colored complex. It can be seen that at the pH extreme where the species NH^+ and HAA predominated and at the other extreme where N and AA^- predominated, the degree of interaction was low. This behavior can be verified visually by noting that the yellow color of a solution containing the vitamins can be instantaneously discharged by strong acidification or alkalinization. The pH of solutions which exhibited maximum absorbance and, therefore, maximum concentration of complex fell in the region where the interactants of equilibria of Eqs. 3 or 4 predominated.

The equilibrium expressed in Eq. 3 can be characterized by the association constant $K' = (NH^+{:}AA^-)/(NH^+)(AA^-)$, or in terms of the analytical concentrations of the vitamins as

$$K' = \left\{\frac{(NH^+{:}AA^-)}{(N)_t(HAA)_t}\right\}\left\{\frac{(H^+) + K_{NH^+}}{H^+}\right\}\left\{\frac{(H^+) + K_{HAA}}{K_{HAA}}\right\} \quad \text{(Eq. 6)}$$

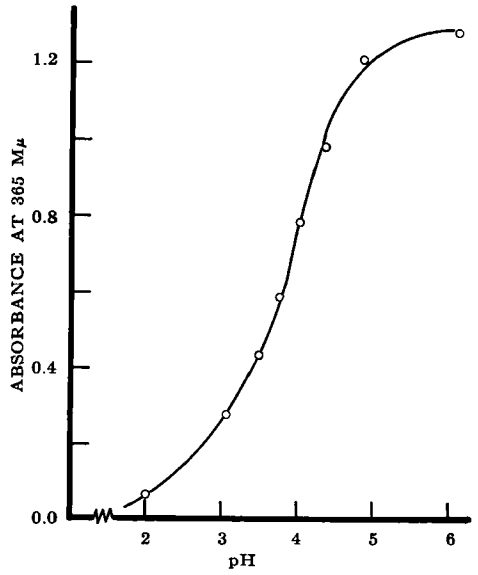

Fig. 5.—A plot illustrating the effect of pH variation on the interaction between ascorbic acid and N^1-methyl nicotinamide at room temperature. Each solution was 0.015 M with respect to N^1-methyl nicotinamide and 1.0 M with respect to ascorbic acid.

where K_{NH^+} and K_{HAA} = acidity constants of protonated nicotinamide and ascorbic acid, respectively.

Similarly, it can be shown that equilibrium of Eq. 4, involving free nicotinamide and free ascorbic acid, can be described by the association constant

$$K' = \left\{\frac{(N{:}HAA)}{(N)_f(HAA)_f}\right\}\left\{\frac{K_{NH^+} + (H^+)}{K_{NH^+}}\right\}\left\{\frac{K_{HAA} + (H^+)}{(H^+)}\right\} \quad \text{(Eq. 7)}$$

Differentiation of Eqs. 6 and 7 to obtain $d(\text{complex})/d(H^+)$, setting the resulting differentials equal to zero, and solving for the hydronium-ion concentrations at which the concentration of complex would be expected to maximize, yielded an identical result for both possible equilibria, that

$$(H^+)_{max.} = (K_{NH^+} \cdot K_{HAA})^{1/2}$$

or

$$pH_{max.} = {}^1/_2 pK_{NH^+} + {}^1/_2 pK_{HAA} \quad \text{(Eq. 8)}$$

Using a value of 3.42 for the pKa of protonated nicotinamide (11) and that of 4.17 for ascorbic acid (12), the pH of maximum concentration of complex was calculated to be 3.80. The experimental curve exhibited a maximum which agreed closely with this theoretically expected value. The close agreement between theory and experiment confirmed that one or both of the equilibria were operative but did not permit a differentiation between the possibilities.

Since it was impossible to differentiate in this way between the equilibria which, on the one hand, involved the ionized, and on the other, the unionized forms of the vitamins, the influence of pH on a similar, previously unreported interaction between ascorbic acid and 3-carbamyl-1-methyl-pyridinium chloride was studied. Here, the degree of ionization of the N^1-methyl nicotinamide was pH independent. It was therefore felt that if a similar interaction occurred and was influenced by pH, then the nature of the influence would point to either unionized ascorbic acid or ascorbate ion and the cationic form of nicotinamide as the interacting species. Interaction did occur and the pH profile shown in Fig. 5 unequivocally implicated ascorbate ion as the species which was involved. This evidence, although indirect, strongly suggests that the predominant equilibrium which resulted in the generation of the yellow color in solutions of ascorbic acid and nicotinamide was that described by Eq. 3.

On the basis of this evidence, the association constants which were calculated from the Benesi-Hildebrand plots by regression analysis and which were based on the analytical concentrations of the vitamins were multiplied by the factor

$$\left\{\frac{(H^+) + K_{NH^+}}{(H^+)}\right\}\left\{\frac{(H^+) + K_{HAA}}{K_{HAA}}\right\}$$

to yield constants which were consistent with the implicated equilibrium. These are presented for the temperatures and wavelengths investigated in Table I. The effect of temperature on the equilibrium was summarized in Fig. 6, where log K' was plotted as a function of the reciprocal of absolute temperature. The enthalpy change which resulted from association was estimated from this graph to be −1,500 cal.

TABLE I.—ASSOCIATION CONSTANTS FOR THE COMPLEX FORMED BY THE INTERACTION OF NH^+ AND AA^- IN AQUEOUS SOLUTION

Temp., °C.	Wavelength Used for Determination, mμ	K' (with 95% confidence range), L./Mole
10	345	1.64 ± 0.038
21	345	1.52 ± 0.024
25	345	1.45 ± 0.035
25	365	1.43 ± 0.020
29	345	1.40 ± 0.020

A number of considerations indicate that charge-transfer forces were responsible for the formation of the ascorbic acid–nicotinamide complex in solution. That the interaction involved ascorbate ion and the cationic form of nicotinamide immediately suggests such a possibility because of the well-known ability of pyridinium compounds to function as electron acceptors in charge-transfer interactions with negatively charged species. In addition, the bathochromic shift which occurred as a manifestation of the interaction is similar to those observed in a number of charge-transfer systems. Furthermore, the association constants determined in the present study are of the same order of magnitude as those reported by Kosower (13) for the charge-transfer complexes of iodide and substituted pyridinium compounds. The observed enthalpy change is approximately the same as that reported by Negoro, *et al.* (14), for the interaction of nicotinamide with *p*-aminosalicylic acid which they attributed to a charge-transfer mechanism.

Evidence has been presented which permits a more quantitative understanding of the interaction between ascorbic acid and nicotinamide, an interaction which has been variously referred to as a pharmaceutical incompatibility and a means of providing a more efficient therapeutic combination. In view of the low association constant of the complex, and the fact that the physiological pH does not favor the interaction, it is doubtful that the activity of the vitamin combination is in any way altered from that of the individual components. In addition to its pharmaceutical significance, the interaction is of interest because it focuses attention on ascorbate

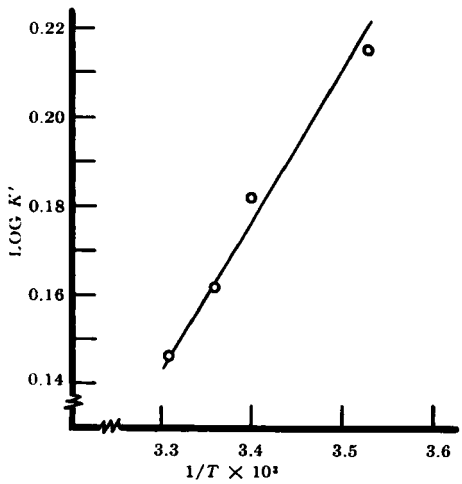

Fig. 6:—A plot illustrating the temperature dependency of the interaction between ascorbic acid and nicotinamide.

ion as a participant in a charge-transfer interaction and points to the possibility that it can interact similarly with enzyme or coenzyme systems in the body. It is conceivable that such an occurrence might be involved in metabolic processes which are dependent on this vitamin.

Determination of Ephedrine Salts in Liquid Dosage Forms

By MARTIN I. BLAKE and DANIEL A. NONA

Analytical procedures are presented for the determination of ephedrine salts in syrups, elixirs, solutions, and injections. The ephedrine is extracted with the strong cation exchange resin, Dowex 50 X-8, and is subsequently eluted with 2 normal hydrochloric acid. After evaporation of the eluate to dryness, the residue is titrated nonaqueously with perchloric acid in dioxane in the presence of mercuric acetate. In formulations containing sodium chloride and other salts, the ephedrine is eluted with an alcoholic solution of ammonia. The eluate is aerated until all the ammonia is expelled. The ephedrine is determined by titration with hydrochloric acid. Comparison is made with the official assay for ephedrine sulfate solution.

EPHEDRINE, ephedrine salts, and their dosage forms have been official since U.S.P. XI and N.F. VI. The official assay procedure has usually involved ether extraction of the alkaloid liberated from the salt combination by addition of base. The ephedrine is then determined by residual alkalimetry. Ephedrine sulfate and phenobarbital capsules (1) are analyzed for ephedrine by a distillation method developed by Hilty (2) and further applied by Hilty and Wilson (3). Until recently ephedrine sulfate capsules (4) were also analyzed by this method. There is no official assay for N.F. XI ephedrine sulfate syrup.

Colorimetric procedures have been developed for the estimation of ephedrine. These have been reviewed by Higuchi and Bodin (5) and Snell and Snell (6).

Ephedrine and ephedrine salts have been determined by nonaqueous titration. Auerbach (7) titrated ephedrine in acetic acid with acetous perchloric acid. Salts of organic bases were titrated with perchloric acid in dioxane by Pifer and Wollish (8). Salts of alkaloids including ephedrine were studied. Titrations were effected visually and potentiometrically. Since chloride ion is too weakly basic to react quantitatively with the perchloric acid, the authors found that by adding mercuric acetate to the titration mixture, the chloride is tied up as undissociated mercuric chloride. The liberated acetate ion is then titratable with perchloric acid. Mercuric acetate itself is essentially undissociated in acetic acid and, therefore, does not titrate as a base. Rink and Lux (9) and Ekeblad (10) determined ephedrine hydrochloride with acetous perchloric acid by applying the method of Pifer and Wollish. "The British Pharmacopoeia" (11) recognizes this procedure for the assay of ephedrine hydrochloride tablets. Chatten and Pernarowski (12) analyzed for ephedrine in oily nasal sprays with acetous perchloric acid. Aqueous sprays were extracted with chloroform prior to nonaqueous titration.

Ion-exchange resins have been employed in the determination of alkaloidal salts including ephedrine hydrochloride and ephedrine sulfate. Amberlite IR-4B, a weak anion-exchange resin, was used by Jindra (13) for ephedrine sulfate but was found unsuitable (14) for ephedrine hydrochloride. The resin removes the acid component of the sul-

Determination of Ephedrine Salts in Liquid Dosage Forms

By MARTIN I. BLAKE and DANIEL A. NONA

Analytical procedures are presented for the determination of ephedrine salts in syrups, elixirs, solutions, and injections. The ephedrine is extracted with the strong cation exchange resin, Dowex 50 X-8, and is subsequently eluted with 2 normal hydrochloric acid. After evaporation of the eluate to dryness, the residue is titrated nonaqueously with perchloric acid in dioxane in the presence of mercuric acetate. In formulations containing sodium chloride and other salts, the ephedrine is eluted with an alcoholic solution of ammonia. The eluate is aerated until all the ammonia is expelled. The ephedrine is determined by titration with hydrochloric acid. Comparison is made with the official assay for ephedrine sulfate solution.

EPHEDRINE, ephedrine salts, and their dosage forms have been official since U.S.P. XI and N.F. VI. The official assay procedure has usually involved ether extraction of the alkaloid liberated from the salt combination by addition of base. The ephedrine is then determined by residual alkalimetry. Ephedrine sulfate and phenobarbital capsules (1) are analyzed for ephedrine by a distillation method developed by Hilty (2) and further applied by Hilty and Wilson (3). Until recently ephedrine sulfate capsules (4) were also analyzed by this method. There is no official assay for N.F. XI ephedrine sulfate syrup.

Colorimetric procedures have been developed for the estimation of ephedrine. These have been reviewed by Higuchi and Bodin (5) and Snell and Snell (6).

Ephedrine and ephedrine salts have been determined by nonaqueous titration. Auerbach (7) titrated ephedrine in acetic acid with acetous perchloric acid. Salts of organic bases were titrated with perchloric acid in dioxane by Pifer and Wollish (8). Salts of alkaloids including ephedrine were studied. Titrations were effected visually and potentiometrically. Since chloride ion is too weakly basic to react quantitatively with the perchloric acid, the authors found that by adding mercuric acetate to the titration mixture, the chloride is tied up as undissociated mercuric chloride. The liberated acetate ion is then titratable with perchloric acid. Mercuric acetate itself is essentially undissociated in acetic acid and, therefore, does not titrate as a base. Rink and Lux (9) and Ekeblad (10) determined ephedrine hydrochloride with acetous perchloric acid by applying the method of Pifer and Wollish. "The British Pharmacopoeia" (11) recognizes this procedure for the assay of ephedrine hydrochloride tablets. Chatten and Pernarowski (12) analyzed for ephedrine in oily nasal sprays with acetous perchloric acid. Aqueous sprays were extracted with chloroform prior to nonaqueous titration.

Ion-exchange resins have been employed in the determination of alkaloidal salts including ephedrine hydrochloride and ephedrine sulfate. Amberlite IR-4B, a weak anion-exchange resin, was used by Jindra (13) for ephedrine sulfate but was found unsuitable (14) for ephedrine hydrochloride. The resin removes the acid component of the sul-

fate salt while the alkaloidal base appears in the eluate which is titrated visually with standard hydrochloric acid. This resin apparently does not split the ephedrine hydrochloride quantitatively. Samuelson (15) has noted that with weakly basic anion exchangers incomplete conversion may occur when salts of fairly strong bases such as ephedrine are involved. Saunders, *et al.* (16), used a strong anion-exchange resin to liberate the free base from ephedrine hydrochloride. Since this resin is a salt splitter, inorganic salts interfere. These authors also noted that weak anion exchangers are unsuitable for salts of strong bases as ephedrine. However, Vincent, *et al.* (17), found Amberlite IR-45 (a weakly basic anion-exchange resin) suitable for the estimation of ephedrine sulfate in liquid dosage forms. The column was washed with water to remove sodium and other interfering components. The ephedrine was removed subsequently by elution with 75% ethanol.

Huyck (18) found that Amberlite IRC-50 was a good adsorbent for ephedrine alkaloid. Blaug and Zopf (19) used this resin to extract the ephedrine from an elixir which also contained an antihistamine salt. The ephedrine was retained by the resin while the antihistamine salt appeared in the eluate. Ephedrine salts were not employed in their study.

The present paper describes procedures for determining ephedrine salts in liquid dosage forms by ion-exchange chromatography and nonaqueous titrimetry. A modification is presented which eliminates interference by inorganic salts and certain synthetic sweetening agents.

EXPERIMENTAL

Preparation of Exchange Column

The strongly acidic cation-exchange resin Dowex 50 X-8 (200–400 mesh) was used in this study. A Mohr buret cut to a length of 30 cm. served as the chromatographic tube. The end of the tube was joined to a glass tip by a 5-cm. piece of rubber tubing. A Hoffman clamp was fixed to the rubber tubing midway between the buret and the glass tip. A plug of glass wool was inserted into the bottom of the buret to support the resin column. Ten grams of resin was added to the tube in the form of a suspension in water. When the resin settled completely, the column was washed with 200 ml. of distilled water, 100 ml. of 1 *N* hydrochloric acid, and finally with distilled water until the eluate was neutral. The column was ready for use. A layer of solvent was maintained above the resin column at all times.

Assay Procedure

Method A.—A 100-mg. sample of ephedrine sulfate or ephedrine hydrochloride, accurately weighed, was dissolved in 10 ml. of distilled water. The solution was added to the resin column. The column was washed with at least 100 ml. of distilled water. The ephedrine was then eluted from the column with 2 *N* hydrochloric acid. One-hundred milliliters of eluate was collected in a 150-ml. beaker. The solution was evaporated to dryness on a steam plate. Ten milliliters of distilled water was added; the solution was again evaporated to dryness. This was repeated once. The residue was analyzed for ephedrine content by nonaqueous titration.

Ten milliliters of glacial acetic acid, 20 ml. of dioxane, and 10 ml. of 6% mercuric acetate in glacial acetic acid were added to the beaker containing the ephedrine hydrochloride residue. The solution, magnetically stirred, was titrated with 0.1 *N* perchloric acid in dioxane using a Fisher titrimeter equipped with a calomel and glass electrode system.

Titration was also effected visually by adding two drops of a 0.2% methyl violet solution in glacial acetic acid to the titration beaker. The proper indicator color change was noted by using indicator solution in conjunction with a potentiometric titration. The color change corresponding to the graphic end point was from a violet to an intense blue coloration and was readily detectable with the addition of one drop of titrant at the end point.

Method B.—A sample of ephedrine hydrochloride or ephedrine sulfate was applied to the resin column as described under *Method A*. The ephedrine was eluted with 5% ammonium hydroxide in 95% alcohol prepared by diluting stronger ammonia water with ethanol. A total of 60 ml. of eluate was collected in a 150-ml. beaker. The solution was gently aerated by passing a stream of air over the beaker until the ammonia was completely expelled from the solution. A study, reported later in this paper, indicated that at least 3 or 4 hours were necessary for this purpose. The liquid level in the beaker was kept constant by adding alcohol from time to time. The solution was then titrated visually with 0.1 *N* hydrochloric acid using three drops of methyl red T.S. as the indicator.

Method C.—After titration of the eluate as de-

[a] Standard deviation; based on at least five determinations. [b] Results of official assay are averages of duplicate runs.

scribed under *Method B*, the solution (now containing ephedrine hydrochloride) was evaporated to dryness and the residue analyzed by nonaqueous titration as described under *Method A*.

Method D.—Certain samples (indicated in Table II) were analyzed for comparative purposes by the procedure described for N.F. XI ephedrine sulfate solution.

For *Methods A*, *B*, and *C* blank runs were conducted with each series of four determinations, and the necessary corrections were made in the calculations. The data for the analysis of ephedrine salts, free and in the presence of sodium chloride, are shown in Table I.

Aeration Time

The time of aeration necessary for complete removal of ammonia from eluate obtained in *Method B* was determined in the following manner. A series of pure ephedrine samples was prepared by weighing accurately 75 to 100 mg. of pure alkaloid into 100-ml. beakers. Sixty milliliters of 5% ammonia in alcohol was added to each beaker. Each solution was subjected to gentle aeration by directing a fine stream of air above the surface of the liquid for varying intervals of time. The solutions were analyzed for ephedrine content by titration with 0.1 *N* hydrochloric acid using methyl red T.S. as the indicator.

Analysis of Liquid Dosage Forms

A number of dosage forms containing ephedrine salts were analyzed by the procedures previously described. For viscous solutions, as the syrup and elixir, an aliquot containing about 100 mg. of ephedrine salt was transferred by pipet to a suitable beaker. The solution was diluted with an equal volume of 50% alcohol and added to the ion-exchange column. When the last of the solution passed below the surface of the resin, the column was washed with 150–200 ml. of distilled water. The ephedrine was eluted from the column as described for *Methods A* or *B*. For the ephedrine sulfate solutions and the injection, a suitable aliquot was added directly to the column and treated as above. The data for the analysis of liquid dosage forms are shown in Table II. Samples designated as I are commercial preparations, those listed as II are preparations routinely prepared in the manufacturing pharmacy of our pharmacy department.

DISCUSSION

The official assay for ephedrine salts, free and in dosage forms, is based on an extraction procedure with ether. It is tedious and time consuming. While no assay is recognized for the syrup, application of the official assay for the solution to the syrup did yield favorable results (Table II).

The strong cation-exchange resin, Dowex 50 X-8, is an effective salt splitter and removes the ephedrine quantitatively from its salt form. Excellent results were obtained by *Method A* for both the hydrochloride and the sulfate. The data are reported in Table I. Since this resin is a salt splitter, sodium chloride interferes. Both sodium ion and ephedrine are retained by the column. Elution with 5% ammonium hydroxide in alcohol (*Method B*) displaces the ephedrine from the column but not the sodium. This proved to be an effective desalting technique. The eluate was aerated by passing a stream of air over the solution until all the ammonia was removed. The effect of aeration time on ephedrine recovery was noted experimentally. Under the conditions used, high results (122.6%), due to the presence of ammonia calculated as ephedrine, were still obtained after aeration for 2.5 hours. All the ammonia was removed by aeration for 3 hours, and there was no appreciable loss of ephedrine after aeration for 8 hours. Results obtained by *Method B* for ephedrine

salts in the presence of sodium chloride are recorded in Table I. The ephedrine hydrochloride formed in *Method B* was then determined by nonaqueous titration (*Method C*) as a confirmatory procedure.

The proposed methods were applied to liquid dosage forms including solutions, an elixir, syrups, and an injection. The data are reported in Table II. Since the solutions contain sodium chloride, *Method A* could not be used. Favorable results were obtained with *Methods B*, *C*, and *D*.

The elixir reported in Table II was a commercial sample and when analyzed by *Method A* gave very high results. The manufacturer upon request was kind enough to supply the formula of the elixir which did contain appreciable amounts of sodium saccharin and sodium chloride. Quantitative results were obtained by *Methods B* and *C*. The elixir responded to the official assay for ephedrine sulfate solution.

The syrups yielded good results by the proposed methods as well as by the official assay procedure for the solution. Since the injection contains sodium chloride, *Methods B* and *C* were used.

Coloring agents found in the elixir and syrup do not interfere. They are readily washed from the column with water. Nonionic agents and acidic components in general, are not adsorbed by the column. Where synthetic sweeteners such as sodium saccharin are used in the formulation, *Method B* must be employed. Other organic bases and their salts will interefere with the proposed methods. However, if the base strength differs significantly from that of ephedrine, a nonaqueous differential titration may be possible.

Since four assays may be conveniently conducted at the same time, the proposed methods are less time consuming and less tedious than the official assay. The procedures are simple, accurate, and applicable to all commonly available liquid dosage forms of ephedrine salts. They should also be applicable to solid dosage forms and to combinations of ephedrine with other therapeutic agents such as barbiturates.

Rate of Anaerobic Degradation of Ascorbic Acid in Aqueous Solution

By PER FINHOLT, ROLF B. PAULSSEN, and TAKERU HIGUCHI

The pH rate profile of the rate of disappearance of ascorbic acid from aqueous solution under anaerobic conditions has been determined at 96°. The dependency on pH is surprisingly low over pH range of 1–11. The profile shows a small but apparently real maximum at pH = pK_{a_1}, an effect which can be rationalized by assuming formation of a salt-acid complex in solutions. The anaerobic rate shows buffer dependency but relatively small ionic strength effect.

ALTHOUGH the oxidative route of degradation of ascorbic acid has been extremely well studied, relatively few papers have appeared dealing with degradative loss of ascorbic acid under anaerobic conditions. Since in practice reduction in the concentration of this vitamin in liquid pharmaceutical preparation appears to follow largely the latter route, serious study of the factors influencing its rate was felt needed. Even in instances where losses in the ascorbic acid concentration are of no major concern, the gas produced in the process often poses a problem.

Previous studies have been largely of qualitative nature. Reichstein and Grüssner (1), for example, showed that when ascorbic acid was heated with 0.2 *N* hydrochloric acid a decrease in the iodine consumption and furfural was formed. Their observation was part of a work on the synthesis of ascorbic acid from 2-keto-L-gulonic acid.

Rate of Anaerobic Degradation of Ascorbic Acid in Aqueous Solution

By PER FINHOLT, ROLF B. PAULSSEN, and TAKERU HIGUCHI

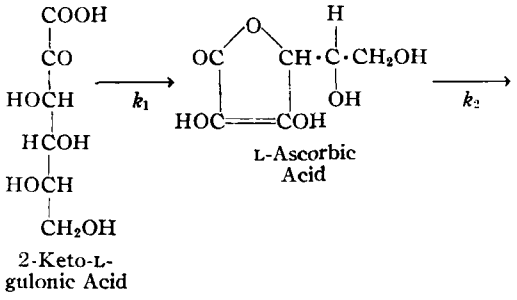
The pH rate profile of the rate of disappearance of ascorbic acid from aqueous solution under anaerobic conditions has been determined at 96°. The dependency on pH is surprisingly low over pH range of 1–11. The profile shows a small but apparently real maximum at pH = pK_{a_1}, an effect which can be rationalized by assuming formation of a salt-acid complex in solutions. The anaerobic rate shows buffer dependency but relatively small ionic strength effect.

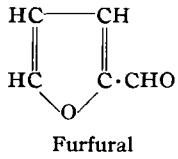
ALTHOUGH the oxidative route of degradation of ascorbic acid has been extremely well studied, relatively few papers have appeared dealing with degradative loss of ascorbic acid under anaerobic conditions. Since in practice reduction in the concentration of this vitamin in liquid pharmaceutical preparation appears to follow largely the latter route, serious study of the factors influencing its rate was felt needed. Even in instances where losses in the ascorbic acid concentration are of no major concern, the gas produced in the process often poses a problem.

Previous studies have been largely of qualitative nature. Reichstein and Grüssner (1), for example, showed that when ascorbic acid was heated with 0.2 *N* hydrochloric acid a decrease in the iodine consumption and furfural was formed. Their observation was part of a work on the synthesis of ascorbic acid from 2-keto-L-gulonic acid.

Received January 2, 1963, from the School of Pharmacy, University of Wisconsin, Madison, and the Institute of Pharmacy, University of Oslo, Oslo, Norway.
Accepted for publication March 1, 1963.
The authors acknowledge the technical assistance of Mr. Harry Ockerlander in carrying out the analyses.
These studies were supported in part by Grant A-3437 (C-2) from the National Institutes of Health, U. S. Public Health Service, Bethesda, Md., and by a grant from the Royal Norwegian Council for Scientific and Industrial Research, Oslo, Norway.

The enolization and lactonization of methyl 2-keto-L-gulonate into ascorbic acid could be brought about by sodium methylate and also by hydrochloric acid. Heating of 2-keto-L-gulonic acid with hydrochloric acid thus is presumed to lead to the consecutive reactions





Regna and Caldwell (2) have studied, again only in the strongly acid solution, the kinetics of this reaction and the kinetics of the transformation of some other 2-ketopolyhydroxy acids to their ascorbic acid analogs and the decomposition of these compounds. For the transformation of 2-keto-L-gulonic acid into L-ascorbic acid in 5 *M* hydrochloric acid at 59.9°, a first-order rate constant $k_1 = 2.53 \times 10^{-3}$ minutes^{-1} was found. For the decomposition of L-ascorbic acid into furfural under the same conditions, the first-order rate constant was 4.91×10^{-4} minutes^{-1}.

Taylor, Fowler, McGee, and Kenyon (3) noted that carbon dioxide is evolved when ascorbic acid was heated, again in 12% hydrochloric acid. They submitted kinetic data on the evolution of carbon dioxide from L-ascorbic acid and from D-glucuronic acid, D-galacturonic acid, pectic acid, alginic acid, celluronic acids, and oxidized starch. The first-order rate constant for the evalution of carbon dioxide from ascorbic acid was more than twice as great as that of its nearest neighbor in the series, D-galacturonic acid. This indicated the profound effect of an enediol structure on the stability of the adjacent lactonized carboxyl group. A rather rapid evolution of carbon dioxide occurs from ascorbic acid until approximately 28% by weight is lost, followed by slow evolution for many hours more, finally attaining a total value in excess of 30%. If only the carboxyl group supplied the carbon dioxide, the evolution should have been 25.0%. The results indicated that the carboxyl group decomposed rapidly and that there is a further slow decomposition evolving more carbon dioxide.

Von Euler and Hasselquist (4) found that by heating ascorbic acid with 1 *N* sodium hydroxide at 100° in nitrogen atmosphere the lactone ring was obviously opened and the salt of the corresponding hexuronic acid was formed.

For the anaerobic degradation of ascorbic acid acid at pH 1.10 Fischer-Jensen (5) found a first-order rate constant $k = 0.323$ hours^{-1} at 90° and $k = 0.801$ hours^{-1} at 100°, thus giving $Q_{10} = 2.5$. The decomposition was faster at pH 2.5 than at pH 6 and was independent of the ascorbic acid concentration.

By heating ascorbic acid solutions of different pH values below 5.5 under anaerobic conditions Cier, Nofre, and Drevon (6) showed that carbon dioxide, furfural, and xylose were formed. The rate of formation of only furfural was followed and was found to be very slow at pH 5 and higher; the rate, however, increased sharply by decreasing pH. The authors proposed the following scheme for the nonoxidative degradation of ascorbic acid in acid medium

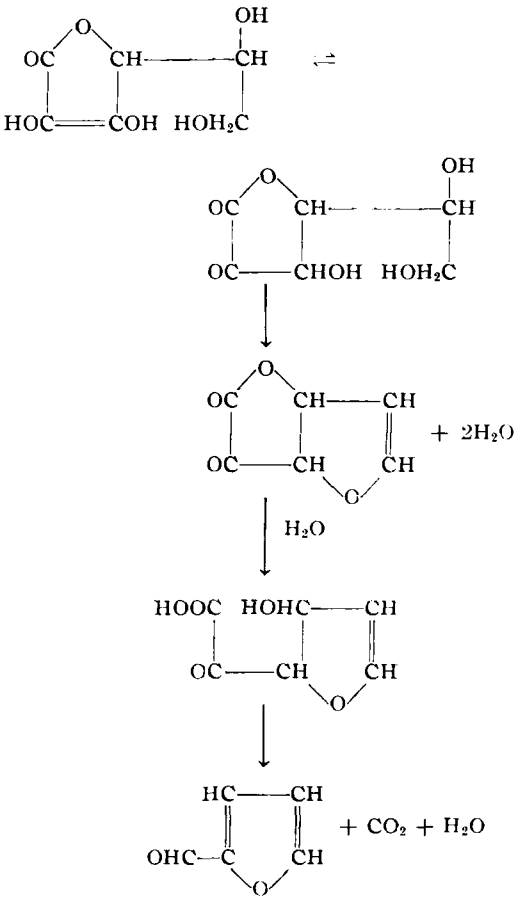


TABLE I.—COMPARISON OF RESULTS OBTAINED BY THE IODOMETRIC METHOD (A) AND BY THE DICHLOROPHENOL-INDOPHENOL METHOD (B) IN ANALYSIS OF ASCORBIC ACID SOLUTIONS OF DIFFERENT pH DEGRADED BY HEATING AT 96°C.

6	7.05	7.05	...	...	...	...	...	...	62	7.28	7.19	...	...	...
$t_{1/2}$	12.7 hr.	13 hr.		25 hr.	25 hr.		75 hr.	75 hr.		145 hr.	145 hr.		82 hr.	79 hr.

This scheme does not explain how the xylose is formed. The authors exclude the possibility of xylose being the precursor of furfural since xylose by heating in slightly acid medium only gives traces of furfural.

The present studies have been concerned with the exact rate of anaerobic degradation of ascorbic acid in acid and in alkaline medium and determination of the extent of catalysis by hydrogen and hydroxyl ions and by general acids and bases.

EXPERIMENTAL

Materials.—Ascorbic acid U.S.P. from Hoffmann-La Roche Co. was used. Iodometric titration of this product according to the method in U.S.P. XVI showed that it contained 99.85% $C_6H_8O_6$.

All reagents used were of analytical grade. The water used was distilled water redistilled from a neutral glass still, boiled and cooled under oxygen-free nitrogen.

Assay.—The residual ascorbic acid concentration of the heated solutions was determined iodometrically. An aliquot part of the sample, usually 5.00 ml., was acidified with diluted sulfuric acid and titrated with 0.01 *N* iodine using a few drops of starch T.S. as indicator.

In some cases the ascorbic acid concentration was also determined by the dichlorophenol-indophenol method given by U.S.P. XVI for ascorbic acid injection.

Degradation Studies.—A 176-mg. quantity (0.001 mole) of ascorbic acid was dissolved in 100 ml. of the appropriate buffer solution containing a sufficient amount of sodium chloride to give the ascorbic acid solution an ionic strength $\mu = 0.50$. The solution was filled into 5-ml. ampuls, and the air in the ampuls was replaced by nitrogen. The ampuls were sealed and heated at 96° in a constant temperature bath. At appropriate intervals ampuls were taken out from the bath, cooled on ice, and the solution analyzed.

Determination of pKa_1 and pKa_2 of Ascorbic Acid at 96° and Ionic Strength $\mu = 0.5$.—pKa_1 was determined by measuring the pH at 96° of solutions containing equal amounts of ascorbic acid (A) and monohydrogen ascorbate (A^-) and a sufficient amount of sodium chloride to give $\mu = 0.50$. $pKa_1 = 3.94$ was found.

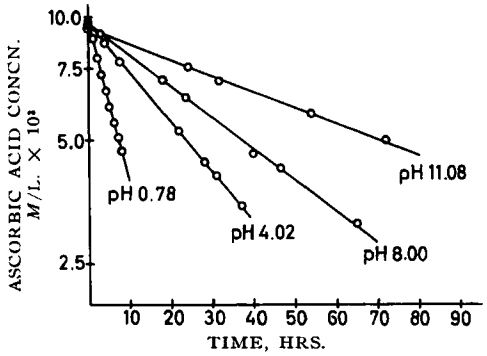

Fig. 1.—Plots showing the overall first-order character of the anaerobic degradation of ascorbic acid at different pH values and 96°C. For the actual runs 0.2 *N* perchloric acid (pH 0.78), 0.5 *M* acetate (pH 4.02), 0.15 *M* borate (pH 8.00), and 0.25 *N* NaOH (pH 11.08) were used.

TABLE II.—HALF-LIFE OF ASCORBIC ACID DEGRADATION AT 96°C. AND DIFFERENT pH VALUES AND DIFFERENT IONIC STRENGTH

Ionic Strength	Half-Life, hrs. pH 1.1	pH 4.0	pH 6.5	pH 10.2
0.1	13.2	31	140.3	35
0.2	13.1	30.5	139.8	35
0.3	...	30	139	36
0.4	12.9	30	...	36
0.5	...	30	137	36
0.6	13.1	...	...	...

pKa_2 was determined by measuring (under nitrogen) the pH at 96° of solutions prepared by mixing equal amounts of monohydrogen ascorbate (A^-) and ascorbate ($A^=$) and adding a sufficient amount of sodium chloride to give $\mu = 0.50$. The following equations were used for calculation of pKa_2

$$pKa_2 = pH - \log \frac{[A^-] - [OH^-]}{[A^-] + [OH^-]} \quad \text{(Eq. 1)}$$

$$\log [OH^-] = pH - 11.70 \quad \text{(Eq. 2)}$$

The relationship between pH and $[OH^-]$ given by Eq. 2 was obtained as the result of pH measurements in solutions of sodium hydroxide of known hydroxyl ion concentration at 96° and $\mu = 0.50$.

It became difficult to determine pKa_2 with great accuracy. The average value of several determinations was $pKa_2 = 10.5$.

RESULTS AND DISCUSSION

Comparison of the Results Obtained by the Iodometric Method and by the Dichlorophenol-Indophenol Method.—Solutions of different pH were heated at 96° and the residual ascorbic acid concentration determined at appropriate intervals according to the iodometric method and the dichlorphenol-indophenol method. The half life ($t_{1/2}$) was found graphically. Table I shows that the two methods gave essentially the same results.

Order of Reaction with Respect to Ascorbic Acid.—The rate of disappearance of ascorbic acid from the solutions was found to be first order with respect to ascorbic acid at pH values from 0.4 up to 11.4. In all cases there was a linear relationship between time and logarithm of residual ascorbic acid concentration as shown in Fig. 1. The absence of lag time strongly suggests that the effective mechanism contains only one rate-determining step involving loss of the reducing capacity of the solutions. If ascorbic acid is initially converted to some other form still capable of reacting with iodine or the indophenol, this step would have to be exceedingly rapid. Since other data suggest that the vitamin is relatively stable under these conditions, it is unlikely that any irreversible formation of a readily oxidizable species takes place to a significant extent.

Primary Salt Effect.—A series of runs were made keeping pH, ascorbic acid concentration, and buffer concentration constant in each series but varying the ionic strength by addition of different amounts of sodium chloride. Table II shows that there was no primary salt effect at pH 1.1, 4.0, 6.5, or 10.2.

Catalytic Effect of General Acids and Bases on the Anaerobic Degradation of Ascorbic Acid.—The catalytic effect of different buffers was determined by making runs with each buffer varying the total buffer concentration by keeping the pH and the ionic strength constant ($\mu = 0.50$). Straight lines were obtained by plotting the observed k values against buffer concentration, the slopes of which were a measure of the catalytic activity of the buffers.

Figure 2 shows that phosphate buffers with pH 2.14, 2.60, and 3.05 have a catalytic effect on the anaerobic degradation of ascorbic acid. At pH $\lesssim$ 2.60, more than 95% of the total ascorbic acid will exist in the undissociated form. It is therefore reasonable to assume that the curves representing the runs at pH 2.14 and pH 2.60 give a picture of the catalytic effect of H_3PO_4 and $H_2PO_4^-$ on the undissociated ascorbic acid. If we assume this, it is possible to calculate the catalytic constants $k_{H_3PO_4}$ and $k_{H_2PO_4^-}$ of H_3PO_4 and H_2PO_4, using the equations

$$k_{obs} = k_o + k_{H_3PO_4} \cdot [H_3PO_4] + k_{H_2PO_4} - [H_2PO_4^-] \quad \text{(Eq. 3)}$$

$$\frac{[H_2PO_4^-]}{C - [H_2PO_4]} = \frac{ka_1}{[H^+]} \quad \text{(Eq. 4)}$$

where k_{obs} = the observed rate constant, k_o = the rate constant at zero buffer concentration = the intercept of the lines with the y-axis, C = total buffer concentration, and $ka_1 = 8.9 \times 10^{-3}$ at 96°, and $\mu = 0.50$.

On this basis, $k_{H_3PO_4} = 3.64 \times 10^{-2}$ hours^{-1} mole^{-1} L.; $k_{H_2PO_4^-} = 4.13 \times 10^{-2}$ hours^{-1} mole^{-1} L.

Figure 3 shows the catalytic effect of phosphate buffers pH 6.00 to 7.50. The zero slopes of the lines representing the runs at pH 7.04 and pH 7.50, where more than 99% of the total ascorbic acid exists as the monohydrogen ascorbate ion, indicates that both

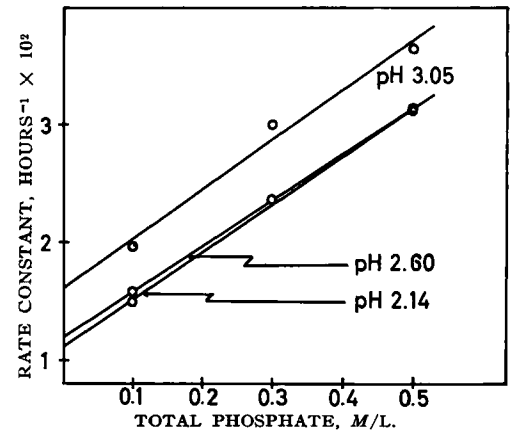

Fig. 2.—Plots showing the effect of phosphate concentration on the pseudo first-order rate constant of the anaerobic degradation of ascorbic acid at fixed pH values. All the runs were made at 96°C. and an ionic strength of 0.50.

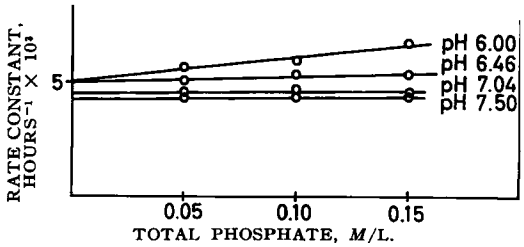

Fig. 3.—Plots showing the effect of phosphate concentration on the pseudo first-order rate constant of the anaerobic degradation of ascorbic acid at fixed pH values. All the runs were made at 96°C. and an ionic strength of 0.50.

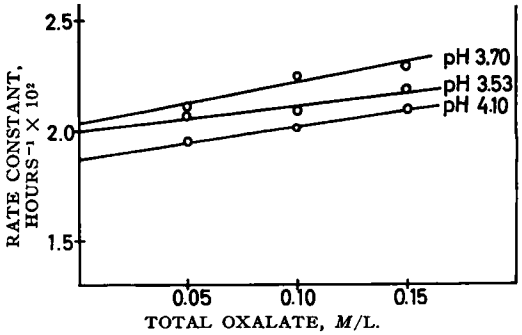

Fig. 4.—Plots showing the effect of oxalate concentration on the pseudo first-order rate constant of the anaerobic degradation of ascorbic acid at fixed pH values. All the runs were made at 96°C. and an ionic strength of 0.50.

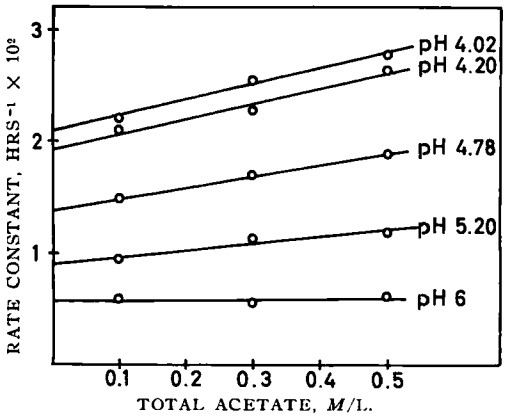

Fig. 5.—Plots showing the effect of acetate concentration on the pseudo first-order rate constant of the anaerobic degradation of ascorbic acid at fixed pH values. All the runs were made at 96°C. and an ionic strength of 0.50.

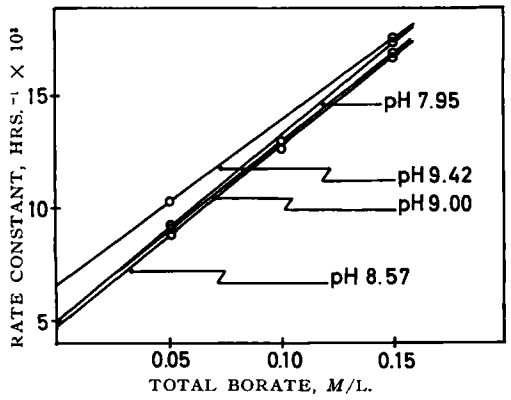

Fig. 6.—Plots showing the effect of borate concentration on the pseudo first-order rate constant of the anaerobic degradation of ascorbic acid at fixed pH values. All the runs were made at 96°C. and an ionic strength of 0.50.

$H_2PO_4^-$ and $HPO_4^=$ are noncatalytic with respect to this ion. The increasing slopes of the lines with decreasing pH may be attributed to the increase in the concentration of undissociated ascorbic acid with decreasing pH.

Oxalate buffers pH 3.7 to 4.1 and acetate buffers pH 4.02 to 6 have some catalytic effect (Figs. 4 and 5). Between pH 3.7 and 6 ascorbic acid will exist as undissociated acid and monohydrogen ascorbate ion. No attempt has been made to calculate the catalytic constants of the different species of these buffers with respect to different forms of ascorbic acid. The zero slope of the line on Fig. 5 representing the run at pH 6 seems to indicate, however, that CH_3COO^- is noncatalytic with respect to monohydrogen ascorbate ion. At pH 6, 99% of the total ascorbic acid will exist as the monohydrogen ascorbate ion, 95% of the total acetic acid will exist as the acetate ion.

The evaluation of the catalytic effect of borate buffers presents some problems because these buffers do not contain only undissociated H_3BO_3 and $H_2BO_3^-$ ions but also the ions BO_2^- and $B_4O_7^=$. The actual concentration of each of these ions cannot be readily determined. It is therefore quite difficult to make an accurate calculation of the ionic strength of the buffer solutions and to calculate the catalytic constant of each specie. The first of the difficulties mentioned may be handled by using the buffer in a relatively low concentration and adding a relatively great amount of a neutral salt. The ionic strength will then be determined mainly by the neutral salt. In our experiments the total buffer concentration never exceeded 0.15 *M* and sodium chloride was added to $\mu = 0.50$.

It is obvious from Fig. 6 that borate buffers have a pronounced apparent catalytic effect on the anaerobic degradation of ascorbic acid. At pH $\gtreqless$ 8.57, more than 98% of the total ascorbic acid will exist as the monohydrogen ascorbate ion. If we make the assumption that boric acid at pH $\gtreqless$ 8.57 will exist mainly as H_3BO_3 and $H_2BO_3^-$, it is possible to calculate the catalytic constants of these species with respect to the monohydrogen ascorbate ion.

We found $k_{H_3BO_3} = 8.03 \times 10^{-2}$ hours^{-1} mole^{-1} L.; $k_{H_2BO_3^-} = 7.81 \times 10^{-2}$ hours^{-1} mole^{-1} L.; pKa of boric acid was determined to be 8.59 at 96°; and $\mu = 0.50$.

It should be kept in mind that no attempt is made here to postulate the exact mode of catalysis. It is, of course, possible that an ester species may be involved with the borate system.

pH-Rate Profile of the Anaerobic Degradation of Ascorbic Acid.—The rate constants at zero buffer concentration can easily be picked from Figs. 2–6. The rate constants are shown in Fig. 7 as a function of pH. The rate constants given in Fig. 7 for pH<2 and pH>10 were found by making runs using perchloric acid solutions or sodium hydroxide solutions of known concentration. pH of the strongly acid solutions at 96° and $\mu = 0.5$ were calculated from

$$\text{pH} = -\log [H^+] + 0.08 \qquad \text{(Eq. 5)}$$

Equation 2 was used for the calculation of pH of the strongly basic solutions.

The pH rate profile (Fig. 7) suggests that the overall degradative rate represents a summation of a relatively large number of separate reactions. It is not possible from the experimental data to establish the correct reactions with certainty, but the following reactions would give a pH rate profile that appears to fit the experimental points well.

$$A + H^+ \xrightarrow{k_1} \text{products} \qquad \text{(Reaction 1)}$$

$$A \xrightarrow{k_2} \text{products} \qquad \text{(Reaction 2)}$$

$$A \cdot A^- \xrightarrow{k_3} \text{products} \qquad \text{(Reaction 3)}$$

$$A^- + A \xrightarrow{k_4} \text{products} \qquad \text{(Reaction 4)}$$

$$A^- \xrightarrow{k_5} \text{products} \qquad \text{(Reaction 5)}$$

$$A^= \xrightarrow{k_6} \text{products} \qquad \text{(Reaction 6)}$$

In these reactions, A = undissociated ascorbic acid, A^- = monohydrogen ascorbate ion, $A^=$ = ascorbate ion; and $A \cdot A^-$ = a complex of undissociated ascorbic acid and monohydrogen ascorbate ion.

The overall velocity is equal to the sum of the rates of all these reactions

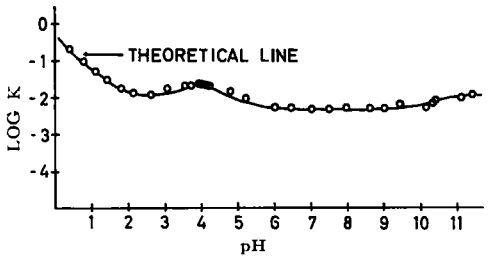

Fig. 7.—pH rate profile of the anaerobic degradation of ascorbic acid at 96°C. The circles represent the experimental results; the line corresponds to that expected theoretically from the six proposed reactions.

$$-\frac{d[A_T]}{dt} = k_1[A][H^+] + k_2[A] + k_3[A\cdot A^-] + k_4[A^-][A] + k_5[A^-] + k_6[A^=] \quad \text{(Eq. 6)}$$

$$[A_T] = [A] + [A^-] + [A^=] \quad \text{(Eq. 7)}$$

If we make the assumption that A^- will exist mainly bound as $A\cdot A^-$ at pH pKa_1, then $[A\cdot A^-]$ will be approximately equal to $[A^-]$.

At pH<pKa_1 $[A^=]$ will be negligible. This means that the following equation will be valid at pH<pKa

$$-\frac{d[A_T]}{dt} = k_1[A][H^+] + k_2[A] + k_3[A^-] + k_4[A^-][A] + k_5[A^-] \quad \text{(Eq. 8)}$$

Because of the overall first-order character of the reaction we have

$$-\frac{d[A_T]}{dt} = k\cdot[A_T] \quad \text{(Eq. 9)}$$

Combining Eqs. 7, 8, 9, and the equations

$$k_{a_1} = \frac{[H^+][A^-]}{[A]} \quad \text{(Eq. 10)}$$

$$k_{a_2} = \frac{[H^+][A^=]}{[A^-]} \quad \text{(Eq. 11)}$$

gives

$$k = \frac{k_1[H^+]^2 + k_2[H^+] + (k_3 + k_5)ka_1}{[H^+] + ka_1} + \frac{k_4ka_1[H^+]A_T}{([H^+] + ka_1)^2} \quad \text{(Eq. 12)}$$

Assuming A to exist mainly as $A\cdot A^-$ at pH>pKa_1, $[A\cdot A^-]$ will be approximately equal to $[A]$. At pH>pKa_1 $k_1[A][H^+]$ will be negligible compared to the other terms in Eq. 6 and we may write

$$-\frac{d[A_T]}{dt} = k_2[A] + k_3[A] + k_4[A^-][A] + k_5[A^-] + k_6[A^=] \quad \text{(Eq. 13)}$$

Combining Eqs. 7, 9, 10, 11, and 13 gives

$$k = \frac{(k_2 + k_3)[H^+]^2 + k_5ka_1[H^+] + k_6ka_1ka_2}{[H^+]^2 + ka_1[H^+] + ka_1ka_2} + \frac{k_4ka_1[H^+]^3A_T}{([H^+]^2 + ka_1[H^+] + ka_1ka_2)^2} \quad \text{(Eq. 14)}$$

From the experimental results the following k values have been calculated: $k_1 = 3.80 \times 10^{-1}$ hours^{-1}; $k_2 = 0.89 \times 10^{-2}$ hours^{-1}; $k_3 = 3.05 \times 10^{-2}$ hours^{-1}; $k_4 = 3.44 \times 10^{-1}$ hours^{-1} mole^{-1} L.; $k_5 = 5 \times 10^{-3}$ hours^{-1}; and $k_6 = 1.21 \times 10^{-2}$ hours^{-1}.

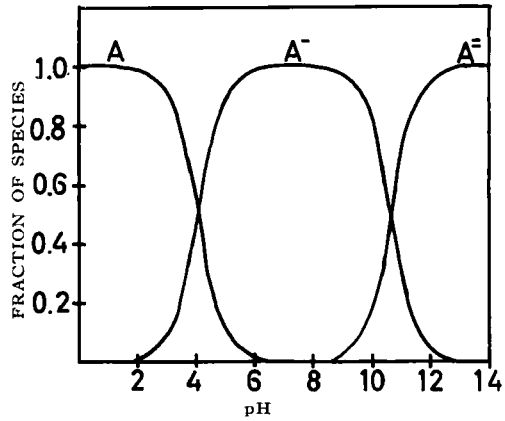

Fig. 8.—Fraction of ascorbic acid species in solution as functions of pH at 96°C. as calculated from the experimentally determined pKa_1 and pKa_2. A = Undissociated ascorbic acid, A^- = monohydrogen ascorbate ion, $A^=$ = ascorbate ion.

On the basis of the species profile shown in Fig. 8, the overall rate profile was calculated using Eq. 12 at pH<pKa_1 and Eq. 14 at pH>pKa_1; the result is shown as a solid line in Fig. 7.

Reaction 4 is suggested since it was found that the half life of the ascorbic acid degradation at pH 4 (= pKa_1 of ascorbic acid) was to some extent dependent on the total ascorbic acid concentration (Table III). No buffer was added in these experiments.

However, there is only a slight decrease in $t_{1/2}$ with increasing ascorbic acid concentration. This means that the apparent dominating reaction or reactions at pH 4 must be first order. Straight lines were obtained in each experiment by plotting the logarithm of residual ascorbic acid concentration against time.

Reaction 4 has nearly no influence on the shape of the calculated profile. At pH 4 where the influence is greatest, the calculated log k value is -1.65 with $k_4 = 3.44 \times 10^{-1}$, and -1.66 with $k_4 = 0$.

The relatively good agreement of the experimental data and the theoretical profile does not of course prove that the proposed Reactions 1–6 are the correct ones. Other reactions could lead to the same observed experimental dependencies.

At pH 6–9 the following three reactions would lead to the same log k/pH dependency

$$A^- \rightarrow \text{products}$$
$$A^= + H^+ \rightarrow \text{products}$$
$$A + OH^- \rightarrow \text{products}$$

The lack of primary salt effect at pH 6.5 indicates that the dominating reaction cannot be $A^= + H^+ \rightarrow$ products, but one of the other two. We have proposed the reaction $A^- \rightarrow$ products, but the reaction $A + OH^-$ cannot be eliminated.

At pH 10 to 11.5 the following two reactions would lead to the same log k/pH relationship

$$A^- + OH^- \rightarrow \text{products}$$
$$A^= \rightarrow \text{products}$$

TABLE III.—HALF-LIFE OF ANAEROBIC ASCORBIC ACID DEGRADATION AT 96°C. AND pH 4 AND DIFFERENT ASCORBIC ACID CONCENTRATIONS

Total Ascorbic Acid Concn., M/L.	$t_{1/2}$, hrs.
0.01	30.3
0.02	29.3
0.03	28.3
0.04	26.8
0.05	25.8

The lack of primary salt effect at pH 10.2 indicates that the dominating reaction cannot be $A^- + OH^- \rightarrow$ products but $A^- \rightarrow$ products.

Attempts to Prove the Existence of an Ascorbic Acid–Monohydrogen Ascorbate Complex.—Reaction 3 presupposes the existence of a complex between ascorbic acid and the monohydrogen ascorbate ion.

It is well known that organic acids are able to form complexes with their anions. Complex formation has been reported between mandelic acid and metal mandelate (7), salicylic acid and sodium salicylate (8), hippuric acid and potassium hippurate (8), succinic acid and potassium succinate (9), benzoic acid and sodium (10), and ammonium benzoate (11), *p*-hydroxybenzoic acid, dihydroxy benzoic acids, phenylacetic acid, adipic acid, saccharin, barbituric acid, barbital, phenobarbital, and their sodium salts (12).

The possible complex formation between ascorbic acid and monohydrogen ascorbate has been investigated by the authors by determination of freezing point depression, boiling point elevation, and solubility studies.

By calculation of the freezing point depression Δt, the following equation was used

$$\Delta t = p - q - 0.0125(p-q)(q-a)$$

where p = the freezing point of water, q = the freezing point of the solution, and a = the temperature to which the solution had been supercooled. Δt for a 0.5 M ascorbic acid solution was 0.943°. Δt for a 0.5 M ascorbic acid solution to which NaOH had been added to pH 4 was 1.301°.

For a 0.05 M ascorbic acid solution the corresponding values were 0.093 and 0.128°.

The boiling point elevation was determined according to Landsberger. There is by this method a condensation of vapor in the solution which is being studied. In our experiments we always used the same amount of a 0.5 M ascorbic acid solution and tried to get nearly the same amount of vapor condensed in each run. The final ascorbic acid concentration was therefore nearly the same in all experiments. Expressed as molality, it was 0.45. The average boiling point elevation Δt of the ascorbic acid solution with the final molality 0.45 was 0.19°. A solution of the same final molality but with NaOH added to pH 4 gave an average boiling point elevation $\Delta t = 0.27°$.

If the addition of sodium hydroxide to the ascorbic acid solutions (to pH 4) had caused no complex formation and if the influence of the ionic interactions in the solutions with pH 4 is neglected, the change in freezing point depression and boiling point elevation would have been 50%. The changes found were 38% for freezing point depression and 42% for the boiling point elevation. Taking into account the influence of the electrostatic attractions between the oppositely charged ions in the solutions with pH 4, our results show either that there is none or there is only a negligible complex formation between ascorbic acid and monohydrogen ascorbate, or the intermolecular forces in the complex are so weak that the complex formation cannot be detected by determination of freezing point depression or boiling point elevation.

Solubility studies were conducted according to the method of Higuchi and Lach (13). Five grams of ascorbic acid was added to 5 ml. of sodium monohydrogen ascorbate solutions of varying concentrations (0–3 M). The mixtures were placed in stoppered glass vials and rotated in a water bath at 30° ±0.1° overnight. An aliquot part of the clear solution was pipeted off and the ascorbic acid concentration determined by titration with 1 N sodium hydroxide.

Accurate results were impossible to obtain because of the high viscosity of the solutions. There was, however, a slight increase in the solubility of ascorbic acid with increasing salt concentration, thus indicating some complex formation. In our opinion it is difficult to draw definite conclusions from solubility studies in these very concentrated solutions and more so since an inseparable salting out effect cannot be excluded.

Our experiments do not prove the existence of a complex between ascorbic acid and monohydrogen ascorbate. On the other hand, they do not exclude this possibility. From a kinetical point of view a reaction that presupposes the existence of an ascorbic acid/ascorbate complex can explain the observed first-order character and the maximum in the pH rate profile at pH = pK_{a_1} of ascorbic acid.

Catechol Monoglyceryl Ether Carbamates

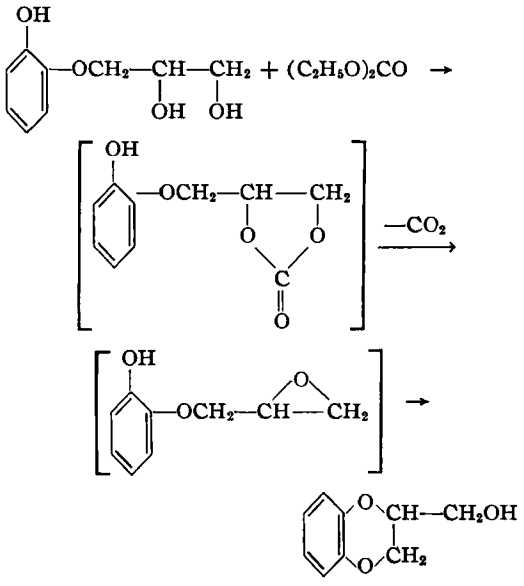
By J. SWIDINSKY, J. KERVENSKI, and B. B. BROWN

A series of carbamates and N-methylcarbamates derived from 3-(*o*-hydroxyphenoxy)-1,2-propanediol was prepared and screened for muscle relaxant activity. An ester interchange between the above diol and diethyl carbonate failed to give 4-(*o*-hydroxyphenoxymethyl)-1,3-dioxolone-2; 2-hydroxymethyl-1,4-benzodioxane was obtained instead. Prior benzylation of the phenolic hydroxyl resulted in the normal formation of the dioxolone. None of the compounds possessed muscle relaxant activity.

THE SUCCESS of 3-(*o*-methoxyphenoxy)-2-hydroxy-1-propyl carbamate, methocarbamol[1] as a muscle relaxant prompted evaluation of similar activity in carbamates derived from the monoglycerol ether of catechol, 3-(*o*-hydroxyphenoxy)-1,2-propanediol (1).

DISCUSSION

The monocarbamates were prepared by the reaction of ammonia and methylamine with 4-(*p*-benzyloxyphenoxymethyl)-1,3-dioxolone-2, followed by debenzylation with hydrogen over palladium-on-charcoal. The blocking of the phenolic hydroxyl group was required when it was discovered that 3-(*o*-hydroxyphenoxy)-1,2-propanediol would not form the corresponding cyclic carbonate, 4-(*o*-hydroxyphenoxymethyl)-1,3-dioxolone-2, upon ester interchange with diethyl carbonate. Instead 2-hydroxymethyl-1,3-benzodioxane was formed. It may be that the initially formed dioxolone decomposed under the conditions of the experiment to give the 1,2-epoxide which then cyclized to the dioxane by reaction with the phenolic hydroxyl



The activation of pyrolysis of cyclic carbonates by hydroxyl groups has been reported by D. B. Pattison (2). For example, he found that a mixture of 2,2-diethylpropanediol and its cyclic carbonate could be distilled at 220° at slightly reduced pressure, whereas the cyclic carbonate of trimethylolpropane decomposed rapidly at 180–200° to give 3-ethyl-3-oxetane methanol. It may well be that a phenolic group may exert a still more powerful influence on the elimination of CO_2 since the internal temperature during the experiment did not exceed 140°.

3-(*o*-Benzyloxyphenoxy)-1,2-propanediol (Table I, No. 1) was prepared by the reaction of 3-(*o*-hydroxyphenoxy)-1,2-propanediol with benzyl chloride in the presence of aqueous sodium hydroxide.

Compound 1 was heated with an excess of diethyl carbonate in the presence of sodium methylate to form 4-(*o*-benzyloxyphenoxymethyl)-1,3-dioxolone-2 (Table I, No. 2).

Compound 2 reacted readily with ammonia and methylamine in isopropyl alcohol solution to give in each case a mixture of two isomeric monocarbamates. These were separated by fractional crystallization into the primary and secondary monocarbamates, Table I, Nos. 3–6. The higher melting member of the pair was tentatively assigned the secondary carbamate structure (3).

Each of these monocarbamates was then debenzylated by hydrogenolysis over palladium-on-charcoal to the corresponding 3-(*o*-hydroxyphenoxy)-1(2)-2(1)-propyl carbamates (N-methylcarbamates) Table I, Nos. 7–10

3-(*o*-N-methylcarbamoxyphenoxy)-1,2-bis-N-methylcarbamoxypropane, Table I, No. 11, was prepared by the reaction of 3-(*o*-hydroxyphenoxy)-1,2-propanediol with excess methyl isocyanate.

The reaction of Compound 1 with methyl isocyanate yielded 3-(*o*-benzoyloxyphenoxy)-1,2-bis-N-methylcarbamoxypropane, Table I, No. 12. Debenzylation of Compound 12 gave 3-(*o*-hydroxyphenoxy)-1,2-bis-N-methylcarbamoxypropane, Table I, No. 13.

EXPERIMENTAL

Reaction of 3-(*o*-Hydroxyphenoxy)-1,2-propanediol with Diethyl Carbonate.—A mixture of 18.4 Gm. (0.1 mole) of 3-(*o*-hydroxyphenoxy)-1,2-propanediol, 35.4 Gm. (0.3 mole) of diethyl carbonate, and 0.5 Gm. of sodium methylate was heated until the distillation of ethyl alcohol ceased. A 1-Gm. quantity of ammonium chloride was added to destroy the sodium methylate. The excess diethyl carbonate was removed at reduced pressure and a maximum internal temperature of 140°. The resi-

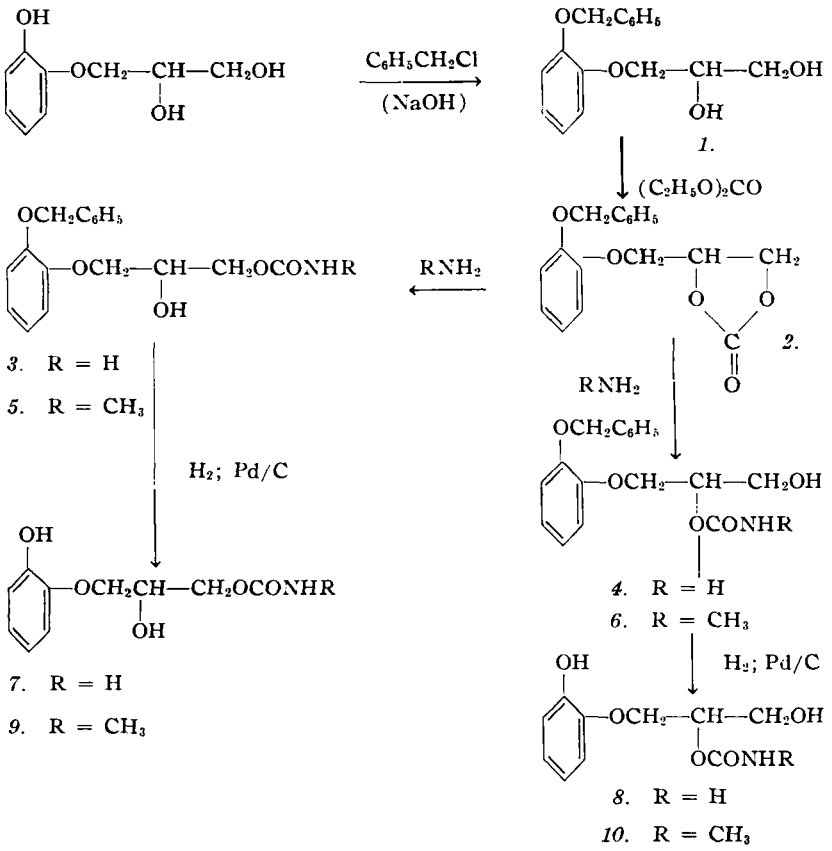
Accepted for publication February 1, 1963.
[1] Marketed as Robaxin by A. H. Robins Co., Inc., Richmond, Va.



due was extracted with boiling cyclohexane to give on cooling 7.9 Gm. of a solid, m.p. 83–86°. Recrystallized from ethyl acetate, it melted at 89–90°. A large depression in melting point was found on admixing with starting material (m.p. 90°). A test for a phenolic group with $FeCl_3$ was negative, and the infrared absorption spectrum showed no maximum for a carbonyl group. The IR absorption spectrum, however, was found to be identical with that of 2-hydroxymethyl-1,4-benzodioxane, which was prepared according to Grün (4) from epichlorohydrin and catechol, m.p. 89–90°. There was no depression in melting point on mixing the two compounds.

3 - (*o* - Benzyloxyphenoxy) - 1,2 - propanediol.—A mixture of 92.1 Gm. (0.5 mole) of 3-(*o*-hydroxyphenoxy)-1,2-propanediol, 62.5 Gm. (0.5 mole) of benzyl chloride and a solution of 24 Gm. (0.6 mole) of sodium hydroxide in 500 ml. water was heated to reflux with stirring for 2 hours. The mixture was cooled and the product extracted with ether. The ether was removed and the residue vacuum distilled to yield 82.1 Gm. (59.8%) of 3-(*o*-benzyloxyphenoxy)-1,2-propanediol-1, b.p. 200–218° at 0.4 mm. The product solidified on standing; the melting point was 81.0 to 82.5° after recrystallization from carbon tetrachloride. The crude distilled material was found to be suitable for subsequent reactions.

4 - (*o* - Benzyloxyphenoxymethyl) - 1,3 - dioxolone-2.—A mixture of 27.4 Gm. (0.1 mole) of 3-(*o*-benzyloxyphenoxy)-1,2-propanediol, 35.4 Gm. (0.3 mole) of diethyl carbonate, and 0.3 Gm. of sodium methylate was heated until ethyl alcohol distillation ceased (maximum internal temperature, 135°). A 0.5-Gm. quantity of ammonium chloride was added to destroy the sodium methylate, and excess diethyl carbonate was removed by vacuum distillation. The residue was dissolved in 400 ml. of hot isopropyl alcohol, treated with 0.5 Gm. of Darco G-60, filtered, and allowed to crystallize to yield 24 Gm. (80%) of 4 - (*o* - benzyloxyphenoxymethyl) - 1,3 - dioxolone-2, m.p. 74–75°.

3 - (*o* - Benzyloxyphenoxy) - 1(2) - hydroxy - 2(1)-propyl Carbamates and N-Methylcarbamates.—The general method for the preparation of these hydroxypropyl carbamates was as follows: ammonia or methylamine (1.2 moles) dissolved in isopropyl (or aqueous isopropyl) alcohol was reacted with compound 2, (1 mole). After standing at room temperature for 4–24 hours, the volatile material was distilled at reduced pressure, and the residue recrystallized from ethyl acetate or isopropyl alcohol to give the higher melting 1-hydroxy-2-carbamate (N-methylcarbamate). The residue from the mother liquor of this crystallization was then recrystallized from petroleum ether-benzene to give the lower melting isomer, the 2-hydroxy 1-carbamate (N-methylcarbamate). The yields of both isomers are based on the amount of Compound 2.

3 - (*o* - Hydroxyphenoxy) - 1(2) - hydroxy - 2(1)-propyl Carbamates and N-Methylcarbamates.—The general method for the removal of the benzyl group from the above benzyloxy carbamates was to shake an isopropyl alcohol solution of the benzyl ether with hydrogen at 2–5 p.s i. over 15% palladium-on-charcoal at 25–50° (the reaction mixture was heated if the hydrogen absorption was sluggish

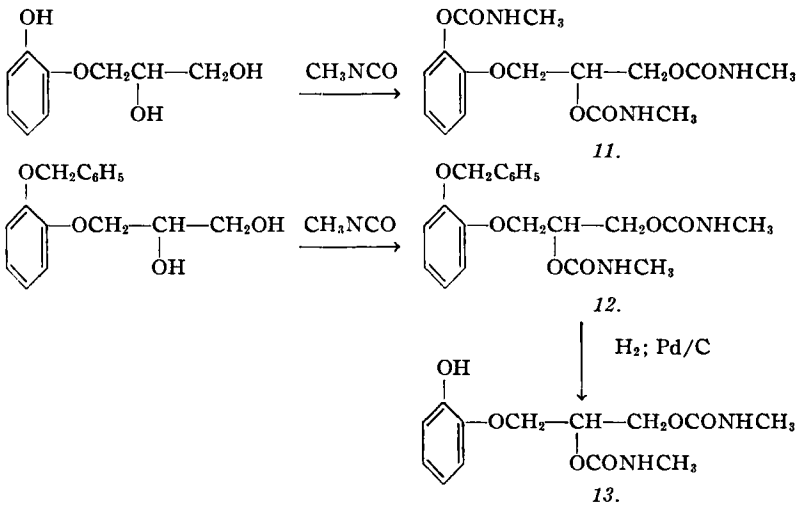
[a] Mixed m.p. 73–76°.

or did not occur at room temperature). The reaction mixture was filtered from the catalyst, evaporated to dryness, and recrystallized from petroleum ether–benzene.

3-(*o*-N-Methylcarbamoxyphenoxy)-1,2-bis-N-methylcarbamoxypropane.—A benzene solution of 36.8 Gm. (0.2 mole) of 3-(*o*-hydroxyphenoxy)-1,2-propanediol was stirred with a large excess of methyl isocyanate and a few drops of pyridine as catalyst until the product crystallizing from the solution was no longer oily. Filtration yielded 43.7 Gm. (61.5%) of 3-(*o*-N-methylcarbamoxyphenoxy)-1,2-bis-N-methylcarbamoxypropane, Table I, No. 11; m.p. 122–124°.

3-(*o*-Benzyloxyphenoxy) and 3(*o*-Hydroxyphenoxy)-1,2-bis-N-Methylcarbamoxypropane.—A benzene solution of 19.2 Gm. (0.07 mole) of Compound 1 was reacted with an excess of methyl isocyanate and a few drops of pyridine. The product which precipitated was filtered to give 14.9 Gm. (54.7%) of 3-(*o*-benzyloxyphenoxy)-1,2-bis-N-methylcarbamoxypropane, Table I, No. 12, m.p. 122–124°. Compound 12, 11.6 Gm., was then debenzylated to 4.8 Gm. (54.3%) of 3-(*o*-hydroxyphenoxy) 1,2-bis-



N-methylcarbamoxypropane, Table I, No. 13, m.p. 55–57°, using the previously given procedure.

BIOLOGICAL RESULTS

All of the above carbamates except Compound 13, for which no suitable vehicle could be found, were screened for muscle relaxant activity in mice. A substance was said to possess muscle relaxant activity if a given dose caused the hind portion of the test animal to go limp while it was still able to walk on its front legs, dragging the back ones behind. All known muscle relaxants gave this test. Using this criterion, none of the above compounds showed significant muscle relaxant activity up to 1000 mg./Kg. However, the ability to delay the onset of pentylenetetrazol induced convulsions appeared to be general, particularly in Compounds 9 and 10.

No deaths to mice resulted from oral intubation of doses up to 1 Gm. per kilogram. Ataxia, paralysis, convulsions, and decreased respiration were notably absent in all tests at these levels.

Toxicity of Plastics Used in Medical Practice I

Investigation of Tissue Response in Animals by Certain Unit Packaged Polyvinyl Chloride Administration Devices

By W. H. LAWRENCE†, J. L. MITCHELL‡, W. L. GUESS, and J. AUTIAN

In the past workers in our laboratory and other investigators have noted that polyvinyl chloride tubings used in medical practice, as administration or collection devices, will release one or more constituents to several types of solvent systems used in pharmacy. Since a great many formulations may be employed in manufacturing these plastic tubings, it was thought that a toxicity study might reveal if one or more of the currently used plastic administration devices might contain an ingredient which could produce a tissue response when implanted in animals. The results of the study revealed that under the experimental conditions used in this study a number of the tubings will produce tissue response while others will not.

For the past number of years, workers in our laboratory have attempted to focus attention on certain problems which might develop in the improper use of plastics, while at the same time encouraging research to develop products which would give the advantages of plastics without introducing potential hazards (1–5). Several approaches in research to the plastic problem have since been undertaken by the laboratory from an academic viewpoint and as a public health service. The work reported in this paper is the first of a series devoted to the exploration of the acute and toxic properties of plastics and the various ingredients which might be incorporated within the polymer to achieve a desired plastic which may be used in medical practice. Specifically, this paper will be devoted to ascertaining if certain plastic tubings (primarily of the polyvinyl chloride type) which are parts of administration devices might contain an ingredient or ingredients which could be considered toxic if released into animal tissue.

EXPERIMENTAL

Selection of Samples for Investigation.—Various types of administration devices having a polyvinyl chloride tubing as a component were obtained in their original package. A number of these packages indicated that the contents were sterile and nonpyrogenic. Each sample was assigned a code number with the manufacturer's name designated by a specific letter. Forty-eight different samples of administration devices from 17 manufacturers or distributors were employed in the investigation (see Table I). Several polyethylene tubings and one unidentified tubing used in a hospital were also included in the total number of samples.

Implantation Studies.[1]—In all the studies reported here only the tubings were evaluated, the other portions of the administration devices being stored for

N-methylcarbamoxypropane, Table I, No. 13, m.p. 55–57°, using the previously given procedure.

BIOLOGICAL RESULTS

All of the above carbamates except Compound 13, for which no suitable vehicle could be found, were screened for muscle relaxant activity in mice. A substance was said to possess muscle relaxant activity if a given dose caused the hind portion of the test animal to go limp while it was still able to walk on its front legs, dragging the back ones behind. All known muscle relaxants gave this test. Using this criterion, none of the above compounds showed significant muscle relaxant activity up to 1000 mg./Kg. However, the ability to delay the onset of pentylenetetrazol induced convulsions appeared to be general, particularly in Compounds 9 and 10.

No deaths to mice resulted from oral intubation of doses up to 1 Gm. per kilogram. Ataxia, paralysis, convulsions, and decreased respiration were notably absent in all tests at these levels.

future investigation. Sections of each sample were taken and cut into strips measuring approximately 1 mm. × 1.5 cm. and were implanted into rabbits in the following manner. For each sample two healthy, female, albino rabbits (1.6 to 2.0 Kg.) were used. Prior to an implantation, the rabbit's back

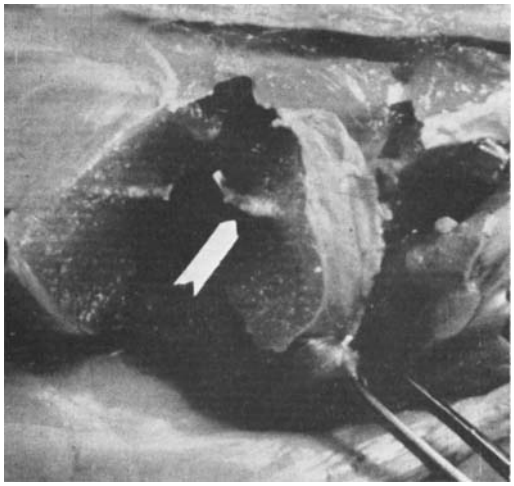

Fig. 1.—Photograph of an implantation site in rabbit muscle showing a sample of tubing X-74 (in center) after 1 week of implant. White-like zone around sample indicates tissue response.

was clipped and the excess hair removed by careful sponging (50% water-alcohol) with a lint-free towel. The rabbits were then anesthetized by an injection into the marginal ear vein of 0.6 ml./Kg. of a solution of pentobarbital sodium (50 mg./ml.) and stretched out on a table. A strip of the plastic was placed into the bevelled point of a 15 G needle having a length of 1.5 in., and the needle was introduced into the paravertebral muscle. Four strips of each sample were introduced (approximately 1 in. apart) into each animal. Two strips of a previously studied polyvinyl chloride tubing were also implanted in an identical manner as controls in the same rabbit.[2] The introduction of these plastic strips was done in a "clean" manner but not under aseptic conditions. Thiomersal solution was applied to all the sites of injection.

After implantation, each rabbit was returned to his cage and observed for a period of 1 week, at which time the animal was sacrificed and the paravertebral muscle exposed. Each implant site was isolated and examined macroscopically for tissue damage compared to the control samples. Tissue reaction or toxic reaction was indicated if an opaque or white-like zone was seen around the implant. Often the "toxic" strip showed an encapsulation which extended into the tissue for several mm. All the controls produced no apparent reaction other than the accepted mild trauma from the introduction of a foreign body. Any strip showing the tissue manifestation described above was regarded as toxic and was so recorded. If a question arose as to the accuracy of the observation, one or two more rabbits were included in the test. Invariably, if one strip showed a toxic effect, the other three strips showed exactly the same picture. The results of this 7-day study are included in Table I. Figure 1 shows a photograph of a section of muscle tissue (in rabbit) with an implanted strip (X-74). A white-like zone around the strip indicates the toxic response. Figure 2 is a subcutaneous implant (in rabbit) of sample

[2] Previous history of this sample has indicated that it is nonreactive to tissue.

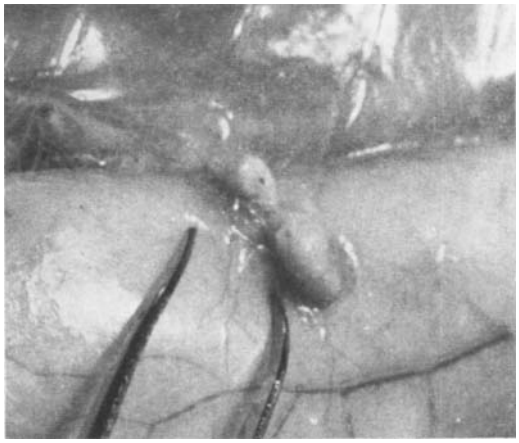

Fig. 2.—Photograph of an implantation site (subcutaneous) in rabbits of sample X-55 showing the toxic response (capsule formation around tubing).

X-55 and clearly demonstrates the formation of a capsule around the implant.

It will be noted that 25 of the 48 samples produced a toxic response under the conditions of the experiment.

Further Implantation Studies of Samples X-37 and X-74 in Rabbits.—It seemed highly desirable to investigate several of the toxic tubings in more detail, and for this reason samples X-37 and X-74 were selected, since adequate quantities of each were on hand with all the packages making up each sample having the same control number. It was felt that the samples should be of the same lot number throughout the investigations because it is known that at times a company may change its formulation for a tubing without revealing that this has been done.

In one series of experiments, several groups of rabbits were implanted with X-37 and X-74 by the intramuscular route as described. Both samples were also implanted by the subcutaneous route in several groups of rabbits. All animals were observed for a period of 28 days, a representative animal from each group being sacrificed at the end of each week for evaluation of toxicity.

Table II.—Reaction Induced in Rabbit Tissue by Samples X-37 and X-74 (Intramuscular Implantation)

Sample	Days 7	14	21	28
X-37[a]	*e*	*e*	*e*	*e*
X-74[a]	*d*	*b*	*b*	*b*
Control	*b*	*b*	*b*	*b*

[a] Four strips of each sample were used in each animal. Two control strips were also employed in the same animal. [b] Nonreactive. [c] Slightly reactive. [d] Moderately reactive. [e] Very reactive.

Table III.—Reaction Induced in Rabbit Tissue by Samples X-37 and X-74 (Subcutaneous Implantation)

Sample	Days 6	14	21	28
X-37[a]	*f*	*f*	*e*	*e*

Control	*b*	*b*	*b*	*b*

[a] Four strips of each sample were used in each animal. Two control strips were also employed in the same animal. [b] Nonreactive. [c] Questionable. [d] Slightly reactive. [e] Moderately reactive. [f] Very reactive.

Table IV.—Reaction Induced in Rat Tissue by Samples X-37, X-55, and X-74 (Implantation in Thigh Muscle)

Sample[a]	Days 7	14	21	28	35
X-37	*g*	*d*	*e*	*e*	*e*
X-55	*f*	*f*	*f*	*f*	*f*
X-74	*d*	*g*	*c*	*c*	*b*

[a] One strip was placed into right thigh of the animal, and a control strip placed into the left thigh. [b] Nonreactive. [c] Questionable. [d] Slightly reactive. [e] Moderately reactive. [f] Very reactive. [g] Sample lost.

Tables II and III show the results and reveal that while X-37 persists to induce a toxic response, X-74 reaches a critical time period after which the toxic response appears to regress to a point where the sites are identical to the control samples.

Surgical implants of both X-37 and X-74 were performed in the brain tissue of the rabbits (five to each sample), and these animals were observed over a period of time up to 1 month. Within a period of 3 to 7 days, several of the rabbits were sacrificed and the brain tissue examined. Both samples produced tissue alteration but X-37 to the greatest degree. Within a 10-day period, several of the rabbits were observed to have a swelling immediate to the implant. Gross examination of the swollen area revealed that the cause of the swelling was because of the accumulation of fluid. It was first thought that an infection had caused the accumulation of fluid, but bacteriological examination of both the tissue and fluid proved this assumption to be false. Daily observation of these rabbits indicated that no general

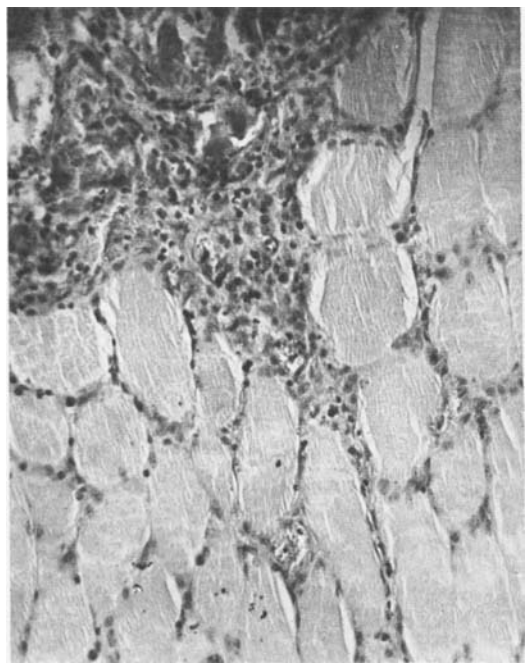

Fig. 3.—Photomicrograph of muscle tissue reaction in rabbit after implantation with sample X-37. Multinucleated giant cells and scattered polymorphonuclear leucocytes are in evidence (1 × 256).

pattern of behavior could be resolved to indicate the effect the implants had. Several of the rabbits died between the third and fourth week. Extensive brain damage could be seen in these rabbits after autopsy.

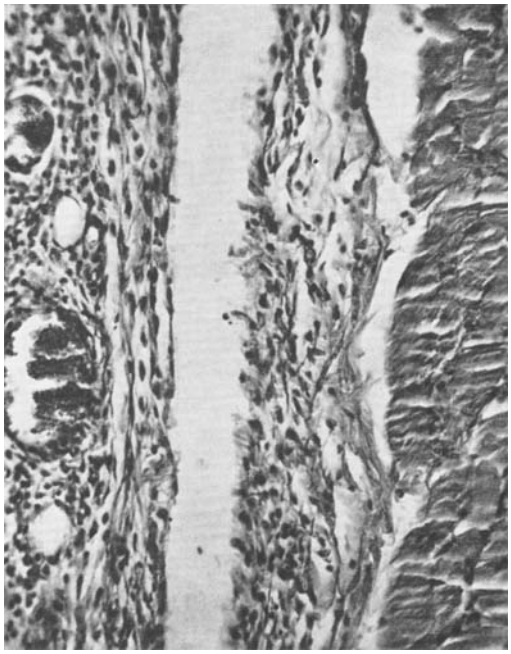

Fig. 4.—Photomicrograph of muscle tissue in rat after implantation with sample X-55. Severe damage to tissue may be noted by observing the formation of fiberous connective tissue (1 × 256).

Fig. 5.—Photomicrograph of muscle tissue in rabbit where a control plastic (nontoxic) was implanted. Mild inflammation may be noted at interface of plastic and tissue because of expected foreign body reaction (1 × 256).

Further Implantation Studies on Samples X-37, X-55, and X-74 in Rats and Mice.—To validate that the reactions seen in the rabbits were not specific to that animal, rats and mice were employed. The rats were of the Holtzman albino type, female, with an average weight of 300 Gm. Uniform samples of the three plastics were implanted by surgical procedure into a pocket formed between two layers of the thigh muscle in three groups of five rats. The implantation sites were closed by sutures. A nonreactive plastic strip (as employed with the rabbits) was implanted in the other leg of each rat as a control. Each week one rat from each group was sacrificed and the sites examined. Table IV summarizes the results.

Samples of the above tubings were surgically implanted into the nape of the neck of three groups of five mice (male, albino, average weight of 30 Gm.). The incisions were sutured, and the mice observed for a period of 1 week at which time they were sacrificed. Toxic reactions were noted for the three in the same order as the rats.

Histopathological Studies.—To rule out that the toxicity was not because of bacterial contamination, sterile transfer was made from a representative number of toxic implants and cultured on agar plates. The absence of growth after the 7-day and 14-day incubation period indicated that the tissue response was due to the plastic or a component in the plastic.

Representative implantation sites were carefully excised from the several animals employed in this study and placed into 10% formalin solution for histological examination. Sections were prepared and stained by the standard hematoxylin-eosin method and examined by a pathologist to confirm the toxic response noted by the macroscopic evidence. Figure 3 is a photomicrograph of tissue reaction (muscle of rabbit) due to X-37. Multinucleated giant cells and scattered polymorphonuclear leucocytes are in evidence indicating the destructive effect of the implant. Severe tissue damage in rats by X-55 is shown in a photomicrograph in Fig. 4. Damage to the tissue has reached a point where fiberous connective tissue may be observed around sections of the plant. Figure 5 is included to show the effect of the control sample of polyvinyl chloride implanted in rabbit muscle. Slight foreign body reaction may be noted along the interface of the plastic and the tissue.

Extraction of Toxic Substance from Plastic.—Ten grams of each sample (X-37 and X-74) were extracted with 75 ml. of 95% ethyl alcohol in a soxhlet extractor for a period of 12 hours. Both samples were removed from the apparatus and rinsed with distilled water, after which they were dried with lint-free towel. Four strips of each sample were implanted by the intramuscular route, and, likewise, the same number of samples were implanted by the subcutaneous route into separate rabbits. These series of animals were sacrificed after 1 week and the sites of implants carefully examined for tissue alteration. None of these strips produced a reaction which differed from the control implants.

The alcoholic extracts were evaporated until a syrupy liquid remained. Approximately 2 to 3 Gm. of the total weight of the plastic sample was extracted by the alcohol. In general the physical ap-

pearance of the syrupy liquid resembled a plasticizer. Strips of nonreactive plastic were placed in intimate contact with the extracts of both samples for a period of 24 hours at which time they were removed and blotted with a lint-free towel. These strips were then intramuscularly implanted in rabbits and the sites examined after 1 week. Each of the strips produced a tissue response indicating that the toxic substance or substances were being released to the alcoholic solvent.

Chromatographic Separation of Components from Extracts.—Alcoholic extracts were prepared, as described before, from samples X-37 and X-74. The solvent was slowly evaporated in a steam bath until the odor of ethanol was no longer apparent. Each sample was then chromatographed on an F & M scientific model 500 gas chromatograph.[3] The operating conditions of the chromatograph were as follows: injection port, 275°; oven, 250°; detector, 250°; helium flow 50 ml./minute.

A 1-M. 1/2-in. aluminum tube was filled with 20% DC silicone grease on 60–80 ASTM mesh chromosorb W[4] and served as the chromatographic column.

Chromatograms of each sample revealed a number of components had been extracted from both of the samples X-37 and X-74. The representative chromatograms of X-37 and X-74 are shown in Figs. 6 and 7. An analysis of both chromatograms indicated that approximately 95 to 99% of the extract consisted of a heavy component or components which were later ascertained to be the plasticizers.

The light components (in Figs. 6 and 7 these would constitute the components resolved on the column in a 16-minute period) were captured by condensing them in a U-tube packed with glass wool and chilled with a dry ice–acetone bath. The heavy fraction or fractions were likewise captured after 16 minutes. Both the light and heavy components were then eluted from the tube with isopentane and the solvent evaporated. Two fractions were then isolated for each sample. These consisted of a fraction of light components and a fraction of heavy components.

Nonreactive plastic strips were kept in contact with each fraction for a period of 24 hours at which time they were intramuscularly implanted into the rabbits. Two strips from each fraction were used since the quantity of the fractions was very small. After 7 days, the animals were sacrificed and the sites examined. The strips containing the light components for both X-37 and X-74 caused a tissue response, while the strips soaked in the heavy components showed no tissue response. No response was seen for the fractions from the control sample. Results of this particular experiment indicated that one or more components in X-37 and X-74 were the causitive agents in eliciting tissue response and that no apparent response was induced by the plasticizers.

It was hoped that various components from the fraction designated as the "light component" could be isolated for implantation studies to pinpoint the substance or substances causing the tissue response; but, unfortunately, the supply of the same lot number of X-37 and X-74 was depleted. This phase of the investigation, therefore, had to be terminated.

DISCUSSION

The results of the study reported in this paper indicate that there are now on the market tubings such as administration devices which contain one or more ingredients in microquantities which will migrate from the tubing and cause a toxic response in tissue when small samples are implanted. Forty-five of the 48 samples were of the vinyl type. Often for these particular tubings, approximately 40 to 60% of the total weight of the material will be the additives such as the stabilizers, antioxidants, colorants, and other components. The implantation studies revealed that 25 of these tubings caused a toxic response in a tissue. It is interesting to note that several manufacturers distributed a number of tubings which showed no tissue response, while other manufacturers produced tubings which showed a tissue response. One should also keep in mind that most of the tubings used in the study were packaged and ready for use. A number of these packages were labeled to indicate that safety tests had been performed on the device; others stated only that the package was sterile and nonpyrogenic.

In recent years several investigators have reported that certain polyvinyl chloride tubings contained one or more toxic ingredients (6). Generally, the causative agent was not the plasticizer but one of the other ingredients. This observation has been confirmed in the study reported in this paper, but it should not indicate that a particular plasticizer might not cause a toxic response under other experimental conditions.

Prior to and during the study, attempts were made to find the formulas used for the various tubings, but it soon became clear that the manufacturer would not, for obvious proprietary reasons, disclose his formula. Certain previous experiments also indicated to us that companies might change their formula for the tubing without indicating to the user that this in fact had been done.

Even though sterile conditions were not used in the implantation experiments, infections were ruled out as the causative agents in producing the toxic responses. If infection was indeed the causative agent, it would certainly have been noted with one or more of the control samples since these were implanted under identical experimental conditions. Confirma-

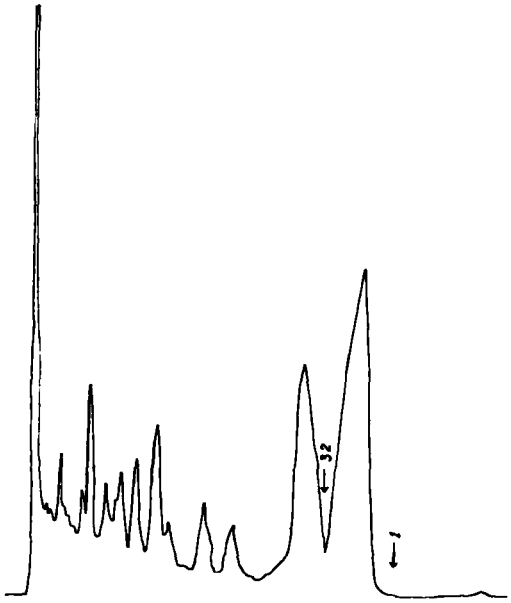

Fig. 7.—Gas chromatogram of extract from sample X-74 showing the number of components in the light fraction (up to 16 minutes) and the two components in the heavy fraction (plasticizers). Note: Same time scale as in Fig. 6.

tion of this fact was made by the bacteriological tests on the "toxic" tissue.

Further investigations with X-37 and X-74 revealed that the toxic ingredient was not because of the component making up the largest bulk of the ethanol extract—the plasticizer or plasticizers—but rather because of one of the number of components referred to as the "light fractions." There was no basis for assuming that the toxic ingredient was a contaminant picked up by the plastic during the manufacturing or packaging process since other tubings from the same manufacturer also showed a toxic effect. Certain investigators have concluded that toxic substances in polyvinyl chloride tubings are probably due to one or more organo-metallic compounds used as stabilizers (6, 7).

The implantation results for X-37, X-55, and X-74 were rather interesting since they did show that the degree of toxicity varied from sample to sample, X-55 eliciting the most severe response while X-74 the least. Sample X-74 lost its toxic activity with time, indicating that the animals were able to nullify or detoxify the offending agent in the plastic.

The implantation method for testing the toxicity of plastics was first developed by Brewer and Bryant (8), who found that certain disposable plastic items could cause a tissue response. This laboratory has since confirmed the value of the implantation technique because it can reveal in a very short period of time (from 3 to 7 days) that the particular plastic item has a component which may be considered undesirable. Cruickshank, *et al.* (9), has suggested the use of tissue cultures as a testing or screening method for plastics.

The question, of course, may now be raised that the tubings which are reported in this paper were never intended to be implanted either in animals or humans; consequently, for their intended use, they may be quite safe. Questions of this sort can best be answered by stating that good public health practice would seem to dictate that no plastic item should contain an ingredient which has a potential harmful ingredient that might leach into a solution to be administered to a patient. Furthermore, since there are tubings which have not shown toxic effects under the experimental conditions employed in this paper, it would seem prudent for manufacturers to re-examine their tubing formulations to remove those offending agents which may become potential sources of danger to patients.

SUMMARY

Forty-eight plastic administration devices were obtained from various sources. For the most part these devices were unit-packaged in sealed or closed packets or cartons. In general the tubings were of the vinyl type. Sections of the tubings from the various devices were investigated by implantation techniques into rabbits, rats, and mice. Morphological and histopathological examinations were used to detect toxic responses in the implanted tissue. The results revealed that 25 of the 48 samples used in the study produced a toxic response. Gas chromatographic techniques with implantation tests suggested that the toxic ingredient or ingredients in several of the tubings were a direct consequence of one or more of the additives, exclusive of the plasticizers.

Interaction of Antihistamines with Hydrocolloids

By HORACE D. GRAHAM and YEDE MARIE BAKER†

Antihistamines of various types form highly insoluble complexes with carrageenan and other sulfated hydrocolloids. The carboxylic acid type hydrocolloids and the proteins, casein and gelatin, formed less insoluble complexes; the neutral polysaccharides and agar (supposedly sulfated) formed gels in the presence of the antihistamines. Pyrathiazine, chlorcyclizine, pyrilamine, and pyrrobutamine formed more insoluble complexes than thenyldiamine, methapyriline, benadryl, and thonzylamine when mixed with carrageenan. The interaction was accelerated by increased temperature up to 75°, was not appreciably affected by pH within the range of pH 2.75 to 6.55 and, at 45°, reaction times of 5–70 minutes produced no essential difference in the amount of benadryl hydrochloride bound per unit of carrageenan (Seakem type 5).

HYDROCOLLOIDS of various types are being added to pharmaceutical products with increasing frequency. Since many of these hydrocolloids are polyanionic, they can enter into strong interactions with cationic drugs such as many of the antihistamines and may affect drug insolubilization, appearance, stability, and prolongation of activity.

Kennon and Higuchi (1) have studied the interaction of benadryl and pyribenzamine hydrochlorides with sodium carboxymethylcellulose (CMC), one of the relatively weaker binders. These studies were undertaken to examine the interaction of a broad spectrum of hydrocolloids with several antihistamines, since any insoluble product formed through such interactions may be of value as sustained release form of the drugs, a topic which has been receiving much attention recently (2–5).

EXPERIMENTAL

Antihistamines.—Pyrrobutamine, pyrilamine maleate, WY 2149, benadryl, pyrathiazine, chlorcyclizine, phenergan, thenyldiamine, methapyrilene, thonzylamine, triprolidine, antistine, and pyribenzamine hydrochlorides were used as received from the various manufacturers and were made up in double distilled water.

The hydrocolloids, other reagents, and equipment and the experimental details have been previously described (5). Hypnean was prepared according to Smith and Montgomery (6).

Where precipitation did not occur, the equilibrium dialysis technique (1, 7) was employed and binding data were obtained using the technique of Hughes and Klotz (8).

The degree of dissociation of the polyelectrolytes and the significance of the Donnan effects were ascertained by the technique of Kennon and Higuchi (1).

Quantitative Determination of the Antihistamines.—For determining the amount of free antihistamine in the experimental systems, the color reactions of Osol and Sideri (9) and the ultraviolet absorption characteristics outlined by Kleckner and Osol (10) were exploited.

Received February 5, 1963, from the Carver Foundation, Tuskegee Institute, Ala.

Accepted for publication March 20, 1963.

This investigation was supported by Grant EF-00173 from the National Institutes of Health, U. S. Public Health Service, Bethesda, Md., to the George Washington Carver Foundation, Tuskegee Institute, Ala.

The authors thank the various companies which donated samples of hydrocolloids and antihistamines.

† Present address: School of Dentistry, Western Reserve University, Cleveland, Ohio.

RESULTS AND DISCUSSION

The sulfated and carboxylic acid type polysaccharides and the proteins formed insoluble complexes with all of the antihistamines tested, while the neutral polysaccharides and agar (supposedly sulfated) produced a gel rather than a precipitate. The antihistamines varied in their ability to precipitate the hydrocolloids and—if carrageenan (Seakem type 5) is taken as the representative hydrocolloid—the relative tendencies of benadryl, pyrrobutamine, pyrathiazine, chlorcyclizine, phenergan, pyrilamine, thenyldiamine, methapyriline, and thonzylamine to form precipitates with this hydrocolloid were calculated to be 1.0, 3.65, 3.54, 1.98, 2.54, 0.96, and 0.28, respectively. Table I and Fig. 1 show the maximum binding capacities of several hydrocolloids for many of the antihistamines used. The high binding capacity of carrageenan is clearly indicated. The maximum binding capacity of furcellaran is slightly less than one-half that of carrageenan, probably a reflection of the sulfate content of these two phytocolloids. CMC, sodium alginate, pectin, and quince seed mucilage differed only slightly in their maximum binding capacities for the antihistamines listed. Of the hydrocolloids listed, locust bean gum and gum guar exhibited the lowest binding capacities for the antihistamines.

Figures 2 and 3 show the extent of the Donnan effects on the binding of several of the antihistamines by CMC and carrageenan (Seakmen type 5). The degree of dissociation of CMC was found to be 61.6% and agrees well with the value of 60% reported by Kennon and Higuchi (1). Carrageenan (Seakmen type 5) was found to be 79.5% dissociated. Harwood (11) calculated the ionization of a 1.5% solution of this hydrocolloid to be 59% and, assuming a molecular weight of 1000, calculated the degree of ionization of a 0.01 *N* solution to 63.4% at 25°. The drastic deviations from the theoretical Donnan-only behavior, in all cases, suggest that the drug cations are bound by the hydrocolloid anions by other mechanism(s). This is substantiated by the gross observations where turbidity occurred when most of the antihistamines were mixed with the hydrocolloids and by the data (Table I) for the maximum binding capacities. When dilute systems of gum tragacanth and sodium alginate were similarly treated, corresponding great deviations from the theoretical curve were observed, again supporting the gross observations and the binding data. Since the antihistamines are cationic in nature, salt formation is probably the most pre-

TABLE I.—MAXIMUM BINDING CAPACITY OF HYDROCOLLOIDS FOR ANTIHISTAMINES, MICROMOLES OF ANTIHISTAMINE BOUND PER GRAM OF HYDROCOLLOID

	Antihistamine

dominant reaction occurring between the polyanionic polysaccharides and the drugs, but hydrogen bonding and van der Waals forces probably also contribute to the total binding.

Figure 4 shows the effect of pH and electrolytes on the binding of benadryl hydrochloride by carrageenan (Seakem type 5). Determinations of the amount of benadryl hydrochloride bound by carrageenan (Seakem type 5) in the presence of several salts revealed that the order of interference may be summarized as: trivalent > divalent > monovalent. Iron and aluminum are particularly interferring and will actually precipitate the hydro-

colloids. Reduced binding of the antihistamines by the hydrocolloids in the presence of electrolytes must be mainly because of the competition for the reactive sites on the antihistamine molecule.

The pH of the medium influences the interaction of the antihistamines with the hydrocolloids. In the alkaline range, the antihistamines will produce a turbidity in the absence of the hydrocolloids. Between pH 2.75 to 6.55 and, in distilled water, only slight differences in the amount of antihistamine bound per milligram of carrageenan (Seakem type 5) were observed. This constancy over such a wide range of pH would probably not hold for hydrocolloids such as CMC whose ionization and stability are severely affected at low pH levels of the medium. In studies on the effect of pH, hydrochloric acid was used to attain the desired acidity. If phosphate buffer is used, then the maximum strength (final molarity of the salt in the medium) must be 0.05 *M*. Beyond this, the amount of antihistamine bound per unit of hydrocolloid decreased, presumably because of the electrolyte effect (Fig. 4).

As the temperature of the interaction medium increased, the reaction between the hydrocolloid and the antihistamine increased, as gauged by the amount of antihistamine bound per milligram of

hydrocolloid. This held true up to 75°. Between 75–85°, there was no measurable difference in binding. Although 45° was not the optimum interaction temperature, it was selected to minimize the possibilities of hydrolysis if the reaction was carried out at higher temperatures.

At 45°, reaction times of 5–70 minutes produced no essential difference in the amount of benadryl hydrochloride bound per milligram of carrageenan (Seakem type 5).

Sustained or timed release of drugs from complexes has been receiving much attention recently (2, 4, 5); the interaction products of hydrocolloids and antihistamines may be of significance in this respect. Table II indicates the solubility of the benadryl-carrageenan and pyrilamine-carrageenan complexes in sodium chloride and hydrochloric acid. These data point to their promise as sustained-release forms of the drugs.

Antihistamines have a great number of pharmacological actions and, though *in vitro* studies may be inconclusive, they may throw some light on *in vivo* mechanisms. Judah (12), in his studies on the interaction of antihistamines *in vitro*, suggested that they prevented mitochondrial swelling by interactions with the mitochondrial membrane. Conceivably, substances closely related to some of the hydrocolloids used in these studies (*e.g.*, heparin, proteins, or chondroitin sulfate) could have been involved. Kobayashi (13) has discussed the binding of histamine by heparin with particular attention to the importance of the sulfate moiety of this compound in the binding process. Since the antihistamines are "histamine antagonists," the strong binding of the antihistamines by the sulfated hydrocolloids reflect the possible role of such types of compounds in the mechanism of action of the antihistamines. The role of proteins in the binding

of antihistamines is also of interest. Maietta (14, 15) has exploited such interactions in using the combined antigen-antihistaminic technique in shortening the treatment of hay fever.

These studies demonstrate that a wide variety of hydrocolloids and antihistamines form highly insoluble complexes which probably can serve as sustained-release forms of these drugs. Conceivably, soluble complexes which are probably formed in most of the systems studied also may be of pharmacological importance.

Effectiveness of Antibacterial Agents Presently Employed in Ophthalmic Preparations as Preservatives Against *Pseudomonas aeruginosa*

By S. ROBERT KOHN†, LOUIS GERSHENFELD, and MARTIN BARR

Seven chemical substances or combinations of these substances presently employed as preservatives in ophthalmic solutions were studied to note their effectiveness as antibacterial agents against 13 different strains of *Pseudomonas aeruginosa*. New *in vitro* methods were devised. Among the latter were techniques to (*a*) differentiate between bacteriostatic and bactericidal activities and (*b*) determine the sterilizing time for each antibacterial agent. The methods presented here have several advantages over those previously employed and those now in use. An *in vivo* procedure was also employed in evaluating these chemical agents to note whether the findings were in agreement with the final results obtained in the *in vitro* studies. The following chemicals were examined: chlorobutanol, benzalkonium chloride, thimerosol, combinations of methyl and propylparaben, phenylmercuric nitrate, phenylethyl alcohol, and polymyxin B sulfate.

BECAUSE OF THE incidence and seriousness of *Pseudomonas aeruginosa* (*Ps. aeruginosa*) infections resulting from the use of contaminated ophthalmic solutions (1–11), various workers have critically investigated the antibacterial agents employed as preservatives in such preparations. The findings of these workers have been contradictory (12–18). The *in vitro* procedures employed in evaluating the effectiveness of the antibacterial agents have been challenged. The following observations are noted. There is need for methods which will determine the effectiveness of (*a*) antibacterial agents used as preservatives in ophthalmic solutions against *Ps. aeruginosa;* and (*b*) substances which are capable of inactivating or inhibiting the antibacterial action of the preservatives used.

The purpose of this paper is to report on studies which were performed in an effort to develop *in vitro* methods more effective than those employed at present and which will establish the efficiency of these antibacterial agents as preservatives in ophthalmic solutions against *Ps. aeruginosa.*

GENERAL CONSIDERATIONS

In devising methods for the evaluation of the effectiveness of antibacterial agents as preservatives in ophthalmic solutions, it is important to develop a technique which will determine the time required for such agents to produce sterility. Most methods which have been used to date did not always take this into consideration. Indeed, they usually measured only the bacteriostatic activity of preservatives.

Until recently, most workers employed a dilution technique to differentiate between the bactericidal and bacteriostatic activities of antibacterial agents. The basis for this procedure is the dilution of the

preservative far below the concentration necessary to have a significant antibacterial effect. If growth of the bacteria occurred, after inoculation of this diluted solution into a subculture medium, the antibacterial agent was considered to possess bacteriostatic activity; if growth did not occur, then the antibacterial agent was reported as possessing bactericidal properties.

The above concept is not considered entirely valid at present. As Klarmann (19) has reported, in some of the dilution techniques, a quantity of the antibacterial agent may be transferred to the subculture medium in a concentration which will produce stasis, and some may become affixed to the cell walls or cells, initially producing stasis. Therefore, a bacteriostatic effect may be produced and misinterpreted for a bactericidal effect. Another disadvantage of the dilution technique is that living bacteria present may be diluted to an infinite concentration and may not grow in the subculture medium.

It is therefore apparent that an important factor in determining the antibacterial activity of preservatives in ophthalmic solutions is the complete inhibition or inactivation of the antibacterial agent in the evaluation procedure, a principle employed by Lawrence (16) and Riegelman, *et al.* (17).

Until recently, investigators had not attempted to correlate the results obtained using the *in vitro* procedures with an *in vivo* test. As pointed out by Riegelman, *et al.* (17), an *in vivo* test has several advantages and becomes an important consideration in procedures used for the evaluation of antibacterial agents employed as preservatives in ophthalmic solutions.

EXPERIMENTAL

The media employed in the experiments are listed in Table I.

General In Vitro Methods

To determine the effectiveness of presently employed antibacterial agents as preservatives for ophthalmic solutions against *Ps. aeruginosa*, four experimental *in vitro* procedures, each with a specific objective, were developed. These are described below.

Experiment I

Purpose.—As previously noted, it is important to distinguish between bacteriostatic and bactericidal activity in evaluating the effectiveness of chemical agents for use as preservatives in ophthalmic solutions. Various substances have been recommended as inactivating or neutralizing agents for the antibacterial activity of the chemicals employed. However, data concerning the effectiveness of inactivating agents are meager. Therefore, *Experiment I* was devised to determine and compare the effectiveness of various media for their ability to inhibit the activity of antibacterial agents against *Ps. aeruginosa*.

Preparation of the Inoculum.—Thirteen strains of *Ps. aeruginosa*, obtained from various sources, were identified by the usual methods including also the cytochrome oxidase test (20, 21), then maintained on agar slants. Two strains of *Ps. aeruginosa*, which were found more resistant to many of the antibacterial agents in preliminary studies were selected for use in this study. Prior to the day of the test, these strains were transferred for at least 3 consecutive days into 10 ml. of nutrient broth and incubated at 37° for 24 hours. On the day of the

[a] Difco Laboratories, Inc., Detroit, Mich. [b] Colgate Palmolive Co., New York, N. Y. [c] Lecithin, (Ex Ovo Soluble) Pfansteihl Laboratories, Inc., Waukegan, Ill. [d] Polyoxyethylene (20) sorbitan mono-oleate, Atlas Powder Co., Wilmington, Del. [e] Polyoxyethylene (20) sorbitan monolaurate, Atlas Powder Co., Wilmington, Del. [f] All media containing nutrient broth, dehydrated, were sterilized by autoclaving at 121° for 15 minutes. [g] All media containing fluid thioglycollate medium dehydrated were autoclaved at 121° for 20 minutes.

test, the cultures were shaken by hand approximately 1 minute to break up clumps and allowed to stand for at least 15 minutes. Dilutions (1:10 and 1:1000) of the 24-hour cultures of the two strains were made using nutrient broth, and the approximate number of viable bacteria were determined by the pour-plate technique. The 1:10 and 1:1000 dilutions of the 24-hour cultures contained approximately 10^8 and 10^6 bacteria per ml., respectively, as noted after incubating the plates at 37° for 48 hours.

Preparation of the Antibacterial Agent–Medium Mixtures.—Four milliliters of each of the various test media was placed in culture tubes (approximately 15 cm. in length and 13 mm. inside diameter) and sterilized. Stock solutions of several concentrations of the antibacterial agents were prepared as aqueous solutions. One milliliter of a sterile stock solution of the antibacterial agent was added to a tube containing 4 ml. of the sterile medium. This was done for each concentration of the antibacterial agent tested and also for each medium being used. The tubes were then shaken by hand to insure a uniform mixture.

Preparation of the Controls.—Controls were employed to determine bacterial contamination (negative controls) and to determine whether the media were capable of supporting the growth of *Ps. aeruginosa* (positive controls). Media prepared with the antibacterial agent but without the presence of *Ps. aeruginosa* were employed as negative controls. Media prepared without the antibacterial agents but with *Ps. aeruginosa* were employed as positive controls.

Procedure.—One-tenth milliliter of the 1:10 dilution of each strain of *Ps. aeruginosa* was added separately to a tube containing a single concentration of the sterile antibacterial agent in the individual medium being tested. This was repeated for each concentration of the antibacterial agent in each medium being tested. Each tube was shaken by hand to insure an even distribution of the bacteria. After 1 hour of contact at 24°, 0.5 ml. was transferred into tubes containing 4.5 ml. of the subculture medium, and the mixture was shaken by hand. After 24 hours of contact at 24°, another transfer of 0.5 ml. was made into tubes containing 4.5 ml. of the subculture medium. The same procedure was repeated with the 1:1000 dilution of the strain used and with the two dilutions of the other strain. All tubes were incubated at 37° for a period of 7 days and observed for the presence or absence of growth. The procedure was repeated to verify the findings.

Experiment II

Purpose.—As previously indicated in the evaluation of the antibacterial activity of chemical agents intended for use as preservatives in ophthalmic solutions, an important consideration is the time required for such agents to kill the bacteria after contact (sterilizing time). *Experiment II* was therefore devised to determine whether the antibacterial agent is fast-acting or slow-acting. This experiment was also designed to show the necessity of developing subculture media containing suitable inactivating agents.

Preparation of the Inoculum.—A 1:10 dilution of each of the 24-hour-old cultures of the 13 strains of *Ps. aeruginosa* was used in this study. Each was prepared as described previously.

Preparation of the Media.—Tubes containing 4.5 ml. of each of the various test media described previously were prepared and sterilized.

Preparation of the Antibacterial Solutions.—Tubes containing 5 ml. of the sterile aqueous antibacterial solutions to be tested were prepared.

Preparation of Controls.—Controls were employed to determine bacterial contamination (negative controls) and to determine whether the media were capable of supporting the growth of *Ps. aeruginosa* (positive controls). Tubes containing 5 ml. of the antibacterial solutions, without the presence of *Ps. aeruginosa*, were employed as negative controls. Solutions prepared without the antibacterial agent but containing *Ps. aeruginosa* were employed as positive controls.

Procedures.—One-tenth milliliter of a 1:10 dilution of each strain of *Ps. aeruginosa* was separately added to a tube containing 5 ml. of the sterile antibacterial solution. This was repeated for all 13 strains. Each tube of the antibacterial agent-bacteria mixture was then shaken by hand. After 1-hour of contact at 24°, 0.5 ml. was transferred into the tube containing 4.5 ml. of the subculture medium. This was then shaken by hand. After 24 hours of contact at 24°, another transfer of 0.5 ml. was made into 4.5 ml. of the subculture medium. All subculture tubes were incubated at 37° for a period of 7 days and observed for the presence or absence of growth. The procedure was repeated to verify the findings.

Experiment III

Purpose.—The purpose of this experiment was similar to that of *Experiment II*, except that the exact sterilizing time (as noted under *Procedure*) was determined.

Preparation of the Inoculum.—Two dilutions (1:10 and 1:1000) of the 24-hour-old cultures of 13 different strains of *Ps. aeruginosa* were used in this experiment. They were prepared as previously described.

Preparation of the Medium.—Four and one-half milliliters of the medium, which had shown the maximum inactivation of the antibacterial agent being tested, was employed.

Preparation of the Antibacterial Solutions.—Tubes containing 5 ml. of the sterile antibacterial solution to be tested were prepared.

Preparation of Controls.—Negative and positive controls were prepared.

Procedure.—The procedure was similar to that employed in *Experiment II*, except for changes in the contact times. If the results of *Experiment II* showed the antibacterial agent to be effective against *Ps. aeruginosa* within 1 hour, *i.e.*, no growth in the subculture tubes containing the 1-hour transfer, then the agent was tested at contact times of 15, 30, 45, and 60 minutes. If the antibacterial agent was shown to be effective between 1 and 24 hours, *i.e.*, no growth in the subculture tubes containing the 24-hour transfers, tests were carried out at 3, 6, 9, and 12 hours of contact. If necessary 15, 18, and 21 hours of contact also were employed. If the antibacterial agent was shown to be ineffective after 24 hours of contact, further studies were not considered warranted.

Experiment IV

Purpose.—In *Experiment III*, the sterilizing time of each chemical agent employed as a preservative in ophthalmic solutions was determined against *Ps. aeruginosa*. Obviously, the sterilizing time must be based on the total destruction of all bacteria. In *Experiment III*, only 0.5 ml. of the antibacterial agent–bacteria mixtures was transferred to the subculture medium. The purpose of this experiment was to determine whether this volume of inoculum was as effective as would be transplants of larger volumes.

Preparation of the Inoculum.—The most resistant strains of *Ps. aeruginosa*, as noted in *Experiment III*, were selected and used in this experiment. A 1:10 and a 1:1000 dilution of the 24-hour-old cultures of the selected strains were used. They were prepared as described previously.

Preparation of the Medium.—The medium used in *Experiment III* was employed here. Four and one-half milliliters, 9 ml., 18 ml., and 45 ml. of the medium, respectively, were placed separately in appropriate containers and sterilized.

Preparation of the Antibacterial Solutions.—The concentration of the antibacterial solution used in this study depended upon the strains of *Ps. aeruginosa* which were selected. A series of four tubes containing 5 ml. of the sterile antibacterial solution was prepared for each dilution of each strain of *Ps. aeruginosa* employed in this experiment.

Preparation of the Controls.—Controls were prepared as described in *Experiment II*.

Procedure.—The contact time used in this experiment was the same as that which revealed no growth immediately following a contact time period which had shown growth in the subculture medium for the strains selected. On the day of the experiment, 0.1 ml. of each of the diluted strains was added separately to each tube in the series containing the antibacterial solution. This was repeated for each strain used in this experiment. Transfers were made from the series of tubes at the selected contact time, using a 0.5 ml., 1 ml., 2 ml., and 5 ml. inoculum into 4.5 ml., 9 ml., 18 ml., and 45 ml. of subculture medium, respectively. The containers of subculture medium–antibacterial agent–bacteria mixtures were shaken by hand. All containers of this subculture medium of the antibacterial agent–bacteria mixture were incubated at 37° for a period of 7 days and observed for the presence or absence of growth. The entire procedure was repeated to verify the findings.

Antibacterial Agents Studied

The antibacterial agents studied for their effectiveness as preservatives for ophthalmic solutions against *Ps. aeruginosa* were as follows: chlorobutanol,[1] benzalkonium chloride,[2] thimerosol,[3] combinations of methylparaben and propylparaben,[4] phenylmercuric nitrate,[5] phenylethyl alcohol,[6] and polymyxin B sulfate.[7] Aqueous solutions of these agents were prepared, sterilized by appropriate procedures, and assayed for content of active ingredient (22).

Fig. 1.—Appearance of the rabbit eye infected with *Ps. aeruginosa*.

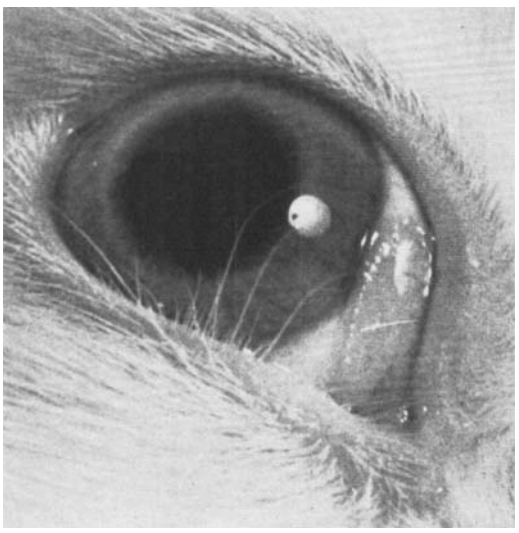

Fig. 2.—Appearance of the normal rabbit eye.

In Vivo Method

Purpose.—The purpose of the *in vivo* study is to prove that (*a*) the results obtained by employing *Experiment III* (*in vitro* method) for noting the efficiency of the antibacterial agents are valid, *i.e.*, the bacteria are incapable of growing in the subculture medium and accordingly are also incapable of producing an ocular infection *in vivo;* and (*b*) the inactivating media utilized in this study are adequate.

Preparation of the Inoculum.—The inoculum of *Ps. aeruginosa* was prepared as previously described. For the most part, the strains of *Ps. aeruginosa* which proved to be the most resistant to the antibacterial agents in the *in vitro* experiments were employed in this study. Occasionally an intermediate strain, with regard to resistance toward the antibacterial agent, and also a mixture of resistant strains were employed. The mixture of resistant strains was prepared on the day of the test by mixing 1 ml. of each of the respective 24-hour-old nutrient broth cultures in a sterile tube and

proceeding as when a single strain of *Ps. aeruginosa* was used.

Preparation of the Antibacterial Agent-Bacteria Mixtures.—One-tenth milliliter of the dilution of the strain or mixture of strains was added to 5 ml. of the sterile preservative solution being investigated. The tube was shaken by hand for approximately 15 seconds and allowed to remain at 24° for a specific contact time, each time period depending on the results obtained in the *in vitro* experiments for the antibacterial agent being studied.

Preparation of the Controls.—A sterile solution of the preservative was employed as a positive control, not only for accidental contamination, but also to detect any action and untoward reaction the preservative might have on the rabbit's eye. A dilution of *Ps. aeruginosa*, containing approximately 10,000 bacteria per ml., was employed as a negative control to determine pathogenicity of *Ps. aeruginosa* in the rabbit's eye.

Procedure.—Two contact time periods were employed for each antibacterial agent-bacteria mixture studied. The contact time periods were selected, as mentioned previously, from the findings of the *in vitro* experiments for the various antibacterial agents tested. The first contact time period selected was the longest period of time which still showed growth of the bacteria in the subculture medium; also the contact time period immediately following the first contact time period was chosen. Obviously, the latter contact time period would have shown no growth of the bacteria in the subculture medium. The first exposure period was employed to prove that when growth of *Ps. aeruginosa* occurs in the subculture medium, an infection could also be produced in the rabbit's eye. The second contact time period was utilized to fulfill the purpose of the *in vivo* experiment.

Usually six rabbits[8] were employed for each antibacterial agent studied. The rabbits were placed by hand in individual cages which were thoroughly cleaned with a disinfectant and live steam after each experiment. The antibacterial agent–bacteria mixture was injected intracorneally into the rabbit's eye. Approximately 0.01 ml. was injected from a one-quarter-ml. tuberculin syringe[9] graduated in 0.01 ml. One-quarter-inch 27-gauge needles[9] were employed. Approximately 5 minutes before each injection, two drops of a 2% butacaine sulfate[10] solution were placed in the conjunctival sacs of each rabbit.

At the first contact time period selected an intracorneal injection of the antibacterial agent–bacteria mixture was given into one eye of each of two rabbits. At the next contact time, another intracorneal injection was given into the other eye of each of the same two rabbits. A third rabbit received an injection of the sterile antibacterial solution (positive control) in one eye and an injection of the diluted bacteria (negative control) in the other eye. The rabbits were observed for a period of 7 days for evidence of ocular infections (see Fig. 1). Figure 1 shows the appearance of an eye infected with *Ps. aeruginosa* 5 days after the injection. Figure 2 shows the appearance of a normal eye. Most eyes infected with *Ps. aeruginosa* were completely closed within 7 days after the injection.

As a further control, swabs were periodically taken of any infected eyes to recover and identify the presence of *Ps. aeruginosa*.

The above procedure was repeated, employing another strain or a mixture of strains of *Ps. aeruginosa*.

RESULTS

From the data obtained from *Experiments I* and *II* employing the different antibacterial agents as preservatives (Tables II and III), the following media were selected to be employed as the inactivating media in *Experiments III* and *IV:* Medium XVIII for chlorobutanol, Medium V for benzalkonium chloride, Medium X for thimerosol, Medium XVIII for combinations of methylparaben and propylparaben, Medium X for phenylmercuric

nitrate, and Medium III for polymyxin B sulfate.

Media XVI and XVIII were found to be the best neutralizing media for phenylethyl alcohol in *Experiment I*. Since the sterilizing time for phenylethyl alcohol was found to be greater than 24 hours, further experiments were not carried out on this chemical in *Experiment II*.

In Table IV a summary of the results obtained in *Experiment III* is presented. The sterilizing times which are listed against *Ps. aeruginosa* for each of the chemical agents are those which have been obtained under severe *in vitro* test conditions (dilution of bacterial inoculum was 1:10). They indicate the time required to kill all of the strains of *Ps. aeruginosa* employed in this study.

The results of *Experiment IV* are not recorded here, but in all cases they indicate that 0.5 ml. was adequate as the volume of antibacterial agent–bacteria mixture used as the transfer in *Experiments II* and *III*.

The results of the *in vivo* experiments indicate that they are in agreement in all instances with the *in vitro* findings of *Experiment III, i.e.*, those solutions which produced growth following transfer into subculture media produced ocular infections; those which did not produce growth did not produce ocular infections.

DISCUSSION

In the evaluation of the effectiveness of antibacterial agents used as preservatives in ophthalmic solutions against *Ps. aeruginosa*, the time required for such an agent to kill the bacteria must be known. The experiments employed in these studies determine the sterilizing time for each antibacterial agent against *Ps. aeruginosa*. In addition, other important factors are evident in the experiments previously described which are not contained in those procedures in current use or those employed in the past.

One advantage is that the procedures do not rely upon a dilution technique to differentiate between bacteriostatic and bactericidal effects of the antibacterial agents being tested. Inactivating agents were employed for this purpose. The latter, incorporated in the subculture media, function by inactivating or neutralizing the antibacterial properties of the chemical agents employed for their preservative activity.

Another advantage of the test procedures employed in this study is that they establish the inactivating or neutralizing ability of the subculture media toward the antibacterial activity of the chemical agents studied. Such data have not been reported previously by the various workers in the field.

In the evaluation of the effectiveness of antibacterial preservatives, it is not only important to determine the time required for sterilization, but it is also necessary to determine whether the bactericidal effect was complete. A method which evaluates the destruction of bacteria but neglects to determine whether a total kill has occurred may

[a] Thirteen strains tested.

prove to be in error. In the experiments employed in this investigation, the adequacy of the volume of the antibacterial agent–bacteria mixture transferred to the subculture media has been evaluated. This has not usually been taken into consideration.

It was noted that the results of the *in vivo* test agreed at all times with the results of the *in vitro* procedures. This was additional evidence of the effectiveness of the inactivating media employed for the various antibacterial chemical agents under study.

An antibacterial agent intended for use as a preservative in ophthalmic solutions should have quick-acting bactericidal activity. There is no exact definition for the term *quick-acting*. In this discussion, an antibacterial agent will arbitrarily be considered to possess *quick-acting* bactericidal activity against *Ps. aeruginosa* if the sterilizing time of that agent was 1 hour or less under the extreme test conditions employed in this study.

Chlorobutanol is not a quick-acting antibacterial preservative aginst *Ps. aeruginosa*. A 12-hour period of contact was required for a 0.5% solution of chlorobutanol, which is the concentration most commonly employed to produce a bactericidal effect in marketed multiple-dose ophthalmic solutions. Lawrence (16) and Riegelman, *et al.* (17), also reported chlorobutanol to be slowly bactericidal against *Ps. aeruginosa*. A 10% Tween 20 nutrient broth medium was found the most effective inhibiting medium for chlorobutanol. The probable mechanism of action whereby Tween 20 acts is probably a binding or association reaction between the chlorobutanol and the Tween.

Of all the antibacterial agents investigated in this study, benzalkonium chloride, in a concentration of 1:5000, revealed the quickest-acting bactericidal activity against *Ps. aeruginosa*. The results obtained for benzalkonium chloride are in agreement with those of Lawrence (16), but they disagree with those of Riegelman, *et al.* (17), who reported a longer sterilizing time against *Ps. aeruginosa*. This may be due to the strains of *Ps. aeruginosa* employed. The subculture medium found to have the greatest neutralizing activity against benzalkonium chloride contained polysorbate 80 (Tween 80) and lecithin as the inactivating agents. Both of these compounds inactivate the antibacterial activity of benzalkonium chloride; however, the mechanisms of inactivation are different. The possible mechanism of action of the polysorbate 80 is a binding or association reaction with the benzalkonium chloride, whereas the negative charge of lecithin is probably responsible for the inactivating role it plays.

TABLE IV.—STERILIZING TIMES AGAINST *Ps. aeruginosa* (10^8) FOR CHEMICAL AGENTS COMMONLY EMPLOYED AS PRESERVATIVES IN OPHTHALMIC SOLUTIONS

Chemical Agents	Concn.	Sterilizing Time
Chlorobutanol	0.7%	9 hr.
Chlorobutanol	0.5%	12 hr.
Benzalkonium chloride	1:5000	45 min.
Benzalkonium chloride	1:10,000	9 hr.
Thimerosol	1:5000	6 hr.
Thimerosol	1:10,000	9 hr.
Methylparaben and propylparaben	0.2% 0.04%	3 hr.
Methylparaben and propylparaben	0.18% 0.02%	6 hr.
Phenylmercuric nitrate	1:10,000	6 hr.
Phenylmercuric nitrate	1:20,000	6 hr.
Phenylethyl alcohol	0.5%	[a]
Polymyxin B sulfate	2000 units/ml.	12 hr.
Polymyxin B sulfate	1000 units/ml.	18 hr.

[a] Sterilization not effected in 24 hours.

The results indicate that thimerosol, in the highest concentration (1:5000) usually employed as an antibacterial preservative in marketed ophthalmic solutions, is too slow-acting in its bactericidal effect (6 hours) against *Ps. aeruginosa*. The inactivating medium employed to neutralize the antibacterial action of thimerosol was fluid thioglycollate medium containing polysorbate 80 and lecithin. The former, by itself, has had general acceptance as the inactivating medium for the antibacterial organic mercurials, there being an interaction between the mercurial ion and the —SH groups of the thioglycollic acid. However, it was found to be less effective than the combination of substances employed in our inactivating medium.

A combination of 0.2% of methylparaben and 0.04% propylparaben possessed a sterilizing time of 3 hours against *Ps. aeruginosa*. However, this concentration is not usually employed in ophthalmic solutions. In a concentration more commonly employed, 0.18% methylparaben and 0.02% propylparaben, the sterilization time required was 6 hours. A Tween 20–nutrient broth medium was employed as the inactivating medium for the antibacterial activity of the parabens. Tween 20 as the major inactivator probably functions by the same mechanism of action as that discussed under chlorobutanol.

The results indicate that phenylmercuric nitrate acts too slowly as a bactericide against *Ps. aeruginosa* for use as an antibacterial preservative in ophthalmic solutions, the sterilizing time being 6 hours. The findings in *Experiments I* and *II* indicated that polysorbate 80 and lecithin in fluid thioglycollate medium was most effective in neutralizing the antibacterial activity of phenylmercuric nitrate and even better than fluid thioglycollate medium by itself. This observation was also made by Riegelman, *et al.* (17). The increase in the inactivating ability of fluid thioglycollate medium when it contains lecithin solubilized by polysorbate 80 is probably because of the interaction of the oppositely charged molecules of lecithin and phenylmercuric nitrate.

A 0.5% solution of phenylethyl alcohol did not have sterilizing power when in contact with *Ps. aeruginosa* for a period of 24 hours and must therefore be considered to be a very inferior antibacterial preservative against this organism.

Polymyxin B sulfate was found to be only slowly bactericidal against *Ps. aeruginosa* and is therefore unsuitable as an antibacterial preservative in multidose ophthalmic solutions. This conclusion does not agree with that of Riegelman, *et al.* (17). However, Riegelman's results could not be duplicated when employing his technique, the inactivating medium used by him and his workers, and utilizing the strains of *Ps. aeruginosa* employed in this investigation. A possible explanation for this discrepancy may be the resistance of the strains of *Ps. aeruginosa* employed toward polymyxin B sulfate. Attention is directed to the fact that Riegelman, *et al.* (17),

did not employ many strains of *Ps. aeruginosa* in their experiments. It was observed that lecithin, suspended with the aid of glycerin in nutrient broth, was most effective in inactivating polymyxin B sulfate. The possible mechanism of action is similar to that given under benzalkonium chloride. It was also noted that nutrient broth containing lecithin solubilized by either Tween 20 or Tween 80 was not as effective as the above-mentioned inactivating medium. This observation was also noted by Riegelman, *et al.* (17), and Bliss and Worth (23). A possible explanation may be that the effective charge of the lecithin molecule is reduced when it is solubilized by the Tweens. This reduction in the inhibiting action of lecithin by the Tweens was not observed with benzalkonium chloride. The Tweens, by themselves, were capable of reducing the antibacterial action of benzalkonium chloride, while they had no such effect on polymyxin B sulfate.

SUMMARY

1. Various *in vitro* studies were carried out to determine the antibacterial effectiveness of various chemical agents to be used as preservatives in ophthalmic solutions against 13 strains of *Ps. aeruginosa*. Methods were devised to (*a*) differentiate between the bacteriostatic and bactericidal properties of the chemical preservatives by formulating suitable inactivating media, (*b*) determine the sterilizing time for each chemical preservative, and (*c*) determine whether the volume of inoculum taken for sampling in the experiment was adequate.

2. An *in vivo* procedure was employed in evaluating the chemical agents to note whether findings would be in agreement with the final results obtained in the *in vitro* studies.

3. The following antibacterial agents used or recommended for use in ophthalmic solutions were thoroughly investigated: chlorobutanol, benzalkonium chloride, thimerosol, combinations of methylparaben and propylparaben, phenylmercuric nitrate, phenylethyl alcohol, and polymyxin B sulfate. Of these, only benzalkonium chloride possessed a sterilizing time against *Ps. aeruginosa* of less than 1 hour.

Effect of Certain Drugs on Perfused Human Placentas II

Vasodilators

By HENRY P. CIUCHTA and RONALD F. GAUTIERI

Perfusion studies conducted on full term human placentas produced the following results: marked vasodilation with isosorbide dinitrate, isoproterenol hydrochloride, nitroglycerin and papaverine hydrochloride, slight vasodilation, and vasoconstriction with cyclandelate and isoxsuprine hydrochloride. Except for alcohol, which produced a slight decrease in the volume flow rate through the placenta, the solvents employed with these drugs had no effect on placental vasculature.

During the past 40 years the action of various agents on placental vasculature has been studied by numerous investigators, including Kosakae (1), Ueda (2), von Euler (3), Schmitt (4), Eliasson and Astrom (5), and Astrom and Samelius (6). The results of these experiments are rather inconsistent. This undoubtedly is partly due to the employment of different experimental procedures and the inability at times to obtain placentas within a short time after delivery. More than likely, the

did not employ many strains of *Ps. aeruginosa* in their experiments. It was observed that lecithin, suspended with the aid of glycerin in nutrient broth, was most effective in inactivating polymyxin B sulfate. The possible mechanism of action is similar to that given under benzalkonium chloride. It was also noted that nutrient broth containing lecithin solubilized by either Tween 20 or Tween 80 was not as effective as the above-mentioned inactivating medium. This observation was also noted by Riegelman, *et al.* (17), and Bliss and Worth (23). A possible explanation may be that the effective charge of the lecithin molecule is reduced when it is solubilized by the Tweens. This reduction in the inhibiting action of lecithin by the Tweens was not observed with benzalkonium chloride. The Tweens, by themselves, were capable of reducing the antibacterial action of benzalkonium chloride, while they had no such effect on polymyxin B sulfate.

SUMMARY

1. Various *in vitro* studies were carried out to determine the antibacterial effectiveness of various chemical agents to be used as preservatives in ophthalmic solutions against 13 strains of *Ps. aeruginosa*. Methods were devised to (*a*) differentiate between the bacteriostatic and bactericidal properties of the chemical preservatives by formulating suitable inactivating media, (*b*) determine the sterilizing time for each chemical preservative, and (*c*) determine whether the volume of inoculum taken for sampling in the experiment was adequate.

2. An *in vivo* procedure was employed in evaluating the chemical agents to note whether findings would be in agreement with the final results obtained in the *in vitro* studies.

3. The following antibacterial agents used or recommended for use in ophthalmic solutions were thoroughly investigated: chlorobutanol, benzalkonium chloride, thimerosol, combinations of methylparaben and propylparaben, phenylmercuric nitrate, phenylethyl alcohol, and polymyxin B sulfate. Of these, only benzalkonium chloride possessed a sterilizing time against *Ps. aeruginosa* of less than 1 hour.

Effect of Certain Drugs on Perfused Human Placentas II

Vasodilators

By HENRY P. CIUCHTA and RONALD F. GAUTIERI

Perfusion studies conducted on full term human placentas produced the following results: marked vasodilation with isosorbide dinitrate, isoproterenol hydrochloride, nitroglycerin and papaverine hydrochloride, slight vasodilation, and vasoconstriction with cyclandelate and isoxsuprine hydrochloride. Except for alcohol, which produced a slight decrease in the volume flow rate through the placenta, the solvents employed with these drugs had no effect on placental vasculature.

During the past 40 years the action of various agents on placental vasculature has been studied by numerous investigators, including Kosakae (1), Ueda (2), von Euler (3), Schmitt (4), Eliasson and Astrom (5), and Astrom and Samelius (6). The results of these experiments are rather inconsistent. This undoubtedly is partly due to the employment of different experimental procedures and the inability at times to obtain placentas within a short time after delivery. More than likely, the

major reason for varying results is the sensitivity of the placenta itself.

Schmitt (4), besides demonstrating that the placenta is devoid of innervation, showed that histamine, posterior pituitary extract, and barium chloride constricted placental vasculature, while amyl nitrite caused a dilatation and adrenaline produced no effect. von Euler (3) conducted extensive studies on "nerve free" vessels of the placenta and found only a constrictor action with epinephrine, acetylcholine, histamine, pitressin, and barium chloride. He postulated that these drugs may act on some intermediate mechanism of the contractile element.

In an earlier work (7) von Euler observed that acetylcholine constricted pulmonary vessels in the rabbit. From these investigations (3, 7) he proposed that a correlation may exist between the responses of placental and pulmonary vessels, since arteries of both organs carry venous blood and are structurally adapted to withstand moderate pressures. Smith and Coxe (8) submitted supporting evidence in observing that pulmonary vessels in cat, dog, swine, and human lungs were constricted with epinephrine, acetylcholine, and histamine.

Experiments conducted by Dornhorst and Young (9) on placental vessels of guinea pig *in situ* indicated that adrenaline and noradrenaline caused a constriction of these vessels by a direct action, thus impairing placental circulation.

Eliasson and Astrom (5) observed vasoconstriction in placental vessels with epinephrine, norepinephrine, dihydroergotamine, acetylcholine, and histamine. Astrom and Samelius (6), in addition to testing the effects of lysergic acid, chlorpromazine, tryptamine, yohimbine, mescaline, phentolamine, phenbenzamine, reserpine, ganglionic blocking agents, and heparin, established the potent vasoconstrictor activity of serotonin on placental vasculature.

Previously in this laboratory (10) it was demonstrated that the vasculature of the placenta undergoes various degrees of vasoconstriction in the presence of narcotic analgesics, serotonin, and relaxin.

Since the actions of many vasoconstrictors on placental vessels have been intensively investigated, a study of the effects of vasodilators on this preparation is indicated. Proof exists that morphine (10) and histamine (5), which usually elicit vasodilation in man, cause vasoconstriction in placental vessels. Therefore, there is a need to determine whether certain vasodilators may also follow a similar pattern of producing an opposite effect on placental vasculature. The placenta provides a valid technique for ascertaining the action of musculotropic drugs because it is devoid of nervous tissue.

Therefore, it was the purpose of this investigation to observe the effects of clinically proved vasodilators alone on placental vasculature, and in certain cases, in the presence of drug induced spasm.

MATERIALS AND METHODS

Full term human placentas were obtained from the hospital 5–15 minutes after normal delivery. Each was transported to the laboratory in a container of 38° preheated Tyrode's solution.

The preparation was flushed free of blood by injecting 10% sodium citrate solution into one of the arteries. Cannulas were inserted into the vein and one artery of the umbilical cord 5–10 cm. from the stalk of the placenta and the remaining umbilical artery was ligated. The whole preparation was then placed in a perfusion chamber containing aerated Tyrode's solution which had a pH range of 7.2 to 7.4 and was maintained at a constant 37° by a Bronwill thermoregulator. The arterial cannula was connected with rubber tubing to a hydrostatic reservoir which was adjusted to yield pressures ranging between 40–60 mm. Hg. The reservoir contained Tyrode's solution which was modified by the addition of 0.525% polyvinylpyrrolidone (Plasdone C). The venous outflow, ranging between 10–60 ml./minute, was measured directly by means of a graduated cylinder and not reperfused.

Two placentas were discarded because the outflow per minute at the onset of the experiment was far below average; it was considered that the volume changes would not be of significant value.

TABLE I.—THE EFFECTS OF DRUGS ON VOLUME FLOW IN PERFUSED HUMAN PLACENTAS

	Composite Results					
Drug	No. of Prepns.	Dose	Vol. Flow (Range), % Increase	Decrease	Av. %	S. D.
Cyclandelate	4	1–4 mg.	11–19	...	15.5	2.6
Cyclandelate	11	1–4 mg.	...	5–15	10.2	3.5
Isoxsuprine	10	1–10 mg.	5–19	...	9.4	4.0
Isoxsuprine	5	1–10 mg.	...	5–11	7.0	2.3
Isosorbide	5	1–2 mg.	25–116	...	49.6	37.4
Isoproterenol	11	2.0 mg.	5–84	...	41.7	28.6
Nitroglycerin (spirit)	5	0.2 ml.	18–159	...	73.4	67.0
Nitroglycerin (aqueous)	6	1–4 mg.	5–36	...	20.3	11.6
Papaverine	9	4–5 mg.	5–65	...	30.4	15.0
Serotonin	9	50–100 mcg.	...	7–81	28.8	24.6

In 85 successful experiments the average duration of each preparation was between 2 and 3 hours.

The following drugs were injected into the rubber tubing adjacent to the arterial cannula in a volume of distilled water not exceeding 1 ml.: cyclandelate,[1] isoxsuprine hydrochloride,[2] isosorbide dinitrate,[1] isoproterenol hydrochloride,[3] nitroglycerin (alcoholic and aqueous vehicles), papaverine hydrochloride, and 5-hydroxytryptamine creatinine sulfate (serotonin). In addition, alcohol and propylene glycol were injected to observe if these vehicles elicited action of their own.

RESULTS

Cyclandelate.—Cyclandelate in doses of 1–4 mg. (four preparations) produced a slight vasodilation of placental vessels. The increase in volume outflow ranged from 11–19% (Table I). However, in 11 preparations there was a decrease in outflow ranging from 5–15% (Table I). After cyclandelate administration, three preparations yielded a change in volume outflow below 5% and were not counted.

The administration of serotonin after pretreatment of a preparation with cyclandelate elicited a typical vasoconstrictor effect. Isoproterenol injection caused an increase in volume outflow after a volume decrease due to cyclandelate.

Isoxsuprine.—The administration of isoxsuprine hydrochloride (10 cases) in doses of 1–10 mg. produced an increase in volume outflow of 5–19% (Table I). In five cases there was a 5–11% decrease in the outflow rate (Table I). A change in the outflow rate below 5% was recorded in 10 preparations.

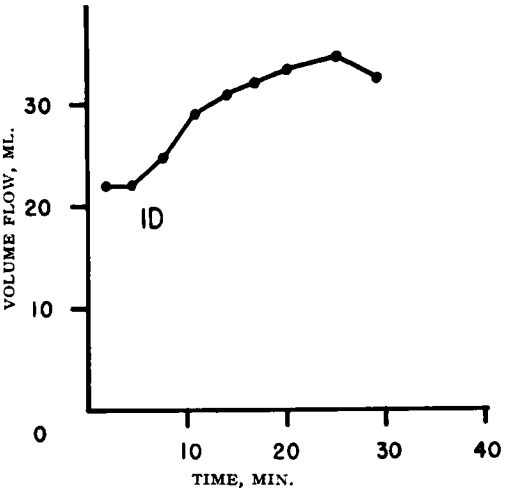

Fig.1—Effect of isosorbide dinitrate (1 mg.) on volume flow rate in vessels of the perfused human placenta.

After a decrease or increase in outflow rate due to isoxsuprine, the administration of serotonin in certain cases brought about vasoconstriction, while subsequent injections of papaverine increased the volume outflow.

Isosorbide.—In a total of five experiments isosorbide dinitrate in doses of 1–2 mg. produced an increase in volume outflow (Fig. 1). The range of outflow was increased 25–116% (Table I). Only one preparation yielded a change in outflow rate below 5%.

The subsequent administration of nitroglycerin caused an even greater increase in the volume outflow in certain preparations.

Isoproterenol.—The administration of 2 mg. of isoproterenol hydrochloride (11 preparations) brought about a powerful vasodilation (Fig. 2) which was of a long duration and not increased by the subsequent injection of cyclandelate in certain cases. The outflow rate increased from 5–84% (Table I). Results obtained from three preparations were under 5%.

Nitroglycerin.—In five cases dramatic increases in volume outflow (Fig. 3) were obtained with the administration of 0.2 ml. of nitroglycerin spirit (92% alcohol as the vehicle). The per cent increase in volume outflow ranged from 18–159 (Table I).

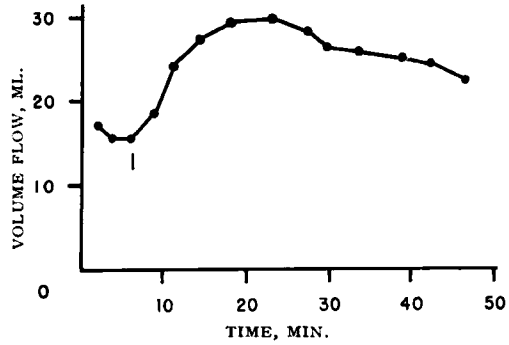

Fig. 2—Effect of isoproterenol (2 mg.) on volume flow rate in vessels of the perfused human placenta.

The administration of 1–4 mg. of nitroglycerin (aqueous vehicle) produced an increase in volume outflow in six cases, having a range of 5–36% (Table I). All preparations yielded increases of 5% or more.

The administration of serotonin in certain preparations following alcoholic nitroglycerin brought about a slight and transient vasoconstriction. Treatment of a preparation with isosorbide after aqueous nitroglycerin caused a significant increase (32%) in volume outflow.

Papaverine.—In nine preparations doses of 4–5 mg. of papaverine hydrochloride produced an increase in volume outflow ranging from 5–65% (Table I). The change in outflow rate of two preparations was under 5%.

The administration of barium chloride (Fig. 4) and serotonin (Fig. 5) following papaverine injection elicited vasoconstriction.

Serotonin.—The administration of serotonin in 50–100-mcg. doses in nine cases evoked a marked decrease in volume outflow ranging from 7–91% (Table I). Significant responses were not obtained in two preparations.

Alcohol.—Injections of 0.2 ml. of alcohol (95%) produced a predominant decrease in outflow in four cases having a range of 4–10%. No change in volume outflow was recorded in two instances.

[2] Supplied through the courtesy of Mead Johnson Research Center, Evansville, Ind.
[3] Supplied through the courtesy of Sterling-Winthrop Research Institute, Rensselaer, N. Y.

Propylene Glycol.—Propylene glycol caused a slight increase in outflow in two cases and a moderate decrease in two preparations.

DISCUSSION

The action of vasodilating agents is mediated through the activation of several different mechanisms, including (*a*) blood vessel musculature, (*b*) specific autonomic receptors and/or their chemical mediators, and (*c*) the central nervous system and its pathways. For example, guanethidine acts predominantly at the nerve-arteriole junction (11, 12) where it depletes norepinephrine in sympathetic nerve endings, thereby bringing about a vasodilating effect. Epinephrine, in small concentrations, produces a hypotensive effect which is mediated through stimulation of the inhibitory β-receptors (13). Papaverine (14), isosorbide (15), nitroglycerin (16), and cyclandelate (17) supposedly

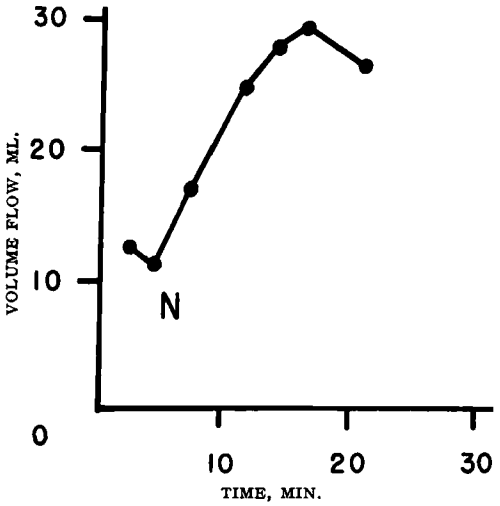

Fig. 3.—Effect of nitroglycerin spirit (2 mg.) on volume flow rate in vessels of the perfused human placenta.

inhibit or depress vessel musculature directly to elicit vasodilation. Isoxsuprine (18), in addition to its direct depressant action (papaverine-like) on vasculature, is thought to activate β-adrenergic receptors. The results of this investigation indicate that, generally, gross qualitative differences do not exist between the activity of the majority of vasodilators on placental vasculature and other circulatory beds.

The administration of cyclandelate to 15 different preparations produced either slight vasodilation or vasoconstriction. In four of these experiments the volume outflow increased above 10%, while in 11 preparations there was a decrease in volume outflow to 15%. In addition, the change in the volume outflow rate after cyclandelate administration in three other preparations was below 5%. Since responses obtained with cyclandelate were rather unpredictable and relatively slight, it is likely that placental vasculature does not possess the specific mechanism upon which this drug exerts its action. Furthermore, since consistent increases in volume outflow were obtained with papaverine and nitroglycerin, agents which affect vascular musculature directly, it follows that cyclandelate does not possess marked depressive musculotropic activity. Therefore, vasodilation that occurs in man after cyclandelate administration may be attributed mainly to some other pathway or mechanism that is not present in isolated placental preparations.

Isoxsuprine produced an increase in volume out-

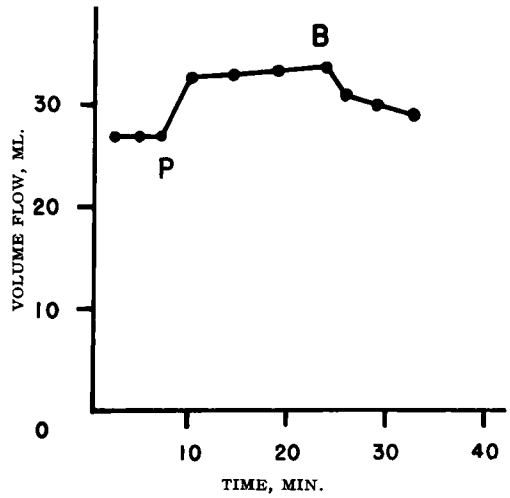

Fig. 4.—Effect of papaverine (5 mg.) and barium chloride (12.5 mg.) on volume flow rate in vessels of the perfused human placenta.

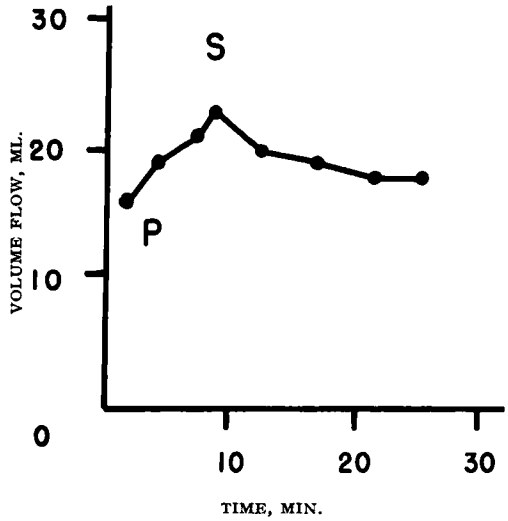

Fig. 5.—Effect of papaverine (5 mg.) and serotonin (50 mcg.) on volume flow rate in vessels of the perfused human placenta.

flow of over 5% in 10 preparations, a decrease of 5–11% in five, and either an increase or decrease of under 5% in 10. These varied responses would seem to indicate that, as with cyclandelate, placental vessels are devoid of a specific pathway upon which isoxsuprine acts. The activity of this agent on β-adrenergic receptors appears relatively slight since the degree and consistency of vasodilation are not comparable to that of isoproterenol which causes dilatation by activating these inhibitory receptors.

Vasodilation of the same magnitude as that produced by papaverine was never observed with isoxsuprine. Therefore, any papaverine-like activity that this agent may possess is relatively weak.

Treatment of placental preparations with isosorbide evoked responses that were qualitatively and quantitatively similar to those obtained from coronary artery studies in isolated hearts (19). These cardiac experiments showed that isosorbide produced an average increase in flow of 30–40% through coronary vessels, while in our investigation the average increment in volume outflow through placental vessels was 49%. Since both types of isolated preparations respond favorably to isosorbide administration, it appears that the effect of this agent depends mostly on its direct action on vascular musculature.

Isoproterenol brought about a sustained dilatation of vessels. However, this increase was not comparable to that occurring in response to alcoholic nitroglycerin or isosorbide. The mechanism of action of isoproterenol *in vivo* is due to stimulation of inhibitory β-receptors (12) and this logically could be the basis for its action on placental vessels.

Organic nitrates are known to be very active in causing dilatation of vessels; therefore, the increase in volume outflow produced in the placenta by nitroglycerin was anticipated. However, nitroglycerin spirit elicited a greater increase in flow than the aqueous preparation. It is possible that alcohol may have increased permeability in a manner to allow more effective cell contact, with the concomitant augmentation in response. This is not in accordance with the fact that the administration of 0.2 ml. of 95% alcohol did not cause dilatation of vessels but on the contrary caused appreciable vasoconstriction. The vasodilating action of alcoholic nitroglycerin was so powerful that subsequent administration of serotonin produced only very slight vasoconstriction.

Studies conducted by Eckenhoff and Hafkenschiel (20) indicate that papaverine is the most efficient coronary dilator. It should be noted that drugs which produce coronary dilation exert similar responses on placental vasculature. Likewise, in this experiment it was found that papaverine caused a prolonged dilation resulting in a marked increase in volume outflow. Furthermore, the action of papaverine was so intense that barium chloride and serotonin did not alter the dilation to any appreciable degree (Figs. 4 and 5).

The possibility exists, as indicated by von Euler (3), that the action of drugs on placental vasculature may correspond to their action on pulmonary vessels. An interesting aspect that should be explored is testing various agents on pulmonary and placental arteries and veins individually. It may be possible that these agents affect pulmonary and placental arteries and veins in a slightly different manner than other systemic arteries and veins which have a completely different oxygen content. Therefore, a correlation may exist between these two types of vessels and their reactions to drugs.

As indicated in a previous investigation (10), the possibility exists that fetal metabolism may be affected in part because of the action of drugs on placental vasculature. This is of significance if directly acting vasoconstricting agents are employed, since constriction of placental vessels may impair fetal tissue oxygenation. It should be kept in mind that in a pregnant patient with a previous history of hypotension the administration of vasoconstrictors may sensitize the placental vasculature and cause subsequent disturbance in fetal circulation. If placental vasoconstriction is suspected *in vivo*, certain of the vasodilators used in this investigation may be employed to counteract it.

Throughout this investigation, as in von Euler's study (3), a valid dose/response relationship does not appear to exist, as similar degrees of action occur with relatively small and large doses. This probably is because of the individual sensistivity of the placenta as well as to a probable lack of specific receptor sites.

Production of Protein and Lipid by *Chlorella vulgaris* and *Chlorella pyrenoidosa*

By ROBERTSON PRATT and EVELYN JOHNSON

Cultures of *Chlorella vulgaris* reach the stationary phase of their growth cycle more slowly than cultures of *C. pyrenoidosa* when both are provided with conditions favorable for their growth. But after 3 weeks of incubation, the yields from the two organisms are nearly identical in terms of packed volume, dry weight, and cell population. There is only a relatively small difference in protein content—about 8 per cent in favor of *C. vulgaris*. There is a somewhat larger difference in lipid content, *C. pyrenoidosa* yielding about 11 to 12 per cent more lipid than *C. vulgaris*. Both species produce more lipid and relatively less protein with increasing age. Accumulation of lipid in excess of about 25 per cent of total dry weight is indicative of waning vigor in cultures of *Chlorella*, and a lipid content that equals or exceeds the protein content is indicative of extreme senescence. Both organisms grow poorly in a nitrogen-deficient medium but differ in their response to it. The yield from *C. vulgaris* is about 80 to 86 per cent of the yield from *C. pyrenoidosa* with respect to packed volume, dry weight, and per cent lipid. Only with respect to per cent protein are the two organisms the same. However, in absolute terms (mg./ml. of culture) *C. vulgaris* yields about 14 per cent less protein and nearly 30 per cent less lipid than *C. pyrenoidosa* in such a medium.

THE YIELD of conventional crop plants is markedly affected by the chemical composition and nutritive value of the substrate. But the ratio of protein/lipid/carbohydrate is not altered substantially. In contrast with this, it has been reported that the protein content of *Chlorella pyrenoidosa* can be varied from about 8 to 58% regularly (on one occasion a value of 88% was found) and that the lipid content can be varied from about 4.5% to more than 85% by simply altering the composition of the inorganic culture solution and properly controlling the incident light intensity, duration of culture, and other environmental factors (1). Carbohydrate concentration appears to be less amenable to alteration, the range being from about 5% to approximately 37%. All values were expressed as per cent of dry weight.

The concentration of nitrogen (or availability of nitrogen?) is reported to be a key factor. Spoehr and Milner (2) stated that high lipid values were never attained when the "residual fixed nitrogen concentration was greater than 0.001 molar" in the medium and that an initial nitrogen concentration of 0.025 *M* was sufficient to ensure that the plants would not reduce the level below 0.001 *M* and would not yield a high lipid value. Not all species of *Chlorella* respond uniformly in this respect. Such manipulation of the nitrogen concentration in the medium does not induce equivalent changes in the proportion of fatty acids produced by *C. vulgaris* (3).

The above observations, if regularly reproducible, would have potential practical import as well as theoretical interest. In the United States, Canada, Great Britain, Japan, and Israel there has been considerable interest in mass culture of *Chlorella* and other unicellular algae as potential future sources of food or food supplements. When the human race can no longer afford the inefficient luxury of the vast land areas and relatively long growth periods required to produce grain and meat and other conventional present-day foods, it may become necessary to resort to mass culture of unicellular algae to provide adequate sustenance for a large portion of the world population. It would be of considerable value to have knowledge of practical means for controlling the protein/lipid/carbohydrate ratio of the crop so that a custom-tailored diet, with respect to these major food components, could be produced. It will be important to know also how different species of algae compare with each other and with existing foods as sources of vitamins and of accessory growth factors. Some quantitative studies of vitamin content of algae and a few nutritional studies with animals have been reported (4–7), but no extensive or systematic evaluation has been published, especially with respect to changes that might occur with alteration of the basal composition of the harvest. The present paper deals with protein and lipid yields from *C. pyrenoidosa* and *C. vulgaris* cultured in media reputed to favor high protein and high lipid yields, respectively.

Received December 20, 1962, from the School of Pharmacy, University of California, San Francisco.

EXPERIMENTAL

Materials and Methods

Organisms.—The strain of *C. vulgaris* employed

has been maintained in the laboratory since 1931 when it was isolated from a pond in Van Cortlandt Park, New York City. Identification was verified at that time by the late Professor Tracy Hazen of Columbia University. *C. pyrenoidosa* (an Emerson strain designated No. C-1-1-1 in the algal culture collection of the Kaiser Foundation Research Institue, Richmond, Cal.) was obtained through the courtesy of Dr. Mary Belle Allen of that institution.

Culture Conditions.—Inocula for experiments were always taken from 4-day stock cultures (inoculated from a long series of 4-day cultures) in liquid medium and were adjusted to provide an initial population of 100 cells/mm.^{3} (100,000/ml.). Stock cultures were illuminated continuously by a water-jacketed, 500-watt incandescent Mazda lamp. The total light intensity (as measured by a Weston photoelectric cell light meter, model 603) was 1,250 f.-c. at the position of the culture flasks. A mixture of 5% CO_2 and 95% air was bubbled through the cultures continuously. The temperature varied between 20 and 22°.

The standard solution for stock cultures and the reference base for experiments consisted of:

KNO_3	0.025 *M*
$MgSO_4 \cdot 7H_2O$	0.020 *M*
KH_2PO_4	0.018 *M*
$FeSO_4 \cdot 7H_2O$	5×10^{-5} *M*
$K_3C_6H_5O_7 \cdot H_2O$	5×10^{-5} *M*
Zn(as $ZnSO_4 \cdot 7\ H_2O$)	0.400 p.p.m.
Cu(as $CuSO_4 \cdot 5H_2O$)	0.004 p.p.m.
Mn(as $MnSO_4 \cdot 4H_2O$)	0.400 p.p.m.
B(as H_3BO_3)	0.020 p.p.m.

A solution containing the three major salts was sterilized in the autoclave (15 minutes at 18-lbs. pressure). The other salts were incorporated in a single solution which was sterilized by filtration and then added aseptically to complete the formulation. The pH of the uninoculated medium is 4.5 to 4.6. As the culture develops, the pH rises to a value of 7.0 to 7.5 in 2 weeks and tends to remain at that level, even with prolonged incubation.

Columnar Pyrex culture vessels (60.5 cm. tall × 43 cm. diam. and each containing 500 ml. of culture medium) were arranged in a circle around a central, water-cooled incandescent light bank consisting of four clear, 60-watt Lumiline show case lamps, which provided 600 f.-c. continuously at the culture vessels. The temperature was 20.5 ± 0.5°.

A 5% CO_2–95% air mixture was introduced continuously through a sintered-glass sparger at the bottom of each vessel and bubbled up through the cultures in a finely dispersed stream which served the dual purpose of providing CO_2 for photosynthesis and retarding settling of the cells. Even so, daily shaking was necessary to maintain a uniform suspension.

Under exceptional circumstances, the cultures developed a population density of about half a million cells/mm.^{3} (actual maximum count = 506 million/ml.) after 3 weeks of growth; but the usual plateau level attained at that time was about 330 to 340 million cells/ml.

The C-2 formulation of Spoehr and Milner (2), henceforth designated SM, was selected as the high-lipid medium. It contains

$(NH_4)H_2PO_4$	0.000825 *M*
$(NH_4)_2HPO_4$	0.000715 *M*
KCl	0.03 *M*
$MgSO_4 \cdot 7H_2O$	0.01 *M*
KH_2PO_4	0.01 *M*
[Fe]	5×10^{-6} *M*

No trace elements (other than iron) were added by the original formulators, since they used "local tap water" which had a "fairly high mineral content," and they found that "the yields of *Chlorella* indicated that the water was adequate for providing micro-elements." However, media for the present experiments were prepared with distilled water. Therefore, micronutrients were added in the same concentration as for the standard medium. Thus, the concentration of iron added in our experiments was ten times that added by Spoehr and Milner. Since the iron content of the tap water they employed is not known, the precise difference in concentration of iron in the two sets of experiments cannot be stated. But it is reasonable to assume that it was at least several-fold higher in our experiments than in theirs. The initial pH of the SM medium before inoculation is 5.9. This value drops rapidly as the organisms begin to grow and soon stabilizes at about pH 3.5. This is consistent with the earlier observations of Pratt and Fong (8).

Analytical Methods

Upon harvest, the cell suspensions were centrifuged and the cell mass was resuspended and washed in distilled water. In harvesting cultures that had nitrogen supplied as ammonium salts, the cells were washed repeatedly until the supernatant gave a negative reaction with Nessler's reagent.

After the final washing, the cells were resuspended in distilled water (0.1 the original harvested volume). Aliquots of this tenfold concentrated suspension were used for determination of packed volume and dry weight by conventional methods. Cell counts were determined with a haemocytometer from the original cell suspension before centrifuging.

Protein was determined by the standard Kjeldahl micro-method (range 10 to 40 mcg. nitrogen) as outlined by Umbreit, *et al.* (9), with modifications adapted from Johnson (10) and Schmidt (11).

Lipids were determined by a procedure adapted from Milner (12), using a paste of freshly harvested cells [100–500 mg. (dry wt.)]. The cell mass was extracted twice with methanol under reflux; then extracted by refluxing three times each with ethyl ether and methanol, alternately, over a period of 2 days. The several fractions were filtered, pooled, and evaporated to dryness. The dry residue was re-extracted with ethyl ether three times to eliminate methanol-soluble sugars. The final ether extract was evaporated to dryness and brought to constant weight in a vacuum desiccator. A fresh 30-ml. portion of solvent was used for each extraction throughout the procedure.

Precision of Methods and Reproducibility of Data

In work of the type reported below it is important to indicate the degree of reproducibility of the data (adequacy of sampling) and the precision of the analytic procedures employed to obtain them (methodology). Among factors affecting adequacy

of sampling we include all the numerous physical factors and manipulative procedures to which the cultures are subjected.

The coefficient of variability (standard deviation expressed as a percentage of the mean $=v$) was chosen as the most appropriate statistical indicator because it relates not only to the reproducibility of one set of data, but also indicates the reliability and reproducibility of several kinds of data. In general, variabilities of two or more distributions, regardless of their units of measurement, may be considered to be related to each other as the corresponding values of v. The procedures upon which the conclusions presented below are based were determinations of dry weight, nitrogen, and lipid. Run on aliquots of a given sample, such determinations routinely yielded highly reproducible values. The critical factors affecting reproducibility of data are in the cultures. Inherent biologic variation cannot be ruled out of any work with living organisms, but strains of *Chlorella* that have been under long laboratory cultivation appear to be quite stable. We believe that the major sources of variability are in certain physical culture conditions which cannot reasonably be controlled with absolute precision and the extensive but necessary manipulation of the cultures from the time of set-up through the time of harvest and preparation of the cells for analysis. In any given run of replicate cultures, some variation occurs. Values of v calculated for duplicate to quadruplicate samples from each of ten cultures were within the following limits: mg. dry wt./ml., 0 to 1.3%; mcg. nitrogen/ml., 0.5 to 5.1%; mg. lipid/ml., 0 to 5.5%.

When averaged data from several series of cultures in different experiments conducted for different lengths of time are compared, larger coefficients of variability are to be expected. Values of v for the data tabulated under *Results* were within the following limits: mg. dry wt./ml. 14 to 14.2%; protein as per cent of dry weight, 6.7 to 8.6%; and lipid as per cent of dry weight, 7.2 to 18%. Packed volume and cell counts are recorded in some of the following tables primarily to round out the picture; they did not form the basis for the specific conclusions reached. The coefficients of variability for these potential indicators of growth in all of the experiments were within the following limits: packed volume, 9.6 to 23.4%; cell count 17.1 to 17.5%.

RESULTS

Averaged data from 12 replicated experiments are summarized in Table I. The comparative data in Table II parts A and B, (based on the figures in Table I) indicate, respectively, the relative value of the standard and the "high-lipid-inducing" media for each organism and the relative performance of the two organisms in each medium.

The tables show clearly the superiority of the standard over the SM medium for growth of both species of *Chlorella*, as indicated by packed volume, dry weight, and protein content. Only with respect to lipid do the cells produce a lower percentage yield in the standard medium than in SM (Table I and Table II, part A, columns *1–4*). The tables also show differences in the responses of the two organisms to the different media, as discussed below.

Packed Volume and Dry Weight.—After 2 weeks, protein content, dry weight, and packed volume of *C. vulgaris* cultured in standard medium are about three to four times those produced in SM medium (Table II, part A, column *1*). After another week, the differences are approximately 3- to 5.5-fold in favor of the standard (Table II, part A, column *2*). A similar trend, differing only in detail, occurs in cultures of *C. pyrenoidosa* (Table II, part A, columns *3* and *4*). During the third week of incubation, the increase in relative dry weight in the standard *versus* the SM medium is less for *C. pyrenoidosa* than for *C. vulgaris;* during the same period the relative values for packed volume and protein decrease in cultures of *C. pyrenoidosa*, while they increase in cultures of *C. vulgaris*. In other words, the superiority of the standard medium over the "high lipid" medium for supporting *C. vulgaris* is more apparent after 3 weeks than after 2 weeks, but the same is not true for cultures of *C. pyrenoidosa*. This can be ascribed, in part, to more rapid attainment of "maturity" by cultures of the latter organism than of the former when both are in standard medium.

For example, the yield in terms of packed volume and dry weight is essentially the same from both organisms at 3 weeks in standard medium (Table I, columns *2* and *6*; Table II, part B, column *6*). But *C. pyrenoidosa* produces about 90% of its packed volume and about 80% of its dry weight in the first 2 weeks of growth (compare columns *5* and *6*, Table I), while the corresponding figures for *C. vulgaris* are 70 and 64% (compare columns *1* and *2*, Table I). Stated another way, *C. vulgaris* still has 30 to 35% of its growth to produce in the third week under the conditions described, but *C. pyrenoidosa* has only 10 to 20% of its yield remaining to be produced. Because of this difference in the growth pattern of the two organisms in the standard medium, and since neither of them makes a substantial gain in packed volume or dry weight during the third week in SM medium (Table I, columns *3*, *4*, *7*, and *8*),

TABLE I.—YIELDS FROM *C. vulgaris* AND *C. pyrenoidosa* IN STANDARD (STD.) AND IN "HIGH-LIPID-INDUCING" (SM) MEDIA (LIGHT = 600 F.-C.)

[a] Std./SM = Yield in standard medium ÷ yield in SM medium. [b] *vulgaris/pyrenoidosa* = Yield from *vulgaris* ÷ yield from *pyrenoidosa*. [c] n.d. = Not determined because cells in SM medium too clumped to permit accurate counting. [d] Calculated from protein expressed as per cent of dry weight. [e] Calculated from lipid expressed as per cent of dry weight.

the disparity between the two media after 3 weeks will be greater for *C. vulgaris* than for *C. pyrenoidosa*. (See Table II, part A, columns *2* and *4*).

Protein Content.—The protein content (expressed as per cent of dry weight of the cells) of both organisms decreases during the third week, regardless of the medium (Table I). However, when the magnitude of the increase in dry weight during that period is taken into consideration, it is found that in terms of absolute yield of protein *C. vulgaris* shows a substantial gain in the standard medium (1.38 mg./ml. of culture at 2 weeks *versus* 2.01 mg./ml. at 3 weeks), whereas cultures of *C. pyrenoidosa* remain virtually static in this respect (1.872 *versus* 1.874), as do both organisms in SM medium (*C. vulgaris* 0.149 *versus* 0.140 at 2 weeks and 3 weeks, respectively: *C. pyrenoidosa* 0.164 *versus* 0.162).

The protein content of *C. vulgaris* in standard medium at 3 weeks is only 3.75% higher than that of *C. pyrenoidosa* when expressed as per cent of dry weight (Table I) but in relative terms (Table II, part B, column *6*) and in terms of absolute yields (2.01 *versus* 1.87 mg./ml. of culture) is about 8% higher. This is just the reverse of the situation at 2 weeks (Table I, column *5* minus column *1;* and Table II, part B, column *5*) and may be taken as further evidence that cultures of *C. vulgaris* attain full productivity more slowly than those of *C. pyrenoidosa* in the standard medium.

Lipid.—*C. pyrenoidosa* has a higher lipid content than *C. vulgaris* at 2 weeks and at 3 weeks, regardless of the medium employed and of whether values are expressed as per cent of dry weight or in absolute terms of mg. of lipid per ml. of culture; both organisms produce more lipid, relative to their dry weight, in SM medium than in the standard (Table III). The percentage lipid content of both organisms grown in SM medium is approximately two to three times their protein content (Table I).

Chlorella cells in SM medium are distinctly abnormal in comparison with those in standard medium. Normal, healthy cultures are a clear, pure green, and the cells are separate, discrete and, when the cultures are shaken, readily form a uniform suspension. Although there is some tendency for settling out, a large proportion of the cells remain in suspension. The cells do not clump, and haemocytometer counts of cell population can be made satisfactorily. Viewed under the microscope, the cells are smooth and rounded; they present a clear, sharp outline.

In contrast to the above, cultures in SM medium

TABLE III.—LIPID CONTENT OF *Chlorella* CULTURES IN STANDARD (STD.) AND IN "HIGH-LIPID-INDUCING" (SM) MEDIA (LIGHT = 600 F.-C.)

Lipid Content	Std. Medium 13–14 days	Std. Medium 20–21 days	SM Medium 13–14 days	SM Medium 20–21 days
	C. vulgaris			
As % of dry weight	21.3	20.45	30.7	37.7
Mg./ml. of culture	0.559	0.845	0.258	0.338
	C. pyrenoidosa			
As % of dry weight	21.8	23.1	37.9	44.8
Mg./ml. of culture	0.723	0.966	0.385	0.465

acquire a distinctly yellowish cast after 5 to 6 days. About 10 days after inoculation cells no longer form a uniform suspension when the cultures are shaken. They are clumped in irregular aggregates, probably containing from a few thousand to several million cells, and the aggregates cannot be separated sufficiently to permit accurate or reproducible counts using the haemocytometer method. The clumps do not long remain in suspension: either they settle out quickly or rise with the gas stream to the surface of the culture where most of them adhere to the sparger inlet tube or to the side of the culture vessel. Many cultures (especially of *C. vulgaris*) soon become virtually water-clear except for a short space near the bottom of the vessel and for the cells adhering to the sparger tube or culture wall at the surface of the medium. Microscopic examination shows the margins of the cells to be wrinkled and convoluted. The cells are several times larger than cells of comparable age in standard medium and each cell appears to contain many smaller cells, often containing still smaller units, as though division had not been completed or, if completed, had not been followed by release of the daughter cells. The pattern is reminiscent of that seen in aged cultures that have been in standard medium for many weeks. It is obvious that the cultures in SM medium are unhealthy, if not actually moribund.

Others also have commented on the altered appearance of cultures in high-lipid-inducing media, noting their yellowish color, changes in the character of the cells, and suggesting that "cells with a high lipid content carry on photosynthesis with a chlorophyll content 1/500 to 1/2000 that of cells with low lipid content" (2). It has been stressed

TABLE IV.—A, DRY WEIGHT, PERCENTAGE PROTEIN, AND LIPID YIELDS FROM *C. vulgaris* AND *C. pyrenoidosa* EXPOSED TO HIGH LIGHT INTENSITY (1250 F.-C.). B, YIELD OF PROTEIN AND LIPID EXPRESSED IN ABSOLUTE TERMS (MG./ML. OF CULTURE)

that to induce development of high-lipid-cells a long growth period and high light intensity are required in addition to low nitrogen concentration in the medium (2). A precise quantitative definition of high light intensity was not given, but calculations based on informed estimates suggested that it was approximately comparable to the 600 f.-c. level adopted for the present work. However, since the maximum lipid value found in the present investigation was 20 to 30% lower than the values reported by the previous workers for a similar medium, it seemed desirable to extend the culture period and to increase the incident light.

Replicate cultures of *C. vulgaris* and of *C. pyrenoidosa* were started in standard and in SM media and were exposed to 1250 f.-c. The column culture vessels were replaced by Fernbach flasks illuminated from below by a water-screened bank of thirty 100-watt Mazda lamps and by Florence flasks placed around a central, water-jacketed 500-watt Mazda lamp. These conditions more nearly simulated those provided by the earlier investigators. The conventional 5% CO_2 in air was provided. The temperature was 22.5 ± 2°.

All cultures in SM medium became progressively more unhealthy, flocculent, and "scummy" looking after the second week. It was mentioned above that (column) cultures with 600 f.-c. illumination acquire a yellowish cast after 5 to 7 days. In the (flask) cultures provided with higher light intensity, the cells become distinctly yellow—so much so that the pellet remaining after cultures are spun down in the centrifuge is clearly yellow with no trace of green. Microscopic examination revealed no contamination. Results from the cultures harvested after 2 weeks and 6 weeks are shown in Table IV.

The dry weight of *C. pyrenoidosa* in SM medium increased only 20% between the end of the second and sixth weeks (Table IV, part A, column *8* ÷ column *7*). In standard medium it increases approximately 145% in the same period (column *6* ÷ column *5*). In both media, the lipid content of the organisms increases considerably during this period, regardless of whether the yields are expressed in terms of per cent of dry weight (Table IV part A, columns *5–8*) or in terms of absolute values (Table IV, part B). However, in terms of the actual amount of lipid formed between the second and sixth weeks, the increase was almost four times greater in the standard medium—1.157 *versus* 0.292 mg./ml. of culture. It was greater on a relative basis also—4.8-fold *versus* 2.1-fold (compare Table IV, part B, column *6* ÷ column *5* with column *8* ÷ column *7*).

C. vulgaris is far less prone than *C. pyrenoidosa* to produce lipid in either medium (Table IV, parts A and B) but, even so, with *C. vulgaris* also the absolute increase in lipid was greater in the standard medium than in SM—0.809 *versus* 0.161 mg./ml. of culture (compare Table IV, part B, column *2* minus column *1* and column *4* minus column *3*). The ratio of the increases in the two media is approximately 5 to 1 in favor of the standard, a figure remarkably close to the 4.8 to 1 ratio found with *C. pyrenoidosa*.

Both organisms, regardless of the medium, give substantially lower protein yields (as per cent of dry weight) after 6 weeks than after 2 weeks (Table IV, part A). However, in terms of the actual amount of protein recoverable from the cells, both organisms make a slight gain during the extended growth period in the standard medium (Table IV, part B). But in SM medium, despite the smaller percentage decreases (Table IV, part A), there is an actual loss of protein (Table IV, part B). This emphasizes the necessity of considering absolute as well as relative yields in experiments of this kind.

The increase in protein, expressed in absolute terms of mg./ml. of culture, between the end of the second and sixth weeks in standard medium (Table IV, part B), accounted for approximately 16% of the total increase in dry weight (Table IV, part A) of *C. vulgaris* and about 8% of the total increase in dry weight of *C. pyrenoidosa*. But increase in lipid calculated in the same way accounted for 31% of the increase in total dry weight of *C. vulgaris* and about 35% of the increase in total dry weight of *C. pyrenoidosa*. Stated another way, the lipid yield from *C. vulgaris* in standard medium doubled with respect to protein yield between the end of the second and sixth weeks and the yield from *C. pyrenoidosa* quadrupled.

DISCUSSION

The experiments described above confirm the observation that *Chlorella* has a higher lipid and lower protein content (both expressed as per cent of dry weight) when cultured in a nitrogen-deficient medium than when provided with an adequate amount and form of nitrogen. However, the experiments show clearly that, important as percentages may be in terms of fundamental biology or biochemistry, values expressed in percentages provide only a partial and sometimes misleading picture. Two examples will be cited. Others have been pointed out

above, and still others can be found by making appropriate calculations from the tabulated data.

Percentage data in Table I indicate less than 4% difference in per cent protein of *C. pyrenoidosa* and of *C. vulgaris* after 2 weeks in column cultures with standard medium and 600 f.-c. illumination. But in terms of actual amount of protein (mg./ml. of culture), the yield from the former was about 35% greater than from the latter. The discrepancies become even greater when performance in different media is considered. After 6 weeks in SM medium in flask cultures with twice as much light, the lipid content of *C. pyrenoidosa* was 43% *versus* 26.2% for the same organism in standard medium—a difference of 16.8% in favor of SM medium. But the actual amount of lipid present in the cultures in standard medium was more than 2.5 times the amount present in cultures reared in the nitrogen-deficient medium, and, as was pointed out above, the actual production of lipid during the last 4 weeks of cultivation was nearly five times as great in the standard as in the nitrogen-deficient medium. It is evident that if one wished to produce fats microbiologically using *Chlorella* as the biosynthetic mediator, much greater yields could be obtained in less time from healthy cells cultured in the standard medium than from the unhealthy cells produced in the SM medium—the higher percentage yields from the latter notwithstanding. It should be pointed out that the composition of *Chlorella* lipids may vary depending on the medium in which the cells develop. Milner (12) noted that the fatty acid content of lipid from high-lipid cells was about three times that of the lipid from low-lipid cells but that the unsaponifiable fraction of the latter was more than three and one-half times greater than that of the former. Even so, in view of the very poor development in SM medium, it is likely that normal cells in standard medium would provide higher absolute yields of any of the lipid fractions than would cells produced in the inferior medium.

Although confirming that *Chlorella* produced in SM medium has a higher percentage of total lipid than those produced in the standard medium, we have been unable to obtain percentage values as high as those reported by Spoehr and Milner (2). An unequivocal explanation for the apparent discrepancy cannot be offered because the experimental conditions used by them cannot be duplicated due to the lack of specific details with respect to light intensity, concentration of trace elements in the medium, and other important factors. It is not possible to obtain a culture of *C. pyrenoidosa* that can be stated authoritatively to be the same Emerson strain as the one with which they worked. It is not clearly stated in the Spoehr and Milner paper that most of their cultures were "aerated" with a carbon dioxide–nitrogen mixture, and we learned this inadvertently only after the present work (employing the conventional carbon dioxide–air mixture, was completed. Whether substitution of nitrogen for air in the "aeration" mixture has a significant effect on the formation of lipid and protein and on the ratio of one to the other is under investigation.

It has been stated that "a culture with any previously obtained R-value [which may be taken as an indicator of per cent lipid] could be grown again at will" (2). In the light of our experiments, we interpret that statement to mean that a given strain of *Chlorella* tends to be genetically stable and remarkably uniform in its response to alterations in the environment. One such response to deficient nitrogen supply is an increased percentage of lipid in the cells—a phenomenon that is a concomitant of senescence and waning vigor and occurrence of which is accelerated in the unfavorable high-lipid-inducing medium.

SUMMARY

Two species of unicellular green algae, *C. vulgaris* and *C. pyrenoidosa*, have been compared with respect to production of protein and of lipid in two different media—one reputed to favor development of high protein content and the other to favor high yields of lipid. The two species were found to differ in their rates of achieving full development and in their tendency to produce protein and lipid.

The standard medium supports healthy, vigorous growth of both species. In this medium *C. pyrenoidosa* attains full development more rapidly than *C. vulgaris*, but the latter has a higher protein content, both in terms of percentage of dry weight and in terms of absolute amount. *C. pyrenoidosa* yields more lipid, both in terms of percentage and of absolute amount. The yield of protein, as per cent of dry weight but not in absolute terms of mg./ml., decreases as cultures of either organism approach full development. Concurrently, the lipid content increases in both species.

When the source of nitrogen is sufficiently limited (situation reputed to favor development of high lipid content) the cultures soon become yellow and sickly. Under these conditions, the lipid content of both organisms (expressed as per cent of dry weight) is approximately two or more times that found in normal healthy cultures of the same age. But the absolute amount of lipid present at full development is markedly less than in normal cultures because of the very much lower dry weight produced under these conditions.

The lipid content of *C. pyrenoidosa* was consistently higher than that of *C. vulgaris* regardless of the culture medium used and whether the content is expressed as percentage of dry weight or in terms of absolute yield.

All the experiments indicated that substantial increase in the proportion of total dry weight accounted for as lipid accompanies aging of the cultures of both species. When the lipid content, expressed as percentage of total dry weight, closely approaches, equals, or exceeds the protein content, the cells are extremely senescent, if not actually moribund.

Thalictrum Alkaloids I

Thalicarpine, A New Hypotensive Alkaloid from *Thalictrum dasycarpum*

By S. MORRIS KUPCHAN, K. K. CHAKRAVARTI, and NAOKATA YOKOYAMA†

A preliminary study of the roots of *Thalictrum dasycarpum* Fisch. and Lall from Wisconsin yielded magnoflorine and a new alkaloid, thalicarpine. Evidence is presented for assignment to thalicarpine of the empirical formula $C_{41}H_{48}O_8N_2$. Thalicarpine was evaluated in a variety of pharmacologic procedures and found to possess a modicum of biological activity.

THALICTRUM TOURN. EX LINN. (*Ranunculaceae*), commonly known as "meadow rue," is a widely distributed genus. Many medicinal uses of *Thalictrum* species in folk remedies have been recorded. *T. foliosum* DC. is found throughout the Himalayas and taken as a tonic, aperient, purgative, diuretic, febrifuge, a remedy for atonic dyspepsia, and used as an application for ophthalmia (1). *T. thunbergii* DC. is used in Japan as a home remedy against stomach ache and diarrhea (2). *T. collinum* Walbr., *T. angustifolium* L., and *T. silvaticum* Koch. have been used in Ukrainian folk medicine as diuretics (3). *T. fendleri* Engelm. was prepared by the Indians of Nevada as a tea to cure gonorrhea; a decoction of the root was used against colds (4). *T. minus* L. is used in south Africa to treat fevers (5). Intravenous injection of the hydrochlorides of the extract of the total alkaloids from *T. minus* L. has recently been shown to exert an effect on the blood pressure and pulse of frogs, cats, and dogs (6).

In the course of a continuing screening program for alkaloid-bearing plants, the roots of *Thalictrum dasycarpum* Fisch. and Lall[1] from Wisconsin were found to afford substantial yields of alkaloids. Pharmacological evaluation of the nonquaternary alkaloid fraction demonstrated potent hypotensive activity in the anesthetized cat after intravenous administration.[2] The present report describes a preliminary study of the alkaloids of *T. dasycarpum* and the isolation and characterization of thalicarpine, a new hypotensive tertiary base. While our work was in progress, the isolation from *T. dasycarpum* of the quaternary alkaloids magnoflorine and berberine was reported (7). However, no work on the nonquaternary alkaloids has appeared to date.

Coarsely ground plant was extracted successively with methanol and 1.5% triethylamine in methanol. The extracts were processed for alkaloid content by the procedure summarized in Fig. 1, whereby an 0.35% yield of crude alkaloids was obtained. Fraction E, the quaternary alkaloid fraction, yielded magnoflorine as the only isolatable component. Study of the nonquaternary phenolic alkaloid Fractions B and D is in progress and will be reported in due course.

The nonquaternary nonphenolic alkaloid Fractions A and C were combined on the basis of their paper chromatographic patterns. Chromatographic fractionation led to isolation of the major alkaloid of the plant (0.07% of the dried roots). The compound showed m.p. 160–161°, $[\alpha]_D^{25}$ + 133° (methanol); + 89° (chloroform), and ultraviolet, infrared, and N.M.R. spectral characteristics which indicated that the material is a new compound. The name *thalicarpine*, reflecting the botanical origin, is proposed for the alkaloid.

The molecular formula $C_{41}H_{48}O_8N_2$ was assigned for thalicarpine on the basis of elemental analysis and molecular weight determination by nonaqueous titration. Analysis showed the presence of seven O-methyl groups and two N-methyl groups. The N.M.R. spectrum in deuterated chloroform solution supports the formula, showing six N-methyl protons, 21 O-methyl protons, 14 aliphatic protons, and seven aromatic protons. The infrared spectrum indicates the presence of aromatic rings and aromatic O-methyl groups, but absence of hydroxyl, carbonyl, and isolated double-bonds.

A sequence of derivatives was prepared to seek confirmation of the empirical formula as well as to provide conversion products useful for structure elucidation. Treatment of thalicarpine with methyl iodide afforded a product which resisted all attempts at crystallization. However, treatment of the amorphous methiodide with alkali yielded a Hofmann methine which was converted to a crystalline methiodide. Analysis afforded results which support a $C_{45}H_{58}O_8N_2I_2$ formula for the Hofmann

methine methiodide. A second Hofmann degradation yielded a des-N-methine, which afforded analytical results indicative of a $C_{39}H_{38}O_8$ empirical formula. The formulas of both methine derivatives support the $C_{41}H_{48}O_8N_2$ formula for thalicarpine. Further structural studies are in progress and will be reported at a later date.

EXPERIMENTAL

Melting points have been corrected for stem exposure. Values of $[\alpha]_D$ have been approximated to the nearest degree. Infrared spectra were determined on a Beckmann IR-5A infrared spectrophotometer. Ultraviolet spectra were determined in methanol on a Cary recording spectrophotometer. The N.M.R. spectra were taken on a Varian A-60 N.M.R. spectrometer. Paper chromatography was conducted by the descending technique on Whatman No. 4 paper pretreated with buffer at pH 3.5.

Extraction of Alkaloids from Thalictrum dasycarpum. Separation into Main Fractions

Coarsely ground *T. dasycarpum* (air dried roots, 17.6 Kg., from middle and southern Wisconsin) was continuously extracted with methanol in a Soxhlet-type extractor. The extraction was continued with a fresh charge of solvent at the end of 3 days. When the extraction was stopped after a total of 10 days, the extract returning to the pot yielded a residue which did not give a positive Mayer's test upon evaporation. The methanol extract was concentrated under reduced pressure to a dark brown semisolid concentrate. The 1 L. concentrate was diluted with 2 L. of water and extracted with 3 L. of petroleum ether (Skellysolve B, b.p. 60–68°) to remove fat. The aqueous methanolic solution was further evaporated to remove most of the methanol, then triturated with 1.5% hydrochloric acid. After rejecting acid insoluble material, the acidic solution was washed with 6 L. of ether, made alkaline with sodium hydroxide, and extracted with 6 L. of ether. The ether extract was washed with water, dried over anhydrous sodium sulfate, and evaporated to dryness under reduced pressure to yield a glass-like alkaloidal residue (Fraction A, 35 Gm.; see Fig. 1). The alkaline solution re-

maining from ether extraction was made more weakly basic to pH 8.5 by adding ammonium chloride and extracted with 6 L. of ether. The ether extract was washed with water, dried over anhydrous sodium sulfate, and evaporated to dryness under reduced pressure to yield a semisolid alkaloidal residue (Fraction B, 3.8 Gm.). The aqueous solution remaining from ether extraction was reserved for study of the quaternary alkaloids.

Next, the marc remaining from the methanol extraction was extracted continuously with 1.5% trimethylamine in methanol for 12 days. When extraction was stopped, evaporation of the extract returning to the pot yielded a residue which did not give a positive test with Mayer's reagent. The trimethylamine-methanol extract was evaporated to dryness, and the residue was triturated with 1.5% hydrochloric acid (1 L.). After rejecting acid-insoluble material, the acidic solution was washed with ether, made alkaline with sodium hydroxide, and extracted with 2 L. of ether. The ether extract was washed with water, dried over anhydrous sodium sulfate, and evaporated to dryness under reduced pressure to yield 11 Gm. of alkaloidal residue (Fraction C). The basicity of the aqueous solution remaining from ether extraction was adjusted to pH 8.5 by adding ammonium chloride. The alkaline solution was then extracted with 2 L. of ether. The ether extract was washed with water, dried over anhydrous sodium sulfate, and evaporated to dryness to yield a semisolid alkaloidal residue (Fraction D, 0.4 Gm.). The aqueous alkaline solution was combined with the corresponding aqueous solution from the methanol extract. The combined solution was re-acidified with concentrated hydrochloric acid and treated with a saturated Reinecke salt solution. The dried precipitate was dissolved in acetone, the solution was clarified by filtration, and treated with a saturated aqueous silver sulfate solution to complete precipitation. Silver Reineckate was removed by filtration; the filtrate was treated with a barium chloride solution to complete precipitation. After removal of barium sulfate by centrifugation, the supernatant solution was evaporated to dryness under reduced pressure to yield 12 Gm. of quaternary chloride mixture (Fraction E).

Isolation of Alkaloids

Fractions A and C, constituting the nonquaternary nonphenolic alkaloids, were combined on the basis of the similarity of their paper chromatographic patterns. Similarly, Fractions B and D, constituting the nonquaternary phenolic alkaloids, were combined.

Fraction E.—The mixture of quaternary chlorides was converted into a mixture of quaternary iodide salts with potassium iodide in aqueous solution. The mixture of iodides was fractionated by successive extraction with chloroform, acetone, and methanol. The methanol extract deposited a crude crystalline solid upon concentration. Repeated recrystallization from methanol gave crystalline magnoflorine iodide as pale-yellow prisms, m.p. 251–252°; $[\alpha]_D^{20}$ + 198° (c 0.23, methanol). The melting point was not depressed on admixture with an authentic sample of magnoflorine iodide.[3] The paper chromatographic behavior and infrared spectrum (Nujol mull) were identical with those of the authentic magnoflorine iodide sample.[4]

The Nonquaternary Nonphenolic Fraction.—The crude alkaloid mixture was fractionated by column chromatography on 1 Kg. Florisil. The column was developed by successive elution with benzene, 10, 30, and 60% chloroform-benzene, chloroform, 20% acetone-chloroform, acetone, and methanol. The 30 and 60% chloroform-benzene eluates, on treatment with ethyl acetate, gave 12-Gm. colorless needles, m.p. 160–161°, $[\alpha]_D^{25}$ + 133° (c 0.83, methanol), + 89° (c 0.88, chloroform), $\lambda_{max.}$ 282 mμ, (ε 17,000), 302 mμ (ε 13,000). The N.M.R. spectrum ($CDCl_3$) showed τ = 7.55, 7.52 (6H, N-methyl), 6.40, 6.29, 6.21, 6.19, 6.17, 6.09, 6.05 (21H, O-methyl), 3.79, 3.47, 3.40, 3.37, 3.32, 1.77 (7H aromatic).

Anal.—Calcd. for $C_{41}H_{48}O_8N_2$: C, 70.67; H, 6.94; N, 4.02; 7 (OCH_3), 31.17; 2 (NCH_3), 8.33. Found: C, 70.72; H, 6.72; N, 4.07; (OCH_3), 27.40; (NCH_3), 7.48.

Hofmann Degradation of Thalicarpine

About 3 mg. of anhydrous potassium carbonate was added to a 3-Gm. solution of thalicarpine (4) in 20 ml. methanol and 10 ml. methyl iodide. The solution was heated under reflux on a steam bath for 6 hours. The reaction mixture was then brought to dryness under reduced pressure to yield a semisolid residue. All attempts to crystallize the residue failed. The amorphous thalicarpine dimethiodide (4.29 Gm.) was dissolved in 25 ml. of methanol, and 10 Gm. of potassium hydroxide was added to the solution in small portions to obtain a clear solution. The reaction mixture was heated on a steam bath for 2 hours under magnetic stirring. The mixture was cooled in an ice bath and then evaporated to dryness under reduced pressure. The dried residue was triturated with 50 ml. of water and 50 ml. of ether. The aqueous layer was washed with another portion of 50 ml. ether. The ether layer and wash were combined, washed with water, dried over anhydrous sodium sulfate, and evaporated to dryness under reduced pressure to yield 3.36 Gm. of semisolid residue. The Hofmann methine thus obtained was also uncrystallizable. The amorphous Hofmann methine was treated with 10 ml. methyl iodide in 20 ml. methanol at the boiling point of the solution for 6 hours. The reaction mixture was then brought to dryness to leave a 4.05-Gm. brown solid. The residue was treated with methanol to give colorless micro prisms, m.p. 275–276° dec., $[\alpha]_D^{25}$ + 0° (c 1.24, methanol), $\lambda_{max.}$ 266 mμ (ε 62,000), 309 mμ (ε 27,000), 323 mμ (ε 28,000), 346 mμ (ε 20,000).

Anal.—Calcd. for $C_{45}H_{58}O_8N_2I_2 \cdot H_2O$: C, 52.64; H, 5.89; N, 2.73; I, 24.72; 7 (OCH_3), 21.16; 4 (NCH_3), 11.31. Found: C, 52.25; H, 5.59; N, 2.91; I, 25.04; (OCH_3), 21.33; (NCH_3), 11.47.

Thalicarpine dimethylmethine dimethiodide (1.2 Gm.) was converted into methochloride by the action of freshly prepared silver chloride to obtain 1.06 Gm. of the glass-like dimethochloride. A 10-Gm. quantity of potassium hydroxide was added in small portions to a solution of the methochloride in 20 ml. of water and 10 ml. of methanol. The reaction mixture was then heated on a steam bath for 3 hours under

[3] The authors thank Professor E. Fujita, Institute for Chemical Research, Kyoto University, Kyoto, Japan, for an authentic sample of magnoflorine iodide.

[4] Experiment by Dr. B. Dasgupta.

magnetic stirring. The vigorous evolution of trimethylamine gas from the reaction mixture was observed during the early part of the reaction. The reaction mixture was then brought to dryness under reduced pressure. The dried residue was triturated with 50 ml. of water and 200 ml. of ether. The aqueous layer was washed with 100 ml. of ether. The ethereal layer was combined with the washing, washed with water, dried over anhydrous sodium sulfate, and evaporated to dryness to leave a 0.75-Gm. yellow oil. The des-*N*-methine crystallized from ether as colorless fine prisms (0.64 Gm.), m.p. 170–172°, $[\alpha]_D^{25} \pm 0°$ (c 2.05, chloroform); $\lambda_{max.}$ 267 mμ (ε 55,000), 317 mμ (ε 31,000); N.M.R. spectrum ($CDCl_3$), τ = 5.76, 5.83, 5.88, 5.91, 6.05, 6.07, 6.19 (21H, O-methyl).

Anal.—Calcd. for $C_{39}H_{38}O_8$: C, 73.80; H, 6.04. Found: C, 73.54; H, 6.20.

PHARMACOLOGICAL RESULTS[2]

Thalicarpine was evaluated in a variety of pharmacologic procedures and found to possess a modicum of biological activity. In acute dose range or toxicity studies, oral doses of 300 mg./Kg. failed to produce discernible gross behavioral changes in the mouse. Intraperitoneal injection of 25 mg./Kg. of thalicarpine to a cat produced sensitivity of the forepaws, rubbing of the neck, and emesis.

The principal action of thalicarpine on blood pressure was depressor in nature. In the cat anesthetized with chloralose, mean arterial blood pressure was lowered transiently following acute intravenous doses ranging from 0.5 to 5 mg./Kg. Lethality, due to respiratory arrest, occurred at a dose of 10 mg./Kg. Bradycardia, respiratory depression, and andrenergic blocking action accounted for the weak hypotensive activity. Anticoagulant, hypoglycemic, and anticonvulsant properties were not observed after oral doses of 100 mg./Kg. in the rat, guinea pig, or mouse, respectively. An oral dose of 50 mg./Kg. caused a slight antidiuretic response in rats hydrated with saline. In the Randall and Selitto test for anti-inflammatory activity oral doses of 50 mg./Kg. of thalicarpine produced a very low order of analgetic activity (25%) and no significant antipyretic action.

In summary, weak hypotensive activity of a transient nature was the principal action of thalicarpine when injected intravenously into the anesthetized cat. Respiratory toxicity and weak adrenolytic activity accompanied this action. Thalicarpine failed to exhibit significant biological activity as an anti-inflammatory, anticoagulant, hypoglycemic, or diuretic agent.

Gas Chromatographic Analysis of Oil of Nutmeg

By ELWINA A. BEJNAROWICZ and ERNST R. KIRCH

Four samples of commercially available oil of nutmeg were analyzed by gas chromatography. Of a number of stationary liquid phases used, a 20 per cent Reoplex 400 on Dichromite gave the best separation. The composition of the oils was determined on the basis of retention times and enrichment.

ESSENTIAL OILS contain volatile compounds representing many classes of organic substances. One such volatile oil is the well known oil of nutmeg (*Myristica*), an important spice used for the flavoring of numerous food products. It is also used as a component of certain types of perfumes and as a flavoring agent for dentifrices (1). The literature lists two oils of myristica—oil of nutmeg and oil of mace. Both are derived from the fruit of *Myristica fragrans* Houtt. (*fam. Myristicaceae*) (2).

The dried seeds of nutmeg contain from 5 to 15% of the volatile oil, as well as from 25 to 40% of a fixed oil, and from 5 to 15% of ash. The rest consists of moisture, fiber, and starch (3, 4).

There are two principal types of nutmeg which are recognized today, and these depend primarily on geographical origin. "Banda nutmegs" or East Indian variety are the finest; the other variety comes from the West Indies (5).

The West Indian type of oil has a lower specific gravity, lower refractive index, and a lower residue on evaporation, but has a higher

optical rotation than the oil obtained from the East Indies.

Nutmeg oil consists principally of terpenes, and about 60% of the oil distils below 180° (6). In 1907, Power and Salway (7) examined a "genuine" oil of Ceylon nutmeg having a specific gravity of 0.8690 at 15° and an optical rotation of 38°4′. They found this oil to contain primarily over 80% of terpenes and 6% terpene alcohols.

In reviewing the literature concerning differences between East Indian and West Indian oil, one finds statements primarily referring to the higher content of terpenes and a lower content of phenols in the West Indian oil. Therefore, it was of interest to undertake an analysis of the nutmeg oil obtained from these two sources, using gas chromatography.

EXPERIMENTAL

Apparatus.—The apparatus employed was Beckman GC-2 gas chromatograph with a four-filament thermal conductivity cell connected to Sargent SR recorder equipped with a K-4 disk integrator. Helium was used as the carrier gas, and the flow rate was maintained at 38 ml. per minute. The filament current used was 380 ma., while the chart speed of the recorder was 1.0 in. per minute.

Column Preparation.—Reoplex 400 (polyethylene glycol adipate) was used as the stationary liquid phase and was supported on 80/100-mesh Diachromite. Approximately 20.0 Gm. of the solid support was required to pack a 6-ft. column. The 5-Gm. liquid phase was introduced by deposition gradually and with constant stirring from a 45 ml. solution in dichloromethane. The resulting mixture was first dried in air, then at 90° in the oven for about 3 hours. Columns used were of copper tubing, 1/4 in. diam. and 6 ft. in length.

Operating Conditions.—Temperatures ranging from 100 to 190° were employed. Samples of 0.005 ml. were used, except in cases where the fraction was collected. Then the sample was increased to 0.05 ml.

Oil Samples and Standard Compounds.—The four commercially available samples of nutmeg oil that were analyzed are listed below along with their respective specific gravities and refractive indices.[1] Sample A (East Indian nutmeg oil U.S.P. extra) n_D^{20}, 1.4804; sp. gr.^{24}, 0.884. Sample B (East Indian nutmeg oil U.S.P.) n_D^{20}, 1.4809; sp. gr.^{24}, 0.897. Sample C (East Indian nutmeg oil U.S.P.) n_D^{20}, 1.4793; sp. gr.^{24}, 0.880. Sample D (West Indian nutmeg oil U.S.P.) n_D^{20}, 1.4756; sp. gr.^{24}, 0.870.

For purposes of identification the retention times and relative retention times of the unknown were compared with a known pure standard sample. In this way a tentative identification of most of the compounds could be made. We have confirmed these particular results by enrichment method, in which known compounds were added individually to the sample chromatographed and compared in each instance to the chromatogram obtained by using the oil alone. Infrared spectra were obtained for unknown peaks. Tables I, II, and III list the retention times and relative retention times of standard compounds at 100 and 160°, respectively. Relative retention times are based on *p*-cymene.

[1] The authors express their thanks to Fritzsche Brothers, Inc., New York, N. Y., for supplying Sample C of oil of nutmeg.

RESULTS AND DISCUSSION

Three commercial samples of an East Indian nutmeg oil and one sample of a West Indian nutmeg oil were analyzed by gas liquid partition chromatography. Of a number of stationary liquid phases that were used, only Reoplex 400 supported on 80/100-mesh Dichromite gave satisfactory results.

That the various components of the nutmeg oils could be separated more efficiently at different temperatures is shown in Figs. 1–3 when Sample A of oil of nutmeg was chromatographed at 100, 130, and 160°, respectively. For example, eight peaks were observed at 100° (Fig. 1), while at 130° the number of peaks increased to ten (Fig. 2). At 160°, two additional peaks were obtained using this same oil (Fig. 3). Similar results were observed with the other samples of the East Indian variety oil.

Attention should be directed to Fig. 2 which shows ten peaks obtained with Sample A at 130°. Comparing this with the chromatograms representing the peaks obtained at 100° (Fig. 1) and 160° (Fig. 3), respectively—and using this same oil—it should be pointed out that in the chromatogram obtained at 100°, peak numbers 8, 9, 10, 11, and 12 (Fig. 3), representing higher retention times, are absent. It was further observed that peak number 3 at 130° (Fig. 2) or 160° (Fig. 3) could be resolved into two components at 100°. One of these peaks (No. 3) we have identified as limonene.

We have used the results obtained at 100 and 160°, respectively, to calculate the percentages of the components of the East Indian oils (Samples A, B, and C). With the West Indian oil (Sample D) two unidentified components which appeared as two distinct small peaks at 130° (Fig. 5) but only as one peak at 160° (Fig. 6) were observed. At temperature of 100° (Fig. 4) these same constituents also appeared as two peaks, but one of them (with the lower retention time) could not be separated distinctly from the preceding one. The results obtained at 130° were also used to calculate the percentages of these two components of the oil. We have based all the percentages as calculated on the total eluted. To keep the peaks within the limits, it is customary to change attenuation at times from component to component. This was done in this investigation also. It is well recognized, however, that a particular area will differ with change in attenuation. Since the percentages are calculated from the integrated signals, and since these signals are proportional to the attenuation, each sample of the oil was re-run at one and the same attenuation.

The samples of the East Indian oil of nutmeg (Samples A, B, and C) that were examined differed in composition not only from the West Indian oil, but they also showed variation in composition from one to the other (Table IV).

All of the oils of the East as well as the West Indian variety were found to contain α-pinene, β-pinene, and limonene. Of the four samples of oil that we have investigated, the West Indian variety contained the highest total percentage (40.1%) of these terpenes, while the East Indian Samples A, B, and C contained 30.9, 30.2, and 33.9-

β-Pinene	12.3	12.6	19.1	14.8
Terpinolene	...	1.4	0.8	...
Limonene	4.7	4.7	2.3	11.9
p-Cymene	1.6	2.6	2.7	4.3
Linalool	10.6	8.1	...	5.9
Camphor	...	...	...	3.4
Terpinen-4-ol	14.5	14.2	19.5	24.7
α-Terpineol	7.7	4.7	4.0	5.0
Geraniol	0.3	11.9	...	3.6
Safrole	6.0	4.2	5.5	...
Eugenol	1.3	3.8	0.3	...
Unknown A	22.2	13.9	25.9	1.7
Unid. (3 components)	4.9	5.4	...	...
Unid. (4 components)	...	...	7.4	11.4

%, respectively. Table IV lists the percentages of individual components in each of the oils. The presence of terpinolene was observed only in Samples B and C and in 1.4 and 0.8%, respectively. One of the peaks which appeared on each of the chromatograms was identified as p-cymene and ranged from 1.6 to 4.3% (Table IV).

It should be noted that linalool and geraniol are absent in Sample C of the East Indian nutmeg oil. Samples A, B, and D contain linalool in 10.6, 8.1, and 5.9%, respectively. Geraniol was found to be present in two samples of the East Indian oil, Samples A and B. It is interesting that there is a large difference in percentage of geraniol in the two oils—namely, 0.3% in Sample A and 11.9% in Sample B. In the West Indian oil, 3.6% geraniol was found.

A component with relative retention times ranging from 5.48 to 5.58 at 100°, 4.15 to 4.31 at 130°, and 3.22 to 3.26 at 160° (Tables V, VI, VII, and VIII) which was present in all the oils, was collected and an infrared spectrum was obtained. By comparison of I.R. spectra, this compound is tentatively identified as terpinen-4 ol. West Indian nutmeg oil contained the highest amount of terpinen-4 ol (24.7%), while East Indian oils as analyzed contained the following percentages of this alcohol: 14.5, 14.2, and 19.5% for Samples A, B, and C, respectively. As can be seen from Figs. 2 and 5, another component is present with a higher retention time (peak 8). This is present in approximate range of 4–8%, depending upon the oil; it has been tentatively identified as α-terpineol using the enrichment procedure.

While safrole and eugenol were absent in the West Indian oil, both of these were present in all three samples of the East Indian variety. The per cent of safrole ranges from 4.2 to 6.0 and that of eugenol from 0.3 to as high as 3.8% (Table IV).

Another component (Unknown A) found in all samples of oil tested had a relative retention time ranging from 37.3 to 38.6 (Tables V, VI, VII, and VIII) at 160°. It was collected and its infrared

spectrum was obtained. The spectrum showed absorption bands usually associated with aromatic ring, 1630 cm.$^{-1}$, 1516 cm.$^{-1}$, 1459 cm.$^{-1}$, and a carbonyl group 1718 cm.$^{-1}$ The quantity of this component ranged from a low of 1.7% in the West Indian oil to a high of 25.9% in Samples C of East Indian variety (Table IV).

Results obtained by the authors differ from those reported for the oil of nutmeg not only qualitatively but also quantitatively, with the possible exception of trace amounts of the esters of fatty acids, which we did not observe under the conditions used. Myristic acid and myristicin which have been reported present in a concentration of 2–3% were not eluted even after 105 minutes at a higher temperature (190°) than that used for the final analysis of the other components of the oils.

In most instances Power and Salway (8) listed the combined percentages of a few components. For example, according to these investigators α-pinene and *d*-camphene make up about 80% of the oil. Others have reported the presence of about 70% of terpenes (α-pinene, *d*-camphene, β-pinene, and dipentene). Analysis of the four samples of oil examined by us confirmed the presence of α-pinene. Samples A, B, C, and D were observed to contain 13.9, 12.9, 12.5, and 13.4% of α-pinene, respectively, while *d*-camphene was not present.

Only a small amount of β-pinene was detected in an oil analyzed in another study (9). The percentages of β-pinene observed in the present study differ considerably. As can be seen from Table IV, the percentage of β-pinene varies from a low of 12.3% to a high of 19.1%.

About 8% of a substance called dipentene was reported present in the oil analyzed by Power and Salway. It is important to note that this substance identified as dipentene by them (8) is not a pure compound but rather a mixture composed of $C_{10}H_{16}$ terpenes. Westaway and Williams (10) have analyzed two synthetic and two natural samples labeled as dipentene. Both types of samples differed both qualitatively and quantitatively. One natural sample contained as high as 80% of limonene; in the other three samples, limonene was present in various lower concentrations. Terpinolene was observed in varying percentages in all four samples. Other terpenes which were reported present by Westaway and Williams in some samples and absent in others include α-pinene, *d*-camphene, β-pinene, tricyclene, α- and γ-terpinene.

A peak labeled number three (Fig. 1) in this study present in each of the four oils and identified as limonene is the main component of dipentene referred to by Power and Salway. Furthermore, Samples B and C contained small amounts of terpinolene which were not reported present in the oil of nutmeg.

Power and Salway (9) identified *d*-linalool, *d*-borneol, "isoterpineol," and geraniol in nutmeg oil. They reported these four alcohols present in about a total of 6%. In this investigation borneol was absent in all samples of nutmeg oil, while another

11. Unknown A	...	...	...	...	38.2	...

component, camphor, was detected in the West Indian oil. Linalool was present in Samples A (10.6%), B (8.1%), and D (5.9%), while it was not observed in Sample C of East Indian variety. The same observation was made as far as geraniol is concerned. We found 3.6% present in the West Indian sample, while two samples of the East Indian variety contain 0.3 and 11.9%, respectively.

The amount of α-terpineol varies depending on the sample of the oil (Table IV). Westway and Williams (10) did not report the percentage of α-terpineol in the oil they investigated.

In 1907 (9), safrole was reported present in about 0.6% in the oil of Ceylon nutmeg. Our analysis confirmed its presence in the East Indian oils only. The amount ranges from 4.2 to 6.0%. This same report mentions the presence of about a total of 0.2% of eugenol and isoeugenol in the oil from Ceylon. A peak corresponding to the retention time of isoeugenol was not observed in the chromatograms. We have observed eugenol in varying amounts in all three samples of the East Indian variety. Samples A, B, and C contain 1.3, 3.8, and 0.3%, respectively, of eugenol.

One of the constituents of the oil, which was not yet reported in literature, was isolated from the oil, using gas chromatography; an infrared spectrum was run. This constituent, which ranges from as low as 1.7% in the West Indian sample to as high as 25.9% in Sample C of the East Indian variety, was tentatively labeled as "Unknown A."

SUMMARY

Four commercially available samples of nutmeg oil were analyzed by gas-liquid chromatography, using 20% Reoplex 400 column. Relative retention times and enrichment procedure were used to identify the constituents of the oils. In some instances infrared spectra were employed.

The following components were present in the three samples of East Indian variety and in the West Indian sample: α-pinene, β-pinene, limonene, *p*-cymene, terpinen-4 ol, α-terpineol, and Unknown A. Terpinolene was found in small amounts and only in two samples of East Indian oil, while linalool and geraniol are absent in one sample of East Indian nutmeg oil. Safrole and eugenol were present in all three samples of the East Indian variety but were not observed in the West Indian sample. Camphor was found in the West Indian oil only.

Differences are also observed between the percentages of the components present not only compared to those listed in the literature but also between the oils analyzed.

Pharmaceutical Applications of the Concept of Equilibrium Moisture Contents

By MORTON W. SCOTT, HERBERT A. LIEBERMAN, and FRANK S. CHOW

Equilibrium moisture content (EMC) data have been obtained for two representative tablet granulations. These data are useful in analysis of drying operations and particularly in predicting final moisture contents obtainable in "dried" products. The effects of drying variables, such as relative humidity and inlet air temperature, on product moisture levels are established. Similarly, the influence of storage conditions on moisture gain is predictable. Data obtained from drying studies with a lactose placebo granulation are used to illustrate the relationship between equilibrium moisture content values and minimum required drying times. The importance and economic advantages obtainable by review of this type data before establishment of moisture specifications for dried materials is illustrated. In addition, equilibrium moisture content values for several tablet fillers, disintegrants, and other pharmaceuticals are presented. Based on these preliminary studies, the EMC concept may have useful applications in the design of moisture stable products.

INTRODUCTION

ADJUSTMENT AND CONTROL of moisture levels is of general importance in the development and manufacture of superior pharmaceutical products. The difficulties encountered in establishing proper levels of moisture can be broadly divided into two categories. The first category includes problems connected with processing and handling operations, such as drying and bulk powder filling, etc. Those problems which relate more directly to formulation design, such as the stabilization of moisture sensitive materials, are included in the second category. Unfortunately, proper attention has not been devoted to either of these problem areas in the pharmaceutical literature.

Scattered reports are available which deal with the effects of moisture on specific pharmaceuticals. Leeson and Mattocks (1) have examined the stability of aspirin stored under elevated humidity conditions. These workers present kinetic interpretations of the data and show that decomposition is dependent on the aqueous vapor pressure and storage temperature. The stability of ascorbic acid at high relative humidities has been studied by de la Vega (2), while Blaug, *et al.* (3), discussed methods of preparing ascorbic acid tablets with reduced moisture sensitivity. The adverse influence of moisture on the flowability of pharmaceutical powders also has been demonstrated (4). The report of Craik and Miller on this subject is noteworthy (5). Attention has been paid also to the moisture vapor transmission characteristics of packaging components used for pharmaceuticals (6). A generalized approach to the problems of moisture control—capable of leading to the improvement of formulation techniques, processing operations, and storage procedures—has not been developed yet.

The present study was undertaken to explore the potential usefulness of the equilibrium moisture content concept as applied to materials of pharmaceutical interest. This concept serves as a basic tool in the design of drying, air conditioning, and humidification operations (7) and would seem to represent a correct starting point for the study of moisture relationships in pharmaceutical products.

EQUILIBRIUM MOISTURE CONTENT

If a solid is exposed to a continual supply of air at constant temperature and relative humidity, the solid will either lose moisture by evaporation or gain moisture until an equilibrium condition is obtained. The moisture present in the solid at this point is defined as the equilibrium moisture content (EMC) under the given exposure conditions. Rigorous thermodynamic treatments of the equilibrium state have appeared in the literature (8, 9). For all cases of practical importance, equilibrium will be established when the vapor pressure exerted by the moisture in the solid equals the partial pressure of the water vapor in the air. A new equilibrium moisture content results with a change in the partial pressure of water in the air. It is customary to

Received March 26, 1962, from the Department of Pharmaceutical Technology, Warner-Lambert Research Institute, Warner-Lambert Pharmaceutical Co., Morris Plains, N.J.
Accepted for publication April 18, 1963.
Presented to Scientific Section, A.PH.A., Las Vegas meeting, March 1962.

express these partial pressures in terms of relative humidities (R.H.) and to express the moisture contents of the solid on a dry basis. The collection of such EMC–relative humidity data can be used to prepare an entire moisture equilibrium curve for the solid. The EMC relationship for a hypothetical hygroscopic solid is shown in Fig. 1.

Point X_S in Fig. 1 represents the EMC of the solid after exposure to air at 100% R.H. Since the partial pressure of moisture in air at this humidity is equal to the vapor pressure of liquid water, all moisture contents above X_S consist in part of liquid water capable of exerting its full vapor pressure. The moisture level between X_S and some higher level X_H is the "unbound moisture" of the solid.

At all moisture contents less than X_S, the moisture present is not capable of exerting its full vapor pressure. This water is "bound" within or on the solid and may be held by chemical or physical adsorption, in capillaries, as the solvent in soluble portions of the solid, or by other mechanisms (7).

Point X_E represents the EMC of the solid after exposure to air at 50% R.H. X_E is the limiting level of "dryness" which can be achieved by treating the solid (initially at some higher moisture content, such as X_H) with air at 50% R.H. The difference between X_H and X_E is defined as the "free water" content of the solid (7).

Equilibrium moisture content curves have been reported for numerous materials including dehydrated foods (10), cereal grains (11, 12), soils (13), and cotton, wood, and leather (14). These EMC curves vary greatly with the type of solid examined. For example, nonporous insoluble solids such as zinc oxide generally show relatively low EMC values over a wide range of relative humidities (14). Fibrous, cellular, and porous solids exhibit broader variations in their EMC levels with changes in relative humidity. Hysteresis effects have been reported (15), and equations describing the adsorption isotherm have been applied (8, 10). Methods for conducting the EMC determinations by static and dynamic (forced convection) techniques have been adequately reviewed in the literature (8).

EXPERIMENTAL

Materials.—Equilibrium moisture content curves were established for the following categories of materials. U.S.P. or N.F. grades were used where specific sources of supply are not listed.

Tablet Fillers: Mannitol, lactose, terra alba (extra pure grade, C. Chrystal and Co.), kaolin, sucrose, and dibasic calcium phosphate.

Tablet Disintegrators: Starch, guar gum (grade A-20-D, Steinhall and Co.), Solka Floc (Brown Co.), and bentonite (C. Chrystal and Co.).

Binding Agents: Ethylcellulose, 10 cps.; methylcellulose, 15 and 400 cps.

Tablet Lubricants: Talc, stearic acid, and magnesium stearate.

Tablet Granulations and Tablets:

Placebo granulation (12–20 mesh) consisting of 85% lactose, 5% methylcellulose (400 cps.) and 10% starch (wet granulated with water).

Antacid granulation (12–20 mesh) based on magnesium trisilicate and wet granulated with syrup.

Ferrous sulfate tablets consisting of 8% ferrous sulfate, 5% anhydrous calcium chloride, 86% of gelatin–terra alba filler, and 1% magnesium stearate compressed to a hardness of 6, 8, and 10 Strong-Cobb units.

Fifty-milligram ascorbic acid tablets containing 86% of gelatin–terra alba filler and 1% magnesium stearate.

Procedure.—Static EMC determinations were made by placing samples of each material into desiccators containing one of the following saturated solutions: ammonium dihydrogen phosphate (93% R.H.), ammonium sulfate (81.1% R.H.), ammonium chloride plus potassium nitrate (71.2% R.H.), magnesium nitrate hexahydrate (52% R.H.), potassium carbonate dihydrate (43% R.H.), and calcium chloride hexahydrate (31.0% R.H.). These specific agents were chosen because the relative humidity established above the saturated solution is relatively constant over the (narrow) range of temperature (25 ± 1°) encountered in this study.

Approximately 15 Gm., or 50–100 tablets, of each test material was used as the sample. Weight gains were recorded after various intervals of storage. When constant weight was achieved, L.O.D. was determined using the Cenco moisture balance (90 volts for 7 minutes). These L.O.D. values were converted to moisture contents (dry basis) and plotted *versus* relative humidity to yield the equilibrium moisture content curves.

Assays for ferrous sulfate and ascorbic acid were done according to the U.S.P. methods.

RESULTS AND DISCUSSION

Pharmaceutical Engineering Considerations.—Figure 2 illustrates the EMC curves for the antacid and placebo tablet granulations. It is recognized that the antacid granulation is far more sensitive to changes in relative humidity than the placebo formulation. The variations in EMC curves obtainable with different materials is clearly illustrated by these data.

EMC relationships (as illustrated in Fig. 2) have immediate usefulness in the selection of proper drying conditions for tablet granulations. For example, the EMC for the placebo granulation at 40% R.H. is approximately 1%. Once this equilibrium moisture content has been reached, no further reduction in moisture content can be achieved by further drying with air at 40% relative humidity. Thus, the moisture contents of tablet granulations during the course of actual drying cycles can be compared to the EMC value to determine when the granulation has reached "dryness." This information can then be used to establish the minimum drying time required under the particular process conditions employed.[1]

The effects of changes in the relative humidity of the drying air on the moisture content of the granulation also are obtainable from Fig. 2. With the antacid granulation, a significant decrease in moisture content is observed with decreasing R.H. With the placebo, however, a decrease from 70 to 30% R.H. has little or no effect on final moisture

[1] For dryer calculations, it is preferable to determine EMC values from moisture desorption studies. The use of adsorption data may introduce slight errors if hysteresis effects are present.

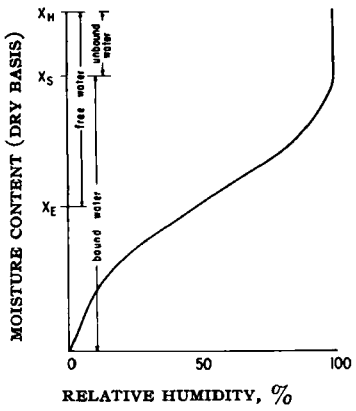

Fig. 1.—EMC curve for a hypothetical hygroscopic solid.

content. If the level of moisture finally present in the placebo granulation after drying with air at 70% R.H. adversely influenced compression characteristics, little improvement would be obtained by drying with air at 30% R.H. This illustrative example can be extended to other properties of the granulation (which are moisture content dependent) such as flow behavior, friability, caking tendencies, etc.

In the case of tray dryers and other units which have heating elements external to the drying chamber, estimates of the EMC at various elevated temperatures can be obtained. This is accomplished by first determining, from psychrometric charts (7), the decrease in relative humidity produced by heating the air to the desired temperature. The equilibrium moisture content of the solid at the elevated temperature is then read from the EMC curve using the new R.H. value as the parameter.[2] These calculations are concerned only with factors of equilibrium moisture contents and do not relate to any changes in the rates of drying which result with changes in R.H. or air temperature. Detailed analyses of these latter factors have appeared in the literature (7).

The EMC curves also have utility in establishing the influence of storage conditions on the moisture content of the product. It is clear that products dried to one moisture level under a given set of drying (or storage) conditions will assume new moisture content values if stored under conditions of different R.H. In the case of the antacid granulation illustrated in Fig. 2, about 9% moisture will be present after storage at 70% R.H. regardless of the moisture content obtained in previous drying operations.[3] No attempt should be made in the drying operations, therefore, to reduce the moisture content of the granulation lower than 9% if the product is subsequently stored at 70% R.H. for protracted intervals.

The compression and flow characteristics of many tablet granulations are influenced by relatively small variations in moisture content. Since quantities of moisture may be adsorbed during "in process" storage, the moisture specifications governing acceptability of such granulations should be based at a level at which successful tableting occurs and not on the moisture content obtained immediately after drying. Limits on the moisture content of the granulations leaving the dryer can be applied, of course, for control of dryer performance.

The moisture level specified for the dry granulation has an important influence on the "throughput" and efficiency of a given dryer. For products

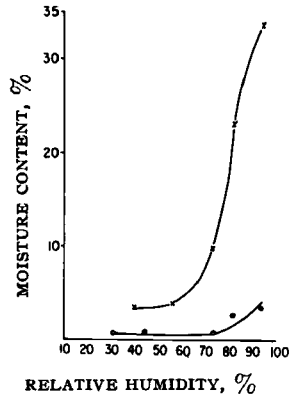

Fig. 2.—EMC curves for placebo and antacid tablet granulation. Key: ×—× antacid, O—O placebo.

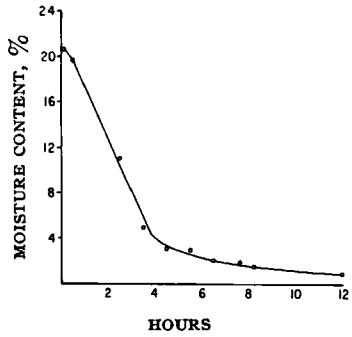

Fig. 3.—Moisture content data for tray drying placebo granulation (inlet air at 104°).

dried to their EMC, drying rates may decrease significantly as the EMC is approached. Thus, disproportionately large amounts of time are required to remove the last amounts of free water. This is illustrated in Fig. 3 with data obtained in tray-drying studies with the placebo. In this case, approximately 6 hours of the total drying time of 10–12 hours was utilized in reducing the moisture content from 3 to 1%— a reduction of only 2%. If it were determined that the granulation was actually acceptable at the 3% moisture content, the drying cycle could be reduced by 6 hours. This would double the output of the tray dryer. Overall thermal efficiency would be increased by an even higher factor. Further, during the last 6 hours of drying, the product temperature will be near that of the inlet air so that elimination of this interval may minimize product decomposition during the drying cycle.

Formulation Considerations.—Figure 4 presents

[2] Temperature has a slight humidity-independent effect on EMC (8). This can be neglected in first approximations with most systems.

[3] This assumes that the storage at 70% R.H. is of sufficient duration for equilibrium to be established. For shorter storage times the moisture content of the product may adjust only partially. Hysteresis effects also are assumed to be negligible.

the EMC curves for representative tablet disintegrators. The high EMC sensitivity of these materials to changes in relative humidity is apparent. These EMC characteristics are not surprising since tablet disintegrators, as a class, comprise agents which are chosen (in a sense) for their water adsorptive abilities. No attempt to select the "best" disintegrators on the basis of EMC criteria was made since other factors also influence their performance.

EMC curves for three modified cellulose tablet binders are shown in Fig. 5. The water insoluble

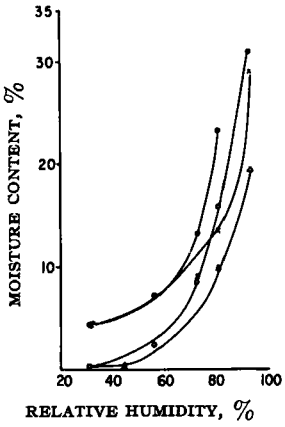

Fig. 4.—EMC curves for tablet disintegrators. Key: Δ—Δ starch, ×—× Solka Floc, O—O guar gum (A-20-D), ●—● bentonite.

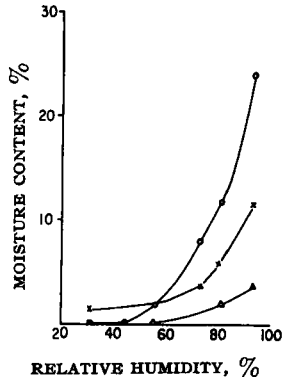

Fig. 5.—EMC curves for tablet binders. Key: O —O methylcellulose (400 cps), × —× methylcellulose (15 cps), Δ —Δ ethylcellulose, (15 cps).

ethylcellulose shows low moisture levels which are sensitive nevertheless to changes in relative humidity. Both grades of methylcellulose have high EMC values, and clear differentiation between the two grades is observed.

Lubricants examined in this study included talc, magnesium stearate, and stearic acid. EMC values for the first two materials were less than 0.5% at all test humidities. Slightly higher results of about 1% were observed for stearic acid. It is probable, however, that this moisture value includes a significant error arising from the loss of other volatile substances (in addition to moisture) which are removed from the acid during the Cenco moisture determination. It was noted further in this study that determinations of moisture levels of less than 1% by the Cenco technique were not generally reliable.

Tablet lubricants are water insoluble materials without pronounced water adsorptive abilities. It is expected that lubricants such as mineral oil, sterotex, and calcium stearate, etc., would show EMC curves similar to those observed above.

Tablet fillers including kaolin, mannitol, terra alba, and dicalcium phosphate had equilibrium moisture contents of less than 1% at all humidities tested. Sucrose was included in this study and, although it evidenced high moisture gain, it did not reach moisture equilibrium at the test humidities during a long storage period (60 days). No reason for this anomalous behavior was apparent. For lactose, the EMC (at the highest humidities) was approximately 2%. This value is higher than that seen with the other fillers and reflects the relative hygroscopicity of this agent.

Extensions of the above considerations to simple formulations can be made. In systems which consist of physical mixtures of two or more agents, each material can seek and reach its own EMC under given storage conditions. The EMC of the mixture will represent a weighted average of the EMC values for the individual components, and predicted EMC values can be obtained for each humidity of interest. Knowledge of the EMC curves for the individual components can be applied in this way to make first estimates regarding the moisture gain of the mixture. This approach also allows a preliminary basis for selection of formula components in line with the desired moisture characteristics of the product.

If no chemical reactions occur during the granulation or tableting of physical mixtures, it can be expected that the EMC curve for these materials will also be related to the EMC values for their individual components. (Changes in particle size of the powders during granulation or compression will effect the absolute values.) The antacid granulation containing high concentrations of relatively hygroscopic materials (sucrose and magnesium trisilicate) therefore would be expected to show higher EMC levels than obtained with the lactose based placebo. Figure 2 indicates that this is true. Similar observations demonstrating the comparative moisture sensitivity of the antacid were made when tablets of both formulations were studied.

EMC values for the placebo granulation were

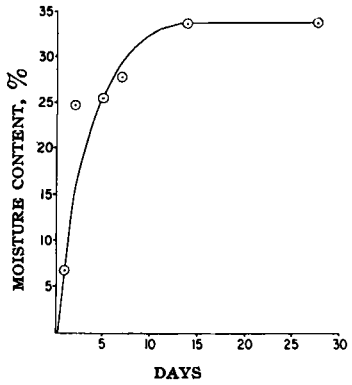

Fig. 6.—Rate of moisture adsorption for antacid granulation at 93% relative humidity.

TABLE I.—STABILITY CHARACTERISTICS OF ASCORBIC ACID TABLETS AT VARIOUS HUMIDITIES

Time, Days		Relative Humidity 93%	81%	73%	56%
3	Assay, %	69	92	100	100

predicted (from a weighted average of the component EMC values) at 4.6, 3.3, and 2.5% at 93, 83, and 71% R.H., respectively. These predictions are in reasonable agreement with the experimentally determined values of 3.5, 2.8, and 1%. While further studies are required to confirm the quantitative aspects of this approach, these experiments do demonstrate the value of the EMC concept for qualitative predictions of moisture content–humidity interrelationships. It is interesting to note that the use of humectants in cosmetic formulations (16) and flow conditioners in fertilizer products (17) are based on similar considerations.

Stability Considerations.—The static equilibration technique used in the present experiments is similar to that generally employed in following the stability of pharmaceuticals under exaggerated humidity conditions. In such systems, little or no flow of air across the sample is obtained, and mass (moisture) transfer occurs by molecular diffusion alone. Rates of moisture adsorption, therefore, can be expected to be low and prolonged storage times will be required before samples attain their equilibrium moisture content. In the present study it was found that storage intervals of at least 15 days were necessary for samples to achieve equilibrium. This is illustrated in Fig. 6 with representative data for the antacid granulation.

For moisture sensitive materials, significant decomposition can occur in the early storage intervals during which nonequilibrium (moisture) conditions prevail. The rate of decomposition observed during this period should be related, however, to the moisture actually present in (or on) the sample. While the moisture content will be influenced in turn by the storage humidity utilized, simple relationships between relative humidity and decomposition rates may not exist.

These points are illustrated by the data of Table I which gives the assay results and corresponding moisture gain of ascorbic acid tablets stored for various time intervals at four different humidities. At any given humidity, increasing amounts of moisture were adsorbed as the storage time was extended. (EMC levels were not established within a 30-day interval). The amount of moisture adsorbed during any given time period decreased with decreasing humidity. Further, assay values of ascorbic acid were related to the amounts of water adsorbed. Kinetic analysis of the data is difficult, however, since moisture equilibrium was not obtained. Rates of moisture transmission in elevated humidity studies of this type may be, in fact, the overall rate-limiting consideration in the decomposition process.

Rates of moisture gain under exaggerated humidity conditions will be influenced by the physical characteristics of the sample such as its surface area and porosity, etc. For tablets, moisture adsorption rates will be related in part to hardness. Increasing tablet hardness should decrease moisture transfer rates within the solid and thereby decrease the overall rate of moisture gain. This should result, in turn, in improved stability with increasing tablet hardness. To test these predictions, tablets were made from a ferrous sulfate granulation and compressed to hardness of 6, 8, and 10 Strong-Cobb units. After a 3-day storage period at 93% R.H. moisture gain was 8.5, 7.2, and 6.8%, respectively. The decomposition of ferrous sulfate in these tablets was 31.7, 28.3, and 24.1%, respectively, and was in line with the moisture gain values.

Further experiments are required to extend these initial observations. For such kinetic studies, vapor diffusion effects which may limit the overall rates of decomposition will have to be considered. Dynamic techniques for achieving rapid moisture equilibration in the solid will be more useful than the static methods routinely employed in such studies.

CONCLUSIONS

The concept of equilibrium moisture content (EMC) defines the relationship between moisture adsorption and relative humidity. This concept is useful in establishing proper drying and storage conditions for pharmaceutical materials.

Equilibrium moisture contents have been obtained for a number of representative pharmaceutical materials. This data is useful in predicting the effects of storage humidity on the moisture adsorbed by simple physical mixtures. The stability of products containing moisture sensitive active ingredients may be related to their moisture content which in turn is predictable from the EMC curves of individual components.

Application of Radioisotopes to Absorption in Pharmaceutical Closures

By GLENN S. CLARK and HOWARD A. SWARTZ

Moisture absorption by rubber stoppers was determined by means of tritiated water. Residual activity in the stoppers and ferrules was determined after storage at room temperature at 50° and observed to be 0.56 and 0.025 per cent, respectively, at maximum for time periods involved.

IN THE PACKAGING of biological and injectable pharmaceutical products, the absorption of packaged components into the package materials with a subsequent loss of product is a critical problem. Mattocks and Milosovich (1) reported on the absorption of water by rubber stoppers and on the effects of inorganic salts in solution. Lowry and Kohman (2) discussed the mechanism of transmission into the stoppers and the role of stopper constituents. Barry (3) described the criteria for judging rubber closures in a symposium on the subject. The absorption of bacteriostatic agents by stoppers was reported by Wing (4, 5) and Sykes (6). The measurement of transmission and product loss, with the evaluation of various packaging materials, has been determined essentially by three methods (7). (*a*) Trial and error, using packaging materials of different types and checking weight losses; (*b*) holding the container and contents (sealed) under a vacuum for an extended time and checking the weight loss; (*c*) the Karl Fisher titration method.

These methods are either approximations and establish a series of assumptions or are time-consuming and complex procedure-wise. The time involved in these tests usually extends over a period of several months for a reasonable evaluation. In addition, many variables are involved that are critical or difficult to evaluate.

In the vacuum test method, the weight losses observed are assumed to be due to solvent transmission through or around the stopper and seal. This procedure may accurately determine a loss but neither permits determination of the actual route of solvent transmission, nor allows detection of potential residual uptake of solvent in the stopper involved.

The Karl Fisher titration method has been widely employed for the determination of water loss and absorption; several modifications have been utilized. The complexity of the procedure and necessity of exact details in application to these problems makes it difficult to obtain reproducible data.

In view of these problems and because of the importance of the data to packaging of biologicals, the evaluation of a testing method utilizing radioisotopes was proposed. It was believed that the application of radioisotopes would permit the accurate determination of true absorption, transmission rates, and the actual routes of losses from the containers. The specificity of radioisotopes appeared to lend itself particularly well to these determinations. In conducting the preliminary test it was determined that 15 vials and stoppers, sealed by conventional methods, would serve to check both the theory and the method.

EXPERIMENTAL

Counting Method.—All samples were counted by means of liquid scintillation counting.[1] The instruments were operated at settings determined to permit an efficiency of 40% for tritiated water. All samples were counted for 10 minutes and corrected for background.

Procedure.—Fifteen glass vials[2] of 9-ml. capacity were divided into three groups of five vials each. A 2.5-ml. quantity of tritiated water[3] with a total measured activity of 1.59×10^6 c.p.m. was added to each group. A 20-mm. rubber stopper,[4] preconditioned by autoclave sterilization and siliconed as in production processing, was added to each vial. A 20-mm. aluminum ferrule[5] was placed into position; the vials were sealed with a Firmpress capping device.[6]

One group of five vials was maintained at room temperature for 2 weeks. A second group was maintained at 50° for 1 week in a constant temperature oven, and the third group maintained at 50° for 2 weeks. These periods at 50° are assumed equivalent to 3 months and 6 months at room temperature, respectively (8). At the conclusion of the designated times, the vials were cooled to room temperature, and the ferrules removed. Each ring

was placed into a glass counting vial,[7] 1 ml. of absolute ethanol added, and 10 ml. of liquid phosphor introduced. (PPO[8] 4.00%, POPOP[9] 0.05%, and toluene to 1 L.) The vials were labeled by group and numbered.

The rubber stoppers were withdrawn with forceps, dusted with talc, and brushed clean to remove any external adhering water. Each stopper was placed into a glass vial and 10 ml. of ethanol was added. The vial was sealed with a screw cap and incubated at 50° for 48 hours to leach residual water. The 48-hour period was observed to achieve complete extraction of the tritium from the stoppers on the basis of a constant specific activity of the alcohol extract. At the end of this time, the vials were cooled to room temperature, opened, and 1-ml. aliquots measured accurately and added to individual glass counting vials containing 10 ml. of the liquid phosphor solution. Five samples of ferrules and identically treated rubber stoppers were prepared for controls and background measurements.

The activity in c.p.m. for each ferrule and stopper was determined as described and compared to the total activity placed originally into the Wheaton vial to determine the per cent of residual activity. These values are tabulated in Table I and plotted for the stoppers in Fig. 1.

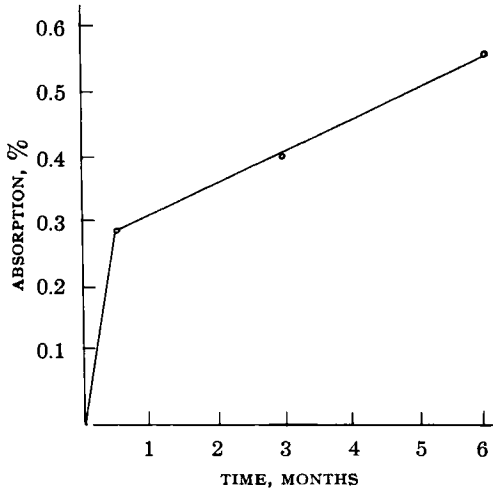

Fig. 1.—The per cent absorption in rubber stoppers *vs.* time in months based on 50°C. incubation periods.

DISCUSSION

The per cent of residual activity detected on both the ferrules and in the stoppers was not the total water uptake or transmission, but only the residue at the conclusion of the incubation period. The rather constant values for the ferrules would indicate that an actual exit passage may occur for the water in the vials, or that this is a saturation level—and once reached, no additional uptake occurs. The uptake of the stoppers, as seen in Table I and Fig. 1, occurs very rapidly and probably commences immediately after sealing the vials. The process is noted to increase in a near linear proportion, reaching the observed peak of 0.55% at the assimilated 6-month period. Whether transmission occurred was not determined, but weighing the sealed vials prior to and at the completion of the incubation periods would serve to measure this factor. This preliminary approach has clearly indicated that uptake into the rubber stoppers does occur, and that a potential exit from the sealed vials may occur around the metal rings. The method is efficient, accurate, and most specific. Any radioactivity detected in the stoppers and on the metal rings could have come only from the tritiated water added to the vials. It should be noted also, that these residues represent a loss of available volume contained within the sealed vial itself, and when an evaluation of solvent loss is made by weighing, this loss would not be detected as it would contribute to total weight.

[9] POPOP—*p*-bis [2-(Phenyloxazol 1)]1-benzene.

SUMMARY

The results of the preliminary study indicate that the use of radioisotopes in evaluating vial closures and stoppers and sealing efficiency offers a very specific and rapid method to obtain information with considerable importance to the packaging of biological products.

Ascorbic Acid Stability in Certain Aqueous and Fruit Juice Vehicles Subjected to Elevated Temperature

By M. C. UPRETY, B. REVIS, and S. M. JAFAR

The effect of heating ascorbic acid in fruit juices for 6 hours in a boiling water bath in the pH range 2.0 to 8.0 was investigated. Pure lime juice, lime juice plus sorbitol (1:1), and lime juice plus glycerol (1:1) were found to be good vehicles. At pH 3.0 the retention was fairly good. Under controlled conditions there was no significant loss even in distilled water. Storage of vitamin C in distilled water at room temperature showed a rapid loss, except at pH 3.0 where the retention was 44 per cent.

IT IS WELL KNOWN that liquid vitamin mixtures gradually deteriorate in their biological potency during storage and during the process of heating. The loss in vitamin potency is dependent on many factors. Various workers have investigated the problem of stability, yet much remains to be done in this direction. Vehicles (1–3) greatly influence the stability of vitamins; an ideal vehicle which may be acceptable to both children and adults has been the subject of long search. With this idea in mind, the present study was undertaken employing fruit juices as vehicles. Fruit juices are preferred because they are natural and palatable. The various formulations used are listed in Table I. Ascorbic acid was subjected to heat in a boiling water bath in the formulations as given in Table I for 6 hours. On the basis of the retention values of ascorbic acid, the suitable vehicles offering maximum protection were employed for further storage studies.

EXPERIMENTAL

Vitamin.—Ascorbic acid (Hoffmann-La Roche and Co., Ltd., Basle, Switzerland) was used.

Vehicles.—Fruit juices, syrup (67% w/v), sorbitol (E. Merck 70% w/v), and glycerol (BDH 75% v/v) were employed. Some of these bases contained 0.15% potassium metabisulfite (E. Merck, henceforth referred to as KMS) and 0.15% cysteine hydrochloride (E. Merck) Table I.

Procedure.—A 5.0 mg./ml. quantity of ascorbic acid was added to the base and the solution was filled in Pyrex test tubes. The pH of all these vehicles was adjusted between 2.0 to 8.0. After recording the initial readings, the test tubes were plugged with cotton and kept in boiling water for 6 hours. Ascorbic acid was estimated by titrating it against standard 2,6-dichlorophenol-indophenol (BDH) solution.

The percentage retention of ascorbic acid after 6 hours of boiling is given in Table I. Another study was made to see the effect of storage on ascorbic acid in glass distilled water at room temperature for a period of 30 days, the results are presented in Table II.

Received January 3, 1963, from the Government Fruit Preservation and Canning Institute, Lucknow, India.
Accepted for publication March 27, 1963.
The authors express their thanks to Dr. D. N. Srivastava, Director, and to Dr. W. B. Daté, Deputy Director, Fruit Utilization, U. P., Ranikhet, for their keen interest in this work.

RESULTS AND DISCUSSION

It is clear from Table II that in distilled water vitamin C was lost to the extent of 70% in all the pH ranges between 2.0 to 8.0, except at pH 3.0 where there was 44% retention. Between pH range 4.0 to 6.0, the destruction was to the same extent, indicating that pH values 4.0, 5.0, and 6.0 behave alike as far as retention of vitamin C in distilled water is concerned.

A slight drop in pH occurred in the sample originally adjusted to pH 8.0. No changes were observed in other sets having a pH 2.0 to 7.0.

At pH 2.0, 7.0, and 8.0 the retention is practically the same. Table II suggests that vitamin C can be stabilized at pH 3.0 in distilled water with the inclusion of some antioxidants and metal binders. Experiments are in progress to stabilize the solution of ascorbic acid at pH 3.0 in distilled water.

At the end of the experimental period (30 days), browning occured at all the pH values under trial. The intensity of the browning was more with corresponding higher pH values. At pH 3.0, browning was comparatively less. It is assumed that the oxidation products of vitamin C were responsible for this browning and probably also because of polymerization of ascorbic acid to furfural. Further work on this aspect is in progress.

It is evident from Table I that even in distilled water ascorbic acid was retained to the extent of 91% at all the pH values, except at pH 4.0 and 7.0, where the retention was 78.0% and 61%, respectively. Hence, it can be concluded that heating does not completely destroy ascorbic acid under controlled conditions of pH in distilled water. This may be explained on the presumption that chances of metallic ion contamination in distilled water are less.

KMS has a stabilizing tendency in the retention of ascorbic acid at all pH values except at pH 2.0. Loss of ascorbic acid in distilled water at pH 4.0 and 7.0 after 6 hours of heating can be counteracted by the addition of KMS at the 0.15% level. Cysteine hydrochloride also has a stabilizing effect on vitamin C at all pH values except pH 2.0.

Lime juice without preservative can retain ascorbic acid to the extent of 100% at pH values 3.0, 6.0, 7.0, and 8.0. At pH values 2.0, 4.0, and 5.0 a slight destruction occurred. Preservative seems to have no influence on the stability of ascorbic acid in lime juice at pH 6.0, 7.0, and 8.0; but at pH

TABLE II.—PERCENTAGE RETENTION OF ASCORBIC ACID DURING STORAGE AT ROOM TEMPERATURE FOR 30 DAYS

Soln. No.	Vehicle	pH 2	3	4	5	6	7	8
1	Distilled water	9.2	44.5	27.3	25.3	25.9	9.8	13.3

3.0 preservative seems to have a destructive effect on the stability of ascorbic acid in lime juice. At pH 2.0 and 5.0, preservative seems to have a stabilizing action. Experiments are in progress to confirm this postulation.

In 50% lime juice plus 50% sorbitol at pH values 2.0, 3.0, 7.0, and 8.0 there was no loss of ascorbic acid. At pH values 4.0, 5.0, and 6.0 the loss was to the extent of 10%.

In 50% lime juice plus 50% glycerol vitamin C, retention was 100% at pH values 3.0, 4.0, and 7.0, while at other pH values the loss was not more than 8.0%.

The combination of 50% lime juice plus 50% syrup was a poor vehicle compared to vehicles No. 6 and 7 (see Table I).

In 70% sorbitol there was no loss of vitamin C after 6 hours of boiling, at pH 3.0, 6.0, 7.0, and 8.0. A slight loss was observed at pH 2.0, 4.0, and 5.0.

Sixty-seven per cent syrup and 75% glycerol do not prove to be good vehicles compared to 70% sorbitol. At pH 2.0 in 67% syrup, there was loss of 50% of vitamin C after 6 hours of boiling. Sorbitol proved to be a good vehicle. This finding to some extent is in conformity with Gerber, *et al.* (4), who showed that in 70% sorbitol and in presence of vitamin B_{12} and ferrous gluconate the degradation of vitamin C can be checked.

Vitamin C deteriorated in 50% mango pulp plus 50% water vehicle at all pH values, both in the presence and absence of KMS. It is interesting to note that 0.15% KMS has a stabilizing effect on the retention of vitamin C after 6 hours of boiling at pH 2.0, 3.0, and 4.0; but the same substance has a deleterious effect at higher pH values, *viz.* 5.0, 6.0, 7.0, and 8.0. This finding is being subjected to repeated trials.

There was no significant loss of vitamin C in both apple juice and pure pineapple juice after 6 hours of boiling at all pH values except pH 4.0. At pH 8.0 there was 20% loss of ascorbic acid in apple juice but none in pineapple juice. Mosambi juice is not a suitable vehicle compared to apple and pineapple juice.

For retention of ascorbic acid, pH 3.0, 6, and 7 were found suitable. pH 4.0 appeared to be on the border line for retention values of ascorbic acid after 6 hours of boiling in all the vehicles tried except vehicles No. 7, 8, 11, and 15. Fifty per cent lime juice plus 50% sorbitol was found to be most suitable for ascorbic acid retention, both from the palatability and economic points of views, although 50% lime juice plus 50% glycerol was better. Apparently there is not much difference between bases No. 6 and 7.

After 6 hours of boiling no change in pH values was observed in the samples previously adjusted to pH value 2.0 and 7.0, but a slight drop in the pH was observed in the test tube originally adjusted to pH 8.0. The result of this investigation indicates that the loss sustained by ascorbic acid during heating for 6 hours in different media is not considerable.

Effect of Enzyme Inhibitors on Acetylcholine-Induced Atrial Arrhythmias

By P. G. ROY†

An investigation was made of the effects of enzyme inhibitors on the acetylcholine-induced atrial arrhythmias. It was found that an interference with normal metabolic processes abolishes the electrical activity of arrhythmic atria. Azide, cyanide, and iodoacetate were the most effective in causing the disappearance of all potentials. Arsenate, fluoride, fluoroacetate, and malonate were considerably less active, while pyrophosphate was least efficacious. It is felt that the inhibition of the Na^+ pump may play an important role in the consistent conversion from the induced arrhythmias to quiescence.

THE REPORT OF CHANG (1), in which iodoacetate was shown to inhibit aerobic as well as anaerobic activity of the isolated rabbit auricle led the way to numerous investigations of enzyme inhibitors on mechanical and electrical atrial parameters (2–10). In keeping with this, Webb and Hollander (11) observed that several enzyme inhibitors produced changes in the membrane electrical properties of rat atrial cells—one of the most characteristic is a shortening of the action potential duration. Since a connection between the amount of energy available, the duration of the action potential, the ionic movements, and the initiation of arrhythmia has been suggested (12, 13), the present work was an attempt to investigate the influence of an interference with normal metabolic processes on the acetylcholine-induced atrial arrhythmias.

EXPERIMENTAL

The methods used for the dissection of rabbit atria, the induction, and the recording of arrhythmias have been described previously (14). Two modifications in the technique need to be pointed out: (*a*) the use of a larger bath containing 150 ml. of Ringer's solution, (*b*) the atria were permitted to recover a regular rhythm in normal Ringer's solution for 90 minutes. The experiments to be described are of two types:

1. Control Acetylcholine (ACh)—induced atrial arrhythmias, the duration of which was noted on surface electrograms until spontaneous arrest.

2. A series of experiments consisting in inducing first the arrhythmias with ACh. On cessation of stimulation, a 5-minute period of arrhythmia was always recorded before the addition of the enzyme inhibitors to the bathing solution. At the end of that time, 1 ml. of their solutions (as sodium salts) was added to make the final concentrations (11) listed in Table I. A reliable criterion of the inhibitory activity was the disappearance of all potentials appearing as quiescence and observed for at least 5 minutes on the surface electrograms. Thereafter, the inhibitor was washed out and (except with iodoacetate and fluoroacetate) the tendency of atria to return to their normal rate and amplitude was usually rapid (10–20 minutes).

RESULTS

Duration of Control ACh-Induced Atrial Arrhythmias.—A summary of these studies is presented in Table I. Of 11 atria, eight developed stable arrhythmias lasting 80 minutes or more, while only three stopped spontaneously within 80 minutes. The period of fibrillation varied from 24 to 155 minutes with a mean duration of 82 minutes. This is not too surprising since the production and maintenance of atrial arrhythmias are dependent upon numerous factors (12, 13).

Enzyme Inhibitors and Atrial Arrhythmias.—The effect of these substances on the ACh-induced arrhythmias is interesting. The data presented in Table I illustrate clearly the capacity of these inhibitors to abolish the electrical activity of arrhythmic atria. It is quite obvious that a quiescence ensues after an interference with the normal metabolic processes of the atrial cells.

Furthermore, there seems to exist a certain relationship between the inhibitory potency and the time required for complete quiescence. Powerful inhibitors, such as azide, cyanide, and iodoacetate proved to be most effective since the disappearance of all potentials was very rapid. As for arsenate, fluoroacetate, fluoride, and malonate—they occupied an

intermediary position, being less active than the former, but more active than pyrophosphate (the least efficacious). Apparently, the lack of activity of pyrophosphate may be associated with the fact that pyrophosphate combines with Ca^{++} and that the walls of the tissue bath slowly became covered with a white layer following its addition. It is not unlikely that the decrease of ionized Ca^{++} neutralized the inhibitory effect of pyrophosphate. The finding that a lack of Ca^{++} in the medium increases the incidence of arrhythmias which tend to be of longer duration supported this suggestion (15).

DISCUSSION

Previous investigations (16) suggested that a mechanism is present in cardiac tissue which actively delays repolarization under normal conditions; this mechanism is maintained by metabolic processes and seemingly is inactivated by ACh. Then, Burn (17) postulated that the onset of atrial fibrillation appears to be linked to the diminution in membrane resistance, to the increased permeability to K^+, and to the increased rate of loss of K^+ which ACh causes. This was extended and confirmed by subsequent works of Klein and Holland (18) and Holland and Briggs (19). They showed that the onset of atrial fibrillation is accompanied by a marked increase in the inward movement of Na^+ and K^+ leaving the tissue in exchange. More recent studies (20–22) established a net increased Cl^- influx during fibrillation that may play an important role in inactivating the marked increase in the inward movement of Na^+. The thesis was developed that maintenance of fibrillation depends upon the rate of entry of Cl^- into a thin barrier, probably the cell membrane, which is the seat of chemical processes driving Na^+ out of the cell (23). According to Woodbury (24), this process whereby the cell continuously uses metabolic energy to maintain an efflux of Na^+ is called active Na^+ transport; the detailed mechanism for utilization of metabolic energy to carry Na^+ out of the cell is not yet known. Nonetheless, Hodgkin and Keynes (25) reported very interesting findings relative to the effect of enzyme inhibitors on the active Na^+ transport. It is beyond the scope of this paper to summarize them all and we shall mention only three: (*a*) Na^+ efflux is decreased to values near zero by the addition, at appropriate concentrations, of a metabolic inhibitor to the bathing fluid. (*b*) K^+ influx is greatly reduced by metabolic inhibitors. (*c*) Na^+ influx and K^+ efflux are not greatly affected by metabolic inhibitors. These observations are well in agreement with those of Leaf (26) who concluded that inhibition of metabolism slows or stops the ion pump so that the Na^+ entering the cell by diffusion cannot be extruded and the K^+ lost from the cell cannot be replaced. The cell membrane potential diminished and Cl^- enters the cell. This requires further entry of Na^+ into the cell to preserve electric neutrality.

Since experimental evidence is increasing that the maintenance of auricular arrhythmias is associated with active ionic movements which are metabolic energy dependent and that the utilization pathways of this energy essential to the Na^+–K^+ exchange seem very sensitive to enzyme inhibitors, it is logical to assume that the inhibition of the Na^+ pump might probably be responsible for the conversion from the induced arrhythmias to quiescence. Indeed, it will appear that if an arrhythmia is to continue, the active Na^+ transport, which is an energy requiring reaction, need not be impaired. When the metabolism is inhibited, the energy supply is cut off through a reduction in the amount of energy available, resulting in a deficient Na^+ pump. The pump being deprived of its source of energy, the Na^+ efflux and the K^+ influx are greatly reduced. The Na^+ will accumulate inside and the K^+ outside the cell. The ionic desequilibrium will tend to lengthen the refractory period usually indicated by a lengthening of the action potential and to delay the return of excitability. Consequently, an atrial fiber which has contracted remains inexcitable for a long time. When excitation spreads to it from a neighboring fiber which is out of phase, the excitation has no result. Thus the arrhythmia stops and quiescence ensues.

In conclusion, it is emphasized that because of the lack of specificity of most enzyme inhibitors, the data presented here do not exclude the possibility that the inactivation of particular enzymes is involved in stopping the electrical activity of arrhythmic atria; they do suggest, however, that the inhibition of the Na^+ pump may be the main contributing factor.

Some Low Boiling Constituents of Peppermint Oil

By WALTER C. McCARTHY, K. VENKATRAMANA BHAT, CHARLES W. ROSCOE, and LOUIS FISCHER

Isobutyraldehyde and *trans*-2-hexenal (leaf aldehyde) have been identified among the low boiling constituents of peppermint oil.

THE IDENTIFICATION of trace low-boiling constituents of peppermint oil has been studied using a forerun fraction normally discarded in the commercial rectification of peppermint oil.[1] It is necessary to remove this small forerun to improve the taste and odor of the finished oil and to comply with the U.S.P. requirement that the dimethyl sulfide be removed. This forerun represents approximately one-tenth of 1% of the throughput of peppermint oil in the distillery and the oil originates from peppermint grown in the states of Washington and Oregon. This forerun is known to contain dimethyl sulfide, a complex mixture of aliphatic aldehydes and alcohols and monoterpene hydrocarbons.

In this study, isobutyraldehyde has been identified in the fraction which distilled at 60–64°, and *trans*-2-hexenal (leaf aldehyde), a common constituent of volatile oils derived from green leaf sources, was identified in the fraction which distilled at 138–142°. Polarimetric data has indicated the presence of (+)-α-methylbutyraldehyde in the fraction which distilled at 91°.

The presence of isovaleraldehyde, previously reported as a constituent of peppermint oil (1), has been confirmed in the fraction collected at 91°. From the optical rotation of this fraction, +3.7° in a 1-dm. tube, one might conclude that it contains about 80% isovaleraldehyde and 20% (+)-α-methylbutyraldehyde.[2]

Thus, the ratio of these two isomers appears to be similar to the corresponding isoamyl alcohol: active-amyl alcohol ratio in fusel oil. Ehrlich (2) has reported that samples of commercial valeraldehyde made by oxidation of fusel oil showed rotations of +2.82° and +3.37°, measured in 1-dm. tubes.

EXPERIMENTAL

The peppermint oil forerun was first fractionated by distillation through a column 20 mm. in inside diameter and 20 ft. high, packed with single turn glass helices, 1/8 in. in diameter.

The fraction which boiled at 60–64°, n_D^{25} 1.3775, was identified as isobutyraldehyde by conversion to its 2,4-dinitrophenylhydrazone derivative, m.p. 183–184°, no depression upon admixture with an authentic specimen.

The fraction which distilled at a constant 91°, n_D^{20} 1.3930, α_D + 3.7°, was shown to contain the previously recorded (1) isovaleraldehyde by conversion to its 2,4-dinitrophenylhydrazone derivative, m.p. 120-121°, no depression upon admixture with an authentic specimen.

The fraction which boiled at 138–142° was shown to contain *trans*-2-hexenal by the preparation of three crystalline derivatives.

The 2,4-dinitrophenylhydrazone derivative, red needles, melted at 146–147°.

Anal.—Calcd. for $C_{12}H_{14}N_4O_4$: C, 51.79; H, 5.07; N, 20.14. Found: C, 51.66; H, 4.80; N, 20.38. This derivative of 2-hexenal is reported to melt at 144° (3), 145 to 145.4° (4), and 147° (5).

The semicarbazone derivative melted at 175°. This derivative of 2-hexenal is reported to melt at 173° (3, 5), 175–176° (6), and 176.4 to 177.2° (4).

The acid (obtained by alkaline silver oxide oxidation of the aldehyde) melted at 32 to 32.5°, after recrystallization from petroleum ether and from dilute alcohol.

Anal.—Calcd. for $C_6H_{10}O_2$: C, 63.13; H, 8.83. Found: C, 63.23; H, 8.84. The melting point of 2-hexenoic acid has been reported as 32° (7), 32–33° (6), and 33° (8).

Received December 19, 1962, from the College of Pharmacy, University of Washington, Seattle.

Accepted for publication February 26, 1963.

This investigation has been supported in part by State of Washington initiative 171 Funds for Research in Biology and Medicine.

[1] The authors thank Mr. Paul A. Tornow, I. P. Callison and Sons, Chehalis, Wash., for providing several gallons of this forerun for us.

[2] Attempts to separate this fraction into two components by fractional distillation were not successful. The work reported herein was done in 1956–1959, before preparative gas chromatography was generally available. This technique would likely be a valuable method today for the separation of such valeraldehyde isomers in sufficient quantities for further investigation.

Determination of Camphor and Menthol in Pharmaceutical Products by Gas Chromatography

By KHALID S. BAHJAT†

A simple, reliable method for the quantitative determination of camphor and menthol in pharmaceutical preparations has not been available until now. A practical gas chromatography method has been developed for the simultaneous quantitative determination of camphor and menthol in pharmaceutical preparations, using a flame ionization detector, Apiezon L column, and an internal standard. The method was successfully applied to both cream and liquid preparations. It is a simple, rapid, and reliable method with an accuracy of ±5 per cent.

SINCE many pharmaceutical preparations contain camphor and menthol, it is desirable to use a method which is both fast and accurate for the simultaneous determination of camphor and menthol. The presently used methods, described in the "Official Methods of Analysis of the Association of Official Agricultural Chemists" (1) are time consuming, requiring at least 4.5 hours for camphor and 2 hours for menthol.

The successful separation of menthol-menthone stereoisomers (2–5) and camphor (6) by gas chromatography suggests that it might be used for the simultaneous determination of camphor and menthol in pharmaceutical preparations. Preliminary work showed that the method is simple and rapid. Also it is possible to determine camphor and menthol at concentrations as little as 0.1%.

EXPERIMENTAL

Apparatus.—F and M model 609 flame ionization gas chromatograph[1] equipped with Disc chart integrator.[2] Nitrogen was the carrier gas. Flow rates were measured by the instrument flow meters. The carrier gas pressure was regulated to approximately 30 psig to maintain a flow rate of about 50 ml. per minute. The air flow rate was 365 ml. per minute, while the hydrogen flow rate was 47 ml. per minute. The column was stainless steel, 8 ft. long, with 0.25 in. O.D. The Hamilton 10-μl. syringe,[3] with Chaney adaptor, was used for sample injection.

Column Packing.—In the search for a suitable liquid phase, Apiezon L, silicone gum rubber, silicone oil 200, Quadrol-Saib, and Carbowax 20M were examined. Finally, 20% Apiezon L on Chromosorb W was selected, since it resolves camphor and menthol completely and the retention times are short—an important factor when many samples are to be assayed.

Chromatography.—The column was conditioned at 250° for 24 hours with a nitrogen flow rate of 50 ml. per minute. The column was not connected to the detector during this period. When running analyses, the column was maintained at 160°, detector block at 240°, and injection port at 274°. Sample size range was from 2.0 to 6.0 μl.

Calibration.—The internal standard technique introduced by Ray (7) was used since it was found to be the most accurate, ±1% being easily achieved. Calibration curves were obtained by measuring the ratio of the peak areas of camphor to internal stand-

[a] Cream samples (others are liquid samples).

ard, or menthol to internal standard and plotting the ratio against the percentage of camphor or menthol. This provided a straight line plot.

Naphthalene was selected as an internal standard after examining cetyl alcohol, ethylbenzene, naphthylamine, decyl alcohol, dodecyl alcohol, and eicosyl alcohol. Naphthalene was purified by sublimation before it was used in the experiment. Alcohol solutions having known amounts of camphor, menthol, and naphthalene were used to construct the calibration curves.

Sample Preparation.—(*a*) The liquid sample was injected directly into the gas chromatograph after the addition of the internal standard. (*b*) For the cream sample, a known weight of the sample was extracted with a known volume of 3A ethanol which contained a known amount of the internal standard. Then the alcoholic solution was injected in the gas chromatograph.

The amount of naphthalene, added to both the liquid sample and the alcoholic sample, should be the same as the amount added to the synthetic samples used in construction of the calibration curves.

RESULTS AND DISCUSSION

Under the conditions chosen, retention times for camphor, menthol, and naphthalene were 7.6, 8.8, and 12.4 minutes, respectively (Fig. 1).

Standard solutions, containing known concentrations of the component (camphor and menthol) being determined, were prepared; the ratios of the peak area of this material to the internal standard were measured. Calibration curves were then obtained (Figs. 2 and 3).

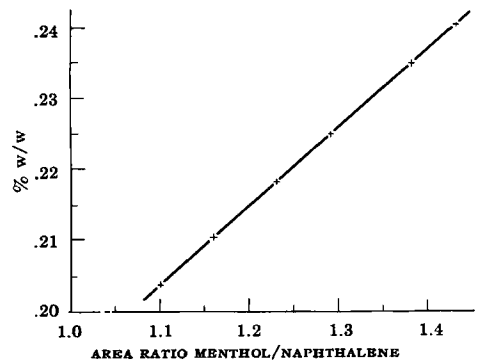

Fig. 3.—Calibration curve for menthol determination.

TABLE II.—PRECISION OF THE METHOD

Menthol		Camphor	
Found, % w/w	Dev. from Mean	Found, % w/w	Dev. from Mean
0.150	+0.003	0.203	+0.003
0.151	+0.004	0.194	−0.006
0.144	−0.003	0.199	−0.001
0.143	−0.004	0.198	−0.002
0.146	−0.001	0.202	+0.002
0.151	+0.004	0.202	+0.002
Av. 0.147		Av. 0.200	

Accuracy.—Samples of cream and liquid preparations were prepared accurately, each with known amounts of camphor and menthol, and were examined under the same conditions as those for camphor and menthol. The results are shown in Table I and are the average of duplicate determinations. The recovery for menthol was 98.53% and for camphor was 99.93%.

Precision.—The precision obtainable with the method applied to duplicate determinations of a synthetic liquid sample is illustrated in Table II. With the camphor, a standard deviation of 1.65% with 95% confidence intervals, ±3.24%, was obtained on six replicate runs, while the menthol results had a standard deviation of 2.45% and 95% confidence intervals, ±4.80%.

SUMMARY

It has been shown that gas chromatography offers a reliable and rapid method for the determination of camphor and menthol simultaneously in cream and liquid pharmaceutical preparations. This assay requires about 30 minutes, and the method is applicable to materials containing concentrations as low as 0.1% (w/w).

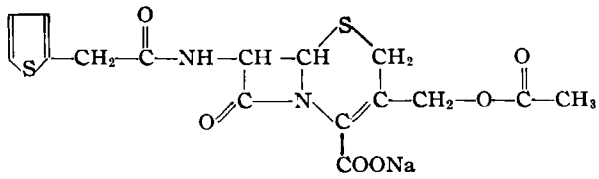
Crystallography of Cephalothin Sodium

By HARRY A. ROSE

CEPHALOTHIN SODIUM is an antibiotic which has shown activity against penicillin resistant organisms. A brief description of the chemistry and microbiological response of the compound has been given elsewhere (1, 2). Data are presented here which permit the identification of this compound by crystallographic methods.

The chemical name of the compound is the sodium salt of 7 (thiophene-2-acetamido) cephalosporanic acid and has the structure



EXPERIMENTAL

This compound can be recrystallized by adding an alcohol to an aqueous solution which results in blades elongated parallel to the c axis. The crystals show the prism 110 and the brachypinacoid 010.

The X-ray powder diffraction data were obtained using copper radiation and nickel filter with a camera 114.6 mm. in diameter. A wavelength value of 1.5418 Å. was used in the calculations. The indexing of the powder pattern was done on the basis of single crystal rotation patterns around both the a and c axes.

Synthesis of 5-Halo-6-methylcinchomeronic Acids

By L. K. GOTTWALD, G. E. McCASLAND, and ARTHUR FURST

New 5-halo-cinchomeronic acids which are structurally related to pyridoxine have been synthesized. These compounds are potential vitamin B_6 antagonists.

IN A CONTINUING SEARCH for antagonists of vitamin B_6 which may be useful as chemotherapeutic agents in tuberculosis or as nonspecific inhibitors of pyridoxine-dependent enzymes, a series of 5-halo derivatives of cinchomeronic acid [3,4-pyridinedicarboxylic acid (I)] were synthesized. These compounds are also useful intermediates for the preparation of substituted nicotinic acids or analogs of pyridoxine (1). An example is the 5-amino-6-methyl derivative II (2–5).

The amino acid II was easily converted by Sandmeyer type reactions to the chloro (III) and bromo (IV) acids in good yields. The iodo acid (V) was obtained by reaction of the diazonium chloride with aqueous potassium iodide. Attempts to prepare the corresponding fluoro acid by the Schiemann reaction, or by diazotization of II in the presence of hydrofluoric acid, were unsuccessful.

The 6-methylcinchomeronic acid VI had previously been prepared by permanganate oxidation (6) of 3-methylisoquinoline and by basic hydrolysis (7) of ethyl 3-cyano-6-methylisonicotinate. We now find that VI is more conveniently prepared from 4-carbomethoxy-3-cyano-6-methyl-2-pyridone (3) by the reaction route VIII → IX → VII → VI. On treatment of the pyridone VIII with phosphorus pentachloride the desired chloro intermediate IX was obtained in good yield. The chloro-diacid VII had previously been prepared by Ryder and Elderfield (8) from the corresponding 3-cyano-4-carboxamide. We find that acidic hydrolysis of the 3-cyano-4-carbomethoxy intermediate IX is equally convenient. Catalytic hydrogenolysis of VII removes the halogen, giving the desired 6-methylcinchomeronic acid VI.

In the course of this work the previously unreported 3-cyano-2,5-dichloro-4-ethoxymethyl-6-methylpyridine (XI) was prepared and characterized.

Biological testing of these compounds is in progress; results will be reported elsewhere.

EXPERIMENTAL

All melting points have been corrected and were measured on a Monoscop or Nalge-Axelrod micro hot stage. Microanalyses by Micro-Tech Laboratories, Skokie, Ill. Infrared spectra were recorded with an Infracord recording infrared spectrometer, using potassium bromide pellets.

5-Chloro-6-methylcinchomeronic Acid Monohydrate (III).—To a well-stirred mixture of 2.15 Gm. of the finely powdered amine (3) (II, m.p. 248°) with 6.0 ml. of 12 *M* hydrochloric acid, kept at from −5 to 0°, was added dropwise over a 10-minute period a solution of 0.9 Gm. of sodium nitrite in 2.5 ml. of water. The mixture became viscous at first but later thinned out. A solution of 0.99 Gm. of cuprous chloride in 1.5 ml. of 12 *M* hydrochloric acid was then added (caution: foaming), and the mixture was allowed to warm to 25°. After heating to 70° for a brief period, the solution was placed in the refrigerator to cool. The white precipitate was collected, washed with water, and dried, giving 1.73 Gm. (74%) of crude product, m.p. 239° dec. A portion of this material was recrystallized from water, giving yellow needles, m.p. 250° with dec. The melting point is dependent on rate of heating.

Anal.—Calcd. for $C_8H_6ClNO_4 \cdot H_2O$: C, 41.14; H, 3.45; Cl, 15.18; N, 6.00; neut. equiv. 117. Found: C, 41.40; H, 3.59; Cl, 15.54; N, 6.00; neut. equiv. 119.

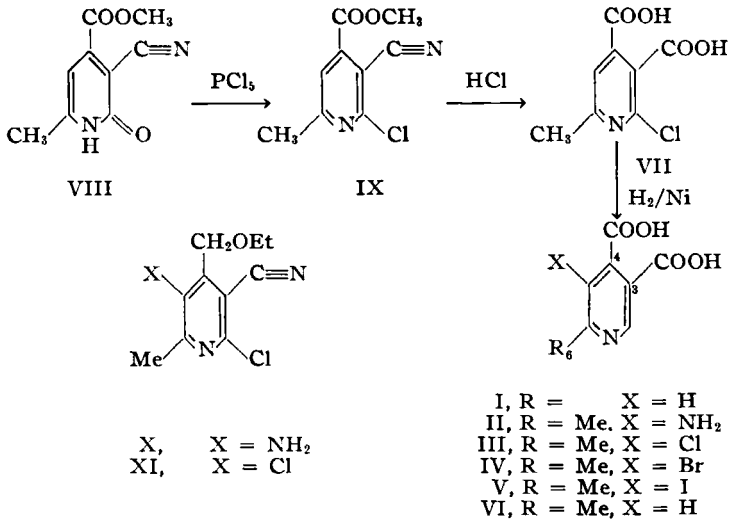
5-Bromo-6-methylcinchomeronic Acid Monohydrate (IV).—The amine (3) (2.15 Gm.) was treated in the manner described above for the chloro analog, but using 8.8 *M* hydrobromic acid, in volumes of 6.0 and 3.0 ml. After final brief heating to 100° and refrigeration, 1.3 Gm. (50%) of the crude product, m.p. 231° dec., was obtained. A portion recrystallized from water gave colorless needles, m.p. 250° with dec. The melting point is almost the same as for the chloro analog and is dependent on rate of heating.

Anal.—Calcd. for $C_8H_6BrNO_4 \cdot H_2O$: C, 34.55; H, 2.90; Br, 28.75; N, 5.04; neut. equiv. 139. Found: C, 34.60; H, 3.02; Br, 28.67; N, 5.11; neut. equiv. 140.

5-Iodo-6-methylcinchomeronic Acid Monohydrate (V).—The amine (3) (2.15 Gm.) was diazotized in the manner described for the chloro analog but using 2.5 ml. of water as solvent for the sodium nitrite. A solution of 1.61 Gm. of potassium iodide in 2.0 ml. of water was added dropwise, to the still cold solution followed by 5.0 ml. additional ice-cold water. The mixture was then allowed to warm to 25°, kept 24 hours, and finally heated to 90–100° for 1 hour. After cooling for several days, the precipitate was collected, washed successively with sodium bisulfite solution and water, and dried, giving 1.51 Gm. (47%) colored crude product, m.p. 240° with dec. A portion recrystallized from water gave tan crystals, melting point unchanged.

Anal.—Calcd. for $C_8H_6INO_4 \cdot H_2O$: C, 29.55; H, 2.48; I, 39.03; N, 4.31. Found: C, 29.81; H, 2.52; I, 39.27; N, 4.24.

The infrared spectra of the chloro, bromo, and iodo acids (III, IV, and V) were very similar, except for small variations in the fingerprint region. The spectra showed O—H stretching absorption at 3500, O—H bending at 1290 and 1263, and carbonyl C=O stretching at 1700 cm.$^{-1}$



I, R = X = H

V, R = Me, X = I
VI, R = Me, X = H

X, X = NH_2
XI, X = Cl

Methyl 2-Chloro-3-cyano-6-methylisonicotinate (IX).—One-hundred milliliters of phosphorus oxychloride was added to a mixture of 25 Gm. of the pyridone (3) (VIII, m.p. 233°) and 29 Gm. of phosphorus pentachloride. The mixture was heated (anhydrous conditions) at 75–100° for 90 minutes. Phosphorus oxychloride was removed by evaporation *in vacuo*. The dark brown residue was crushed and poured into 100 ml. of ice water. After brief stirring, the product was collected, washed with water, and dried, giving 25.6 Gm. of crude product, m.p. 112–115°. This material was recrystallized from ligroin (1500 ml.), giving 18.5 Gm. (66%) of yellow needles, m.p. 115–116°. A sample recrystallized for analysis melted sharply at 118.5°.

Anal.—Calcd. for $C_9H_7ClN_2O_2$: C, 51.33; H, 3.35; Cl, 16.83; N, 13.30. Found: C, 51.53; H, 3.32; Cl, 16.60; N, 12.97.

2-Chloro-6-methylcinchomeronic Acid (VII).—One-hundred milliliters of 6 *M* hydrochloric acid was added to 10 Gm. of the cyano-ester (IX). The mixture was heated at 90–100° for 5 hours, then cooled. A 2.5-Gm. quantity of yellow crystals was obtained after refrigeration, m.p. 205° dec. The filtrate was evaporated *in vacuo*, giving a yellow residue. The combined crystals and residue were recrystallized from water, giving 4.59 Gm. (45%) of yellow crystals, m.p. 205° with dec. [reported (8) m.p. 205°].

The infrared spectrum showed strong absorption at 2860, 1700, 1290, 1260, and 690 $cm.^{-1}$

6-Methylcinchomeronic Acid (VI).—A 4.0-Gm. portion of the chloro acid (VII) and 2.3 Gm. of sodium hydroxide were dissolved in 75 ml. of water. The mixture was hydrogenated with Raney nickel catalyst at 3 Atm./25° until theoretical hydrogen uptake was reached (about 4 hours). The mixture was filtered and the filtrate adjusted to pH 3 with 16 *M* nitric acid (about 2.7 ml.). The solution was concentrated *in vacuo* to 20 ml., and refrigerated until crystallization was complete, giving 1.3 Gm. (39%) of colorless product, m.p. 240° dec. A sample was recrystallized from water for analysis, giving colorless crystals, m.p. 250° with dec. (reported (7) m.p. 249–251° dec.).

Anal.—Calcd. for $C_8H_7NO_4$: C, 53.04; H, 3.90; N, 7.73; neut. equiv. 90.5. Found: C, 52.54; H, 3.80; N, 7.54; neut. equiv. 90.0.

The infrared spectrum showed strong absorption at 2450, 1700, 1400, 1260, 1060, 892, and 808 $cm.^{-1}$

3-Cyano-2,5-dichloro-4-ethoxymethyl-6-methylpyridine (XI).—A 2.0-Gm. portion of the monochloro-amine (9)(X) was stirred with 5.0 ml. of 12 *M* hydrochloric acid. A clear solution was at first obtained, but the hydrochloride salt soon precipitated. The mixture was treated with sodium nitrite (0.80 Gm.) and cuprous chloride (0.88 Gm.) in the manner described for the chloro compound (III). After final brief heating to 40°, and refrigeration, 1.3 Gm. (63%) of product was obtained, m.p. 50°. A sample recrystallized from ethanol for analysis melted at 52–53°.

Anal.—Calcd. for $C_{10}H_{10}Cl_2N_2O$: C, 49.00; H, 4.11; Cl, 28.93; N, 11.43. Found: C, 48.86; H, 4.19; Cl, 29.07; N, 11.30.

The infrared spectrum showed strong absorption at 2950, 2300, 1590, 1410, 1240, 1160, 1090, 845, 775, and 665 $cm.^{-1}$

Interaction Between Polyvinyl Alcohol and Procaine Hydrochloride

By C. BOTRÈ and F. M. RICCIERI

The interaction between procaine hydrochloride and polyvinyl alcohol was studied in terms of a determination of the activity coefficient of chloride ions in aqueous solution by means of membrane electrodes. γ_{Cl^-} shows a discontinuity in solution of procaine hydrochloride as a function of the dilution. This discontinuity is enhanced and shifted toward diluted range when amounts of polyvinyl alcohol are present in solution and also a polyelectrolyte behavior is observed.

INTERACTION of macromolecules with chemicals is of great and increasing interest, particularly in the field of compounds with pharmacological activity. Local anesthetics (8–10), steroidic hormones, barbiturates, penicillins, salicylates, and sulfonamides were studied in connection with their interactions with macromolecules (1–7). In some cases the complex formation between several local anesthetics and macromolecules determines a sharp increase in potentiating both duration and intensity of local anesthetic activity (13).

The results obtained by studying the interaction of procaine hydrochloride (PrHCl) and polyvinyl alcohol (PVA) are reported.

EXPERIMENTAL

Materials.—Procaine hydrochloride reagent analytical grade was supplied by Carlo Erba, S.p.A., Milan, Italy. Polyvinyl alcohol from Polymer Consultants, Ltd., London, England, had a molecular weight of 128,000, according to light scattering measurements carried out in our laboratory. Dialyzer tubing of cellulose was supplied by A. H. Thomas Co., Philadelphia, Pa. All other reagents were analytical grade.

Procedure.—Membrane equilibrium dialysis and potentiometric measurements were carried out at room temperature; viscosity and conductivity measurements were performed in a thermostatic bath at 25°.

The solutions of procaine hydrochloride and procaine hydrochloride–polyvinyl alcohol investigated were brought into equilibrium across a dialyzing membrane. For this purpose, two arrangements were set up: (*a*) conventional bags containing the mixed solution of polymer and drug dipped into a vessel containing the drug solution was shaken from time to time, and (*b*) the dialyzing membrane (of about 55 mm. in diam.) was clamped tightly between the flanges of two half cells with a capacity of approximately 50 ml. each. The solution of procaine and procaine + polymer contained in the two half cells was stirred continuously with two glass rods, squeezed at the tips, and running at the same speed into the solution. Both systems were maintained at room temperature until equilibrium was established. Before and after the experiments, the procaine concentration at the two sides of the membrane was determined by measuring the optical densities at 290 mμ with a Beckman (DU) spectrophotometer.

The activity of chloride ions of the solutions containing procaine hydrochloride was determined with positively charged membranes (Permaplex A20). The apparatus and detailed procedure for these potentiometric determinations have been described elsewhere (11).

Conductometric measurements performed in thermostatic bath at 25° ± 0.01 were recorded with a Philips a.-c. bridge, using a cell that allowed the dilution of the stock solution about 15 times.

RESULTS AND DISCUSSION

The membrane equilibrium dialysis measurements obtained in the study of the interaction with polyvinyl alcohol are shown in Fig. 1. The ordinate represents the ratio between the concentration of drugs at the two sides of the membrane at equilibrium; the variation of concentration of polymer is reported on abscissa. The slope of the straight line obtained clearly indicates that an interaction takes place between drug and polymer chain.

Figure 2 shows the activity coefficient of chloride ions (lower) and the specific conductivity (higher) determined in simple PrHCl solution as a function of the PrHCl concentration.

The simpler and more intuitive explanation of such phenomenon could be the existence of small aggregates of PrHCl molecules in water solution above a certain concentration. In fact, the discontinuity and the trend of the plots are similar to that of laurylsulfate and/or similar colloidal electrolytes in the concentration range where the critical micelle concentration takes place (11).

When PVA is added, the plot below the critical point becomes sharply parallel to the abscissa, and the discontinuity is shifted towards lower concentrations of PrHCl (Fig. 3). This shift is also proportional to the concentration of PVA in solution. The localization of the concentration where the break takes place was determined by conductometric and potentiometric measurements; in both cases the agreement was very good.

Below the critical point, the behavior of the activity coefficient is invariant with the concentration and typical of polyelectrolytes (12), while (as previously mentioned) the trend of the plot in absence of polymer in diluted solution is very similar to that of simple electrolytes.

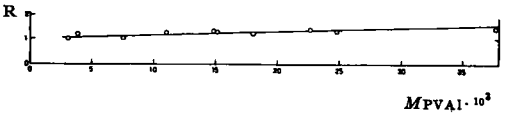

Fig. 1.—Membrane equilibrium dialysis measurements. The ordinate represents the ratio of drug on both sides of the membrane at equilibrium; the abscissa represents the concentration of polymer.

Received March 20, 1963, from the Institute of Pharmaceutical Chemistry, University of Rome, Rome, Italy.
Accepted for publication April 15, 1963.
The authors are greatly indebted to Prof. G. Giacomello for helpful suggestions and stimulating discussions.
The authors gratefully acknowledge the Colgate-Palmolive Co., New York, N. Y., which sponsored and financially supported this work.

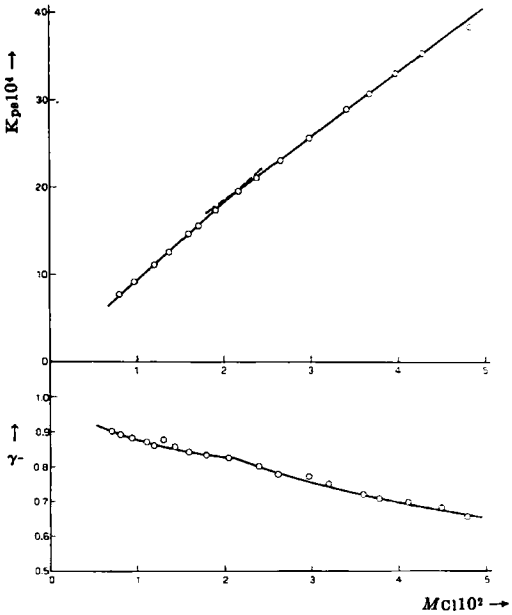

Fig. 2.—The activity coefficient of chloride ions (lower) and the specific conductivity (higher) determined; simple PrHCl solution is shown as a function of PrHCl concentration.

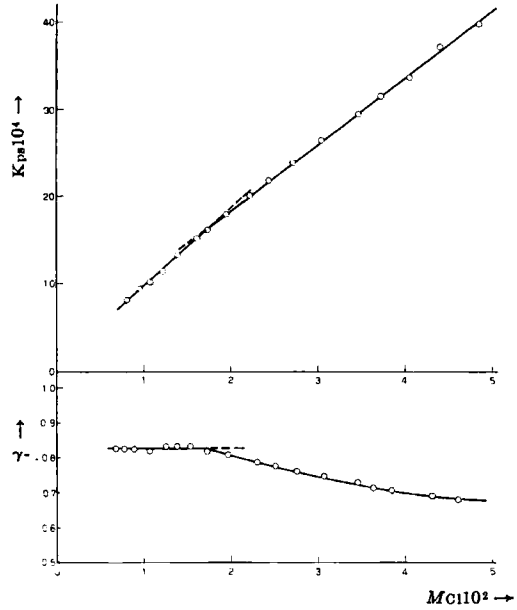

Fig. 3.—Activity coefficient of chloride ions (lower) and specific conductivity (higher) determined in PrHCl solution (PVA also being present) as a function of PrHCl concentration.

In a previous paper (10) Higuchi and co-workers showed that when PrHCl was admixed with polyvinylpyrrilidone (PVP) no interaction takes place. To confirm our potentiometric results, this experiment was reproduced. The determination of activity coefficient of chloride ions with membrane electrodes was perfectly identical to the values of PrHCl in water, thus confirming the lack of interaction.

In conclusion, the results reported here indicate that an interaction takes place between PrHCl and PVA and that the determination of the activity coefficient can be considered a useful method to provide information about interactions between drugs and macromolecules.

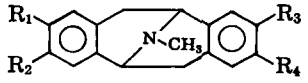
Structure of Bisnorargemonine

Sir:

Bisnorargemonine, $C_{19}H_{21}NO_4$, $[\alpha]_D^{25}$ $-265.8°$ (CH_3OH), is an alkaloid first isolated by Kier and Soine (1) from *Argemone munita* subsp. *rotundata* (Rydb.) G. B. Ownb. It was originally given the trivial designation of *rotundine* which was later changed to *bisnorargemonine* when it became evident that the original name was already in use (2). Bisnorargemonine was found to be closely related to argemonine (2) since it produced the latter on diazomethylation. The structure of argemonine has recently been elucidated by us (3) and independently confirmed by Stermitz and co-workers (4), thus establishing the basic ring structure as that of *N*-methylpavine (I), the structure of which had previously been established by Battersby and Binks (5) on the synthetic compound.



I. R_1, R_2, R_3, R_4, = OCH_3
II. R_1, R_3 = OH; R_2, R_4 = OCH_3
III. R_1, R_2 = OH; R_3, R_4 = OCH_3
IV. R_1, R_4 = OH; R_2, R_3 = OCH_3

As a continuation of our interest in the *Argemone* alkaloids, we have examined the structural possibilities for bisnorargemonine and assign II as the structure based on the evidence cited below.

Bisnorargemonine possesses two phenolic groups and two methoxyl groups. Our previous findings have ruled out a vicinal catechol arrangement of the hydroxyls (2) such as in structure III because 4-ethoxy-5-methoxy-phthalic acid and *N*-methyl-4-ethoxy-5-methoxy-phthalimide have been demonstrated as oxidation products from treatment of diethylbisnorargemonine with potassium permanganate and manganese dioxide-dilute sulfuric acid, respectively. The remaining structural possibilities would be II and IV.

We have utilized the nuclear magnetic resonance spectrum of bisnorargemonine to establish our structural assignment. Considering the two possibilities, it is evident that a decision can readily be made on the basis of the aromatic proton and methoxyl proton absorptions. Structure II has four aromatic protons, all of which differ and, therefore, should be resolvable into four singlets of one proton each. Likewise, the methoxyl groups in II are dissimilar and should show two singlets of three protons each. On the other hand, structure IV has two pairs of identical aromatic protons and two identical methoxyl groups. This should result in two aromatic proton singlets of two protons each and one methoxyl proton singlet of six protons. The nuclear magnetic resonance spectrum of bisnorargemonine[1] showed four nicely separated aromatic proton singlets of one proton each at 3.10, 3.25, 3.34, and 3.44τ and two methoxyl singlets of three protons each at 6.13 and 6.19τ. This establishes the structure of bisnorargemonine as II.

Book Notices

Tropical Therapeutics: Its Pharmacologic Aspects. By ROGER A. LEWIS. Charles C Thomas, Publisher, 301-327 East Lawrence Ave., Springfield, Ill., 1963. x + 276. 14½ × 22½ cm. Price $11.50.

A general pharmacology text is presented which emphasizes drugs likely to be employed in treating diseases in the moist tropics and hot arid zones. Dr. Lewis has had considerable experience in Ghana and India and while he does include general chapters on pharmacology and its relationship and application to drug therapy, the most valuable contribution will be concerning tropical therapy. It seems to be more suitable as a medical student's guide in clinical practice in a tropical area.

Investigation of Rates and Mechanisms of Reactions. Edited by S. L. FRIESS, E. S. LEWIS, and A. WEISSBERGER. John Wiley & Sons, Inc., 605 Third Ave., New York 16, N. Y., 1963. xii + 879 pp. 14½ × 22½ cm. Price $30.00.

Rates and mechanisms of reaction in organic chemistry with the relevant theories which have been presented receive thorough discussion and analysis in this volume in two parts. The work is concerned with the theoretical and experimental tools used to establish the operative mechanisms of reactions. Examples of investigations are given as models for related reactions and where appropriate, comment on possible variations, adaptations, and refinements are included. Part I deals with the kinetic methods and Part II with the nonkinetic methods.

Spices. By JOHN W. PARRY. Chemical Publishing Co., Inc., 212 Fifth Ave., New York, N. Y., 1962. 226 pp. 15.5 × 23.5 cm. Price $8.75.

Clear and simple anatomical descriptions of the external features and internal structures of the various spices are presented in the first part of this work and the chemical composition of spices is presented in the second part. Where pertinent, histological drawings are presented to assist in microscopic examination. For the most part, the material is presented in monograph style.

Paramedical Microbiology. By STANLEY E. WEDBERG. Reinhold Publishing Corp., 430 Park Ave., New York 22, N. Y., 1963. 14½ × 22½ cm. xv + 462 pp. Price $6.75.

A textbook on microbiology of particular value to pharmaceutical educators and pharmacy students is presented. From experiences at the University of Connecticut, Dr. Wedberg has organized the materials for students who have a considerable interest in the application of microbiological principles within their chosen field but less interest in becoming professional microbiologists. Historical background material has been minimized and coverage of nonmedical phases of microbiology is limited to allow greater emphasis on the practical aspects of microbiology in the medically oriented sciences.

Bilharziasis. Edited by G. E. W. WOLSTENHOLME and MAEVE O'CONNOR. Little, Brown & Co., 34 Beacon Street, Boston, Mass., 1963. xiii + 433 pp. 12½ × 20 cm. Price $11.50.

Twenty-six world authorities present a thorough discussion of modern aspects of research on bilharziasis and its control in this Ciba Foundation Symposium volume. The progress to date is summarized and hopeful lines for future work are delineated.

Practical & Industrial Formulary. By MITCHELL FREEMAN. Chemical Publishing Co., Inc., 212 Fifth Ave., New York, N. Y., 1962. v + 297 pp. 14.5 × 22 cm. Price $7.95.

Hundreds of formulas from cosmetics and perfumes to veterinary preparations are presented in this small cyclopedia intended to provide authentic, concise, and practical information for technical and nontechnical people alike. The great bulk of the book is in recipe form and contains appendices listing suppliers, conversion tables, composition of foods, and other general information helpful to those who utilize the volume.

Intestinal Biopsy. Edited by G. E. W. WOLSTENHOLME and MARGARET P. CAMERON. Little, Brown & Co., 34 Beacon St., Boston, Mass., 1963. 11½ × 18 cm. Price $2.95.

Another Ciba Foundation study group series, this volume presents materials on intestinal biopsy. Topics covered include dissecting microscope appearance of intestinal mucosa, electron microscope study of fat absorption in normal subjects and in patients with idiopathic steatorrhoea, effects of a gluten-free diet on intestinal histology in coeliac disease, significance of mucosal damage, biopsy studies on the pathogenesis of coelica sprue, and intestinal biopsy in tropical sprue.

Pentose Metabolism in Bacteria. By B. L. HORECKER. John Wiley & Sons, 605 Third Ave., New York 16, N. Y., 1963. 11½ × 18 cm. Price $4.00.

A general discussion of the function of the oxidative pathway and the role of pyridine nucleotide coenzymes in the overall energy economy of the cell, and mechanisms for the interconversion of hexoses and pentoses as well as new reductive pathways recently discovered in the filamentous fungi are presented. Additional consideration is given to a comparative study of pentose fermentation mechanisms and their biochemical basis and enzyme mechanisms in aldol and ketol condensations.

Biochemistry. By P. H. GELLINCK. Holt, Rinehart, and Winston, Inc., 383 Madison Ave., New York 17, N. Y., 1963. viii + 308 pp. 14½ × 22½ cm. Price $6.00.

An introductory text book for students with limited backgrounds in organic chemistry and biology is presented. Emphasis has been placed upon the simplicity of the presentation though the more complex formulas and structures are included where necessary. The book appears to be too brief and superficial for most needs of pharmacy students.

Dr. Lewis has had considerable experience in Ghana and India and while he does include general chapters on pharmacology and its relationship and application to drug therapy, the most valuable contribution will be concerning tropical therapy. It seems to be more suitable as a medical student's guide in clinical practice in a tropical area.

Investigation of Rates and Mechanisms of Reactions. Edited by S. L. FRIESS, E. S. LEWIS, and A. WEISSBERGER. John Wiley & Sons, Inc., 605 Third Ave., New York 16, N. Y., 1963. xii + 879 pp. 14½ × 22½ cm. Price $30.00.

Rates and mechanisms of reaction in organic chemistry with the relevant theories which have been presented receive thorough discussion and analysis in this volume in two parts. The work is concerned with the theoretical and experimental tools used to establish the operative mechanisms of reactions. Examples of investigations are given as models for related reactions and where appropriate, comment on possible variations, adaptations, and refinements are included. Part I deals with the kinetic methods and Part II with the nonkinetic methods.

Spices. By JOHN W. PARRY. Chemical Publishing Co., Inc., 212 Fifth Ave., New York, N. Y., 1962. 226 pp. 15.5 × 23.5 cm. Price $8.75.

Clear and simple anatomical descriptions of the external features and internal structures of the various spices are presented in the first part of this work and the chemical composition of spices is presented in the second part. Where pertinent, histological drawings are presented to assist in microscopic examination. For the most part, the material is presented in monograph style.

Paramedical Microbiology. By STANLEY E. WEDBERG. Reinhold Publishing Corp., 430 Park Ave., New York 22, N. Y., 1963. 14½ × 22½ cm. xv + 462 pp. Price $6.75.

A textbook on microbiology of particular value to pharmaceutical educators and pharmacy students is presented. From experiences at the University of Connecticut, Dr. Wedberg has organized the materials for students who have a considerable interest in the application of microbiological principles within their chosen field but less interest in becoming professional microbiologists. Historical background material has been minimized and coverage of nonmedical phases of microbiology is limited to allow greater emphasis on the practical aspects of microbiology in the medically oriented sciences.

Bilharziasis. Edited by G. E. W. WOLSTENHOLME and MAEVE O'CONNOR. Little, Brown & Co., 34 Beacon Street, Boston, Mass., 1963. xiii + 433 pp. 12½ × 20 cm. Price $11.50.

Twenty-six world authorities present a thorough discussion of modern aspects of research on bilharziasis and its control in this Ciba Foundation Symposium volume. The progress to date is summarized and hopeful lines for future work are delineated.

Practical & Industrial Formulary. By MITCHELL FREEMAN. Chemical Publishing Co., Inc., 212 Fifth Ave., New York, N. Y., 1962. v + 297 pp. 14.5 × 22 cm. Price $7.95.

Hundreds of formulas from cosmetics and perfumes to veterinary preparations are presented in this small cyclopedia intended to provide authentic, concise, and practical information for technical and nontechnical people alike. The great bulk of the book is in recipe form and contains appendices listing suppliers, conversion tables, composition of foods, and other general information helpful to those who utilize the volume.

Intestinal Biopsy. Edited by G. E. W. WOLSTENHOLME and MARGARET P. CAMERON. Little, Brown & Co., 34 Beacon St., Boston, Mass., 1963. 11½ × 18 cm. Price $2.95.

Another Ciba Foundation study group series, this volume presents materials on intestinal biopsy. Topics covered include dissecting microscope appearance of intestinal mucosa, electron microscope study of fat absorption in normal subjects and in patients with idiopathic steatorrhoea, effects of a gluten-free diet on intestinal histology in coeliac disease, significance of mucosal damage, biopsy studies on the pathogenesis of coelica sprue, and intestinal biopsy in tropical sprue.

Pentose Metabolism in Bacteria. By B. L. HORECKER. John Wiley & Sons, 605 Third Ave., New York 16, N. Y., 1963. 11½ × 18 cm. Price $4.00.

A general discussion of the function of the oxidative pathway and the role of pyridine nucleotide coenzymes in the overall energy economy of the cell, and mechanisms for the interconversion of hexoses and pentoses as well as new reductive pathways recently discovered in the filamentous fungi are presented. Additional consideration is given to a comparative study of pentose fermentation mechanisms and their biochemical basis and enzyme mechanisms in aldol and ketol condensations.

Biochemistry. By P. H. GELLINCK. Holt, Rinehart, and Winston, Inc., 383 Madison Ave., New York 17, N. Y., 1963. viii + 308 pp. 14½ × 22½ cm. Price $6.00.

An introductory text book for students with limited backgrounds in organic chemistry and biology is presented. Emphasis has been placed upon the simplicity of the presentation though the more complex formulas and structures are included where necessary. The book appears to be too brief and superficial for most needs of pharmacy students.

Book Notices

Tropical Therapeutics: Its Pharmacologic Aspects. By ROGER A. LEWIS. Charles C Thomas, Publisher, 301-327 East Lawrence Ave., Springfield, Ill., 1963. x + 276. 14½ × 22½ cm. Price $11.50.

A general pharmacology text is presented which emphasizes drugs likely to be employed in treating diseases in the moist tropics and hot arid zones. Dr. Lewis has had considerable experience in Ghana and India and while he does include general chapters on pharmacology and its relationship and application to drug therapy, the most valuable contribution will be concerning tropical therapy. It seems to be more suitable as a medical student's guide in clinical practice in a tropical area.

The *Journal of Pharmaceutical Sciences* is published monthly by the American Pharmaceutical Association, at 20th & Northampton Sts., Easton, Pa. Second-class postage paid at Easton, Pa., and at additional mailing office.

All expressions of opinion and statements of supposed fact appearing in articles or editorials carried in THIS JOURNAL are published on the authority of the writer over whose name they appear, and are not to be regarded as necessarily expressing the policies or views of the American Pharmaceutical Association.

Offices—Editorial, Advertising, and Subscription Offices: 2215 Constitution Ave., N. W., Washington, D. C. 20037. Publication Offices: 20th & Northampton Streets, Easton, Pa.

Annual Subscription—United States and foreign, $15.00; single copies. $1.50; combined rate with the *Journal of the American Pharmaceutical Association*, $20.00. Subscription rates are subject to change without notice. Members of the American Pharmaceutical Association may elect to receive the *Journal of Pharmaceutical Sciences* as a part of their annual $27.00 A.Ph.A. membership dues.

Claims—Missing numbers will not be supplied if claims are received more than 60 days after the date of the issue, or if loss was due to failure to give notice of change of address. The Association cannot accept responsibility for foreign delivery when its records indicate shipment has been made.

Change of Address—Members and subscribers should notify at once both the Post Office and the American Pharmaceutical Association, 2215 Constitution Ave., N. W., Washington, D. C. 20037, of any change of address.

The Editor comments

OF WHAT SIGNIFICANCE STATISTICS?

We have been pleased to note that a greater appreciation of the usefulness and value of statistics is gradually evolving in the scientific community. Perhaps the greatest impetus for this awakening comes from the field of clinical testing. By applying proven, reliable statistical methods, test data which on first glance appeared to lead to certain conclusions have been shown to be of highly dubious worth; conversely, in other cases, the opposite sometimes has been true. And more recently, the same or similar mathematical principles have been applied to the disciplines of analytical chemistry, bacteriology, and pharmacology, to name just a few.

The utilization of this valuable tool has been fostered in a number of ways. Many colleges are offering introductory and even advanced courses in statistics to regular day students, and evening lectures to those who wish to further their education while engaged in full-time employment. A number of larger industrial concerns have made arrangements for in-plant lecture courses by qualified instructors so as to provide their employees with the opportunity to study the fundamentals of this subject. And many of our ambitious colleagues, armed with one or two textbooks on statistics, have gained a reasonably good grasp of the principles, solely through home study.

Unfortunately, however, some workers have become overly enthusiastic following their introduction to this science. Like a child with a new toy, they employ it with neither discrimination nor discretion. It is our opinion that if the data obtained from a certain study are too meager to warrant publication, then dressing up the results with mathematical trimmings will not transform the material into a first-rate manuscript. Furthermore, it is not necessary to belabor the obvious. If in an experiment with 50 mice, all 50 died, statistics generally will add nothing to the interpretation.

For the most part, however, the science of statistics has proven to be a very worthwhile aid with much of the work currently in progress both in university and industrial laboratories. We confidently expect that as it becomes better known and understood, it will come to serve us even more, and will take a prominent place among the other indispensible tools of the pharmaceutical scientist. The more prudently statistics are applied, the sooner this day will come.

Review Article

Column Partition Chromatography in Pharmaceutical Analysis

By JOSEPH LEVINE

PERHAPS THE MOST widely applied separation process used in the analysis of pharmaceutical products is liquid-liquid extraction, wherein a solute is distributed between two immiscible phases. Its concentration in each of the two phases at equilibrium is governed by its distribution coefficient. Partition chromatography may be regarded as an extension of conventional liquid-liquid extraction, in which one of the two liquid phases is present in the form of a film sorbed by particles of an inert support. A very large surface area is required to reach equilibrium within a reasonable time interval, since interphase transfer of solute takes place at the liquid-liquid interface. The large surface area is furnished by the finely divided particles of the support.

The support is variously referred to as the solid phase, the supporting phase, the supporting medium, or the inert phase; the sorbed liquid is known as the immobile phase, the internal phase, the nonmobile phase, or the stationary phase; and the second liquid phase is termed the mobile phase, the developing solvent, or the eluant.

Column chromatography has been defined as "uniform percolation of a fluid through a column of more or less finely divided substance, which selectively retards certain components of the fluid" (1). Cassidy (2) defines partition chromatography as "a method of separating substances by distributing them between two liquid phases, one of which is mobile and the other essentially fixed by sorption to a support." He does not, however, restrict the process to liquid-liquid distribution; he states that "the support itself may or may not be active in the separation process." Catch, *et al.* (3), said that "doubtless the process (occurring on the column) is a combination of 'chemical' chromatography and 'partition' chromatography."

Meinhard (4) attributed to the supporting material a major role in the separation process. According to him, a layer of adsorbed liquid at a solid-liquid interface may extend to a depth of 100 molecules or more if the solid is "wetted" by the liquid. The structure of the adsorbed layer is modified to various degrees by the adsorbent. Therefore the liquid layer does not behave as an independent entity during the chromatographic process; the stationary phase is comprised of the layer of liquid as modified by the adsorbent. Hence the difference between ordinary chromatography and partition chromatography depends primarily on the media. Büchi and Soliva (5), on the other hand, exclude the effect of the support. They state that partition chromatography is not concerned with the equilibrium between adsorbed and dissolved material, but only with an equilibrium of dissolved material in two solvents which are immiscible or of limited miscibility.

The concept of partition chromatography was introduced in 1941 by Martin and Synge (6) during an investigation of the amino acid composition of wool. Initially they used a 40 stage countercurrent extraction apparatus to separate

Received from the U. S. Department of Health, Education, and Welfare, Food and Drug Administration, Bureau of Biological and Physical Sciences, Division of Pharmaceutical Chemistry, Washington 25, D. C.

the acetylated amino acids (7). In seeking mechanical means to simplify this process, they sorbed the aqueous phase on finely divided silica gel and packed the mixture in a glass tube. By this means, one of the liquid phases was retained in a rigid position, while the second liquid phase simply percolated through it, making contact in passing.

Martin and Synge visualized the chromatographic column as a number of separate and consecutive regions, in each of which equilibrium of the solute is attained between the mobile and immobile phases. Thus each region or "theoretical plate" is equivalent to a separate vessel of a countercurrent extraction apparatus. In practice, they found that a column 20 cm. in length gave a separation equivalent to that of over 1000 theoretical plates.

In their characterization of the column as a series of "theoretical plates," Martin and Synge presented a mathematical analysis of the process which occurs on the column. In a column having a large number of theoretical plates, they let r = the serial number of the plate, Q_r = the quantity of solute in plate r, v = the volume of solvent used in the development of the chromatogram, α = the equilibrium partition coefficient of the solute = concentration in nonmobile phase/concentration in mobile phase, A = area of column, A_s = area of nonmobile phase, A_L = area of mobile phase, h = height of equivalent theoretical plate, $V = h(A_L + \alpha A_s)$, and R = (movement of band of maximum concentration)/(movement of mobile solvent).

Considering the case where a unit mass of a single solute is put onto the first plate and then followed by pure solvent, they constructed a table showing the quantity of solute in each plate after successive infinitesimal volumes of mobile phase have passed through. From this they showed that the quantity of solute in each plate is given by

$$Q_{(r+1)} = \frac{1}{\sqrt{2\pi r}} (v/rV)^r e^{r-v/V}$$

When $v/rV = 1$, $Q_{(r+1)}$ is a maximum and equal to $1/\sqrt{2\pi r}$ so that the position of maximum concentration has moved a distance hv/V directly proportional to the volume of liquid, v, which has passed through.

Now

$$R = \frac{hv/V}{v/A} = \frac{Ah}{V} = \frac{A}{A_L + \alpha A_s}$$

Then the partition coefficient, α, is $A/RA_s - A_L/A_s$. Martin and Synge found that partition coefficients calculated by this formula agreed closely with the values obtained by conventional procedures. They plotted a curve showing the ideal separations attainable by partition chromatography and discussed the factors contributing to deviations from their theoretical values. The principal source of the deviation is adsorption of solute by the supporting material. Among the other causes are diffusion of the mobile phase, which is affected by temperature, rate of flow, and changes in partition coefficient with change in concentration. Interaction of two solutes, with the more strongly adsorbed solute "eluting" the less strongly adsorbed, can result in separations better than theoretical.

Craig (8) did not accept the correlation between liquid-liquid partition ratios and rates of migration of bands on a column to be proof that partition chromatography is a liquid-liquid extraction process. He believed that "at best this evidence is only circumstantial, and probably reflects more the uniform shift in nearly any physical property in a homologous series than the particular property responsible for such an observed effect." He found the results of partition chromatography to be of very little use in selecting systems for countercurrent distribution. He stated that "certainly, the difference between countercurrent distribution and so-called partition chromatography is much greater than that between Tswett (adsorption) chromatography and partition chromatography. In fact there seems little to be gained by assuming that liquid-liquid partition plays any significant role in the latter process." Subsequent developments in partition column techniques support the interpretation of Martin and Synge. Separations based upon the degree of ionic dissociation, as discussed below, are patently liquid-liquid partition phenomena. The contribution of adsorption is subordinate and merely a complicating factor in these separations.

METHODOLOGY

Commercial silica, designated by Martin and Synge (6) as "pure precipitated" silica, was used as the supporting phase in the introductory application of column partition chromatography. Even in the initial publication on this technique, however, it was noted that separate lots of silica vary significantly with respect to their adsorptive power and their capacity for sorption of water. Several procedures have been reported for pre-

paring and standardizing silica gel suitable for use as a support (6, 9–12). Isherwood (13) and Resnik, *et al.* (14), described purification processes designed to decrease the adsorptive properties of the material.

A number of other materials have been used instead of silicic acid. Synge (15) and Elsden and Synge (16) used raw potato starch as the supporting medium for the aqueous phase. Various forms of cellulose have been used in column partition chromatography as well as in paper chromatography. In a note, Gordon, *et al.* (17), referred to the use of cellulose powder. Hough, *et al.* (18), prepared powdered cellulose by rubbing ashless filter tablets through an 80-mesh sieve. Baker, *et al.* (19), and Brindle, *et al.* (20), used Solka-Floc, a commercial powdered cellulose. Mitchell and Haskins (21) used a pile of 40 circles of filter paper as a column. Stoll and Kreis (22) used cotton linters, which are minute fibers of almost pure cellulose. In a discussion of the nature of supporting material, Martin (1) observed that the initial concept of cellulose as a completely inert support for aqueous phase has changed in favor of one considering the hydrated cellulose to be a strong polysaccharide solution or a complex gel. He concluded that the most ideal partition effect is achieved with siliceous earth (kieselguhr, diatomaceous earth, infusorial earth).

The first use of this material as supporting phase was reported by Catch, *et al.* (3), who used Hyflo Super-Cel[1] in the separation of the penicillins. The use of Celite[1] 545, which is now probably the most widely used supporting phase, was introduced by Peterson and Johnson (23). Other grades of Celite (503 and 535) have been used (24, 25). In a number of publications the material is simply termed "kieselguhr," with no further reference to its identity, source, or quality.

Hegedüs, *et al.* (26), washed Hyflo Super-Cel with a series of organic solvents to remove extractable impurities. Carol, *et al.* (27), removed alkaline buffering impurities of Celite 545 by an acid treatment. An acid-washed Celite 545 is now commercially available.

Stoll and Kreis (22) prepared "diatom stone" (diatomitstein) for use as support by calcination of a mixture of kieselguhr and clay. Chilton and Partridge (28) used 60-mesh Pyrex glass powder as support in the separation of the pomegranate alkaloids.

Although siliceous earth has a much lower adsorptive capacity than silicic acid, losses of alkaloid due to adsorption on this support have been reported (28, 29). Modification of the immobile phase (30) or of the mobile phase (31) has been very effective in eliminating this loss by adsorption. Graf (32) used activated alumina as supporting phase, but he recognized that the process occurring on the column was not simple partition chromatography.

Celite 545 is the most uniform in particle size of the siliceous earths commercially available in this country. The particle size of Celite 545 is 20–40 μ; of Celite 535, 10–40 μ; of Celite 503, 6–40 μ; of Hyflo Super-Cel, 2–20 μ (33).

Howard and Martin (34) modified kieselguhr to permit "reverse phase" partition chromatography. They treated Hyflo Super-Cel with dimethyldichlorosilane, thereby attaching hydrophobic alkyl groups to the surface of the particles. Using this modified material, a nonpolar organic solvent which is normally used as mobile phase may be used as immobile phase, while an aqueous solution of a polar solvent becomes the mobile phase. Boldingh (35) used a column of powdered vulcanized rubber, partly swollen by treatment with benzene. The rubber functions as both supporting phase and immobile phase.

Water was used as immobile phase in the initial applications of partition chromatography (6). Catch, *et al.* (3), used a solution of alkali carbonate. Following this, various aqueous solutions were substituted for water as immobile phase. Isherwood (13) used 0.5N sulfuric acid to suppress the ionization of weak organic acids. Peterson and Johnson (23) used 27 N to 35 N sulfuric acid, and Graham (36) used concentrated hydrochloric acid. Ferric chloride solution was used (37) to achieve complexation with phenolic compounds.

Nonaqueous fluids may also be used as immobile phase in partition chromatography, in conjunction with immiscible organic solvents. Among those which have been used are nitromethane (38), propylene glycol (19), formamide (39), absolute ethanol (40), and a mixture of concentrated and fuming sulfuric acid (41).

A solution of the sample itself may be used as immobile phase in the partition column, eliminating a preliminary extraction step. Graf (32) and Schill and Ågren (42) added sufficient supporting phase material directly to an aqueous extract of alkaloid-bearing plant material to sorb the liquid. Baker, *et al.* (19), mixed Solka-Floc with an oil solution of adrenocorticosteroids. Banes (43) extended this mode of sample preparation to drugs in various dosage forms.

The apparatus used in partition chromatog-

[1] Marketed by Johns-Manville Corp.

raphy may be quite simple. It requires only a glass tube to which an outlet tube is attached. Flow of the mobile phase may be regulated by a stopcock or by a screw clamp on rubber tubing attached to the outlet tube. A support is generally placed at the lower end of the column to retain the column packing. This may be a perforated or a sintered disk, either sealed in or fitted, or it may be a simple wad of cotton or glass wool. Although catalogs of most laboratory equipment suppliers list chromatographic columns with stopcocks, disks, and ground glass connections, the simple column without such fittings is not commercially available at this time.

Several procedures have been described for mixing the immobile phase with the support and for packing the column with this mixture. The immobile phase may be added directly to the solid (6) or to a stirred suspension of the supporting phase in immobile solvent (44). In preparing columns using silica gel, Fischbach, *et al.* (11), determined the ratio of immobile phase to support by adding the fluid to the solid in small increments, mixing after each addition until the mixture became sticky and began to "ball." They then used 5 to 10% less immobile phase than this quantity to prepare the column. Haenni, *et al.* (45), found that a ratio of slightly less than 1 ml. of aqueous immobile phase per gram of Celite 545 is about the correct proportion to prepare a pack with suitable physical characteristics. However, satisfactory separations have been reported (37) with a ratio of 7 ml. of aqueous phase to 5 Gm. of Celite 545. Chilton and Partridge (28) found that 7 Gm. of powdered glass was required to support 1 ml. of aqueous phase.

A number of variaitons in the preparation of the columns have been described. Martin and Synge (6) transferred a slurry of the prepared mixture in chloroform to the column in small portions. As the chloroform ran through, the gel, which floated in the chloroform, packed down and did not refloat during addition of further amounts of slurry. Ramsey and Patterson (12) applied compressed air at a definite pressure to pack the mixture, while Bergström and Sjövall (46) applied reduced pressure at the outlet of the column. Many authors stipulate that a head of fluid be maintained above the packing. Graf (32) simply transferred the prepared mixture to the empty column and compressed it by tamping with a glass rod.

For the resolution of compounds which have relatively small differences in partition coefficients, it is essential that the column be carefully and uniformly packed. This high degree of uniformity in the column packing is not necessary for the resolution of mixtures which are separated because of relatively wide differences in their solubility characteristics, their ionic species or their ionic strengths. Nevertheless, many published analytical procedures which are based upon these properties have specified the preparation of the very meticulously packed column, although the same results can be obtained with a very simple, rapidly prepared column. (Compare, *e.g.*, References 47 and 48.)

The rate of elution or development may be controlled in several ways. The mobile phase may flow over the partition column by gravity, with the aid of air pressure above the column, or by connecting the outlet of the column to a suction flask and applying reduced pressure. The rate of flow may be controlled by the amount of pressure or vacuum applied, with a stopcock or a screw-clamp on tubing attached to the outlet of the column, by the height of the head of fluid above the column, or by the density of the column packing. Rates of flow of mobile solvent have been reported over a range of from $1^1/_4$ ml. per hour (26) to 10 ml. per minute (49). Haenni, *et al.* (45), discuss critically the factors involved in determining optimum flow rate. The same authors describe an apparatus for obtaining a highly uniform flow rate throughout the development of the chromatogram (44).

TECHNIQUES

Partition chromatography was first conceived as a form of countercurrent distribution. Most of the early applications of the technique were designed to achieve separations based on relatively small differences in distribution coefficients. It was soon found that processes other than simple countercurrent extraction can be conducted very conveniently and efficiently on the partition chromatographic column. These range in complexity from the isolation of a single substance from its dosage form to the conducting of a chemical reaction on the column in the immobile phase. Frequently the modifications of the partition process were patterned on techniques used in adsorption chromatography, but many were designed specifically for the partition column. In adsorption chromatography, a mixture of materials may be selectively desorbed by changing solvents after the elution of the first component. In partition chromatography, the same process is applied to substances having significantly different partition coefficients. This

procedure was introduced by Evans and Partridge (50), who separated hyoscine and hyoscyamine on a *kieselguhr:pH 6.2 buffer* column,[2] eluting the hyoscine with ether and the hyoscyamine with chloroform. Marvel and Rands (51) used mixed solvents as eluant, increasing the proportion of polar solvent stepwise; Donaldson, *et al.* (52), devised an apparatus for achieving this increase continuously.

The influence of buffers upon the separation of substances which form dissociable salts has been discussed by several investigators. Jensen and Svendsen (53) showed that while strychnine and brucine cannot be separated by elution from a column in which water is immobile phase, they are readily separated if buffers at pH 7 or lower are used.

The relationship between degree of dissociation and rate of elution is derived from the equation (54): $\log \alpha' = \log \alpha + \text{pH} - \text{pK}$, where α' is the partition coefficient of the dissociated compound, α is the partition coefficient of the undissociated compound, and K is the dissociation constant.

Büchi and Soliva (5) point out that the partition coefficient of a weak acid or base in a buffer solution is a simple function of pH. In an extension of this equation to encompass mixtures of bases, they showed that, at a constant pH, the degree of separation which is achieved conforms to

$$\beta = \frac{\alpha' B_1}{\alpha' B_2} = \frac{\alpha B_1}{\alpha B_2} \cdot \frac{K B_2}{K B_1}$$

where β is termed the "separability factor" and B_1 and B_2 are weak bases. Bettschart and Flück (55) treated the subject in a similar manner. Bottomley and Mortimer (56) stated that alkaloids are eluted from a buffered column in order of their $\text{pH}_{1/2}$ values (where the term $\text{pH}_{1/2}$ designates the pH at which $\log \alpha' = 0$; *i.e.*, the compound is distributed equally in the two phases).

Schill and Ågren (42) performed on the partition column the counterdistribution of a base between an organic solvent and aqueous acid or alkali, which constitutes the basis of the classical alkaloidal assays. They used 0.5 *M* H_3PO_4 as immobile phase to trap the alkaloids from ether solution while neutral or acidic components passed through the column. They then transformed the immobile phase to an alkaline pH *in situ* with ammonia-saturated chloroform, which eluted the alkaloid as the liberated free base. Solutions of diethylamine in ether (57) and of triethylamine in chloroform (58) have been used for the same purpose. Bitman and Sykes (25) bubbled gaseous carbon dioxide onto a column containing sodium hydroxide as immobile phase to convert it to sodium bicarbonate.

Carless (57) changed the pH of the buffer used as immobile phase gradually and continuously, progressing from pH 3.0 to pH 4.8 by adding 0.1% pyridine to the developing solvent. He considered this process analogous to gradient elution methods, since a pH gradient existed down the column. To achieve the inverse process, acidification of an alkaline immobile phase *in situ*, a chloroform solution of glacial acetic acid has been used (59).

Multistage columns to separate mixtures of drugs (59) have been reported. Separate stages having acid and alkali as immobile phase were used either as layers in the same column or in separate columns arranged in series (58). These layers "trap" alkaloidal or acidic drugs as their water-soluble salts from solution in the nonaqueous mobile phase. The separated drugs were recovered after reversal of the pH of the immobile phase as described above.

PROCEDURES

Steroids.—Column partition chromatography has been widely used in the separation of the steroid hormones, particularly the estrogenic steroids. Nyc, *et al.* (60), separated estriol, estradiol, and estrone by reverse-phase partition on a rubber column. The stationary phase was powdered rubber swollen in 10% methanol saturated with benzene. A mixture of the estrogens in 20% methanol was passed onto the column; estriol was eluted with this same solvent. Estradiol was removed with 40% methanol, and estrone with 60% methanol. Swyer and Braunsberg (61), using a column of *Celite 535:2.3 N sodium hydroxide*, with benzene as eluant, separated estrone and estradiol in order; estriol remained on the column. Stern and Swyer (62), using the same system, successfully eluted the estriol with chloroform-butanol (3 + 1). Haenni, *et al.* (45), described in detail the optimum conditions for quantitative separation of estrogenic diols. They used Celite 545 as support and 0.4 *N* sodium hydroxide as stationary phase. This concentration of sodium hydroxide was selected as requiring the minimum volume of developing solvent to achieve a desired degree of separation of β-estradiol from α-dihydroequilin. They weighed the importance of temperature, flow rate of eluant, ratio of immobile to mobile phase, and degree of pack-

[2] This terminology will be used to designate the supporting phase: immobile phase combination.

ing of the column as factors in the separation. The effect of temperature is twofold. The partition coefficients of the diols change at different rates with temperature, and the band volume of the individual compound varies inversely with temperature. Two columns were described. The estradiols and dihydroequilins as a group were separated from the dihydroequilenins on one and the estradiols were separated from α-dihydroequilin on the second. They defined the volume of mobile solvent required for the elution of each component, giving the correction of these volumes for variations in temperature. The same authors (44) described the analysis of commercial estrogenic preparations, including oil solutions, tablets, and suspensions. The mixture of α-dihydroequilin and α- and β-estradiol was separated from nonestrogenic impurities, traces of estrone and equilin, and the dihydroequilenins, and the individual components of the mixture were determined by a differential colorimetric procedure. A collaborative study (63) of the combined chromatographic separation and colorimetric procedure was conducted for the determination of the physiologically active estradiol-17β. (At the time of publication the configurations of the estradiols had not been established. It was later shown that the compound then referred to as α-estradiol is actually estradiol-17β.)

Bitman and Sykes (25) separated estrone, estradiol, and estriol in a two-step operation. They eluted estrone and estradiol successively with benzene from a column of sodium hydroxide on Celite, in a procedure analogous to those described above. The more strongly acidic estriol was not eluted under these conditions. After the pH of the immobile phase was lowered by bubbling carbon dioxide over the column, benzene eluted the liberated estriol.

Carol, *et al.* (64), described the preparation of the previously unreported diol, β-dihydroequilin. They reduced the ketosteroid equilin with aluminum isopropoxide to a mixture of α- and β-dihydroequilin, and separated the two isomers on a *Celite:0.4 N sodium hydroxide* column similar to that described above. The β-isomer was eluted with benzene and the α-isomer with ether. Using the same partition system, Banes, *et al.* (65), resolved the "isoequilin A" of Hirschman and Wintersteiner (66) into two major constituents, 8-dehydro-14-isoestrone and 9-dehydro-14-isoestrone. They also isolated the latter compound from equine pregnancy urine extracts.

Beall and Grant (67) showed that the water-soluble conjugated estrogens in concentrates prepared from equine pregnancy urine can be extracted with chloroform from aqueous solution as their cyclohexylamine complexes. However, troublesome emulsions frequently formed during the extraction with conventional liquid-liquid extraction techniques. Carol, *et al.* (68), employed partition chromatography for the extraction. They mixed the sample with Celite 545, added water to dissolve the conjugated estrogens in the preparation and simultaneously constitite an immobile phase, and transferred the mixture to a column. Chloroform eluted the nonconjugated estrogenic materials, together with extractable impurities from the urine concentrate and the soluble tablet excipients. This elution was followed by a chloroform solution of dicyclohexylamine acetate which eluted the chloroform-soluble complex. Graham (69) later found that chloroform eluted significant proportions of conjugated estrogens from tablets containing surface-active agents in their formulations, and substituted ether for chloroform as pre-wash. A mixture of ether and methylene chloride was used to dissolve the dicyclohexylamine acetate and elute the conjugated estrogen complex. In an extension of this procedure, Graham (36) passed the elute containing the conjugated estrogen-dicyclohexylamine complex directly onto a second column, in which concentrated hydrochloric acid is the immobile phase. In a single operation the complex is dissociated, the conjugated estrogen cleaved, and the liberated estrogen eluted.

Snair and Schwinghamer (70) employed partition on *Celite 545 : polyethylene glycol 600* for the assay of estradiol propionate in oil solution. Without the chromatographic purification, sterols present in the oil base interfered with the colorimetric determination of the liberated estradiol. They reported analyses of about 115% for samples in sesame oil and of about 90% for solutions in corn, cottonseed, or peanut oil. After the purification, recoveries in the range of 99.6% to 102.4% were obtained for all samples.

Wolff (71) used a *Celite 545:nitromethane* column, with *n*-heptane as mobile phase, in the quantitative determination of progesterone in oil. Chromatography yielded pure progesterone uncontaminated by oil constituents.

Butt, *et al.* (72), separated progesterone, desoxycorticosterone, and testosterone on a Hyflo Super-Cel column, using 70% methanol as stationary phase and *n*-hexane as mobile phase.

Carol (73) used Celite 545, with 80% ethanol as stationary phase and iso-octane as mobile phase, for the quantitative separation of progesterone and testosterone in commercial aqueous suspensions.

Katzenellenbogen, *et al.* (40), separated androsterone and 5β-androsterone on a silica gel column, using absolute ethanol as immobile phase and petroleum ether–methylene chloride (1:1) as eluant. Bergström and Sjövall (74) employed reverse-phase partition to separate the cholic acids. They used siliconized kieselguhr, prepared as described by Howard and Martin (34), as supporting phase, chloroform-heptane (9 + 1) as immobile phase, and 58% methanol as mobile phase. Cholic acid, deoxycholic acid, and lithocholic acid were eluted in order, with recoveries of 70 to 90%. Hauton (75) applied gradient elution to the same separation. Siliconized kieselguhr was used as support and chloroform–*sec*-octanol (1 + 1) as immobile phase. The mobile phase entered the column from an apparatus consisting of two reservoirs, one containing methanol and the other water, delivering a mixture with a continuously increasing concentration of water. Sharp separations of cholic, deoxycholic, and lithocholic acids were obtained, with recoveries of 97 ± 2%.

Baker, *et al.* (19), isolated steroids from a hog adrenal extract, using Solka-Floc as support, propylene glycol as immobile phase, and toluene as mobile phase. They mixed the extract with Solka-Floc and placed it above the propylene glycol segment of the column. The oily components were eluted initially, followed by cortisone and hydrocortisone. Haines (76) used a *silica gel*:*ethylene glycol* column, with cyclohexane–methylene chloride as mobile phase, to separate (in order) 11-desoxycorticosterone, corticosterone, cortisone, and hydrocortisone. Heftmann and Johnson (77) separated 11-desoxycorticosterone, 11-dehydrocorticosterone, cortisone, hydrocortisone, and Δ-4-pregnene-17α, 21-diol-3,20-dione, on a *silicic acid*:*water* column. They used as developing phase petroleum ether mixed with increasing proportions of methylene chloride, added as described by Donaldson, *et al.* (52). Morris and Williams (78) separated corticosteroids from lipids by reverse-phase chromatography, using petroleum ether as immobile phase on siliconized Celite with 50% methanol as mobile phase. The initial eluate contained a mixture of 11-dehydrocorticosterone, corticosterone and cortisone, and the next fraction contained a mixture of cortisone and hydrocortisone. These were further resolved on a *Celite*:*ethylene glycol* column, with petroleum ether–toluene (2 + 8) as mobile phase.

Banes (79) described a procedure for the complete chemical assay of adrenal cortex extracts in their commercial dosage forms. Two columns were employed for the complete separation of the steroids. In the first column, Celite 545 was the support, formamide-water (1 + 1) the immobile phase, and benzene the mobile phase. The first fraction of eluate contained a mixture of 11-dehydrocorticosterone and corticosterone, the second fraction cortisone, and the final fraction hydrocortisone. The mixture of 11-dehydrocorticosterone and corticosterone was completely resolved upon the second column in which formamide-water (4 + 1) was immobile phase on Celite and benzene-isooctane (3 + 2) the mobile phase. In evaluating the procedure he obtained recoveries of 95 to 102% from a mixture of 1 to 2 mg. of each of the four compounds.

Jones and Stitch (80) separated dehydroepiandrosterone from epiandrosterone on a *silicic acid*:*nitromethane* column, using 3% chloroform in petroleum ether as mobile phase.

Stoll and Kreis (22) applied partition chromatography to the separation of the squill glycosides. They used cotton linters as supporting phase, water as immobile phase, and ethyl acetate as mobile phase. Hegedüs, *et al.* (26), chromatographed the strophanthus glycosides on *Hyflo Super-Cel*:*water*, with mobile solvents of increasing polarity, progressing from petroleum ether-benzene to chloroform. They isolated several new glycosides.

Banes and Carol (81) described a procedure for the quantitative determination of digitoxin, gitoxin, and digitoxigenin in digitoxin tablets. They used a mixture of formamide and water (2 + 1) as immobile phase on Celite 545. An extract of the sample was added to the column and the chromatogram was developed with chloroform-benzene (1 + 9). The forerun contained digitoxigenin, which was followed by digitoxin. To recover gitoxin, they extruded the column contents into a separator and extracted the gitoxin with chloroform. Recoveries of 95.6 to 102.3% of standard preparations were obtained. In a modification of this procedure (43), a solution or suspension of the sample itself in formamide-water was used as immobile phase. Iso-octane was used to elute digitoxigenin, benzene-chloroform (3 + 1) the digitoxin, and chloroform the gitoxin. The gitoxin content of digoxin preparations was determined (82) by converting it to dianhydrogitoxigenin and

isolating it by elution with iso-octane from a *Celite:50% ethanol* column.

Antibiotics.—Among the earliest applications of partition chromatography was the separation of the penicillins. Catch, *et al.* (3), used a solution of an alkali carbonate with either silicic acid or Hyflo Super Cel as support. Ether or amyl acetate was the mobile phase. Fischbach, *et al.* (83), separated penicillin K quantitatively from mixtures with the other penicillins, on a column of *silicic acid:20% phosphate buffer at pH 6.4*, using ether as mobile solvent. The same authors (11) separated penicillins K, dihydro F, F, and G using a similar system. Recoveries of known mixtures were 99% for penicillin K, 82% for penicillin dihydro F, 99% for penicillin F, and 98% for penicillin G. Low recoveries of penicillin dihydro F (80–85% in all cases) was attributed to destruction during the treatment. Higuchi and Peterson (84) identified the individual penicillins in mixtures by hydrolyzing them to obtain their characteristic acids and separating the acids on Celite columns. Either 30 *N* sulfuric acid or a mixture of sulfuric and phosphoric acids (8 + 11) was used as immobile phase and benzene as mobile phase.

Higuchi, *et al.* (85), separated intact chloramphenicol from its degradation products, eluting the latter from a *silica gel:water* column with chloroform and the intact antibiotic with chloroform–ethyl acetate (2–10%).

Analgesics.—Higuchi and Patel (86) applied partition chromatography to the analysis of mixtures of acetylsalicylic acid, acetophenetidin, and caffeine. After removing the acetylsalicylic acid in a separator, they separated the other two components on a column of 20 Gm. of silicic acid and 20 ml. of water. Chloroform–isopropyl ether (1 + 3) was used to elute the acetophenetidin, and chloroform to elute the caffeine. Smith (87) used Celite 545 as support and chloroform-ether (1 + 9) as eluant for the same separation. Banes (43) used a column segment of 5 ml. of 2 *N* hydrochloric acid on 5 Gm. of Celite 545 for the separation. Above this was placed a segment prepared by mixing 6 Gm. of Celite with 6 ml. of a solution of the caffeine and acetophenetidin in formamide-water (2 + 1). Ether was used for elution of the acetophenetidin and chloroform for the caffeine. Levine (59) used a two-stage column to separate the three components without prior extraction of acetylsalicylic acid. The first stage, 2 ml. of 4 *N* sulfuric acid on 2 Gm. of Celite, trapped caffeine from an ether solution, and the second stage, 2 ml. of 1 *N* sodium bicarbonate on 2 Gm. of Celite, trapped acetylsalicylic acid as its salt. Ether eluted the neutral acetophenetidin and chloroform the caffeine. To recover the acetylsalicylic acid, the bicarbonate stage was acidified *in situ* with a solution of acetic acid in chloroform, and the liberated acetylsalicylic acid was eluted with chloroform. The caffeine and acetylsalicylic acid eluates were received directly in volumetric flasks and their concentrations measured spectrophotometrically, without further treatment. Indemans and Mulder (88) substituted 4 *N* sodium hydroxide for the 1 *N* sodium bicarbonate to increase the capacity of the column, in order to chromatograph samples large enough to permit gravimetric measurement. Stroes (89) reported that the 50 ml. of chloroform specified by Levine is insufficient to elute the caffeine quantitatively, and that 100 ml. is necessary. In a collaborative study of the procedure conducted by Smith (90), however, quantitative recoveries with the specified volumes of eluants were obtained.

Heuermann and Levine (58) separated combinations of acetylsalicylic acid, acetophenetidin, and caffeine with codeine, antihistamines, and/or barbiturates, using multiple columns. For the combinations with codeine or the antihistamines, the sodium bicarbonate and sulfuric acid stages were placed in separate columns arranged in such a manner that effluent from one ran directly onto the second. After elution of the acetylsalicylic acid, acetophenetidin, and caffeine exactly as in the procedure for this combination alone, the codeine or antihistamine was eluted after conversion from its salt to the chloroform-soluble free base with a solution of triethylamine in chloroform. For combinations with barbiturates, a third column, with tripotassium phosphate solution as immobile phase, was placed in series between the sodium bicarbonate and the sulfuric acid columns. The very weakly acidic barbiturate passed through the sodium bicarbonate column, but was held on the more strongly alkaline tripotassium phosphate column, while the other components passed through. The barbiturate was eluted after acidification of the column with acetic acid in chloroform.

To separate acetophenetidin from isopropylantipyrine, Indemans and Mulder (88) suspended the mixture in 4 *N* sulfuric acid, precipitated the isopropylantipyrine with potassium ferrocyanide, added Celite, and transferred the mixture to a column. Ether eluted the acetophenetidin alone.

The separation of caffeine from acetophenetidin by the procedure of Higuchi and Patel (86) is based upon partition of caffeine between water, the immobile phase, and the mobile phase. It is for this reason that the relatively long column, containing 20 ml. of immobile phase, is required. In the procedure of Levine (59), on the other hand, the separation is based upon salt formation. Caffeine, while feebly basic, will form salts with strong acids; therefore only 2 ml. of immobile phase is sufficient to trap the caffeine as its salt from ether solutions. If a less concentrated acid (*e.g.*, 2 *N* sulfuric acid) is used, the caffeine is not quantitatively retained; if a more concentrated acid (*e.g.*, 6 *N* sulfuric acid) is used, the caffeine is not eluted quantitatively by the specified volume of chloroform.

The procedure for the analysis of acetylsalicylic acid combinations was adapted to apply to the analysis of acetylsalicylic acid in its various dosage forms, including flavored, colored, buffered, and enteric-coated tablets (37). The same publication describes the determination of the free salicylic acid content of acetylsalicylic acid. Ferric chloride solution is used as immobile phase to retain salicylic acid as its complex while acetylsalicylic acid, which has no phenolic hydroxyl group, passes through. In this separation, only dilute solutions of ferric chloride will remove salicylic acid from chloroform, and acetylsalicylic acid removes ferric chloride from the column as the chloroform-soluble salt. A balance must therefore be maintained to provide a sufficiently low concentration of ferric chloride to trap the salicylic acid, and at the same time provide a sufficiently large quantity to insure an excess over that removed by the acetylsalicylic acid. For a 200-mg. sample, an effective balance was achieved by using 5 Gm. of Celite and 7 ml. of 2% ferric chloride solution. The salicylic acid remains on the column as its purple ferric ion complex. The salicylic acid is eluted after the complex is dissociated with a solution of acetic acid in chloroform.

Barbiturates.—In a procedure for the determination of phenobarbital in mixtures with salicylates (91), a chloroform solution of the mixture is passed over a *Celite 545:2 M dipotassium phosphate* column. The salicylates remain on the column while phenobarbital passes through. Byers (92) applied this procedure to phenobarbital–acetylsalicylic acid combinations. Lach, *et al.* (93), used a column of pH 9.2 buffer on Celite 535 to separate diphenylhydantoin from phenobarbital. Chloroform eluted the diphenylhydantoin and butanol-chloroform (1 + 9) the phenobarbital. Recoveries of 99 to 100% were obtained. Sabatino (94) separated phenobarbital from other barbiturates (secobarbital, pentobarbital, amobarbital, or butabarbital) on a Celite column, using formamide-water (2 + 1) as immobile phase. Iso-octane–chloroform (1 + 1) eluted the barbiturate other than phenobarbital, and chloroform eluted the latter. Stroes (89) separated phenobarbital from aprobarbital on a Celite column with pH 9 buffer as immobile phase. Chloroform eluted the aprobarbital and ether the phenobarbital. The separation of barbiturates from combinations with acetylsalicylic acid, acetophenetidin, and caffeine (58) has been described above.

Alkaloids.—Graf (32) applied a combination of adsorption and partition chromatography to the assay of alkaloid-bearing crude drugs. Although adsorption has a much greater role in this procedure than in the others discussed in this review, sufficient features of partition chromatography are retained to warrant its inclusion. In this procedure, an alkaline aqueous suspension of the powdered crude drug, constituting the immobile phase, is stirred with sufficient activated alumina to prepare a dry mixture. The alkaloid is eluted with an immiscible solvent. Strong or weakly polar solvents may be used, depending upon the activity of the alumina. This procedure was used in the assay of lobelia, ephedra, nux vomica, hydrastis, cinchona, yohimbe, ipecacuanha, solanacea, and other drugs. In applying this procedure to opium, Graf found alumina to be too strongly adsorbent and substituted kieselguhr as supporting phase. Ethylene chloride was used to elute the alkaloids other than morphine, along with the coloring matter. The morphine was eluted with chloroform-isopropanol (3 + 1). When alumina was used as support, elution of the by-alkaloids and coloring matter with ethylene chloride was incomplete; these contaminated the morphine in the ensuing elution.

Belladonna Alkaloids.—Schill and Ågren (42) extracted belladonna alkaloids in a similar manner. They made the crude extract alkaline with sodium carbonate, sorbed the solution on kieselguhr, and packed the mixture in a column. They passed the chloroform eluate from this column, containing the alkaloids together with neutral extractives, over a second kieselguhr column in which 0.5 *M* phosphoric acid was immobile phase. This column retained the alkaloids, while the neutral components passed through. They eluted the alkaloids with

ammonia-saturated chloroform, which made the immobile phase alkaline *in situ*.

Atropine, in solutions containing phenol as preservative, has been separated from its hydrolytic product, tropic acid (95). Two columns were used in series. The upper contained the sample solution, made alkaline with sodium bicarbonate, as immobile phase on Celite 545; the lower column contained *Celite:0.2 N sulfuric acid*. Chloroform extracted the atropine and phenol from the upper column; the alkaloid was retained on the lower column, while phenol passed through. Tropic acid was eluted from the upper column with a solution of acetic acid in ether. To recover the atropine from the lower column, a segment of 1 Gm. of Celite and 1 ml. of concentrated ammonium hydroxide was added to the column, and chloroform was passed over it. The added segment was effective in saturating the chloroform with ammonia.

The combined effect of partition coefficient and dissociation constant upon the separation of alkaloids has been discussed above. Evans and Partridge (50) applied this effect to the separation of hyoscine and hyoscyamine. They used kieselguhr as support and, as immobile phase, a series of phosphate buffers ranging in pH from 6.2 to 7.4. The 6.2 buffer was most efficient in separating the two alkaloids. At this pH, the hyoscine is completely eluted with ether long before any hyoscyamine appears in the eluate. The latter is readily eluted with chloroform. The same authors (96) used pH 7.3 buffer to separate the alkaloids of Australian *Datura Ferox* and Indian henbane. Using ether as mobile phase, they eluted (in order) hyoscine, hyoscyamine, and metaloidine; chloroform then eluted tropine from extracts of the latter species. Evans and co-workers (97–100) isolated a number of alkaloids from the individual plant parts of several *Datura* species on *kieselguhr:phosphate buffer* columns at pH 5.4 to 6.6, using petroleum ether, ether, and chloroform as developing solvent. Santoro and Matz (101) separated the belladonna alkaloids from dosage forms containing chlorpheniramine and phenylpropanolamine, using a Hyflo Super-Cel column with pH 7.0 buffer as immobile phase. Chlorpheniramine was eluted with carbon tetrachloride–cyclohexane (1 + 1) and the belladonna alkaloids were eluted with chloroform. Phenylpropanolamine remained on the column.

Veratraea Alkaloids.—In a series of publications, Parks and associates described the application of partition chromatography to the separation of the sabadilla alkaloids. Hennig, Higuchi, and Parks (102) using *silicic acid:pH 8.5 phosphate buffer*, with chloroform containing 1–3% ethanol as mobile phase, separated the water-soluble sabadilla alkaloid group into five fractions, including the new alkaloid sabatine. Svoboda and Parks (103) prepared pure veratridine and cevadine by chromatography of a crude alkaloid mixture on *silicic acid:pH 4.0 or 4.25 buffer*. Stuart and Parks (104) chromatographed fractions obtained by countercurrent distribution on a *silicic acid:pH 5.0 buffer* column, with chloroform as eluant. They isolated the pure alkaloid vanilloylcevine. Mitchner and Parks (29) used two systems, silicic acid as support and pH 5.90 buffer with benzene as mobile phase, or pH 3.95 buffer with chloroform as mobile phase, in an investigation of the separation of veratridine and cevadine. They compared the chromatographic separations with those obtained by countercurrent distribution, and found that effects other than partition occurred on the column. They attributed this to the tailing effect due to adsorption.

Brown and Kupchan (24) incorporated bromthymol blue in the immobile phase of a Celite column to monitor the separation of the alkaloids, the location of the bands being shown by the indicator. The polar layer of an equilibrated mixture of ethylene chloride–Skellysolve B, methanol, and water (3 + 12 + 2 + 0.24) was used as immobile phase and the nonpolar layer as developing phase. They separated commercial "Veratrine" into two completely homogeneous bands, cevadine and veratridine. Using the same system, they obtained three bands from *Zygadenus paniculatus:* the first contained neogermitrine, the second a mixture of neogermidine and germidine, and the third pure zygacine.

Levine and Fischbach (30) separated "protoveratrine" into its components, protoveratrines A and B, on a Celite column, using as immobile phase pH 3.5 buffer–ethylene glycol (2 + 1). Benzene eluted the protoveratrine A and ethylene chloride the protoveratrine B. When aqueous buffer was used without the glycol, losses occurred due to adsorption. The same authors (105) modified the procedure for application to commercial protoveratrine preparations which contained associated alkaloids. They substituted pH 3.0 buffer–ethylene glycol (2 + 1) as immobile phase. Carbon tetrachloride–ethylene chloride (3 + 2) eluted protoveratrine A; ethylene chloride eluted alkaloids intermediate between protoveratrines A and B in hydrophilic strength; chloroform–ethylene chloride (2 + 1) eluted protoveratrine B; and finally chloroform

eluted the more strongly hydrophilic alkaloids. Paper chromatography was used to monitor the separations.

Hegi and Flück (106) used *kieselguhr:pH 4.2 buffer* columns for the separation of pairs of veratrum alkaloids. They used chloroform-ether (40 + 160), chloroform-ether (90 + 110), and chloroform to separate the alkaloid pairs protoveratrine A–protoveratrine B, germitetrine, and jervine-veratrobasine. They used this same chromatographic procedure in isolating new alkaloids from the above-ground portions of *Veratrum album* (107). Kupchan and Gruenfeld (108) resolved the components of a commercial *Veratrum viride* alkaloid preparation on a *Celite:pH 4.25 buffer* column, eluting successively with benzene, benzene-chloroform, chloroform, and chloroform-methanol. They rechromatographed certain of the fractions on alumina, and isolated and identified a total of 13 alkaloids.

Ergot Alkaloids.—Brindle, *et al.* (109), separated the water-insoluble ergot alkaloids ergocristine and ergocristinine. They used Solka-Floc as support, pH 3.4 buffer as immobile phase, and ether as mobile phase. Carless (57) used a column of pH 3.0 buffer on ashless cellulose powder in the chromatography of the ergot alkaloids. With ether as eluant, the alkaloids moved down the column in the order ergocristinine, ergocristine, ergosine, and ergotamine. The water-soluble alkaloids, ergonovinine and ergonovine, remained at the top of the column. Ergosine and ergotamine moved very slowly, requiring inordinate volumes of eluate. Increasing the pH of the immobile phase accelerated their movement, but resulted in incomplete separation of the faster-moving ergocristinine and ergocristine. Pyridine (0.1%) was added to the developing solvent, thereby establishing a pH gradient on the column; the pH was raised from 3.0 to 4.8 after passage of 100 ml. of solvent. With this procedure, the slower moving alkaloids were eluted more rapidly and the zones compacted. To elute the water-soluble alkaloids, the column was made alkaline with a solution of diethylamine in ether. Recovery studies using the individual pure alkaloids yielded 90–95% except for ergotamine, for which recoveries were about 80%.

Graf and Neuhoff (110) described the quantitative determination of the water-insoluble and water-soluble groups of ergot alkaloids. They triturated the sample of ground ergot with ammonium hydroxide and methanol, added sufficient silica gel to prepare a dry mixture, and transferred it to a column above a segment of *silica gel:pH 7 buffer*. They eluted the alkaloids with chloroform-trichloroethylene (1 + 1), monitoring the separation by fluorescence under ultraviolet illumination. In control experiments with mixtures of ergotamine and ergonovine they obtained recoveries of 96 to 100%. Their assays of crude ergot gave somewhat higher values than those obtained by non-chromatographic procedures, particularly for the water-soluble group.

Alexander and Banes (111) separated the water-soluble and water-insoluble groups on a *Celite:0.1 M citric acid* column. They passed a chloroform solution of ergot extract over the column and eluted the water-insoluble group with chloroform. They then extruded the column, added sodium bicarbonate to render the immobile phase alkaline, and reconstituted the column. The water-soluble group of alkaloids was eluted with chloroform. Recoveries of 95 to 98% of ergonovine were obtained. To determine the extent to which the water-insoluble alkaloids appear in the water-soluble alkaloid fraction, they chromatographed the pure water-insoluble alkaloids ergotamine and ergocristine by the same procedure. The quantity of the alkaloids found in what would be the water-soluble fraction was equivalent to no more than 3% of the ergonovine present in a normal sample. These authors, like Graf and Neuhoff (110), found that the chromatographic procedure gave higher values, particularly for the water-soluble group, than the conventional shake-out procedure of the National Formulary XI (112).

Van de Langerijt (113) separated ergotamine and ergotaminine on a *Celite:formamide* column, using benzene-petroleum ether (9 + 1) as developing solvent. Ergotaminine was eluted first, followed by ergotamine. The cutting of fractions was monitored by fluorescence of bands under ultraviolet light. Lysergic acid and lumiergotamine present in the sample remained on the top of the column.

Alexander (114) described a procedure for the determination of ergotamine and ergotaminine in its dosage forms, including combinations with acetophenetidin, caffeine, barbiturates, etc. The sample was first chromatographed on a column of *Celite:50% citric acid solution* with ether. The ergot alkaloids remained on the column while the neutral or acidic components passed through. The column was extruded, the aqueous phase was made alkaline, and the combined ergotamine and ergotaminine

were extracted with chloroform. The extract was passed over a second Celite column, in which 25% (w/v) citric acid was the immobile phase. Ergotaminine was eluted with chloroform, with recoveries of 98 to 100%. The column was extruded and ergotamine extracted as before; recoveries of 97 to 98% were obtained. Pin Liang and Tonh-Hui Chou (115) separated ergonovine from the water-insoluble ergot alkaloids on a *Celite:pH 3.4 buffer* column. Chloroform eluted the latter group; ergonovine remained on the top of the column, and was eluted with ammonia-saturated chloroform. Recoveries of over 95% were obtained. Voight and Kaehler (116) adapted a paper chromatographic separation of ergot alkaloids to a column, using cellulose powder as support, 0.2% tartaric acid as immobile phase, and ether-acetone-water (2:4:2) as developing solvent. The peptide alkaloids were eluted first, followed by the clavine fraction. Ammonium hydroxide (1 drop per 100 ml.) was then added to the eluant. Ergonovine, ergonovinine, and lysergic and isolysergic amides were eluted serially.

Rauwolfia Alkaloids.—Pure reserpine was isolated from commercial reserpine preparations by chromatography on a Celite column, using a mixture of 0.05 *M* citric acid and alcohol (5 + 2) as immobile phase and chloroform–alcohol–iso-octane (100 + 40 + 200) equilibrated with water as eluant (117). After a forerun was discarded, spectrophotometrically pure reserpine was eluted.

The weakly basic alkaloids, mainly reserpine and rescinnamine, were separated from *Rauwolfia serpentina* preparations, with a slightly modified immobile phase (118). Chloroform was used as eluant, and 0.5 *N* sulfuric acid and 10% dipotassium phosphate were used as immobile phase on separate segments of the column, to separate reserpine from its acidic degradation products and the more polar alkaloids (119).

Hayden, *et al.* (120), separated the three weakly basic rauwolfia alkaloids, reserpine, deserpidine, and rescinnamine. They equilibrated *n*-heptane, chloroform, morpholine, and formamide (715 + 110 + 1 + 25), and used the lower layer as immobile phase and the upper layer as eluant. With a column of 25 Gm. of Celite and 20 ml. of immobile phase, and quantities of about 1.5 mg. of alkaloid, they found that after a 125 ml. forerun, deserpidine was eluted in the next 75 ml.; after the next 25 ml., reserpine was eluted in 110 ml.; and after the following 60 ml., rescinnamine was eluted in the next 200 ml. Recoveries of deserpidine, reserpine, and rescinnamine averaged 99%, 97%, and 95%, respectively.

Opium Alkaloids.—Lindblad and Ågren (121) used a *Hyflo Super-Cel:pH 2.0 phosphate buffer* column to separate several opium alkaloids. Ether eluted narcotine, chloroform eluted papaverine, and ammonia-saturated chloroform eluted codeine. Büchi and Huber (122), using a *kieselguhr:pH 4.6 buffer* column and benzene-ether (1 + 3) as developing solvent, eluted first a mixture of narcotine and papaverine and then thebaine. Codeine was eluted with ammonia-saturated chloroform. Lach, *et al.* (123), separated morphine from pseudomorphine on a *Celite 535:pH 6.5 buffer* column. Chloroform containing 15% butanol eluted pure morphine, leaving the pseudomorphine on the column. Yeh and Lach (124), using a similar column, eluted degradation products of pseudomorphine with chloroform containing 5% butanol; pure morphine was then recovered as before.

Other Alkaloids.—Welsh (125) determined epinephrine and norepinephrine in mixtures by chromatographing their triacetyl derivatives on a *Celite:water* column. Benzene eluted the triacetyl epinephrine and chloroform the triacetyl norepinephrine. Buffer (pH 4) was used as immobile phase and chloroform as eluant to separate triacetylepinephrine from its degradation products (126).

Jensen and Svendsen (53) separated strychnine and brucine on a kieselguhr column with pH 7 buffer as immobile phase. The strychnine was eluted with ether and the brucine with chloroform.

Chilton and Partridge (28) separated the pomegranate alkaloids of the commercial mixture pelletierine tannate, using powdered glass as support and pH 6.8 buffer as immobile phase. They found that with kieselguhr excessive loss was incurred due to adsorption. The aconite alkaloids were separated on a *kieselguhr:pH 7 buffer* column, with first ether and then chloroform as mobile phase (127).

To avoid gelation which occurs in the separator on extraction of pilocarpine from solutions containing methylcellulose, the sample solution has been used to constitute the immobile phase on Celite (128). Chloroform eluted the alkaloid quantitatively.

Salts of Bases.—The classical analytical procedures for alkaloids are based upon the general rule that the nondissociated form (free base) will enter the organic phase and the dissociated form (the salt) will enter the aqueous

acidic phase during distribution between the immiscible solvents. With selection of the proper acid, however, it is possible to extract the specific salt of most alkaloids and organic bases with chloroform directly from the acidic aqueous solution. Although the distribution coefficient may be relatively unfavorable, quantitative recoveries are obtained because of the efficient extraction which is obtained by column partition chromatography. Application of this means of distribution to the analysis of a large variety of alkaloids and related bases in their dosage forms is thus feasible. Schill and Ågren (129) applied this property to the separation of hyoscyamine hydrochloride from scopolamine hydrochloride. They used a *kieselguhr:1 N hydrochloric acid* column for the separation; chloroform eluted the hyoscyamine hydrochloride quantitatively while the scopolamine salt remained on the column. The authors attributed the separation simply to the solubility of hyoscyamine hydrochloride and the insolubility of scopolamine hydrochloride in chloroform. It has been shown (31) that solubility of the salt in chloroform is only one factor governing the extractability of the salt from aqueous solution. Salts having comparable solubility in chloroform may vary widely in their partition characteristics. In the distribution of diphenhydramine hydrochloride and of cyclizine hydrochloride (both of which are readily soluble in chloroform) between chloroform and aqueous hydrochloric acid solution, the proportion of diphenhydramine in the chloroform phase at equilibrium increases with increasing concentration of acid, while that of cyclizine decreases.

The procedure of Haddock and Evers (130) for the separation of strychnine from quinine was adapted to partition chromatography (43). The separation of the two alkaloids was more complete, the analyses more accurate, and the manipulations much more simple than in the original procedure, in which the extractions were performed in separators. A *Celite 545:2 N hydrochloric acid* column was used for the separation; chloroform eluted strychnine while quinine was retained on the column. Dihydrocodeinone was separated from pheniramine on a similar column; the latter is retained on the column while dihydrocodeinone passes through (131).

It has been shown that acids other than hydrochloric may be used to effect the differential extraction of salts of alkaloids and organic bases, and that by proper selection of acid, significant degrees of specificity can be achieved. Nitric acid (1 *N*) was used as immobile phase (132) for the separation of codeine from pyrilamine, methapyrilene, and pheniramine; chloroform eluted codeine from this column while the antihistamines were retained. The chloroform eluate was passed onto a *Celite:0.5 N sulfuric acid* column, which retained the codeine while the neutral and acidic extractives of the sample (*e.g.*, a cough syrup) passed through. This partition system was not applicable to the separation of codeine from phenindamine, since this antihistamine is not retained on the nitric acid column. To separate this combination, a *Celite:0.5 N sulfamic acid* column was used, with chloroform as mobile phase. The phenindamine passed through while codeine was retained.

Miller (133) reported that while the chromatographic procedure of Banes (43) for the determination of strychnine in elixir of iron, quinine, and strychnine was applicable to freshly prepared elixir, high values were obtained for aged samples. He showed (134) that this was caused by the partial degradation of quinine to one or more products not separated from strychnine in the chromatographic step. Pure strychnine was isolated from the aged elixir on a three-stage column (135). In the first stage, a solution of *p*-toluenesulfonic acid in the sample constituted the immobile phase. The second stage was *Celite:2 N hydrochloric acid*, and the third stage *Celite:1 N tartaric acid*. Ether, passed over the first stage alone, eluted one or more of the quinine degradation products which accompanied strychnine in the previous procedure. Chloroform then eluted the quinine, strychnine, and the remaining quinine degradation products. The chloroform eluate was passed through the second stage, which retained the quinine, and over the third stage, which retained the strychnine, while the remaining quinine degradation products passed through. Strychnine was recovered from this stage with chloroform-triethylamine as described above. If 1 *N* sulfuric acid was used rather than tartaric acid in the third stage, the final separation was not obtained; the quinine degradation product was retained together with the strychnine.

Levine and Ottes (136) showed that the analysis of alkaloidal preparations by extraction of the salt with chloroform from aqueous solution of *p*-toluenesulfonic acid is applicable to a large variety of alkaloids. A solution of the dosage form in 10% *p*-toluenesulfonic acid is used as immobile phase on Celite. Ether elutes neutral and acidic constituents of the sample, and chloro-

form elutes the alkaloid-*p*-toluenesulfonic acid complex. This eluate is passed over a *Celite:1 N sodium hydroxide* column, which retains the acid moiety while the alkaloid passes through. Centigram quantities of alkaloid can be isolated by this procedure. Quantitative recoveries were obtained with strychnine, quinine, atropine, codeine, emetine, physostigmine, dihydrocodeinone, quinidine, and homatropine. Low recoveries resulted with cocaine, apomorphine, and arecoline, while morphine, pilocarpine, procaine, and phenylephrine were retained completely. This procedure was adapted (31) to the quantitative analysis of those antihistamine preparations for which the procedure *Salts of Organic Nitrogenous Bases* is official in U.S.P. XVI (137). *p*-Toluenesulfonic acid could not be used for all of the compounds, since the ether used in the purification step eluted varying quantities of several bases. It has been found that this phenomenon is the cause of the low recoveries of cocaine, arecoline, and apomorphine mentioned above. For these compounds the *p*-toluenesulfonic acid was replaced by 2 *N* hydrochloric acid or, in the case of those which were eluted by ether from this acid, 5% sulfamic acid solution. In the final procedure as adopted, 10% *p*-toluenesulfonic acid is used for chlorpheniramine, doxylamine, pyrilamine, and tripelennamine; 2 *N* hydrochloric acid for chlorcyclizine, cyclizine, and diphenhydramine; and 5% sulfamic acid for phenindamine and promethazine. Tailing occurred during the elution of several of the compounds with chloroform, but was completely eliminated by adding 1% glacial acetic acid to the chloroform eluant; quantitative recoveries of all of the compounds were obtained.

Miscellaneous Applications.—Theivagt and Campbell (138) separated vitamin D from vitamin A on a Celite 545 column, using polyethylene glycol 600 as immobile phase and isooctane as eluant. The *R* values of the two vitamins, calculated by the formula developed by Martin and Synge (6), predicted that vitamin D should come off the column in $^1/_3$ the volume required to elute vitamin A. The experimental values were very close to the theoretical. The procedure was applied to pharmaceutical products, including multivitamin tablets and liquids and fish liver oils. Quantitation of the isolated vitamin D agreed closely with results obtained by the U.S.P. bioassay. A similar chromatographic system, substituting *n*-hexane for iso-octane as eluant, was used (139) to separate vitamin A from β-carotene, vitamin E, and oxidized vitamin A. The progress of the vitamin A band in the column was monitored by occasional examination in low intensity ultraviolet light. Recoveries of 98 to 101% were obtained for vitamin A added to multivitamin preparations; 98 to 103% from mixtures with oxidized vitamin A; 95% for mixtures with vitamin E; and 92 to 102% for fortified margarine.

Higuchi, *et al.* (140), separated the parabens (*p*-hydroxybenzoic esters) on a silicic acid column, using methanol–water–sulfuric acid (7.5 ml. + 3 ml. + 1 drop) as immobile phase and carbon tetrachloride–Skellysolve B (1 + 1) as eluant. The parabens were eluted in the order butyl, propyl, ethyl, methyl.

In a procedure for the determination of piperazine by acetylation and extraction of the diamide, Perlmutter (141) reported the usual separator extraction to be quite laborious. Because of the unfavorable distribution coefficient, a minimum of ten extractions is necessary for quantitative recovery. To improve the procedure, he mixed an alkaline solution of piperazine with Celite 545 and stirred the mixture with acetic anhydride to form the diamide. The material was transferred to a column (142) and the diamide was eluted with 200 ml. of chloroform.

In the determination of glyceryl trinitrate in its dosage forms, Levine and Hohmann (143) separated the ester from its degradation products chromatographically. They eluted the ester with iso-octane from a column in which a solution of the sample in 50% acetic acid was the immobile phase and Celite 545 the support.

De Ropp (144) chromatographed the phenolic fraction of *Cannabis sativa* "red oil" on a *Celite:dimethylformamide* column with cyclohexane. He separated tetrahydrocannabinol, cannabinol, and cannabidiol in that order.

Schwartz, *et al.* (145), used two chromatographic systems for the determination of naphazoline and its hydrolytic products, 1-naphthylacetic acid and its ethylenediamine monoamide. Chloroform eluted 1-naphthylacetic acid from a *silicic acid:water* column while the amide and intact naphazoline remained on the column. The latter two compounds were separated on a *Celite:pH 8.5 buffer* column. The intact material was eluted with *n*-heptane–chloroform (65 + 35) and the amide with chloroform. The naphthylacetic acid was retained on this column. The chromatographic behavior of the other hydrolytic product, ethylenediamine, was not determined.

Taraszka and Marcus (146) separated adiphenine from its hydrolytic product, β-diethylaminoethanol, on a *silicic acid:pH 4.8 buffer* column, using chloroform as eluant. The adiphenine was eluted and determined by nonaqueous titration. Recoveries of 99.1 to 100.7% were obtained. It was not established whether the second hydrolytic product, diphenylacetic acid, remained on the column, but this compound did not interfere in the titration.

Several procedures have been described in which operations other than simple extraction take place in the partition system. The hydrolysis of the conjugated estrogens on a chromatographic column, in which the hydrolytic reagent, concentrated hydrochloric acid, is the immobile phase, has been described above (22). Levine and Fischbach (30) adapted to the partition column the familiar acid-dye procedure for the determination of alkaloids. They used a solution of chlorophenol red in a mixture of ethylene glycol and pH 3.5 buffer as immobile phase. Portions of chloroform containing various quantities of protoveratrine were passed over the column successively. The eluate contained quantities of dye proportional to the alkaloid content of each aliquot of chloroform. Clark (147) determined phenylephrine in combinations with other bases in formulations such as cough syrups. The sample, made alkaline with dipotassium phosphate, constituted the immobile phase. Chloroform eluted the accompanying bases, such as codeine and antihistamines, together with neutral extractives. A chloroform solution of acetic anhydride was then passed onto the column, acetylating the phenylephrine *in situ*. The product, diacetylphenylephrine, was then eluted quantitatively with chloroform.

APPLICATIONS

Partition chromatography constitutes an integral step in the analysis of four products which are included in the official compendia of the United States: digitoxin, digitoxin injection, and digitoxin tablets (148), based upon the procedure of Banes, *et al.* (81); ouabain and ouabain injection (149), based upon the procedure of Banes and Houk (150); ergotamine tartrate injection (151), based upon the procedure of Alexander (114); acetylsalicylic acid, acetophenetidin, and caffeine capsules and tablets (152), based upon the procedure of Levine (59).

Analytical procedures employing partition chromatography have been adopted as official methods of analysis of the Association of Official Agricultural Chemists, following validation by collaborative studies. These include: ergotamine in tablets, applicable in presence of caffeine, acetophenetidin, phenobarbital, and belladonna alkaloids (153), based upon the procedure of Alexander (154); elixir of iron, quinine, and strychnine (155, 156), based upon the procedures of Banes (43), Miller (134), and Levine (135); phenobarbital in mixtures with salicylates (157), based upon the procedure of Banes (91); phenobarbital in mixtures with acetylsalicylic acid (47), based upon the procedure of Byers (92); acetophenetidin, acetylsalicylic acid, and caffeine (48), based upon the procedure of Levine (59) and collaborative study by Smith (90); β-estradiol (158), based upon the procedure of Haenni, *et al.* (45); norepinephrine in preparations of epinephrine (159), based upon the procedure of Welsh (160); phenylpropanolamine (161), based upon the procedure of Smith (162); digitoxin (163), based upon the procedure of Banes (164); determination of codeine in presence of antihistamines (165), based upon the procedure of Levine (132); determination of conjugated estrogens (166), based upon the procedure of Carol, *et al.* (68), and collaborative study of Banes (167); determination of piperazine (168), based upon the procedure of Perlmutter (142); determination of dihydrocodeinone in presence of antihistamines (169), based upon the procedure of Levine (131).

SUMMARY

The importance of liquid-liquid extraction in pharmaceutical analysis makes column partition chromatography particularly useful in this field. This review of the literature shows how several of the unsatisfactory features of early applications of the technique have been overcome or circumvented. These include availability of material suitable for use as supporting phase, means for limiting or preventing loss due to adsorption, further means for monitoring separations, and simplification of experimental technique. The recent introduction of such variations as multistage columns and the separation of combinations of organic bases by differential solvent extraction from solution in a specific acid facilitates the analysis of complex mixtures which are resistant to analysis by conventional procedures. Communications from colleagues indicate that these developments have given new impetus to the use of column partition chromatography in pharmaceutical analysis.

Powdered Particle Interactions: Suspension Flocculation and Caking II

By BERNARD ECANOW and ROBERT G. WILSON

The flocculation of a bismuth subnitrate suspension has been explained as principally due to forces other than van der Waals acting between the suspended particles. Two basic types of bonds are described. The conclusions are supported by microscopic data and by data on relative suspension heights obtained from a series of controlled flocculation experiments. These findings disagree with a proposed concept, which views the flocculation of a bismuth subnitrate suspension as the end result of the action of van der Waals forces, following the neutralization of the zeta potential of the suspended particles.

IN THE INITIAL paper of this series (1), a 2% sulfamerazine suspension was chosen for a study of the phenomena of flocculation and of caking. Particles of sulfamerazine were suspended in dilute dioctyl sodium sulfosuccinate solution, and either aluminum or ferric ions were introduced as the flocculating agent. It was shown that flocculation was influenced both by wetting agent concentration and by the chemical reaction that took place between the above trivalent cations and the anions of the wetting agent. Where the chemical reaction was a dominant factor in flocculation, the mechanics were visualized as the adsorption of wetting agent anions on the surface of the sulfamerazine particles, followed by a chemical coprecipitation between the flocculating agent cations and the adsorbed anions. An analogous reaction is obtained when common soaps react with the heavy metal ions in "hard" water.

The sulfamerazine suspension system was previously discussed in the literature (2, 3).

Received June 19, 1962, from the College of Pharmacy, University of Illinois, Chicago.
Accepted for publication April 10, 1963.
Abstracted from a thesis submitted by Robert G. Wilson to the Graduate School, University of Illinois at the Medical Center, Chicago, in partial fulfillment of Doctor of Philosophy degree requirements.

Powdered Particle Interactions: Suspension Flocculation and Caking II

By BERNARD ECANOW and ROBERT G. WILSON

The flocculation of a bismuth subnitrate suspension has been explained as principally due to forces other than van der Waals acting between the suspended particles. Two basic types of bonds are described. The conclusions are supported by microscopic data and by data on relative suspension heights obtained from a series of controlled flocculation experiments. These findings disagree with a proposed concept, which views the flocculation of a bismuth subnitrate suspension as the end result of the action of van der Waals forces, following the neutralization of the zeta potential of the suspended particles.

IN THE INITIAL paper of this series (1), a 2% sulfamerazine suspension was chosen for a study of the phenomena of flocculation and of caking. Particles of sulfamerazine were suspended in dilute dioctyl sodium sulfosuccinate solution, and either aluminum or ferric ions were introduced as the flocculating agent. It was shown that flocculation was influenced both by wetting agent concentration and by the chemical reaction that took place between the above trivalent cations and the anions of the wetting agent. Where the chemical reaction was a dominant factor in flocculation, the mechanics were visualized as the adsorption of wetting agent anions on the surface of the sulfamerazine particles, followed by a chemical coprecipitation between the flocculating agent cations and the adsorbed anions. An analogous reaction is obtained when common soaps react with the heavy metal ions in "hard" water.

The sulfamerazine suspension system was previously discussed in the literature (2, 3).

Received June 19, 1962, from the College of Pharmacy, University of Illinois, Chicago.
Accepted for publication April 10, 1963.
Abstracted from a thesis submitted by Robert G. Wilson to the Graduate School, University of Illinois at the Medical Center, Chicago, in partial fulfillment of Doctor of Philosophy degree requirements.

It had been suggested that the flocculation was due to the interaction of the van der Waals forces operating after the zeta potential of the particles had been neutralized by the flocculating agent. This proposal was questioned on two counts (1): (*a*) The particles were in macro-particulate suspension, rather than in colloidal dispersion. Van der Waals forces, although presumably present, have not been shown to be of significance in the type of system studied, where particles are above the colloidal size range. (*b*) The flocculation was virtually immediate, on mixing, and thus was more typical of a chemical reaction than of the reaction rate associated with the action of van der Waals forces. Burton (4) has shown that the coagulation of a colloidal system, following the neutralization of particle charge, is a slow process which depends upon the Brownian movement of the particles.

A bismuth subnitrate suspension which could be flocculated by the addition of monobasic potassium phosphate solution was also reported in the literature (2, 3). The flocculation reaction was discussed in terms of zeta potential and van der Waals forces. This again raised the above questions relative to particle size and speed of the flocculation reaction. The bismuth subnitrate-monobasic potassium phosphate suspension system has in this report been considered from a different viewpoint, with the thought that both flocculation and caking phenomena might be explained on some basis other than that previously proposed.

In the exploratory work, a 2% bismuth subnitrate suspension was reacted with a flocculating agent, and the degree of flocculation was judged empirically from the settling rate. This could be done, since flocculated particles settle more rapidly than do the same particles in a deflocculated state. The words, "flocculated" and "deflocculated," are here used in accordance with the definition given by Fischer and Gans in their chapter in Alexander (5). The following compounds, at a concentration of 1 mmole of phosphate per 100 ml. of suspension, were tested for their flocculating ability.

Flocculating Agent	Relative pH of the Additive in Solution	Flocculating Action
Tri-sodium phosphate	12.0	little
Dibasic sodium phosphate	8.7	little
Monobasic sodium phosphate	4.3	marked
Phosphoric acid	2.2	marked

As can be seen, there was little flocculating action for additive solutions of high pH, but a marked degree of flocculation at lower levels of pH. Since the same concentration of phosphate was present in each case, it seemed that flocculation was pH-dependent. This finding lent credence to the thought that a chemical reaction might be involved.

Bismuth subnitrate for pharmaceutical use is a white, slightly hygroscopic powder. Under the microscope, the powder can be resolved to transparent, orthorhombic crystals averaging 10 to 15 μ in size. The compound may be produced by several quite comparable processes. Perhaps the simplest is to prepare a solution of bismuth nitrate in nitric acid solution of the proper strength and to then pour this solution into a large quantity of water. The bismuth nitrate promptly hydrolyzes, precipitating bismuth subnitrate from an acid medium. Nitric acid is a product of the hydrolysis reaction as well as being present in the initial bismuth nitrate solution. The precipitated bismuth subnitrate is separated by filtration or centrifugation, is carefully dried, and is sold in this form. Because of the conditions of the process, bismuth subnitrate resuspends in water to give a slightly acid medium. An alternate production method (6) is to add sodium carbonate to bismuth nitrate in acid solution until the pH rises to 5.0. At this point, the precipitated bismuth subnitrate is separated and carefully dried as before. Both of the methods discussed will give bismuth subnitrates of variable composition, and the pH obtained on resuspending the solid will be influenced both by the manufacturing process and by the extent to which the material was dried.

Hückel (7) has discussed the "iso-poly bases" at some length. These are compounds which are known to form a variety of weakly basic hydroxides. The hydrolysis of an iso-poly base leads to a hydrated oxide of the compound, or to an oxide complexed with an indeterminate number of water molecules. The composition and structure of the hydroxide, as well as its initial formation, are all strongly pH dependent. Hückel has also said that the size of the iso-poly cations formed can be strongly influenced by the types of anions present in the precipitation medium. The attainment of the hydrolysis equilibrium is described as a slow process, and one in which the initial reversible equilibrium reaction is frequently followed by an irreversible aging process. Because various products may be formed at the different stages of the reaction, and because these products may then be taken to different stages of the aging process, it follows that the end result of the hydrolysis reaction is a product which is variable and complex in its composition.

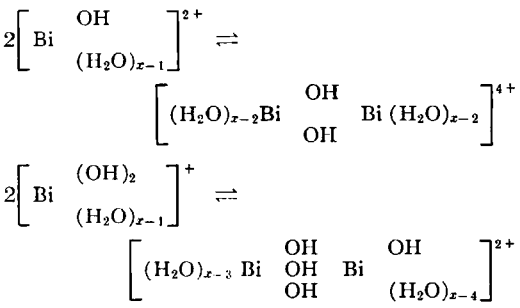
Hückel did not specifically deal with bismuth subnitrate. However, a footnote in his work indicates that the hydrolysis reactions of the bismuth salts are thought to be comparable to those of trivalent chromium. Utilizing Hückel's presentation, but substituting trivalent bismuth for chromium, the following outlines some of the typical reactions of an iso-poly base.

(*a*) The formation of "aquo-cations."[1]

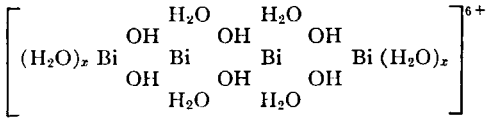
$$Bi^{3+} + xH_2O \rightleftharpoons Bi(H_2O)_x^{3+} \rightleftharpoons \left[\begin{matrix} & OH & \\ Bi & & \\ & (H_2O)_{x-1} & \end{matrix}\right]^{2+} \rightleftharpoons \left[\begin{matrix} & (OH)_2 & \\ Bi & & \\ & (H_2O)_{x-2} & \end{matrix}\right]^{+} \rightleftharpoons \left[\begin{matrix} & (OH)_3 & \\ Bi & & \\ & (H_2O)_{x-3} & \end{matrix}\right]$$

[1] As in Hückel's work, bonding lines are not drawn in the illustrated compounds.

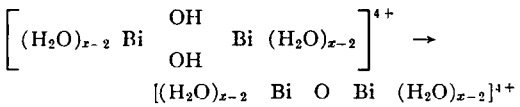
(*b*) The formation of polynuclear complexes. (In the course of this process, water is lost and the hydroxyl groups interact to link the bismuth atoms through "ol" bridges)



The following compound is illustrative of the further course of the reaction

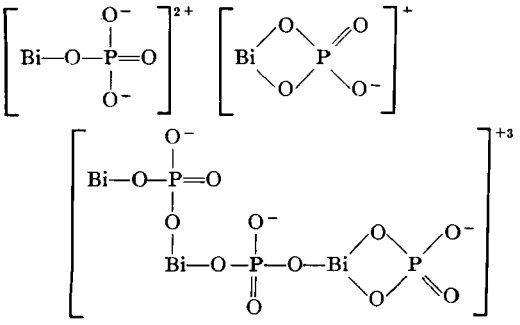


(*c*) An irreversible aging process. (The "ol" bridges are dehydrated and become "oxy" bridges.)

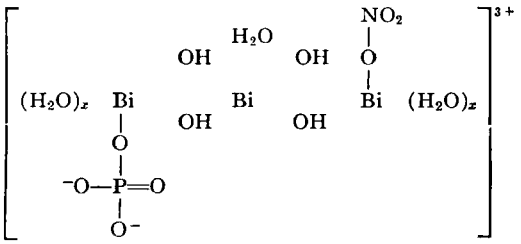


The above reactions seem reasonable when viewed in the light of data gathered by Kirk and Othmer (6). They report that a crystalline precipitate of the general formula, $Bi_2O_3 \cdot N_2O_5 \cdot 2H_2O$, is obtained when bismuth nitrate is added to water. With a 6% nitric acid solution, the composition shifts to $Bi_2O_3 \cdot N_2O_5 \cdot H_2O$. On further acidification, the precipitated material has the formula, $6Bi_2O_3 \cdot 5N_2O_5 \cdot 9H_2O$, and this in turn becomes $10Bi_2O_3 \cdot 9N_2O_5 \cdot 7H_2O$, when the suspension is heated to 70°. It can be seen that the transition from one state to the next involves a gradual loss of water and hydroxyl groups, which correlates with the reaction sequences indicated by Hückel's work.

Trivalent bismuth ions will also react with phosphate ions to produce the very slightly soluble bismuth phosphate. The latter compound is normally designated in the literature by its empirical formula, $BiPO_4$. However, structural requirements would indicate a crystal growth based on compounds of the following type



Reaction with phosphate ions at pH levels that would promote the formation of bismuth subnitrate would add to the complexity of the precipitate. The following suggests what might be found



EXPERIMENTAL

Method.—In this investigation, the bismuth subnitrate suspensions described by Haines and Martin (2, 3) were selected for study. Following the exploratory tests, the suspension concentration was raised to the 10% solids level, so that differences in suspension height would be more apparent and could be measured with greater relative accuracy. Settling rates were rapid enough to make this change practical. The experimental results were obtained and reported in accordance with the procedures discussed by Ward and Kammermeyer (8).

Equipment.—Settling data were obtained in 100-ml., glass-stoppered cylindrical graduates. Suspension heights could be measured within ±0.5-ml. accuracy, which was more than sufficient to establish a difference between the various suspension formulations.

Materials.—The same batch of a commercial grade of precipitated bismuth subnitrate (bismuth subnitrate N.F. supplied by Merck and Co., Inc., Rahway, N. J.) was used in the test series. The suspending medium was distilled water. Acid solutions were obtained by dilution from the concentrated commercial products, which were 70% nitric acid (supplied by E. I. du Pont de Nemours and Co., Wilmington, Del.) and 85% phosphoric acid (supplied by Mallinckrodt Chemical Works, St. Louis, Mo.). The two salts, monobasic potassium phosphate and trisodium phosphate, were of reagent grade (supplied by Merck and Co., Inc.).

Procedure.—The studies were run on a 10% bismuth subnitrate suspension, prepared by placing the bismuth subnitrate in a cylindrical, glass-stoppered graduate, adding about 30 ml. of distilled water, and shaking until a uniform suspension was obtained. A measured amount of dilute acid was added, the suspension again shaken, and the volume brought to 100 ml. by the further addition of distilled water. Where sodium citrate or trisodium phosphate were involved in the tests, they were introduced as concentrated solutions prior to the addition of the dilute acid solution.

The prepared suspensions were allowed to age for 8 hours, resuspended by shaking, then set aside for undisturbed settling. Readings on the suspension heights were taken approximately 48 hours later. Mechanical vibration or gentle agitation of any kind during the settling process had a marked effect upon the resultant height of the sediment. It is essential that settling take place of its own

accord. After the suspension heights had been recorded, the pH of each suspension medium was taken on a Beckman pH meter (glass electrode model H2), and the data were correlated with the suspension heights.

RESULTS

The bismuth subnitrate used in this series of experiments was found to suspend in water to give a pH of 3.05. A milky, uniform suspension was obtained, from which the bismuth subnitrate

All suspensions were shaken vigorously prior to sampling.

particles slowly settled to form a dense precipitate. The supernatant liquid took several days to clear, which is indicative of the slowness of the settling rate. After all of the suspension had settled, the cylindrical graduate could be inverted, with the precipitate holding its shape and position at the bottom of the graduate. However, it was possible to resuspend the material easily if the compact precipitate was mechanically disrupted before the mixture was shaken. The appearance of the bismuth subnitrate crystals, microscopically, is shown in Fig. 1*a*, *d*, and *l*.

In the initial group of tests, various amounts of 7% nitric acid solution were added to a series of 10% bismuth subnitrate suspensions. The results are shown in Fig. 3. The bismuth subnitrate flocculated, and its relative suspension height more than doubled as the pH dropped below 1.0. A microscopic study showed that the individual bismuth subnitrate crystals were clumped into loose aggregates. Figure 1*e* compares the flocculated material against the original finely-divided suspension of crystals. The aggregates had a rapid settling rate and settled to leave a clear solution. It was found that the increase in suspension height was due to the voids between and within the aggregates as they slowly settled to form the precipitate. When the cylindrical graduate was carefully inverted, the precipitated material tended to hold its shape. In other words, there was some resistance to sediment flow under these conditions. The flocculated material could easily be resuspended by shaking. It should be emphasized, though, that the resuspended material was still in the aggregated condition and could not be shaken back to individual crystals, such as those seen in the untreated bismuth subnitrate suspension. To continue with this portion of the experimental work, it seemed of interest to study the acid-base response of the flocculation mechanism. Since the degree of flocculation was increased by hydrogen ion concentration, could the response be reversed by hydroxyl ions? A bismuth subnitrate suspension was treated with nitric acid until the pH had been reduced to approximately 0.8. The acid was then back-titrated with potassium hydroxide solution. A slight decrease in suspension height was seen, but certainly not a return to the original level. Whatever the changes induced by acid, it seemed they could not be reversed by a simple change in the pH.

Next, experiments were run in which the pH was followed as acids were added to bismuth subnitrate suspensions. Normal acid-base type neutralization curves might logically be expected, but this was not the

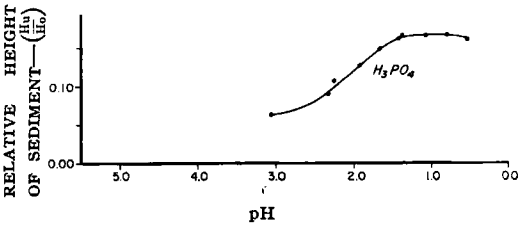

Fig. 4.—Relative height of sediment *vs.* pH for a bismuth subnitrate suspension flocculated by phosphoric acid.

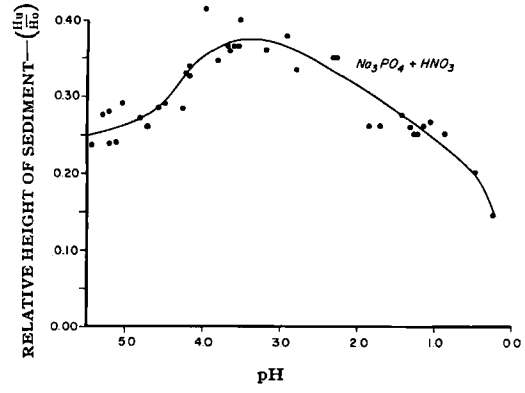

Fig. 5.—Relative height of sediment *vs.* pH for a bismuth subnitrate suspension flocculated by trisodium phosphate (4.72% w/v) and various amounts of nitric acid.

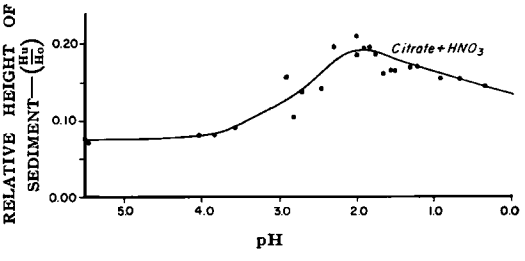

Fig. 6.—Relative height of sediment *vs.* pH for a bismuth subnitrate suspension flocculated by sodium citrate (9.80% w/v) and various amounts of nitric acid.

case. Titration of a 10% bismuth subnitrate suspension with either nitric acid or phosphoric acid gave a pH curve that was virtually identical with the pH curve obtained by titrating distilled water, if the distilled water was first adjusted to the initial pH of the bismuth subnitrate suspension. Although it is known that bismuth subnitrate will dissolve in strong mineral acids, quite concentrated acids are required. The pH must be well below 0.5 before a significant degree of dissolution is seen. The above observations suggested the existence of crystal surface changes as the result of the decrease in pH level. An equilibrium reaction appeared to be involved.

Figure 3 demonstrates the flocculation response as nitric acid was added to a bismuth subnitrate suspension. As the pH decreased, the relative suspension height showed a marked increase. The test was rerun, using phosphoric acid as the additive. Figure 4 gives the results of this test series, and it is apparent that the response was very similar to that obtained with nitric acid. The photographs of Fig. 1*d*, *e*, and *f* serve to illustrate the change that takes place as these acids are added. As hydrogen ion concentration increases, the individual crystals tend to clump together; the clumps act to give a bulkier, more readily resuspendable precipitate. In the lower pH range, the sediment would hold its shape when the graduate was cautiously inverted. This resistance to flow was more marked for the phosphoric acid series than for the nitric acid series. A definite "form" or "structure" was present, and it would have been possible to describe the sediment as a "soft cake." This correlates with the comments of Haines and Martin (2, 3). Simple shaking sufficed to resuspend the material.

The action of phosphate ion was further investigated through the addition of an excess of trisodium phosphate to a series of 10% bismuth subnitrate suspensions. Varying amounts of nitric acid were added, and data on relative suspension height *versus* pH were obtained and plotted as in Fig. 5. At all of the pH levels shown the relative suspension height was three or more times the height of the untreated material, and there was a maximum response between the pH levels 3.0 and 4.0. The flocculated material could easily be resuspended by shaking. However, here again, there was some evidence of a "structure" within the sediment. The experiment was run again, but sodium citrate was used in place of the trisodium phosphate. The results were somewhat comparable, as shown in Fig. 6. However, marked flocculation was not obtained until the pH had dropped below 3.0. The maximum fell between pH 1.5 and 2.5, and the relative suspension height decreased as pH decreased below 1.5. Microscopic studies on the test groups gave the typical photographs shown in Fig. 1. The graphical results have been summarized in the composite plot of Fig. 2.

DISCUSSION

Bismuth subnitrate is a crystalline material, occurring as transparent, elongated orthorhombic particles. Since the crystals themselves were identical in microscopic appearance throughout the course of each experiment, the variation in degree of flocculation must be because of differences in the composition of the molecular layers at the surface of the crystals. A crystal surface may vary in both the magnitude and sign of its electrostatic charges depending on the nature of the chemical groups residing in, or projecting from, its surface layer. The characteristics of the bismuth subnitrate crystal surface are influenced by the previous history of the crystal and by the chemical environment into which the crystal is placed.

The concept of a bonding between crystal surfaces is also required for an explanation of the experimental results. Such an attraction would be the end product of crystal surface conditions and could involve such things as electrostatic bonding, hydrogen bonding, or perhaps even van der Waals forces. When flocculating agents are present and the bismuth subnitrate crystals approach closely to one another, there is an attraction which culminates in a bonding of one crystal to the other. The bonding forces appear strong enough to hold the crystals in fixed relative positions during normal, undisturbed settling, but are weak enough to allow agitation to break the sediment into clumps of crystals, or for gentle vibration to reduce the relative suspension height by causing the suspension to settle more than it would under gravitational effects alone.

If one of the flocculated suspensions is shaken vigorously, the bismuth subnitrate is resuspended. However, it is not resuspended in the form of the individual crystals, but instead in the form of clumps of crystals, such as have been shown in our photographs taken through the microscope. The size of the clumps is determined by the force of the agitation used in resuspending the material, and by the number and strength of the bonding forces between the crystal surfaces. An additional factor is the variation in the density of the clumps. Our photographic work demonstrates an increase in density as the strength of the flocculating agent increases. The change in the density of the aggregates corresponds to an increase in the number or strength of bonds between the crystals.

In light of the above, the phenomenon of flocculation for a bismuth subnitrate suspension may be discussed as follows.

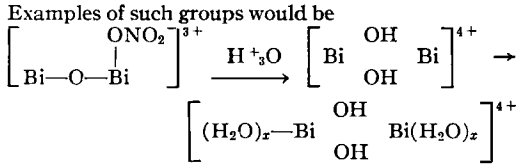
(*a*) When bismuth subnitrate crystals are produced, it appears that they have relatively few reactive points on their surfaces. It is presumed that the drying step tends to "seal in" some of the potentially active sites, as for example by the dehydration of "ol" bridges to "oxy" links.

$$\left[\begin{array}{ccc} & OH & \\ Bi & & Bi \\ & OH & \end{array}\right]^{4+} \rightarrow [Bi{-}O{-}Bi]^{4+} + H_2O$$

The drying step would leave the surface with fewer "ol" groups. As a result, the particles in suspension would have less tendency to clump, would settle independently under the influence of gravity, and would be piled randomly on top of each other in the sediment. As settling continues, the crystals would tend to realign themselves, filling the void spaces and bringing large areas of the crystal surfaces into close proximity with each other. After standing for several days, the bismuth subnitrate precipitate has the ability to retain its shape when the container is inverted. However, vigorous shaking, plus some mechanical dislodging of the sediment, will promptly resuspend the individual crystals. This may be viewed as a sediment in which there are bonds between the crystals, but in which the

bonds are relatively weak and few in number. They are effective in giving "form" or "structure" to the sediment, only because of the close contact between relatively large areas of the crystal surfaces. When the particles are in suspension, the bonding forces are so weak and few in number that they are ineffective in holding the crystals together.

(*b*) When nitric or phosphoric acid is added to a bismuth subnitrate suspension, reactive groups of various kinds will be formed on the crystal surfaces. Examples of such groups would be

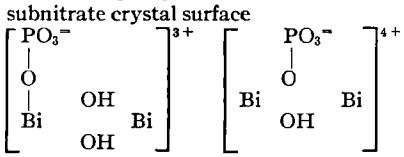


The higher the concentration of hydronium ion as flocculating agent, the greater the number of potential bonding sites that come into existence; thus the stronger is the total potential for forces of attraction and of bonding.

As small amounts of flocculating agents are introduced, there is a very loose clumping of the crystals in suspension. As these settle, the total effect of the bonding forces is weak enough to allow the crystals some freedom to realign themselves and thus to reduce the size of the voids in the sediment. However, the forces are active enough to prevent the complete realignment that was seen in the untreated bismuth subnitrate sediment.

At higher levels of flocculating agent, more and more bonding sites are created on the crystal surfaces. Their cumulative effect is strong enough to attract and bond tightly the individual crystals into compact, closely knit aggregates. When these aggregates settle, the crystals tend to be held in fixed relative positions and are thus unable to realign themselves to fill the voids in the sediment. Since the voids are present, the relative suspension height is correspondingly increased.

(*c*) The final system considered was that in which phosphate or citrate ions were introduced prior to the addition of the acid. Both anions give a somewhat similar response, so the discussion will be limited to the flocculating ability of the phosphate ion. Trisodium phosphate will react with the bismuth subnitrate crystal surface



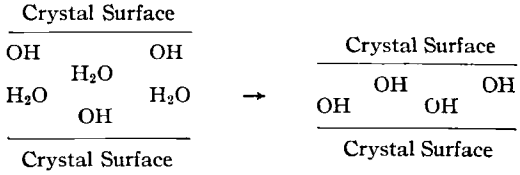
As has been said, some "ol" bridges and positive charges are present on the original crystal surface. It is for this reason that flocculation may be obtained at pH levels above the initial pH of the bismuth subnitrate suspension. In this region, however, there are relatively few of these "ol" bridges available for reaction, and the crystals tend to clump into very loose masses. As acid is added to this system, "oxy" links are converted to "ol" bridges and nitrate groups leave the crystal surface as ions. Additional bonding sites are thus formed.

The additional sites and the relatively high strength of the bonding forces developed by the presence of the phosphate groups give the loose, lacy clumps of bismuth subnitrate crystals a high degree of structural form. When they settle in the form of a precipitate, a vast amount of void space is enclosed. The sediment bulks to the unexpectedly large relative suspension heights noted between pH 3.0 and 2.0. As more and more acid is added, the number of bonding sites is increased, and the attractive forces tend to draw the crystals into clumps that are increasingly compact. The compactness eliminates the voids, and when the clumps settle, they enclose less void space even though their structural framework may be stronger than that obtained at the higher levels of pH. Thus the relative suspension height drops off from the maximum level and approaches the value given by the simple addition of phosphoric acid to a bismuth subnitrate suspension.

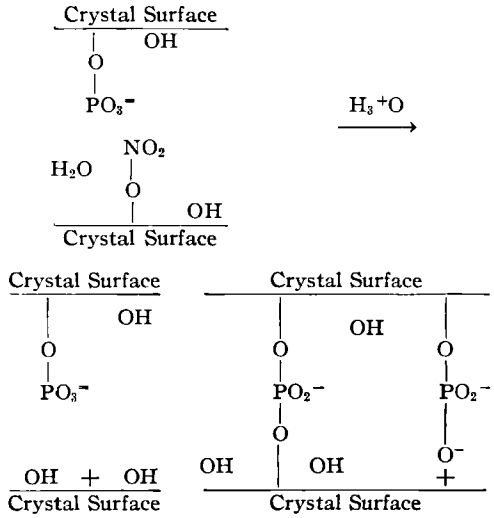
It should be emphasized that the response to the addition of phosphoric acid is different than that obtained when trisodium phosphate is added and followed by nitric acid. The fundamental difference lies in the characteristics of the clumps of crystals that are formed. In the phosphoric acid series, the crystals clump into relatively tight masses right from the start, and the compactness increases as additional acid is added. With trisodium phosphate, the initial clumping is very loose and does not become compact until sufficient nitric acid has been added to drop the pH below 2.0.

CONCLUSIONS

The flocculation of a bismuth subnitrate suspension has been explained in terms of a crystal surface phenomenon—one in which there is a mutual interaction between crystals that culminates in a bonding of one crystal to another. Two types of bonds seem to be the chief contributors, and these can be described on the basis of their relative strengths



Weak Bonds—"ol" Bridging



Strong Bonds—"Phosphate" Bridging

The weaker bonds are present to some extent in the original suspension, and the number of such bonds that can be formed increases as the concentration of hydrogen ion is increased. The stronger bonds are formed in the presence of phosphate ions, and again the number of potential bonds increases as the pH falls. An increase in hydrogen ion concentration tends to open additional reactive sites on the crystal surface.

The bonding between crystals gives rise to a clumping of crystals. As the clumps settle in the suspension medium, voids are formed both within and between the clumps. The differences in relative suspension height, from one system to the next, are a function of the number and size of the void spaces trapped within the sediment.

Where the bonds are weak and relatively few in number, a flocculated system fails to develop. The crystals sediment without the formation of voids, and the relative suspension height is at a low value. However, within the compacted sediment, the few weak bonds are able to exert sufficient bonding power to give the sediment some structural properties. Thus it shows some resistance to resuspension.

As the number of weak bonds increases, their total strength becomes sufficient to bond the crystals into a flocculated system. The crystals, although bound together, are able to adjust their relative positions as the precipitate settles. During this readjustment, the voids are decreased in size and an intermediate suspension height is obtained.

With a further increase in the number of weak bonds, the floc becomes quite compact. The bound crystals are capable of bridging the voids and of retaining them within the sediment. At this point, for the system involving weak inter-crystalline bonds, the relative suspension height reaches a maximum.

Where the bonds are strong but relatively few in number, as when sodium triphosphate is added to a bismuth subnitrate suspension, flocculation is seen. The floc settles, and the crystals are able to shift somewhat to eliminate a portion of the void space. However, a significant amount of void space is retained, and the sediment bulks to a substantial degree.

As more flocculating agent is added to form the stronger bonds, the density of the clumps increases slightly, but more importantly, the rigidity of the floc is increased. Thus when the material sediments, it is able to retain the voids and bulks to an extremely high relative suspension height.

SUMMARY

The bismuth subnitrate crystal surface is not easily described through structural formulas It is a highly solvated, three-dimensional complex involving hydrogen bonds, hydroxy links, ionic charges, and electrostatic bonds. The diagrams contained in this report should be considered as suggestive of the actual condition of the crystal surface rather than restrictive on the reader's concept of such a surface. Attention has been directed toward specific, isolated groups that are believed to be present.

When bismuth subnitrate is suspended in water, the crystal surface assumes a net positive charge because of the presence of ionic bismuth charges at the highly solvated surface. As phosphate is added to such a system, it reacts with both the "ol" groups and the available bismuth charges, first neutralizing the surface charge and then continuing to react further as more phosphate is added, until the surface charge has been reversed by a preponderance of phosphate ions bound to the surface. This concept finds support in the caking diagram of Martin (9), in which it was shown that the surface charge of suspended deflocculated bismuth subnitrate particles could be reversed by adding monobasic potassium phosphate to a suspension of bismuth subnitrate. The electrophoretic data was obtained in terms of particle movement, but was converted to zeta potential values when the caking diagram was drawn. Although zeta potential is a valid concept, its use in this situation tends to cloud the fact that the phosphate ions are reacting with the crystal surface—not gathering as an ionic atmosphere to shield the underlying charge on the particle surface.

A neutralization and reversal of net surface charge by chemical reaction of phosphate ions with the bismuth subnitrate crystal surface is the basic factor in the flocculation reaction under consideration in this report. It is important to recognize that a neutralization of net surface charge would yield a particle surface having "ol" groups, sites of positive charge, and sites of negative charge. The particle will not respond to electrophoresis at such an isoelectric point (a point at which there is a balance between negative and positive surface charges on the bismuth subnitrate particle). But if two crystal surfaces should come into close contact with each other, even at the isoelectric point, there would be ample opportunity for chemical or electrostatic interactions to occur between the surfaces and to end with the bonding of the two crystals in a flocculent state.

Effect of Certain Tablet Formulation Factors on Dissolution Rate of the Active Ingredient I

Importance of Using Appropriate Agitation Intensities for *in Vitro* Dissolution Rate Measurements to Reflect *in Vivo* Conditions

By GERHARD LEVY

Evidence is presented to show that solid dosage forms are exposed to relatively low agitation intensities after oral administration, and that it is often mandatory to use similar mild agitation conditions for predictive *in vitro* dissolution tests. Based on considerations of the effect of stirring rate on boundary layer thickness, it is demonstrated that the effective surface area of heterogenous pellets (analogous in some respects to certain prolonged release dosage forms) may be different when such pellets are exposed to high and low agitation intensities, respectively. A proportionality between dissolution rate and the square root of stirring rate, demonstrated by others with rotating disks of inorganic salts, has been found to apply also to rotating disks of certain organic weak acids. It is shown that the ratio of dissolution rates of two or more drugs, when rates are determined by the rotating disk method, is independent of stirring rate, provided this proportionality or a similar more general relationship applies.

RECENT RECOGNITION that the availability for gastrointestinal absorption of drugs contained in compressed tablets is often reflected by *in vitro* dissolution rates and not by tablet disintegration times has stimulated the development and use of dissolution rate tests for compressed tablets (1–4). Ideally, the validity of a particular *in vitro* dissolution rate test for a given drug must be assured and proper interpretation of data made possible by demonstrating the correlation between *in vitro* and clinical data and by calibrating the former against the latter. The feasibility of such an approach has been demonstrated in a previous report from this laboratory (1). Based on physiologic considerations, we utilized a very low agitation intensity in our *in vitro* test (1, 5). In a study of the relation of *in vitro* dissolution rate to the rate of absorption of methylprednisolone implants in rats, Hamlin and co-workers have found that the *in vivo* results correlated only with those *in vitro* data that were obtained from dissolution tests utilizing very low agitation intensities (6). These workers were the first to point out the importance of stirring rate in dissolution rate studies of pharmaceuticals. The present communication deals with the development of meaningful dissolution rate tests for certain oral medication and includes the results of physiologic and physicochemical studies concerned with the effect of agitation intensity on the rate of dissolution of conventional compressed tablets and certain related dosage forms.

In this laboratory we have emphasized particularly the study of agitation conditions to which ingested tablets may be exposed in the stomach. One reason for this emphasis has been that solids may be retained in the stomach for a considerable length of time (7); therefore, the intestinal absorption of the ingested drug sometimes may be limited initially mainly to that portion which is dissolved in gastric fluids which flow into the intestine. Another reason for studying dissolution under conditions representative of gastric conditions has been the desirability (in many instances) that drugs reach intestinal absorption sites in absorbable (*i.e.*, dissolved) form, either because such drugs may be intrinsically slowly absorbed, or because they are absorbed only from the proximal region of the small intestine (26). Finally, part of our emphasis on gastric dissolution stems from our interest in the biopharmaceutics of salicylate drugs. Salicylates can be absorbed from the stomach, and their rapid dissolution and absorption is desirable in order to obtain a prompt analgesic effect. Perhaps more important is the prevention of serious mucosal erosion and bleeding because of aspirin solids that, on occasion, may lodge in the rugae of the gastric mucosa. Rapid dissolution of these solids will shorten the time of contact of the drug with the mucosa, and will tend to minimize the incidence and severity of mucosal damage (1, 8).

EXPERIMENTAL

Radio-opaque Tablets.—The radio-opaque tablets

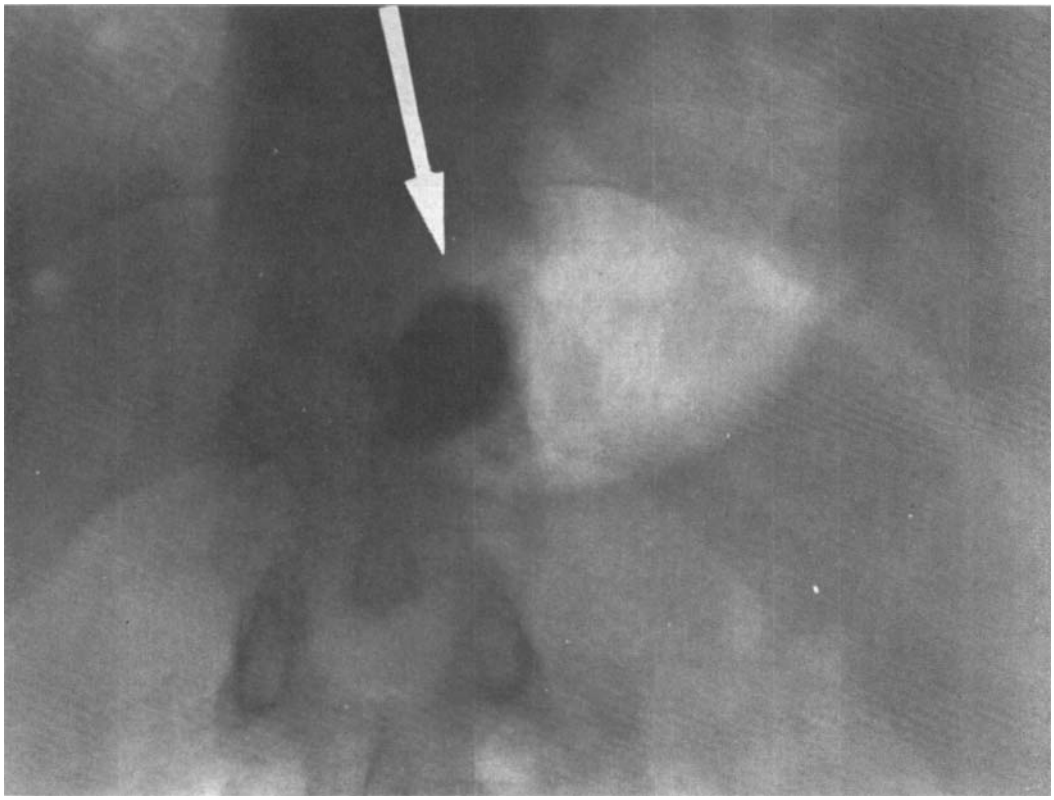

Fig. 1.—Radio-opaque tablet in human stomach 13 minutes after ingestion. Tablet is just beginning to disintegrate, as evidenced by the still noticeable tablet outline.

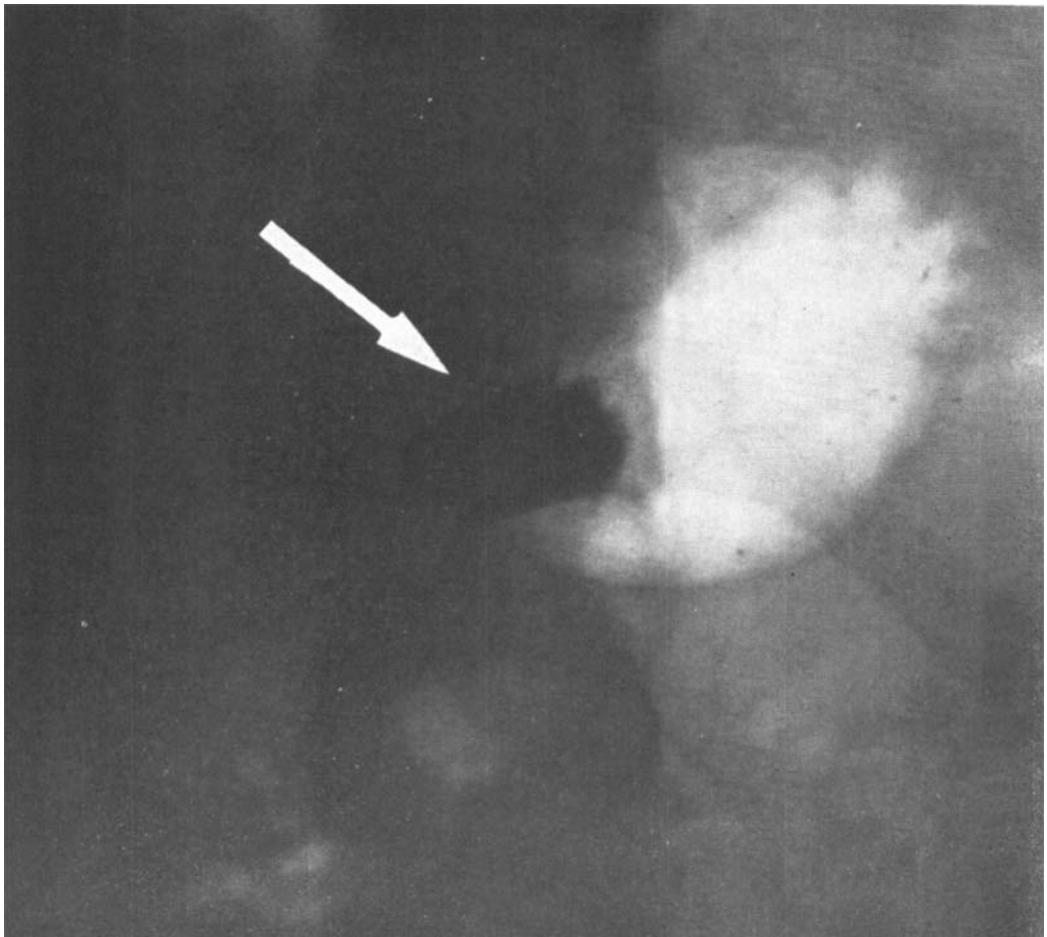
Fig. 2.—Radio-opaque tablet in human stomach 30 minutes after ingestion. Enlarged diameter of radio-opaque spot *vs.* Fig. 1 indicates that tablet has disintegrated.



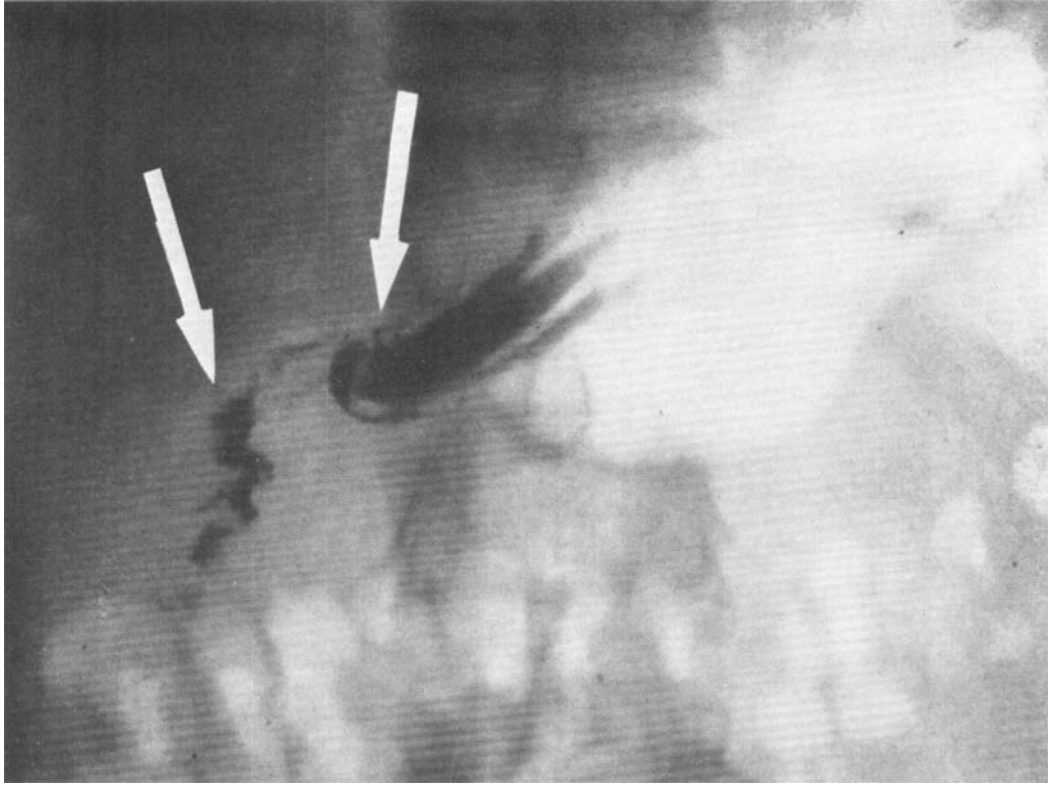


Fig. 3.—Radio-opaque tablet in human stomach 45 minutes after ingestion. Granules are passing through pylorus into small intestine. Note that granules are not dispersed throughout the stomach at any time.

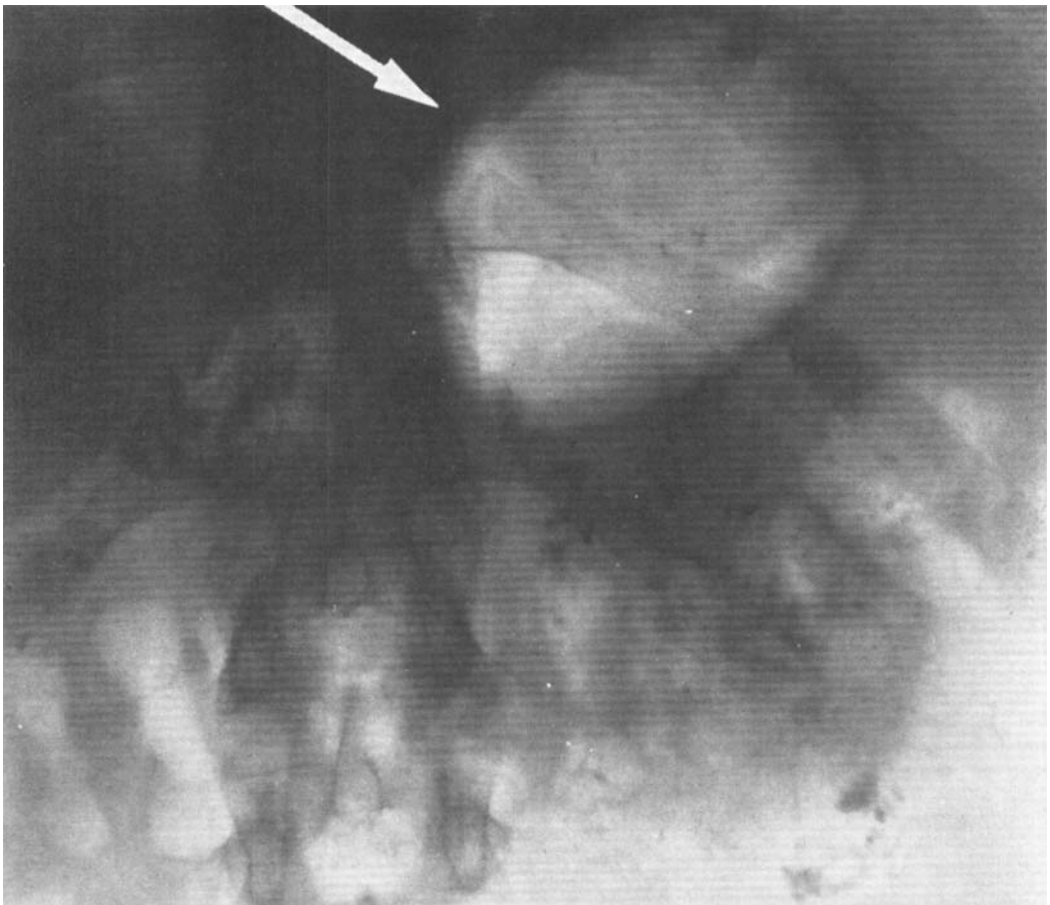
Fig. 4.—Radio-opaque tablet solids in human intestine 60 minutes after ingestion of tablet. Arrow points to empty stomach. Granules are well dispersed in intestine and are apparent as very small radio-opaque spots.



used in this study were prepared by wet granulation of barium sulfate with starch paste and subsequent compression of the dried granulation to which dry starch had been added as a disintegrant.

Dissolution Rate Determinations.—Dissolution rates of conventional tablets were determined by the beaker method and by the oscillating tube method. The *beaker method* involves the use of a double-wall, 400-ml. capacity beaker and a propeller-type stirrer attached to an electronic-controlled stirring motor. The method has been described elsewhere in detail (5). The *oscillating tube method* makes use of a plexiglass cylinder (2.5 × 19.5 cm.) with a 100-mesh stainless steel wire screen on the bottom. The cylinder is attached to the basic unit of the U.S.P. tablet disintegration apparatus (where it replaces the standard basket-rack assembly). The cylinder is immersed in a beaker (placed in a constant temperature bath) containing 800 ml. 0.1 *N* HCl at 37°, the apparatus is set in motion, a tablet is dropped into the cylinder, and the medium is sampled at intervals by a fritted-glass immersion filter tube.

Intrinsic dissolution rate determinations and certain other experiments were carried out by the *rotating disk method* which has been described elsewhere (18). The *static disk method* is a modification of the rotating disk method. The stem of the pellet holder is inserted in a one-hole rubber stopper which serves as a closure for 12-dram plastic vials containing 25 ml. of 0.1 *N* HCl at 37°. The end of the pellet holder, and therefore the exposed face of the pellet, is thus immersed in the solvent. The entire assembly is placed in an incubator set at 37°. The pellet holder is removed from the solution at appropriate intervals (usually 1 or 2 hours), the plastic parts are dried carefully with tissue (without touching the pellet surface), and the assembly is placed in another vial which contains fresh solvent. After removal of the pellet assembly, an aliquot of the solution contained in the vial is assayed and, by appropriate calculations based on concentration and volume, the total amount of dissolved drug is established. This procedure yields data which may either be expressed in terms of an average dissolution rate (amount/area/time) or be plotted cumulatively as amount dissolved *versus* time.

Analytical Methods.—Salicylic acid was determined spectrophotometrically with a Beckman DU spectrophotometer. Solutions were diluted appropriately with 0.1 *N* HCl. Aspirin solutions were hydrolyzed by heating with sodium hydroxide, then analyzed for salicylic acid.

Microenvironmental pH was estimated by immersing the miniature electrodes of a pH meter (Leeds and Northrup model 7664) into a paste prepared from crushed tablets and 0.1 *N* HCl.

RESULTS AND DISCUSSION

Agitation Intensities Encountered in the Human Stomach.—X-ray motion pictures of the human stomach (viewed by the author) show that the agitation of gastric content during normal contractions is mild. It appears a valid assumption, therefore, that the particles from a disintegrated tablet are not dispersed throughout the stomach but rather remain as an aggregate. In support of this assumption of minimum agitation, it has been observed in animals that different foods, when ingested successively, remain in the stomach as different "layers" which do not intermix (9). Similar observations have been made recently in the human stomach by means of the fiberscope (10). Other pertinent reports are those of Ivy, *et al.*, who have remarked on the lack of significant mixing of material held in the fundus of the stomach (11), and several that deal with the regional differences in gastric pH—for example, Tomenius and Williams (12). Accordingly, we developed a dissolution rate test in which the agitation intensity is just sufficient to assure homogeneity of the medium for proper sampling. In this test the solids of the disintegrated tablet remain as an aggregate or "mound" in the center of the bottom of the beaker (5).

The essential correctness of our assumptions has been borne out by the excellent correlation of our *in vitro* test with *in vivo* data (1). However, it has been felt that more direct evidence could be obtained by a serial X-ray study of the behavior of a radiopaque tablet in the human stomach. Such tablets were formulated from barium sulfate in a manner assuring their rapid disintegration (U.S.P. disintegration time was only 3.5 minutes). Figures 1–4 are X-ray photographs taken 13, 30, 45, and 60 minutes after ingestion of a whole tablet with approximately 50 ml. of water.[1] The outline of the tablet was still apparent 13 minutes after ingestion, indicating that the tablet was just beginning to disintegrate. (The longer *in vivo* disintegration time suggests that the U.S.P. test may be too vigorous, or it may reflect the retarding effect of gastric mucous observed by Abbott, *et al.* (13)). Thirty minutes after ingestion, the tablet was totally disintegrated, but the solids remained in an aggregate approximately 2–3 cm. diam. (Fig. 2). The next picture (Fig. 3) was taken at 45 minutes, just as fluoroscopic examination showed that the solids were entering the small intestine. It can be seen that no dispersion of the solid particles occurred while they resided in the stomach. In the final picture of the series (Fig. 4), it is apparent that thorough dispersion of the particles did occur in the small intestine.

Subsequent to our study, Weiss, *et al.* (14), have reported the results of their gastroscopic observations of aspirin tablets in the human stomach; the results tend to confirm our findings. They noted during a period of 10 to 40 or 50 minutes after the ingestion of whole aspirin tablets that "frequently (the aspirin) appeared as a white gelatinous mass of granules adherent to the mucosa" and "in the more marked cases of bleeding, the pulverized mass of aspirin, coagulated blood, and mucus formed an adherent gelatinous layer of 10 to 15 mm. in diameter."

Differences in Comparative Dissolution Rates That May be Encountered When Using Different Agitation Conditions for Compressed Tablets.—The increase in dissolution rate of drugs contained in compressed tablets, when they are subjected to increasing agitation intensities, does not follow a simple mathematical relationship. A variety of effects, characteristic of each formulation, come into play and account for the need to use appropriate

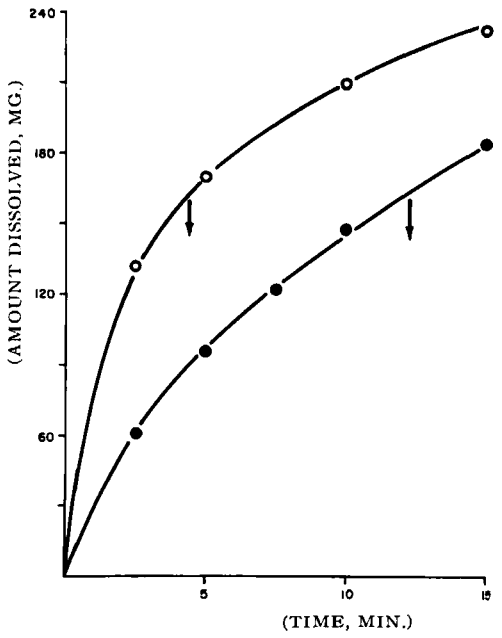

Fig. 5.—Dissolution of aspirin tablets (●) and "buffered" aspirin tablets (○) determined by the beaker method. Vertical arrows point to half-dissolution times.

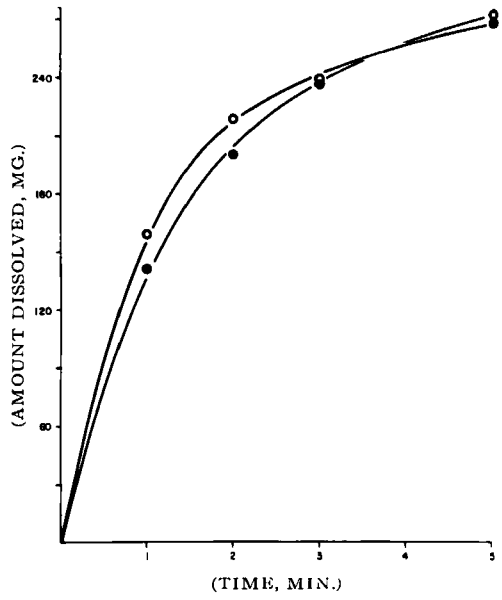

Fig. 6.—Dissolution of aspirin tablets (●) and "buffered" aspirin tablets (○) determined by the oscillating tube method.

agitation conditions for meaningful *in vitro* tests. When the solids of a disintegrated tablet form an aggregate or "mound," the effective surface area with respect to dissolution is primarily the surface of the mound, depending to some extent upon the porosity of the aggregate and the viscosity of the fluids in the interstices, among other factors. Under these conditions, the effect of particle size (specific surface area) on dissolution rate is considerably less than when the particles are dispersed throughout the medium by intensive agitation. This is evident from data presented in a following communication (15). The effect of other tablet components upon the dissolution rate of the active ingredient is also reduced under conditions of intensive agitation because of the greater physical separation of these components and the drug. On the other hand, such effects can be considerable in the microenvironment of a solid aggregate. They may result from high viscosity due to hydrocolloids and gums, lowering of interfacial tension by surfactants, other adsorption phenomena, changes in zeta potential associated with the presence of ionic species, chemical reactions because of high concentrations of potential reactants in the microenvironment, and particularly, changes in the pH of the microenvironment. These effects can directly or indirectly affect the primary drug particles and modify their rate of dissolution.

The importance of these considerations becomes evident from the following experiment. The dissolution rate of aspirin contained in (*a*) a proprietary product of plain aspirin in compressed tablets and (*b*) a proprietary product of aspirin and alkaline additives in compressed tablets was determined by two different methods. One was our previously described beaker method (5) which utilizes a very low agitation rate and permits the solid particles to remain on the bottom of the beaker as an aggregate. The other test was by the oscillating tube method which involves relatively high agitation intensities and causes the solid particles of the disintegrated tablets to be dispersed in the dissolution medium. The results of dissolution rate tests of the two tablet products, using the two different test methods, are shown in Figs. 5 and 6. Each point in the figures represents an average value obtained from four tablets.

Under the low agitation conditions of the beaker method, the tablets containing aspirin and alkaline additives dissolved much more rapidly than plain aspirin tablets. This is in accord with results of human absorption tests of these products conducted previously in our laboratory (1). The vertical arrows in Fig. 5 denote half-dissolution times—one comparative measure of dissolution rates. These times differed approximately threefold. At no time did the extreme values of the two types of tablets overlap. On the other hand, there was practically no difference in dissolution rates of the two tablet formulations when tested by the oscillating tube method (Fig. 6). The ranges of the respective values overlapped at all times, and half-dissolution times were essentially the same.

The difference in the results obtained by the two methods can be explained readily. In an aggregate of disintegrated tablet solids, the alkaline components of the "buffered" aspirin tablet caused an increase in the pH of the microenvironment from approximately pH 1 (0.1 *N* HCl) to about pH 5.6. This increase in pH results in a more rapid dissolution of aspirin particles (8).[2] The dissolution rate enhancing effect is absent when aspirin and alkaline components are physically separated by intensive

[2] A similar formulation approach can be used to increase the dissolution rate of other weak acids.

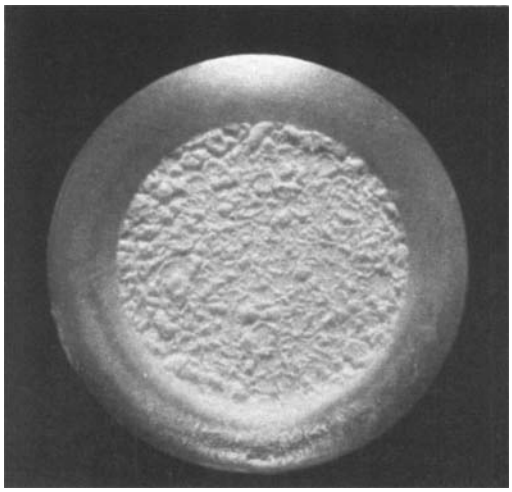

Fig. 7.—Pitted surface of a pellet made from pure salicylic acid granules and 3% magnesium stearate. Picture was taken after dissolution of 10 mg. salicylic acid from the pellet surface. (Pellet diameter, 1.27 cm.)

agitation, since the amount of alkaline components is insufficient to alter significantly the bulk pH of the medium. Thus it is evident that dissolution tests using agitation intensities sufficient to cause dispersion of particles would yield misleading results when used in the evaluation of the described type of pharmaceutical product.[3]

In this connection it is appropriate to comment upon the findings of Rubin, *et al.* (16), and Davison, *et al.* (17). These workers determined the pH of gastric fluids in humans after administration of a commercial "buffered" aspirin tablet product. They found no significant change in pH compared with control values. This should not be surprising on the basis of the quantities of alkaline components involved and the usual acidity and volume of gastric fluids. However, the significance of the cited observations can be misinterpreted easily. It must be recognized that the dissolution rate enhancing function of the alkaline components is because of their ability to raise the pH of the microenvironment, and that the absence of any change in bulk pH is of little pertinence in this respect.

In the course of studies of the effect of tablet formulation factors upon the dissolution rate of the active ingredient, we have also encountered differences in comparative dissolution rates as a function of agitation intensity in formulations that differed in starch content, granule size, and type of lubricant. These studies will be reported in subsequent communications.

Effect of Stirring Rate on the Rate of Dissolution from Irregular Surfaces of Heterogeneous Solids.—A phenomenon encountered in determinations of dissolution rate by the rotating disk method (18) may be pertinent to dissolution rate studies of nondisintegrating tablets containing several components, such as certain sustained-release pellets that consist of drug particles dispersed in a more slowly dissolving matrix. Pellets which were prepared by compressing a mixture of pure 20–40-mesh granules of salicylic acid and 3% magnesium stearate powder developed a rough pitted surface during dissolution. This effect became evident after dissolution of approximately 5 mg. of drug from the pellet, which had an exposed surface area of 1.27 cm.^{2} The surface pitting, which is clearly evident in a photograph of a representative pellet (Fig. 7), is because of the relatively rapid dissolution of salicylic acid granules, and the slower erosion of the hydrophobic magnesium stearate in the interstices between granules. In a dissolution rate determination where the pellets were rotated at 555 r.p.m. in 0.1 *N* HCl at 37°, an initial dissolution rate of 22.8 mg./hour/cm.^{2} was found. After 5 mg. of salicylic acid had dissolved and pits had formed on the pellet surface, the slope of the amount dissolved *versus* time plot increased until it yielded an apparent dissolution rate value of 34.6 mg./hour/cm.^{2} (19). This apparent 52% increase in dissolution rate can be attributed to the increase in surface area of the pellet as a result of pitting. When a similar test was conducted under static conditions (*i.e.*, the pellet was immersed in 0.1 *N* HCl but was not rotated), the dissolution rate was of course considerably lower (1.97 mg./hour/cm.^{2}), but the characteristic formation of surface pits did occur. However, pitting was not accompanied by an increase in apparent dissolution rate.

The observations described above can be explained on the basis of the changes in the thickness of the boundary layer as a function of stirring rate. The effective boundary layer thickness δ can be determined by (20)

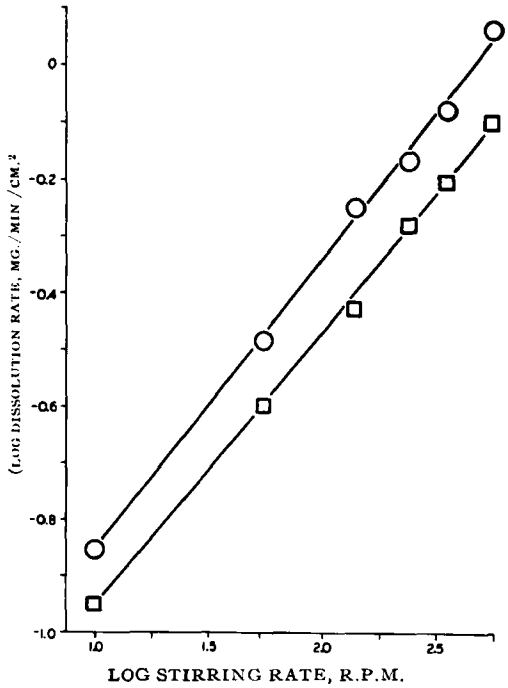

Fig. 8.—Plot of logarithm of dissolution rate *vs.* logarithm of stirring rate (spinning disk method). Key: (○) aspirin, (□) salicylic acid. (Dissolution rates of aspirin are expressed in terms of salicylic acid.)

[3] This should not detract from the usefulness of the oscillating tube method and similar methods to reflect the relative dissolution rates (particularly in the intestine) of many other types of drugs.

$$\delta = \frac{DSC_s}{R} \qquad \text{(Eq. 1)}$$

where D is the coefficient of diffusion, S is the surface area, C_s is the solubility, and R is the intrinsic dissolution rate. The diffusion coefficient of salicylic acid at 37°, calculated from Edwards' data (21), is 11.3×10^{-6} cm.²/second. This value is only slightly affected by concentration and may therefore be used as such. The solubility of salicylic acid in 0.1 N HCl at 37°, as determined in our laboratory, is 2.66 mg./ml. Thus, the boundary layer thickness for the pellets used in this study could be calculated by

$$\delta = \frac{(11.3 \times 10^{-6})(1.27)(2.66)}{R} \qquad \text{(Eq. 2)}$$

or

$$\delta = \frac{3.82 \times 10^{-5}}{R} \qquad \text{(Eq. 3)}$$

where δ is expressed in cm. and R is expressed in mg./second.[4]

The thickness of the boundary layer covering a pellet rotated at 555 r.p.m. is therefore

$$\frac{3.82 \times 10^{-5}}{6.34 \times 10^{-3}} = 0.0060 \text{ cm.}$$

while under static conditions, the boundary layer thickness is

$$\frac{3.82 \times 10^{-5}}{5.47 \times 10^{-4}} = 0.070 \text{ cm.}$$

The depth of the surface pits may be approximated in the following manner. The granules used to prepare the pellets were those which passed a 20-mesh screen but not a 40-mesh screen. This is equivalent to a granule diameter range of 0.042 to 0.084 cm. The maximum average depth of a surface pit may be considered to be equivalent to the average diameter of the granules and probably more realistically to one-half or two-thirds of this value. Since the pellets were compressed at very high pressure (20,000 lb.), it is likely that the granules were distorted in a manner which caused their elongation in a direction parallel to the pellet face and a decrease in diameter normal to the pellet face (22). Such a flattening would cause the depth of the pits on the pellet surface to be even smaller than indicated above. On the basis of all these considerations, the depth of the pits should, in all probability, be somewhat less than 0.04 cm. It is thus apparent that under static conditions (as contrasted with rapid agitation conditions) the surface irregularities would be effectively covered by the boundary layer, and the effective surface area of the pellet would not be increased by pitting. For this reason, there is no increase in the apparent rate of dissolution of the pellet during a static dissolution test. On the other hand, the thickness of the boundary layer covering the surface of a pellet rotating at 555 r.p.m. is insufficient to cover the pits which are formed during the dissolution process. Therefore, the effective surface area of the pellet increases as the smooth surface of the pellet becomes pitted; this results in an increase in apparent dissolution rate.

Although this may not be recognized readily upon initial consideration, the above can be pertinent to the evaluation of dissolution characteristics of certain nondisintegrating pellet-like dosage forms, such as some sustained-release tablets composed of a drug dispersed in a relatively hydrophobic matrix. These dosage forms are exposed to relatively mild agitation *in vivo*, and their effective surface area under these conditions may differ considerably from the effective surface area that is functional at higher stirring rates that may be used in an *in vitro* test. However, stirring rate should not be important if the rate of dissolution is limited by the rate of diffusion through a nondissolving coating or matrix, or if the boundary layer is not on the surface but within the tablet—as is the case with certain prolonged release tablets containing drug in a permanent plastic matrix.

Significance of Intrinsic Dissolution Rate Values Determined at Relatively High Stirring Rates.—For practical purposes, *intrinsic* dissolution rate determinations are frequently made at rather high stirring rates. In view of the emphasis placed in the present communication on the importance of using low stirring rates for dissolution rate tests of pharmaceutical dosage forms, the validity of biopharmaceutical interpretations based on intrinsic dissolution rate values obtained at high stirring rates (8, 23, 25) may be questioned. When the intrinsic dissolution rates of two substances differ by two or three orders of magnitude at high stirring rates, there should be little doubt that similar differences, at least qualitatively, should obtain at low stirring rates and under appropriate *in vivo* conditions. But what about differences in dissolution rates at high stirring rates that are only 50% or so in magnitude?

Cooper and Kingery (24) have recently presented the following equation which relates the diffusion-controlled dissolution rate from the surface of a rotating disk to the velocity of rotation (stirring rate),

$$j = 0.621\, D_o\, (V^*/D^*)^{1/3}\, (\omega/V_\infty)^{1/2}\, \Delta C \qquad \text{(Eq. 4)}$$

where j is the flux density of solute entering the solvent (dissolution rate per unit area), D_o is the diffusion coefficient of the solute in saturated solution, V^* is the effective viscosity in the immediate vicinity of the solid-liquid interface, D^* is the weighted average diffusion coefficient of the solute in the solvent (assuming that D varies with concentration), ω is the angular velocity (in radians per second) of the rotating disk, V_∞ is the bulk viscosity, and ΔC is the concentration differential, representing the difference between interface and bulk concentration. Under our usual experimental conditions, ΔC is maintained essentially constant and is equal to the solubility C_s of the solute in the solvent. In such cases,

$$j = K\omega^{1/2} \qquad \text{(Eq. 5)}$$

where

$$K = 0.621 D_o\, (V^*/D^*)^{1/3}\, (1/V_\infty)^{1/2} C_s$$

Equation 5 may also be written as

$$j = K_1\, (\text{r.p.m.})^{1/2} \qquad \text{(Eq. 6)}$$

[4] Certain complications associated with the application of Eq. 3 to heterogeneous pellets may cause the calculated δ values to be slightly too high (19). However, this will not affect the validity of the subsequent comments.

where

$$K_1 = 0.3236\ K$$

Expressed logarithmically, Eq. 6 yields

$$\log j = 0.5 \log (\text{r.p.m.}) + \log K_1 \quad \text{(Eq. 7)}$$

According to Eq. 7, a plot of the logarithm of dissolution rate (expressed here in mg./minute/cm.^{2}) *versus* the logarithm of stirring rate (expressed in r.p.m.) should yield a straight line with a slope of 0.5. This has been found by others to be the case with inorganic salts (20, 24).

We now present data to show (*a*) that the described relationship between dissolution rate and stirring rate holds for the apparatus used in our studies, and (*b*) that this relationship applies to compounds other than inorganic salts.

Using the rotating disk procedure (18), which is a modification and adaptation of the technique of Nelson (25), we determined intrinsic dissolution rates of aspirin and salicylic acid in 0.1 *N* HCl and 37° at stirring speeds ranging from 10 to 555 r.p.m. The data, appropriately plotted, are shown in Fig. 8. Each of the points in the figure represents from two to ten separate determinations. These points yield satisfactory straight lines which were fitted by the method of least squares. The slope of the line for salicylic acid is 0.492 and that for aspirin is 0.515. As is evident, the experimental slope values are very close to the theoretical value.[5]

It can be shown that the ratio of dissolution rates of two compounds is independent of stirring rate, provided the Cooper-Kingery equation or a similar, more general equation applies. Equation 7 may be rearranged to

$$\log (\text{r.p.m.}) = 2 \log j + K_2 \quad \text{(Eq. 8)}$$

where

$$K_2 = -2 \log K_1$$

On the basis of Eq. 8, at any given stirring rate

$$2 \log j_a + K_{2a} = 2 \log j_b + K_{2b} \quad \text{(Eq. 9)}$$

where the letter subscripts denote j and K_2 values for compounds *a* and *b*, respectively. Then

$$\log \frac{j_a}{j_b} = 1/2(K_{2b} - K_{2a}) \quad \text{(Eq. 10)}$$

and

$$\frac{j_a}{j_b} = 10^{1/2\,(K_{2b} - K_{2a})} = \text{constant} \quad \text{(Eq. 11)}$$

[5] This has also been found true for the dissolution of these weak acids in pH 8.0 Sorensen buffer solution.

In general, the ratio of the dissolution rates of two or more compounds will be independent of stirring rate as long as the respective dissolution rates increase with stirring rate according to the general equation

$$\text{dissolution rate} = (\text{constant})\,(\text{stirring rate})^a \quad \text{(Eq. 12)}$$

and the value of *a* is the same for each compound.

When these conditions are met, comparative dissolution rate data obtained at high stirring rates reflect properly the relative dissolution rates encountered at lower stirring rates. However, the observations by Hamlin and co-workers (6), and work currently in progress in this laboratory indicate that, in certain instances, the effect of stirring rate on dissolution rate cannot be described by either the Cooper-Kingery equation or by the general Eq. 12. In such cases it is often imperative to use appropriately low stirring intensities in intrinsic dissolution rate determinations for biopharmaceutical purposes.

Effect of Certain Tablet Formulation Factors on Dissolution Rate of the Active Ingredient II

Granule Size, Starch Concentration, and Compression Pressure

By GERHARD LEVY, JANET M. ANTKOWIAK, JOSEPHINE A. PROCKNAL, and DONALD C. WHITE

The effect of various tablet formulation and processing factors on the rate of dissolution of the active ingredient of model tablets (prepared by double compression) was investigated. Dissolution rate increased with decreasing granule size (over the range 16–20 mesh to 60–80 mesh), but not strictly proportionally to the corresponding increase in the apparent surface area of the granules. Increasing starch content of granules (varied from 0 to 20 per cent) resulted in an increase in dissolution rate. Increasing precompression pressure (varied from 715 to 5720 Kg./cm.^{2}) caused an increase in dissolution rate. This was probably due to fracturing of the harder granules into smaller particles with greater specific surface area or bonding of the softer granules (prepared at lower slugging pressure) during their compression into tablets.

THE RATE of absorption and the physiologic availability of many drugs that are administered orally in solid form is a function of their rate of dissolution in gastrointestinal fluids (1–3). Certain tablet formulation and processing factors apparently affect the dissolution rate of drugs contained in tablets, since it has been found that generically identical tablet products made by different manufacturers exhibit significant differences in dissolution rate of the active ingredient (4). In a number of instances, poor tablet formulation has been shown to cause a significant reduction of physiologic availability of the active ingredient and impairment of clinical response (for example, see References 5–8).

There is frequently no correlation between tablet disintegration time and dissolution rate (2–4), or the nature of this correlation (if it exists) is variable and may be affected significantly by the nature of the formulation (9). Various aspects of tablet formulation and production have been the subject of extensive studies; but, unfortunately, disintegration tests rather than dissolution tests have been used to determine the effect of formulation and processing variables on the rate of release of the active ingredient. The need for information concerning the effect of tablet formulation factors on dissolution rate has led to studies that are the subject of this series of communications. The present communication deals with the effect of granule size, starch content of granules, and precompression (slugging) pressure on the rate of dissolution of the active ingredient of compressed tablets.

Received February 19, 1963, from the Biopharmaceutics Laboratory, School of Pharmacy, State University of New York, at Buffalo, Buffalo.
Accepted for publication March 8, 1963.

EXPERIMENTAL

Preparation of Tablets.—Compressed tablets were made by double compression with a Carver hydraulic press, model B, using a conventional set of punches and die placed in a special holder. The punches were flat-faced and 1.27 cm. diam. Slugs were prepared from approximately 1 Gm. of powder and were subsequently broken into granules with a mortar and pestle. The granules were separated into the desired size fractions by sieving. Small amounts (sufficient for approximately 12 tablets) of the different granulations were mixed gently but thoroughly with other components of the formulation in small plastic vials. Quantities of mixture necessary to prepare a single tablet were weighed on an analytical balance and compressed into tablets. Preparation of mixtures and tablets took place on the same day on which the dissolution tests were made. The composition and other specifications of the experimental tablet preparations are listed in Table I.

Dissolution Rate Determinations.—Dissolution rates were determined by the beaker method, which has been described in detail (4). In one instance, the oscillating tube method (10) was used, except that the volume of dissolution medium was reduced to 300 ml.

GENERAL COMMENTS

In terms of physiologic realities, poor tablet formulation resulting in decreased dissolution rate of the active ingredient is most likely to affect the rate of gastrointestinal absorption of relatively poorly water-soluble weak acids. This is so because weak acids are generally well absorbed from the stomach (11) but dissolve much more slowly in acidic than in neutral or basic media (12, 13). On the other hand, weak bases dissolve much more rapidly in acidic than in basic media and generally are not absorbed to a significant extent from the stomach. Any retardation in dissolution of a weakly acidic drug may be reflected readily by slower absorption rate (2). A similar effect is less likely in the case of weak bases because of their more rapid dissolution

in the acidic gastric fluids and because their absorption is restricted almost exclusively to the intestine. Therefore, gastric emptying rate rather than dissolution is likely to be the rate-limiting factor in the absorption of weak bases.[1]

These considerations have led to the use of a poorly water-soluble weak acid as the active ingredient in the tablet formulations prepared for this study. In view of the availability of an *in vitro* dissolution test method which has been shown to yield data which correlate with human absorption rate studies of salicylates (2), the weak acid salicylic acid was chosen. This compound has the additional advantages of stability and availability of a simple and direct method of analysis.

Studies described in this and the following communication (15) deal with certain formulation and processing variables encountered in the preparation of compressed tablets by double compression. This method of preparation does not involve the use of binders and liquids which could complicate considerably any reasonably well controlled study of variables associated with the preparation of tablets by wet granulation. However, many aspects of the results of the present study should be equally applicable to the preparation of tablets by wet granulation. It is recognized that the results obtained with tablets compressed with a hydraulic press may, in some instances, differ from those obtained with tablets compressed by means of a conventional tablet machine.

The effect on dissolution rate of some of the formulation variables studied may be mediated in some instances by a modification of granule and/or tablet disintegration rates. No attempt was made to evaluate the relative contribution of these as well as of certain microenvironmental factors.[2] The formulations, methods of preparation, and particularly the active ingredient, were chosen primarily for the purpose of obtaining model systems capable of yielding useful information. Accordingly, the choice of formulations was not restricted to those which might be of direct commercial pertinence.

RESULTS AND DISCUSSION

Aging Effects.—Preliminary experiments were carried out to determine the effect of aging on the dissolution rate of drug contained in compressed tablets because others have found that granulations prepared at different times may exhibit differences in properties (16). Salicylic acid granules were stored at room temperature in a desiccator containing Drierite; tablets were prepared from these granules after 1, 3, and 5 weeks of storage. Dissolution rates were determined on the same day on which the tablets were compressed. The results (shown in Fig. 1) indicate that dissolution rate changed significantly with granule age. To prevent significant bias or distortion of results because of

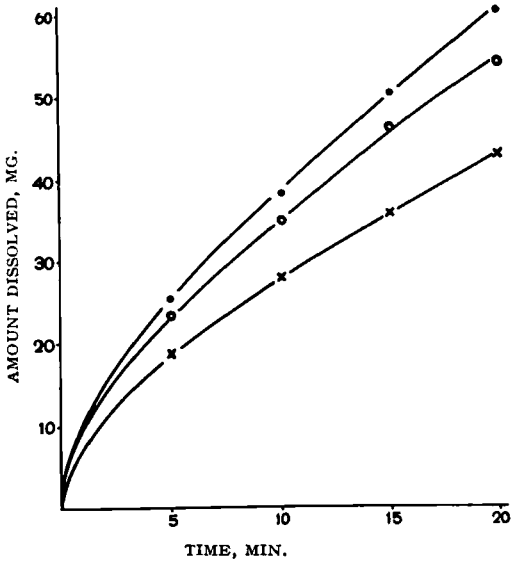

Fig. 1.—Effect of granule age on dissolution rate of salicylic acid contained in compressed tablets. Key: ●, one week; ○, 3 weeks; ×, 5-week-old granules. (Average of 10 tablets each, formula A.)

[1] Relatively rapid dissolution in acidic media and poor absorption from the stomach may be the reasons why the rate of absorption of tetracycline hydrochloride has been found to be independent of particle size (14).

[2] The reader may refer to the first paper of this series (10) for an explanation and description of microenvironmental factors.

aging effects, all subsequent experiments were conducted in the form of a latin-square design; dissolution tests for a given experiment were carried out as rapidly as possible to make all measurements within a few days. This also reduced possible bias because of effects resulting from fluctuations of temperature and humidity.

Effect of Granule Size.—Figures 2 and 3 show dissolution rate data for tablets made from 16–20-mesh, 20–40-mesh, 40–60-mesh, and 60–80-mesh granules, respectively. It is evident that the dissolution rate increases with decreasing granule size. However, this increase is not strictly proportional to the increase in the apparent surface area of the granules (Table II). The surface area ratios listed in Table II were calculated on the assumption that the granules were spherical and had smooth surfaces. The ratios should be approximately correct even if these assumptions do not obtain, because shape factor and surface roughness should be about the same for granules of all sizes used.[3] Dissolution rate ratios could be calculated from initial dissolution rates because these were approximately constant until 15% of the drug content of a tablet had dissolved. The increase in dissolution rate from

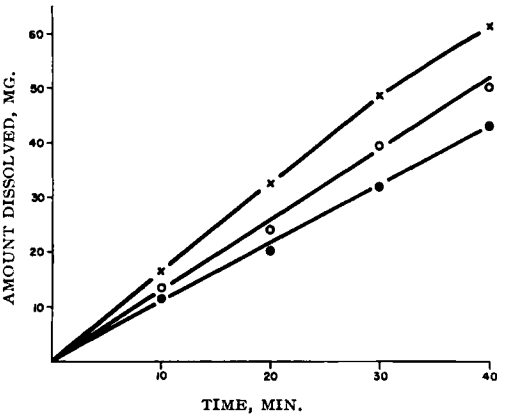

Fig. 2.—Effect of granule size on dissolution rate of salicylic acid contained in compressed tablets. Key: ●, 16–20 mesh; O, 20–40 mesh; ×, 40–60 mesh granules. (Average of 10 tablets each, formula B.)

tablets containing 20–40-mesh and 40–60-mesh granules (compared with tablets made from 16–20-mesh granules) was not so great as the increase in apparent surface area. This is because the disintegrated tablet particles remain as an aggregate on the bottom of the beaker (due to the low intensity of agitation), and the surface area of drug exposed to the solvent is primarily the surface of the aggregate. This effect has been explained in greater detail in the first paper of this series (10).

The much greater dissolution rate of tablets prepared from the smallest granules (60–80 mesh) is because these granules are small enough to be dispersed somewhat in the medium despite the low intensity of agitation. This permits moving solvent to come in contact with a greater portion of the potentially available surface. The granule size which would show such an effect in the human stomach

[3] It has been shown recently that the shape factor for 20–30-mesh anisometric crystals of salicylamide could be assumed to remain constant at least until about 30% was dissolved (17).

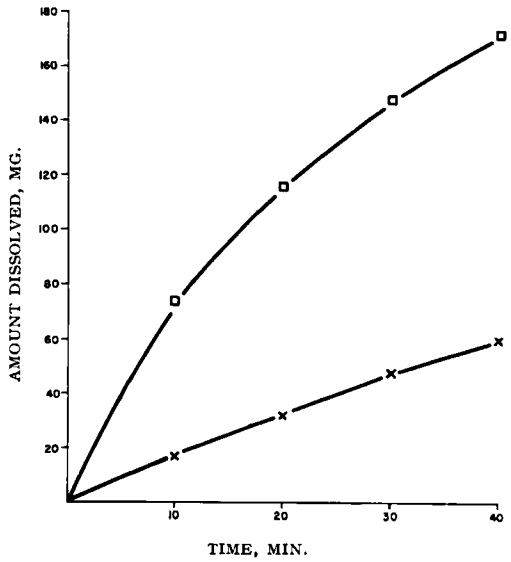

Fig. 3.—Effect of granule size on dissolution rate of salicylic acid contained in compressed tablets. Key: ×, 40–60 mesh; □, 60–80-mesh granules. (Average of 10 tablets each, formula B.)

would depend on the specific gravity of the granules and on gastric motility and cannot be estimated readily except by *in vivo* X-ray studies.

Effect of Starch Content of Granules.—Increasing the starch content of granules from 5 to 20% resulted in an increase in the dissolution rate of salicylic acid (Fig. 4), probably because of more rapid and thorough disintegration of the granules. (It is known that tablets disintegrate more rapidly when the starch content is increased (18, 19).) In this instance, dissolution rate determinations were also made with the oscillating tube apparatus (Fig. 5), and the results, although qualitatively similar, differ somewhat from those obtained by the beaker method. This illustrates again the need to use appropriate methodology for dissolution rate studies of compressed tablets (10.)

Effect of Granule Compression Pressure.—Tablets were prepared from granules made from slugs compressed at pressures ranging from 715 to 5730 Kg./cm.[2] As shown in Fig. 6, dissolution rates increased with increasing precompression pressure. This may be due to fracturing of drug particles at higher slugging pressure, yielding smaller primary particles. Such an effect was observed by Higuchi, *et al.*, with aspirin (19). Fragmentation

of the more highly compressed granules during subsequent tableting may also occur. Finally, the softer granules obtained at lower precompression pressures are more likely to undergo bonding during tableting, and thus yield larger granules. Visual observations suggest that the latter effect is operative, but this does not exclude a possible contribution because of one or both of the other effects.

It has been found that aspirin administered in

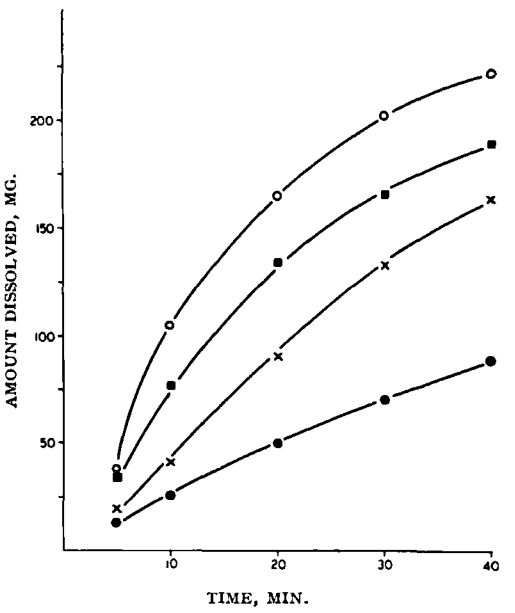

Fig. 6.—Effect of precompression pressure on dissolution rate of salicylic acid contained in compressed tablets. Key: ●, 715 Kg.; ×, 1430 Kg.; ■, 2860 Kg.; O, 5730 Kg. pressure per cm.^{2} (Average of five tablets each, formula D.)

tablets made at very high compression pressure was more rapidly absorbed by humans than aspirin administered in tablets compressed at lower pressure (20); this could be because of the same effects reported here.

Although the data shown in Figs. 4 and 6 represent separate experiments carried out at different times, the dissolution rate curve in Fig. 6 for the tablets made from granules prepared at 1430 Kg./cm.^{2} pressure (and containing 15% starch) falls between the curves for tablets made from granules that were also compressed at 1430 Kg./cm.^{2} and contain 10 and 20% of starch, respectively (as shown in Fig. 4).

CONCLUSIONS

Results of this study indicate that some of the more important tablet formulation and processing variables may affect the dissolution rate of the active ingredient. The magnitude of these effects must be determined individually for each tablet product, and their significance with respect to the rate of gastrointestinal absorption and the physiologic availability of the active ingredients must be assessed on the basis of several additional considerations (10, 21). The results of the present investigation should only be interpreted as indicative of the general nature of the effects on dissolution rate of the tablet formulation and processing factors studied.

Nonclassical Antimetabolites XIV

Some Factors in Design of Irreversible Inhibitors Effective at Low Concentration

By B. R. BAKER, R. P. PATEL, and PRABODH I. ALMAULA

5-(Bromoacetyl)salicylic acid (XII) irreversibly inhibits glutamic dehydrogenase and lactic dehydrogenase about as well as the standard exoalkylating agent, 4-(iodoacetamido)salicylic acid, at one-tenth the concentration of the standard; most of this increased reactivity is because of the higher reactivity of the halogen in XII. Three of the four iodoacetamido compounds that reversibly bound to lactic dehydrogenase more tightly than the standard gave irreversible inhibition at 10–20 per cent the concentration necessary for the standard. Three carbophenoxyamino heterocyclic acids showed no irreversible inhibition of lactic dehydrogenase, but were effective irreversible inhibitors of glutamic dehydrogenase at one-tenth the concentration of the standard compound.

THE CONCEPT (2) that a properly designed inhibitor can reversibly complex with the active site of an enzyme, then become irreversibly bound within the complex by alkylation adjacent to the active site (exo-alkylation) has had strong experimental support (3, 4). Similar observations have been independently and subsequently made in the area of hapten immunochemistry (5) and with chymotrypsin (6).

The exo-alkylation phenomenon is illustrated (4) by Eq. 1. In the experimental evidence for this phenomenon, it was shown that the rate of irreversible reaction between the inhibitor AB and the enzyme, to form the irreversible complex, II, was dependent upon the concentration of reversible complex, I; that is, the rate of inactivation could not be increased once the enzyme was saturated with the inhibitor. The amount of reversible complex, I, can be calculated from the measurable dissociation constant, K_I, of the enzyme-inhibitor complex.

$$E\!\!<^{H} + AB \rightleftharpoons E\!\!<^{H} \cdots AB \rightarrow \underset{\text{I}}{} \quad E\!\!\overset{\frown}{\cdots A} + BH \quad \text{(Eq. 1)}$$
II

Of obvious importance to chemotherapy is that a sufficient intracellular concentration of an inhibitor must be obtained to effect the target enzyme site of an invading cell. In order to overcome an insufficient intracellular concentration of inhibitor, it would be necessary to find inhibitors that will operate at lower concentrations. There are two ways in which exo-alkylating irreversible inhibitors effective at lower concentrations could be obtained. First, a compound that can saturate the enzyme at a lower concentration (smaller K_I) will operate equally as effectively as an agent that requires a higher concentration to saturate the enzyme (larger K_I); second, if a more active alkylating group, B, in structure I is employed, the rate of inactivation of the enzyme should be the same at proportionally lower inhibitor concentrations. The design, synthesis, and evaluation of both types are the subject of this paper.

d series, R = $ICH_2\overset{\overset{O}{\|}}{C}NH-$
e series, R = $C_6H_5O\overset{\overset{O}{\|}}{C}NH-$

4). A number of compounds have been observed (7) to give lower I_{50} values[1] for LDH and GDH[2] than the prototype, salicylic acid (8). For example, salicylate had I_{50} = 19 on LDH, coumarin-3-carboxylic acid (III*a*) had I_{50} = 1.7, 2-hydroxycinchoninic acid (IV*a*) had I_{50} = 0.18, and 1,6,7-trimethyl-2-quinolone-3-carboxylic acid had I_{50} = 0.20; thus these compounds had K_I values of 0.1 to 0.01 of the original salicylic acid. The structural feature necessary for inhibition of LDH and GDH that these compounds had in common was the 1,2- or 1,3- relationship of oxo (or hydroxyl) and carboxyl groups (7).

Two other compounds that should reversibly inhibit LDH and GDH are 4-hydroxyquinoline-3-carboxylic acid (V*a*) and 2-hydroxyquinoxaline-3-carboxylic acid (VI*a*). The latter was resynthesized (10) and showed reversible inhibition of LDH and GDH; however, the I_{50} concentration could not be reached because of the amount of absorption of light at 340 mμ by the compound. It was expected that the carbophenoxyamino (9, 11) and iodoacetamido derivatives of III–VI should show lower K_I values than the standard compound, 4-(iodoacetamido)salicylic acid (3, 4) and therefore could potentially operate as exo-alkylating agents at lower concentrations than that used for the standard compound.

EXPERIMENTAL

Reagents.—α-Ketoglutaric acid, sodium pyruvate, DPN, LDH, and GDH were purchased from Sigma Chemical Co. and from Nutritional Biochemical Corporation; LDH was the crystalline enzyme isolated from rabbit skeletal muscle, and GDH the crystalline enzyme isolated from mammalian liver.

Determination of I_{50} Values.[1]—The procedure employed for LDH was the same as that previously described (7, 8), except that 0.05 *M* Tris buffer (pH 7.4) and 1 m*M* pyruvate were employed (12). The I_{50} values for GDH were determined in the same fashion as for LDH using cell concentrations of 1 m*M* α-ketoglutarate and 75 m*M* ammonium sulfate in 0.05 *M* Tris buffer (pH 7.4). In some cases with colored compounds (for example compound IV*d*), the I_{50} concentration could not be reached because of insufficient light transmission at 340 mμ for the kinetic study. In such cases, the highest concentration possible was used that allowed full light transmission at 340 mμ and the I_{21} or I_{30} was noted; these I_x values could be converted to the K_I values in Table II by the calculations shown in the section on *Results*.

Enzyme Inactivation Procedure.—The LDH inactivation procedure (4), as later modified (12), was employed. The GDH incubations were run as previously described (4). In all incubations for determination of irreversible inhibition, three incubation solutions were run simultaneously and were made from the same master enzyme-DPNH solution (4): (*a*) a solution of the test compound, (*b*) a standard of 2 m*M* 4-ISA, and (*c*) an enzyme control with no inhibitor. All runs were duplicated at least twice. An occasional bad run was readily elimi-

[1] The I_{50} is defined as the concentration of inhibitor (I) that will give 50% inhibition of enzymic reaction in the presence of 1 m*M* concentration of substrate *S* (8). The I_{50} and the enzyme-inhibitor (EI) dissociation constant K_I can be interrelated (9) by the dissociation constant, K_m, of the enzyme-substrate complex with use of the formula

$$K_I = K_m \times I/S = K_m \times I_{50}$$

[2] Abbreviations: LDH, lactic dehydrogenase; GDH, glutamic dehydrogenase; DPNH, reduced diphosphopyridine nucleotide; 4-ISA, 4-(iodoacetamido)salicylic acid.

TABLE II.—RELATIVE EFFECTS OF INHIBITORS ON LDH AND GDH

Compd. No.	Thiosulfate Reactivity	Enzyme	$K_I \times 10^4$	Inactivation, Rate	Incubation Concn.[a]
4-ISA	1.0[c]	LDH	17[b]	1.0[c]	2.0
		GDH	8.5[b]	1.0[c]	2.0
XII	19	LDH	13	1.2, 1.2	0.2
		GDH	11	0.65, 0.63	0.2
III*d*	1.13	LDH	3.1[d]	0.45, 0.59	0.4
IV*d*	0.63	LDH	3.2[e]	0.56, 0.46	0.2
V*d*	...[g]	LDH	0.87	0, 0	0.2

		GDH	2.4	1.0, 1.3[f]	0.2
V*e*	...	LDH	1.1[d]	0, 0	0.13[h]
		GDH	2.3[d]	0, 0	0.13[h]
VI*e*[i]	...	...	...	...	...

[a] Millimolar concentration of inhibitor; 2 m*M* 4-ISA used for comparison (see *Methods*). [b] These values calculated from the I_{50} (7) (see *Results*) are slightly different from the K_I values obtained by Lineweaver-Burk plots (4) and agree within experimental error for both methods (9). [c] Arbitrary values for relative purposes; these are not the same absolute value for LDH and GDH. [d] Calculated from I_{50} value. [e] Calculated from I_{20} value. [f] This compound showed a rate saturation effect (4, 12) in two runs comparing 0.12 and 0.24 m*M* and comparing 0.15 and 0.30 m*M* (Fig. 3) with ratios of 1.4 and 1.1, respectively; calcd. ratios from Eq. 4: 1.5 and 1.4. [g] Sodium salt too insoluble to determine, but all N-aryl iodoacetamides previously measured have shown 1.0 ± 0.4. [h] Maximum concentration obtainable at 0° in Tris buffer (pH 7.4) was 0.20 m*M*. [i] Solubility less than 0.2 m*M* at 0° in Tris buffer (pH 7.4) and therefore K_I and irreversible inhibition not determined.

nated if the control or standard did not behave properly.

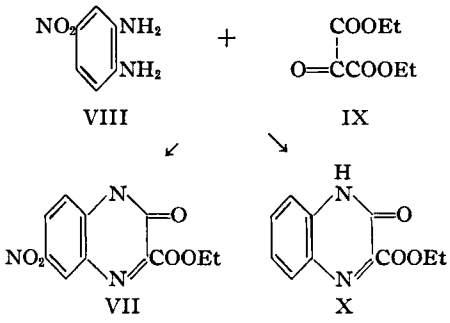
Reactivity of Halogen.—The method for determination of the relative halogen reactivity previously employed (4) was not satisfactory for the compounds listed in Table II. Whereas 4-ISA had a half reaction time with thiosulfate of about 60 minutes at 0°, 5-(bromoacetyl)salicylic acid (XII) had half reacted at this temperature and concentration in about 3 minutes. Satisfactory kinetics were obtained when the reaction and the blank were diluted tenfold; XII reacted 19 times faster than 4-ISA (Table II).

The other compounds in Table II (III*d*–VI*d*) formed insoluble sodium salts at 0° with the previous method (4). The method was modified by allowing the reaction to proceed at 24°, but the increased rate in reaction was compensated by running the kinetics at a fourfold dilution of that previously used (4). The standard compound, 4-ISA was rerun under these warmer, more dilute conditions; comparisons are listed in Table II where 4-ISA is given an arbitrary rate of 1.0.

CHEMISTRY

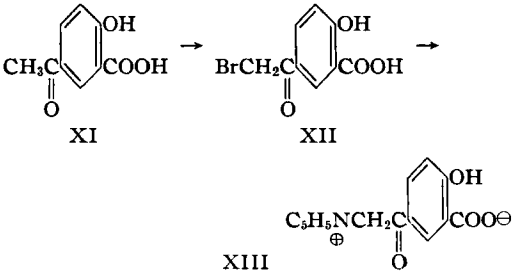
Methods.—All of the potential irreversible inhibitors were synthesized by reaction of III*c*–VI*c* with iodoacetyl chloride (7) or with phenyl chloroformate (9), as previously described or by suitable modification of the conditions as noted in Table I. The requisite 6-aminocoumarin-3-carboxylic acid (III*c*) was obtained by stannous chloride reduction of 6-nitrocoumarin-3-carboxylic acid (III*b*) (13); catalytic reduction gave deeply colored amorphous products that could not be purified. 6-Amino-2-hydroxycinchoninic acid (IV*c*) was best prepared by ferrous ammonium sulfate reduction of the nitro acid (IV*b*) (14); in this case catalytic reduction gave poor and unreproducible yields of IV*c*. Catalytic reduction of 4-hydroxy-6-nitroquinoline-3-carboxylic acid (V*b*) in the presence of two equivalents of hydrochloric acid afforded 6-amino-4-hydroxyquinoline-3-carboxylic acid (V*c*) in 37% yield.

Although condensation of 4-nitro-*o*-phenylenediamine (VIII) with ethyl oxomalonate might be expected to give two isomers, VII and X, only one isomer could be isolated. Since the reaction proceeds by initial condensation of the oxo-group of IX with the stronger *meta*-amino group of VIII, the product could be expected to be VII. Analogous reactions involving *o*-diamines of differing amine strengths



have been described (15, 16). Saponification of VII afforded VI*b* in 77% yield. Considerable difficulty was encountered in reducing VI*b* to the amine VI*c*. Catalytic reduction frequently led to over-reduction products. The best method found for this reduction was ferrous ammonium sulfate; the product was easily isolated in pure form, but the yields were only fair.

A candidate for an exo-alkylating inhibitor with a more reactive alkylating group was 5-(bromoacetyl)-salicylic acid (XII). This compound was prepared by bromination of 5-acetylsalicylic acid (XI) (17) in ether.



That the bromine had entered the methyl group and not the ring was shown by conversion of XII to the pyridinum betaine (XIII) and by the high reactivity of the halogen of XII towards thiosulfate (Table II). Compound XII has the same melting point described for XII prepared by another route (18) that appeared technically unattractive.

Synthesis[3]

6-Nitrocoumarin-3-carboxylic Acid (*IIIb*).—Condensation of 10 Gm. of 5-nitrosalicylaldehyde with 10 Gm. of ethyl malonate in 200 ml. of boiling ethanol containing 1 ml. of piperidine gave a 98% yield of ethyl 6-nitrocoumarin-3-carboxylate, m. p. 194–196° [lit. m.p. 198° (13)]. Considerable difficulty was experienced in finding proper conditions for saponification of the ester. Precipitation by ordinary acidification gave a product still containing potassium and apparently containing an opened lactone ring. The following procedure gave a good product each time.

A mixture of 1.00 Gm. of ester and 10.6 ml. of 5% alcoholic potassium hydroxide was stirred for 90 minutes, during which time the orange potassium salt of the product separated. Sufficient water was added to just dissolve the potassium salt; the solution was added in a thin stream with good mechanical stirring to 60 ml. of 3 *N* hydrochloric acid. The product, which gradually separated, was collected on a filter, washed with water, and recrystallized from ethyl acetate; yield, 0.50 Gm. (56%), m.p. 227–229° [lit. m.p. 234–235° (13)].

6-Aminocoumarin-3-carboxylic Acid (*IIIc*).—A 2.00-Gm. (9.5 mmole) quantity of *IIIb* was added to 6 Gm. of stannous chloride dihydrate in 6 ml. of 12 *N* hydrochloric acid. The mixture was warmed gently on the steam bath until the exothermic reaction had started, then was controlled by cooling in an ice bath. The solution was then heated on the steam bath for 2 hours. Spin-evaporation *in vacuo* gave a thick syrup to which 100 ml. of water was added. The yellow product gradually crystallized; yield, 1.8 Gm. (95%), m.p. 224–226°, that was suitable for further transformations. Recrystallization from dilute alcohol gave crystals, m.p. 234°; $\nu_{max.}^{KBr}$ 3400 (OH, NH); 1725 (lactone and carboxyl C=O); no nitro bands near 1520 and 1340 cm.$^{-1}$.

Anal.—Calcd. for $C_{10}H_7NO_4 \cdot H_2O$: C, 53.8; H, 4.07; N, 6.27. Found: C, 53.6; H, 4.01; N, 6.26.

6-Amino-2-hydroxycinchoninic Acid (*IVc*).—A solution of 2.0 Gm. (8.5 mmoles) of *IVb* (14) in 6 ml. of water and 6 ml. of concentrated ammonium hydroxide was poured with stirring into a boiling solution of 23 Gm. of ferrous ammonium sulfate hexahydrate in 50 ml. of water. Then 20 ml. of concentrated ammonium hydroxide was added in small portions over a period of 20 minutes with stirring, but without additional heating. The mixture, after being heated an additional 30 minutes on the steam bath, was filtered, and the cooled filtrate acidified to about pH 4 with acetic acid. The product was collected on a filter and washed with cold water; yield 1.0 Gm. (57%), m.p. above 300°; this material is suitable for further transformations. Recrystallization from water gave pale yellow needles, m.p. above 300°, whose infrared spectrum indicated a zwitterion structure; $\nu_{max.}^{KBr}$ 3450 (NH); 1670 (amide C=O); 1600 cm.$^{-1}$ (carboxylate). Catalytic reduction was not as satisfactory since the product could not always be isolated and at best gave a 46% yield.

Anal.—Calcd. for $C_{10}H_8N_2O_3$: C, 58.8; H, 3.93; N, 13.7. Found: C, 58.5; H, 4.24; N, 13.5.

6-Amino-4-hydroxyquinoline-3-carboxylic Acid (*Vc*).—A mixture of 1.00 Gm. (4.2 mmoles) of *Vb*, 200 ml. of 70% ethanol, 0.083 ml. of 12 *N* hydrochloric acid, and 100 mg. of platinum oxide was shaken with hydrogen at 2–3 Atm. until reduction was complete (about 24 hours). The filtered solution was spin-evaporated to dryness *in vacuo* leaving 0.20 Gm. of product. An additional 0.10 Gm. was obtained by extracting the catalyst precipitate with 5 ml. of 1 *N* NaOH, then acidification of the filtrate; total yield, 0.30 Gm. (37%), m.p. above 300°, that was suitable for the next step. Recrystallization from ethanol-water gave the analytical sample, m.p. above 300°; $\nu_{max.}^{KBr}$ 3500, 3400 (NH); 1675 (carboxyl C=O), 1620 cm.$^{-1}$ (C=N or amide C=O).

Anal.—Calcd. for $C_{10}H_8N_2O_3$: C, 58.8; H, 3.93; N, 13.7. Found: C, 58.7; H, 3.80; N, 13.6.

Ethyl 3-Hydroxy-7-nitroquinoxaline-2-carboxylate (VII).—A 6.96-Gm. (0.04 mole) quantity of ethyl ketomalonate was added to a mixture of 6.12 Gm. (0.04 mole) of 4-nitro-*o*-phenylenediamine and 125 ml. of absolute ethanol. The mixture was refluxed with gentle stirring for 7 hours. The hot solution was filtered, the filtrate was diluted with 100 ml. of water, treated with 1 Gm. of charcoal at the boiling point, then filtered. On being cooled, the filtrate deposited 5 Gm. (48%) of product, m.p. 225–227°. By recrystallization from absolute ethanol an analytical sample was obtained, m.p. 227°; $\nu_{max.}^{KBr}$ 3500 (NH); 1750 (ester C=O), 1652 (amide C=O); 1525 cm.$^{-1}$ (NO_2).

Anal.—Calcd. for $C_{11}H_9N_3O_5$: C, 50.2; H, 3.42; N, 15.9. Found: C, 50.2; H, 3.54; N, 15.7.

3-Hydroxy-7-nitroquinoxaline-2-carboxylic Acid (*VIb*).—A mixture of 3.0 Gm. (11.4 mmoles) of ethyl ester (VII) and 60 ml. of 3 *N* sodium hydroxide was stirred for 4 hours. Then 500 ml. of water was added and the nearly clear solution was filtered. The filtrate was added to 60 ml. of 3 *N* hydrochloric acid with stirring. The yellow product was collected on a filter and washed with water; yield, 1.8 Gm. (67%), m.p. 265° dec. suitable for the next step. For analysis a sample was recrystallized from 2-methoxyethanol to give yellow crystals, m.p. 267° dec.; $\nu_{max.}^{KBr}$ 3500 (NH); 1750 (carboxyl C=O); 1640 (amide C=O); 1525 cm.$^{-1}$ (NO_2).

Anal.—Calcd. for $C_9H_5N_3O_5$: C, 45.9; H, 2.14; N, 17.9. Found: C, 46.1; H, 2.31; N, 17.9.

3-Hydroxy-7-aminoquinoxaline-2-carboxylic Acid (*VIc*).—This was prepared by ferrous reduction of *VIb* as described for the *preparation of* *IVc* in 40% yield, m.p. above 300°. A sample was dissolved in 10 ml. of 1 *N* sodium hydroxide for analysis. The solution was filtered, then acidified with 3 *N* hydrochloric acid with ice cooling; the product was collected and washed with water. This reprecipitation was repeated once more to give yellow crystals, m.p. above 300°; $\nu_{max.}^{KBr}$ 3400, 3350, 3200 (NH); 1690 (carboxyl C=O); 1630, 1580 cm.$^{-1}$ (C=N or amide C=O).

[3] Melting points were taken in capillary tubes in a Meltemp block and are uncorrected. Infrared spectra were determined in KBr pellets with a Perkin-Elmer 137B recording spectrophotometer. Enzyme kinetics and ultraviolet spectra were determined with a Cary 11 recording spectrophotometer.

Anal.—Calcd. for $C_9H_7N_3O_3$: C, 52.7; H, 3.44; N, 20.5. Found: C, 52.6; H, 3.58; N, 20.2.

6-(Carbophenoxyamino)coumarin-3-carboxylic Acid (IIIe).—A 1.04-Gm. (6.72 mmoles) quantity of phenyl chloroformate in one portion was added to a rapidly stirred solution of 1.00 Gm. (4.4 mmoles) of 6-aminocoumarin 3-carboxylic acid (III*c*) in 50 ml. of water containing 1.12 Gm. of sodium bicarbonate and cooled to 3° in an ice bath. After being stirred for 3 hours in an ice bath, during which time part of the yellow product separated as the sodium salt, the mixture was filtered. The filtrate was acidified to pH 3 with 3 *N* hydrochloric acid; the product was collected on a filter and washed with water.

The insoluble sodium salt was added to 50 ml. of water preheated to 70°. After being stirred for a few minutes, the solution was cooled, acidified, and the product collected. This process should be repeated until no more product is obtained on acidification of an extract. Extended heating of the sodium salt in water causes hydrolysis of the carbophenoxy group.

The dried, combined precipitates were recrystallized from ethyl acetate to give yellow crystals; yield, 0.75 Gm. (52%), m.p. 218–220°; $\nu_{max.}^{KBr}$ 3300 (NH); 1730 (lactone C=O); 1705 (urethane C=O); 1690 (carboxyl C=O); 737 and 685 cm.$^{-1}$ (monosubstituted phenyl). (See Table I for analytical data.)

All compounds prepared by this method are listed in Table I under *Method A*. In some cases, the sodium salt was soluble and all of the product was obtained by acidification of the filtered alkaline solution (*Method B*); in some cases all of the product separated as sodium salt and none was obtained by acidification of the filtered alkaline solution (*Method C*). In one case, the sodium salt of the starting material was insoluble at 0° and it was necessary to run the reaction at 40° (*Method D*).

4-Hydroxy-6-(iodoacetamido)quinoline-3-carboxylic Acid (V*d*).—To a stirred solution of 250 mg. (1.2 mmoles) of V*c* in 5 ml. of 2% sodium hydroxide (2.4 mmoles) cooled in an ice bath was added 0.45 Gm. (2.4 mmoles) of iodoacetyl chloride in one portion. The mixture was stirred for 30 minutes, then the product (free acid) was collected on a filter and washed with water; yield, 270 mg. (61%), m.p. above 300°. Recrystallization from 2-methoxyethanol by addition of water gave the pure product, m.p. above 300°; $\nu_{max.}^{KBr}$ 3400 (NH); 1660 (amide and carboxyl C=O); 1600 cm.$^{-1}$ (C=C). (See Table I for analytical data.)

Compound V*c* could not be acylated by *Method A* in sodium bicarbonate, since the proton was not removed from the zwitterion with aqueous sodium bicarbonate. Compounds prepared by this route are listed in Table I under *Method E*.

5-(Bromoacetyl)salicylic Acid (XII).—A solution of 0.28 ml. of bromine in 50 ml. of ether over a period of 2 hours was added to a magnetically stirred solution of 0.92 Gm. (5.11 mmoles) of 5-acetylsalicylic acid (XI) (17) in 100 ml. of reagent ether protected from moisture. The filtered solution was spin-evaporated to dryness *in vacuo;* yield, 1.3 Gm. (98%), m.p. 132°. Recrystallization from chloroform gave 0.90 Gm. (68%) of white crystals, m.p. 152°; $\nu_{max.}^{KBr}$ 3100 (OH); 1670 cm.$^{-1}$ (C=O).

Anal.—Calcd. for $C_9H_7BrO_4$: C, 41.7; H, 2.70; Br, 30.7. Found: C, 41.9; H, 2.89; Br, 30.6.

The halogen was lost if the compound was recrystallized from protic solvents; the compound should be stored in a desiccator. A melting point of 152° has been reported for XII prepared by a different route (18).

5-(ω-Pyridiniumacetyl)salicylate Betaine (XIII).—A solution of 1.0 Gm. (3.8 mmoles) of XII in 10 ml. of reagent pyridine was heated on a steam bath for 30 minutes. On cooling, 1.0 Gm. of a crystalline precipitate was obtained that was a mixture of XIII and its hydrobromide salt, m.p. 180–200° dec. A hot solution of the salt in 20 ml. of water was neutralized with a solution of 0.24 Gm. of anhydrous sodium acetate dissolved in 0.5 ml. of water. After standing overnight at 3°, the mixture was filtered and the product washed with ice water; yield, 0.42 Gm. (42%), m.p. 262–264°. Recrystallization from water gave white crystals, m.p. 271°.

Anal.—Calcd. for $C_{14}H_{11}NO_4$: C, 65.4; H, 4.30; N, 5.44. Found: C, 65.1; H, 4.46; N, 5.37.

RESULTS[4]

Comparison of Halogen Reactivities.—When the rate data with sodium thiosulfate and the iodo compounds were plotted as second-order reactions, straight lines were obtained. The slope of a given line gave the relative halogen reactivity compared to 4-ISA (4, 12). The relative reactivities are recorded in Table II where 4-ISA is given an arbitrary value of 1.0. The bromoketone, XII, was 19 times as reactive as 4-ISA. The iodoacetamido derivatives (III*d*–VI*d*) had the same order of halogen activity as 4-ISA, as expected from previous comparisons (12, 19).

K_I Values of Inhibitors.—The I_{50} value[1] could be determined from a plot of Vo/V against I where Vo = velocity of the enzyme reaction without inhibitor, and V = velocity in the presence of I concentration of inhibitor. Where $Vo/V = 2$, $I = I_{50}$; the K_I could be calculated (9) from

$$K_I = K_m \times I_{50} \qquad \text{(Eq. 2)}$$

Both α-ketoglutarate and pyruvate had $K_m = 2.5 \times 10^{-4}$ in our system. These K_I values are listed in Table II.

In some cases noted in Table II, the I_{50} concentration could not be reached because of insufficient transmittance of light at 340 mμ; absorption by the compound did not allow observation of the decrease in 340 mμ absorption necessary for following the enzyme rate. In such cases, the near maximum Vo/V obtainable with the slits not quite wide open in the spectrophotometer could be used for calculating the K_I; obviously these results will have about twice the error in the absolute value of K_I at I_{20} or I_{30}. These I_{20} or I_{30} could be converted to K_I values by use of the corresponding I_{20} or I_{30} values of 4-ISA and the $K_I = 17 \times 10^{-4}$ for the latter compound. Since I_{50} measures the amount of EI complex at 50% inhibition and I_{20} measures the amount of EI complex at 20% inhibition, the ratio of Eq. 3 is derivable. Thus from the I_{20} and I_{50} values of 4-ISA and

$$I'_{20}/I_{20} = I'_{50}/I_{50} = K_I'/K_I \qquad \text{(Eq. 3)}$$

[4] The capable technical assistance of Maureen Vince and Dorothy Ackerman is gratefully acknowledged.

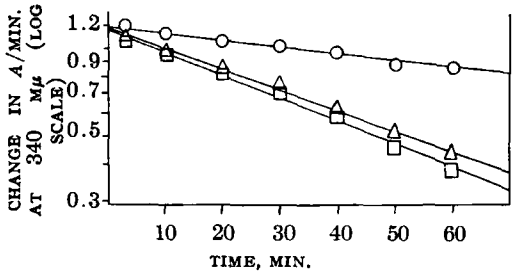


Fig. 1.—Comparative irreversible inhibition of LDH·DPNH by 4-ISA and 5-(bromoacetyl)salicylic acid (XII). Key: ○, LDH·DPNH control; △, 2 m*M* 4-ISA; □, 0.2 m*M* XII.

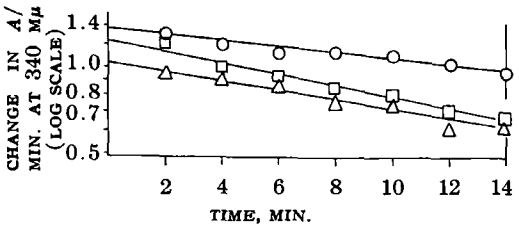

Fig. 2.—Comparative irreversible inhibition of GDH·DPNH by 4-ISA and 6-carbophenoxyamino-2-hydroxycinchoninic acid (IV*e*). Key: ○, GDH·DPNH control; △, 2 m*M* 4-ISA; □, 0.2 m*M* IV*e*

the I_{20} of an unknown compound, the K_I of an unknown compound can be estimated. The K_I values calculated from I_n values less than I_{50} are noted in Table II.

5-(Bromoacetyl)salicylic acid (XII) was reversibly bound to LDH and GDH slightly stronger than 4-ISA. The carbophenoxyamino (III*e*–V*e*) and iodoacetamido (III*d*–VI*d*) heterocyclic carboxylic acids were bound to LDH and GDH 3.5 to 15 times stronger than 4-ISA.

Irreversible Inhibition by Compounds in Table II.—The inactivation rates of LDH and GDH by 4-ISA are assigned arbitrary values of 1.0; it should be noted that the absolute rates of inactivation of the two enzymes by 4-ISA are not identical. The relative rate of inactivation by a given compound is listed in Table II. In each experiment, 4-ISA was compared simultaneously with the new compound, since for reasons still unknown (4) the absolute rate of inactivation of the enzyme can vary twofold from experiment to experiment, but the relative rates usually duplicate with 30%.

The halogen of 5-(bromoacetyl)salicylic acid (XII) was 19 times as reactive as that of 4-ISA, and XII irreversibly inhibited LDH at 120% rate of 4-ISA with concentrations of 0.2 m*M* and 2 m*M*, respectively (Fig. 1); 0.2 m*M* of XII also irreversibly inhibited GDH at 65% of rate of 4-ISA at 2 m*M*.

None of the carbophenoxyamino compounds (III*e*–V*e*) irreversibly inhibited LDH, but two irreversibly inhibited GDH at one-tenth the concentration needed for 4-ISA. For example, 6-carbophenoxyamino-2-hydroxycinchoninic acid (IV*e*) at 0.2 m*M* give about the same rate of inactivation of GDH as 2 m*M* 4-ISA (Fig. 2); IV*e* also showed a rate saturation effect (Fig. 3).

Three of the four iodoacetamido compounds (III*d*, IV*d*, VI*d*) at one-tenth to one-fifth the concentration of 4-ISA showed irreversible inhibition of LDH at 45–83% the rate shown by 4-ISA. An example is 7 - (iodoacetamido) - 3 - hydroxyquinoxaline - 2-carboxylic acid (VI*d*) shown in Fig. 4. The fourth compound (V*d*) was a strong reversible inhibitor of LDH but showed no irreversible inhibition.

DISCUSSION

As shown in Fig. 1 and Table II, 0.2 m*M* of 5-(bromoacetyl)salicylic acid (XII) irreversibly inhibited LDH at 1.2 times the rate of 2 m*M* 4-ISA. There are four factors that can influence the rate of irreversible inhibition by exo-alkylation: (*a*) the extent of *EI* complex formation which can be calculated (4) from the K_I by Eq. 4, (*b*) the ability of the reversibly bound inhibitor to bridge to a nucleophilic group on the enzyme surface adjacent to the active site (12, 19), (*c*) the nucleophilic character of the

$$EI = \frac{E_t}{\frac{K_I}{I} + 1}$$

where E_t = total enzyme concentration (Eq. 4)

enzyme being alkylated (9, 11), and (*d*) the electrophilic character of the alkylating group. If factors (*b*), (*c*), and (*d*) were identical for 4-ISA and XII, then XII should have irreversibly inhibited LDH at about 3.8 times the rate of 4-ISA, which can be calculated from the ratio = 19 × 0.13/0.70, where 19 is the increased thiosulfate reactivity, 0.70 is the fractional amount of enzyme in the *EI* complex with 2 m*M* 4-ISA, and 0.13 is the fractional amount of enzyme in *EI* complex with 0.2 m*M* of XII. Therefore, factors (*b*), (*c*), or (*d*) or any combination of the three are contributing to the ratio of irreversible inhibition. In addition, the enzymic nucleophilic group, if not SH, probably has a different ratio of rate of reaction between XII and 4-ISA than the 19 observed with thiosulfate.

It can be calculated from Eq. 4 that at a concentration of 0.2 m*M* only 13% of total LDH is reversibly complexed by XII. This 13% appears to be close to the point of bimolecular alkylation of other enzymes where no complexing is required, which could be quite disadvantageous in the intact cell. In fact, however, the practically nonexistent energy barrier for complexing contrasts sharply with the energy barrier involved in a bimolecular reaction; this differential has been given an elegant mathematical treatment by Singer, *et al.* (5).

Although the carbophenoxy compounds in Table II were strongly bound to LDH reversibly, these showed no irreversible inhibition; the lack of irreversible inhibition of LDH by other carbophenoxy compounds has been previously noted (9, 11). Since all but one of these earlier carbophenoxy compounds could irreversibly inhibit GDH (11), it was not surprising that the carbophenoxy compounds, III*e*–IV*e*, irreversibly inhibited GDH. Of importance to this discussion is the low concentrations necessary for irreversible inhibition, as expected from the low K_I values; only a concentration one-

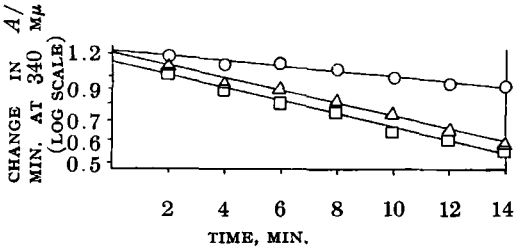

Fig. 3.—Rate saturation of irreversible inhibition of GDH·DPNH by 6-carbophenoxyamino-2-hydroxycinchoninic acid (IV*e*). Key: ○, LDH·DPNH control; △, 0.15 m*M* of IV*e*; □, 0.30 m*M* of IV*e*.

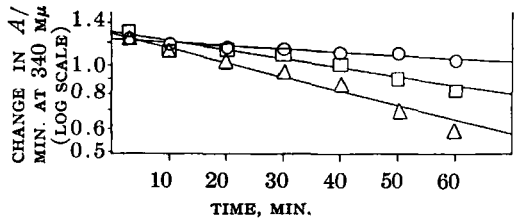

Fig. 4.—Comparative irreversible inhibition of LDH·DPNH by 4-ISA and 7-(iodoacetamido)-3-hydroxyquinoxaline-2-carboxylic acid (VI*d*). Key: ○, LDH·DPNH control; △, 2 m*M* 4-ISA; □, 0.2 m*M* VI*d*.

tenth that of 4-ISA (Table II) or one-twentieth of other carbophenoxyamino derivatives of salicylic acid (11) was required. As yet no carbophenoxy compounds have been found that give irreversible inhibition of LDH by the exo-alkylation mechanism, but the search for such a compound is continuing.

One of the carbophenoxy compounds was investigated further to demonstrate that reversible complexing at the active site was a necessary prerequisite for irreversible inhibition. 6-Carbophenoxyamino-2-hydroxycinchoninic acid (IV*e*) showed a rate saturation effect (Fig. 3); doubling the concentration of inhibitor from 0.15 m*M* to 0.30 m*M* gave an increase in inactivation rate of 1.1, somewhat less than the calculated ratio of 1.4 from Eq. 4 and definitely less than 2.0 if the inactivation occurred by bimolecular reaction (tail-alkylation). In a check run comparing 0.12 m*M* and 0.24 m*M*, the ratio of inactivation rates was 1.4 compared to a calculated value of 1.5.

All of the iodoacetamido compounds (III*e*–VI*d*) showed reversible inhibition of LDH with K_I's one-fifth to one-twelfth of 4-ISA. In addition, three of the four showed at least one-half the rate of irreversible inhibition of 4-ISA at one-fifth to one-tenth the concentration required for 4-ISA. The fourth compound (V*d*) showed no irreversible inhibition. This difference is most probably because of the bridge principle of specificity (12, 19), since in V*d* the distance of the iodomethylene group from the 1,2-oxo-carboxylic acid groups involved in binding is quite different than the distance between the corresponding groups of III*d*, IV*d*, and VI*d*.

The fact that a number of these compounds with lower K_I could inhibit LDH and GDH at correspondingly lower concentrations than used for 4-ISA gives another line of evidence supporting the exo-alkylation phenomenon as an explanation for the mode of selective denaturation of LDH and GDH by these alkylating inhibitors.

It can be concluded that in the design of an exo-alkylating irreversible inhibitor for a given enzyme careful attention should be given to use compounds that give the most tight-reversible binding possible. The more reactive bromoacetyl group of XII gives faster inactivation and allows design of a potential *in vivo* inhibitor that can vary in alkylating ability from the slow-reacting chloroacetamido group to the fast-reacting iodomethyl ketone group; in this way the proper balance between the highest reactivity with the least destruction of inhibitor by random reactions prior to the attack of the target site by the irreversible inhibitor can be maintained.

By placing the bromoacetyl group on III–VI, compounds should be obtained that would give irreversible inhibition of LDH *in vitro* at concentrations approaching 10^{-5} *M*, within the utilizable range for *in vivo* activity. As pointed out earlier (1, 4), our *in vitro* approach must by necessity ignore for the time the important problems of transport and membrane permeability present in an *in vivo* system. However, if necessary the carboxyl group of inhibitors such as II–VI could be masked by ester or amide functions to give a latent activity that could be regenerated by intracellular nonspecific amidases or esterases. It is our opinion that such an approach to LDH inhibitors is worthy of further pursuit.

Peppermint and Spearmint Tissue Culture II

Dual-Carboy Culture of Spearmint Tissues

By CHING-JU WANG† and E. JOHN STABA

A 5-day old, 15 per cent (v/v) spearmint cell inoculum in a dual-carboy system containing modified T-medium with 2,4-dichlorophenoxyacetic acid (0.5 p.p.m.), Dow Corning-B antifoam (500 p.p.m.), and bacitracin (5 p.p.m.) is suggested for good cell suspension growth.

APPLICATIONS of plant tissue cultures may be forthcoming for evaluating herbicides and plant growth regulators, for the production of food, for testing drug efficacy and toxicity, and for the production of economically useful compounds. Basic microbial techniques have been used to grow large quantities of plant tissue in suspension cultures (1–3).

Air has been supplied to plant suspension cultures containing less than 0.5 L. of medium by agitating glass flasks on various shakers (4–7), or to larger volumes of medium by forcing sterile air through open-end tubing or spargers in a carboy or pilot-plant fermentor (1, 3, 8, 9). Agitation may be produced by the aeration process itself (1, 2) or by magnetic bar stirring devices (9).

This study reports the growth characteristics of spearmint (*Mentha spicata* L.) cell inocula of known cell number in dual-carboys receiving constant air flow and agitation. The effect of certain antifoam and antibiotic compounds on spearmint tissue growth is also reported.

EXPERIMENTAL

The spearmint stem-callus tissues studied were approximately 1-year-old and had been established by the method previously published (7). Suspension cultures in this study were maintained and subcultured on our modification of Murashige's and Skoog's tobacco medium (T-medium) with 0.5 p.p.m. of 2,4-dichlorophenoxyacetic acid (2,4-D). Murashige's and Skoog's tobacco medium (10) was referred to as modified Murashige's medium in our previous publications (7, 11).

Erlenmeyer Flask Cultures.—Preliminary experiments were performed in 250-ml. Erlenmeyer flasks containing 50 ml. of medium to determine the effects of cell inoculum concentrations, antifoams, and antibiotics on the growth of spearmint suspension cultures.

Received January 18, 1963, from the College of Pharmacy, University of Nebraska, Lincoln.
Accepted for publication March 26, 1963.
Supported by grants from the American Cancer Society (W3505-992) and the Society of the Sigma Xi and R. E. S. A. Research Fund.
Portion of a thesis submitted by C. J. Wang to the Graduate College, University of Nebraska, in partial fulfillment of Master of Science degree requirements.
Presented to the Pharmaceutical Science Section, American Association for the Advancement of Science, Philadelphia meeting, December 1962.
† Present address: College of Pharmacy, University of Michigan, Ann Arbor.

The 15-day-old cell inocula for these experiments were prepared by a method previously published (12). After inoculation, the flasks were incubated on a reciprocal shaker (stroke: 9 cm.; rate/minute: 88), at room temperature (about 27°) and light. Relative growth was calculated as:

$$\text{Relative Growth (\%)} = \frac{\text{Growth average (four flasks) of each experiment}}{\text{Growth average (four flasks) of control}} \times 100$$

Dual-carboy Cultures.—Each carboy of the dual-carboy system (Fig. 1) was simultaneously aerated by a forced flow of sterile, moistened air through a T tube attached to a stainless steel sparger (porosity:

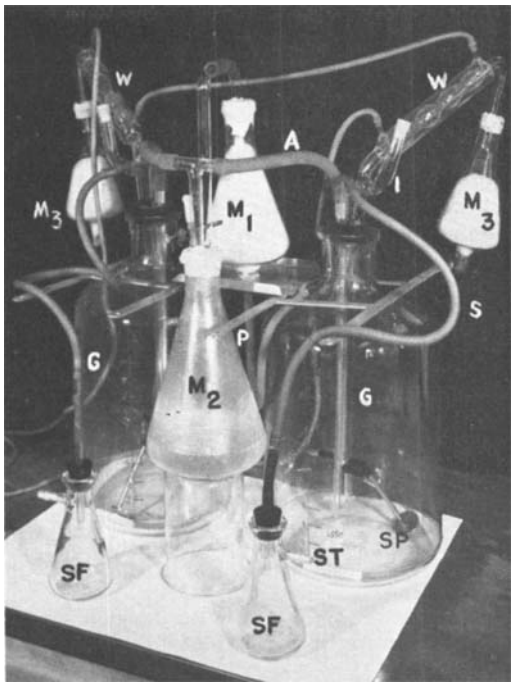

Fig. 1.—Dual-carboy apparatus. *A*, air inlet tubing connected to stainless steel tube and sparger; *I*, innoculation tube; *G*, 12-L. carboy; *M*, modified 1-L. flask with cotton for air sterilization; *M*2, 2-L. flask with distilled water for water saturation of air; *M*3, modified 500-ml. flask with cotton as air vent; *P*, air inlet tube connected to a gas flowmeter; *S*, sampling tube; *SF*, sampling flask; *SP*, stainless steel sparger; *ST*, magnetic bar; *W*, water condenser.

[a] Expressed in p.p.m. [b] Relative growth was determined after 21 days of culture. Each flask received 1 ml. of inoculum containing 1.9×10^6 cells (3.5 mg. cellular dry weight).

10 μ).[1] Agitation was produced by a 7.5-cm. Teflon-coated magnetic bar rotating at 90 r.p.m. on the base of each carboy. Two rates of air flow were studied; 4.5 L./minute (aeration condition I) and 27 L./minute (aeration condition II). The air flow was measured through a gas-flow meter[2] at room temperature. Pressures over the sulfite medium were 1.16 Atm. for the slower flow rate and 1.33 Atm. for the faster one. The dual-carboy system was mounted in a water bath maintained at 28°. Measured temperature variance of the medium within the carboys was negligible.

Oxygen absorption rates (OAR) of aqueous sulfite solutions in the dual-carboy system and Erlenmeyer flasks under the conditions specified in Table I were determined by standard procedures (13, 14).

The inocula for the dual-carboy system were prepared as follows. Approximately 100 ml. of 15-day-old cell suspension was transferred aseptically into a 2-L. Erlenmeyer flask containing 300 ml. of medium and grown for 5 days on the reciprocal shaker. This new cell suspension was then aseptically passed through a 602μ-mesh nylon sieve[3] and used as inocula for the carboys. Each carboy was inoculated with 15% by volume of new cell suspension and cultured in the water bath at 28° for 8 days. A sample was taken daily from each carboy for 8 days and examined for cell concentration, cellular dry weight, and the pH change in the medium.

Semiquantitative determinations were made on each medium sample for dextrose, fructose, and sucrose by a chromatographic procedure previously published (12). Aqueous standard solutions of sucrose (1.5%), fructose (1.5%), and dextrose (1.0%) were used. Whatman No. 1 chromatographic papers were spotted with the standard solutions (2, 4 and 10 μl.), control nutrient medium (10 μl.), and the medium filtrates (10 μl.). The presence of dextrose was confirmed by Clinistix[4] test paper.

RESULTS

Erlenmeyer Flask Cultures.—The heaviest inoculum (3 mg. cellular dry weight/flask) produced a maximum yield within 15 days (Table II). With smaller inocula (0.25, 1 and 2-mg. cellular dry weight/flask), proportionately less growth resulted within 15 days, but the cultures achieved a maximum growth within 30 days.

None of the six antifoam compounds studied at the low or high concentration levels appreciably affected spearmint tissue growth (Table III).

Amphotericin, griseofulvin, and/or oxytetracycline (5 p.p.m.) inhibited spearmint tissue suspension growth. The effects of penicillin G, bacitracin, tylosin, tylosin with nystatin, and nystatin are shown in Table IV. Tylosin and griseofulvin were autoclaved with the medium, but the other antibiotics were added aseptically to the medium after dilution with sterilized double-distilled water.

TABLE IV.—EFFECT OF ANTIBIOTICS ON SPEARMINT SUSPENSION GROWTH

Antibiotic	Concn.[a]	Relative Growth, %[b] Generation 1	Generation 2	Generation 3
Penicillin G[c]	60	101.7	...	...
Bacitracin[c]	5	92.8	106.3	...
Tylosin[c]	100	46.9	112.3	100.7
Nystatin and tylosin[c]	25 20	23	...	...
Nystatin[d]	25	52.2	...	...
	50	11.8	...	...
	125	0.0	...	...

[a] Expressed in p.p.m., except nystatin which is expressed as u./ml. [b] Determined after 15 days of culture. [c] Each flask received 4 ml. of inoculum containing 872 × 10^3 cells (2.3 mg. cellular dry weight). [d] Each flask received 4 ml. of inoculum containing 338 × 10^3 cells (1.6 mg. cellular dry weight).

Bacitracin (5 p.p.m.) was routinely used as a constituent in the medium for dual-carboy cultures.

The OAR values obtained under certain specified conditions for 250-ml. Erlenmeyer flasks and the dual-carboy system are shown in Table I. At no time did the OAR values for the sulfite medium in the dual-carboy system exceed the value for the flasks.

Dual-carboy Cultures.—Preliminary growth studies in the dual-carboy system indicated that a 15% (v/v) inoculum resulted in greater yields than a 5% (v/v) inoculum, and that a 5-day-old inoculum resulted in greater yields than did a 30-day-old inoculum.

The results obtained from carboy I under aeration condition I are shown in Fig. 2. The growth yield of spearmint tissue in carboy I under aeration condition I was 112.13 Gm. fresh weight, and that in carboy I under aeration condition II 95.70 Gm. fresh weight after an 8-day growth cycle. The growth yield in carboy II was 10% of that of carboy I under aeration condition I and 40% of carboy I under aeration condition II.

The utilization of sucrose, fructose, and dextrose by tissues in carboy I grown under aeration condition I is shown in Fig. 3.

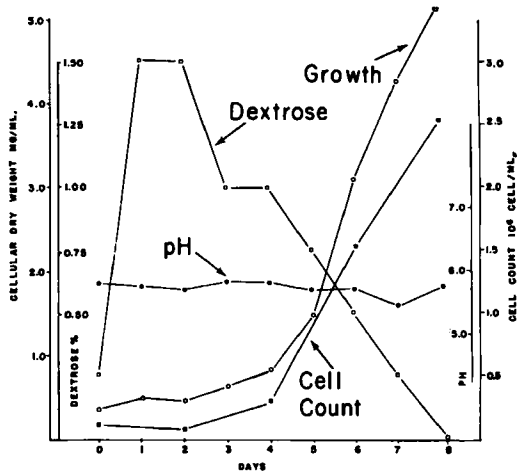

Fig. 2.—Spearmint suspension growth in carboy I containing 3 L. of modified T-medium with DC-B antifoam (500 p.p.m.) and bacitracin (5 p.p.m.). Inoculum: age, 5 days; quantity, 15% v/v; dry weight, 2 mg./ml.; cell number, 824 × 10^3 cells/ml. Final growth yield under aeration condition I: 112.13 Gm. fresh weight.

DISCUSSION

Torrey (15) has suggested that the smaller the inoculum the more complex the medium must be to reduce the time required for cells to "condition" the medium. Blakely and Steward (16) have reported that filtered and rigorously washed low-cell-content inocula of angiosperm cells on agar medium exhibited a very low frequency of colony formation. Our results indicate that the smaller the inoculum concentration of rigorously washed spearmint cells, the longer the lag phase of suspension growth. After 30 days of culture, however, the four inoculum concentrations tested resulted in a similar growth yield (Table II).

Tulecke and Nickell (2) used 300 p.p.m. of Dow Corning-A (DC-A) in their carboy cultures of various plant tissues with no apparent toxicity. We selected DC-B (500 p.p.m.) for routine use because of its lack of toxicity to spearmint suspension culture and the ease with which it may be dispersed in an aqueous medium.

Certain antibiotics have been reported to control microbial contamination in plant tissue cultures (2, 3, 17–19). However, none appear to have been accepted as a routine constituent of plant-growth media. Although nystatin (25 u./ml.) with tylosin (20 p.p.m.) is reported not to inhibit carrot, grape, and rose suspension cultures, we found that nystatin (25 u./ml.) or nystatin (25 u./ml.) with tylosin (20 p.p.m.) will inhibit spearmint suspension growth. Penicillin (10 u./ml.) and bacitracin (5 p.p.m.) is reported to stimulate the growth of sorrel tumor tissue (17), and penicillin (20 p.p.m.) not to inhibit Ginkgo-pollen, holly-stem, or rose-stem-callus suspension growth (2). Penicillin (60 p.p.m.) and bacitracin (5 p.p.m.) were not inhibitory to spearmint suspension cultures. Bacitracin (5 p.p.m.) was routinely used in media for dual-carboy cultures.

Convolvulus cell suspensions are reported to divide most frequently 1 week after inoculation and *Haplopappus* cell suspensions 3 days after inoculation (20). Similarly, our preliminary studies indicated that a 5-day-old, 15% v/v inoculum passed through a 602 μ-mesh nylon sieve gave more growth in the dual-carboy system than either 15 or 30-day-old tissue inocula.

Plant tissue culture growth may be reported as Growth Index (GI) values

$$GI = \frac{\text{Final fresh weight growth}}{\text{Initial fresh weight inoculum}} \quad (2).$$

The Growth Efficiency Index (GEI) value suggested

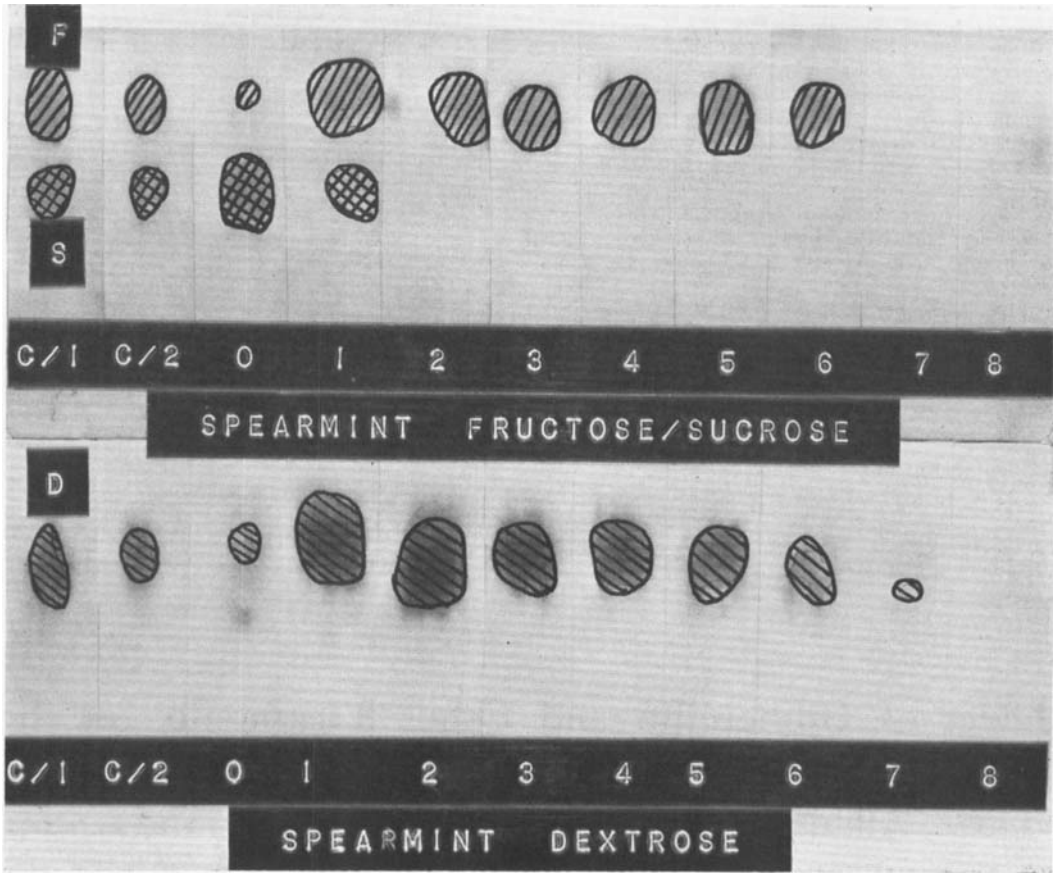

Fig. 3.—Chromatograms of fructose (*F*), sucrose (*S*) and dextrose (*D*) samples (10 μl.) taken at daily intervals (0–8) from the spearmint suspension culture described in Fig. 2. C/1: control *F*, *S*, *D*, (0.15 mcg.); C/2: control *F*, *S*, *D*, (0.075 mcg.).

below would consider the GI at maximal growth, as well as the volume of medium used and the time required for maximal tissue growth. The GEI is expressed as

$$\text{GEI} = \frac{\text{GI at maximal growth}}{\text{Medium (L.)} \times \text{days required for maximum growth}}$$

The GI and GEI values calculated for Ginkgo-carboy cultures were 8.7 and 0.03, respectively (2), and 14.9 and 0.11 for rose carboy cultures, respectively (1). The GI and GEI values for the spearmint carboy culture shown in Fig. 2 are 20.8 (112.13/5.4) and 0.87 (20.8/3 x 8), respectively. The GI and GEI values shown in Table II for the 3.0-mg. dry weight inocula grown in 250-ml. Erlenmeyer flasks are 157.3 (3.46/0.22) and 209.7 (157.3/0.05 × 15), respectively. Dry weight of spearmint cell tissues may be converted to approximate tissue fresh weight by the factor 7.3.

The poor growth repeatedly obtained in carboy II of the dual-carboy system suggested that the stainless steel sparger used in carboy II might be toxic to spearmint suspension cultures. Dyer and Richardson (21) reported that types 316 and 304 stainless steels occasionally slightly inhibited algal cultures. The effects of the presence of six different stainless steel spargers on spearmint suspension growth were tested by growing each sparger separately with cells in Erlenmeyer flasks. Various degrees of growth inhibition were observed, varying from complete inhibition or good growth with blackening of the suspension medium, to normal growth.

Spearmint suspensions grown in carboy I gave similar growth yields with either 4.5 L. of air/minute or 27 L./minute. Therefore, it appears that the amount of air supplied by the lower flow rate is adequate for good growth of spearmint tissue in the dual-carboy system used.

Sequoia semipervirens callus cultures and *Vinca rosea* crown-gall callus cultures hydrolyze certain oligosaccharides (22). Tulecke, *et al.* (23), reported that fructose and dextrose predominated in Ginkgo pollen itself. Bürstrom (24) demonstrated that excised roots hydrolyze sucrose in liquid media. In carboy I of the dual-carboy system (Figs. 2 and 3) sucrose was completely hydrolyzed to dextrose and fructose by the third day of culture. Both dextrose and fructose were absent in the culture medium after 8 days.

CONCLUSIONS

A dual-carboy system enabled 112.13 Gm. of spearmint tissue (GI, 20.8; GEI, 0.87) to grow in one carboy receiving an inoculum of known cell volume (15% v/v), age (5 days), cell number

(824×10^3 cells/ml.), and air flow (4.5 L. air/minute) within 8 days. An air flow rate of 27 L./minute did not increase growth materially.

Spearmint suspensions in the dual-carboy system completely hydrolyzed sucrose to dextrose and fructose by the third day of culture. Both dextrose and fructose were absent in the culture medium after 8 days.

None of six antifoam compounds studied appreciably affected spearmint suspensions. Dow Corning-B (500 p.p.m.) is suggested for foam control.

Five parts per million of either amphotericin, griseofulvin, and/or oxytetracycline inhibited spearmint suspension growth. Bacitracin (5 p.p.m.) is suggested for bacterial prophylaxis.

Effect of Gibberellin and Other Treatments on the Germination and Subsequent Biogenesis of Alkaloids in *Datura stramonium* Linné

By EDWARD L. CALDWELL† and LEO A. SCIUCHETTI

Stramonium **seeds were subjected to two "cold treatments," to treatment with gibberellic acid (GA) and with concentrated sulfuric acid (SA). The rate and percentage of germination were markedly reduced by the cold treatments, whereas they were significantly increased by the GA and SA treatments. A threefold increase in germination percentage was noted in the former group and a twofold increase in the latter. Plants from the GA, SA, and control groups were allowed to grow to maturity. Characteristic gibberellin effects were not noted in plants receiving a gibberellin-seed treatment. However, the early growth of this group was markedly reduced. At the final harvest total plant weight was slightly less than controls. Fluctuations in the alkaloid concentration of the plant organs were noted. At the final harvest the total content of alkaloids was about 87 per cent of controls. The growth rate of the SA group was considerably lower than controls initially, but, the total dry weight at the final harvest approximated the controls. Both decreases and increases in the concentration of alkaloids in the plant organs were observed. The total plant alkaloids of this group at the final harvest were about the same as controls.**

Treatment of seeds with gibberellic acid (GA) has hastened germination and promoted an earlier and more uniform emergence of the seedlings of many crop plants (1–8) and several medicinal plants (9–11). Treatment of belladonna seeds with concentrated sulfuric acid resulted in an increase in the germination rate (12). Acid scarification and various types of "cold treatments" have been recommended as pregermination treatments of seeds to stimulate germination (13, 14). A review of the literature, however, has indicated that a study of such treatments on the subsequent growth and alkaloid biogenesis of stramonium has not been conducted.

The purpose of this study was (*a*) to determine and compare the effects on the germination of stramonium seeds of a freeze-thaw method (FT), a constant freeze method (CF), treatment with GA, and treatment with concentrated sulfuric acid

(824×10^3 cells/ml.), and air flow (4.5 L. air/minute) within 8 days. An air flow rate of 27 L./minute did not increase growth materially.

Spearmint suspensions in the dual-carboy system completely hydrolyzed sucrose to dextrose and fructose by the third day of culture. Both dextrose and fructose were absent in the culture medium after 8 days.

None of six antifoam compounds studied appreciably affected spearmint suspensions. Dow Corning-B (500 p.p.m.) is suggested for foam control.

Five parts per million of either amphotericin, griseofulvin, and/or oxytetracycline inhibited spearmint suspension growth. Bacitracin (5 p.p.m.) is suggested for bacterial prophylaxis.

Effect of Gibberellin and Other Treatments on the Germination and Subsequent Biogenesis of Alkaloids in *Datura stramonium* Linné

By EDWARD L. CALDWELL† and LEO A. SCIUCHETTI

Stramonium **seeds were subjected to two "cold treatments," to treatment with gibberellic acid (GA) and with concentrated sulfuric acid (SA). The rate and percentage of germination were markedly reduced by the cold treatments, whereas they were significantly increased by the GA and SA treatments. A threefold increase in germination percentage was noted in the former group and a twofold increase in the latter. Plants from the GA, SA, and control groups were allowed to grow to maturity. Characteristic gibberellin effects were not noted in plants receiving a gibberellin-seed treatment. However, the early growth of this group was markedly reduced. At the final harvest total plant weight was slightly less than controls. Fluctuations in the alkaloid concentration of the plant organs were noted. At the final harvest the total content of alkaloids was about 87 per cent of controls. The growth rate of the SA group was considerably lower than controls initially, but, the total dry weight at the final harvest approximated the controls. Both decreases and increases in the concentration of alkaloids in the plant organs were observed. The total plant alkaloids of this group at the final harvest were about the same as controls.**

Treatment of seeds with gibberellic acid (GA) has hastened germination and promoted an earlier and more uniform emergence of the seedlings of many crop plants (1–8) and several medicinal plants (9–11). Treatment of belladonna seeds with concentrated sulfuric acid resulted in an increase in the germination rate (12). Acid scarification and various types of "cold treatments" have been recommended as pregermination treatments of seeds to stimulate germination (13, 14). A review of the literature, however, has indicated that a study of such treatments on the subsequent growth and alkaloid biogenesis of stramonium has not been conducted.

The purpose of this study was (*a*) to determine and compare the effects on the germination of stramonium seeds of a freeze-thaw method (FT), a constant freeze method (CF), treatment with GA, and treatment with concentrated sulfuric acid

(SA); and (*b*) to ascertain what changes such treatment would have on the subsequent growth and alkaloid biogenesis of the plant.

EXPERIMENTAL

Procedure—Five-hundred nearly uniform seeds were selected from a 1958 seed crop of *Datura stramonium*, var. *inermis* that had been gathered in March 1959 from a plant which had been allowed to over-winter. The seeds were divided into five equal groups. Group A was treated by alternate freezing and thawing during 1 week, *i.e.*, a 24-hour freezing period was followed by a similar thawing period. Group B was kept frozen for 1 week. Group C was treated with a 50 p.p.m. solution of GA[1] for 18 hours. Group D was treated for 1 minute with concentrated sulfuric acid and then washed free of the acid. Group E received no treatment and served as controls. The seeds were dusted with Fermocide[2] and planted on April 2, 1959, under greenhouse conditions in flats containing soil composed of sand, sandy loam, and peat moss. About 50 Gm. of complete organic fertilizer[3] was thoroughly mixed into each flat of soil prior to planting. Daily counts were made for a 5-week period, even though germination had apparently ceased by the end of the third week.

Since seeds of the control group (Group E) were not soaked in distilled water for 18 hours, but were planted directly in the soil in the dry state, a subsequent experiment was performed in 1963 to determine whether the beneficial response from the treatment with the GA solution was due to in i-bition of water or to a stimulating effect of the growth regulator. One-hundred seeds were soaked for 18 hours in a 50 p.p.m. solution of GA, and a similar number was soaked for the same period of time in distilled water. The time of planting, the experimental conditions, and observation period approximated that of the initial experiment.

On May 2, the second phase of this experiment was started. Twenty-four seedlings, each from the GA, SA, and control groups were transplanted into pots containing a mixture of sand, sandy loam, peat moss, and 50 Gm. of complete organic fertilizer. Since the plants grown from seeds receiving the cold treatments did not show a significant beneficial response during germination, they were discarded.

The plants from the three groups were arranged at random in the greenhouse. On May 19 (zero time), height measurements were taken and the first harvest of plants from each of the three groups was made. Height measurements were taken twice weekly thereafter, and the remaining plants were harvested in groups of eight from each of the test groups at the end of 2 and 4 weeks. The division of the plant into its morphological parts during each harvest, fresh and dry weight determinations, pulverization, pooling, and storage of the powdered material were conducted in a manner described in a previous publication (15). The pooled samples were analyzed for total alkaloids (calculated as scopolamine) by the Brummett-Sciuchetti method (16).

Germination Observations.—The seeds first germinated on the ninth day following planting. The seeds treated with GA germinated more rapidly, and a greater per cent of them germinated than did those from the other groups (Fig. 1). The seedlings from this group appeared healthy; they did not appear chlorotic; damping-off did not occur; and satisfactory growth was sustained throughout the 5-week germination period. About a threefold increase was noted in the germination percentage of the seeds treated with GA compared with untreated seeds. About twice as many plants germinated from seeds treated with sulfuric acid as from untreated seeds. The habit of this group approximated the controls. The FT and CF groups demonstrated lower rates and percentages of germination than the controls (Fig. 1). These seedlings, likewise, appeared to be similar in appearance to the controls.

The subsequent experiment which was performed to determine whether the favorable response from soaking seeds in a gibberellin solution was due to water imbibition or to a stimulus to germination by the GA solution, demonstrated a similar, although a less pronounced trend, as that described above. For example, the number of seedlings emerging from the GA-treated group was eight at the eighth day following planting, 18 at the 12th day, 25 at the 16th day, 35 at the 20th day, 40 at the 24th day, and 40 at the 28th day. The corresponding figures for the seeds soaked in distilled water only were 1, 7, 12, 15, 16, and 16. These results indicate that the increased rate of germination and higher percentage germination was due to the stimulating effect of the GA.

Growth Observations.—The plants were observed daily during the 4-week growth period following the first harvest. There were no appreciable differences

TABLE I.—AVERAGE HEIGHTS[a] OF STRAMONIUM PLANTS

Treatment	Harvest Time, Wks.	Av. Height, cm.	Control, %
Control	0	11.04	...
SA	0	10.35	93
GA	0	11.16	101
Control	2	28.59	...
SA	2	28.63	100
GA	2	26.61	93
Control	4	48.63	...
SA	4	50.95	104
GA	4	44.36	91

[a] Heights in cm. are the average of eight plants.

in the habit of the treated and untreated groups. All plants appeared healthy and vigorous and none were chlorotic. Only slight changes in height were noted in the treated groups (Table I). At the final harvest, the SA group was slightly taller than controls, while the GA group was shorter. Marked stem elongation was not observed in the latter.

Fresh and Dry Weights.—Appreciable reductions in the dry weights of plants grown from treated seeds were generally noted at the first two harvests (Table II). At the terminal harvest the total dry weight of the SA group was about 96% of the controls, and that for the GA group was about 91%. These decreases were not considered significant. The growth rate of the SA group, although less than controls, was generally somewhat higher than the GA group. A study of the dry weight data indicated that the seed treatments retarded growth initially, but these plants approached the controls by the final harvest.

Concentration of Alkaloids.—The alkaloid analysis was performed on pooled samples by the Brummett-Sciuchetti method (16). Considerable fluctuations were noted in the concentration of alkaloids in the organs of the plants grown from treated seeds (Table III). Generally, slightly reduced concentrations compared with controls were noted in the leaves-tops of the treated groups. The stems of the plants grown from seed treated with sulfuric acid had an appreciably lower concentration of alkaloids at the first harvest, but a slight increase at the final harvest. A reverse trend was noted in the GA group. The roots of the SA group had a significant increase (147% of controls) at the second- and fourth-week harvests. On the other hand, the roots of plants grown from seeds treated with GA had a significant reduction at zero time but only a slight decrease at the fourth week. The SA treatment of seeds elicited a favorable response more often than did the GA treatment.

Total Plant Alkaloids.—The total alkaloids per plant and per plant organ were obtained by multiplying the dry weight of the plant part by the per cent of alkaloids obtained from the alkaloid analyses and expressing the results in milligrams (Table IV). It was noted that at each harvest plants grown from treated seeds produced less total alkaloids than the controls. The most significant decrease was at the second harvest where the total alkaloid content per plant of the GA group was only 64% of the controls. This was because of a significant decrease in plant growth and a marked reduction in the concentration of leaves-tops alkaloid. By the final harvest this group had 87% of the total alkaloids of the controls. On the other hand, the total alkaloids per plant of the SA group showed an appreciable decrease compared with controls at the first harvest, a considerable reduction at the second harvest, and approximately the same content at the final harvest. In general, the aerial parts of the treated groups showed significant decreases in total alkaloids at the first harvest, marked reductions at the second harvest, and only minor decreases

[a] Calculated from dry weight and alkaloid analyses data; per plant = leaves-tops + stems + roots.

at the terminal harvest. The roots of the SA group contained considerably more alkaloids than controls throughout the 4-week growth period, while the GA group had appreciably less total alkaloids (Table IV).

DISCUSSION AND CONCLUSIONS

The GA-treated seeds showed about a threefold increase over untreated seeds in germination percentage and also demonstrated a more rapid rate of germination. Treatment of belladonna seeds (10) and of hyoscyamus seeds (9) with GA has also promoted an earlier and more uniform emergence of seedlings and caused a higher percentage of seeds to germinate. Throughout the observation period the habit of these plants closely resembled the controls, except that they were slightly shorter than plants grown from untreated seed. Characteristic gibberellin effects, such as taller and spindlier plants, greater internodal elongation and a chlorotic appearance, have been reported (11,15–19) when plants were treated with GA. These effects were not observed in plants grown from seed treated with GA. It was noted from dry weight data that during the early stages of growth the seed treatment induced a deleterious effect on growth. Although these plants weighed less than controls at the final harvest the reduction in plant growth was not considered significant. This is in contrast to a generally beneficial effect usually reported for *Daturas* treated with GA (11, 15, 16, 18).

Inconsistent trends were observed regarding the concentration of alkaloids in the plant organs. Both increases and decreases, compared with the control group, were noted at the various harvests. The increased concentration in the aerial parts of the plant noted in some cases from treatment of seeds with GA differs from the reductions usually noted when *Daturas* are treated with the growth hormone (15, 16, 18). Although the total alkaloid content of the GA group was somewhat less than controls at the final harvest, the seed treatment with GA was considered beneficial since a greater and more uniform emergence of seedlings was obtained. The results obtained by the gibberellin-seed treatment in this experiment were generally similar to that in the study with belladonna seeds (10) which was being conducted concurrently with this one. However, a general increase in alkaloid formation was noted in belladonna grown from gibberellin-treated seeds.

Treatment of seeds with sulfuric acid induced about a twofold increase in germination percentage over untreated seeds. A more rapid and uniform emergence of seedlings was also noted in this group. The habit of this group approximated the controls. The growth rate of the SA group was considerably slower than the controls initially, however, at the final harvest the total dry weight of this group was about the same as controls. Both decreases and increases were noted in the concentration of alkaloids in the plant organs throughout the 4-week growth period. No significant difference in total plant alkaloids was noted in the SA group compared with controls at the final harvest. This differed from belladonna grown from seed treated with sulfuric acid since belladonna was stunted in growth and contained about 40% of the alkaloids of controls (10).

The application of various cold treatments to stramonium seeds did not cause an increase in germination. Actually the germination rate and total germination were considerably less in seeds treated by the constant freeze method and the freeze-thaw method. It was concluded that treating stramonium with gibberellic acid or sulfuric acid was beneficial since both the rate of germination and the number of seedlings germinating were significantly increased. The growth and total alkaloid content of the treated groups were not materially different from controls at the final harvest. These treatments are suggested when it is desirable to increase the germination of stramonium, especially when seeds are planted in late winter or early spring.

Some Crystalline Modifications of the *tert*-Butylacetates of Prednisolone and Hydrocortisone

By JOHN A. BILES

Four phases of each of the two steroid esters have been identified. The phases have been characterized by using optical crystallography, X-ray powder diffraction, and infrared spectrometry. The optical crystallographic properties, melting points, densities, molar refractions, infrared spectra, and *d* distances are presented.

THE EFFECT of polymorphism on the activity of a drug has been emphasized in the recent literature. McCrone has stated (1) that the thermal stability of a drug depends on the polymorphic form and that "often the performance of a given compound can be improved through change to a different polymorphic form." Frederick said that occasionally a polymorph would be found whose properties were such that it would stand out in clinical effectiveness. He cautioned, however, that such a favorable polymorph might not be isolated for every compound studied (2). Higuchi, in discussing the physical chemical analysis of the percutaneous absorption process, stated that the highest thermodynamic potential possible for the penetrating agent must be used to obtain the maximum rate of penetration. Different crystalline modifications may exist having different free energies—thus different thermodynamic activities (3).

Two polymorphs of 6-α-methylprednisolone have been isolated (4). Ballard and Nelson prepared pellets of each of the two polymorphs and found that Form II of the steroid was absorbed after implants in rats 1.7 times as fast as Form I. They also reported that Form II was 1.2 times more soluble than Form I (5). There is evidence of four polymorphs of hydrocortisone alcohol, two of hydrocortisone acetate, and six crystalline modifications of cortisone acetate (6–8). Smakula and co-workers have reported one amorphous form and four polymorphs of 17-β-estradiol (9). Progesterone and ethynylestradiol are reported to be polymorphic (10, 11). Dickson, Page, and Rogers summarized the polymorphism of some additional steroids (12).

Cooper has stated that prednisolone *tert*-butylacetate (TBA) was at least trimorphic, and that this polymorphism presented a problem in formulation procedures (13). Rogers and Conbere reported that hydrocortisone TBA was dimorphic, while Williams reported that this ester was trimorphic (6, 14). The purpose of this communication is to report the crystalline modifications of the TBA of prednisolone and hydrocortisone. Each phase has been characterized by using three different tools. It was found that each tool could be successful in identifying the phase, but that the combination provided a powerful technique for identification and isolation of each of the crystalline modifications.

Received March 16, 1962, from the Pharmaceutical Chemistry Laboratories, School of Pharmacy, University of Southern California, Los Angeles.

Accepted for publication April 3, 1963.

The author extends his thanks to Merck Sharp and Dohme Laboratories, West Point, Pa., for the generous supply of steroids and the Lederle Laboratories, Pearl River, N. Y., for their assistance.

This study was supported in part by an American Cancer Society Institutional Grant to the University of Southern California, Los Angeles.

EXPERIMENTAL

Crystallization of the Steroid Esters.—The two steroid esters were crystallized from various organic solvents at various temperatures. The crystals were collected following crystallization and dried. The crystals obtained were heated on the Kofler melting point block to determine phase changes and the melting point.

Hydrocortisone TBA was crystallized from various water-alcohol mixtures. Phase I, *i.e.*, the first modification obtained, was isolated from 20% ethanol. When the 90% alcoholic solution saturated with the steroid was allowed to evaporate at room temperature, Phase II was isolated. These methods of isolating the two phases have been described previously (14). A glass was isolated when hydrocortisone TBA was crystallized from chloroform. A white crystalline powder was obtained on scratching the glass. This was found to be a new crystalline modification and was designated as Phase III. A phase transition occurred when phase III was heated to 170°. In this manner Phase IV was isolated. It was also determined that when Phase I was heated on the Kofler block, a phase change occurred at approximately 140°. The phase obtained was identical with Phase IV.

The prednisolone TBA was crystallized from water-alcohol mixtures also. Phase I was isolated from 20% ethanol. Phase II was isolated from 90% ethanol. When the prednisolone ester was crystallized from 50% ethanol, three separate phases were distinguished by optical crystallographic procedures. Two of the modifications corresponded to Phases I and II. The third modification was termed Phase III; however, this phase could not be isolated in a

pure form. A fourth modification of the steroid was isolated when crystallized from acetone and termed Phase IV.

Determination of Solvates.—The amount of solvent bound to the steroid ester was determined by molar absorptivities and weight loss studies.

Determination of Physical Properties.—The procedures for the determination of the optical crystallographic properties, densities, and molar refractions have been described elsewhere (15, 16). The optical crystallographic properties of the modifications are recorded in Table I. The melting points, densities, and molar refractions of the phases are recorded in Table II. Photomicrographs of the phases are

shown in Fig. 1. The photomicrographic techniques have been described previously (17).

Nujol mulls were prepared and the infrared absorption spectra were obtained using the Perkin-Elmer infracord spectrophotometer. The spectra of the crystalline modifications are illustrated in Fig. 2.

The X-ray powder analysis was made using a General Electric XRD-5 spectrometer.[1] The diffracted copper radiation (filtered by nickel) was detected by a quantum counter and was automatically recorded. The intensity of radiation was read as 2θ. The 2θ values were converted to d distances using the Bragg equation. The d distances are recorded in Table III.

RESULTS AND DISCUSSION

Four separate phases of the TBA of prednisolone and hydrocortisone have been isolated. One phase of prednisolone TBA was anhydrous; a second phase was isolated from 95% ethanol and found to be a monoethanol solvate. A third phase was identified but not isolated when crystallized from 50% ethanol. A fourth phase, crystallized from acetone, was found to be the hemisolvate form of the ester. When Phases II and IV of prednisolone TBA were dried in the Abderhalden at 140°, Phase I was obtained. The phase transition can also be observed on the Kofler block. Identification of the phases were determined by infrared and X-ray diffraction powder analyses and optical crystallographic analysis.

Phases I and II of hydrocortisone TBA were isolated by crystallizing from ethanol. Phase I was isolated when crystallized rapidly from ethanol, while Phase II was isolated on slow evaporation of the solvent. Both phases were found to be monoethanol solvates. Phase III of hydrocortisone TBA was isolated from a chloroformic solution. The phase was determined to be a hemichloroform solvate. When Phases I, II, and III were heated in the Abderhalden apparatus and on the Kofler block Phase IV was isolated. The latter phase is anhydrous.

The physical properties of all phases were studied. The melting points (uncorrected), densities, and molar refractions are reported in Table II. The optical crystallographic properties of the various phases are recorded in Table I. An outstanding feature of optical crystallography is the identification and characterization of crystalline substances in heterogeneous systems. Only with this method was Phase III of the prednisolone ester studied extensively.

The photomicrographs of the phases are shown in Fig. 1. The photomicrograph of Phase II of hydrocortisone TBA shows that the crystal solvate dissolved rapidly in the immersion oil. The same oil was used to immerse Phase I of the same ester. Thus, the rates of dissolution of the dimorphic phases in a mineral oil–bromonaphthalene immersion oil are different. Similar cleavage planes were observed of Phase IV of hydrocortisone TBA when Phases I or III were heated to 170°. The melting point of Phase I and resolidification were observed

[1] The infrared and X-ray spectra were determined in the Pharmacy Research and Development Laboratories, The Upjohn Co., Kalamazoo, Mich.

under the microscope when using the Kofler block. No melting was observed when Phase III was converted to Phase IV by heating to 170°.

The X-ray powder patterns for the seven phases of the two steroid esters isolated were obtained using an XRD-5 spectrometer. The *d* distances are recorded in Table III. The first reflection for all phases, with one exception, corresponded to a distance of 14 + Å. Often this distance is indicative of the longest length of the unit cell. The first reflection which appeared for Phase III of the hydrocortisone ester corresponded to a distance of 22.64 Å.

[a] Wavelength of 1.54051 Å. [b] (s) is strong and (m) is medium.

The infrared spectra for the phases are presented in Fig. 2. Since Phase III of the prednisolone ester could not be isolated in pure form, no spectra are submitted. The infrared spectra of the various phases are different and are of value for phase identification. The author observed that a given phase could be identified more easily using the XRD-5 spectrometer than using the infrared spectrometer. Gaebler, Parsons, and Beher have stated that X-ray diffraction methods are more effective than infrared methods in distinguishing compounds from mixtures (18). The hydroxyl stretching frequencies for the crystal phases varied between 3413 cm.$^{-1}$ for Phase IV of the prednisolone ester and 3534 cm.$^{-1}$ for Phase II of the hydrocortisone ester. Two peaks were observed for Phase IV of the hydrocortisone ester. One vibration was recorded at 3636 cm.$^{-1}$ which was indicative of a free hydroxyl group. The other vibration was recorded at 3448 cm.$^{-1}$, indicative of rather strong hydrogen bonding.

Interaction of Urea and Thiourea with Benzoic and Salicylic Acids

By SANFORD BOLTON

Urea forms soluble complexes of low stability with benzoic acid in water, methanol, and dioxane. With salicylic acid, urea forms insoluble interaction products which can be isolated from the above solvents. On the basis of these results a procedure for the separation of salicylic acid from benzoic-salicylic acid mixtures is described. Thiourea forms only soluble complexes of low stability. The difference in the extent of interaction in the different solvent systems is explained on the basis of competing solute-solvent interactions, which can be translated into terms of solute solubilities.

ALTHOUGH in recent years much work has been reported on the formation of molecular complexes in pharmaceutical systems, the complexing agents used have often been toxic or medicinally potent substances. The desirability of investigating the complexing properties of nontoxic or less potent compounds is apparent. In the present study, urea, a comparatively innocuous drug, has been examined as a possible complexing agent.

Clathrates, or inclusion compounds of urea, have found useful application in the separation of closely related hydrocarbons (1–4) and mixtures of structurally related fatty acids (5, 6). Inasmuch as these urea inclusion complexes usually involve very small molecules such as CO_2 and H_2O_2 or straight chain hydrocarbons and their derivatives, it became of interest to study the interaction of urea solutions with more complex molecules where clathrate formation is not possible. Evidence of nonclathrate complexes of urea and pharmaceutically important substances has appeared in the literature. For example, aqueous solubilities of terramycin (7) and benzocaine (8) were shown to be increased in the presence of urea. Solid tetracycline-urea complexes have been prepared which have improved stability and solubility properties over the uncomplexed drug (9–11). Complexes of sulfonamides (12), wool fat alcohols (13, 14), quinoxaline (15), detergents (16–18), and barbituric acid derivatives (19) with urea have also been described.

In this report the interactions of urea and thiourea (chosen for purposes of comparison) with benzoic and salicylic acids have been followed by means of solubility studies. The high affinity of urea for water resulted in a low complexing tendency in this solvent. (See References 7 and 8.) Therefore, two nonaqueous solvents, methanol and dioxane, were also used. Although, in general, the degree of interaction was small in all cases, definite complexes were found. The difference of the solubility characteristics of the urea–benzoic acid and urea–salicylic acid complexes in the nonaqueous solvents suggested a possible separation procedure of salicylic acid from benzoic-salicylic acid mixtures. One approach to such a separation is described.

EXPERIMENTAL

Solubility Studies

A. Aqueous Solutions.—The interactions in aqueous solution were followed by determining acid solubility as a function of urea (thiourea) concentration. Excess benzoic (0.25 Gm.) and salicylic (0.625 Gm.) acids were equilibrated with 10 ml. of solutions of varying urea and thiourea concentrations by rotating the mixtures in capped vials for 18 hours in a constant temperature water bath at 30 ± 0.1°. All solutions were made 0.1*N* with H_2SO_4 to prevent dissociation of the acid species. The amount of acid in solution was determined concurrently by two methods: (*a*) titration of a clear aliquot with standardized NaOH solution; and (*b*) spectrophotometric examinations utilizing the peak for benzoic acid at 274 mμ and salicylic acid at 302.5 mμ.

B. Nonaqueous Solutions.—The interactions in methanol and dioxane were followed by determining acid solubility as a function of urea (thiourea) concentration and urea (thiourea) solubility as a function of acid concentration. Approximately 3 ml. of solution was equilibrated as in *A* for at least 24 hours in vials equipped with polyethylene-lined caps. The amounts of reagent in excess during the solubility studies are tabulated in Table I.

The mixtures were analyzed as follows. One milliliter of a clear aliquot was pipeted into a tared 10-ml. beaker, and the solvent was removed by evaporation with the aid of gentle heat. The residue was weighed and acid content was determined by titration with a standardized NaOH solution. The urea content could then be determined by difference. (Since the solutions often contained large concentrations of reactants, it was very difficult to measure total solution volume accurately. This presented no problem when only soluble interaction species were formed, as the method of analysis gave

molar concentrations directly; i.e., the concentration of complexing agent added equalled the concentration found in solution. The points on the graphs after the appearance of an insoluble species are approximations, since changes in solution volume during the precipitation process could not be determined.)

RESULTS

Interaction Studies

A. Aqueous Solution.—Figure 1 illustrates the effect of urea and thiourea on the solubilities of benzoic and salicylic acids in water. Only in the case of the salicylic acid–urea interaction did an insoluble interaction product appear before urea or thiourea saturation. Along the first plateau region of this curve an insoluble species appeared; along the immediately following descending portion the precipitate showed acid-urea ratios between 1–1 and 2–1. Calculation of the acid-urea ratio from the phase diagram according to Higuchi and Lach (20) suggested formation of a 1–1 complex which could not be reconciled with the analysis of the insoluble phase in this region of the curve. The form of the following portion of the curve suggested that a new insoluble species was being formed, and analysis of the precipitate in this region corresponded to a 1–1 complex. After this plateau region the apparent solubility of acid increased slowly, although the insoluble phase still consisted of a 1–1 species. The high concentrations of urea at the latter portions of the curve undoubtedly were at least partially responsible for the unusual solubility pattern of the acid and no effort was made to rationalize the curve in this region.

Because of the high concentrations of complexing agent used and the uncertainty of the nature of the interaction products, stability constants for the interactions were not calculated. It is apparent by inspection of Fig. 1, however, that the stability of salicylic acid complexes were stronger than the benzoic acid complexes, and the thiourea complexes were stronger than the urea complexes.

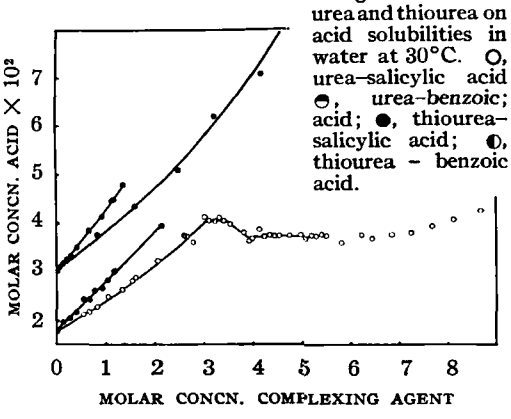

Fig. 1.—Effect of urea and thiourea on acid solubilities in water at 30°C. ○, urea–salicylic acid ◒, urea–benzoic; acid; ●, thiourea–salicylic acid; ◐, thiourea – benzoic acid.

B. Nonaqueous Solutions.—Figures 2, 3, and 4 illustrate the results obtained in methanol and dioxane. Figure 2 shows the effect of urea on the acid solubilities in these solvents. Thiourea showed no complexing tendencies under these conditions; these data are not included in the plot. The solubilities of the acids decreased slightly in the presence of thiourea. A slight decrease or lack of change of acid solubility did not necessarily indicate a lack of interaction in these systems. At the high solute concentrations used in these studies, if no interaction takes place between the solutes, we might expect a competition for solvent molecules and a resultant substantial decrease in solubility. In fact, this mutual "squeezing out" of the solute molecules probably occurred to some extent in most of the systems in this study. Urea formed a 1–1 insoluble complex with salicylic acid in both methanol and dioxane. The final plateau regions in these curves indicate saturation with respect to urea as well as complex and the systems are invariant. The plateaus formed in the benzoic acid–urea systems were due to urea saturation; only soluble species were formed in these systems. It is apparent that urea complexed more strongly with benzoic acid in dioxane than methanol.

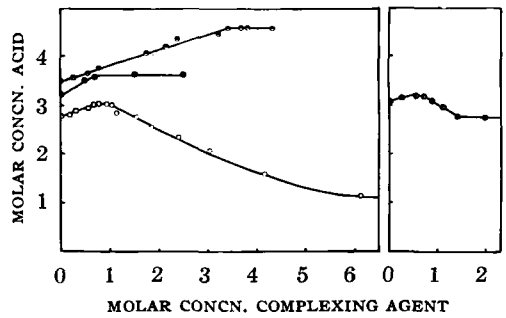

Fig. 2.—Effect of urea on acid solubilities in methanol and dioxane at 30°C. ○, urea–salicylic acid–methanol; ◒, urea–benzoic acid–methanol; ◐, urea–salicylic acid–dioxane; ●, urea–benzoic acid–dioxane.

The effect of the acids on urea and thiourea solubility in dioxane and methanol is shown in Figs. 3 and 4. These studies further establish the nature of the interactions, especially those in dioxane where urea and thiourea solubilities were comparatively small. The low interaction tendency of thiourea in methanol was confirmed. However, in dioxane, the solubility of thiourea was increased

to a small extent in the presence of the acids; salicylic acid proved to be the slightly stronger complexing agent (Fig. 4). Also the comparatively strong interaction of urea with the acids in dioxane is clearly illustrated in Fig. 4. Again, the final invariant regions in these curves are caused by saturation of the system by complexing agent.

Comparison of the extent of interaction, somewhat obscure in most cases in the acid-saturated system (Fig. 2), can be made from examination of Figs. 3 and 4. The urea–salicylic acid complex was stronger in dioxane than methanol and the urea–salicylic acid complex was stronger than the urea–benzoic acid complex in dioxane.

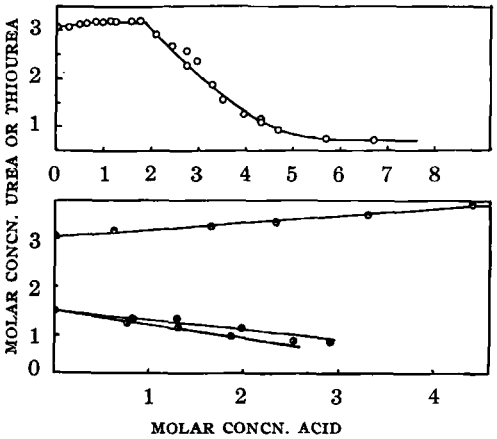

Fig. 3.—Effect of acid on urea and thiourea solubilities in methanol at 30°C. ○, urea–salicylic acid; ◓, urea–benzoic acid; ◑, thiourea–salicylic acid; ●, thiourea–benzoic acid.

Separation of Salicylic Acid from Salicylic-Benzoic Acid Mixtures

A procedure for a separation of salicylic acid from mixtures with benzoic acid was designed based on the low solubility of the urea–salicylic acid complex compared to the urea–benzoic acid complex in methanol. Methanol, rather than dioxane, was chosen as the solvent for the procedure because the low solubility of urea in dioxane reduced the amount of salicylic acid which it can precipitate. (The system, urea–salicylic acid–dioxane, became invariant due to urea saturation with almost 3*M* salicylic acid in solution, while the invariance point in methanol left only 1*M* salicylic acid in solution. See Fig. 2. Also, because of the greater solubility of urea in methanol, urea solubilized benzoic acid more in methanol than in dioxane.

The method of separation was as follows. One gram of a mixture of salicylic and benzoic acids was shaken with 1 ml. of methanol and $^2/_3$ Gm. of urea for approximately 1 hour at 30°. The resultant precipitate was filtered and sucked dry under

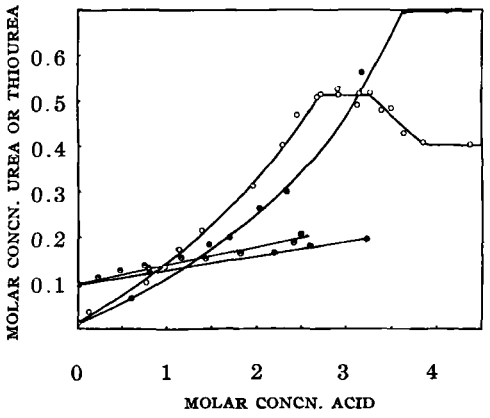

Fig. 4.—Effect of acid on urea and thiourea solubilities in dioxane at 30°C. ○, urea–salicylic acid; ●, urea–benzoic acid; ◓, thiourea–salicylic acid; ◐, thiourea–benzoic acid.

vacuum. The dried precipitate was weighed and mixed with 15 ml. of water per 2 Gm. of precipitate. This slurry was stirred with a magnetic stirrer for 5–7 minutes to dissolve the urea, and the remaining solid was collected in a sintered-glass funnel and dried. The salicylic acid content of this residue was assayed by measuring the color produced with ferric chloride using a Bausch and Lomb spectronic 20 colorimeter (21). Further salicylic acid purity can be achieved by repeating the process. (See Table II.)

Table II shows the results of this separation for two acid mixtures. No effort was made to recover salicylic acid quantitatively, and the column headed *Ppt. Recovered* is merely for information. More quantitative yields could be obtained by repeating the process on the alcohol soluble portion.

DISCUSSION

As mentioned before, no effort was made to calculate equilibrium constants since the exact nature of the interactions was not known. However, in order to have a basis on which to compare the extent of interaction in the different systems, values were calculated according to Higuchi and Zuck (22) from the initial portions of the curves as if 1–1 complexation were occurring. Table III shows the results of these calculations.

The effect of solvent on the extent of interaction may be explained on the basis of competitive reactions between solute and solvent molecules, *i. e.*, the greater the interaction of the solutes with the solvent, the lower will be the complexing tendency between solute molecules. This effect can be translated in terms of solubility which is a measure of solute-solvent interaction forces. Since the solubilities of the two solutes should be a factor in deter-

mining the magnitude of the interaction, it is well to know the solubilities of all the species involved. In the present studies, solubilities can be conveniently obtained from the figures, except for urea and thiourea in water, which are approximately 10 *M* and 2 *M*, respectively (23). It is apparent from these considerations that the degree of interaction seems to be directly related to the solubilities of the interacting species. The acid-urea interactions are strongest in dioxane > water > methanol. Considering that all species are extremely soluble in methanol, the small reactivity in this solvent would be expected. A further look at the dioxane and water systems reveals that in each solvent one component is very soluble, while one component is relatively insoluble; the acids are insoluble in water, while urea is insoluble in dioxane. A comparison of actual solubility values shows that the solubilities of both the insoluble and soluble components in water are greater than both values in dioxane. This, it seems, would account for the greater complexing tendency in dioxane. Exactly analogous considerations apply and hold for the thiourea interactions. It is interesting that the degree of interaction for thiourea is very similar in both water and dioxane and the products of thiourea and acid solubilities are also very close in both solvents.

Similar observations have been made by Marvel and Lemberger (24) and Gans and Higuchi (25). In both cases, differences in complexing tendencies in different solvents were attributed to competing solvent-solute interactions. Unfortunately, the solubilities of the complexing agents in the solvents studied were not determined and an analysis similar to the above one cannot be made.

The toxic nature of thiourea and its low complexing tendencies in these nonclathrate type systems suggest a limit to its possible usefulness. On the other hand, results presented here and past reports of urea complexes strongly recommend further investigation of urea as a complexing agent in pharmaceutical systems. Its low complexing tendency in water should be more than compensated by its high solubility and comparative nontoxicity.

Mechanisms of Steroid Oxidation by Microorganisms III

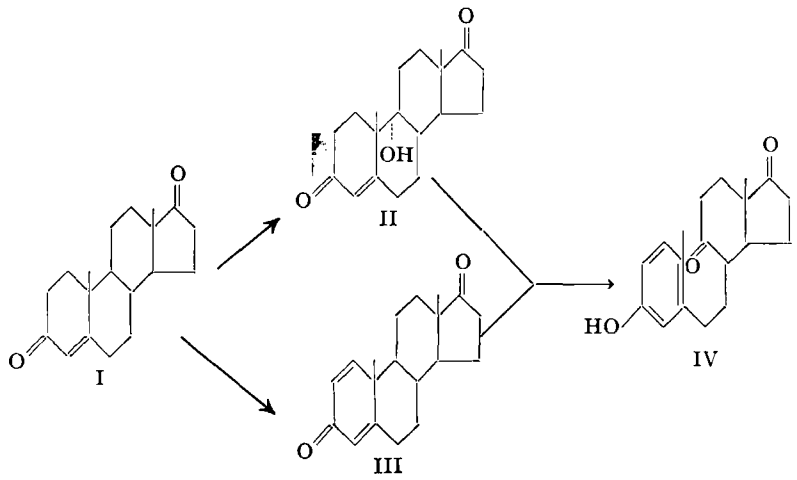
Enzymatic Mechanism of Ring A Aromatization

By CHARLES J. SIH and A. M. RAHIM

Evidence is presented to show that the aromatization of 9α-hydroxyandrost-4-en-3,17-dione and 19-hydroxyandrost-4-en-3,17-dione involves a 1,2-dehydrogenation by the steroid 1-dehydrogenase to afford vinylogs of β-hydroxyketones which may undergo spontaneous nonenzymic rearrangement (reverse aldolization) to give their respective phenols. This mode of aromatization differs from the human placental system in that it requires a typical flavoprotein electron acceptor for activity; oxygen and $NADPH_2$ are not required for aromatization. Also, the relative rates of oxidation follows the order 19-norandrost-4-en-3,17-dione > 19-oxoandrost-4-en-3,17-dione > 19-hydroxyandrost-4-en-3,17-dione.

ONE PATHWAY of steroid degradation by microorganisms involves a 9α-hydroxylation, followed by a 1,2-dehydrogenation (or vice versa) with the formation of a 9,10-seco phenol (1). The degradation of androst-4-en-3,17-dione could thus be visualized as follows: androst-4-en-3,17-dione (I) → 9α-hydroxyandrost-4-en-3,17-dione (II) or androsta-1,4-diene-3,17-dione (III) → 3-hydroxy-9,10-seco-androsta-1,3,5(10)-triene-9,17-dione (IV).

We have previously postulated that the microbial aromatization of 9α-hydroxyandrost-4-en-3,17-dione and 19-hydroxyandrost-4-en-3,17-dione probably involved a 1,2-dehydrogenation followed by reverse aldol condensation, their results were obtained solely from the intact microorganism. A preliminary communication (3) on the enzymatic mechanism of this aromatizing reaction has appeared. In view of the importance of this mechanism we wish to record in detail



Scheme I

This mechanism of Ring A aromatization is of biochemical interest since it bears close similarity to the formation of estrogens from androgens in mammals (2). Although Dodson and Muir (1) our examinations of reactions using partially purified enzyme preparations which are significant in establishing and confirming the proposed mechanism of Dodson and Muir.

EXPERIMENTAL

Materials and Methods

Cytochrome *c*, nicotinamide-adenine dinucleotide (NAD), nicotinamide-adenine dinucleotide phosphate (NADP), reduced nicotinamide-adenine dinucleotide ($NADH_2$), and reduced nicotinamide-

adenine dinucleotide phosphate ($NADPH_2$) were obtained from Sigma Chemical Co. Phenazine methosulfate was purchased from the Aldrich Chemical Co. Whatman No. 1 paper from H. Reeve Angel and Co. was used for paper chromatography. 2,3 - Dichloro - 5,6-dicyanobenzoquinone (DDQ) was purchased from the Ealing Corp. 9α-Hydroxyandrost-4-en-3,17-dione was prepared according to the method of Sih (4). 9α-Fluorohydrocortisone was synthesized according to the method of Fried and Sabo (5). All melting points were uncorrected and were determined in open soft-glass capillaries. Values of $[\alpha]_D$ have been approximated to the nearest degree. Ultraviolet absorption spectra were determined on a Cary model 11 MS recording spectrophotometer. Infrared spectra were recorded on a Beckman IR 5A double beam infrared recording spectrophotometer. Microanalyses were carried out by Mr. J. Alicino of Metuchen, N. J. Protein was estimated by the method of Gornall, *et al.* (6). Phenolic steroids were detected on paper chromatograms by spraying with diazotized sulfanilic acid (7). Spectrophotometric measurements were made on a Beckman DU spectrophotometer equipped with a Gilford multiple sample absorbance recorder model 2000 (8).

The conditions and the procedure used for the growth of *N. restrictus*, the purification of the steroid 1-dehydrogenase, and the details of the phenazine methosulfate-cytochrome *c* assay have been described previously (9). The solvent system for paper chromatography consisted of toluene-propylene glycol (10) and the R_f values of the steroids used in this work are shown in Table I. Δ^4-3-Oxo and $\Delta^{1,4}$-3-oxo steroids were assayed quantitatively after their elution from the paper chromatogram; their absorbances at 240 mμ were taken as a measure of their concentration (9). Phenolic steroids were assayed spectrophotometrically by measuring the increase in absorbance at 280 mμ (11).

Enzymatic Transformation of 9α-Hydroxyandrost-4-en-3,17-dione (II) into 3-Hydroxy-9,10-seco - androsta - 1,3,5(10) - triene - 9,17 - dione (IV).—A 100-mg. quantity of phenazine methosulfate and 50,000 units of 1-dehydrogenase (specific activity 1000) in a total volume of 400 ml. of 0.03 *M* phosphate buffer, pH 7.0, was added to 200 mg. of II. After a 4-hour incubation, the reaction was terminated by the addition of 6 *N* HCl and the protein precipitate was removed by filtration. The filtrate was extracted with three 150-ml. portions of chloroform, dried over sodium sulfate, and taken down to dryness. The residue was taken up in 75 ml. of benzene-ether (1:1) and extracted with three 35-ml. portions of 5% NaOH. The aqueous layer was acidified and extracted with 40-ml. portions of chloroform three times; the chloroform layer was dried over sodium sulfate and concentrated to dryness to give 168 mg. of residue. Two recrystallizations from acetone-petroleum ether afforded 94 mg. of IV, m.p. 122–124°; $[\alpha]_D^{25}$ +98° in chloroform (c, 0.9); $\lambda_{max.}^{alc.}$ 280 mμ (ε 2700); $\lambda_{max.}^{Nujol}$ 2.95, 5.75, 5.86, 6.23, and 6.66μ, identical to an authentic specimen.

Anal.—Calcd. for $C_{19}H_{24}O_3$: C, 75.97; H, 8.05. Found: C, 76.23; H, 8.53.

Enzymatic Dehydrogenation of 9α-Fluorohydrocortisone.—To 100 mg. of 9α-fluorohydrocortisone was added 50 mg. of phenazine methosulfate and 50,000 units of 1-dehydrogenase (specific activity 700) in a total volume of 500 ml. of 0.03 *M* phosphate buffer, pH 7.0. After incubation for 16 hours, the reaction was terminated by the addition of HCl and the mixture was extracted with 100 ml. of methylisobutyl ketone three times. The combined methylisobutyl ketone extract was dried over sodium sulfate and concentrated to dryness to give 89 mg. of residue. Two recrystallizations from ethanol gave 65 mg. of crystals, m.p. 265–269° dec., identical in all respects (mixed melting point and infrared spectrum) with an authentic sample.

Reaction of 9α-Hydroxyandrost-4-en-3,17-dione with 2,3 - Dichloro - 5,6 - dicyanobenzoquinone.—A 500-mg. quantity of DDQ was added to 400 mg. of 9α - hydroxyandrost - 4 - en - 3,17 - dione in 20 ml. of dioxane. The mixture was refluxed for 16 hours under nitrogen. On cooling, the hydroquinone separated and filtered off. The filtrate was diluted with an equal volume of chloroform and poured onto an acid washed alumina column (20 Gm.). Elution with chloroform afforded 20 mg. of a compound, m.p. 120–122°, $\lambda_{max.}^{alc.}$ 280 mμ (ε 2600), whose infrared spectrum was identical to an authentic sample of IV.

Enzymatic Conversion of 19-Hydroxyandrost-4-en-3,17-dione into Estrone.—To 20 mg. of 19-hydroxyandrost-4-en-3,17-dione was added 10 mg. of phenazine methosulfate and 5000 units of 1-dehydrogenase (specific activity 1000) in a total volume of 100 ml. of 0.03 *M* phosphate buffer, pH 7.0. After a 12-hour incubation, the reaction was terminated by the addition of 6 *N* HCl and extracted with 50-ml. portions of chloroform three times. The combined chloroform extract was dried over sodium sulfate and taken down to dryness. Two recrystallizations from chloroform-methanol afforded 10 mg. of crystals, m.p. 260–262°, identical in all respects (melting point, mixed melting point, and infrared spectrum) with an authentic specimen of estrone.

In a separate experiment 1 mg. of 19-hydroxyandrost-4-en-3,17-dione was mixed with 500 mcg. of phenazine methosulfate and 1000 units of 1-dehydrogenase (specific activity 900) in a total volume of 4 ml. of 0.03 *M* phosphate buffer, pH 7.0. After a 2-hour incubation, the mixture was distilled and the distillate gave a positive reaction for the presence of formaldehyde (12). By omitting the 19-hydroxyandrost-4-en-3,17-dione from the reaction mixture, the distillate gave no purple color.

TABLE I.—*Rf* VALUES OF STEROIDS IN THE TOLUENE–PROPYLENE GLYCOL SYSTEM

Compd.	*Rf*
Androst-4-en-3,17-dione	0.90
9α-Hydroxyandrost-4-en-3,17-dione	0.35
Androsta-1,4-diene-3,17-dione	0.82
Androst-4-en-3-one,17β-ol	0.45
Androsta-1,4-diene-3-one-17β-ol	0.40
19-Hydroxyandrost-4-en-3,17-dione	0.10
19-Oxoandrost-4-en-3,17-dione	0.75
19-Norandrost-4-en-3-one-17β-ol	0.40
3-Hydroxy-9,10-seco-androsta-1,3,5(10)-triene-9,17-dione	0.33
3-Hydroxyestra-1,3,5-triene-17-one	0.37
9,10-Seco-androst-4-en-3,9,17-trione	0.85

RESULTS

In a previous paper we have reported the conversion of 9α-hydroxyandrost-4-en-3,17-dione into the 9,10-seco phenol (IV) by crude cell-free extracts of *N. restrictus* (13). Since phenazine methosulfate was required for this transformation, it was suspected that the steroid 1-dehydrogenase was involved in this conversion. Figure 1 shows that, using partially purified steroid 1-dehydrogenase (tenfold), a similar conversion could be obtained, evidenced by the rapid disappearance of absorbance around 240 mμ, accompanied by an increase in absorbance at 280 mμ. Thus all subsequent experiments were performed using this partially purified enzyme preparation. To substantiate further the participation of the steroid 1-dehydrogenase in this aromatization reaction, several quinones were tested for their ability to serve as electron acceptors because steroid 1-dehydrogenase has been implicated as a flavoprotein. Table II shows that the relative efficiency of these quinones as electron acceptors were the same with either androst-4-en-3,17-dione or 9α-hydroxyandrost-4-en-3,17-dione as the substrate. Figure 2 shows that the pH optimum of this aromatization reaction is around 9.0, identical to that of the oxidation of androst-4-en-3,17-dione. Because of the difficulty in preparing 9α-acetoxyandrost-4-en-3,17-dione and microorganisms contain esterases capable of hydrolyzing acetoxyl groups, 9α-fluorohydrocortisone was incubated and was readily converted into 9α-fluoroprednisolone by the same enzyme system. (See *Experimental.*)

Two possible mechanisms of this Ring A aromatization reaction involving the steroid 1-dehydrogenase were apparent and these can be represented as

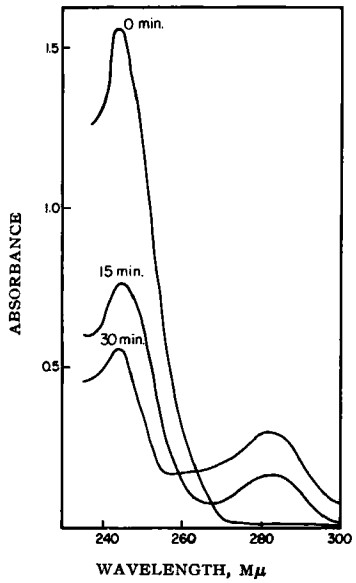

Fig. 1.—Oxidation of 9α-hydroxyandrost-4-en-3,17-dione to 3-hydroxy-9,10-seco-androsta-1,3,5(10)-triene-9,17-dione by purified steroid 1-dehydrogenase. The reaction mixture consisted of 600 mcg. of 9α-hydroxyandrost-4-en-3,17-dione, 500 mcg. of phenazine methosulfate and 25 units of 1-dehydrogenase (specific activity 1000) in a total volume of 4 ml. of 0.03 *M* phosphate buffer, pH 7.0. At the indicated time intervals the reaction was terminated by the addition of HCl and extracted with 1 ml. of chloroform. After separation of the layers by centrifugation, 0.2 ml. of the chloroform layer was diluted with 2.8 ml. of chloroform.

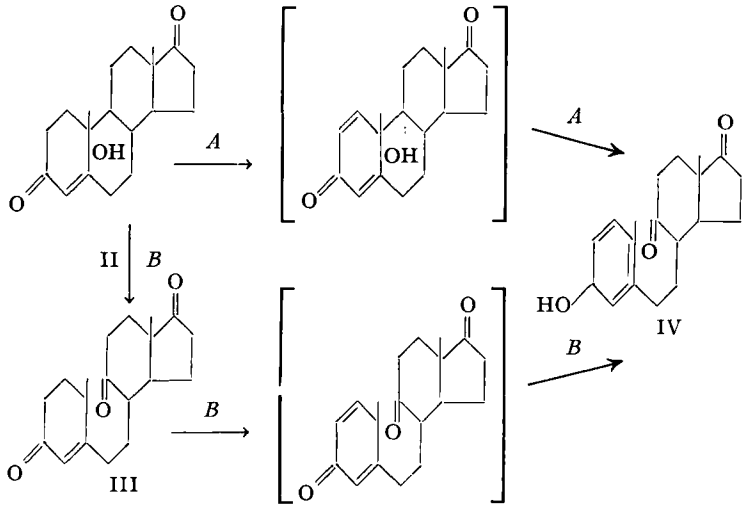

Scheme II

Mechanism *A* involves the introduction of a 1,2-double bond to form a vinylog of a β-hydroxyketone which could undergo facile rearrangement (reverse aldolization) to give a 9,10-seco phenol (IV). Mechanism *B* involves the abstraction of the 9α-hydroxyl proton to yield 9,10-seco-androst-4-en-3,9,17-trione (III); introduction of a 1,2-double bond into the latter compound affords a $\Delta^{1,4}$-dienone system which could also undergo chemical rearrangement to give a 9,10-seco phenol (IV). In order to distinguish these two mechanisms, 9α-hydroxyandrost-4-en-3,17-dione and 9,10-seco-androst-4-en-3,9,17-trione were incubated with the steroid 1-dehydrogenase. Figure 3 shows that the former compound was readily oxidized whereas 9,10-seco-androst-4-en-3,9,17-trione was not. This experi-

ment eliminates the latter compound as a possible intermediate and makes Mechanism *B* an unlikely one.

Table III shows that in the absence of phenazine methosulfate little if any 9α-hydroxyandrost-4-en-3,17-dione was metabolized. The slight decrease is probably due to the contamination of a trace amount of the natural electron acceptor. Addition of NAD and NADP did not stimulate the rate of metabolism of 9α-hydroxyandrost-4-en-3,17-dione, whereas on addition of phenazine methosulfate a rapid disappearance was observed.

On paper chromatograms we have been unable to detect the presence of 9α-hydroxyandrosta-1,4-diene-3,17-dione; the first demonstrable product has been the 9,10-seco phenol even when careful kinetic studies were made within the pH range of 4.8 to 9.0. Although it is well known that vinylogs of β-hydroxyketones undergo rearrangement very easily even by ordinary chemical means, methyl-3,11-dioxo-14,19-dihydroxy-$\Delta^{1,4}$, 14β-etiadienate has been obtained in very small yields as a by-product of a chemical reaction (14). This encouraged us to attempt to synthesize 9α-hydroxyandrosta-1,4-diene-3,17-dione by using mild chemical methods. However, when 9α-hydroxyandrost-4-en-3,17-dione was refluxed with DDQ, only 9,10-seco phenol (IV) was obtained in low yields; we were unable to detect the presence of the desired product on paper chromatograms.

Because this aromatization reaction bears close similarity to the mammalian conversion of androgens into estrogens, several of the intermediates in the mammalian pathway were incubated with the microbial system. 19-Hydroxyandrost-4-en-3,17-dione (V) was converted into estrone (VI). (See *Experimental.*) The distillate of the reaction mixture gave a positive test for the presence of formaldehyde (12), but the ratio of estrone to formaldehyde has been erratic and varied from experiment to experiment. In the absence of an electron acceptor such as phenazine methosulfate, very little 19-hydroxyandrost-4-en-3,17-dione (V) was metabolized. $NADH_2$ and $NADPH_2$ gave no stimulation (Table IV). 19-Oxoandrost-4-en-3,17-dione was also transformed into estrone by the same enzyme preparation; no attempt was made to determine the one-carbon fragment. Figure 4 shows the relative rates of oxidation follows the order: androst-4-en-3,17-dione>19-norandrost-3-en-3,17-dione>19-oxoandrost-4-en-3,17-dione>19-hydroxyandrost-4-en-3,17-dione. These rates were identical when the same experiment was carried out under anaerobic conditions.

TABLE II.—EFFECT OF DIFFERENT ELECTRON ACCEPTORS ON THE METABOLISM OF 9α-HYDROXYANDROST-4-EN-3,17-DIONE AND ANDROST-4-EN-3-ONE-17-OL[a]

Electron Acceptor	Relative Rate: 9α-Hydroxyandrost-4-en-3,17-dione	Relative Rate: Androst-4-en-3-one-17β-ol
1,2-Naphthoquinone	100	100
Phenazine methosulfate	83	86
Menadione	62	65
1,4-Naphthoquinone	47	51
2,6-Dichlorophenol indophenol	50	48
2,3-Dichloro-5,6-dicyanobenzoquinone	30	34

[a] The reaction system contained 1.5 μm. of 9α-hydroxyandrost-4-en-3,17-dione or androst-4-en-3-one-17β-ol, dissolved in 0.1 ml. of dimethylformamide, 1.5 μm. of various electron acceptors, and 20 units of enzyme (specific activity 500) in a total volume of 4.0 ml. of 0.03 *M* phosphate buffer, pH 7.0. After 10 minutes, the reaction products 3-hydroxy-9,10-seco-androsta-1,3,5(10)-triene-9,17-dione and androsta-1,4-diene-3-one-17β-ol were assayed as in Fig. 2.

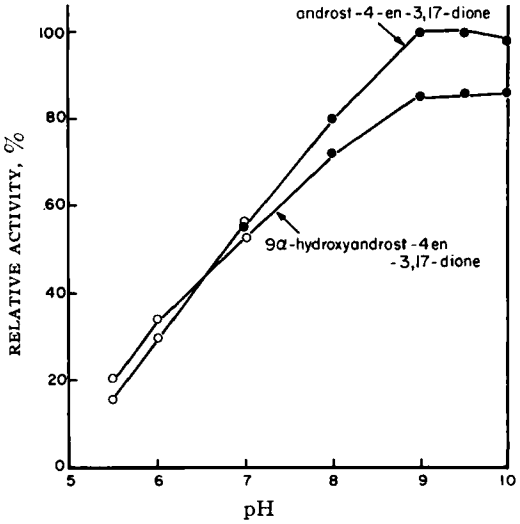

Fig. 2.—Effect of pH on the rate of oxidation of androst-4-en-3,17-dione and 9α-hydroxyandrost-4-en-3,17-dione. Key: O——O, 0.03 *M* phosphate; ●——●, 0.03 *M* tris (hydroxymethyl) aminomethane buffer. The reaction systems contained 1 mg. of androst-4-en-3,17-dione or 9α-hydroxyandrost-4-en-3, 17-dione, 500 mcg. of phenazine methosulfate, and 25 units of 1-dehydrogenase (specific activity 800) in a total of volume of 4 ml. of 0.03 *M* phosphate or Tris buffer. After 10 minutes, the reaction was terminated by acidification; androsta-1,4-diene-3,17-dione was assayed by the paper chromatographic method, and 9,10-seco phenol (IV) was assayed as in Fig. 1.

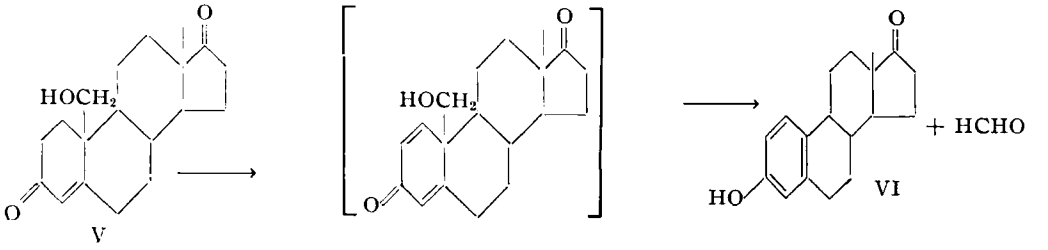

Scheme III

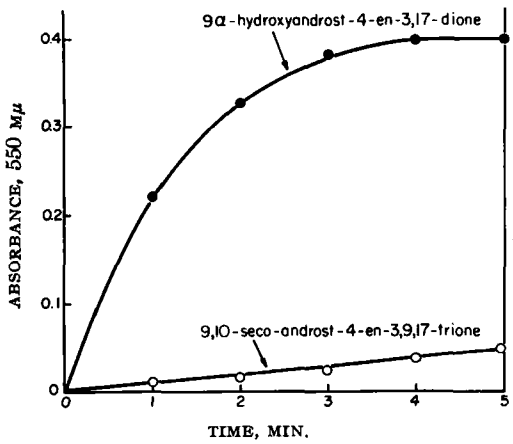

Fig. 3.—Reaction of 9α-hydroxyandrost-4-en-3,-17-dione and 9,10-seco-androst-4-en-3,9,17-trione with purified 1-dehydrogenase. The assay system contained 2 mg. of cytochrome *c*, 100 mcg. of steroid in 0.1 ml. of methanol, and 25 units of enzyme (specific activity 1000) in a total volume of 3 ml. of 0.03 *M* phosphate buffer, pH 7.0. The reaction was initiated by the addition of 0.1 ml. of a 1% phenazine methosulfate solution.

TABLE III.—EFFECT OF PHENAZINE METHOSULFATE ON METABOLISM OF 9α-HYDROXYANDROST-4-EN-3,17-DIONE[a]

Additions	9α-Hydroxyandrost-4-en-3,17-dione, μm. 20 min.	45 min.
None	1.59	1.36
NAD (1.5 μm.)	1.57	1.43
NADP (1.5 μm.)	1.56	1.48
Phenazine methosulfate (1.5 μm.)	0.03	0.00

[a] The reaction mixture contained 1.65 μm. of 9α-hydroxyandrost-4-en-3,17-dione in 0.2 ml. of dimethylformamide and 40 units of enzyme (specific activity 1000) in a total volume of 4 ml. of 0.03 *M* phosphate buffer, pH 7.0. The reaction was stopped at the indicated time intervals by the addition of 1 ml. of chloroform; 9α-hydroxyandrost-4-en-3,17-dione was determined by the paper chromatographic method.

DISCUSSION

The results described show that the conversion of 9α-hydroxyandrost-4-en-3,17-dione into 3-hydroxy-9,10-secoandrosta-1,3,5(10)-triene-9,17-dione requires the presence of an electron acceptor characteristic of flavoproteins (15); the relative efficiency of these electron acceptors follows the same order regardless of whether androst-4-en-3,17-dione or 9α-hydroxyandrost-4-en-3,17-dione was used as the substrate. It is interesting to note that DDQ is also capable of serving as an electron acceptor for the steroid 1-dehydrogenase which confirms the results of Ringold and Turner (16), who have shown that chemical 1,2-dehydrogenation using DDQ involves the abstraction of trans-diaxial hydrogens similar to that of the microbial system. The same enzyme system was capable of converting 9α-fluorohydrocortisone into 9α-fluoroprednisolone and the aromatization reaction exhibited an alkaline pH optimum around 9.0 which is characteristic for steroid 1-dehydrogenase. All these results support the view that the aromatization of 9α-hydroxyandrost-4-en-3,17-dione involved the introduction of a 1,2-double bond by the steroid 1-dehydrogenase.

TABLE IV.—EFFECT OF PHENAZINE METHOSULFATE ON METABOLISM OF 19-HYDROXYANDROST-4-EN-3,17-DIONE[a]

Additions	19-Hydroxyandrost-4-en-3,17-dione, μm. 20 min.	45 min.
None	1.57	1.44
NAD (1.5 μm.)	1.56	1.49
$NADH_2$ (1.2 μm.)	1.56	1.50
NADP (1.5 μm.)	1.59	1.56
$NADPH_2$ (1.2 μm.)	1.58	1.52
Phenazine methosulfate (1.0 μm.)	1.48	1.16

[a] The reaction mixture contained 1.65 μm. of 19-hydroxyandrost-4-en-3,17-dione in 0.2 ml. of dimethylformamide, and 40 units of enzyme (specific activity 900) in a total volume of 4 ml. of 0.03 *M* phosphate buffer, pH 7.0. The reaction was terminated by the addition of 1.0 ml. of chloroform at the indicated time intervals and the 19-hydroxyandrost-4-en-3,17-dione was estimated by the paper chromatographic method.

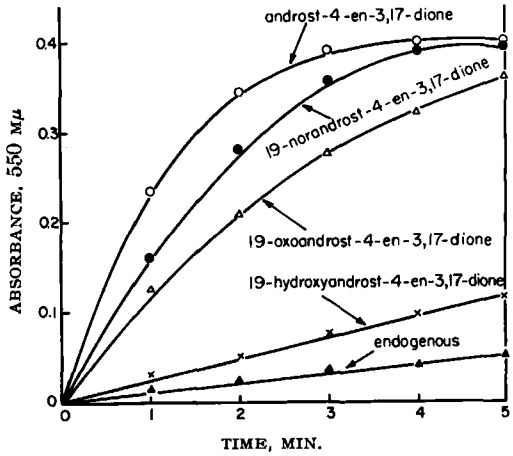

Fig. 4.—The relative rates of oxidation of 19-methyl, 19-nor, 19-oxo, and 19-hydroxy steroids by steroid 1-dehydrogenase. The assay system is the same as that of Fig. 3.

As the enzyme system failed to metabolize 9,10-secoandrost-4-en-3,9,17-trione, this obviously eliminated the alternate pathway B as depicted under Scheme II.

In the absence of an electron acceptor very little 9α-hydroxyandrost-4-en-3,17-dione was metabolized, and NAD and NADP showed no stimulation. Also, the kinetics of 9α-hydroxyandrost-4-en-3,17-dione oxidation (Fig. 3) showed no lag phase. All these results indicate that the first step in the metabolism of 9α-hydroxyandrost-4-en-3,17-dione involves a 1,2-dehydrogenation by the steroid 1-dehydrogenase. Although we have been unable to detect the presence of 9α-hydroxyandrosta-1,4-diene-3,17-dione, it is well known that vinylogs of β-hydroxyketones could undergo rearrangements very easily, and many attempts to prepare this type of compound have failed; *e.g.*, treatment of 19-acetoxyandrosta-1,4-diene-3,17-dione with $NaHCO_3$ or esterase resulted in the formation of estrone (17, 18).

19-Nor, 19-hydroxy, and 19-oxo androstenediones were converted into estrone when incubated with the same enzyme system. However, in the absence of an electron acceptor little 19-hydroxyandrost-4-en-3,17-dione was metabolized. This again eliminated an alternate mechanism involving deformylation prior to 1,2-dehydrogenation.

In view of the foregoing evidence, the aromatization of 9α-hydroxy and 19-hydroxyandrost-4-en-3,17-dione involve a direct 1,2-dehydrogenation to give vinylogs of β-hydroxyketones which undergo spontaneous nonenzymic rearrangements (reverse aldolization) to give their respective phenols. The microbial aromatizing system differs from that of the human placental microsomes in that (*a*) the relative rate of oxidation follows the order 19-nor>19-oxo>19-hydroxy, (*b*) oxygen and $NADPH_2$ are not required in the aromatization reaction, and (*c*) a suitable electron acceptor characteristic of flavoproteins is needed.

Identification of Sympathomimetic Amines as Tetraphenylborates

By J. E. SINSHEIMER and EDWARD SMITH†

The tetraphenylborate salts of sympathomimetic amines are readily isolated in a highly pure state even from low concentrations in complex mixtures. Therefore, melting points, infrared, and ultraviolet spectral characteristics of these salts were studied as an aid to the identification of the medicinally important sympathomimetic amines.

CHATTEN AND LEVI (1) and Fischer and Plein (2) have prepared derivatives for the identification of sympathomimetic amines and have listed references for the identification of these amines. Characterization through tetraphenylborate (TPB) salts would be a valuable addition to these present methods for identifying sympathomimetic amines.

Isolation of organic bases as their TPB salts and subsequent identification by melting point is well established (3–12). Determination of various alkaloids and chemotherapeutic agents by ultraviolet spectra of their TPB salts has also been reported (13, 14). Chatten, Pernarowski, and Levi (15) have prepared the TPB salts of a series of local anesthetics and have reported their ultraviolet and infrared spectra.

In general, TPB derivatives of organic bases

are readily isolated in a pure form even from low concentrations in complex mixtures. Therefore, the melting points and spectral properties of these salts are recorded in this paper as an aid to the identification of this important group of amines.

EXPERIMENTAL

Apparatus and Materials.—Melting points were determined by the U.S.P. capillary tube method with a modified Thiele tube and a calibrated ASTM thermometer. Ultraviolet spectra were determined with the use of a Cary model 11 recording quartz spectrophotometer. Infrared spectral studies were made on Perkin-Elmer model 21 infrared spectrophotometers with sodium chloride or calcium fluoride optics.

Amine TPB salts were prepared as previously described (16) by addition of sodium TPB solution to acetate buffered solutions of the amine. The sympathomimetic amine salts studied and their melting points are listed in Table I. Reagents were of A.R. or U.S.P. grade and were used without additional purification.

650 cm.$^{-1}$ with the use of KBr disks. Approximately 1-mg. samples of dried TPB salts were mixed with 200 mg. of potassium bromide for 30 seconds with a steel capsule and pestle on a Wig-L-Bug.[1] The mixed sample in a KBr die was subjected to vacuum for 5 minutes before and also while being pressed at 20,000 p.s.i. for 5 minutes.

DISCUSSION

The rate of formation of the TPB salts was the same as in the amperometric titration of these amines with TPB (16). Precipitates formed rapidly, except for phenol and catechol derivatives. Phenol derivatives generally precipitated after 1 hour, except with metaraminol and nylidrin. No TPB salt could be obtained from nylidrin, while TPB salts of metaraminol and catechol derivatives could only be prepared after stirring for several hours.

Washing TPB salts free of excess reagent and drying under vacuum yields compounds which are sufficiently pure for identification purposes (8, 9, 15). Crane has found crystallization to be unnecessary and to decompose TPB salts in some instances (8).

The melting or decomposition points observed are listed in Table I.

[1] Crescent Dental Manufacturing Co.

Ultraviolet Spectra. —The ultraviolet spectra of amine TPB salts are summations of the absorbance of TPB and parent amine. Therefore, any strong absorbance maxima of the amine can still be detected; characterization of the U.V. spectra of sympathomimetic amine TPB salts follows that of the spectra of the parent amine, *per se*, as reported for example by Thies and Özbilici (17). Phenylalkyl, phenolic, and catechol amine derivatives can be distinguished by changes in absorbance in the region of the TPB maxima (266 and 274 mμ). Typical spectra of TPB salts are given in Figs. 1-3. Figure 4 illustrates the contribution due to TPB. Table II is a summary of molar absorptivities of TPB salts of the amines and includes sodium TPB for comparison.

The ultraviolet characteristics of most TPB salts in acetate buffer are similar to those in methanol. The disappearance of the minima of the TPB absorbance (264 and 272 mμ) is the predominant change and results in the appearance of shoulders instead of peaks as illustrated in Fig. 4. Phenol derivatives as illustrated in Fig. 5 represent an exception in that minima were observed and the relative intensity of the peaks was altered by a change to the acidic media.

Infrared Measurements.—The TPB ion exhibits absorbance characteristics due to monosubstituted phenyl and boron-aryl (18, 19) groups as shown by Chatten, Pernarowski, and Levi (15) for sodium TPB. It is noted that potassium bromide itself readily absorbs moisture, producing additional absorbance in the 3500 and 1650 cm.$^{-1}$ regions. Although there is a similarity in spectra because of the absorbance due to the TPB group, no two spectra are identical.

The differentiation of closely related compounds can be illustrated by a comparison of the spectra of tuaminoheptane and methylhexaneamine tetraphenylborates. As shown in Fig. 6, calcium fluoride optics accentuate spectral differences for the two compounds in the CH stretching region, a difference which is difficult to detect with sodium chloride optics as illustrated by the spectra of these two salts in Fig. 7. Methylhexaneamine has a definite increase in the CH_3 stretching absorbance at 2962

and 2872 cm.$^{-1}$ compared to the CH_2 stretching absorbance at 2926 and 2853 cm.$^{-1}$ This is consistent with the increased CH_3 to CH_2 ratio from 2:4 in tuaminoheptane to 3:2 in methylhexaneamine.

The spectra of sympathomimetic amine TPB salts obtained with potassium bromide pellets on the model 21 spectrophotometer with sodium chloride optics are illustrated in Figs. 7–13. It can be seen from these spectra that TPB salts serve as a convenient medium for the isolation and identification of various members of a series of amines.

SUMMARY

The preparation of TPB salts of sympathomimetic amines together with their melting points, ultraviolet, and infrared spectra have been shown to be useful for the identification of these amines.

Advantages of the Hematocrit Method for Testing Isotonicity of Injectable Solutions

By IVO SETNIKAR and OLIMPIA TEMELCOU

Fifty solutions of substances of pharmaceutical interest, all found nonhemolytic at iso-osmotic concentration by Hammarlund and Pedersen-Bjergaard (11) on human blood, were tested for their hemolytic properties and isotonicity on rabbit red cells using the hematocrit method. It was demonstrated that several of these solutions showed some hemolytic properties on rabbit red cells because they were not isotonic at iso-osmotic concentration. Other solutions precipitated hemoglobin; this explains the absence of hemolysis when the hemolytic method was used. The reasons are given for preferring the hematocrit method to the hemolytic method for testing isotonicity and general compatibility with blood.

THE HEMOLYTIC METHOD (1–12) is probably among the simplest for testing the compatibility of injectable solutions with erythrocytes. However, it has the following drawbacks when the isotonicity of solutions has to be tested.

(*a*) It is not possible to calculate the isotonic concentration from a hemolysis-preventing concentration because the ratio between these two concentrations can vary considerably (14, 15). (*b*) The compatibility is tested by adding a very small quantity of blood to the solution. Thus the environment is very different from the actual conditions of injection. In particular, the pH depends on the pH of the solution and is not buffered by the blood (11). As a result, the information on the compatibility of the solution with erythrocytes may be misleading. (*c*) In absence of hemolysis it is difficult to distinguish between a real prevention of hemolysis and a precipitant action on hemoglobin (9, 15, 16). (*d*) The substances present in the solution may alter the colorimetric determination of hemoglobin in solution either by altering the absorbance of hemoglobin or by interfering with their own color with the colorimetric reading (11). For this reason the quantitative appreciation of hemolysis may be incorrect.

The hematocrit method (15, 16), which gives direct information on the isotonicity of a solution and which is performed in environmental conditions much closer to the actual conditions of injection, therefore seems better suited to test injectable solutions for isotonicty with erythrocytes and for general compatibility with blood.

In this paper a series of substances were tested for their isotonicity on rabbit red cells using the hematocrit method. All these substances were selected from those which, at iso-osmotic concentrations, were found not hemolytic on human blood by Hammarlund and Pedersen-Bjergaard (11).

Received January 4, 1963, from the Research Division, Recordati, Laboratorio Farmacologico S. p. A., Milan, Italy.
Accepted for publication March 5, 1963.

METHOD

The solutions to be tested were mixed 1 : 1 (v/v) with a suspension of red cells as previously described (16).

The hematocrit determinations were performed using tubes of 3-mm. diam. and a length of 100 mm. in duplicate on serial concentrations of the solution to be tested. In the concentration scale, the iso-osmotic and (if possible) the isotonic concentration, were included. Hemolysis on the supernatant was classified in the following way: absent (0); light (L), with a concentration of hemoglobin up to 0.5%; medium (M), with a hemoglobin concentration from 0.5 to 3%; heavy (H), with a hemoglobin concentration of more than 3%. The hemoglobin concentration was not determined on the supernatant of each sample but by comparing the sample with hematocrit tubes containing hemoglobin solutions in serial concentration. Complete hemolysis gave a hemoglobin concentration of 15%.

RESULTS

Rabbit Red Cells.—The substances tested for isotonicity and for hemolytic effects by the hematocrit method are listed in Table I. The iso-osmotic concentrations given in Table I are based on the experimental data obtained with human erythrocytes by Hammarlund and Pedersen-Bjergaard (17).

With regard to hemolysis, Table I shows that the results obtained on the carbohydrates and polyalcohols, all with six or more C atoms, were in agreement with those found by the hemolytic method by other investigators (8, 11). Moreover, the isotonic concentration found for these compounds was equal to the iso-osmotic concentration.

Iso-osmotic concentrations of calcium, magnesium, potassium, and sodium salts provoked in many instances a light or moderate hemolysis in disagreement with the results obtained by the hemolytic method. For 13 out of 32 of these solutions, the hematocrit method showed that the isotonic concentration for rabbit blood was different from the iso-osmotic concentration.

The miscellaneous substances, at iso-osmotic concentration, produced hemolysis with the exception of tetraethylammonium chloride. It was found also that the isotonic concentrations were

consistently higher than the iso-osmotic concentration.

Some of the solutions described in Table I under *Miscellaneous* were tested also by the hemolytic method on rabbit blood following the procedure described by Shaw and Husa (13). The compatibility of these solutions with rabbit hemoglobin was tested, adding to 10 ml. of these solutions 0.1 ml.

TABLE I.—ISOTONIC CONCENTRATIONS AND HEMOLYSIS OBSERVED WITH THE HEMATOCRIT METHOD ON RABBIT RED CELLS

	Iso-osmotic Concn., %	Isotonic Concn. Range, %	Hemolysis Observed at Iso-osmotic Concn.	Hemolysis Observed at Isotonic Concn.	Approximate Ratio between Isotonic and Iso-osmotic Concn.
Carbohydrates and Polyalcohols					
Dextrose U.S.P.	5.51	5.5 to 5.6	O	O	1
d-Fructose	5.05	5.0 to 5.1	O	O	1

[a] Hemolysis not appreciable because of the intense coloration of the sodium fluorescein solution. [b] An increase of concentration increases hemolysis and diminishes hematocrit values. [c] Denaturation and flocculation of hemoglobin. [d] Dark color of the red cell column. [e] Transparent red cell column. [f] Transparent red cell column with some floccules. [g] Transparent and brownish-red cell column. [h] The minimum hemolysis was observed at concentrations ranging from 6 to 8%. [i] Dark precipitate. [j] Precipitation.

TABLE II.—HEMOLYTIC AND HEMOGLOBIN PRECIPITATING ACTIVITIES OF SOME SOLUTIONS

	Iso-osmotic Concn., %	Hemolytic Method		Compatibility with Rabbit Hemoglobin	
		Hemolysis	Color Changes	Precipitation	Color Changes
Ammonium phosphate dibasic	1.76	O[a]		...	...
Ammonium sulfate	1.68	L[a]		...	...
Amphetamine phosphate N.F.	3.47	O[a]		...	...
Amphetamine sulfate U.S.P.	4.23	L[a]		...	...
Atropine sulfate U.S.P.	8.85	O[a]	dark	...	dark
Phenol U.S.P.	2.80	O	grey	complete	grey
Silver nitrate U.S.P.	2.74	O	dark	almost complete	dark

[a] A layer of hemoglobin in solution was noted on the surface of the red cell sediment.

of a 20% rabbit hemoglobin solution obtained from red cells washed three times with 0.9% NaCl and hemolyzed with repetitive freezing.

Table II shows that the results obtained on ammonium phosphate and sulfate, amphetamine phosphate and sulfate, and atropine sulfate roughly agree, in regard to hemolysis, with those described by Hammarlund and Pedersen-Bjergaard (11). However, a thin layer of hemoglobin in solution was always noted above the red cell sediment, showing that a partial hemolysis was present and explaining the hemolysis observed with the hematocrit method (*cf.* Table I). The hematocrit method seems therefore more sensitive for hemolysis, probably because comparatively about 100 times more red cells are added to the solution to be tested.

Phenol and silver nitrate provoked precipitation of hemoglobin; this explains the absence of hemolysis reported by Hammarlund and Pedersen-Bjergaard (11). The precipitation appeared very clearly in the hematocrit tubes showing the incompatibility of these substances with blood. Using the hemolytic method, a darkening and shrinking of the red cells with a milky appearance of the solution (for phenol) was reported (11)—phenomena which may be sometimes overlooked and not necessarily attributed to an incompatibility with blood.

Hemolysis—as shown in Table I for amphetamine sulfate, dextro-amphetamine sulfate, and ephedrine sulfate—is not necessarily correlated with osmotic pressure, since on increasing the concentration of these substances an increase of the osmotic pressure can be demonstrated together with an increase of hemolysis. An example of this behavior is given in Table III.

Human Red Cells.—Since Hammarlund and Pedersen-Bjergaard obtained their results on human red cells and since a difference between human and rabbit red cells is demonstrated in osmotic behavior (3, 15, 16), the hematocrit method was performed for some solutions on human red cells to establish whether the disagreement found between the results obtained by the hematocrit and the hemolytic method might be attributed to species differences.

TABLE III.—HEMATOCRIT VALUE AND HEMOLYSIS OBSERVED ADDING ONE VOLUME OF RABBIT RED CELLS TO ONE VOLUME OF DEXTRO-AMPHETAMINE SULFATE IN DIFFERENT CONCENTRATIONS

Dextro-amphetamine Sulfate Concn., %	Hematocrit Value	Hemoglobin in the Supernatant, %	Estimated Percentage of Hemolyzed Cells
4.0	0.87	5.5	4.3
5.0	0.76	2.2	3.5
6.0	0.67	0.3	0.7
7.0	0.63	0.2	0.4
8.0	0.56	0.3	0.9
9.0	0.54	2.5	7.3
10.0	0.50	5.1	17.0
Plasma	0.50	0	0

TABLE IV.—HEMATOCRIT VALUES AND HEMOLYSIS OBSERVED ON HUMAN RED CELLS WITH ISO-OSMOTIC CONCENTRATIONS OF DIFFERENT SUBSTANCES

Substance	Iso-osmotic Concn., %	Hematocrit Value	Hemolysis
Amphetamine sulfate U.S.P.	4.23		total
Atropine sulfate U.S.P.	8.85	0.65	light
Decamethonium bromide	5.00		total
Dextro-amphetamine sulfate U.S.P.	4.20	0.80	high
Ephedrine sulfate U.S.P.	4.54	0.75	high
Sodium acetate anhydrous	1.18	0.50	0
Sodium benzoate U.S.P.	2.25	0.50	light
Sodium citrate U.S.P.	3.02	0.48	0
Sodium phosphate dibasic $\cdot 2H_2O$	2.23	0.50	0
Plasma	..	0.50	0

In Table IV a hematocrit value higher than 0.50 indicates hypotonicity—a hematocrit value lower than 0.50, hypertonicity. Table IV shows that the results obtained on human red cells reproduce those obtained on rabbit red cells, with very slight differences for sodium acetate and dibasic sodium phosphate, the first of which showed a little higher osmotic pressure on human red cells and the second a little higher osmotic pressure on rabbit red cells compared to the red cells of the other species.

DISCUSSION

The results presented in this paper and those of the literature (1, 16) show that relatively few molecules or ions are unable to penetrate the red cells and therefore (18) to exert an osmotic pressure through the cell membrane. For this reason it must again be emphasized that isotonicity can be tested only by putting the solutions directly in contact with cells and cannot be calculated on the basis of the molecular weight and probable micellar behavior, or on the basis of physical methods as is suggested

also in recent literature (20). The danger involved in these procedures was demonstrated for iso-osmotic urea solutions by Setnikar and Temelcou (16).

Using the hematocrit method it can be demonstrated that, among the substances which are of interest for pharmaceutical formulation, some carbohydrates and polyalcohols exert an osmotic pressure through the erythrocyte membrane which can be predicted on the basis of the colligative physical properties of these solutions. For these solutes the red cell membrane appears therefore impermeable.

The same can be said for salts with calcium, magnesium, potassium, and sodium cations. In these cases the osmotic pressure exerted through the cell membrane is the same as if the total amount of ions in solutions was prevented from passing through the cell membrane. This confirms the view that it is enough for the membrane to be impermeable to the cation or to the anion component of a salt to be impermeable to the whole salt of which the ion is a part (19).

Particular mention should be given to sulfate and phosphate ions, which, according to Davson (19), impede the penetration of the cation component into the red cells so that the whole salt can exert an osmotic pressure. The results of this paper show, however, that the iso-osmotic concentration of the phosphate and sulfate salts (*cf.* the ammonium, amphetamine, atropine, and ephedrine salts reported in Table I) is always lower than the isotonic concentration, that iso-osmotic concentrations always produce partial hemolysis and that often these substances affect the red cells in a way which makes the red cell column almost transparent. Therefore, these anions can not be considered equal (as Hammarlund and Pedersen-Bjergaard (11) suggested) to the cations already mentioned, which are unable to cross the cell membrane.

Among the really impermeable ions tetraethylammonium must finally be mentioned (*cf.* Table I).

Norlander and Sandell (21) and Setnikar and Paterlini (22) pointed out that for hypodermic use, strict isotonicity is not critical for good tolerance. The same was demonstrated by Hammarlund and Pedersen-Bjergaard (11) for intravenous solutions when small quantities are injected. This seems to diminish the importance of an accurate method as the hematocrit one for testing isotonicity of injectable solutions. Such a method becomes, however, indispensable for solutions which must be injected in large quantities into the blood stream or in some particular cases, *e.g.*, for solutions designed for rachidean administration. In this case the small quantity of cerebrospinal fluid and its slow replacement (23) can not buffer liquids which are not isotonic to a tolerable osmotic pressure, so that the very delicate nervous cells may be damaged.

In any case, it is very important to recognize damaging solutions, *i.e.*, strongly hemolytic (of the saponin type) or with a precipitating or denaturing action on proteins (as zinc sulfate, phenol, etc.). The former are easily detected both with the hemolytic and the hematocrit method; the latter are more immediately detected with the hematocrit method because a precipitation on the red cell column is immediately noted.

Qualitative and Quantitative Tests for Stannous Fluoride

By JOHN J. HEFFERREN

A series of qualitative and quantitative assay procedures are presented for stannous fluoride. These data are the result of a cooperative project of the American Dental Association with the major manufacturers and users of stannous fluoride. The physical and chemical characteristics of stannous fluoride are described. The methods selected to define stannous fluoride and other methods which might be utilized are discussed.

STANNOUS FLUORIDE is an agent which has been used topically as a simple solution, in dentifrices, and in other mixtures to reduce the incidence of dental caries (1). This monograph is part of a continuing program to provide data on those drugs and chemicals which are described in "Accepted Dental Remedies." The tests are designed to be applied to stannous fluoride as such and to capsules and aqueous solutions containing stannous fluoride. The limits set in these tests are based on normal analytical and manufacturing variation.

It should be recognized that the particular tests and methods described do not necessarily represent those used by any particular firm, but rather those which have been selected as generally applicable. It is expected that there will be capsules or solutions of stannous fluoride containing interfering substances which will require modification of these methods. The terminology of the "United States Pharmacopeia" has been used wherever possible.

DESCRIPTION

Physical Properties.—Stannous fluoride (SnF_2; mol. wt. 156.70) is a white, crystalline solid with a bitter, salty taste, m.p. 212–214°, b.p. 845–855°. It is freely soluble in water and practically insoluble in alcohol, ether, and chloroform. The pH of an 8% aqueous solution is about 2.3.

Identity Tests.—Transfer to a small test tube about 100 mg. of stannous fluoride and dissolve in 10 ml. of water. Mix on a spot plate 2 drops of this solution with 2 drops of 1% silver nitrate; a brown-black precipitate forms (presence of stannous ion).

Transfer to a small test tube 2 drops of mercuric chloride T.S. (6.5 Gm./100 ml. water) and add 1 drop of the above stannous fluoride solution; a white milky precipitate forms. Further addition of stannous fluoride solution gives a brown-black precipitate (presence of stannous ion).

Transfer 1 drop of the above stannous fluoride solution to a spot plate, add 1 drop of 0.001 *M* alizarin complexan and 1 drop of 0.001 *M* cerous nitrate; a lilac-blue color forms (presence of fluoride ion).

Purity Tests.—Dry about 1 Gm. of stannous fluoride, accurately weighed, at 105° for 4 hours; the loss in weight is not more than 0.5%.

Transfer 10 Gm. of stannous fluoride, accurately weighed, to a 400-ml. plastic beaker and add 200 ml. of water. Stir with a plastic rod for 3 minutes or until no more solid dissolves. Filter the mixture through a tared Gooch crucible tightly packed with asbestos fiber. Thoroughly wash first with about 50 ml. of 1% ammonium fluoride and then with about 200 ml. of water. Dry the residue at 105° for 4 hours and weigh. The water-insoluble residue does not exceed 0.2%.

ASSAY

Stannous Ion.—Place 200 ml. of water, 100 ml. of hydrochloric acid, and a few boiling chips in a 500-ml. Erlenmeyer flask. Boil the mixture for 10 minutes; add 0.25 Gm. of stannous fluoride, accurately weighed. In an inert atmosphere such as carbon dioxide or oxygen-free nitrogen, swirl the flask to dissolve the stannous fluoride, and cool the solution to room temperature. Add 5 ml. of starch T.S. and titrate in an inert atmosphere with 0.1 *N* potassium iodate to the blue starch end point. Each milliliter of 0.1 *N* potassium iodate is equivalent to 7.835 mg. of stannous fluoride. The amount of stannous fluoride, SnF_2, is not less than 95.0% nor more than 105.0%.

Preparation of Potassium Iodate Titrant.—Transfer about 3.6 Gm. of potassium iodate in 200 ml. of oxygen-free water containing 1 Gm. of sodium hy-

Received March 14, 1963, from the Division of Chemistry, American Dental Association, Chicago, Ill.

Accepted for publication April 9, 1963.

This monograph was prepared through the cooperation of the major manufacturers and users of stannous fluoride. The following individuals represented their respective firms in this project: L. D. Apperson, Colgate-Palmolive Co.; William E. Cooley, The Procter & Gamble Co.; H. J. Keily, Lever Brothers Co.; Marguerite Moran, M & T Chemicals, Inc.; Wayne E. White, Ozark-Mahoning Co.

The cooperation of the firms in providing data and the technical assistance of Gordon Schrotenboer, Henry Koehler, and Mira Zimmerman are gratefully acknowledged.

droxide and 10 Gm. of potassium iodide to a 1000-ml. volumetric flask; dilute with oxygen-free water to the mark and mix.

Standardization of Potassium Iodate Titrant.—Transfer 0.25 Gm. of reagent grade tin, accurately weighed, to a 500-ml. Erlenmeyer flask, add 100 ml. of hydrochloric acid, and 2 drops of 2% antimony trichloride, and allow the mixture to stand at room temperature until all the tin has dissolved. Carefully add 180 ml. of water and 10 ml. of sulfuric acid and mix. Add a nickel coil, prepared from a coiled piece of 3 × 6-in. reagent grade nickel sheet which has been washed with petroleum ether, boiled in 1:2 hydrochloric acid for 5 minutes and rinsed with water. (The coil should be treated with acid before each use.) Add 5 Gm. of hydrogen-reduced iron powder, and wash down the sides of the flask with water. Gently boil the mixture for 20 minutes in an inert atmosphere. Maintaining the inert atmosphere, cool the mixture to room temperature, add 5 ml. of starch T.S., and titrate with the potassium iodate titrant to the blue starch end point. Each milliliter of 0.1 *N* potassium iodate is equivalent to 5.935 mg. of tin.

Soluble Tin.—Transfer 0.1 Gm. of stannous fluoride, accurately weighed, to a 500-ml. volumetric flask. Add about 300 ml. of water, vigorously shake for about 5 minutes, fill to the mark with water, and mix. Filter a portion of the mixture through a piece of hard filter paper, discarding the first 10 ml. of filtrate. Transfer 2 ml. of the filtrate to a 50-ml. volumetric flask and add 10 ml. of 30% sulfuric acid and 5 drops of thioglycolic acid. Similarly, prepare a blank and three standard tin solutions containing 2, 5, and 10 ml., respectively, of *Standard Tin Solution B*, which contains 0.04 mg. tin/ml. Dilute each of these solutions with water to a total volume of 40 ml. Add 2 ml. of 2% sodium lauryl sulfate and gently swirl to mix with a minimum of foaming. With gentle swirling, add 2 ml. of *dithiol solution*, cool to room temperature, fill to the mark with water, and mix. Spectrophotometrically determine the absorbances of the solutions containing tin in 1-cm. cells at the maximum at about 530 mμ using the reagent blank as a reference. Prepare a plot of absorbance *versus* tin concentration using the absorbances of the standard tin solutions. Determine the tin concentration in the stannous fluoride solutions using this plot. The amount of stannous fluoride is not less than 95.0% nor more than 105.0%.

Preparation of Reagent.—Standard Tin Solution A.—Transfer 0.2 Gm. of reagent grade tin, accurately weighed, to a 1000-ml. volumetric flask and dissolve in 250 ml. of hydrochloric acid. Cool the solution to room temperature, fill to the mark, and mix. This solution is stable for about 1 month.

Standard Tin Solution B.—Transfer 50 ml. of *Standard Tin Solution A* to a 250-ml. volumetric flask, fill to the mark with water, and mix. This solution should be freshly prepared.

Dithiol Solution.—Transfer 0.15 Gm. of dithiol to a 100-ml. beaker, add 8 drops of thioglycolic acid, and 50 ml. of 2% sodium hydroxide, and stir to dissolve the dithiol. Filter the solution if it is not clear. The dithiol solution stored in a glass-stoppered bottle in the refrigerator is stable for about 1 week. The solution should be discarded if a precipitate forms.

Soluble Fluoride.—Transfer 0.2 Gm. of stannous fluoride, accurately weighed, to a 100-ml. volumetric flask. Add about 70 ml. of water, vigorously mix for about 5 minutes, fill to the mark with water, and mix. Transfer 10 ml. of this solution to a 100-ml. volumetric flask, fill to the mark with water, and mix. Transfer 10-ml. of the last solution to a third 100-ml. volumetric flask, fill to the mark with water, and mix. Prepare a standard fluoride solution containing 10 mcg./ml. of fluoride ion using sodium fluoride reagent. Transfer 1, 2, 3, and 4 ml. of the standard fluoride solution and 5 ml. of the final stannous fluoride solution to 100-ml. volumetric flasks. Add 10 ml. of zirconium-SPADNS reagent to each of the above volumetric flasks plus a flask for the blank, fill to the mark with water, and mix. Spectrophotometrically determine the absorbances of the blank and fluoride-containing solutions in 1-cm. cells at the maximum at about 590 mμ using SPADNS reference solution as a reference. Prepare a plot of absorbance *versus* fluoride concentration using the absorbances of the sodium fluoride solutions. Determine the concentration of fluoride in the stannous fluoride solution using this plot. The amount of stannous fluoride is not less than 92.0% nor more than 108.0%.

Reagents.—*Solution A.*—Dissolve 3.16 Gm. SPADNS [4,5-dihydroxy-3(*p*-sulfophenylazo)-2,7-naphthalenedisulfonic acid, trisodium salt, Eastman No. 7309] in 550 ml. of water.

Solution B.—Transfer 0.133 Gm. of zirconium oxychloride octahydrate, $ZrOCl_2.8H_2O$, to a 500-ml. volumetric flask and dissolve in 50 ml. of water. Add 350 ml. of hydrochloric acid, fill to the mark with water, and mix.

SPADNS Reference Solution.—Dilute 50 ml. of *Solution A* with 500 ml. of water and 35 ml. of hydrochloric acid. The SPADNS reference solution is stable.

Zirconium-SPADNS Reagent.—Mix equal volumes of *Solutions A* and *B*. The resulting solution stored in an amber bottle is stable.

DOSAGE FORMS

Capsules

Identity and Purity Tests.—Capsules of stannous fluoride respond to the identity tests in the monograph for stannous fluoride.

Assays—*Stannous Ion.*—The stannous ion as determined by the procedure in the monograph for stannous fluoride is not less than 90.0% nor more than 110.0% of the labeled amount.

Fluoride Ion.—The fluoride ion as determined by the procedure in the monograph for stannous fluoride is not less than 90.0% nor more than 110.0% of the labeled amount.

Solutions

Solutions of stannous fluoride respond to the identity tests and assay methods described in the monograph for stannous fluoride. Solutions of stannous fluoride should be prepared from oxygen-free purified water and used immediately.

DISCUSSION

Nebergall and co-workers prepared stannous fluoride in 86% yield by reacting stannous oxide

moistened with oxygen-free water with a 10% molar excess of 48% hydrofluoric acid (2). This is

$$SnO + 2HF \rightarrow SnF_2 + H_2O \quad \text{(Eq. 1)}$$

an exothermic reaction from which the stannous fluoride crystallizes as the reaction mixture cools. Stannous fluoride is also prepared by reacting powdered tin with anhydrous hydrogen fluoride (3, 4).

From studies of stannous fluoride as an ingredient in solid fuels containing uranium or plutonium fluoride, Thamer and Meadows (5) found that dry stannous fluoride was unusually stable under essentially anhydrous conditions or those of low humidity. Molten stannous fluoride at 650° in an oxygen-free atmosphere in a mechanically-shaken, platinum-lined bomb did not undergo decomposition after 3 months. In the reverse reaction, tin and stannic fluoride in a similar bomb at 700° for 2 hours were substantially converted to stannous fluoride. In this work, the melting and the boiling points of stannous fluoride were reported as 213 ± 1° and 850 ± 5°, respectively. During the boiling point determination in a copper still, about 3% of the distillate was oxidized to the oxyfluoride, $SnOF_2$.

Stannous fluoride and the other stannous halide salts exhibit many similar physical and chemical properties (6). Stannous fluoride solutions probably contain Sn^{++}, SnF^+, $SnF_2°$, SnF_3^-; the existence of $SnF_4^=$ is considered to be possible but not likely. If an excess of fluoride is present in the solution, the SnF_3^- entity is more prevalent. The stannous fluoride in aqueous solutions undergoes hydrolysis to form the sparingly soluble stannous hydroxide which gives the solution a cloudy appearance. In this hydrolysis reaction, a number of entities, as indicated by Eq. 2, can exist. The sparingly soluble stannous hydroxide, represented for simplicity as $Sn(OH)_2$, may lose water to form stannous oxide. In the presence of oxygen or oxidizing agents, the stannous ion undergoes oxidation to form the stannic ion.

$$Sn^{++} \xrightarrow{OH^-} SnOH^+ \xrightarrow{OH^-} [Sn(OH)_2] \xrightarrow{OH^-} [Sn(OH)_3]^- \quad \text{(Eq. 2)}$$

Stannous fluoride is freely soluble in water (7, 8). The solubility of stannous fluoride in solutions maintained at temperatures from 0 to 106° (the boiling point) is a straight line relationship (Fig. 1) (7). The specific gravity of a saturated solution of stannous fluoride at 25° is about 1.51; thus a saturated solution at 25° contains about 63% stannous fluoride, weight by volume (63 Gm./100 ml.).

Typical pH values of freshly prepared stannous fluoride solutions are given in Table I.

In general, the pH of a stannous fluoride solution gradually decreases on standing, and this decrease is accompanied by the formation of insoluble hydrolysis products.

Acidic fluoride solutions can etch the surface of the glass electrode, thereby reducing the electrode life. This reaction (Eq. 3) can be a problem in

$$SiO_2 + 4HF \rightarrow SiF_4 + 2H_2O \quad \text{(Eq. 3)}$$

solutions containing 1% or more of stannous fluoride.

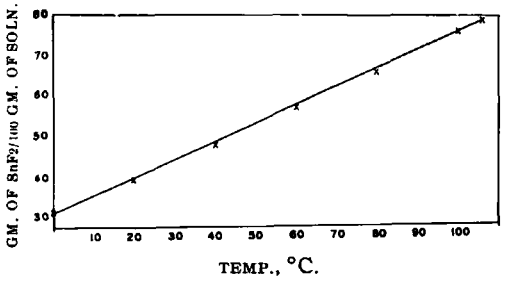

Fig. 1.—The solubility of stannous fluoride in water as a function of the temperature of the solution.

TABLE I.—pH OF FRESHLY PREPARED STANNOUS FLUORIDE SOLUTIONS

8%—2.3	2%—2.8
5%—2.5	1%—3.0
0.4%—3.2	

When the glass electrode is used to determine the pH of stannous fluoride solutions, the pH meter should be standardized with two buffer solutions. This procedure will reduce the possibility that a damaged glass electrode can be standardized at the pH of one buffer and still be inaccurate over a relatively small pH range. The sleeve-type reference electrode is preferred for measuring the pH of stannous fluoride solutions because the flow rate of electrolyte is much faster. There is a tendency for the small orifice containing the asbestos thread at the tip of the fiber-type reference electrode to become blocked. The pH of stannous fluoride solutions should be measured quickly to reduce the exposure of the electrodes to the solutions.

Stannous fluoride is somewhat more stable than stannous chloride and both are more stable in acidic solutions. The results of an early study with stannous chloride and fluoride are shown in Fig. 2. The solutions were freshly prepared and assayed immediately after the adjustment of the pH with sodium hydroxide. The assay procedure included centrifugation to remove the insoluble material,

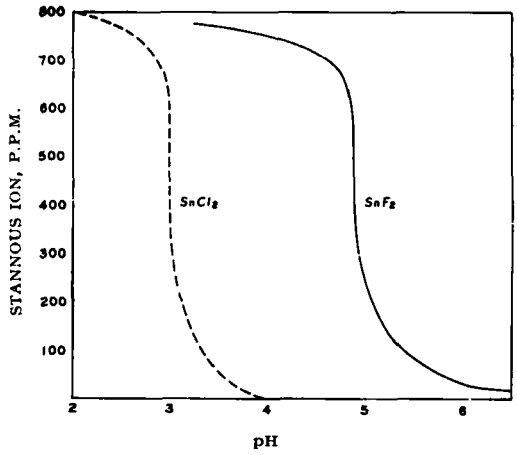

Fig. 2.—Stannous ion concentration of stannous chloride and fluoride (1000 p.p.m. Sn^{++}) solutions after adjustment of the pH of the solution with sodium hydroxide.

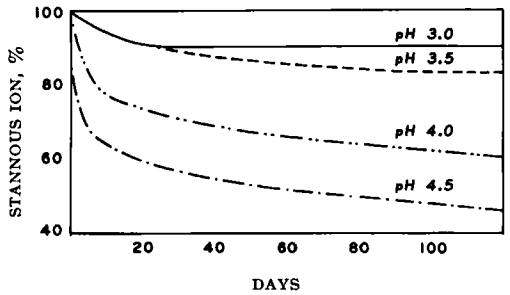

Fig. 3.—Effect of aging on stannous ion concentration in 0.4% aqueous solutions of stannous fluoride. The pH of the solutions was adjusted with sodium hydroxide.

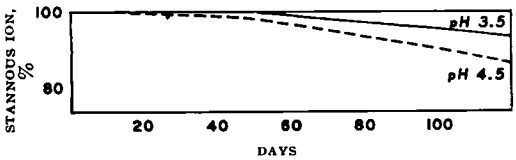

Fig. 4.—Effect of aging on stannous ion concentration of 0.4% stannous fluoride in an equal volume mixture of glycerin and water. The pH of the solutions was adjusted with sodium hydroxide.

then an iodine titration of the soluble stannous ion. In this early study, the soluble stannous ion content at the native pH of stannous chloride and fluoride was only about 85% of the theoretical value of 1000 p.p.m. This initial loss was probably because of a number of factors, including the purity of the particular samples of the stannous salts. As the pH's of the stannous chloride and fluoride solutions were raised from their native values around pH 3, the soluble stannous ion concentration dropped rapidly.

The effect of aging 0.4% aqueous solutions of stannous fluoride at different pH values is shown in Fig. 3. The pH of these stannous fluoride solutions was adjusted with sodium hydroxide, and the solutions stored in plastic bottles under an inert atmosphere. The plastic bottles then were stored in glass containers under an inert atmosphere. Here again, the greater stability of the soluble stannous ion in solutions at the native pH of stannous fluoride was demonstrated.

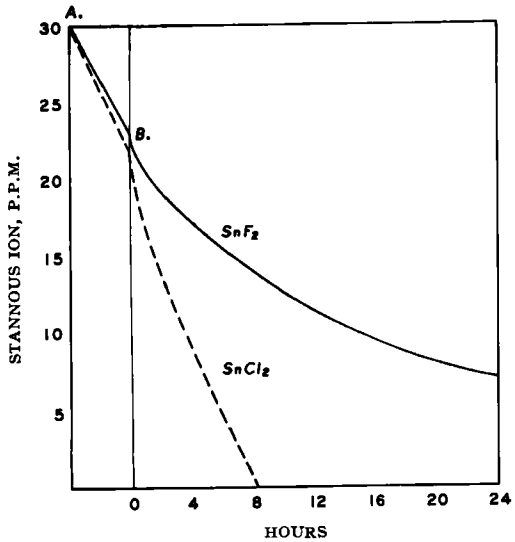

Fig. 5.—Stannous ion concentration of 0.0048% stannous chloride (30 p.p.m. Sn^{++}) and 0.004% stannous fluoride (30 p.p.m. Sn^{++}) at the time of dispensing into animal bottles and upon aging in these bottles. Key: A, initial concentration; B, concentration at time of dispensing.

The effect of adding glycerin or other highly water-soluble materials such as sugars, gums, etc., to stannous fluoride solutions is shown in Fig. 4. These stannous fluoride solutions were aged under the same conditions as those described in Fig. 3. When glycerin and these other materials are added, the activity of the free stannous ion is reduced; thus the rate of hydrolysis is reduced.

The stability data on the soluble stannous ion concentration in solutions of stannous fluoride in Figs. 3 and 4 were obtained from solutions prepared with degassed, distilled water stored in plastic containers under an inert atmosphere. With these conditions, the primary decomposition reaction is that of hydrolysis. The oxidation of the stannous ion is kept at a minimum. Stannous fluoride solutions stored without an inert atmosphere or in glass bottles decompose much more rapidly because three routes of decomposition are possible—hydrolysis, oxidation, and reaction with glass. In all such stability studies with stannous salts, it is important to centrifuge the solutions before assaying soluble stannous ion iodimetrically. The colloid-like, insoluble stannous hydroxide formed in a hydrolysis reaction is solubilized by the acidic iodimetric titration medium and thus is determined as soluble stannous ion.

As is true with most compounds, stannous fluoride is more stable in concentrated solutions. In animal experiments utilizing the drinking water as a route of administration, the exposure of very dilute solutions of stannous fluoride to the atmosphere can result in a significant loss in the soluble stannous ion. Francis (9) observed that the concentration of soluble stannous ion in mixtures containing an initial concentration of 30 p.p.m. decreased rapidly within a few hours (Fig. 5). In these experiments with rats, the solutions were prepared in the morning and transferred immediately to the usual liquid dispensing bottles of laboratory animal cages. As a result of the significant loss in soluble stannous ion concentration, it would be very easy to obtain misleading animal data. For this reason, Francis suggested that the stannous salts be administered topically rather than in the drinking water.

In all these stability studies, the concentration of soluble stannous ion was reported as a function of time, pH, or both. In these solutions, which contained essentially no foreign cations, the soluble fluoride remained relatively constant. Introduction of soluble calcium salts or calcium salts solubilized by the acidity of the solutions can significantly reduce the soluble fluoride ion concentration by the formation of calcium fluoride. The reduction in the soluble fluoride concentration reduces the overall complexing effect of the solution and therefore the stannous ions are more susceptible to hydrolysis.

Qualitative Tests.—There are many identity tests in standard chemistry texts for the stannous and fluoride ions of stannous fluoride. The two tests for stannous ion in the monograph are oxida-

tion-reduction reactions involving the oxidation of stannous to stannic ion and the reduction of silver and mercuric ions to the respective metals. By adding the stannous fluoride solution dropwise to mercuric chloride, it is possible to see the formation of the intermediate white mercurous chloride, which is then further reduced.

The reaction of fluoride with the cerium or lanthanum complex of alizarin complexan (3-aminomethylalizarin-N,N-diacetic acid) is one of the few, if not the only positive colorimetric response to fluoride ion. The alizarin complexan was prepared by Belcher and co-workers by a Mannich-type condensation of alizarin, iminoacetic acid, and formaldehyde (10). The alizarin complexan is now available from Burdick & Jackson Laboratories of Muskegon, Mich.

Polarography.—Polarography is one of the most important techniques for the detailed study of stannous fluoride alone and in combination with other agents. The hydrolysis of stannous fluoride is an example of a reaction which can be studied polarographically. The stannous ion in aqueous stannous fluoride solutions readily undergoes complex formation and partial or complete hydrolysis. Partial hydrolysis is a form of complexing in which the average number of hydroxyl groups bound per stannous ion is less than two. Polynuclear complexes involving Sn—OH—Sn bonds are frequent products of partial hydrolysis when no large excess of fluoride or other complexing anion is present.

Polarographically, freshly prepared stannous fluoride solutions (0.001 to 0.01 *M* stannous fluoride in 0.1 *M* potassium perchlorate) at or below their natural pH generally yield reversible cathodic waves at half-wave potentials of −0.45 to −0.50 volts (D.M.E. *versus* S.C.E.). Typical values of $i_d/Cm^{2/3}t^{1/6}$ are 3.7 to 4.4 at 25°. The presence of Sn-OH bonds and polynuclear complexes affects both the half-wave potential and the diffusion current. The polarographic behavior of any particular solution depends on the history of the stannous fluoride used—for example, its exposure to moist air, as well as the pH, ionic strength, and age of the solution. Aging of the solution or the presence of other complexing agents often leads to irreversible reduction waves.

Maxima sometimes observed in the reduction waves can usually be suppressed by addition of 0.001 to 0.01% gelatin. Complete suppression of the maxima sometimes lowers the overall diffusion current to a measurable degree.

With extremely rigorous control of manipulative variables, including careful exclusion of dissolved air from solutions, it is possible to use polarography for quantitative analysis of stannous ion in stannous fluoride solutions; however, the relatively simple iodimetric method is usually preferred. The main usefulness of polarography is in detecting and measuring changes in the nature of the soluble stannous species caused by complexing, including hydrolytic reactions.

The references (11–13) do not deal specifically with polarography of stannous fluoride but do contain extensive background information about the hydrolysis of stannous fluoride, fluoride complexes of stannous ions, and polarography of tin ions under various conditions.

Amalgam-Electrode Potentiometry.—Potentiometry with a tin amalgam electrode is a technique allied to polarography that has been useful in study of tin complexes (14). From a measurement of the equilibrium potential between stannous ions in solution and tin in the amalgam, the amounts of free and complexed stannous ions can be calculated. The situation is analogous to measurement of half-wave potentials in polarography. The potentiometric method has been used to measure the stabilities of polynuclear hydroxy complexes of tin in solutions of stannous perchlorate.

Purity Tests.—The purity test involving loss of weight on drying at 105° may be a measure of the hydrogen fluoride as well as the moisture content of the sample because hydrogen fluoride or hydrofluoric acid is used in the manufacture of stannous fluoride. The water-insoluble materials are usually the sparingly soluble hydrolysis products of stannous fluoride.

The metallic impurities in stannous fluoride can be determined spectrographically or colorimetrically (15). In the spectrographic procedure, the fluoride is usually removed by treatment with nitric acid in a platinum crucible. The usual limits placed on these materials in stannous fluoride are: iron–0.05%, nickel–0.05%, copper–0.01%, lead–0.005%, antimony–0.005%, and arsenic–0.0003%. The total of these materials should be less than 0.1%.

Assays.—The iodimetric determination of stannous ion is not a specific method; however, in most situations it is a convenient and generally applicable method (15). The titration depends upon the

$$Sn^{++} + I_2 \rightarrow Sn^{++++} + 2I^- \qquad \text{(Eq. 4)}$$

reaction of iodine with stannous ion to form iodide and stannic ions, respectively. The two commonly used iodine titrants are an iodine solution containing potassium iodide to solubilize and reduce the volatilization of the iodine and slightly alkaline iodate solution containing potassium iodate and iodide. The iodate-iodide reagent releases iodine

$$IO_3^- + 5I^- \xrightarrow{H^+} 3I_2 + 3H_2O \qquad \text{(Eq. 5)}$$

when added to the acidic titration medium (Eq. 5). The iodate titrant requires an acidic titration medium; the iodine titrant does not. Although the iodate reagent is generally considered to be somewhat more stable, both reagents should be stored in amber bottles and standardized at reasonable intervals.

Because the stannous ion is easily oxidized by the oxygen in air, it is important to carry out the titration in an inert atmosphere such as carbon dioxide or oxygen-free nitrogen. Specially purified nitrogen can be purchased as such or prepared by passing the nitrogen over heated copper turnings or through Fieser's hydrosulfite solution (16). A good quality deionized or distilled water should be used in all the assays. The water used in the preparation of the reagents should be made oxygen-free by boiling and cooling under an inert atmosphere or by degassing with purified nitrogen. Polarographic measurements suggest that the degassing procedure is somewhat more efficient in removing the oxygen.

Since there are a number of variables which can affect the iodimetric determination of stannous

fluoride, it is important to standardize the titrant using conditions and reagents as similar as possible to those used in the actual titrations. The most common method of standardizing the titrant is the use of reagent grade tin (15). Another standard which may sometimes be more convenient is sodium thiosulfate. The sodium thiosulfate reagent which has been standardized against arsenic trioxide or other suitable reference standard is especially useful in standardizing very dilute titrants.

Starch is the most common indicator for iodimetric titrations. The presence of detergents in the titration medium may interfere with the colorimetric end point by absorbing the starch. With these mixtures and others containing color interfering agents, the iodimetric titration can be followed potentiometrically with a potentiometer and a set of platinum and glass electrodes or a platinum combination electrode. This particular titration is quite suitable to a number of automatic and semiautomatic titration setups. Using the potentiometric or colorimetric starch end point, it is possible to titrate with iodine titrants with a normality as low as 0.005.

Since the iodimetric procedure is basically an oxidation-reduction procedure, any agent which can act as an oxidizing or reducing agent can interfere with the titration. A more specific method for the determination of tin is reaction with dithiol to form the red tin-dithiol complex which absorbs at about 530 mμ (15, 17).

The ion exchange method for the fluoride in stannous fluoride is a nonspecific assay which is useful in routine manufacturing control. In this method, the tin ion is reacted with the acid form of strongly acidic cation exchange resin such as Dowex 50W-X8 to release hydrogen ions. The hydrofluoric acid formed by the reaction is then titrated with standard base to the phenolphthalein end point. Because of the hydrofluoric acid formed in this reaction, plastic laboratory equipment should be used for this assay. Other halide salts and many other salts can interfere with the assay by participating in the exchange reaction with the resin.

A recent review describes the many methods which are available for the determination of fluoride (18). One of the major problems in the determination of fluoride is the separation of the fluoride from other interfering ions, such as calcium, phosphate, and sulfate, which are frequently present with fluoride in biological and other materials. Although ion exchange, paper chromatography, and other methods have been used for the separation of fluoride from interfering ions, the three most important procedures have been perchloric acid distillation, pyrolytic decomposition, and perchloric acid diffusion. The carefully controlled perchloric acid distillation of the fluoro-silicon compound usually described as fluosilicic acid (H_2SiF_6) has been one of the most widely used procedures (19). This procedure has been modified for micro work by utilizing nitrogen instead of steam as a carrier gas for the distillation, thereby greatly reducing the volume of distillate required for complete recovery of the fluoride (20). Separation by pyrolysis depends upon the hydrolytic decomposition of halides at about 1000° in the presence of superheated steam (21, 22). The most recent method of separation is the diffusion of hydrogen fluoride gas formed by the reaction of the

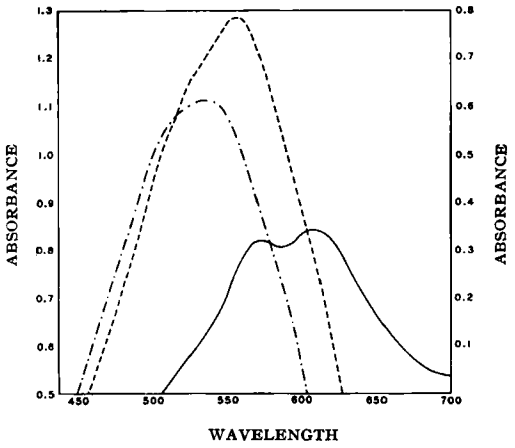

Fig. 6.—Spectra of lanthanum-alizarin complexan (reagent) and its fluoride adduct. Key: ——, reagent *vs.* water (abs. 0.5 to 1.5); - - - - -, reagent-fluoride *vs.* water (abs. 0.5 to 1.5): and ——, reagent-fluoride *vs.* reagent (abs. 0 to 1.0).

fluoride in the sample with perchloric acid (23). From the standpoint of equipment required and overall simplicity, the diffusion method, which utilizes plastic micro Conway dishes, is the preferable method of separating the fluoride. After the fluoride has been separated from the interfering ions, a wide variety of methods can be utilized for the determination.

The reaction of fluoride with lanthanum or thorium chloranilates has been utilized for fluoride determinations (24, 25). The insoluble chloranilate salts react with fluoride to form the soluble chloranilic acid and the corresponding insoluble fluoride salt. The concentration of the solubilized chloranilic acid is then determined by the absorbance at two different wavelengths depending upon the fluoride concentration, for example, 2 to 100 p.p.m., 530 mμ, 0.5 to 3 p.p.m., 330 mμ. While the chloranilate methods are not sensitive to most common anions, except for phosphate, the methods utilize a two-phase system with its consequent disadvantages.

The reaction of cerium or lanthanum alizarin complexan with fluoride is one of the few positive color reactions for fluoride. Unlike most bleaching methods involving a decrease in absorption as the fluoride ion concentration increases, the reaction of the cerium or lanthanum complex with fluoride results in an increase in absorption and a shift in wavelength of the maximum. The cerium complex of alizarin complexan (3-aminomethylalizarin-N,N-diacetic acid) is red with an absorption maximum in water at about 495 mμ (26). The reagent reacts with fluoride to form a blue-purple color with a maximum at about 567 mμ. The wavelength for the colorimetric determination is at about 610 mμ. At this wavelength, the maximum difference between the absorption spectra of the fluoride-containing complex and the cerium chelate occurs. The spectra of the corresponding lanthanum compounds are illustrated in Fig. 6. The wavelength of the maximum for this method and for any colorimetric method should be determined for each instrument and with each lot of dye. The stability of this

blue fluoride complex has been increased by using acetonitrile-water (1:5) mixture as a solvent for the color reaction (27).

The colorimetric methods which depend on the bleaching of the color of metal chromophoric combinations due to the stronger complexing of the metal ion by fluoride are older and generally more widely used fluoride methods. The zirconium-alizarin red S mixture utilizes color measurement at 520–525 mμ (28). The alizarin red S reaction product with fluoride has also been titrated with thorium nitrate, which depends upon the formation of the insoluble thorium fluoride (28). Two other zirconium lakes which have a low sensitivity to foreign ions and a high sensitivity to fluoride are the zirconium-eriochrome cyanine R (29) and zirconium-SPADNS [4,5-dihydroxy-3-(*p*-sulfophenylazo)-2,7-naphthalenedisulfonic acid, trisodium salt] (30). The SPADNS reagent, which is stable indefinitely, has increased sensitivity to fluoride when the molar ratio of zirconium to SPADNS is 1 to 12 (23).

Stannous ion does not interfere with the zirconium-SPADNS color reaction. Thus, it is possible to determine the soluble fluoride in a particular sample of stannous fluoride by simply dissolving the sample in water and diluting to a fluoride concentration ordinarily used in this procedure, 1–4 mcg./ml. When there is any doubt about the composition or contaminants of the sample, it is much safer to separate the fluoride from the rest of the sample before the determination.

Commercial detergents used for cleaning laboratory ware usually contain phosphate or sulfate ions, which interfere with most fluoride methods. Thus, it is important that the rinsing subsequent to washing the laboratory ware be adequate to remove all traces of these interfering ions.

Some Possible Errors in the Plotting and Interpretation of Semilogarithmic Plots of Blood Level and Urinary Excretion Data

By JOHN G. WAGNER

Semilogarithmic plots of amount (or per cent) not excreted against time will be curved either if (a) the wrong asymptote is used, or (b) absorption is still proceeding during the interval observations are made. Factor (a) causes "convex decreasing" type of curvature, whereas factor (b) causes "concave decreasing" type of curvature. If both factors are operative, it is possible to obtain an apparently linear semilogarithmic plot; however, the rate constant estimated from the linear segment is meaningless. Models and actual data from the literature are used to illustrate these points. Using a simple model, it is shown that rate constants estimated from terminal segments of semilogarithmic plots of amount not excreted or of blood levels may be appreciably lower than the true values. The implications of these factors in making in vitro–in vivo correlations are discussed.

VAN LIEW (1) indicated that concavity[1] of a semilogarithmic curve may result from operation of one of four types of systems. Application of the "backward projection" technique to "convex decreasing" semilogarithmic plots of blood level and urinary excretion data can lead to linear components from which rate constants between assumed independent compartments may be estimated. Van Liew showed that another interpretation may be the operation of a continuum of exponential processes.

Assuming the independent compartment model applies to blood level and urinary excretion data, this report will discuss (*a*) other causes of curvature of semilogarithmic plots, (*b*) possible errors in plotting and interpreting such data, and (*c*) the implications of these factors in making *in vitro–in vivo* correlations.

Several types of semilogarithmic plots are commonly utilized. In these, time is plotted as the abscissa and the ordinates plotted on the logarithmic scale are (**A**) urinary excretion rate (amount/unit time or per cent of dose/unit time), (**B**) amount (or per cent) not excreted, and (**C**) blood (serum or plasma) concentration. Data plotted as the ordinate of Cartesian coordinate paper frequently are (**D**) cumulative amount or per cent of the dose excreted, (**E**) urinary excretion rate, and (**F**) blood (serum or plasma) concentration; again, time is plotted as the abscissa in each of these. On the semilogarithmic plots, curvature of the type discussed by Van Liew (1) is termed "convex decreasing" (analogous to Curve A in Fig. 3) to distinguish it from another type of curvature termed "concave decreasing" (analogous to segments AB in Figs. 1 and 2).

Received March 14, 1963, from the Product Research and Development Unit, The Upjohn Co., Kalamazoo, Mich.
Accepted for publication April 3, 1963.

[1] The terminology used in this report would describe the type of curvature Van Liew discussed as "convex decreasing." See Fig. 12 for the descriptions.

EXPERIMENTAL

Consider Model I:

$$X \xrightarrow[(0.180\,\text{hr.}^{-1})]{k_1} Y \xrightarrow[(0.090\,\text{hr.}^{-1})]{k_2} Z$$

Let us assume that (*a*) the rate constants, k_1 and k_2, are first-order rate constants and have the values shown; (*b*) 100% of the "drug" is initially in compartment X at time, $t = 0$; (*c*) the volumes of compartments X, Y, and Z are equal. This is an idealized model for first-order absorption and first-order elimination if X is considered to be the reservoir of "drug" at the absorption sites, Y is drug in the volume of distribution, and Z is drug lost by various processes from the volume of distribution. Figure 1 is a semilogarithmic plot of per cent of "drug" in Y against time based on the above model; it is analogous to type (**C**) plot, above. The plot has pronounced "concave increasing" curvature during the interval when most of the drug is leaving X. Although the curve is actually continuous, only some of the values have been calculated and the points joined; this is the case in other examples shown too. At point A only 13.8% and at point B only 2.28% of the "drug" is left in X. It would be easy to interpret segment AB as a straight line, especially if the assay error for the drug were relatively large as is often true with blood assays. The segment BC appears linear even with the idealized values obtained from the model. Estimation of k_2 from the segment BC gave a value of 0.080 hours^{-1} which is 11% lower than the actual value of 0.090 hours^{-1}.

Using Model I, a type (**B**) plot is shown as Curve I in Fig. 2. The per cent of "drug" not in compartment Z would be analogous to per cent of drug not excreted if all the drug initially in X were excreted unchanged in the urine, Z. Note that Curve I is "concave decreasing" from A to B. For times beyond B the plot appears linear. Estimation of k_2 from the segment BC gave a value of 0.0866 hours^{-1} which is 3.8% lower than the actual value of 0.0900 hours^{-1}. This example indicates that estimation of k_2 from "urinary data" (sampling in Z) is more accurate than estimation of k_2 from "blood level data" (sampling in Y) in the same time interval. In actual practice the higher concentrations of drug in urine than in blood and the greater accuracy and precision of urine assays compared with blood assays also contribute to greater accuracy from urine data than blood data.

When constructing type (**B**) plots, values of ($Ae°$-Ae) must be calculated where $Ae°$ is the amount of drug excreted in the urine at "infinite time" (about ten half-lives is usually an adequate collection time). The ($Ae°$-Ae) values or the percentages $Ae°$-$Ae/Ae° \times 100$, are plotted on the logarithmic axis. $Ae°$ is called the asymptote of the first-order plot. Some authors incorrectly use the administered dose for the value of $Ae°$ when they do not show experimentally that the dose is excreted completely in the urine. An example of use of such an incorrect asymptote is shown as Curve II in Fig. 2. Curve II was constructed by assuming that the "dose" initially in X of Model I was 125 mg. but that only 100 mg. of the intact "drug" appeared at infinite time in Z; however, rather than using the correct value for $Ae°$, namely 100 mg. as in Curve I, the incorrect value of 125 mg. (the "dose") was utilized to calculate the percentages. Curve II is "concave decreasing" from D to E but becomes apparently linear from E to F; from F to G the curve is "convex decreasing." One could interpret that in such a plot the segment EF represents first-

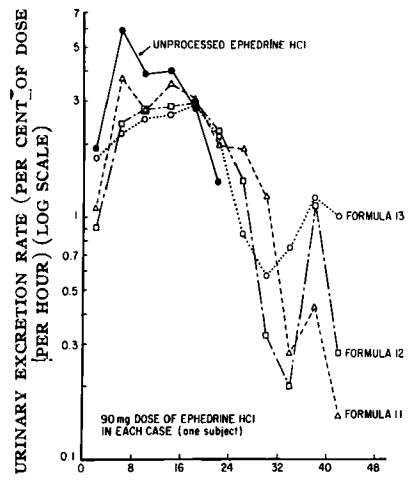

Fig. 6.—Type (A) plots derived from data in Figs. 4 and 5.

order loss of drug from the body or appearance in the urine, particularly if little or no data were collected beyond point F. The rate constant estimated from segment EF is 0.0481 hours^{-1} which is approximately one-quarter and one-half of the actual values of k_1 and k_2, respectively. The rate constant derived from segment EF is purely "artificial" and bears no real relationship to either of the rate constants k_1 and k_2. In this example the effect of "absorption still proceeding" (*i.e.*, transfer of significant amounts of "drug" from X to Y), which causes "concave decreasing" curvature,[2] and the effect of using the wrong asymptote, which causes "convex decreasing" curvature, cancel each other. The net effect is an apparently linear segment which is completely artificial.

Consider Eq. 1

$$\frac{Ae^\circ - Ae}{Ae^\circ} \times 100 = (100)\{10^{-k(t-t_0)}\} \quad \text{(Eq. 1)}$$

This equation, according to theory, should fit urinary excretion data in two situations: (*a*) where t_0 is the end of the distribution-tissue equilibration phase following intravenous administration of the drug, or (*b*) where t_0 is the end of the absorption and tissue equilibration phase following oral administration and where $t > t_0$ in both cases. Figure 3 is a semilogarithmic plot of Eq. 1 with k equal to 0.03 for both Curves A and B. Assume the dose is 100 mg. but that only 80 mg. of drug appears in the urine in infinite time. Curve B was constructed using the correct asymptote, namely $Ae^\circ = 80$; the line is straight and has a slope of -0.03. Curve A was constructed using Ae° = dose = 100. Note that Curve A is "convex decreasing." Rate constants estimated from the points between 0 and 15 hours or between 15 and 30 hours would be greatly in error.

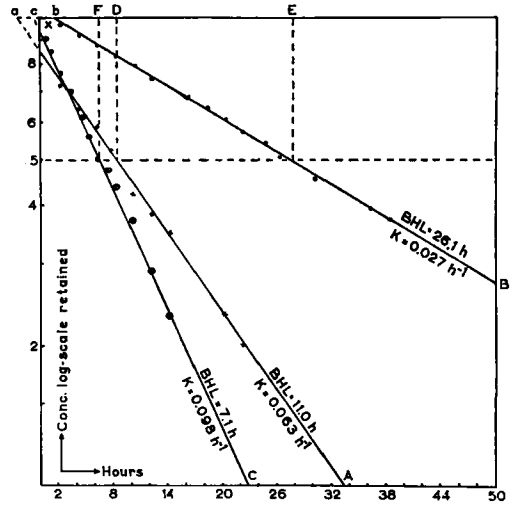

Fig. 7.—Reproduction of Fig. 32 of Simoons (2).

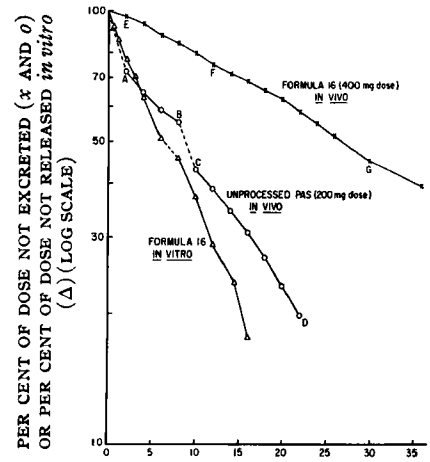

Fig. 8.—Tabular data of Fig. 7. replotted.

[2] "Concave decreasing" curvature may also be observed if the drug elimination process is zero order (rather than first order) and the blood concentration is plotted against time on semilogarithmic paper. In such a case, replotting the data on Cartesian coordinate paper should yield a linear plot of blood level against time.

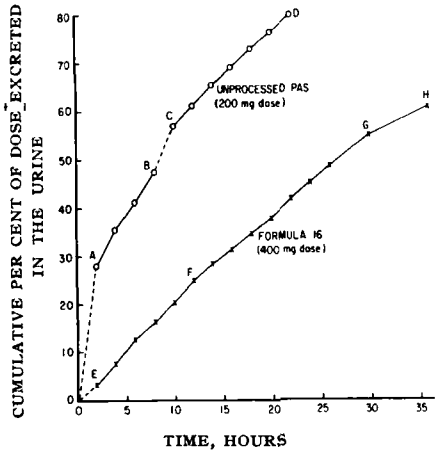

Fig. 9.—Type (**D**) plots derived from data in Figs. 7 and 8.

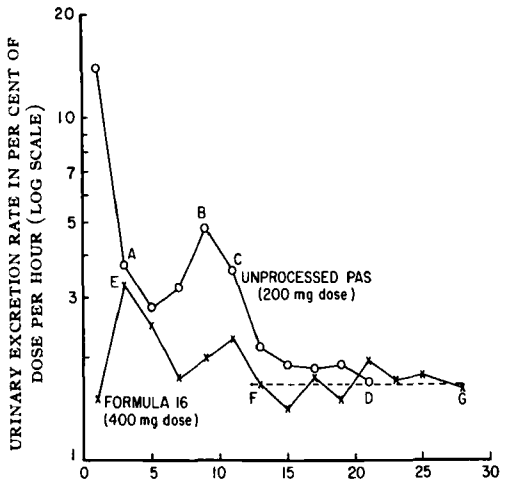

Fig. 10.—Type (**A**) plots for data shown in Figs. 7, 8, and 9.

Practical examples of the operation of some of the factors discussed above are found in the plots and data of Simoons (2). At different times a human subject was administered 90-mg. doses of ephedrine hydrochloride as unprocessed drug and in the form of three different sustained-release formulations. Urine was collected at regular intervals and analyzed for drug content. Formula 13 was tested *in vitro* using a new apparatus.[3] Figure 4 is a reproduction of Fig. 31 of Simoons (2). The tabular data (2) on which Fig. 4 was based were replotted and are shown in Fig. 5. In Fig. 5 the data points were merely joined, whereas in Fig. 4 straight lines were drawn through the points and extrapolated; data points have been left off the extrapolated regions of Fig. 4. The situation in Fig. 5 is analogous to Curve II in Fig. 2. No meaningful rate constant(s) can be calculated from any of the plots shown in Fig. 5. Also, since Ae° was not determined in any of the experiments (since urine was not collected long enough), a type (**D**) plot (such as Figs. 4 and 5) should not be made at all for data. Type (**A**) plots, derived from the same data, are shown in Fig. 6. The excretion rates are plotted against the midpoints of the urinary collection intervals over which the rates were calculated. Simoons (2) and Cummings and Martin (3) plotted the rates against the times at the end of the collection intervals; this distorts the plots and leads to erroneous conclusions. The peculiar curvature at the tail ends of the plots shown in Fig. 6 are not readily explained but may be because of continued irregular absorption and/or a recycling phenomenon. Although Fig. 6 is a "valid" plot for these data, it is obvious that no meaningful rate constants can be estimated.

Another example is taken from Simoons (2). At different times a human subject was administered 200 mg. of unprocessed *p*-aminosalicylic acid (PAS) and 400 mg. of PAS in the form of ten sustained-release tablets (formula 16). The latter were also tested *in vitro* using the new apparatus.[3] Figures 7–11 are derived from the same data given by Simoons (2). Figure 7 is a reproduction of Fig. 32 of Simoons (2). The tabular data (2), on which Fig. 7 were based, were replotted and are shown in Fig. 8. In Fig. 8 the data points were merely joined, whereas in Fig. 7 straight lines were drawn through the points. Inspection of the plot of the *in vitro* data in Fig. 8 indicates there are two essentially linear segments, one between 0.5 and 6 hours, the other between 8 and 16 hours, with a discontinuity between them from 6 to 8 hours; this is a different interpretation than the single linear plot shown in Fig. 7. Inspection of the plots of the *in vivo* data in Fig. 8 indicates curvature in the segments EF, FG, AB, and CD, with a discontinuity from B to C. No meaningful rate constants can be estimated from these *in vivo* data as was done by Simoons in Fig. 7. Again, since Ae° was not determined in either of the *in vivo* experiments, type **B** plots (such as Figs. 7 and 8) should not be made at all for these data. The type **D** plots for these data, shown in Fig. 9, support this statement; at times D and H, when urine collection ceased, excretion of drug in the urine was incomplete, but one could not predict that the entire dose (100%) would be excreted. Note that the segmentation of the plots shown in Fig. 8 is also apparent in Fig. 9. A type **A** plot is more "sensitive" than either types **B** or **D**. The type **A** plots for the same data are shown in Fig. 10. These plots show double peaks indicative of a recycling phenomenon. The plot for the unprocessed PAS did not become linear during the observation period; hence, no rate constant for loss of drug from the body can be calculated. Formula 16 gave an essentially constant excretion rate averaging 1.67% of dose/hour or 6.68 mg. of PAS/-hour in the 13 to 28-hour interval. This is a considerably different interpretation than the first-order rate constant of 0.027 hours^{-1} shown on Fig. 7. The variability about the mean rate in the 13- to 28-hour interval is exaggerated due to the logarithmic scale in Fig. 10; this variability is not nearly so evident in the type (**E**) plot of the same data shown in Fig. 11. Figure 11 has a considerably different appearance than Fig. 25 of Simoons (2), yet both were derived from the same tabular data.

[3] The apparatus is described in Reference 2. A commercial model, the Erweka Tester Type AT-3, is distributed by the Chemical and Pharmaceutical Industry Co., Inc., New York, N. Y.

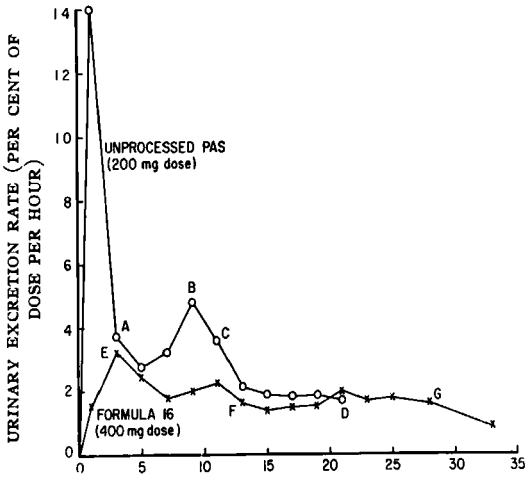

Fig. 11.—Type (E) plots derived from tabular data of Fig. 25 of Simoons (2).

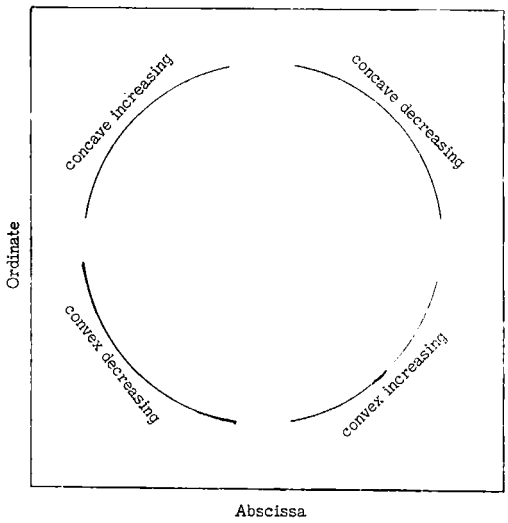

Fig. 12.—Description of concavity of semilogarithmic curve. The definitions assigned to the curve are those of James and James (6).

DISCUSSION

Given a set of urinary excretion data for interpretation, one should first make two types of plots: (*a*) a plot of cumulative amount excreted to time *t* against time *t*, and (*b*) a semilogarithmic plot of excretion rate (amount/unit time) against the midpoints of the urinary collection intervals.[4] If the first plot indicates an asymptote was reached, then (*c*) a semilogarithmic plot of amount not excreted against time should also be made. Theory (4) predicts that plots (*b*) and (*c*) should have terminal linear segments and that the rate constant derived from these linear segments should be same and equal to the rate constant for loss of drug from the volume of distribution. Care should be used to insure that the segments used do not show curvature and that "artifacts" are not produced by using the wrong asymptote in the third type of plot. Comparison of the three types of plots prepared from the same set of data allows more accurate interpretation and permits comparison of different segments as has been done in the figures in this report. Even in the absence of evidence of curvature in the terminal segments of the semilogarithmic plots one should be aware that the most likely situation is that the estimated rate constant will be less (the half-life greater) than the true value. This is also true of semilogarithmic plots of blood level against time.

The rate constant for clearance (or biological half-life) of a drug in the body is independent of dosage form effects if the data are properly collected and interpreted. Apparent deviation from this independence is purely an artifact due to inadequate data or misinterpretation of data. It is the author's experience that the rate constant for clearance (or biological half-life) of a drug in the body is almost always independent of the route of administration in a given species if the data are properly collected and interpreted. However, there are physiologic reasons for differences with some drugs.

The magnitude and duration of blood levels and urinary excretion of a drug can be markedly altered by dosage form effects, as many investigators have shown (5). An interesting and necessary area of research is to try to correlate *in vivo* and *in vitro* results obtained with different dosage forms. This research is "interesting" since correlation of *in vivo* results with physical constants such as rate of dissolution, solubility, and partition coefficient may someday lead to the ability to predict behavior of new drugs and old drugs in new dosage forms or at minimum reduce the number of biological experiments necessary and aid in experimental designs. Such research may someday be necessary for adequate control of pharmaceutical products, but we do not have enough knowledge today to apply such criteria adequately and rigorously.

It is obvious from the experimental part of this report that the apparent correlations of *in vitro* and *in vivo* results of Simoons (2) were only apparent and not real. In fact, it is completely spurious to correlate rate constants derived from *in vitro* dissolution tests with rate constants for clearance (or biological half-lives) of the drugs derived from blood level and urinary excretion data. If dissolution of the drug from its dosage form *in vivo* partly, or completely, rate limits its absorption, then the "correlation" should involve the use of blood level or urinary excretion data in the time interval shortly after administration. However, it is necessary to know the rate constant for clearance to perform the calculations (4, 5). Quantitative correlations are needed in this research area. The author trusts this report illuminates some of the pitfalls.

[4] If the cumulative curve is fitted by a polynomial and the derivatives estimated at the data points, then the excretion rate (the derivative) should be plotted against the time at the end of the collection intervals.

Synthesis and Activity of 1-Alkyl-2-aryl-2,3-dihydro-4(1H)-quinazolinones

By HARVEY GURIEN† and BERNARD B. BROWN

Only one 1-alkyl-2-aryl-2,3-dihydro-4(1H)-quinazolinone has previously been reported, 1-methyl-2-phenyl-2,3-dihydro-4(1H)-quinazolinone (1). We have prepared a series of such novel quinazolinones and tested them for analgesic and sedative activity. These substances were obtained by reaction of the appropriate *o*-alkylaminobenzamide with an aromatic aldehyde in ethanol containing a small amount of hydrochloric acid according to the scheme

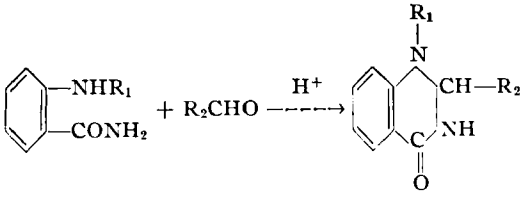

Table I summarizes the physical properties of these substances.

EXPERIMENTAL

1-Alkyl-2-aryl-2,3-dihydro-4(1H)-quinazolinones.—As a general procedure, 0.038 mole of the *o*-alkylaminobenzamide was mixed with 0.050 mole of aldehyde in 30 ml. of ethanol containing one drop of concentrated hydrochloric acid. The mixture was then refluxed for 36 hours. Removal of the solvent was carried out at reduced pressure and the residual solid was recrystallized from toluene. Substituted *o*-alkylaminobenzamides were obtained by reaction of the corresponding isatic anhydrides with ammonia.[1]

PHARMACOLOGICAL DATA[2]

None of the compounds tested showed any significant analgesic, sedative, or muscle relaxant activity in mice at levels up to 100 mg./Kg. when dosed intravenously using propylene glycol–water suspensions. Prostration and decreased activity were observed in the test animals when compounds IV, V, VI, and VII were administered at levels of 100–300 mg./Kg.

Adsorption of Certified Dyes by Starch

By GEORGE ZOGRAFI† and ALBERT M. MATTOCKS

The adsorption of five anionic certified dyes, FD&C Red No. 3, FD&C Blue No. 2, FD&C Green No. 1, FD&C Yellow No. 5, and Ext. D&C Red No. 15, by rice starch, wheat starch, and three varieties of cornstarch, was measured. Adsorption was found to fit the Langmuir equation in all cases. The extent of adsorption by the various cornstarches is related to the ratio of amylopectin to amylose, an increase in adsorption occurring with an increase in the amylopectin content. No dye adsorption was observed when potato starch was used. This is believed to be because of the presence of phosphate ester groups not present in the other starches.

ONE OF THE most troublesome applications of dyes in pharmaceutical products is the coloring of compressed tablets. It is generally found that the wet mass is uniform in color, but that the large granules, after drying, have a high concentration of dye at the surface and a low concentration beneath the surface. Thus, dye migrates toward the outside during drying and compression of this mixture, causing spotted tablets. At the present time, although pigments have been reported to yield evenly colored tablets (1, 2), there is no general means for predicting the facility of migration or preventing the migration of water-soluble dyes during tablet manufacture.

It was felt that studies concerned with dye affinity for solids would be of value to those concerned with this problem since an improvement of dye-solid affinity should reduce migration. This report is concerned with the affinity of selected water-soluble anionic, certified dyes for various natural starches. Starch was chosen since it is widely used in tableting, is available from a variety of different natural sources, and is insoluble in water at moderate temperatures.

EXPERIMENTAL

General Procedure for Measurement of Adsorption.—Adsorption studies were conducted using Kimax, heavy duty, screw-capped centrifuge tubes (Kimble Glass Co.) which have a capacity of about 40 ml. Tin-lined screw caps (Arthur H. Thomas) were used since they were found not to adsorb dye. A rubber ring was placed around the neck of the tube to prevent leakage. To maintain constant temperature and thorough mixing, the tubes were placed on a rotating wheel in a water bath at 30 ± 0.1° and were continuously rotated at 32 r.p.m. Approximately 1 Gm. of starch, accurately weighed, and 20 ml. of dye solution were placed into the tubes. These were placed in the bath and removed after 48 hours, since this was previously determined to be the time required to ensure equilibrium. The tubes were centrifuged at 2500 r.p.m. for 5 minutes, and a 10-ml. aliquot of dye solution was removed. Controls containing only dye solution were treated in the same manner and more than one sample for each dye concentration was used.

Dyes Investigated.—Since there are a large number of water-soluble certified dyes, those chosen for study are representative of the chemical groups into which most of these dyes fall. Ext. D&C Red No. 15 (formerly FD&C Red No. 1) was chosen as an azo dye, FD&C Green No. 1 as a triphenylmethane dye, FD&C Yellow No. 5 as a pyrazalone dye, FD&C Blue No. 2 as an indigo dye, and FD&C Red No. 3 as a xanthine dye. All dyes were obtained from the Calco Chemical Division, American Cyanamid Co., and were used as received.

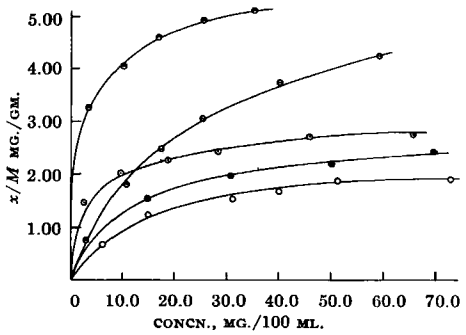

Fig. 1.—Plots of milligrams of dye adsorbed per gram of cornstarch, (x/M), *vs.* milligrams of dye per 100 ml. of solution at equilibrium for FD&C Red No. 3 (●), FD&C Blue No. 2 (⊖), Ext. D&C Red No. 15 (⊙), FD&C Yellow No. 5 (⊕), and FD&C Green No. 1 (○).

The concentration of dye in solution was measured spectrophotometrically using a Beckman model DU spectrophotometer. Absorbance measurements were made at 504 mμ for Ext. D&C Red No. 15, 527 mμ for FD&C Red No. 3, 426 mμ for FD&C Yellow No. 5, 620 mμ for FD&C Blue No. 2, and 428 mμ for FD&C Green No. 1. The final dilution of all dyes, except FD&C Red No. 3, was made into a phosphate-citrate buffer at a pH 5.00, while the final dilution of FD&C Red No. 3 was made into a borate buffer at pH 9.20. The pH values were measured using a Beckman model G pH meter.

Starches Investigated.—Starches utilized in this investigation included those from potato, rice, wheat, and three varieties of corn. The cornstarches included U.S.P. cornstarch containing about 72% amylopectin and 28% amylose, waxy maize starch commercially available with the brand name, Amioca,[1] and containing 100% amylopectin, and Amylon,[1] a cornstarch containing about 60% amylose and 40% amylopectin.

RESULTS

From the difference in dye concentration before and after contact with starch, the number of milligrams of dye adsorbed per gram of starch, x/M, was calculated for each concentration of dye used.

Received January 18, 1963, from the College of Pharmacy, University of Michigan, Ann Arbor.
Accepted for publication March 15, 1963.
† Present address: College of Pharmacy, Columbia University, New York, N. Y.

[1] Obtained from National Starch and Chemical Corp., New York, N. Y.

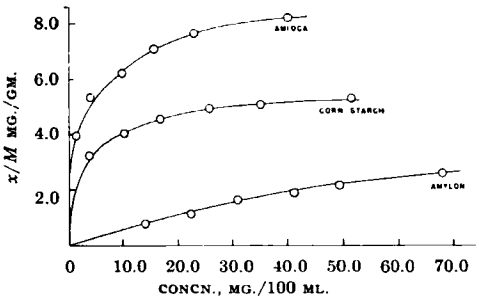

Fig. 2.—Plots of milligrams of FD&C Red No. 3 adsorbed per gram of starch, (x/M), *vs.* milligrams of dye per 100 ml. of solution at equilibrium for three varieties of cornstarch.

Adsorption of all dyes occurred on all starch samples except potato starch, which did not adsorb these dyes. Figure 1 shows a typical plot of x/M *versus* C, the concentration of dye in solution at equilibrium, for all five dyes on cornstarch. Figure 2 shows the marked differences in adsorption for a particular dye on the three cornstarches. The data obtained were found to fit the Langmuir adsorption equation

$$x/M = \frac{k_1 k_2 C}{1 + k_1 C} \qquad \text{(Eq. 1)}$$

where k_1 and k_2 are constants. This is shown in Fig. 3 by the fit of the data to the linear form of this equation

$$C/(x/M) = \frac{C}{k_2} + \frac{1}{k_1 k_2} \qquad \text{(Eq. 2)}$$

From plots of $C/(x/M)$ *versus* C the constants, k_1 and k_2, were evaluated as shown in Table I. The constant, k_2, expressed in milligrams adsorbed per unit mass of adsorbent, is the maximum value for x/M at a given temperature. This can be seen by applying the Langmuir equation at high concentrations, where the value of k_1C becomes much greater than 1, and

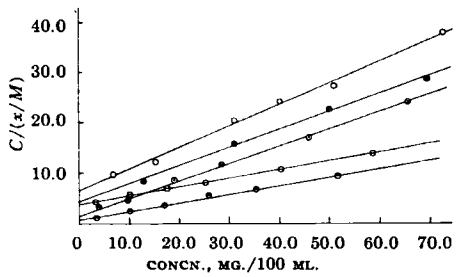

Fig. 3.—Langmuir plots for the adsorption of dyes on cornstarch; FD&C Red No. 3 (●), FD&C Blue No. 2 (⊖), Ext. D&C Red No. 15 (⊙), FD&C Yellow No. 5 (⊕), and FD&C Green No. 1 (○).

$$x/M = k_2 \qquad \text{(Eq. 3)}$$

The constant, k_1, expressed in 100 ml./mg.$^{-1}$ indicates the fraction of maximum adsorption per unit concentration. This is apparent at low concentrations where C may be considered to be much less than 1 and

$$\frac{x/M}{k_2} = k_1 C \qquad \text{(Eq. 4)}$$

DISCUSSION

A comparison of the constants, k_1 and k_2, indicates that there is little difference in adsorption of a particular dye on corn, rice, and wheat starches, although the particle sizes are quite different (3). Calculation of the maximum number of dye molecules adsorbed, utilizing k_2 values, indicates more adsorption than is accountable for on the basis of surface adsorption on the starch grains. This, plus the fact that 48 hours is required to reach equilibrium, suggests that penetration of the various dyes into the starch grain is occurring. As has been shown with cellulose (4), the adsorption probably occurs at the hydroxyl groups of the starch granule. Whether the anionic or the nonionic polar group of the dye is responsible for this interaction has not been definitely determined. Hydrogen bonding between nonionic polar groups of a dye

[a] On the basis of the dry weight of the starches. [b] Blank spaces indicate little or no adsorption. [c] Units of 100 ml./mg. [d] Units of mg./Gm.

and cellulose hydroxyl groups has been proposed (4).

A comparison of the adsorption by the three varieties of cornstarch indicates that Amioca adsorbed all dyes to the greatest extent, U.S.P. cornstarch next, and then Amylon. This trend is related to the amylopectin content. Recent studies concerned with anionic dye binding of soluble starches have shown the opposite results (5): the less interaction occurring, the higher the proportion of amylopectin. This is attributed to the greater rigidity of the branched portions of starch in solution compared to the more flexible linear amylose chains. One would not necessarily expect interactions involving the intact starch grain to be the same as that in solution. The results presented here confirm this.

The lack of anionic dye adsorption on potato starch is apparently because of the presence of phosphate esters (6) which impart a negative charge to the potato starch grain, but which are absent in the other starches. Schoch and Maywald (7) have shown that potato starch and carboxylated starches adsorb cationic dyes strongly but do not adsorb anionic dyes. Adsorption of anionic dyes on potato starch has been observed when neutral electrolytes are added (8). These would be expected to reduce the repulsive forces between the dye and starch by breaking down the electric double layer.

In view of the observed affinity of anionic certified dyes for starch it would appear that the addition of starch to a tablet granulation before the addition of the dye solution should aid in preventing color migration. A recent communication (9) has indicated that starch does enhance color distribution and prevent migration when added to tablet granulations.

In general, it is proposed that adsorption isotherm data can be used to study color migration problems. These isotherms indicate the amount of dye adsorbed as a function of that amount remaining in solution. Since it is the dye in solution which migrates upon drying, the objective should be to minimize this concentration while increasing the amount adsorbed. For systems described by the Langmuir equation the constants, k_1 and k_2 can be considered as a measure of the extent of adsorption for a given dye concentration and the maximum amount of adsorption, respectively. Therefore, by measuring adsorption as a function of such factors as temperature, solvent, electrolyte concentration, and the presence of tablet components, it should be possible to pick systems giving maximum dye adsorption with a minimum of dissolved dye, resulting in maximum color distribution.

Further studies are being conducted and will be reported in a future communication.

Reduction of 1,2,3-Trimercaptopropane Content of Dimercaprol

By EDWARD G. RIPPIE† and ALBERT A. KONDRITZER

A multiple batch extraction procedure is described which can serve to reduce the trithiol content of dimercaprol to levels conforming to the U.S.P. XVI monograph.

Previous reports (1, 2) indicate the presence of the trithiol, 1,2,3-trimercaptopropane, in many laboratory, pilot plant, and commercial lots of dimercaprol (BAL). The toxicity of BAL is substantially increased by this impurity and the revised monograph on dimercaprol appearing in the first U.S.P. XVI supplement contains limits on the concentration in which it may be present. Many lots of BAL, presently available for drug use, contain far more than the established 1.5% limit of the trithiol. Since BAL is not currently manufactured in this country, a purification process is needed.

This report presents the results of a study of the removal of 1,2,3-trimercaptopropane from BAL by a liquid-liquid extraction procedure, using petroleum ether as the extracting solvent. This method may be used with a variety of solvents under various experimental conditions, *e.g.*, BAL saturated with water to increase the partitioning of the trithiol into the organic solvent phase to obtain basic information of value for the development of a commercial process for the purification of BAL containing excessive quantities of the trithiol impurity.

EXPERIMENTAL

Materials.—BAL purified by passage through a partition chromatographic column, followed by distillation at low pressure; 1,2,3-trimercaptopropane, hereinafter designated as TSH; petroleum ether, shaken with concentrated sulfuric acid over a period of several days and distilled between 35–50° were employed.

Procedure.—Known concentrations of TSH in BAL were equilibrated with petroleum ether. The volume of the BAL was chosen sufficiently large so that it was not significantly changed by the extraction. The petroleum ether phase was analyzed for sulfhydryl content, and the resultant data utilized in calculations of extraction efficiency.

and cellulose hydroxyl groups has been proposed (4).

A comparison of the adsorption by the three varieties of cornstarch indicates that Amioca adsorbed all dyes to the greatest extent, U.S.P. cornstarch next, and then Amylon. This trend is related to the amylopectin content. Recent studies concerned with anionic dye binding of soluble starches have shown the opposite results (5): the less interaction occurring, the higher the proportion of amylopectin. This is attributed to the greater rigidity of the branched portions of starch in solution compared to the more flexible linear amylose chains. One would not necessarily expect interactions involving the intact starch grain to be the same as that in solution. The results presented here confirm this.

The lack of anionic dye adsorption on potato starch is apparently because of the presence of phosphate esters (6) which impart a negative charge to the potato starch grain, but which are absent in the other starches. Schoch and Maywald (7) have shown that potato starch and carboxylated starches adsorb cationic dyes strongly but do not adsorb anionic dyes. Adsorption of anionic dyes on potato starch has been observed when neutral electrolytes are added (8). These would be expected to reduce the repulsive forces between the dye and starch by breaking down the electric double layer.

In view of the observed affinity of anionic certified dyes for starch it would appear that the addition of starch to a tablet granulation before the addition of the dye solution should aid in preventing color migration. A recent communication (9) has indicated that starch does enhance color distribution and prevent migration when added to tablet granulations.

In general, it is proposed that adsorption isotherm data can be used to study color migration problems. These isotherms indicate the amount of dye adsorbed as a function of that amount remaining in solution. Since it is the dye in solution which migrates upon drying, the objective should be to minimize this concentration while increasing the amount adsorbed. For systems described by the Langmuir equation the constants, k_1 and k_2 can be considered as a measure of the extent of adsorption for a given dye concentration and the maximum amount of adsorption, respectively. Therefore, by measuring adsorption as a function of such factors as temperature, solvent, electrolyte concentration, and the presence of tablet components, it should be possible to pick systems giving maximum dye adsorption with a minimum of dissolved dye, resulting in maximum color distribution.

Further studies are being conducted and will be reported in a future communication.

Reduction of 1,2,3-Trimercaptopropane Content of Dimercaprol

By EDWARD G. RIPPIE† and ALBERT A. KONDRITZER

A multiple batch extraction procedure is described which can serve to reduce the trithiol content of dimercaprol to levels conforming to the U.S.P. XVI monograph.

Previous reports (1, 2) indicate the presence of the trithiol, 1,2,3-trimercaptopropane, in many laboratory, pilot plant, and commercial lots of dimercaprol (BAL). The toxicity of BAL is substantially increased by this impurity and the revised monograph on dimercaprol appearing in the first U.S.P. XVI supplement contains limits on the concentration in which it may be present. Many lots of BAL, presently available for drug use, contain far more than the established 1.5% limit of the trithiol. Since BAL is not currently manufactured in this country, a purification process is needed.

This report presents the results of a study of the removal of 1,2,3-trimercaptopropane from BAL by a liquid-liquid extraction procedure, using petroleum ether as the extracting solvent. This method may be used with a variety of solvents under various experimental conditions, *e.g.*, BAL saturated with water to increase the partitioning of the trithiol into the organic solvent phase to obtain basic information of value for the development of a commercial process for the purification of BAL containing excessive quantities of the trithiol impurity.

EXPERIMENTAL

Materials.—BAL purified by passage through a partition chromatographic column, followed by distillation at low pressure; 1,2,3-trimercaptopropane, hereinafter designated as TSH; petroleum ether, shaken with concentrated sulfuric acid over a period of several days and distilled between 35–50° were employed.

Procedure.—Known concentrations of TSH in BAL were equilibrated with petroleum ether. The volume of the BAL was chosen sufficiently large so that it was not significantly changed by the extraction. TABLE I.—RESULTS OF EXTRACTION OF TSH FROM BAL WITH PETROLEUM ETHER

1	2	3	4	5	6	7	8
	Before Extn.		Iodine Titer per ml. Petroleum Ether		TSH mg./ml. Petroleum		
Ampul No.	BAL mg.	TSH mg.	BAL + TSH	TSH	Ether Phase	BAL Phase	K
1	2431.6	21.1	0.988	0.127	0.592	10.1	.0586
2	2487.0	64.1	1.223	0.377	1.758	29.6	.0594
3	2443.9	122.9	1.529	0.703	3.277	56.5	.0580
4	2545.2	236.8	1.945	1.151	5.366	101.3	.0529
5	2535.4	329.5	2.217	1.449	6.755	137.7	.0489
6	Pure BAL	.....	0.868	0.000	...	...	Av. (1–4)
7	.....	Pure TSH	10.119	10.119	47.175	...	.0572

Approximately 2-ml. volumes of BAL were weighed into glass ampuls. The TSH, in varying amounts, was then weighed into the ampuls to give the desired concentrations. Exactly 2 ml. of petroleum ether was pipetted into each ampul and the ampuls quickly sealed with an oxygen-gas flame and shaken for 3 hours in a thermostated water bath at 24.5°. After removing each ampul from the bath, a 1-ml. sample of the petroleum ether phase was withdrawn as quickly as possible and pipetted into an excess of 0.1 *N* iodine; back titration was carried out with 0.1 *N* thiosulfate solution.

RESULTS

The data are presented in Table I. Columns *2* and *3* represent the quantities of BAL and TSH weighed into each ampul. The iodine titer of the petroleum ether phase, representing the sum of BAL and TSH, is given in column *4*. The iodine titer due to the TSH content of each ampul was calculated as follows. The iodine titer of the petroleum ether extract of the pure BAL (ampul 6) was multiplied by the mole fraction of BAL in the BAL phase of each ampul; the resultant corrected iodine titer due to the BAL in the petroleum ether extract of each ampul was subtracted from the corresponding titer of column *4* to give column *5*. The TSH content of the petroleum ether phase in mg./ml. is given in column *6*. The amounts of BAL and TSH in the BAL phase were then recalculated for the amount removed by extraction, and the concentration of TSH in the BAL phase is given in column *7*. The partition coefficient in column *8* is the mg. TSH per ml. petroleum phase divided by mg. TSH per ml. BAL phase. The average partition coefficient obtained, $K = 0.0572$, may be used in calculations applicable to the purification of BAL contaminated with trithiol.

The feasibility of the extraction method was verified by the multiple extraction of a typical BAL sample. A volume of petroleum ether equal to that of the BAL was used for each successive extraction step. The fraction of trithiol originally present which remains in the BAL after n extractions under these conditions is $(1 + K)^{-n}$. Therefore, 41 extractions would be expected to result in a 10-fold reduction in trithiol concentration. This was found to be the case experimentally. The percentage loss of BAL into the petroleum ether equals 0.435 × (number of volumes of petroleum ether used in the extraction). Except for convenience, little is gained in the way of efficiency by use of continuous extraction against a multiple extraction performed in this way.

Identification of Some Barbiturates in Blood by Use of Thin-Layer Chromatography

By JOHN A. PETZOLD, WALTER J. R. CAMP, and ERNST R. KIRCH

A simple, rapid method for the identification of mixtures of barbiturates when present in blood is described. This procedure is especially useful in differentiating between amobarbital and pentobarbital.

THE PROCEDURES involving the identification of certain barbiturates leave much to be desired. This is particularly true when it is necessary to establish the presence of barbiturates in the blood and urine as the agents causing comas in hospital patients or deaths in medical-legal cases.

Two popular approaches of identification using paper seem to be those similar to Algeri, *et al.* (1), and Stevens (2), involving either the treatment of the paper chromatogram after elution of the barbiturate or treatment of the barbiturate before spotting in order to differentiate between saturated and unsaturated groupings attached to the pyrimidine ring. Among the many investigators using thin-layer chromatography, Frahm, *et al.* (3), using piperidine: petroleum ether as the mobile phase, and Eberhardt, *et al.* (4), using isopropanol: ammonia: chloroform as the mobile phase, have reported success in the separation of several barbiturates.

We would like to report a simple, rapid method of

10	A + B + C + D + E	0.50 + 0.62 + 0.75	0.27 + 0.39 + 0.50 + 0.74

[a] Rf values given here represent the average of four determinations. [b] Code to barbiturates present: (A) secobarbital, (B) amobarbital, (C) pentobarbital, (D) phenobarbital, (E) diallylbarbituric acid.

identification of five barbiturates more commonly encountered either alone or in a mixture during the toxicological studies in the Coroner's Laboratories of Cook County, Ill. The procedure is based on the differences in the R_f values obtained after treatment of the barbiturates with 4N H_2SO_4.

EXPERIMENTAL

Apparatus.—The apparatus used was essentially the one designed by Stahl (5), using 8 × 8-in. glass plates.

Adsorbent.—Silica gel G (Merck) was used.

Mobile Phase.—Acetone:*n*-butyl alcohol:ammonium hydroxide, concentration 9:9:2 was employed.

Reagents.—Silver acetate, A.R., 1% aqueous solution; diphenylcarbazone, A.R., 0.1% in 95%; ethyl alcohol; sulfuric acid, 4*N*; chloroform, reagent grade; sodium hydroxide, A.R., 0.45*N*; ammonium chloride, A.R., approximately 16%; Florisil, 60/100 mesh were employed.

Standard Solution of Barbiturates.—The following barbiturates were used in an alcoholic solution of a concentration of 2 mcg./μl.: secobarbital U.S.P., diallylbarbituric acid N.F., phenobarbital U.S.P., amobarbital U.S.P., pentobarbital U.S.P.

PROCEDURE

Each plate was covered to a thickness of about 250 μ with a paste consisting of 4 Gm. silica gel in 12 ml. distilled water. Precautions were taken to prevent air bubbles. The chromatoplates were dried in air for 15 minutes followed by a drying period of 30 minutes at 105°.

The plates while still hot were spotted in duplicate with 3 μl. of the alcoholic solution of the barbiturates. Immediately after application of the barbiturates, one spot of each duplicate was treated with 5 μl. of 4N H_2SO_4, and the chromatoplates were heated in an oven at a temperature of 125° for 1 hour. After cooling in air to room temperature, the chromatoplates were placed into a chamber containing the mobile phase. The solvent front ascended to the proper height within 1 hour. After drying at room temperature in a stream of air for 15 minutes, the barbiturates were developed as purple-blue spots using the standard method of spraying with silver acetate followed by the diphenycarbazone (1).

Table I shows the typical results obtained using the standard barbiturate stock solutions.

Extraction and Identification from Blood.—Five milliliters of blood containing barbiturate(s) were extracted with 50 ml. of chloroform and the extract evaporated to dryness in a stream of air. The residue was taken up in 10 ml. of chloroform, passed through a Florisil column, and the barbiturate(s) eluted with 10% methyl alcohol in chloroform as described by Stokes, *et al.* (6). The methanol-chloroform eluate was evaporated to dryness in a stream of air and taken up in 100 μl. of ethanol. Six to twelve microliters of the alcoholic extract was spotted on a silica gel chromatoplate and the barbiturates identified as described above.

When quantitative as well as qualitative results were desired the 0.45*N* NaOH extract obtained in the method of Stokes, *et al.* (6), was acidified to a pH of 2–3 and extracted with 50 ml. of chloroform. The residue left after evaporation to dryness in a stream of air was taken up in 100 μl. of ethanol and treated as described above.

Urine when extracted and purified as described by Stokes, *et al.* (6), produced comparable results.

Effect of Inorganic Cation on the Fecal-Hydrating Action of Dioctylsulfosuccinate in Rats

By P. M. LISH and G. P. CASTEN

The calcium and sodium salt forms of dioctylsulfosuccinate were tested in rats for ability to prevent dehydration of the feces. The drugs were equally potent on a weight basis indicating that potency was directly related to the diester content of the materials and independent of the inorganic cation.

SODIUM DIOCTYLSULFOSUCCINATE[1] is now widely used in medicine as a fecal-softening agent. Recently a calcium salt of dioctylsulfosuccinate was marketed for the same purpose. The calcium salt is claimed to be twice as active as the sodium salt. The effectiveness of the sodium salt as a fecal softener in rats and mice was described recently by Lish and Dungan (1). The objective of the present study was to determine the influence of the cation on the fecal-hydrating action of dioctylsulfosuccinate in rats.

METHOD

The test materials were compared for ability to produce fecal-hydration following oral administration to rats. The technique used was adapted from Miller (2) with modifications essentially as described previously by Lish and Dungan (1). Minor deviations from the latter description were the use of ten animals per dosage level and restriction of observation periods to the 1, 2, and 4-hour intervals, post administration of the test agent. Rats were designated *positive* or *negative* responders depending on whether the water content of the dropped stools was sufficiently high to stain the absorbent paper on which they fell. The method of Litchfield and Wilcoxon (3) was used to evaluate the all or none type data.

Sodium content of sodium dioctylsulfosuccinate ($C_{20}H_{37}O_7SNa$; formula wt. 444.6) was 5.1%. Calcium content of calcium dioctylsulfosuccinate ($C_{20}H_{37}O_7S$ 1/2Ca; formula wt. 441.6) was 4.5%. All dosages were expressed as weight of the salt.

RESULTS

Results are shown in Table I. Data obtained at the 4-hour period post-drug dosage are presented graphically in Fig. 1. Dosages responsible for wet feces in 50% of the rats (ED_{50}) were 123.9 mg./Kg., and 110.8 mg./Kg., for the sodium and calcium salts, respectively. Statistical treatment revealed no significant difference in potency.

Gas Chromatographic Separation of Amines by Special Selectivity

By J. S. SAWARDEKER and J. L. LACH

This study deals with the separation of several aliphatic amines by the use of metal complexation in GLC.

THE USE OF complex formation in the various branches of theoretical and applied chemistry and allied fields is now generally recognized. However, the use of complex formation, although highly promising, has received little attention in gas chromatography. Bradford (1), in his gas chromatographic studies employing solid silver nitrate in glycol, achieved a selective retardation of unsaturated hydrocarbons demonstrating interaction between vapor and metal atoms. Barber (2) reported marked increase in retention times of many individual compounds using molten stearates of metals, Mn, Co, Zn, Cu, and Ni as column liquids against retention times on apiezon L. Separation of amines in general has constituted a difficult task. Recently Sze (3) achieved separation of a mixture of ten amines using tetrahydroxyethylethylenediamine and tetraethylenepentamine as partition liquids in GLC. They report that the results are promising but not satisfactory.

EXPERIMENTAL

Equipment.—F & M 500 gas chromatograph with thermal conductivity cell and equipped with Minneapolis Honeywell recorder y143x(58).

Procedure and Results.—Two columns were prepared from 1/4-in. O.D. copper tubing. In column one, the stationary phase Gas Chrom P was coated with 2% SE-30 from a solution in methylene chloride, the solvent being removed by rotary vacuum evaporator. In the second, the stationary phase (Gas Chrom P) was coated with 2% SE-30 as above and then impregnated with 4% silver nitrate. A mixture containing triethylamine (b.p. 89.5°), diethylamine (b.p. 55.5°), and *n*-butylamine (b.p. 77.8°) in the proportion 1:2:1, respectively, was investigated using the two columns. Helium was employed as the carrier gas. The chromatograms are illustrated in Figs. 1 and 2. For the column containing SE-30 only, the mixture emerged as a single peak with isothermal operation at 50°. In the second column containing SE-30 and silver nitrate temperature programming from 50 to 175° was necessary for complete separation, since isothermal operation at 50° was ineffective. Apparently no decomposition was detected on the chromatogram. Isothermal operation at higher temperature gave poor results. Interestingly enough, it was found that the amines were well retained and the order of retention for the amines was 1° > 2° > 3°. Figure 3 shows the chromatogram of a mixture of triethylamine, diethylamine, and *n*-butylamine in the proportion 1:1:2, respectively, illustrating the separation achieved which may be quantitative. However, no attempt was made to study the separation quantitatively.

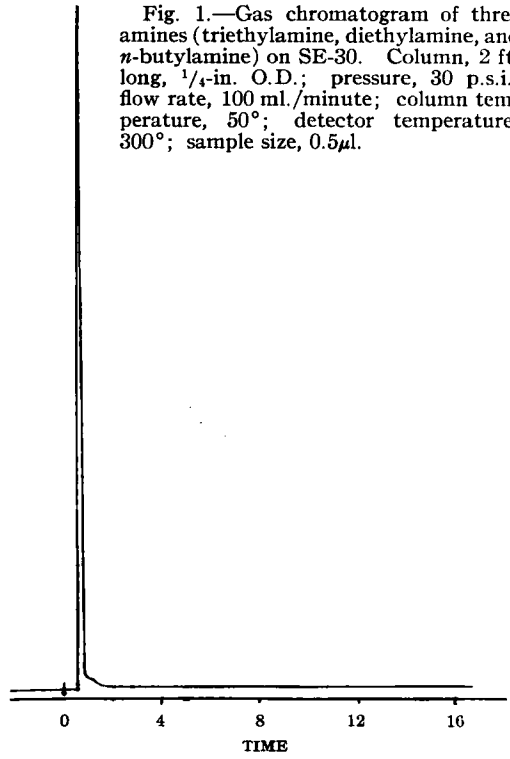

Fig. 1.—Gas chromatogram of three amines (triethylamine, diethylamine, and *n*-butylamine) on SE-30. Column, 2 ft. long, 1/4-in. O.D.; pressure, 30 p.s.i.; flow rate, 100 ml./minute; column temperature, 50°; detector temperature, 300°; sample size, 0.5 µl.

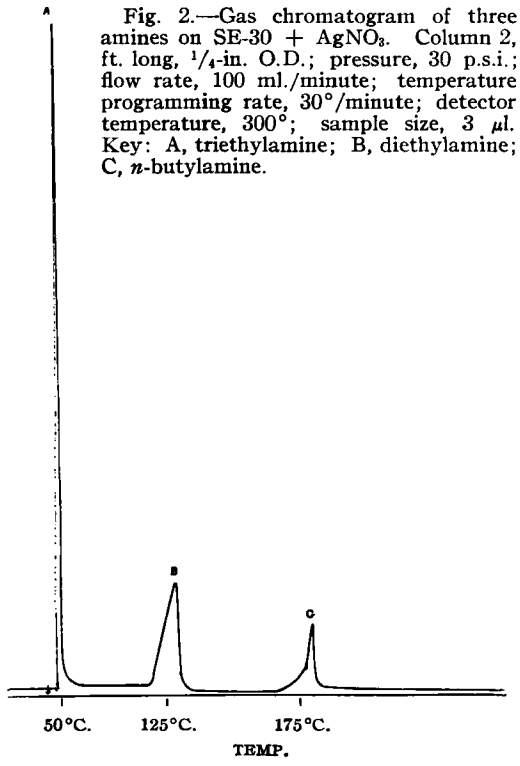

Fig. 2.—Gas chromatogram of three amines on SE-30 + $AgNO_3$. Column 2, ft. long, 1/4-in. O.D.; pressure, 30 p.s.i.; flow rate, 100 ml./minute; temperature programming rate, 30°/minute; detector temperature, 300°; sample size, 3 µl. Key: A, triethylamine; B, diethylamine; C, *n*-butylamine.

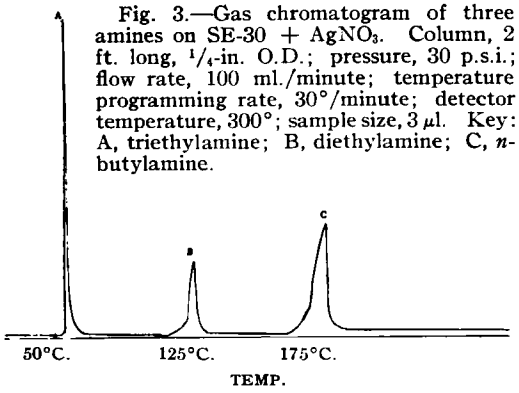

Fig. 3.—Gas chromatogram of three amines on SE-30 + $AgNO_3$. Column, 2 ft. long, 1/4-in. O.D.; pressure, 30 p.s.i.; flow rate, 100 ml./minute; temperature programming rate, 30°/minute; detector temperature, 300°; sample size, 3 μl. Key: A, triethylamine; B, diethylamine; C, *n*-butylamine.

DISCUSSION

It is evident from the chromatograms that the three amines pass through the various types of chromatographic columns at substantially different rates which are not governed by their boiling points. Silver nitrate seems to exhibit dramatic selectivity for these amines. It is difficult to state the exact nature of forces involved in the separation. However, in view of the fact that silver ion is capable of forming chelates, the strong retention behavior observed is indicative of chelate formation between the metals and the amines. It is of interest that a significant rise in temperature had to be employed to elute the 2° and 1° amines. This is consistent with the tendency for coordination increases with decreasing substitution $RNH_2 > R_2NH > R_3N$. As further evidence supporting complex formation, we observed that ethylenediamine, which theoretically is capable of forming a stronger chelate with silver, is so strongly retained that it could not be eluted even at 200°. Elution at higher temperatures was not attempted because of possible thermal decomposition of the silver nitrate. However, the use of silver bromide in place of the silver nitrate did permit use of higher temperature. In this silver bromide column ethylenediamine did emerge as a peak at a temperature of 250°.

It is of interest that the column length for this study was only 2 ft. Increasing the column length was not advantageous, and shortening it did not give good results. The method appears to be highly promising for separation of related compounds. Further studies are in progress; a complete report will be published at a later date.

Synthesis of 5,5-Dimethyl-2,4-oxazolidinedione-2-C^{14} (DMO-2-C^{14})

By THOMAS C. BUTLER and JACK D. DAVIDSON

DMO-2-C^{14} was synthesized for use in measurements of the pH of intracellular water. It was prepared by condensing urea-C^{14} with n-butyl 2-methyllactate in the presence of sodium butylate in butanol solution. The yield of DMO-2-C^{14} from 1 mmole of urea-C^{14} was 58 per cent, and the product was radiochemically homogeneous as demonstrated by paper chromatography. The ionization exponent was determined by a system of solvent partitioning. A method is described for determination of DMO-2-C^{14} in biological samples.

THE MEASUREMENT of the pH of the water inside living cells is a difficult problem that has been approached in many ways (1). Of the various methods used, that based on the measurement of the intracellular and extracellular concentrations of a weak organic acid or base is probably most widely applicable and least subject to theoretical objections. Until recently, nearly all of the work based on this principle has employed carbon dioxide as the indicator compound. In 1959, Waddell and Butler (2) suggested that the weak acid, 5,5-dimethyl-2,4-oxazolidinedione (DMO), has the attributes desirable in a compound for the measurement of intracellular pH and should have advantages over carbon dioxide for that purpose. Using ultraviolet spectrophotometric methods for the analytical determinations of DMO in plasma and tissue, they employed the distribution of DMO for the calculation of the intracellular pH of dog muscle. Subsequently, DMO has been used by other workers in a number of different investigations of intracellular pH.

For an *in vitro* study of the intracellular pH of tumor cells, it became evident that the relatively large amount of DMO required in a sample for spectrophotometric measurement would impose undesirable restrictions on the design and scope of the experiments. A more sensitive method of measurement, as would be provided by the use of radioactive DMO, would avoid these restrictions. The synthesis of DMO-2-C^{14} was accordingly carried out. In the course of the subsequent study of tumor cells, experience with the use of DMO-2-C^{14} (in conjunction with inulin-carboxyl-C^{14} for measurement of extracellular water) has confirmed the expected advantages. Very small samples suffice, and the concentration of DMO added can be made low enough to cause no significant derangement of cellular function. Measurements of radioactivity

can be performed with greater rapidity and probably with greater accuracy than can the corresponding spectrophotometric analyses.

EXPERIMENTAL

DMO was synthesized by a modification of the method of Stoughton (3). Urea-C^{14} was condensed with an ester of 2-methyllactic acid in the presence of sodium butylate with the production of DMO and ammonia.

The *n*-butanol was dried over anhydrous potassium carbonate. The urea was desiccated. All glassware used prior to the addition of water was oven dried shortly before use.

A lump of clean sodium weighing somewhat more than 500 mg. was dissolved in 20 ml. of *n*-butanol. After titration, the solution was adjusted to contain 1 mmole of sodium per ml. In a 15 × 150-mm. glass-stoppered test tube 60 mg. (1 mmole) of urea-C^{14} of specific activity 1 mc./mmole was dissolved in 1.5 ml. of *n*-butanol with the use of heat. To this solution were added 1.0 ml. of the sodium butylate solution (1 mmole) and 0.17 ml. of *n*-butyl 2-methyllactate (1 mmole). The loosely stoppered tube was heated in an oven at 100° for 1 hour. It was then cooled in an ice bath, and 2.5 ml. of water was added. The tube was shaken and the butanol layer was transferred by pipet to another glass-stoppered tube, in which it was shaken with 2.5 ml. of 1 *N* sodium hydroxide. The butanol was discarded. The two aqueous extracts were combined in one tube and washed with two 5-ml. portions of ethyl ether, which were discarded. The aqueous solution was acidified with 1 ml. of concentrated hydrochloric acid and washed with 5 ml. of 2,2,4-trimethylpentane, which was discarded. The aqueous solution was then extracted with three 5-ml. portions of ethyl acetate, which were combined in a glass-stoppered tube. The ethyl acetate was washed with 2 ml. of water, which was discarded. It was then evaporated in the tube by drawing over a stream of air with an impinger (4). The residue, which at first was a colorless liquid, gradually became an almost completely crystalline white mass. After desiccation, the crude product consisted of 80% DMO by weight. It contained no radioactive constituent other than DMO and no nonradioactive impurity that interferes with its use. Further purification, with attendant losses, has accordingly not been carried out. The product has been kept in methanol solution, and portions of this solution have been evaporated for preparation of aqueous solutions for use in the biological experiments.

Radiochemical homogeneity was demonstrated by paper chromatography. A small volume of the methanol solution was spotted on Whatman No. 2 paper. A descending system was used in which 1,2-dichloroethane was the moving phase and water the stationary phase. The chromatogram was scanned with a Scanogram II automatic windowless paper chromatogram scanner with associated ratemeter and recorder. No radioactivity could be detected outside of a single spot with R_f 0.63. In one chromatogram 20 mcg. of authentic unlabeled DMO was spotted on a track adjacent to DMO-2-C^{14}. The nonradioactive track was cut into strips 2.5 cm. long, which were eluted with a buffer of pH 9 for study of ultraviolet absorption. The ultraviolet absorbing material was located at a position on the chromatogram identical to that of the radioactivity. DMO-2-C^{14} that has been in methanol solution for 3 years has been shown by paper chromatography still to be radiochemically homogeneous.

An aliquot of 1/100 of the total methanol solution was evaporated for preparation of an aqueous solution that was used to provide still smaller fractions of the total for measurement of the yield in terms of ultraviolet absorbing material and in terms of radioactivity. A buffer of pH 9 containing 1/10,000 of the total yield per ml. had an ultraviolet absorption spectrum identical to that of the ionic species of authentic DMO, with an absorption maximum at 208 mμ. From comparison with standards this solution was calculated to have a concentration of 7.5 mcg./ml. The total yield is thus calculated to be 75 mg. (58%). The radioactivity of a sample of 1/10,000 of the total yield was measured by liquid scintillation counting in comparison with a benzoic acid-C^{14} standard. The activity of the sample was 0.054 μc. The total C^{14} yield would be 540 μc., corresponding to a specific activity of 0.93 mc./mmole. Owing to uncertainties in the accuracy of the C^{14} assays, the spectrophotometric estimate of yield is the more accurate, but the agreement between ultraviolet absorption and radioactivity measurements is within the expected experimental error.

The ionization exponent of DMO-2-C^{14} was determined by partitioning a measured amount of the compound between 50% ethyl acetate–50% toluene (v/v) and several buffers of different pH values and of ionic strength of 0.16. The partitioning was carried out at 37°. Radioactivity in the upper phase was measured by liquid scintillation counting by the procedure described below for the determination of DMO-2-C^{14}. The partition coefficients were calculated from these measurements. The value of pK′ was calculated from the theoretical relationship between partition coefficient and pH of the aqueous phase (5). The value so calculated did not differ by as much as the experimental error from that of 6.13 as previously measured spectrophotometrically for the unlabeled compound (2). The value of 6.13 has accordingly been used in the calculation of intracellular pH.

The following method has been found suitable for the determination of DMO-2-C^{14} in biological materials. About 100 mg. of a liquid sample or of a preparation of homogenized cells is weighed in a tared glass-stoppered test tube. One milliliter of 5 *M* monobasic sodium phosphate plus 5 ml. of 50% ethyl acetate–50% toluene (v/v) are then added to the tube. After the tube is shaken and centrifuged, 4 ml. of the upper phase is transferred to a counting vial. To the vial is then added 14 ml. of a solution of the following composition: toluene 93% (v/v), methanol 7% (v/v), and 2,5-diphenyloxazole 0.4% (w/v). Radioactivity is measured by scintillation counting. This method is applicable to samples containing inulin-carboxyl-C^{14} and DMO-2-C^{14}, since the former compound is not extracted into the organic solvent.

Reinvestigation of the Biological Activities of Diacetylapomorphine and "Triacetylapomorphine"

By JOSEPH G. CANNON, JEROME F. HENSIAK, and ALLAN M. BURKMAN

Diacetylapomorphine has been shown to possess emetic activity nearly identical to that of apomorphine itself, corroborating findings of some earlier workers and contradicting certain others. "Triacetylapomorphine" has been demonstrated to be completely nonemetic (in agreement with the original literature report) and to possess moderate hypotensive properties.

DIACETYLAPOMORPHINE and "triacetylapomorphine" were first prepared by Tiffeneau and Porcher (1) in 1915. "Triacetylapomorphine," an amide resulting from ring cleavage of diacetylapomorphine, was reported as being devoid of emetic activity.[1] In a series of papers, Tiffeneau first reported that diacetylapomorphine was equally as potent an emetic as apomorphine (2); later, that it was twice as potent (3). Tiffeneau's explanation for this high emetic activity of diacetylapomorphine was that it is rapidly hydrolyzed in the body to free apomorphine. However, the experiments of Eddy (4) tend to contradict this hypothesis; this worker demonstrated that, in compounds related to morphine, masking of hydroxyls by alkyl or acetyl functions eliminated central emetic activity.[2] Of particular significance is 3,4-dihydroxyphenanthrene, which is structurally similar to apomorphine and is a moderately potent emetic; diacetylation renders this molecule nonemetic.[2] Since the work of Tiffeneau is rather old, and since his various publications contradict Eddy's reports and each other, it seemed advisable to reinvestigate the pharmacological properties of the acetylation products of apomorphine.

"Triacetylapomorphine" was prepared by heating apomorphine hydrochloride in acetic anhydride according to the method of Tiffeneau (1). It displayed no emetic activity when administered subcutaneously to dogs in a dose range up to 100 times the dependable emetic dose of apomorphine. It did not elicit the characteristic pecking syndrome in pigeons (5), and it exhibited no antiacetylcholinesterase activity. However, it showed moderate hypotensive activity.

Diacetylapomorphine was prepared in 10% yield by treating apomorphine hydrochloride with acetic anhydride and pyridine at room temperature according to the method of Small (6), using Tiffeneau's procedure (1) for recrystallization. This compound appeared to be identical to apomorphine in regard to minimal emetic dose and time of onset of action, although the severity of vomiting is of a lower order. It is a potent pecking syndrome stimulant in the pigeon.

Received May 4, 1963, from the College of Pharmacy, State University of Iowa, Iowa City, and the College of Pharmacy, University of Illinois, Chicago.

Accepted for publication June 14, 1963.

This study was supported in part by Grant NB 04349-02 from the National Institutes of Health, U. S. Public Health Service, Bethesda, Md.

[1] The abstract of *Reference* 2, as reported in *Chem. Abstr.*, 8, 3191(1914), incorrectly states that "triacetylapomorphine" is identical to apomorphine in its physiological properties.

[2] While the acetylated and alkylated compounds often induce symptoms of nausea in the cat (as indicated by excessive salivation and licking), they are considered here as being nonemetic since they did not cause actual vomiting.

TABLE I.—RESULTS OF BLOOD PRESSURE LOWERING EXPERIMENT

Min. After Injection	B.p., mm.	Respirations/ Min.
0	80	21
0.5	80	20
1	82	23
3	66	28
5	45	25
10	37	25
15	30	22
20	32	24
30	29	24

EXPERIMENTAL

"Triacetylapomorphine" was triturated in a few drops of polysorbate 80[3] and was suspended in 50% propylene glycol solution. For the emesis test, 0.1 to 10 mg./Kg. was administered subcutaneously to six dogs, from whom food had been withheld for 16 hours; however, 15 minutes prior to the injection, the dogs were given about 0.25 lb. of food, an amount insufficient to allay hunger, but enough to provide some bulk in the stomach in the event that vomiting were elicited. During an 8-hour period, there was no evidence of emesis or nausea; that is, there was no salivation, and appetite remained.

For the blood pressure lowering experiment, 4 mg./Kg. of "triacetylapomorphine" was administered intravenously to a 10-Kg. dog, anesthetized with sodium pentobarbital and previously tested for tone and autonomic dominance of peripheral blood vessels in the following manner: Carotid occlusion gave a substantial rise in blood pressure; intravenous injection of 1.5 mcg./Kg. of epinephrine hydrochloride brought about a 25-mm. rise in blood pressure and respiratory depression; intravenous injection of 0.5 mcg./Kg. of methacholine chloride resulted in a 35-mm. drop in blood pressure and mild hyperpnea. The results of the experiment are recorded in Table I.

Carotid occlusion reflex was tested and epinephrine injected at intervals; carotid reflex was depressed but not abolished, and epinephrine response was unaltered.

Diacetylapomorphine was dissolved in a small amount of 0.1 *N* HCl, and was administered in solution, buffered to pH 5.5 with MacIlvain's phosphate-citrate buffer. Four dogs received doses of 0.1 to 0.2 mg./Kg. subcutaneously. For comparison, two dogs received apomorphine hydrochloride, 0.1 and 0.2 mg./Kg., respectively. Emesis occurred within 5 minutes in all cases.

Effect of Some Perfume Oils on Dehydrogenases in *Escherichia coli*

Sir:

Since the discovery that perfume oils inhibit the growth of bacteria (1, 2) we have investigated the antimicrobial properties of many such oils further (3, 4). The mode of action by which bacteria are killed by perfume oils remains unknown but Gal'perin and Dunaeva (5, 6) have reported that essential oils affect dehydrogenases in paramecia and helminths. Since essential oils are commonly used in perfume oil formulas it was thought that bacterial dehydrogenases might be affected by perfume oils.

We selected as the test organism *Escherichia coli* ATCC 11229. The bacteria were harvested after 24 hours from nutrient agar slants and washed three times with sterile physiological saline by centrifugation. A 2-ml. quantity of washed packed cells was added to 3 ml. of 1:1000 perfume oil solution (1% alcoholic). After 30 minutes of contact the cells were removed by centrifugation and washed three times with sterile saline and suspended in saline to 300 Klett units in the Klett-Summerson photoelectric colorimeter using the No. 42 filter with a spectral range of 400 to 465 mμ. This treated standard cell suspension was used for all subsequent experiments.

The dehydrogenase activity was determined by the Thunberg technique (7). The substrates used were glucose, succinic acid, and malic acid. The color intensity of the methylene blue in the Thunberg tubes was recorded every 4 minutes for a total of 32 minutes. All experiments were run at least in duplicate with controls and were replicated several days later.

Perfume oil of bouquet No. 821, sweet grass, lilac water, and bouquet No. 21 completely inhibited glucose, succinic acid, and malic acid dehydrogenase. Plate counts of the standard cell suspension showed no reduction in cell number compared to controls. However, after 2-hour exposure of the test organism to each perfume oil, plate counts revealed a 10 to 50% reduction depending upon the oil used. This finding suggests that perhaps the reduction of dehydrogenases precedes the death of the cell.

E. coli was exposed to perfume oil of neroli (artificial), evergreen bouquet, osheana, and chypre 66D at a concentration of 1:2000 in the same manner as above and dehydrogenase activity measured. It was found that oil of neroli and evergreen bouquet completely inhibited all tested dehydrogenases, while oil of osheana and chypre 66D caused little effect on glucose dehydrogenase, more than 90% inhibition of succinic dehydrogenase, and complete suppression of malic dehydrogenase.

Essential oils and their components are presently being investigated for their effects on bacterial dehydrogenases.

It was found that oil of neroli and evergreen bouquet completely inhibited all tested dehydrogenases, while oil of osheana and chypre 66D caused little effect on glucose dehydrogenase, more than 90% inhibition of succinic dehydrogenase, and complete suppression of malic dehydrogenase.

Essential oils and their components are presently being investigated for their effects on bacterial dehydrogenases.

Studies on *Catharanthus lanceus* (*Vinca lancea*) I. Isolation of Leurosine, Perivine, and Yohimbine

Sir:

Demonstration of reproducible anticancer activity by extracts from *Catharanthus roseus* (*Vinca rosea*) against the P-1534 leukemia in DBA/2 mice prompted Svoboda, *et al.*, to initiate intensive phytochemical studies on this plant to establish the nature of the substance(s) responsible for this activity. These investigators have reported on the isolation of more than 40 alkaloids from *C. roseus*, including four with oncolytic activity: vincaleukoblastine (1),[1] leurosine (3), leurocristine, and leurosidine (4).

Two of these alkaloids are now available for use in the treatment of Hodgkin's disease,[2] choriocarcinoma,[2] and acute leukemia in children.[3]

We have initiated studies on leaf material from a related plant, *Catharanthus lanceus*,[4] using the alkaloid fractionation scheme reported by Svoboda, *et al.* (5). Alumina chromatography of the (*A*) fraction has yielded leurosine and perivine, previously reported only from *C. roseus* (3) in addition to yohimbine which has been reported from *C. lanceus* roots (6) and several other sources. The identity of these alkaloids was established by comparison of certain physical data to that of reference material. The data used were derived from infrared and ultraviolet absorption spectra, electrometric titrations, X-ray powder diffraction patterns, melting point and mixed melting point determinations, and thin-layer chromatographic studies. Details concerned with the isolation of these three alkaloids and others will be published at a later date.

It is also of special interest to communicate that leurosine, an alkaloid reported effective against the P-1534 leukemia in DBA/2 mice (7), was isolated in the course of our investigation from an alkaloid fraction which on replicate testing proved ineffective in producing a prolongation of life against this tumor system. This confirms a previous report by Svoboda indicating that alkaloids highly active against the P-1534 leukemia can be present in crude fractions which exhibit limited or negative antitumor activity under identical test conditions (4). Svoboda has advanced that this anomaly could be due to toxic inactive material being present in crude mixtures which also contain active anticancer alkaloids (4).

This confirmation of the isolation of an active oncolytic alkaloid from an inactive crude fraction, suggests that a reevaluation of current test methods used for the detection of anticancer activity in crude botanical extracts is necessary.

The Editor comments

GOVERNMENT'S ROLE IN RESEARCH

A special Committee has been created in the U. S. House of Representatives with the specific purpose of conducting an investigation into government spending and involvement in science, research, and technology. The Select Committee on Government Research under the chairmanship of Rep. Carl Elliott, was just concluding its first few days of hearings when the assassination of President Kennedy brought an abrupt interruption to the Committee's activities. However, the hearings are expected to resume this week.

The A.PH.A. is among those who have been asked to testify; in fact, its spokesman originally was scheduled to appear on the Tuesday morning following the ill-fated Friday in Dallas. It should be noted that the Elliott group plans a very broad spectrum investigation into all research activities in which the federal government participates. As such, the invited witnesses cover a broad range including many from aeronautics and rocketry. The preliminary calendar released by the Committee's staff listed the A.PH.A. as the only organization invited from the pharmaceutical field, and with the exception of the American Medical Association, the only non-government organization from the health field.

It is our opinion that the inquiry being conducted by this Committee can have a very healthy effect on all of our research efforts—private as well as government. Federal support for research and technology has increased at an unbelievable rate during the past two decades, from $74 million in 1940 to $12.2 billion in 1963. Considering the size of this expenditure, relatively little overall coordination or long range planning has been devoted to making sure that the most efficient and effective programs are being supported in an effort to reach goals which are laudable, but which at times are very general or ill-defined. Closer Congessional scrutiny should also serve to help avert repetition of those few cases of loosely managed funds which have recently come to the attention of Congress, and which have made virtually all federal research expenditures suspect in the eyes of some Congressmen.

Consequently, it appears to be a very appropriate time for stock-taking. We sincerely hope and expect that the inquiry will prove to be beneficial to the federal government, the project grantees, and the American taxpaying public.

Review Article

Preclinical Evaluation of Drugs for Evidence of Teratogenic Activity

By HAROLD M. PECK

"If certain congenital malformations can be attributed in certain animals to dietary deficiency, anoxia, cortisone, or genetic constellations, one must not conclude without further proof that comparable malformations in man are due to similar adverse conditions. Such premature conclusions, usually not drawn by the experimentor but by a reader whose imagination and beliefs exceed his knowledge, can create superstitions in modern garb. If such a reader is also a writer with access to medical or popular journals, his unfounded beliefs are carried to millions, whereby new superstitions are established. . . . A single observation of an abnormal child born to a mother who had been in an automobile accident, becomes, if reported in a popular magazine, psychologically, a hundred thousand observations which seem to establish a causal relationship between two events. The whispered word is powerful, but the written word endures." Joseph Warkany, National Foundation Conference on Congenital Malformations, 1959 (1).

THE CIBA FOUNDATION SYMPOSIUM on Congenital Malformations (2) and reviews by Wilson (3) and Giroud and Tuchmann-Duplesis (4) refer to many agents that have been shown to have teratogenic effects in animals. These vary from anticancer drugs to essential nutritional elements as shown by the following:

TERATOGENIC AGENTS FOR ANIMALS

Alkylating Compounds
- Chlorambucil
- Busulfan (human)

Cytotoxic or Antimitotic Agents
- Actinomycin D

Nutritional Factors

Deficiency
- Oxygen
- Riboflavin
- Pantothenic Acid
- Folic Acid
- Vitamin A

Antimetabolites
- 6-Aminonicotinamide
- Methotrexate

Physical
- X-ray (human)
- Nuclear
- Ultrasonics
- Trauma

Excess
- Vitamin A
- Carbon Dioxide

Infectious Agents
- Rubella (human)
- Influenza (?) (human)

Some drugs used to treat cancer are effective because of their depressant effects on rapidly proliferating cells and, therefore, may have an adverse effect on the rapidly growing animal or human embryo. Similarly, antimetabolites, by interfering with essential nutritional materials such as vitamins, could be expected to have teratogenic properties. The effect of German Measles, or Rubella, on the human fetus is well known, but the effect of other viral agents such as the influenza virus (5) has not been substantiated.

Some other well known agents have been

Received from the Merck Institute for Therapeutic Research, West Point, Pa.
Based, in part, upon a presentation to the Scientific Section, A.PH.A., Miami Beach meeting, May 1963.

shown to have teratogenic properties in animals but do not have any proven effect on the human fetus.

TERATOGENIC AGENTS FOR ANIMALS

Penicillin	Salicylates
Chlorpromazine	Trypan Blue
Prochlorpemazine	Galactose
Hypoglycemia Sulfonamides	Thalidomide (human)
Insulin	Pilocarpine
Chlortetracycline	Sulfanilamide

Seemingly, thalidomide is the outstanding exception. Other drugs, as an aftermath of the thalidomide incident, have been accused of being teratogenic for man, but a causative relationship has not been proven to the satisfaction of all. No doubt many other drugs will be accused of producing malformations in humans.

Warkany (6) stated the problem clearly when he said:

> "We should be very cautious in making general statements about these drugs. One could easily make a mistake and accuse a drug wrongly. The cases in which a drug has been proven to be teratogenic in humans are very few. Dose and time play a role, and probably also the genetic constitution. But, if we are not careful, we may hear very soon that aspirin causes malformations. This should not happen since our animal experiences are usually very different from therapeutic attempts in man."

Murphy (7) pointed out that in the embryo the outcome of a drug effect, under the conditions of a limited number of doses—

> "Depends also on the specific drug as well as the quality and density of events taking place within the embryo. . . . The choice of a mammal with a longer gestation time might be expected to accomplish a decrease in the density of events taking place during a given time period and, therefore, decrease the probability of a foetal abnormality from a single dose of a growth-inhibiting agent. On the other hand, choice of an animal with a much shorter period of gestation would accomplish the purpose of increasing the density of events occurring during a given period and increase the probability of abnormalities."

This would suggest that, of the laboratory animals commonly used for preclinical evaluations of safety, the mouse would be the ideal species for testing for the teratogenic properties of a drug and the dog would be least valuable.

However, the conditions employed in the more academic teratogenic studies may not apply to the preclinical evaluation of safety since the drug should be administered daily in reasonable, nonstressing doses.

The problem of evaluating the safety of a drug for the fetus is not new and is similar to that routinely faced by the toxicologist and the clinician when a new compound is evaluated for its safety for initial clinical trials. The nature of the toxicity of a drug for the animals may be well known and on the basis of this knowledge and the other biological properties of the agent, a scientific judgment must be made of the relative risk for its trial in man. In the same way, as Beyer (8) pointed out—

> "Since such a substantial list of important agents can elicit fetal anomalies under laboratory conditions, the relevance of such findings to the prognostication of similar clinical outcomes requires a broad basis for judgment. Depending on methodology and experimental design, an important teratogenic action of one compound could be missed and another might be indicted unjustly."

The toxicologic and teratogenic evaluations of a drug are interrelated and require the same general considerations of its chemical and biologic properties and proposed clinical use. It may be useful then to discuss briefly the principles of the toxicologic evaluation of a new drug since these principles will apply also to the teratogenic evaluation of that drug.

The toxicologic, or safety, evaluation of new drugs in animals encompasses a great deal more than the determination of acute lethal doses and the daily administration of relatively small doses which may provide a relative "margin of safety." It is important also to produce toxicity in subacute and chronic studies. As the complexity of the biologic properties of drugs increases and as our knowledge of the mechanism of action on these drugs increases, the testing for possible adverse side effects can expand also to provide greater assurance of safety and to alert the clinician to potential toxic effects in the human. Factors which should be considered in the safety evaluation of therapeutic agents are:

- Chemical structure and properties
- Route of administration
- Reversible alterations
  - Primary and secondary biologic attributes
  - Endocrinologic properties
  - Biochemical properties
  - Organ function
  - Normal body constituents
  - Anatomical changes
    - Gross and microscopic
    - Organ weights
- Metabolism of the drug
  - Degradation
  - Conjugation
  - Elimination

Clinical
Proposed use (disease, dose, duration of treatment, etc.)
Possible misuse

Thus, the safety evaluation of a drug may now include an overall consideration of its chemical properties, its pharmacologic, endocrinologic or biochemical attributes, its effects on normal body functions and normal body constituents, the manner in which the body excretes or degrades the agent, and the potential of the drug to produce reversible changes of body function or anatomical structures. Any of these properties might be a primary attribute of the drug and the activity necessary for its therapeutic use. In addition, the proposed clinical use, and possible misuse, of the agent must be considered. In general, the more serious the disease, the more risk is acceptable; conversely, if a disease is of minor consequence, the drug must have a large safety factor.

TYPES OF UNDESIRED EFFECTS

The types of undesired effects of a drug may be grouped into four general classes: (*a*) exaggerated primary attributes, (*b*) secondary attributes, (*c*) hypersensitivity, and (*d*) "true" toxicity.

The first class includes the undesired effects due to overdosage, or to an accentuation of the desired effects of the drug. Some individuals may be unusually sensitive to the drug so that an average therapeutic dose may become an overdose. Occasionally, the interaction of two or more simultaneously administered drugs may result in an accentuation of the biologic attributes of one of the drugs.

The second class of side effects includes those related to the secondary biologic attributes of the agent. The dryness of the mouth caused by anticholinergic agents, the nausea and respiratory depression caused by the narcotics, and the sedation produced by some antihistaminics are examples of these. Such side effects are usually reversible when the drug is withheld and are not necessarily detrimental to the health of the individual. Nevertheless, they are disturbing and, thus, there is always an effort on the part of the organic chemist and the pharmacologist to synthesize new compounds (molecular manipulation) to reduce the secondary attributes, and to increase, relatively, the effect of the primary attribute.

The third class, hypersensitivity, includes a large group of undesired side effects resulting from the sensitization of an individual to the drug. These side effects may be severe, as in anaphylaxis, or may be relatively minor, as in a skin rash. Unfortunately, there is no reliable methodology by which the incidence or type of hypersensitivity can be predicted by presently known animal experiments.

The most important class of side effects is that of the "true toxicity" of a drug. This toxicity may be unrelated apparently to any known pharmacodynamic activity of the drug and, therefore, may be unpredictable from the results of the pharmacological studies. As a general rule, the production of these important side effects requires daily administration of the drug and, thus, they are not disclosed in the short term pharmacologic studies where only one or two doses may be given. Indeed, several months of daily administration of large doses may be required to produce a toxic effect. A relationship between incidence of toxic effects and magnitude of dose is usually present, thus permitting an estimation of a "margin of safety." The "true toxicity" may result in reversible or irreversible lesions and may be detrimental to the health of the individual.

One of the functions of the pharmacologist in the safety evaluation of a new drug is to set the probable clinical dose and to predict the side effects of the first two classes. The function of the toxicologist is to demonstrate the hazards related to the first three classes and, of most importance, he must determine the potentialities of the drug with regard to the production of "true toxicity" and also must make an evaluation of its effect on reproduction.

To fulfill these functions, the toxicologist assumes that all agents are toxic if examined under the proper conditions using appropriate parameters of observation. The toxicity of a drug is examined by the acute administration of lethal doses and by the daily administration of moderate and large doses for short (subacute) and long (chronic) periods of time. He may use several routes of administration but the major route is that which is to be used clinically. Two or more species of animals may be used in both the long and short term studies since there may be species differences in sensitivity to the drug. The toxicity found in these studies may be biochemical, hematologic, endocrinologic, enzymatic, anatomic, etc., or any combination of these.

The pharmacodynamic activity of the drug may be such that the primary or secondary attributes limit the toxicologic investigations because sufficiently large doses cannot be used to produce the "true toxicity." If, for example, a

sedative action is sufficiently great, the animal cannot eat or drink properly and, since prolonged fasting or starvation can cause biochemical and anatomical alterations, it may be difficult to determine if starvation effects are related to starvation or to the "true toxicity" of the drug. In other words, in the safety evaluation of a drug, the toxicologist cannot permit primary or secondary drug effects to alter the animal sufficiently that the end results may be attributed incorrectly to a toxic effect of the agent, or, that a "true" toxic effect may be hidden by these indirect effects. In these cases, the toxicologist must limit the magnitude of the doses to levels that will permit a relatively normal daily activity of the animal.

TERATOGENIC STUDIES

All of this may appear to be far from the subject of evaluation of teratogenic effects of drugs. However, the preceding remarks provide a basis for the principles of the evaluation of the teratogenic properties of an agent. Factors such as anorexia, hormonal changes, or sedation, which can be primary attributes of drugs, may have an effect on reproduction or on the fetus and must be considered. It certainly would not be reasonable to give such large doses of an agent that anorexia would occur for long periods of time and then to expect to have a normal reproduction cycle and normal fetuses. Similarly, if one is examining the teratogenic effects of a barbiturate in a study which requires dosing prior to mating, the dosage must be sufficiently small, or temporarily stopped, so that sedation will not interfere with mating.

There are three major types of teratogenic studies that can be employed for safety evaluations of new drugs:

Established pregnancy
  Single dose
  Multiple dose
Single generation (breeding) study
  Drug administration prior to mating and throughout pregnancy
  Two or more litters by same female
Multiple generation studies
  Drug administration prior to mating and throughout pregnancy
  Young animals fed medicated diet after weaning and mated when mature
  Two or more generations produced

The first is the administration of drug to animals in which pregnancy has been established. Drug administration is initiated, usually several days after conception, and may be continued for several days or as long as desired. Such studies are of relatively short duration and are particularly useful in the larger animals. Here, there is no possibility that the drug will interfere with fertility, mating, or implantation of the ova. The study can be continued through delivery, lactation, and weaning. Single doses may be of no real value at an early stage of development of a new drug. Indeed, this type of study may be hazardous because a teratogenic effect of an agent may be limited to a very brief phase of embryonic or fetal development and thus missed if the single dose is given at the wrong time.

The second type of teratogenic study includes more than just testing for teratogenic effects and may be called a "single generation study" or "breeding study." In this experiment, both the male and female animals are given the drug daily for some period prior to mating (60 days has been suggested), and drug administration is continued throughout pregnancy and, if desired, until the pups are weaned. Holding the pups until weaning may reveal types of malformations which would not be evident if the animals were sacrificed and examined at birth. The breeder animals continue to receive drug and, after the first litter is weaned, should be remated to produce a second litter. In some instances, part of the mothers may be sacrificed just before delivery and the fetuses examined. If a normal incidence of pregnancy is not obtained, the treated female animals may be mated with control male animals and treated male animals with control female animals to determine if the fertility of one sex is impaired. The large number of parameters that can be evaluated point out the usefulness of this type of study. In addition, this reproduction study can be conducted as a part of the chronic toxicity studies. Thus, in single or multiple generation reproduction studies it is possible to evaluate

Fertility of male and female,
Implantation of the ova,
Development of the embryo and fetus,
Resorption,
Abortion,
Delivery,
Live births,
Size of litters,
Teratogenic effects,
Viability of the newborn,
Growth of young,
Quality of mother's milk (nutritional and toxicity).

A third type of reproduction study is the multigeneration experiment. Here a litter is produced, the pups are permitted to mature, and are mated to produce a new generation. Drug administration is started for the original parents, prior to

maturing, and continued for each generation until the desired number of generations have been obtained. This cycle can be repeated as frequently as desired, precautions being taken to prevent mating between litter mates. The parents of each generation may be discarded when the young are weaned. An evaluation of possible genetic abnormalities produced by an agent may be detected by this type of experiment as well as the parameters listed in the second type of study mentioned previously. These studies are necessarily of relatively long duration, depending upon the reproduction cycle of the species being used. The mouse is probably the best species for this type of test because of the relatively short reproduction cycle, rapid maturation, and the large number of animals that can be employed.

In all of these studies, the young animal can be examined in a number of ways. Gross examination of the fetus, or the newborn, clearing and staining of the fixed animal, X-ray studies, and autopsy examination permit an evaluation of teratogenicity. The specimen can be prepared for microscopic examination also. Enzyme studies can be made of the fetus or the newborn. Acute toxicity studies may be conducted on the control newborn or weaned animals to determine age differences of drug toxicity.

The use of an adequately large control group of male and female animals is a must for all teratogenic, reproduction, and routine toxicity studies. Incidental lesions occurring within animal species are so frequent that, unless there are enough controls, certain types of lesions (or fetal malformations) may be difficult to evaluate with regard to drug effect.

The conduction of these studies appears to be rather straightforward. However, because environmental factors may interfere with normal reproduction cycles in some animals, it is advisable to use quiet draft-free rooms with well regulated temperature and humidity. It is advisable also to have special personnel assigned to such studies so the animals will be accustomed to them and will not be disturbed at critical times such as delivery. Variations in litter sizes, fertility, and percentage pregnancies may complicate the interpretation of results. Thus, it may be wise to obtain a first litter without treatment, although this adds considerably to the duration of the experiment. It is also important to know, if possible, the normal incidence and types of malformations that occur in the species and strains of the animals being used.

A useful collateral study is the determination of the transfer of the drug across the placental membrane. Such a test might determine the best species to be used in a teratogenic evaluation of a drug, since the value of a teratogenic study is questionable if the drug is not transferred across the placenta to the fetus. It is reassuring to be able to give large doses of a drug to a pregnant animal without evidence of any effect on the reproduction cycle, or on the fetus, when it is known that large amounts of drug, or its metabolites, actually reach the fetus.

As indicated earlier, the dosage of the drug should be selected so that the secondary pharmacodynamic effects will not interfere with conception or nutrition (9) and activity of the mother. In addition, since some agents may interfere with normal biologic functions as a primary attribute, this type of effect on the fetus must be judged carefully. In other words, the doses selected should take into consideration the therapeutic and tolerated doses and not be so far above the therapeutic dose, or so close to the toxic dose, that the reproduction studies cannot be interpreted meaningfully. For example, by using a single maximally tolerated intraperitoneal dose of caffeine, Nishimura (10) obtained an incidence of 18 to 43% malformations in the mouse. Thus, there is a possibility that the occurrence of malformations at unreasonably high doses might result, unjustly, in the rejection of an otherwise valuable agent.

Other methods of teratogenic studies may not be applicable because the conditions of these tests are not comparable to the conditions obtained in the uterus of the intact mammal. Thus, the chicken embryo (11–14), the seaurchin (15, 16), the isolated fertilized rabbit egg (17), and the zebra fish egg (18, 19) may be valuable for certain aspects of teratogenic studies, but they lack the pharmacologic response, the metabolic alterations, and the elimination of the drug which may occur in the mammal. These studies appear to be most useful for studying the mechanism of action of known teratogenic agents, but their value for determining the teratogenic properties of unknown agents in the evaluation of safety has not been determined. There is too much chance of missing a critical period in a one or two dose experiment and thus a potent teratogenic agent might be accepted as safe. As these techniques accumulate, they may be found useful as collateral studies, but we should not, at the present time, accept them in place of the mouse, the rat, or the rabbit as the major tests for teratogenic effects of a drug. Nor should positive teratogenic effects in these

specialized tests be permitted to overweigh negative results in the mammal.

In conclusion, the evaluation of new drugs for possible teratogenic properties may be conducted as a part of the toxicologic evaluations of the same agents. The same considerations of the chemical and biological properties, the metabolic fate of a drug and its proposed clinical use, as applied to an evaluation of its toxicity, may be applied also to its teratogenic evaluation. Teratogenic studies of new agents should be conducted under reasonable nontoxic daily dosage schedules in the intact mammal to permit a more valid interpretation of the results than may be obtained from single dose experiments, or than may be obtained from the results of studies in the nonmammalian species.

At the present time, if new drugs can be shown to have teratogenic potentialities in animals, such findings should, at most, serve as a warning to clinicians—

> "If such (animal teratogenicity) became a legal barrier to human consumption, patients would be denied the benefits of some antibiotics, cortisone and even aspirin" (20).

SUMMARY

The evaluation of new drugs for possible teratogenic properties may be conducted as a part of the toxicologic evaluations of the same agents. The same considerations of the chemical and biological properties, the metabolic fate of a drug and its proposed clinical use, as applied to an evaluation of its toxicity, may be applied also to its teratogenic evaluation. Teratogenic studies of new agents should be conducted under reasonable nontoxic daily dosage schedules in the intact mammal to permit a more valid interpretation of the results than may be obtained from single dose experiments, or than may be obtained from the results of studies in the nonmammalian species.

Biopharmacology of Anabolic Agents II

Radio-Phosphorus Uptake in Molars of Rats Fed Norethandrolone and Phosphorus-Enriched Caries-Test Diets

By STANLEY M. SHAW†, HAROLD S. BAILEY, and JOHN E. CHRISTIAN

No statistically significant difference existed between the radio-phosphorus content in the molar teeth of animals treated with norethandrolone and the respective control animals. In addition, radio-phosphorus levels in the molar teeth of norethandrolone-treated animals fed a high phosphorus diet equalled the radio-phosphorus level in those animals on a high phosphorus diet alone. These results were not effected by the age of the animal within the experimental period studied, nor was there a difference in these results upon comparison of first, second, and third molar teeth with their respective controls.

CONSIDERABLE experimental evidence concerning the cariostatic effect of phosphorus may be found in the literature. For example, a very pronounced cariostatic effect has been obtained with supplements of dibasic sodium phosphate (1–9). Previous experiments in our laboratories (10) indicated that when 2% disodium phosphate is added to a caries-test diet, Sprague-Dawley strain albino rats have less tooth decay in molar teeth than the respective controls.

The addition of norethandrolone to the caries-test diet fed Sprague-Dawley albino rats increased the incidence of molar tooth decay over that found in animals fed the basic caries-test diet alone. When 2% disodium phosphate was added to the diet of norethandrolone-treated animals, the caries incidence was decreased. The incidence approximated that of control animals fed the caries-test diet supplemented with 2% disodium phosphate. Also, the addition of 2% disodium phosphate to the diet of norethandrolone-treated animals considerably reduced the caries incidence in molar teeth when compared to norethandrolone-treated animals fed the basic caries-test diet only. Thus, it would appear that the addition of 2% disodium phosphate to the diet caused a reversal of norethandrolone cariogenesis under the experimental conditions employed.

According to Solomons, Irving, and Neuman (11), and others, the organic matrix of dentin consists mainly of collagen, with small amounts of mucopolysaccharides similar to chondroitin sulfate. They found that freshly decalcified human dentin could induce formation of hydroxyapatite from calcium-phosphorus solutions. Also, Takuma (12) observed the regular deposition of crystals on the matrix fibrils in human dentin. Therefore, the fibrous protein of dentin and enamel plays a significant role in the deposition and growth of apatite crystals.

Norethandrolone has been shown to exert an effect on the synthesis of chondroiten sulfate and collagenous tissues (13). In addition, upon clinical testing, norethandrolone has been found to increase phosphorus retention (14–16). Since norethandrolone has an effect on phosphorus retention and collagen synthesis, a study of the influence of norethandrolone on phosphorus deposition in rat molar swas undertaken. In an investigation of this type radiological techniques utilizing radio-phosphorus seemed to be the logical procedure.

EXPERIMENTAL

A total of 192 weanling Sprague-Dawley strain albino rats, weighing from 45–50 Gm. each, was divided randomly into four groups of 48 animals each (24 females and 24 males). Sexes were separated and the animals housed three to a cage on screenwire bottoms. All animals were given concentrated vitamin A, D, and E supplement by mouth weekly and distilled water *ad libitum*. All rats were

[a] NP (Group 1) = norethandrolone plus 2% Na_2HPO_4 added to diet. [b] P (Group 2) = 2% Na_2HPO_4 added to diet. [c] N (Group 3) = norethandrolone added to diet. [d] C (Group 4) = basic diet.

weighed twice weekly. Animal cages were washed with soap and water, rinsed and dried three times a week, while the special feeding cups were washed each morning. All animals were injected intraperitoneally once a week with radio-phosphorus, with the dosage based on 2 μc. per 100 Gm. of body weight. The solutions for injection were prepared from a stock solution of $H_3P^{32}O_4$ in weak HCl by diluting, volumetrically, measured aliquots with 0.001 *M* sodium phosphate to desired volumes. Radio-phosphorus concentrations were prepared not to exceed a volume of 1 ml. per injection per animal.

Animals were given identically weighed quantities of diet with each group fed variations of the basic caries-test diet (Stephan Diet 580)[1] as follows: Group 1 was fed the basic diet to which was added 2% Na_2HPO_4 and norethandrolone, Group 2 was fed the basic diet with added 2% Na_2HPO_4, Group 3 was fed the basic diet with added norethandrolone, and Group 4 was fed the basic diet only.

When 2% Na_2HPO_4 was added to the diet, the salt replaced an equal amount of cane sugar. An analysis of the caries-test diet was obtained to determine the content of phosphorus in the basic diet compared to that in the basic diet plus added Na_2HPO_4. The basic diet contained 0.36% phosphorus, or about half the phosphorus found in the basic diet supplemented with Na_2HPO_4 (0.70% phosphorus). Thus, the animals subsisting on basic diet received considerably less phosphorus than those animals fed the basic diet with added Na_2HPO_4.

Those animals being treated with norethandrolone received a dose closely approximating 5 mg./Kg. of body weight per day during the entire 56-day experimental period. This was accomplished by thoroughly incorporating the drug into the basic caries-test diet. The amount of drug incorporated was based on the average daily weight of the animals in each treated group. A weighed quantity of this diet was placed in each special feeder for those animals receiving the drug sufficient for daily requirements. The following morning refused food was discarded after weighing. Dosage calculations were based on food consumed per day by each cage of three animals over the 56-day period.

At the end of 2 weeks, 48 animals (representing six animals of each sex from each experimental group) were sacrificed with chloroform. Bilateral extractions of the maxillary and mandibular molars were performed. The upper jaw (left and right), first molar teeth were paired and weighed with a model H-5 gram-atic mettler balance. The teeth were dissolved in approximately 1 ml. of nitric acid, with the aid of infrared heat lamps, in a pyrex glass planchet 1 in. in diameter and $^5/_{16}$ in. in depth. This procedure was followed for upper jaw second and third molars, as well as for all lower jaw molars. The samples were dried with infrared heat lamps, the radioactivity determined and corrected for decay.

Determination of radioactivity was accomplished with Tracerlab "1000" scalers connected to shielded end-window geiger tubes. Each sample was counted five times, with sufficient time allowed to accumulate at least 500 counts per determination, thus incurring a probable error of approximately 3%. Additional groups of 48 animals, distributed as in the 2-week study, were sacrificed at 4, 6, and 8-week intervals. The animals were treated in the

same manner as those rats killed after 2 weeks of experimentation.

One male animal died in each of the following groups: Group 1 and 4 of the 4-week time interval, and Group 1 and 2 of the 6-week time interval. Two male animals died in the Group 3 of the 4-week study.

RESULTS AND DISCUSSION

Table I shows the relation of the radio-phosphorus content in the various male and female molar teeth based on statistical comparisons. Tables II and III show the radio-phosphorus located in the molar teeth of male and female rats, respectively.

It would seem that, under the conditions of this experiment, norethandrolone had no effect on radio-phosphorus deposition in rat molars in animals on high or low phosphorus caries-test diets compared with their respective controls. Table I shows that the radio-phosphorus levels in the norethandrolone-treated animals fed a high phosphorus diet (NP) equalled the radio-phosphorus levels in those animals on a high phosphorus diet only (P), in 44 out of 48 comparisons. In 47 out of 48 comparisons no difference existed that was statistically significant between the radio-phosphorus content of the teeth of animals treated with norethandrolone (N) and the respective controls (C) at 2, 4, 6, and 8-week intervals.

Radioassay at 2-week intervals was conducted in an attempt to determine if differences existed in the effect of norethandrolone in the more recently erupted teeth compared with those previously formed. The relations of phosphorus uptake in the norethandrolone-treated animals, with or without added phosphorus, to controls were similar at all time intervals. Therefore, a change in the effect of norethandrolone on radio-phosphorus uptake in rat molars compared with controls over a period of time could not be shown. Also, a difference in the effect of the drug on radio-phosphorus uptake between first, second, and third molars compared with controls could not be shown.

It has been stated that norethandrolone had a phosphorus retention effect when administered clinically (14–16). If this is true in the rat, under the experimental conditions in this study, then apparently the increased phosphorus retention had little or no effect upon the uptake of radio-phosphorus in the rat molar. This can be seen from the fact that radiation levels in the norethandrolone animals were equivalent to those in the control group both with and without high phosphorus diets. A further study is in progress to determine if norethandrolone has a phosphorus retention effect in the rat under our experimental conditions.

The most widely accepted opinion of the crystal structure and chemical composition of tooth mineral

is that it is basically hydroxyapatite, *i.e.*, $Ca_{10}(PO_4)_6(OH)_2$, although certain deviations, such as substitution of carbonate for phosphate and fluoride for hydroxide, are recognized.

Since phosphorus is an integral part of the hydroxyapatite crystal, it may be assumed that the amount of P^{32} present in molar teeth of rats upon administration of radio-phosphorus is dependent upon three factors. These are (*a*) the production of crystalline hydroxyapatite and its deposition in the matrix, (*b*) ion-transfer across the crystal-solution interface along with intracrystalline exchange, and (*c*) resorption (17).

Little has been done to study the effect of drugs on the physical processes of ion-transfer and intracrystalline exchange in osseous material. It will be necessary at this point, therefore, to assume similarity in this process among all experimental groups within the limits of biological error. There is no reason to assume similarity among experimental groups as far as the metabolic processes are concerned and, therefore, we are relating P^{32} uptake as being indicative of calcification.

Table I shows that the radio-phosphorus content in the norethandrolone-treated rats equalled that found in the respective control groups. This was observed in comparisons of molar teeth from rats fed basic diet plus norethandrolone and Na_2HPO_4 (NP) to rats fed basic diet and Na_2HPO_4 (P), and comparisons of molars from animals fed basic diet and norethandrolone (N) to animals fed basic diet only (C). It would appear that, under the conditions of this experiment, norethandrolone had little or no effect upon calcification.

If norethandrolone had a positive effect upon the synthesis of the collagenous fibrils making up the protein matrix and the mucopolysaccharides making up ground substance, then it could be assumed that a greater rate of calcification would take place. This would seem to be true since Frank (18) showed that hydroxyapatite crystals are laid down on newly formed fibrils of the organic matrix. Also, Belanger (19) found that hydroxyapatite crystal growth occurs soon after the formation of fibrous protein. Carstrom (20) has stated that collagen controls calcification by effecting crystallization of apatite in dentin. In addition, Sobel and his collaborators (21) suggest that, while collagen induces nucleation, the complete system is more complex and probably includes sulfated mucopolysaccharide or mucoprotein. Although it cannot be conclusively stated from this one experiment, it would appear that norethandrolone had little or no effect on collagen synthesis in the rat molar. Further study using radio-sulfur and normal diets and analysis of the radio-sulfur uptake might throw additional light on this particular aspect of the problem. In summary of the above, the results of

[a] Group 1 = norethandrolone plus 2% Na_2HPO_4 added to diet. [b] Group 2 = 2% Na_2HPO_4 added to diet. [c] Group 3 = norethandrolone added to diet. [d] Group 4 = basic diet.

this experiment would indicate that the caries resistance of norethandrolone-treated animals fed diets containing 2% disodium phosphate is not related to phosphorus deposition, rate of calcification, or collagen synthesis in rat molars.

A study of Tables II and III shows that the radio-phosphorus content of the teeth in the animals on high phosphorus diets was at a lower value than the radio-phosphorus content in the teeth of animals on low phosphorus diets. This effect was not related to the presence or absence of norethandrolone. This was true in the majority of all comparisons made.

There probably is no one explanation for these results. One reason could be a dilution factor occurring in those animals on a high phosphorus diet. Since the use of a particular phosphate ion from the metabolic pool in synthesis is a random procedure, the greater ratio of nonradioactive ions to radioactive ions would tend to lower the activity in the synthesized dental tissue in those animals on a high phosphorus diet.

Probably of greater importance is the relation of added dietary phosphorus to urinary phosphate elimination. Sivachenko (22) found that heavy administration of nonradioactive phosphorus and calcium salts was most effective in increasing the rate of P^{32} elimination in rats.

Goldman and Bassett (23) studied renal regulation of phosphorus excretion in male patients with normal phosphorus metabolism. They found that daily oral administration of a mixture of sodium and potassium phosphates caused a significant increase in the serum phosphorus level in the patients. This was followed by an increase in urinary phosphorus.

It would appear that the difference in activity in the teeth of high-phosphorus *versus* low-phosphorus animals might be accounted for by these above factors.

CONCLUSIONS

The influence of norethandrolone on radio-phosphorus deposition in rat molars of animals on high and low phosphorus caries-test diets was determined.

Radio-phosphorus levels in the molar teeth of norethandrolone-treated animals fed a high phosphorus diet equalled the radio-phosphorus levels in those animals on a high phosphorus diet alone.

No statistically significant difference existed between the radio-phosphorus content in the molar teeth of animals treated with norethandrolone and the respective control animals.

The radio-phosphorus content of the molar teeth in animals on high phosphorus diets was at a lower value than the radio-phosphorus content in the teeth of animals fed low phosphorus diets. This effect was not related to the presence or absence of norethandrolone but might be accounted for by ion dilution or an increased rate of phosphorus elimination.

No change in the effect of norethandrolone on radio-phosphorus uptake in rat molars, with or without added phosphorus, over a time interval was shown.

A difference in the effect of norethandrolone on radio-phosphorus uptake between first, second, and third molar teeth compared with respective controls was not observed in either animals fed a high phosphorus diet or rats on a low phosphorus diet.

Antibacterial Agents Not Presently Employed as Preservatives in Ophthalmic Preparations Found Effective Against *Pseudomonas aeruginosa*

By S. R. KOHN†, LOUIS GERSHENFELD, and MARTIN BARR

Fifty-one chemical substances, not heretofore employed as preservatives in ophthalmic solutions, were examined for their effectiveness as antibacterial agents against 13 different strains of *Pseudomonas aeruginosa*. *In vitro* and *in vivo* methods were employed. Eleven of these agents showed a satisfactory sterilizing time against these strains. Further study of the following is indicated to determine their practical use as effective preservatives in ophthalmic preparations: Intexsan LB, Intexsan MB, Dichloran, DMBC, Cetol, Arquad 16, Virac, Betadine, Biopal VRO, chlorhexidine, and colistin.

A COMMONLY FOUND and hazardous contaminant in ophthalmic solutions is *Ps. aeruginosa*. The latter causes a serious type of corneal ulcer encountered in ophthamology, often resulting in the loss of the infected eye.

The chemicals which are commonly employed as antibacterial agents in multidose ophthalmic solutions were investigated for their effectiveness against 13 strains of *Ps. aeruginosa*, utilizing in each instance inactivating media of determined neutralizing activity for subculturing (1). Only benzalkonium chloride had a sterilizing time of less than 1 hour against the 13 strains of bacteria (1). An antibacterial substance which has a sterilizing time greater than 1 hour may be arbitrarily considered to be too slow-acting for use as a preservative in multidose ophthalmic solutions. Accordingly, this investigation was undertaken to determine the length of time required for sterilization by various antibacterial agents not heretofore employed as preservatives in ophthalmic solutions against *Ps. aeruginosa*. The main purpose was to ascertain whether any of these chemicals were capable of sterilizing in less than 1 hour.

EXPERIMENTAL[1]

Antibacterial Agents.—The chemicals studied for their effectiveness as antibacterial agents for ophthalmic solutions against *Ps. aeruginosa* were: 37 quaternary ammonium compounds: myristyl gamma-picolinium chloride,[2] Hyamine 1622,[3] Hyamine 10-X,[4] Hyamine 3500,[5] Hyamine 2389,[6] Emcol E-11,[7] Emcol E-607,[8] Emcol E-6075,[9] Ruson,[10] Tetrosan 3, 4D,[11] Tetrosan 60%,[12] Onyxide 75%,[13] BTC-776,[14] Intexsan MB-50,[15] Intexsan LB-50,[16] Intexsan LCB-50,[17] Intexsan LQ-75,[18] Intexsan OE-75,[19] Dichloran,[20] Cetol,[21] Bromat,[22] Bretol,[23] Germitol,[24] SD-75,[25] CTA-Stearate,[26] cetyl pyridinium bromide,[27] Laurol,[28] DMBC,[29] Arquad 12,[30] Arquad 16,[31] Arquad 18,[32] Arquad C,[33] Arquad S,[34] Arquad T,[35] Arquad HT,[36] cetyl pyridinium chloride,[37] and lauryl pyridinium chloride;[38] eight amphoteric surface-active agents: Tego 103-S,[39] Janusol,[40] Miranol OM-SF Concentrate,[41] and Miranol C2M Concentrate,[42] Miranol MSA Modified,[43] Miranol 2MCA Modified,[44] Product BCO,[45] and Product BDO;[46] three iodophors: Biopal VRO,[47] Virac,[48] and Betadine;[49] and a group of miscellaneous agents including Agosan,[50] chlorhexidine,[51] and colistin.[52]

Test Bacteria.—Two dilutions (1:10 and 1:1000) of 24-hour-old cultures of 13 different strains of *Ps. aeruginosa* (1) were used in this study. The bacteria were identified and the cultures prepared as previously described (1).

In Vitro Method.—The chemicals were studied for their effectiveness as bactericidal agents against 13 strains of *Ps. aeruginosa* using a procedure as noted in *Experiment III*, described in a previous study (1). The inactivating media employed for the purpose of neutralizing the antibacterial agents were evaluated using experiments which were also previously described (1). The most effective neutralizing media for use in these studies are listed in Table I.

In Vivo Method.—The purpose and the method employed for verifying the *in vitro* results (sterilizing times) for each of the antibacterial agents using an *in vivo* procedure have been reported (1). This same technique was used in this study.

RESULTS

Table II presents a summary of the results obtained. All of the antibacterial agents listed in this table gave results which indicate that they have a sterilizing time against 13 different strains of *Ps. aeruginosa* equal to or better than 1:5000 benzalkonium chloride. The sterilizing times (1) listed have been obtained under the severe *in vitro* test conditions and have been verified by an *in vivo* technique. In the latter procedure, those solutions of chemicals which produced growth in the subculture media produced ocular infections; those which did not produce growth did not produce ocular infections. The agents which gave longer sterilizing times than that given by 1:5000 benzalkonium chloride (45 minutes) are not listed in Table II.

Received April 12, 1963, from the Department of Pharmaceutics, College of Pharmacy, Wayne State University, Detroit, Mich., and the Philadelphia College of Pharmacy and Science, Philadelphia, Pa.

Accepted for publication April 30, 1963.

This study was carried out by S. Robert Kohn, Philadelphia College of Pharmacy and Science, Philadelphia, Pa., in partial fulfillment of Doctor of Philosophy degree requirements.

DISCUSSION

Among the 37 quaternary ammonium compounds studied, the following quats were found to be equal to or better than benzalkonium chloride in their bactericidal effectiveness against *Ps. aeruginosa:* Intexsan LB, Intexsan MB, DMBC, Cetol, Dichloran, and Arquad 16. Their sterilizing times were 45 minutes or less. However, before these compounds are employed as antibacterial preservatives in ophthalmic solutions, their toxicity, ocular irritability, stability, and compatibilities with the common ophthalmic drugs and vehicles must be determined. It should be mentioned that Medium V inactivated 1:1000 dilutions of the "quats," the strongest concentration studied.

The amphoteric surfactants possess either a positive or negative charge in solution depending on the pH of the latter. Based on the probability that an acid solution would cause the amphoteric surfactants to assume a positive charge, they were studied both in aqueous solutions and in aqueous solutions containing 1% boric acid. However, only one of these compounds, namely Tego 103-S, when used in a concentration of 1:1000, possessed antibacterial activity against *Ps. aeruginosa* after 24 hours of contact in either aqueous solutions or aqueous solutions containing 1% boric acid. Furthermore, the sterilizing time against *Ps. aeruginosa* was too long (9 hours), revealing no improvement over benzalkonium chloride.

Inasmuch as Virac is a quaternary-iodine complex, the inactivating medium employed in the investigation of the iodophors was the same medium as that employed for the quaternary ammonium compounds but with the addition of sodium thiosulfate to inactivate the iodine. The neutralizing medium, Medium XIX, was capable of neutralizing iodophors in concentrations of 500 p.p.m. of iodine, the strongest concentration tested.

It was noted that the iodophors, in either aqueous solutions or in aqueous solutions containing 1% boric acid, were effective against *Ps. aeruginosa* in concentrations as low as 25 p.p.m. of available iodine. It is known that iodophors are more stable in acid solutions and hence more effective. It should be emphasized that aqueous solutions containing 25 p.p.m. of available iodine had pH values in the acid range. Thus, there was no difference in the antibacterial effectiveness of the iodophors against *Ps. aeruginosa* in aqueous solutions or in aqueous solutions containing 1% boric acid. However, it was observed that the iodophors in aqueous solutions containing 10 p.p.m. of available iodine did not have pH values in the acidic range. Thus, the sterilizing times for the iodophors against *Ps. aeruginosa* in aqueous solutions (10 p.p.m. available iodine) required more than 1 hour of contact, while the same iodophors in aqueous solutions containing 1% boric acid were effective against *Ps. aeruginosa* after 30 minutes of contact.

From the findings in this study, it would appear that Virac, Betadine, and Biopal VRO may possibly be used as effective preservatives in ophthalmic solutions. However, as stated previously for the quaternary ammonium compounds, other properties of these iodophors, which are desired for antibacterial preservatives used in ophthalmic solutions, must be thoroughly investigated before employing the iodophors in such solutions. Medium VIII, fluid thioglycollate medium, was found to be an

TABLE II.—STERILIZING TIMES AGAINST *Ps. aeruginosa* (10^8) FOR CHEMICAL AGENTS NOT HERETOFORE EMPLOYED AS PRESERVATIVES IN OPHTHALMIC SOLUTIONS WHICH SHOW PROMISE FOR FURTHER STUDY

Chemical Agent	Concn.	Sterilizing Time, Min.

Colistin	500 units/ml.	15
Colistin	250 units/ml.	45

[a] In aqueous solution and in 1% boric acid solution. [b] In 1% boric acid solution only.

effective inactivating agent for Agosan, neutralizing 1% w/v of the substance, the highest concentration studied. This was to be expected, since the sulfhydryl groups in the thioglycollate are reactive not only with mercurial ions but also with other metallic ions.

Agosan, in a concentration of 0.5% possessed a sterilizing time against *Ps. aeruginosa* of 6 hours, a time period which is not an improvement over that for 1:5000 benzalkonium chloride.

Medium XX, which contained 0.5% sodium lauryl sulfate in nutrient broth medium, neutralized chlorhexidine in concentrations up to 1:1000, the strongest concentration studied.

Chlorhexidine in concentrations of 1:50,000 had a sterilizing time of 30 minutes for *Ps. aeruginosa*. Stronger concentrations had a faster sterilizing time. Further investigations are indicated for chlorhexidine as they concern toxicity, irritability, stability, and compatibility with the common medicaments and vehicles.

Medium III was found to be a good inactivating agent for colistin, neutralizing 2000 units/ml., the strongest concentration studied. Medium III was selected because colistin, like polymyxin B sulfate, is a polypeptide and carries a positive charge.

Colistin, in a concentration of 250 units/ml., had a sterilizing time of 45 minutes against *Ps. aeruginosa*. In stronger concentrations, the sterilizing time was reduced considerably.

SUMMARY

Fifty-one chemical substances, not heretofore employed as preservatives in ophthalmic solutions, were studied for their effectiveness against 13 different strains of *Ps. aeruginosa*. *In vitro* and *in vivo* methods were employed. Sterilizing times were determined in each instance and these were compared with that of benzalkonium chloride.

Thirty-seven quaternary ammonium compounds were investigated for their antibacterial effectiveness against *Ps. aeruginosa*. Of these, only six were found to possess equal or superior activity against *Ps. aeruginosa* compared to benzalkonium chloride. These included Intexsan LB, Intexsan MB, Dichloran, DMBC, Cetol, and Arquad 16.

Eight amphoteric surfactants were studied for their antibacterial effectiveness against *Ps. aeruginosa*. They were all found to be inadequate for use as antibacterial preservatives in ophthalmic solutions when compared to benzalkonium chloride.

Three iodophors, Virac, Betadine, and Biopal VRO were investigated and found to possess sterilizing times of less than 1 hour against *Ps. aeruginosa*.

Three other antibacterial agents, namely Agosan, chlorhexidine, and colistin, were investigated for their antibacterial activity against *Ps. aeruginosa*. Chlorhexidine and colistin were each found to possess sterilizing times of less than 1 hour against *Ps. aeruginosa*. Agosan required a longer sterilizing time.

Comparative Hydrolytic Rates of Some Tropine Esters

By J. M. PATEL and A. P. LEMBERGER

A study has been carried out on the chemical kinetics of the hydroxyl ion catalyzed hydrolysis of nor-atropine, tropine phenylacetate, tropine phenoxyacetate, tropine *p*-nitrobenzoate, atropine ethylbromide, and atropine benzylchloride. The purpose of the study was to observe the effects of various acid moieties in tropine esters on overall reaction rate. The experimental results would seem to indicate that a number of factors may be involved, including steric, inductive, and hyperconjugation effects.

THE RELATIVE RATES of second-order alkaline hydrolysis of atropine (1), homatropine (2), atropine methylbromide, and homatropine methylbromide (3) have been reported previously. The purpose of this investigation was to study further the influence of inductive and steric factors on the hydrolytic cleavage of these esters. The kinetics of the hydroxyl ion catalyzed hydrolysis of nor-atropine were studied in order to establish hydrolytic rates for what might be considered the base compound. Tropine phenylacetate, tropine phenoxyacetate, and tropine *p*-nitrobenzoate were prepared and rates of hydrolysis determined. In addition, atropine ethylbromide and atropine benzylchloride were prepared and studied.

THEORY

Previous studies (1–3) have shown hydroxyl ion catalyzed hydrolysis to occur with tropine esters. Since nor-atropine, tropine phenylacetate, tropine phenoxyacetate, and tropine *p*-nitrobenzoate can exist as the free base or as the protonated form in solution, two hydrolytic pathways are possible. For convenience, hydrolysis of the free base will be designated Reaction 1, hydrolysis of the protonated form of the ester will be designated Reaction 2.

Received February 28, 1963, from the School of Pharmacy, University of Wisconsin, Madison.

Accepted for publication April 29, 1963.

Supported by a grant from the Research Committee of the Graduate School from funds supplied by the Wisconsin Alumni Research Foundation.

In accord with the theoretical concepts employed by Higuchi, *et al.* (4), in their study on procaine, the reaction kinetics may be

$$-\log t_{1/2} = \log (OH^-) - \log [K_b + (OH^-)] + \log \left[\frac{k_1(OH^-)}{0.693} + \frac{k_2 \cdot K_b}{0.693}\right] \quad \text{(Eq. 1)}$$

where k_1 and k_2 are the second-order rate constants at high pH (Reaction 1) and low pH (Reaction 2), respectively, and K_b is the dissociation constant of the base.

At relatively high hydroxyl ion concentration, where $OH^- >> K_b$, Eq. 1 reduces to

$$-\log t_{1/2} = \log (OH^-) + \log \frac{k_1}{0.693} \quad \text{(Eq. 2)}$$

Conversely, at low hydroxyl ion concentration, where $K_b >> OH^-$ it simplifies to

$$-\log t_{1/2} = \log (OH^-) + \log \frac{k_2}{0.693} \quad \text{(Eq. 3)}$$

It is apparent, then, that at high pH and at low pH the rate of hydrolysis should be directly proportional to hydroxyl ion concentration even though the mechanism of hydrolysis changes.

In the case of esters containing quaternary nitrogen, such as atropine ethylbromide and atropine benzylchloride, the mechanism of hydrolysis remains the same throughout the entire pH range.

EXPERIMENTAL

Materials.—Nor-atropine sulfate (K and K Laboratories) was recrystallized from ethanol and water.

Since nor-atropine, tropine phenylacetate, tropine phenoxyacetate, and tropine *p*-nitrobenzoate can exist as the free base or as the protonated form in solution, two hydrolytic pathways are possible. For convenience, hydrolysis of the free base will be designated Reaction 1, hydrolysis of the protonated form of the ester will be designated Reaction 2.

Received February 28, 1963, from the School of Pharmacy, University of Wisconsin, Madison.

Accepted for publication April 29, 1963.

Supported by a grant from the Research Committee of the Graduate School from funds supplied by the Wisconsin Alumni Research Foundation.

In accord with the theoretical concepts employed by Higuchi, *et al.* (4), in their study on procaine, the reaction kinetics may be

$$-\log t_{1/2} = \log (OH^-) - \log [K_b + (OH^-)] + \log \left[\frac{k_1(OH^-)}{0.693} + \frac{k_2 \cdot K_b}{0.693}\right] \quad \text{(Eq. 1)}$$

where k_1 and k_2 are the second-order rate constants at high pH (Reaction 1) and low pH (Reaction 2), respectively, and K_b is the dissociation constant of the base.

At relatively high hydroxyl ion concentration, where $OH^- >> K_b$, Eq. 1 reduces to

$$-\log t_{1/2} = \log (OH^-) + \log \frac{k_1}{0.693} \quad \text{(Eq. 2)}$$

Conversely, at low hydroxyl ion concentration, where $K_b >> OH^-$ it simplifies to

$$-\log t_{1/2} = \log (OH^-) + \log \frac{k_2}{0.693} \quad \text{(Eq. 3)}$$

It is apparent, then, that at high pH and at low pH the rate of hydrolysis should be directly proportional to hydroxyl ion concentration even though the mechanism of hydrolysis changes.

In the case of esters containing quaternary nitrogen, such as atropine ethylbromide and atropine benzylchloride, the mechanism of hydrolysis remains the same throughout the entire pH range.

EXPERIMENTAL

Materials.—Nor-atropine sulfate (K and K Laboratories) was recrystallized from ethanol and water.

Tropine phenylacetate, tropine phenoxyacetate, and tropine *p*-nitrobenzoate were prepared by reacting tropine hydrochloride with the appropriate acid chloride as described below. Phenylacetyl chloride was prepared according to the procedure of Auwers (5), phenoxyacetyl chloride was prepared according to the procedure of Rosenmund and Zetzsche (6), and *p*-nitrophenylacetyl chloride was obtained commercially.

A 2.0-Gm. quantity of the appropriate acid chloride was added to 2.5 Gm. of tropine hydrochloride in 20 ml. of dry chloroform. The reaction mixture was refluxed gently for 12 hours until evolution of hydrochloric acid ceased. The reaction mixture was extracted several times with water; the aqueous solution of ester salt was then made alkaline with 6% ammonia solution and immediately extracted with chloroform. Chloroform solutions were extracted four times with 5% hydrochloric acid solution, and the aqueous solution evaporated to dryness under vacuum (29°). The residue was dissolved in absolute ethanol, filtered, and anhydrous ether added until the solution just became hazy. Crystals which formed over 36 hours were filtered off and dried at 80°. The hydrochloride salt of the ester was recrystallized twice following the procedure outlined above and dried at 100°. Yields were poor but sufficient ester was obtained for hydrolytic studies.

Atropine ethylbromide and atropine benzylchloride were prepared by refluxing atropine base with an excess of ethyl bromide or benzyl chloride in a vessel fitted with an air condenser. The reaction mixture was cooled and allowed to stand for 24 hours. The appropriate ester was recrystallized from anhydrous ether and dried at 100°.

Buffer System.—To maintain hydroxyl ion concentration essentially constant at low pH values, the buffer solutions shown in Table I were used. For high pH, $Ba(OH)_2$ solution was used. Since the concentration of ester was kept low relative to the $Ba(OH)_2$ concentration, the pH remained

[a] Calculated from literature data (1–3).

essentially constant during the course of the reaction.

Procedure.—The desired quantity of buffer solution was placed in a thermostatically controlled bath at the desired temperature and allowed to reach temperature equilibrium. One milliliter of a solution containing sufficient ester to give the reaction mixture a concentration of approximately 1 mg./ml. was added and mixed by inverting the flask several times. The first sample of the reaction mixture withdrawn immediately was designated as the "0" minute sample and analyzed for residual ester. Progress of the reaction was followed by the withdrawal of samples at suitable time intervals and determination of residual ester concentration.

For nor-atropine, the method reported in the literature for atropine (1) and homatropine (2) was followed. For tropine phenylacetate, tropine phenoxyacetate, and tropine *p*-nitrobenzoate, carbon tetrachloride was used for extraction because extraction was incomplete with chloroform as the solvent.

Second-order reaction rates of the quaternary salts, atropine ethylbromide, and atropine benzylchloride were followed by indicator photometry as described by Patel and Lemberger (3), using "Alizarin yellow R" solution for determining OH^- ions. It was found that the indicator was very sensitive to atmospheric oxidation; therefore 0.003 *M* sodium sulfite was added to the 0.00655 *M* $Ba(OH)_2$ solution, and the $BaSO_3$ formed acted as an antioxidant. The precipitated excess $BaSO_3$ was filtered off and the concentration of the hydroxyl ions was determined by titration.

RESULTS

Influence of Ester Concentration.—At constant temperature and hydroxyl ion concentration, the rate of hydrolysis of nor-atropine, tropine phenylacetate, tropine phenoxyacetate, and tropine *p*-nitrobenzoate was observed to be first-order with respect to ester in agreement with earlier studies (1, 2).

Influence of Hydroxyl Ion Concentration.—The effect of hydroxyl ion concentration on the rate of hydrolysis of nor-atropine (expressed in terms of half life in minutes of the ester) is illustrated in Fig. 1. Rate measurements were carried out for tropine phenylacetate, tropine phenoxyacetate, and tropine *p*-nitrobenzoate, one at high pH and one at low pH to obtain k_1 and k_2 for Reaction 1 and Reaction 2, respectively. K_b was determined from the pH of a half neutralized solution of the salt of the ester at 30°. These results are shown in Table II.

Temperature Dependency.—Figure 1 further verifies that above pH 12.0 the mechanism of

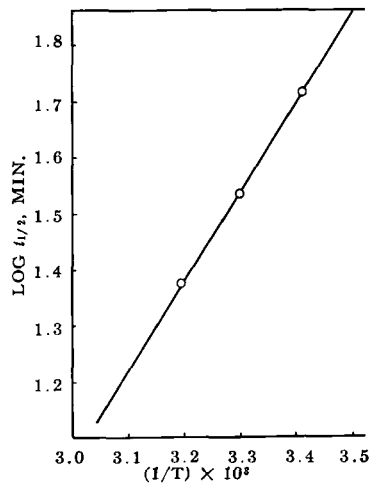

Fig. 2.—Temperature dependency of Reaction 1 for nor-atropine.

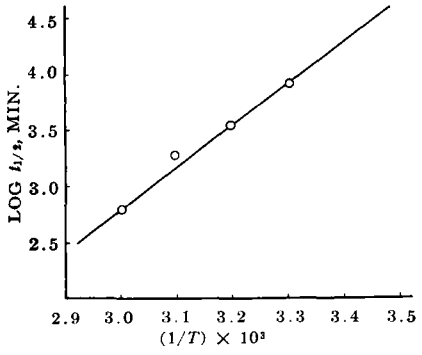

Fig. 3.—Temperature dependency of Reaction 2 for nor-atropine.

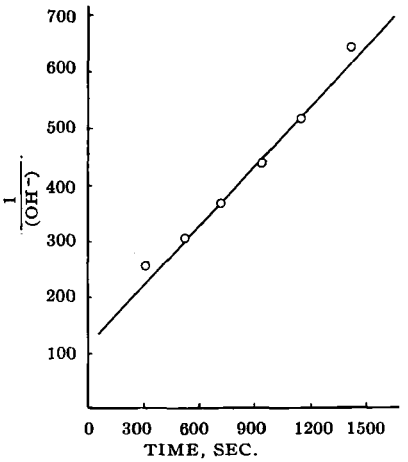

Fig. 4.—Typical bimolecular rate plot for the alkaline hydrolysis of atropine ethylbromide at 25.0°C. when alkali and ester are equal.

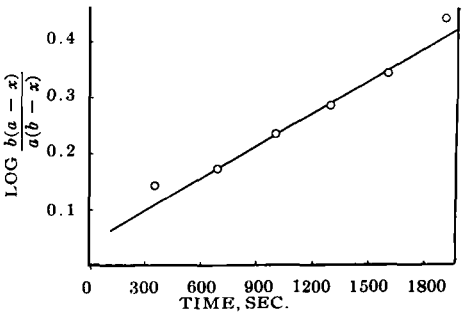

Fig. 5.—Typical bimolecular rate plot for the alkaline hydrolysis of atropine benzylchloride at 15.0°C. when alkali (*a*) and ester (*b*) are not equal.

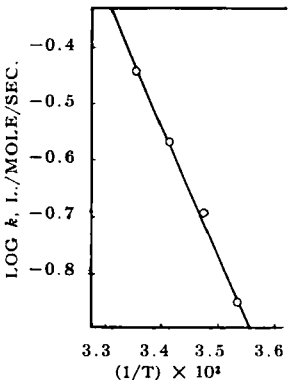

Fig. 6.—Arrhenius plot of the bimolecular rate constants for the alkaline hydrolysis of atropine ethyl bromide.

hydrolysis of these esters is that of Reaction 1, and that below pH 8.5 the mechanism is that of Reaction 2. Half lives were determined at different temperatures to study the temperature dependency of Reaction 1 and Reaction 2, respectively.

The logarithms of half life periods in minutes for these esters were plotted against the reciprocal of absolute temperatures and the straight line relationships obtained as illustrated in Figs. 2 and 3 indicate that the mechanism responsible for the ester hydrolysis is not altered by changes in temperature. The apparent activation energies were determined from the slopes of the plots and the frequency factors calculated from

$$k = se^{-\frac{E}{RT}}$$

The results are given in Table II.

Quaternary Salts.—The kinetics of the alkaline hydrolysis of the ester groups in atropine ethylbromide and atropine benzylchloride were determined by estimation of the slopes appropriate to the bimolecular rate expression

$$\frac{1}{a-x} = kt + \text{constant} \qquad \text{(Eq. 5)}$$

$$\log \frac{b}{a} \cdot \frac{(a-x)}{(b-x)} = \frac{kt\,(a-b)}{2.303} \qquad \text{(Eq. 6)}$$

$\frac{1}{a-x}$ was plotted against time when $a = b$ and $\log \frac{b}{a} \cdot \frac{(a-x)}{(b-x)}$ was plotted against time when $a \neq b$ where a and b are initial concentrations and $(a-x)$ and $(b-x)$ are concentrations at time intervals for the alkali and ester, respectively.

Hydroxyl ion concentration was calculated from the absorbance data.

Typical bimolecular rate plots for the hydrolysis of atropine ethylbromide and atropine benzylchloride are given in Figs. 4 and 5. Rate constants were determined at four different temperatures. Bimolecular rate constants are plotted against reciprocal of absolute temperature in Figs. 6 and 7. The rate constants at 30°, activation energies, and frequency factors are given in Table II.

DISCUSSION

Nor-atropine was studied extensively. The rather nice fit between the predicted relationship and the experimental points shown in Fig. 1 indicates that the hydrolytic Reactions 1 and 2 are mainly responsible for the hydrolysis of nor-atropine in aqueous solution. This behavior seems typical of the pattern of hydrolysis shown by other tropine esters reported previously (1–3). For this reason rate constants for hydrolysis of the other tropine esters reported here were determined at high (Reaction 1) and low (Reaction 2) pH only.

Of the esters listed in Table II tropine phenylacetate was observed to have the lowest hydrolytic rate for both Reactions 1 and 2. For convenience, hydrolysis rates of the other esters are compared to this compound. Thus, in Reaction 1 both atropine and nor-atropine hydrolyze approximately

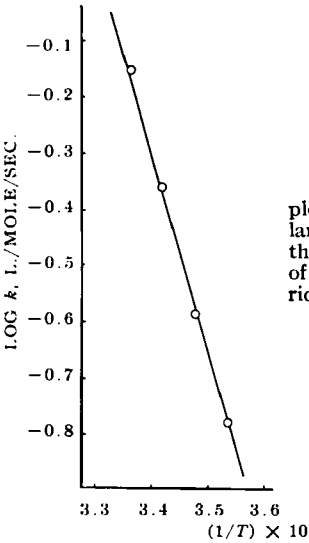

Fig. 7.—Arrhenius plot of the bimolecular rate constants for the alkaline hydrolysis of atropine benzylchloride.

five times faster than tropine phenylacetate; in Reaction 2 they are two and three times faster, respectively. This seems to indicate that replacement of one hydrogen on the nitrogen of nor-atropine with a methyl group to form atropine has virtually no effect on the rate of ester hydrolysis. With both these esters it is possible that the hydroxyl group in the acid moiety is responsible for an inductive effect on the carbonyl carbon. If this is true, the increase in positive character of the carbonyl carbon would facilitate hydrolysis of nor-atropine and atropine to account for the greater rate of hydrolysis relative to tropine phenylacetate.

In Reaction 1 tropine *p*-nitrobenzoate hydrolyzes approximately 25 times faster than tropine phenylacetate and in Reaction 2 eight times faster. The nitro group attached to the ester through the benzene ring seems to play a significant role in influencing hydrolytic rate. This has previously been observed (7, 8) and been attributed to the strong electron withdrawing tendency of the *p*-nitrobenzoyl group

TABLE III.—

Acid	Dissociation Constant, 25°C.	pKa
Phenylacetic	4.88×10^{-5}	4.31
Phenoxyacetic	5.56×10^{-5}	4.25
Tropic	7.50×10^{-5}	4.12
p-Nitrobenzoic	3.48×10^{-4}	3.46
Mandelic	4.29×10^{-4}	3.37

and the consequent formation of a highly positive center on the carbonyl carbon.

Homatropine is seen to hydrolyze 30 times faster than tropine phenylacetate by Reaction 1 and 15 times faster in the protonated form. This further confirms the inductive effect of the α-hydroxyl group in enhancing the positive character of the carbonyl carbon atom resulting in acceleration of the nucleophilic attack by hydroxide ion as reported previously (2).

As might be expected, if inductive effects are significant, the relative rates of hydrolysis of these esters should parallel the dissociation constants of the respective acids. Table III shows that this is mostly true. An exception is noted in the case of tropine phenoxyacetate whose rate of hydrolysis is 60 times faster by Reaction 1 and 11 times faster by Reaction 2 than the reference ester. These rates seem unusually high, considering that the dissociation constants of the acids are almost equal. It is possible that some other factor such as a steric effect may be involved, thus causing a greater hydrolytic rate than anticipated.

These observations are also apparent from the plot of log k_1 against log k_2 shown in Fig. 8. It can be seen that as polarity of the acid increases, the rate constants k_1 and k_2 increase. Similar observations have been made by Roberts and Moreland (9) in which they studied the electrical effects of substituted groups in saturated systems. They found that as the polarity of the acid increased, the effect of hydrolysis of its esters increased. It is also evident from Fig. 8 that the effect of polarity is more predominant in case of Reaction 1 than in Reaction 2, which would indicate that inductive effects are more prominent in hydrolysis of the base form of the ester.

The bimolecular rate of reaction of the quaternary nitrogen esters is of the same order of magnitude as the rate for the protonated form. Previous authors (3, 10) attribute this to the positive charge atmosphere which attracts hydroxyl ions to the vicinity of the carbonyl carbon in esters of esters of this type. Of the quaternary salts atropine methylbromide and atropine ethylbromide hydrolyze at approximately the same rate. There is some question whether the increased rate observed in atropine benzylchloride is truly significant. If so, it could perhaps be attributed to a steric facilitation by the relatively large benzyl group.

Quantitative Determination of Morphine in Opium by Gas-Liquid Chromatography

By E. BROCHMANN-HANSSEN and A. BAERHEIM SVENDSEN†

Although morphine may be gas chromatographed as such, its phenolic properties cause adsorption which produces tailing and makes quantitative work impossible. This difficulty was overcome by converting morphine to its trimethylsilyl ether which gave a symmetrical elution peak suitable for quantitative estimation. The alkaloids of opium were extracted and morphine separated from nonphenolic alkaloids by ion-exchange resins. The morphine fraction was allowed to react with hexamethyldisilazane, tetraphenylethylene was added as the internal standard, and the solution was gas chromatographed on a column of silicone rubber SE-30.

DURING THE PAST few years, the gas chromatographic method has become increasingly important for analysis of high molecular weight compounds of biological origin. In 1960 Lloyd, *et al.* (1), gas chromatographed 45 different alkaloids, including the major alkaloids of opium at temperatures slightly above 200°. Eddy, *et al.* (2), used gas chromatography for the determination of the origin of opium based on the peak height ratios of several of the major alkaloids.

When working with alkaloids on low-loaded columns, tailing can often cause considerable difficulties. The support material will contain active spots which will not be sufficiently covered by the stationary liquid to prevent adsorptive effects. Adsorption can be reduced to a great extent if the support material is washed with acid and alkali and treated with dichlorodimethylsilane (3), hexamethyldisilazane (4), and/or a surface-active agent (4–6). Phenolic alkaloids, such as morphine, are difficult to gas chromatograph even on a treated support. If adsorption takes place, it will affect the retention time as well as the height and area of the emerging peak, and quantitative work becomes impossible. This difficulty may be overcome by converting the phenolic hydroxyl groups to esters or ethers. Hexamethyldisilazane is excellently suited for this purpose (7). At room temperature it produces trimethylsilyl ethers in quantitative yield.

Perhaps the most crucial step in a quantitative determination of morphine in opium is the extraction. Strongly acidic cation-exchange resins have been shown to effect rapid and efficient extraction of alkaloidal crude drugs including opium (8–11). The total alkaloids thus extracted may be effectively purified and phenolic and nonphenolic alkaloids separated by means of a strongly basic anion-exchange resin (9, 10). Such purification prior to the gas chromatographic analysis increases the life of the column, the specificity of the method, and simplifies the quantitative evaluations.

During the development of the method described below, two internal standards were used, tetraphenylethylene and laudanosine, which are eluted on either side of morphine 3,6-di-trimethylsilyl ether (Fig. 1). Both standards, however, give the same results. Tetraphenylethylene is readily available and is stable at the experimental conditions of this method. Most of our samples were analyzed with this substance alone as the internal standard.

EXPERIMENTAL

Twelve opium samples were analyzed. Eleven of these were authenticated samples obtained through the United Nations' Division of Narcotic Drugs.

Preparation of the Sample.—Two-hundred milligrams of finely powdered opium was triturated in a glass mortar with 1 ml. of hot water. Gradually, 10 ml. of hot water was added while stirring. The stirring was continued for 5 minutes, and the aqueous extract was decanted into an extraction

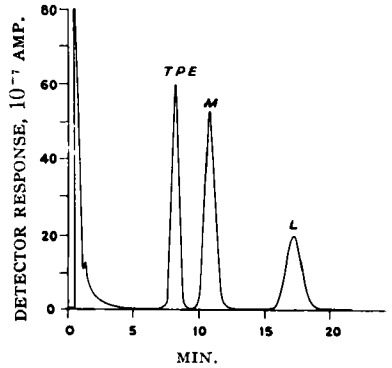

Fig. 1.—Gas chromatogram of morphine (M) isolated from a sample of opium by ion-exchange techniques. Tetraphenylethylene (TPE) and laudanosine (L) are added as internal standards.

tube (8) containing 3 Gm. of an analytical grade of Dowex 50-X_2, 50–100 mesh. The residue was extracted twice more with 10 ml. of hot water each time and the extracts added to the extraction tube. The opium residue was then washed quantitatively into the tube with enough hot water to give a volume of about 50 ml. The tube was shaken mechanically for 15 minutes. The liquid was allowed to drain slowly from the extraction tube, and the resin in the tube was washed with about 50 ml. of water.

The alkaloids on the resin were eluted slowly with 100 ml. 1 *N* methanolic ammonia (68 ml. of concentrated ammonia, 700 ml. of reagent grade methanol, and enough water to make 1000 ml.). The eluate was allowed to pass through a 1.2 cm. × 30-cm. column of an analytical grade of Dowex 1-X_1, 50–100 mesh. The resin was previously activated with 4 *N* sodium hydroxide and washed free of excess alkali with distilled water. The cationic resin was washed with 50 ml. of 70% methanol, and the washings allowed to flow through the anionic-exchange column. Finally, the anionic-exchange resin was washed with water until the washings were neutral to phenolphthalein, and morphine was eluted slowly with 100 ml. of 0.5 *N* acetic acid. The morphine eluate was collected in a 250-ml. round-bottomed flask and evaporated to dryness in a rotating vacuum evaporator. To remove completely the last traces of water and acetic acid, 10 ml. of absolute ethanol was added and removed under reduced pressure. This was repeated a second time. Thirty-five milligrams of tetraphenylethylene was added to the flask, and the internal standard and alkaloidal residue were dissolved in 2 ml. of pyridine, which had been redistilled over phosphorus pentoxide. One milliliter of hexamethyldisilazane was added to the solution, the flask was stoppered with a glass stopper, and set aside for 24 hours.

Gas Chromatography.—The instrument used for this work was a Barber-Colman model 15 gas chromatograph equipped with an argon ionization detector containing 56 μc. of Ra-226. The column was a glass U-tube, 4 ft. long and 4 mm. in inside diameter. The solid support was Gas-Chrom P, 60–80 mesh, which was washed with concentrated hydrochloric acid, methanolic potassium hydroxide, dried, and treated with hexamethyldisilazane (4). The dried and siliconized support was coated with 0.1% of polyethylene glycol 9000 and, finally, with 4% of silicone rubber, SE-30 (7). The column temperature was maintained at 183°, the injection port (flash heater) temperature was 280°, and the detector cell temperature was 240°. The gas pressure at the inlet was 20 lb., producing a gas flow of 250 ml. per minute. The solutions to be analyzed were injected with a Hamilton microliter syringe, the usual sample size being about 3 μl., corresponding to about 20 to 30 mcg. of morphine. The instrument was operated at submaximal sensitivity to reduce the noise level and gain linearity of detector response. The peak areas were measured with a planimeter, each area reading being based on the average obtained from the cumulative value of ten consecutive tracings. The area ratio of morphine (M) to tetraphenylethylene (TPE) was determined, the corresponding weight ratio obtained from a standard curve, and the percentage of morphine in the sample calculated.

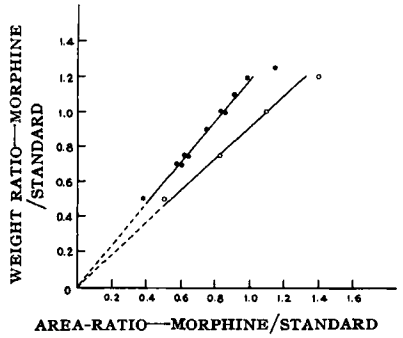

Fig. 2.—Standard curves for morphine with two internal standards. Key: ●, morphine/tetraphenylethylene; ○, morphine/laudanosine.

Standard Curve.—In each of several glass vials were placed 20 mg. of tetraphenylethylene, 20 mg. of laudanosine base,[1] and known amounts of anhydrous morphine base ranging from 10 to 25 mg. The substances were dissolved in 2 ml. of dry pyridine; 1 ml. of hexamethyldisilazane was added. The vials were stoppered with polyethylene stoppers and set aside at room temperature. The reaction appeared to be complete in 16 to 18 hours. An additional reaction time of several days produced no change in the result. The solutions were gas chromatographed, and the weight ratio of morphine to the internal standard was plotted against the corresponding ratio for the peak areas. A straight line was obtained over a range sufficiently great to include all samples encountered (Fig. 2).

The linear range of the argon ionization detector is narrower than that of most other detectors used in gas chromatography (12). However, by adjusting the amount of internal standard added to the unknown it is always possible to work within the linear part of the curve. Although our standard curve appeared to be very reproducible, we deemed it desirable to check it with new standard solutions every day that unknown samples were gas chromatographed.

RESULTS AND DISCUSSION

The contents of morphine in the opium samples analyzed are recorded in Table I. The results are compared with results obtained by other workers using different methods. The reproducibility of the method is satisfactory. Based on a total of 40 determinations of ten different opium samples, the precision, calculated as the standard deviation, was 0.15%.

It is well known that the lime method used by the U.S.P. for determination of morphine in opium does not give results which are absolutely correct. One reason for this is that the crystallization of morphine is incomplete so that a certain amount is lost in the mother liquor (16, 17). It has also been shown that the morphine crystals are contaminated with other opium alkaloids (17). Mannich's method (18), which is based on precipitation of the dinitrophenyl ether of morphine, is considered by many workers to give more accurate results (14, 17, 19, 20).

Fulton (21, 22) has described certain phenolic opium alkaloids which follow morphine very closely

[1] We are indebted to Mallinckrodt Chemical Works, St. Louis, Mo., for supplying us with this alkaloid.

UNE612	15.4	15.4
	15.6	15.5

in many of its reactions and extractions. They are present in amounts up to 1.5% and may lead to high results if the analytical procedure is not sufficiently specific. It is possible to remove them by extracting the acidified morphine fraction with chloroform in the presence of dichloroacetic acid (15). These alkaloids do not interfere in the gas chromatographic determination of morphine. Table II shows that inclusion of an extra purification step *via* dichloroacetic acid does not change the results.

The generally higher results obtained by the gas chromatographic method than by the other procedures referred to in Table I are probably due to a more complete extraction of opium by the ion-exchange resin and a more quantitative recovery during the purification steps.

2-Aminobenzenethiol Derivatives as Potential Psychotherapeutic Agents

By KARL A. NIEFORTH

A structural similarity between reserpine and chlorpromazine is described and a series of derivatives of 2-aminobenzenethiol designed to match the similarity is synthesized and tested for pharmacologic activity.

THE APPARENT tranquilizing activity of reserpine and chlorpromazine is qualitatively the same, although the two compounds are quite different structurally. It is postulated that the two compounds act by two pharmacologically distinct mechanisms—reserpine by trophotropic stimulation and chlorpromazine by ergotropic inhibition according to the terminology of Hess (1).

With the use of molecular models, a structural similarity may be seen between the two compounds (see Fig. 1). The diagram represents the positional relationships of three atoms in the two compounds and shows the location of an aromatic structure. Position *A* represents the phenolic oxygen of reserpine or the sulfur of chlorpromazine; position *B*, the aromatic nitrogen of each compound; and position *C*, the aliphatic nitrogen of each compound. It must be kept in mind that the positions also could represent any bioisosteric modification. A similarity of

UNE612	15.4	15.4
	15.6	15.5

in many of its reactions and extractions. They are present in amounts up to 1.5% and may lead to high results if the analytical procedure is not sufficiently specific. It is possible to remove them by extracting the acidified morphine fraction with chloroform in the presence of dichloroacetic acid (15). These alkaloids do not interfere in the gas chromatographic determination of morphine. Table II shows that inclusion of an extra purification step *via* dichloroacetic acid does not change the results.

The generally higher results obtained by the gas chromatographic method than by the other procedures referred to in Table I are probably due to a more complete extraction of opium by the ion-exchange resin and a more quantitative recovery during the purification steps.

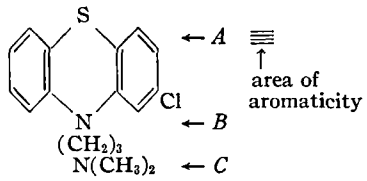
Reserpine



Chlorpromazine

Fig. 1.—Structural similarity of reserpine and chlorpromazine as obtained with Stuart-Briegleb molecular models.

the compounds which is difficult to express by a diagram but readily visible by the use of molecular models is the proximity in space occupied by substituents on position 2 of promazine and position 16 of reserpine. This may explain why substituents on position 2 of promazine have a greater effect on activity than do similar substituents on other positions of the phenothiazine structure.

It has been proposed that the sites involved in the activity of reserpine and chlorpromazine are specific for the corresponding drugs because of the apparent dissimilarity of structures. On the basis of the similarity shown in Fig. 1, it seems that the two sites involved in CNS activity may be closely related in physical characteristics or that only one site may be involved, the latter being more probable. This particular arrangement of atoms does not necessarily result in reserpine-chlorpromazine type CNS depression as illustrated by the stimulant imipramine (2). In some instances, activity may be found in compounds possessing only a part of the total arrangement such as the depressant tetrabenazine (3).

The compounds in this series (Table II) were designed to have a hybrid reserpine-chlorpromazine activity. Activity of this type would suggest the existence of a single site with differences which are observed in the pharmacodynamic actions accounted for by secondary effects of the drugs. Figure 2 shows the reaction scheme which was suitable for the synthesis of the test compounds.

The circuitous route to compound VII from compound II was necessitated by the difficulty encountered in separating the products of methylation of compound II. Methyl 2-acetamidophenyl sulfide and its N-methyl analog decomposed upon distillation and could not be used to form methyl 2-methylaminophenyl sulfide without tedious recrystallizations. For this reason, methyl 2-benzenesulfonamidophenyl sulfide and its N-methyl derivative were used as intermediates. These two compounds could be separated and purified easily by their solubilities in alkaline solution and were prepared in good yields. The sulfonamide procedure could have been used for the preparation of all of the alkyl 2-methylaminophenyl sulfides (Table I), but purification of the acetyl derivatives was more rapid than was recrystallization of the sulfonamide derivatives.

EXPERIMENTAL

Alkyl 2-Aminophenyl Sulfides (II).—These compounds were synthesized by well documented procedures in good yields. Running the reaction under nitrogen improved its appearance but had little effect on the yields.

Alkyl 2-Acetamidophenyl Sulfides (III).—One mole of alkyl 2-aminophenyl sulfide and 1 mole of pyridine were dissolved in 500 ml. of ether and 1 mole of acetyl chloride added over the period of 1 hour. The mixture was stirred for 1 hour, poured into diluted hydrochloric acid, extracted with ether, and distilled at reduced pressure.

Alkyl 2-(N-methyl)-acetamidophenyl Sulfides (IV).—Alkyl 2-acetamidophenyl sulfide (0.8 mole) was added to a sodium dispersion (1.0 mole in 300

[a] Melting points were taken on a Thomas melting point apparatus and are uncorrected. [b] Prepared by Foster, D., and Reid, E., *J. Am. Chem. Soc.*, **46**, 1941(1924). [c] Recrystallized from 95% ethanol. [d] Microanalyses were carried out by Alfred Bernhardt, Mikroanalytisches Laboratorium, Max-Planck-Institut, Mulheim (Ruhr), Germany.

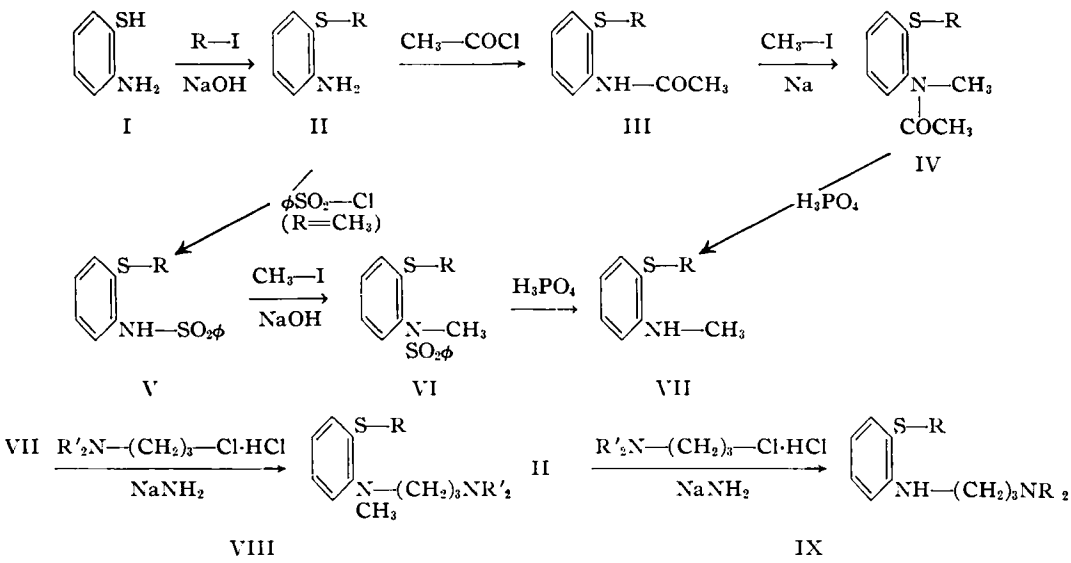

Fig. 2.—Synthetic procedure.

ml. of toluene) and stirred on a steam bath for 10 hours. After cooling to room temperature, methyl iodide (1.0 mole) was added with stirring over a period of 2 hours. The reaction was stirred for an additional hour without heating. The solvent was removed and 20 ml. of ethanol added to destroy excess sodium. An aqueous suspension of the residue was extracted with ether and the ethereal solution distilled at reduced pressure.

Methyl 2-Benzenesulfonamidophenyl Sulfide (V).—A mixture of methyl 2-aminophenyl sulfide (1.0 mole) and pyridine (1.0 mole) was dissolved in 500 ml. of ether. Benzenesulfonyl chloride (1.0 mole) was added with stirring over a period of 30 minutes. The reaction was heated on a steam bath for 30 minutes, after which it was extracted with dilute hydrochloric acid. The ether was evaporated and the residue solidified by cooling.

Methyl 2-(N-methyl)-benzenesulfonamidophenyl Sulfide (VI).—A solution of methyl 2-benzenesulfonamidophenyl sulfide (0.2 mole) was prepared by dissolving it in 275 ml. of 5% sodium hydroxide. Methyl iodide (0.24 mole) was added during 30 minutes with stirring. The reaction was then refluxed for 1 hour, cooled to room temperature, and filtered. The solid product was treated with 20% sodium hydroxide to remove any starting material and then recrystallized from 95% ethanol.

Alkyl 2-Methylaminophenyl Sulfides (VII).—These compounds could be prepared from either methyl 2-(N-methyl)-benzenesulfonamidophenyl sulfide (VI) or alkyl 2-(N-methyl)-acetamidophenyl sulfides (IV) in the same manner. The reactant was heated at 150° for 18 hours with an excess of orthophosphoric acid. The reaction was cooled and carefully neutralized with dilute sodium hydroxide solution. The mixture was extracted with toluene or benzene while still warm before the precipitation of sodium phosphate. The solvent was removed and the residue distilled at reduced pressure.

Alkyl N-(N'-dialkylaminoalkyl)-N-methylaminophenyl Sulfides (IX).—Alkyl 2-methylaminophenyl sulfide (0.09 mole) was heated in 200 ml. of toluene with sodium amide (0.2 mole) for 24 hours. Dialkylaminoalkylchloride hydrochloride (0.08 mole) was added in one addition; the reaction was heated and stirred for an additional 24 hours. The toluene was

removed, and a small amount of ethanol was added to destroy residual sodium amide. The ethanol was removed, the residue was suspended in a saturated solution of potassium carbonate, and extracted with ether. The ether was removed and the residue distilled at reduced pressure. This is a modification of a procedure reported by Huttrer (4).

Isopropyl N-(N'-Diethylaminopropyl)-aminophenyl Sulfide (VIII).—This compound was prepared in the same manner as compound IX. Isopropyl 2-methylaminophenyl sulfide (0.13 mole) was reacted with sodium amide (0.25 mole) in 200 ml. of toluene. After heating the mixture for 24 hours, 3-diethylaminopropylchloride hydrochloride was added and heated for 24 hours. The product was isolated in the manner described above in a yield of 82%. Compounds of this type have been previously reported (5).

These compounds were screened for gross pharmacologic activity using the Hippocratic screen method (6). Biphasic activity was exhibited by an initial increase in motor activity accompanied by evidence of disorientation and stereotypy in the form of head shaking, chewing motions, and prancing of the forelimbs. This was followed by ataxia and decreased motor activity 1 hour after intraperitoneal injection. One compound, isopropyl N-(N'-diethylaminopropyl)-aminophenyl sulfide exhibited only motor activity depression without an initial increase.[1]

Effect of Certain Tablet Formulation Factors on Dissolution Rate of the Active Ingredient III

Tablet Lubricants

By GERHARD LEVY and ROBERT H. GUMTOW

A hydrophobic tablet lubricant (magnesium stearate) has been found to retard the dissolution of salicylic acid from model compressed tablets, while a water-soluble, surface-active lubricant (sodium lauryl sulfate) enhanced markedly the dissolution rate. Experiments with nondisintegrating disks indicate that the more commonly used hydrophobic lubricants (magnesium stearate, aluminum stearate, stearic acid, talc) decrease the effective drug-solvent interfacial area and thereby decrease the rate of dissolution of the drug, while water-soluble lubricants (sodium oleate, sodium lauryl sulfate) do not have this effect. The dissolution rate enhancing effect of sodium lauryl sulfate (in the case of conventional tablets) is not due to any modification of microenvironmental pH or solubilization by micelles, but rather to the better penetration of solvent into tablets and their component granules and the resulting greater availability of drug surface.

THE EFFECT of formulation and processing factors on the dissolution rate of active ingredients of compressed tablets has been the subject of extended investigation in this laboratory (1, 2). The present report deals with the effects of tablet lubricants and the mechanisms by which they may modify the dissolution rate of pharmaceuticals contained in tablets.

The more commonly used tablet lubricants are hydrophobic substances. Their water-repellent effect is evidenced by their tendency to increase markedly the disintegration time of tablets (3–5). When lubricants are added to a tablet granulation, they form a coat around individual granules which remains more or less intact during the process of tablet compression (3). Interference by these agents with the dissolution of drugs in aqueous media is therefore a likely possibility.

An extensive study of currently used and potentially useful tablet lubricants by Strickland, *et al.* (6), revealed that a few water-soluble substances are effective lubricants. Presumably, these substances, unlike hydrophobic lubricants, will not interfere with the dissolution of tablet ingredients. For this reason, both hydrophobic lubricants as well as certain water-soluble lu-

[a] SA = Salicylic acid. [b] Kg./cm.^{2} [c] U.S.P. mesh size of granules used for preparation of tablets.

bricants were used in this study. They were selected on the basis of high R value[1] and ejection force lowering capability from among those evaluated by Strickland, *et al.* (6). The particular dissolution test for compressed tablets (beaker method) and the experimental tablet formulations used in this study were chosen for reasons that have been discussed previously (1, 2).

EXPERIMENTAL

Preparation of Tablets

Salicylic acid tablets were prepared according to a method described previously (2). Composition and processing conditions of the two experimental preparations are listed in Table I. All lubricants were passed through a 100-mesh sieve.

Dissolution Rate Determination for Tablets.—Dissolution rates were determined by the beaker method (7) and in one instance also by the oscillating tube method (1). For the latter procedure, the volume of dissolution medium was reduced to 300 ml.

Preparation of Disks

Salicylic acid powder was precompressed at 6000 lb. total force into 0.5-in. diam. slugs by a modified hydraulic press (Carver, model B). The slugs were crushed into granules with mortar and pestle, and the 20–40-mesh granule fraction was collected by sieving. Lubricant was added to the granules in a small plastic vial, and these were mixed gently but thoroughly by rotating the vial. The granulation was compressed into thin, nondisintegrating disks of $^1/_2$ in. diam. with the modified hydraulic press, using 20,000 lb. total force. In one instance, disks were prepared directly from 100-mesh salicylic acid powder and from a mixture of salicylic acid powder (100 mesh) and lubricant.

Dissolution Rate Determinations for Disks.—Dissolution rates were determined by the rotating disk (8, 9) and static disk (1) methods, using 0.1 *N* hydrochloric acid at 37° as the dissolution medium. Speed of rotation for the rotating disk experiments was 555 r.p.m. Except where otherwise indicated, all data shown in the figures represent the average of duplicate determinations.

RESULTS AND DISCUSSION

Studies with Compressed Tablets.—A commonly used and very effective hydrophobic lubricant (magnesium stearate) and a very effective (6) water-soluble lubricant (sodium lauryl sulfate) were used in these studies. Figure 1 shows the effect of these agents on the dissolution rate of salicylic acid in compressed tablets made from granules containing pure drug. Magnesium stearate decreased dissolution rate appreciably, while sodium lauryl sulfate had the opposite effect. Figures 2 and 3 show the effect of magnesium stearate and sodium lauryl sulfate, respectively, on the dissolution rate of salicylic acid tablets made from granules that contained salicylic acid and starch. Again, magnesium stearate decreased and sodium lauryl sulfate increased the dissolution rate of salicylic acid. Comparison of Fig. 1 with Fig. 3 shows that sodium lauryl sulfate had a greater enhancing effect when it was incorporated in tablets that were made from starch-containing, *i.e.*, disintegrating granules. The latter formulation was also tested by means of the oscillating tube method (compared with the

beaker method). The results of this experiment, shown in Fig. 4, though quantitatively different, are qualitatively similar to those obtained with the beaker method.

Cooper and Brecht (10) have found that incorporation of surfactants into tablet formulations was an effective means of reducing tablet disintegration time. Sodium lauryl sulfate had no significant effect in their experience, but this is probably due to their use of calcium lactate tablets as the test system. Sodium lauryl sulfate reacts with calcium ion to yield a water-insoluble compound. Ward and Trachtenberg (11) have found that sodium lauryl sulfate did reduce the disintegration time of tablets made from amphenidone and sulfadiazine, respectively.

The experimental results depicted in Figs. 1–4 parallel those obtained from studies of the effect of stearates (3–5) and surfactants (10, 11), respectively, on the disintegration rate of tablets. However, this does not mean that the effect of these lubricants on dissolution rate is mediated solely or even primarily by their modification of tablet disintegration rates. In fact, the experimental tablet preparations used in this study were formulated in a manner which resulted in their rapid disintegration in order to minimize the effect of differences in tablet disintegration rates.

In the case of sodium lauryl sulfate, the dissolution rate enhancing effect could be due in part to an increase in microenvironmental pH (2),[2] to solubilization by micelles (12), and to more complete wetting of the drug solids (12). The dissolution rate retarding effect of magnesium stearate could be partially the result of delayed granule disintegration and reduced contact between drug and solvent. To investigate most of these possibilities it was desirable to eliminate totally tablet disintegration rate as an experimental variable. This was accomplished by the use of nondisintegrating pellets (disks) made from pure drug granules and lubricant.

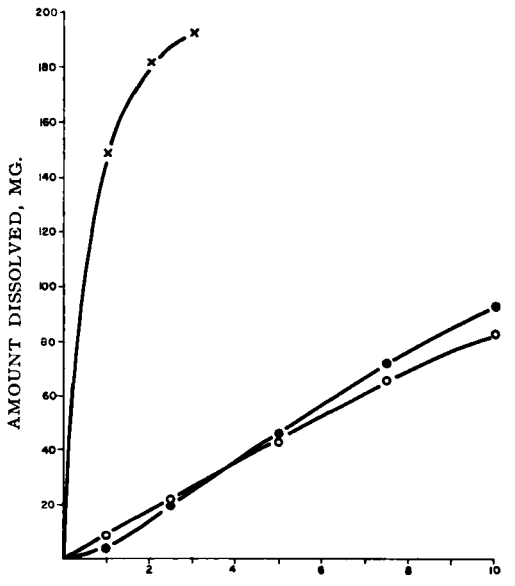

Fig. 4.—Effect of lubricant on dissolution rate of salicylic acid contained in compressed tablets (formula B) as determined by the oscillating tube method. Key: O, 3% magnesium stearate; ●, no lubricant; ×, 3% sodium lauryl sulfate. (Average of five tablets each).

[2] A slurry of sodium lauryl sulfate in 0.1 *N* hydrochloric acid at 37° has a pH of approximately 9.2.

Studies with Nondisintegrating Disks.—As shown in Fig. 5, sodium lauryl sulfate had no effect on the dissolution rate of salicylic acid from the surface of nondisintegrating disks. This indicates that neither increased microenvironmental pH nor micellular solubilization are the cause for the dissolution rate enhancing effect of sodium lauryl sulfate observed in experiments with compressed tablets.

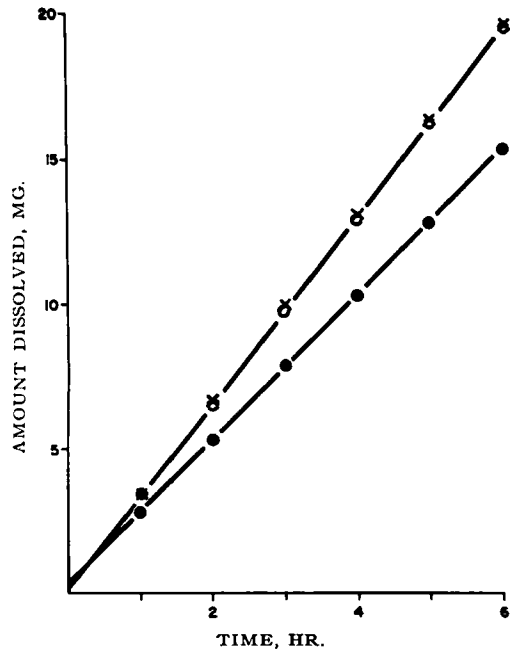

Fig. 6.—Effect of lubricant on the rate of dissolution of salicylic acid from static disks. Key: ●, 3% magnesium stearate; O, no lubricant; ×, 3% sodium lauryl sulfate.

The plot of amount dissolved *versus* time for disks containing magnesium stearate, also shown in Fig. 5, was somewhat unusual. Though linear (except for the first experimental point), it yielded a positive time intercept upon extrapolation. This suggested that magnesium stearate formed an impervious surface barrier which had to be removed before dissolution of drug could occur. If the surface of magnesium stearate–containing disks is, indeed, covered by an impervious barrier of the lubricant, then the apparent "lag-time" should be even greater under conditions where the mechanical effect of stirring is absent. However, when the dissolution rate was determined by the static disk method, there was no increase in apparent "lag-time," but rather, there was no apparent "lag-time" whatsoever (Fig. 6).

To determine whether the apparent "lag-time" found with rotating disks was real, experiments were carried out in which the dissolution medium was sampled every 2 minutes. This established that the apparent "lag-time" was because of an apparent increase in dissolution rate after about 5 mg. of drug had dissolved. Specifically, dissolution rate was constant until about 4 mg. of drug had dissolved, then gradually increased until it became constant once again after about 7 mg. had dissolved. The dotted line in Fig. 5 represents the experimentally determined initial dissolution rate of salicylic acid from magnesium stearate–containing disks. The subsequent change in apparent rate is seen readily.

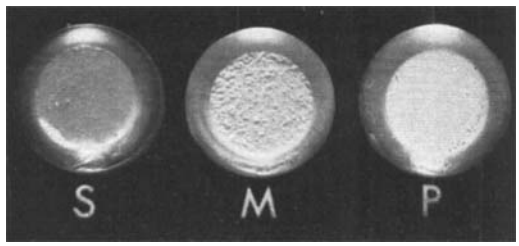

Fig. 7.—Surface of disks after dissolution of 10 mg. salicylic acid. Key: S = containing 3% sodium lauryl sulfate, M = containing 3% magnesium stearate, P = containing only pure salicylic acid.

These results may be explained on the basis of the changing surface characteristics of disks made from salicylic acid granules and magnesium stearate. The lubricant is confined to the surface and intergranular regions of the disks (3) and, as a result, the granules are surrounded by a water-insoluble matrix. As some of the salicylic acid dissolves, it leaves pits on the surface of the disk. This

represents an increase in surface area which results in a more rapid dissolution of drug from the rotating disks. Although pits develop also on the surface of static disks, no increase in apparent dissolution rate occurs because the boundary layer at the solid-solvent interface of static disks is sufficiently thick to cover the pits (1). Pitting does not occur on the surface of disks which contain a water-soluble lubricant or no lubricant at all (Fig. 7). It does occur whenever any of the hydrophobic lubricants that were studied are used (Table II).

A comparative evaluation of the effect of various lubricants on dissolution rate by the rotating disk method had to be carried out in a manner which prevented complications because of pitting. This was accomplished by determining only initial dissolution rates, (*i.e.*, before apparent increases due to pitting had occurred). The results of the experiments are shown in Figs. 8 and 9. Magnesium stearate, aluminum stearate, sodium stearate, stearic acid, and talc all decreased the dissolution rate. Evaluation of relative effects of these agents is complicated because there is no assurance that their specific and/or effective surface areas were exactly equal, but magnesium stearate appears to have the most pronounced retarding effect. A concentration dependency is evident from the difference between the dissolution rate from disks containing 1.5% and 3%, respectively, of magnesium stearate. It is interesting that magnesium stearate not only retards dissolution rate more than does stearic acid, but that it also prolongs tablet disintegration time more than stearic acid (3).

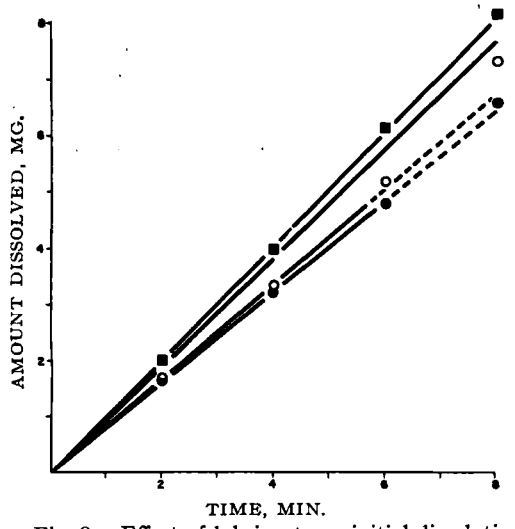

Fig. 9.—Effect of lubricants on initial dissolution rate of salicylic acid from rotating disks. Key: ●, 3% sodium stearate; O, 3% talc; ■, 3% sodium oleate; ——, no lubricant (from Fig. 8).

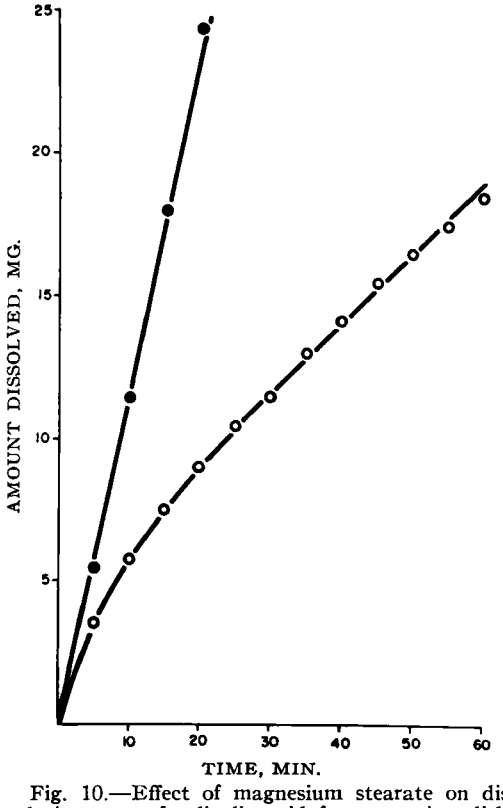

Fig. 10.—Effect of magnesium stearate on dissolution rate of salicylic acid from rotating disks made from fine salicylic acid powder. Key: O, 3% magnesium stearate; ●, no lubricant added.

The water-soluble sodium oleate had no significant effect on dissolution rate from disks and neither did sodium lauryl sulfate (Figs. 5 and 9). The dissolution rate retarding and pitting effect of sodium stearate appears unusual since this substance is stated to be water-soluble (13). However, it is also stated to be slowly dissolving (13). Addition of milligram amounts of sodium stearate to 0.1 *N* hydrochloric acid at 37° (the dissolution medium used in these studies) did not result in solution (and possible reprecipitation) of the substance, and it must be assumed that sodium stearate acts like a poorly soluble and hydrophobic agent under the conditions of this study.

One experiment was conducted with rotating disks

made from salicylic acid powder (100 mesh) and 3% magnesium stearate in order to determine whether a marked increase in the ratio of surface areas of drug:lubricant would result in a quantitative modification of the dissolution-retarding effect. The results of the experiment (shown in Fig. 10) indicate that the dissolution-retarding effect of magnesium stearate was somewhat greater in the case of disks prepared from salicylic acid powder (compared with disks made from granules). Therefore, the lubricant content of disks made from granules was sufficient to cover the surface of all granules; otherwise the retarding effect of lubricant would have decreased when drug granules were replaced by finely powdered drug. The initial curvature in the dissolution curve of magnesium stearate–containing disks made from salicylic acid powder (Fig. 10) was found repeatedly and may be because of a lower concentration of lubricant at the surface of the disk, from which it could have been removed mechanically by handling or during compression of the disk.

On the basis of these experiments it may be concluded that hydrophobic lubricating agents may retard the dissolution of drugs contained in compressed tablets not only by prolonging the disintegration time of both tablets and granules but also by reducing the area of the interface between drug particles and solvent. The surface of pellets made from salicylic acid and a hydrophobic lubricant represents a complex physicochemical system because the "true" surface area with respect to salicylic acid is difficult to estimate. This is the reason why the boundary layer thickness calculations in the first paper of this series were stated to be only reasonable approximations (1).

The dissolution rate enhancing effect of sodium lauryl sulfate appears to be due to increased wetting and to better solvent penetration into the tablets and granules as a result of the interfacial tension lowering effect of the surfactant. This conclusion is in accord with observations by Wurster and Seitz (12), who have found that dissolution of pellets with artificial pores is more rapid when the dissolution medium contains sodium lauryl sulfate, due mainly to better contact between solvent and the drug surface. Since sodium lauryl sulfate has excellent tablet lubricating activity (6), its use for this purpose appears advantageous, except where specific incompatibility or stability problems are present.

Of interest is a recent case where the addition of a surfactant to a tablet formulation resulted in better absorption of the drug (14). This was attributed first to a physiologic effect of the surfactant (an unlikely possibility because of the small amount of surfactant involved), but subsequent studies revealed that this was a dosage form effect (15, 16). It is apparent from the results of the present study that a surfactant can enhance the dissolution rate of drugs contained in compressed tablets and thereby cause them to be more rapidly and more completely absorbed.

CONCLUSIONS

It may be concluded from the results of this investigation that hydrophobic tablet lubricants can retard the dissolution of drugs from compressed tablets. The magnitude of this effect may be expected to depend, among other factors, upon the particular lubricant, its concentration, its particle size, the drug, the tablet formulation, various processing variables, and the conditions (particularly with respect to agitation intensity) under which dissolution is taking place. Hydrophilic lubricants apparently do not retard dissolution[3] and, if they have surface-tension lowering capability, may enhance the rate of dissolution of drugs contained in compressed tablets.

[3] This statement is made with the qualification that surfactants can retard dissolution in certain systems because of their adsorption on the surface of the dissolving substance (17) or possibly by facilitating particle aggregation (18). However, it is felt that these effects would not be important with compressed tablets containing very small amounts of a surface active lubricant.

Mechanism of Sustained-Action Medication

Theoretical Analysis of Rate of Release of Solid Drugs Dispersed in Solid Matrices

By T. HIGUCHI

Theoretically expected rates of release of solid drugs incorporated into solid matrices have been derived for several model systems. Mathematical relations have been obtained for cases (a) where the drug particles are dispersed in a homogeneous, uniform matrix which acts as the diffusional medium and (b) where the drug particles are incorporated in an essentially granular matrix and released by the leaching action of the penetrating solvent. Release from both planar surface and a sphere is considered. The unidimensional release rates are shown to follow our earlier equation derived for release from ointment bases. Release rates from spherical pellets by both model mechanisms are shown not to followfi rst-order relationships. The analyses suggest that for the latter system the time required to release 50 per cent of the drug would normally be expected to be approximately 10 per cent of that required to dissolve the last trace of the solid drug phase in the center of the pellet.

THE PRESENT COMMUNICATION is concerned with the results of a theoretical analysis of mathematical relationships governing the rate of release of solid drugs randomly dispersed in solid matrices. Systems of this type have been widely studied and utilized recently as bases for dosage forms which provide more or less continuous release of medicaments over relatively long periods (1). Both Wiegand and Taylor (2) and Wagner (3) showed that per cent released time data reported in the literature for many sustained-release preparations give linear pseudo (or apparent) first-order rates over the terminal portions of the data from about 0.5 hour to the time the test was completed. The present study is an effort in relating the rate of release of drugs from such systems to the pertinent physical constants based on simple laws of diffusion.

Two geometric systems have been considered: (*a*) unidirectional leaching or extraction from a simple planar surface, and (*b*) three dimensional leaching or extraction from a spherical pellet. This would correspond most closely to the release process from an insoluble tablet matrix or certain sustained-action pellets.

Two mechanisms of release from these systems have been treated. (*a*) Extraction of the medicament by a simple diffusional process through and from an enveloping, homogeneous matrix. The drug is presumed to go successively from the crystal surfaces into the uniform matrix and out into the bathing solvent which in turn acts as a perfect sink. (*b*) Leaching of the medicament by the bathing fluid which is able to enter the drug-matrix phase through pores, cracks, and intergranular spaces. The drug is presumed to dissolve slowly into the permeating fluid phase and to diffuse from the system along the cracks and capillary channels filled with the extracting solvent. Intragranular diffusion is assumed, in this instance, to be insignificant. The two mechanisms are depicted schematically in Fig. 1.

It should be explicitly pointed out that the analyses reported here relate to these particular model systems, whereas the analyses of Wiegand and Taylor (2) and of Wagner (3) related to release data derived from formulated sustained-release or prolonged-action formulations. Actual dosage systems may be complicated by (*a*) simultaneous break-up of the matrix, (*b*) partial dissolution of the matrix substances, (*c*) one fraction of the dose being in a matrix form and the remainder of the dose being in a different, nonmatrix and readily available form, and (*d*) drug on the surface being released more rapidly than drug in the matrix. Where such complications are absent, the treatments under *Theoretical Analysis* are believed to yield the correct relationships.

THEORETICAL ANALYSIS

Release from a Planar System Having a Homogeneous Matrix.—The amount of total drug released from such a system into a bathing medium acting essentially as a perfect sink would be determined by the relationship

$$Q = \sqrt{Dt(2A - C_s)C_s} \qquad \text{(Eq. 1)}$$

where Q = the amount of drug released after time t per unit exposed area, D = the diffusitivity of the drug in the homogeneous matrix media, A = the total amount of drug present in the matrix per unit volume, and C_s = the solubility of the drug in the

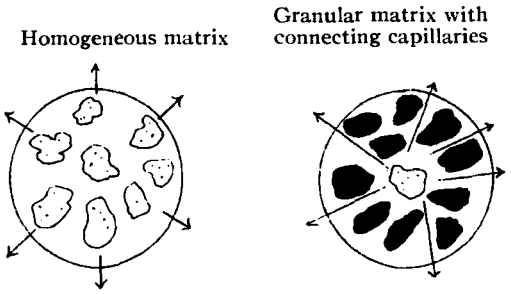

Fig. 1.—Two methods of drug release from the pellets.

matrix substance. We initially derived this equation for release from an ointment base containing finely dispersed drugs (4), but it is evident that it would be equally applicable for release from a sustained-action matrix of this type.

Release from a Planar System Having a Granular Matrix.—For the leaching type release mechanism occurring through diffusion movement utilizing intergranular openings, the above relation must be modified for the effective volume where diffusion can occur and the effective diffusional path. It can readily be seen for this system that

$$Q = \sqrt{\frac{D\epsilon}{\tau}(2A - \epsilon C_s)C_s t} \qquad \text{(Eq. 2)}$$

where Q = the amount of drug released after time t per unit exposed area, D = the diffusitivity of the drug in the permeating fluid, τ = the tortuosity factor of the capillary system $\geqq 3$, A = the total amount of drug present in the matrix per unit volume, C_s = the solubility of the drug in the permeating fluid, and ϵ = the porosity of the matrix.

The derivation of the above expression is essentially the same as Eq. 1, except that the cross-sectional area of the diffusional path must be reduced by the porosity factor ϵ, and the apparent solubility of the drug in the total system per unit volume must also be decreased by the same factor. The tortuosity factor, τ, is introduced to correct, in the same sense used in the classical Kozeny equation, for the lengthened diffusional path caused by the necessary lateral excursions.

For both equations the derivation (4) is based on the existence of a pseudo steady state condition during the release process and on the assumption that the drug particles are quite small relative to the average distance of diffusion and are uniformly distributed in the matrix. The equations would be essentially valid for systems in which A is greater than C_s or ϵC_s by a factor of three or four. Of course, if $A < C_s$ or ϵC_s, the drug would no longer be present as a solid and a different equation would apply.

Since the porosity factor in Eq. 2 refers, of course, to the porosity of the leached portion of the pellet, it differs from the initial porosity of the initially formed matrix. The difference would correspond directly to the volume of free space previously occupied by the extracted component or components. Thus

$$\epsilon = \epsilon_o + KA$$

for systems where the drug is the only extractable component, K being introduced to convert A to its corresponding volume fraction. K is equal to the specific volume of the drug = 1/(density of the drug) if A is expressed in terms of grams of drug per milliliter. For those instances where the initial porosity, ϵ_o, is very small or where the fraction of the matrix volume occupied by the drug is relatively large $\epsilon \cong KA$ and Eq. 2 reduces to $Q = A\sqrt{DK/\tau(2 - KC_s)C_s t}$. Thus for these systems it would appear that the fraction of the drug released at anytime is essentially independent of A.

Release from a Spherical Pellet Having a Homogeneous Matrix.—Any attempt to derive an exact solution for a system of this type is, of course, impossible since it would require an exact coordinate description of the distribution pattern of the dispersed particles. A reasonably accurate and useful mathematical solution can be based on the same assumption which permitted solution of the two-dimensional system. We can again assume for the case $A \gg C_s$ that a pseudo steady state condition would exist during the leaching or extraction process and that a sharp front will be formed between the partly leached or extracted part of the sphere and the untouched portion. This state of affairs is shown in Fig. 2 where a_o = the radius of the whole pellet, a' = the radius of that part still unextracted, and a = the polar radius of any region under consideration, and the remaining symbols are the same as before.

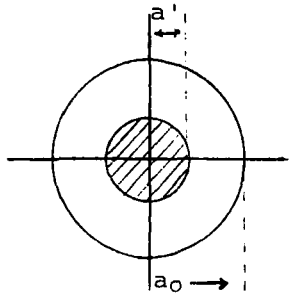

Fig. 2.—Schematic diagram of drug distribution in a partly extracted pellet.

It is evident in such a system that the concentration gradient is essentially zero for $a < a'$. The concentration in the region between a' and a_o will be a function of a and is assumed to be that fixed by Fick's first law.

Under pseudo steady state conditions as described above the total amount of material, SdQ, being released per unit time, dt, will be given by Fick's first law as

$$\frac{SdQ}{dt} = -4\pi a^2 D\frac{dC}{da} \qquad \text{(Eq. 3)}$$

where S is the diffusional area for $a' \leqq a \leqq a_o$. Integrating this from a to a_o we obtain

$$\left(\frac{SdQ}{dt}\right)_t\left(\frac{1}{a} - \frac{1}{a_o}\right) = 4\pi DC_a$$

where C_a = concentration at a or

$$\left(\frac{SdQ}{dt}\right)_t = \frac{4\pi DC_a}{\left(\frac{1}{a} - \frac{1}{a_o}\right)} = \frac{4\pi DC_s}{\left(\frac{1}{a'} - \frac{1}{a_o}\right)} \qquad \text{(Eq. 4)}$$

since $C_a = C_s$ at $a = a'$ and $C_a = 0$ at $a = a_o$ and

$$C_a = C_s \frac{a'}{a} \frac{(a_o - a)}{(a_o - a')} \quad \text{(Eq. 5)}$$

an expression which relates concentration to a in the region $a' < a < a_o$.

It is apparent that the total amount of the drug contained by the pellet at time = t is the sum of that in the unleached portion ($a < a'$) and that in the region no longer saturated with the drug ($a' < a < a_o$). Or the total residual amount of drug equals

$$\frac{4}{3}a'^3\pi A + \int_{a'}^{a_o} 4\pi a^2 C_a da \quad \text{(Eq. 6)}$$

$$= \frac{4}{3}\pi a'^3 A + \int_{a'}^{a_o} 4\pi a^2 C_s \frac{a'}{a}\frac{(a_o - a)}{(a_o - a')} da$$

$$= \frac{4}{3}\pi a'^3 A + \frac{4}{6}\pi C_s \frac{a'}{a_o - a'}(a_o^3 - 3a_o a'^2 + 2a'^3)$$

$$= 4\pi\left[\frac{a'^3}{3}A + \frac{C_s}{6}a'(a_o^2 + a'a_o - 2a'^2)\right] \quad \text{(Eq. 7)}$$

The change in the residual drug concentration corresponding to a change $-da'$ would then be

$$= 4\pi\left[Aa'^2 + \frac{C_s}{6}(a_o^2 + 2a'a_o - 6a'^2)\right](-da') \quad \text{(Eq. 8)}$$

This should in turn be equal but opposite in sign to the total flux over the period involved

$$\left(\frac{SdQ}{dt}\right)dt = \frac{4\pi DC_s}{\left(\frac{1}{a'} - \frac{1}{a_o}\right)}dt =$$

$$4\pi\left[Aa'^2 + \frac{C_s}{6}(a_o^2 + 2a'a_o - 6a'^2)\right]da'$$

$$DC_s dt = \left(\frac{a_o - a'}{a_o a'}\right)\left[Aa'^2 + \frac{C_s}{6}(a_o^2 + 2a'a_o - 6a'^2)\right]da' \quad \text{(Eq. 9)}$$

Integrating from a_o to a' we obtain

$$A(a_o^3 + 2a'^3 - 3a_o a'^2) +$$

$$C_s\left(4a'^2 a_o + a_o^3 \ln\frac{a_o}{a'} - a_o^3 - a_o^2 a' - 2a'^3\right) = 6DC_s a_o t \quad \text{(Eq. 10)}$$

For $C_s \ll A$ the above reduces to

$$a_o^3 - 3a'^2 a_o + 2a'^3 = \frac{6a_o}{A}DC_s t \quad \text{(Eq. 11)}$$

Equation 10 represents a general solution to the proposed problem since it permits determination of a' as a function of time, t, if the constants of the system, a_o, A, C_s, and D are known. Since the residual amount of drug at any time is already expressed by Eq. 7 in terms again of a', the total amount of drug released as a function of time can be readily calculated. Since any attempt to convert Eq. 10 into an explicit solution for a' as a function of t would result in a cumbersome relationship, it is more feasible in practice to obtain t as a function of a' and the amount of release also as a function of a' from Eq. 7 and then correlate the two dependent variables.

A general solution to Eq. 11 can be obtained in this implicit manner. For this it is more convenient to transform Eq. 11 into a dimensionless relationship

$$1 - 3\left(\frac{a'}{a_o}\right)^2 2\left(\frac{a'}{a_o}\right)^3 = \frac{6DC_s}{Aa_o^2}t = BT \quad \text{(Eq. 12)}$$

In this form the left hand expression in terms of a'/a_o is dimensionless and is independent of any units of measure employed. The factor, $B = 6DC_s/Aa_o^2$ is dimensionless except for time and can be calculated from the constants of the system. Since the fraction of drug remaining in the pellet for this system where $A \gg C_s$ would be

$$\text{Residual fraction of drug in pellet} = \left(\frac{a'}{a_o}\right)^3 \quad \text{(Eq. 13)}$$

we can readily prepare a plot of the residual fraction remaining in the pellet as a function of relative time. Actual time unit can be substituted in real systems where the constants comprising B are determinable. The results are shown for different (a'/a_o) values in Table I and are plotted in Fig. 3. It is evident

TABLE I.—CALCULATION OF RELEASE RATE FROM SPHERICAL PELLET $A \gg C_s$[a]

Time Scale		Drug Remaining (%) in Pellet

[a] Equation 11.

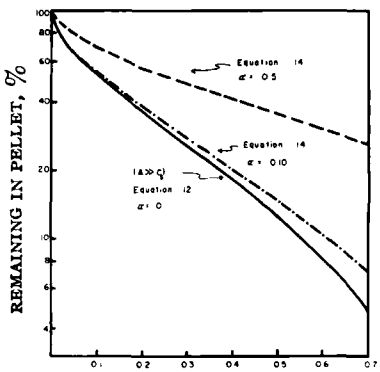

Fig. 3.—Influence of $\alpha = C_s/A$ values on rate of release.

from the table that the physical significance of B is that for the case $A \gg C_s$ its reciprocal corresponds to that time when the last trace of the solid drug dissolves into the matrix. Under these conditions the pellet can be considered to be totally exhausted. Also from the table it is apparent that the drug is very rapidly released at the beginning, approximately 50% of it being released at $t = 0.1 \times 1/B$.

The values shown in Table I have been plotted in Fig. 3 in the usual semilogarithmic fashion to show that the release rate predicted by this mechanism departs significantly from the first-order behavior. Aside from what appears to be a large initial surge of release, however, the plot yields a surprisingly linear relationship over a relatively wide range. This seems to arise from the fact that it is actually sigmoidal in nature and the apparent linear relationship observed (2, 3) may for some system be coincidental and for others be because of different overall mechanism.

In Fig. 4 the fraction of drug released from a sphere calculated from Eq. 11 is compared to that expected from Eq. 1 on the basis that the total exposed surface is $4\pi a_o^2$. The plot has been made as a function of $(Bt)^{1/2}$ since this affords a linear relationship for the two-dimensional system. It is evident that at the beginning the two equations predict a similar extent of release, as expected, since a plane of the same area would be a good approximation for the sphere in this phase. It is only beyond 50% release that significant deviation is evident between the two equations.

The more general Eq. 10 which takes into account the amount of drug remaining in the partly extracted region can be solved in an identical manner based on Eqs. 7 and 10. Setting $C_s = \alpha A$ and rearranging Eq. 10 we obtain

$$1 + 2\left(\frac{a'}{a_o}\right)^3 - 3\left(\frac{a'}{a_o}\right)^2 + \alpha\left[4\left(\frac{a'}{a_o}\right)^2 + ln\,\frac{a_o}{a'} - \frac{a'}{a_o} - 2\left(\frac{a'}{a_o}\right)^3 - 1\right] = \frac{6DC_st}{Aa_o^2}$$

or

$$1 - \alpha + 2(1-\alpha)\left(\frac{a'}{a_o}\right)^3 - (3 - 4\alpha)\left(\frac{a'}{a_o}\right)^2 - \alpha\left(\frac{a'}{a_o}\right) + \alpha\, ln\,\frac{a_o}{a'} = \frac{6DC_st}{Aa_o^2} \quad \text{(Eq. 14)}$$

Release behavior predicted by this equation for several values of α are also shown in Fig. 3. Residual fraction in these instances based on Eq. 7 would be

$$\text{Residual Fraction} = \left(\frac{a'}{a_o}\right)^3 + \frac{\alpha}{2}\left[\left(\frac{a'}{a_o}\right) + \left(\frac{a'}{a_o}\right)^2 - 2\left(\frac{a'}{a_o}\right)^3\right] \quad \text{(Eq. 15)}$$

Since in most real systems α is usually very small, any term containing it as a factor can normally be ignored.

Plots shown in Fig. 3 are, in a sense, universal relationships in that they permit estimation of the release behavior for all systems for given α values. They indicate that the relative release rates (*i.e.*, the fraction released per unit time) from pellets of this type would be inversely proportional to the square of the radius of the pellet and the drug concentration but directly proportional to the solubility and the diffusitivity of the drug. The plot shown for $\alpha = 0.5$ is less valid than the others since the assumed pseudo steady state condition requires A to be significantly larger than C_s. Actually α must be considerably smaller for the spherical three-dimensional system for the steady state situation to exist than for the planar system. This is especially true for higher states of depletion.

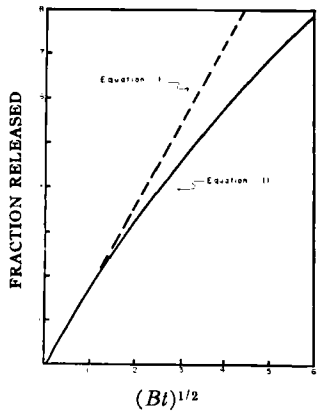

Fig. 4.—Comparison of Eqs. 1 and 11.

Release by Leaching from Granular Spherical Pellet.—The solution to the rate of leaching by external solvent (*e.g.*, gastric fluid) of solid drugs uniformly dispersed in granular spherical pellets can be developed exactly as in the preceeding case. It is evident that the dimensionless expression corresponding to Eq. 14 will take the form

$$(1-\alpha) + 2\left(\frac{a'}{a_o}\right)^3(1-\alpha) - \left(\frac{a'}{a_o}\right)^2(3 - 4\alpha) - \alpha\left(\frac{a'}{a_o}\right) + \alpha\, ln\left(\frac{a_o}{a'}\right) = \frac{6D\epsilon C_st}{\tau Aa_o^2} \quad \text{(Eq. 16)}$$

where $\alpha = \epsilon C_s/A$ and $\epsilon = \epsilon_o + KA$, and the remaining symbols the same meanings as before with D being the diffusitivity in the solvent. If as in the two-dimensional case we take the initial porosity, ϵ_o, as being negligible we obtain

$$(1-\alpha) + 2\left(\frac{a'}{a_o}\right)^3(1-\alpha) - \left(\frac{a'}{a_o}\right)^2(3 - 4\alpha) - \alpha\left(\frac{a'}{a_o}\right) + \alpha\, ln\left(\frac{a_o}{a'}\right) = \frac{6DKC_st}{\tau a_o^2}$$

For $\alpha \ll 1$, this reduces to

$$1 + 2\left(\frac{a'}{a_o}\right)^3 - 3\left(\frac{a'}{a_o}\right)^2 + \frac{6DKC_st}{\tau a_o^2} \quad \text{(Eq. 17)}$$

where the residual fraction $= (a'/a_o)^3$.

In these analyses it has been tacitly assumed that the time of extraction begins with the slightly porous pellet already permeated by the extracting solution. Since in practice such pellets (or "cores") will be taken dry there will be a short lag time corresponding to that required to wet the interior of the matrix. This time, however, should normally be relatively small compared to the duration of action of such medications.

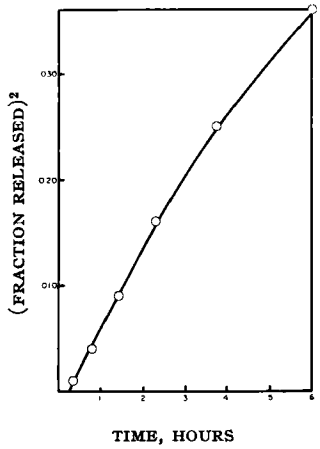

Fig. 5.—Comparison of Simoons' experimental data (5) with Eq. 17.

GENERAL DISCUSSION

The several solutions to the release behavior of the systems considered are believed to be essentially exact for the models employed. Experimental data available appear to substantiate these analyses (5).

In real systems, however, a number of other factors may come into play which may modify the total behavior. The models employed assume that the systems are neither surface coated, nor that their matrices undergo significant alteration in the presence of moisture. Since in real systems these play varying roles in modifying the release pattern of sustained-action dosage forms, any attempt to apply these equations must be made with this in mind.

Other serious deviations from the derived relationship may occur for systems which tend to differ significantly from the adopted models. For example, for pellets containing a relatively high percentage of drugs the leaching process would tend to weaken the matrix structure and produce erosion. This may play a significant role in altering the observed real rate. Another effect which is not considered in these treatments is the influence of solvent flow induced within the pellets by external agitation. This effect, however, will be important only with pellets of relatively high porosity.

In Fig. 5 data reported by Simoons in his interesting paper on experimental measurements of release rate of sustained-action medication (6) for relatively insoluble drug hard compressed (his Fig. 15) are plotted in the form of square of fraction released against extraction time. The extraction data show a short lag time probably corresponding to that required to wet the pellets. This is followed by a release pattern closely matching that predicted by Eq. 17, the smooth line representing the theoretical values and the points, the experimentally observed values reported by Simoons. The total theoretical curve was based on experimentally observed time for 50% release and the initial lag time.

Dielectric Constants of Complex Pharmaceutical Solvent Systems I

Water-Ethanol-Glycerin and Water-Ethanol-Propylene Glycol

By D. L. SORBY, R. G. BITTER, and J. G. WEBB

Dielectric constants of water-ethanol-glycerin and water-ethanol-propylene glycol systems have been experimentally determined. The measured values were found to differ from values calculated according to simplification of the Onsager-Kirkwood equation, regardless of whether composition of the various solutions was expressed on the basis of weight percentage or volume percentage. Dielectric constant values presented in this paper are recommended for precise adjustment of solvent polarity in formulation work and data are presented to be of maximum use in this respect.

MOORE (1) HAS PRESENTED a method wherein manipulation of solvent dielectric constant is utilized to produce dissolution of a solute at a desired concentration and to blend pharmaceutical solvents to a predetermined degree of polarity. In this method, certain simplifying assumptions are made, one being that the dielectric constant of a complex solvent mixture may be calculated to a good approximation by taking the sum of the products of volume composition and dielectric constant for each individual component in the mixture. This method of calculating dielectric constants of complex mixtures is based on a simplification of the Onsager-Kirkwood

equation and would theoretically be correct only if the mixture of substances exhibited properties of an ideal solution. Since most common pharmaceutical solvent systems are composed of substances which exhibit a high degree of intermolecular association and are seldom ideal in their behavior, dielectric constants of such systems would not usually be expected to be a simple additive function of the concentrations of the components as described above. In these situations, the method of obtaining the dielectric constant by calculation would be expected to give only rough approximations of the true value for the solvent mixture in question. It was also stated (1) that while more precise work would require that compositions of the solvent mixtures be stated on the basis of weight per cent, volume compositions could be substituted in the calculations for convenience in formulation work. It was implied that as a result of expressing concentration on a volume percentage basis, the calculated values would not be as precise as when weight per cent had been used.

Decroocq and Jungers (2), however, have presented data showing that if concentrations of the individual components are expressed on the basis of volume percentage when using the simplified form of the Onsager-Kirkwood equation described above, agreement between experimental and calculated dielectric constants is better than when concentrations are expressed on the basis of mole fraction. From results of studies on binary mixtures exhibiting ideal or nearly ideal behavior, Decroocq and Jungers estimated that calculated values would usually be within 1% of experimental values when volume percentage is used as the concentration variable. Their report also presented data showing large deviations between experimental and calculated dielectric constants when the binary solutions studied were non-ideal in their behavior.

Thus one might expect that use of volume per-

centage in these calculations should not produce less precise results than when alternative methods, such as weight per cent or mole fraction, are used for expressing concentrations of the various components of a system.

In actual practice, precise values of dielectric constants of complex, multi-component solutions can best be obtained by direct experimental measurement. The scientific literature contains much data pertaining to dielectric constants of binary mixtures, *e. g.*, (2–5), but little information concerning the more complex mixtures utilized in pharmaceutical formulations. The objectives of this research were to (*a*) determine relationships existing between dielectric constant and composition experimentally in two common pharmaceutical solvent systems, water-ethanol-glycerin and water-ethanol-propylene glycol, (*b*) determine the accuracy of calculated dielectric constants and the method of expressing compositions (weight percentage, or volume percentage) producing the better agreement between experimental and calculated values for these complex systems. Information of this type would be useful for precise adjustment of solvent polarity in pharmaceutical formulation work and, in addition, would be of potential interest to various types of physicochemical investigations of the behavior of these complex non-ideal systems.

EXPERIMENTAL

Materials and Reagents.—Since data were desired for systems actually encountered in pharmaceutical formulation practice, the materials used in this study were of commercially available grades. The following materials were used without further purification; ethanol, 92.3% w/w; propylene glycol, 99.5% w/w; and glycerin, 95.0% w/w. Distilled water was used in preparing all samples.

Acetone, reagent grade, was distilled over calcium chloride and stored, protected from atmospheric moisture, until needed for calibrating the instrument used to measure dielectric constants of the test mixtures.

Preparation of Test Samples and Collection of Data.—Sets of test mixtures were prepared so that in a given set all samples contained the same ratio of ethanol to glycerin or ethanol to propylene glycol. The water content of mixtures in each set was varied throughout a range of concentration, usually including samples containing 20, 40, 60, and 80% by weight of water. The amount of water present in the stock solutions of ethanol, propylene glycol, and glycerin was taken into consideration in all calculations of solvent composition. Duplicates were prepared of each different sample.

The required amount of each ingredient needed to make a 100-Gm. quantity of sample was weighed with an accuracy of ±0.05 Gm. into glass-stoppered Pyrex bottles. The bottles were then immersed in a constant temperature bath at 25.0°. When thermal equilibrium was established, the specific gravity of each sample was determined by the pycnometer method using water at 25.0° as the reference solution. The remainder of the sample was returned in the thermostat until measurement of the dielectric constant was performed.

Dielectric constants of the test mixtures were determined with a Sargent, model V, chemical oscillometer standardized with water-acetone mixtures of known dielectric constant (6). Approximately 10 ml. of the test sample was pipetted into

the test cell of the oscillometer and the scale reading recorded. This measurement was made in duplicate for each sample, the test cell being cleaned and dried between each reading. The dielectric constant for each test mixture was obtained by comparing the scale reading on the oscillometer to a standard curve constructed by plotting dielectric constant against scale reading for the water-acetone standards described above.

Specific gravity and dielectric constant values determined for the various samples in the two systems of solvents tested are given in Tables I and II.

Treatment of Data.—Plots of dielectric constant *versus* weight per cent water were made for each set of samples having the same constant ratio of ethanol to glycerin or ethanol to propylene glycol. Water concentrations which theoretically would have been needed to produce samples having dielectric constant values of 70, 60, 50, etc., in each set were determined from curves drawn through points representing the experimental data. The amount of ethanol and glycerin or propylene glycol in each hypothetical sample was determined from a knowledge of their ratio in the sample and the difference between the per cent water and 100%. These derived solvent compositions (Tables III and IV) were plotted on a ternary diagram and tie lines were drawn which best fitted all points representing solutions expected to exhibit the same dielectric constant (Figs. 1 and 2). The per cent by volume compositions of the test samples were calculated by the usual methods from knowledge of their weight per cent compositions and experimentally determined specific gravities. Solutions theoretically giving dielectric constants of 70, 60, 50, etc., were determined graphically and plotted on ternary diagrams as described above (Figs. 3 and 4). The values derived from the experimental data and used to prepare Figs. 3 and 4 are summarized in Tables V and VI.

Dielectric constants measured for solutions of compositions given by points picked at random from the curves in Figs. 1–4 verified the accuracy of these curves as being within ±0.5 units of the dielectric constant specified for the given curve.

DISCUSSION

In Figs. 1 and 2, dielectric constants have been plotted as a function of both calculated and experimentally determined solvent composition. It is apparent that rather large deviations exist between theoretical and experimental values. In addition, dielectric constant is not in most cases in these systems a linear function of the weight composition. These deviations are not unexpected when one considers the strong tendencies for interaction between the molecular species involved. While data for other ternary solvent systems are lacking in the scientific literature, deviations of this magnitude are found when calculated values of dielectric constants are compared with data of other investigators (3, 5) for water-ethanol and water-glycerin systems. Values of dielectric constants reported in the literature (3, 5) are in general good agreement with the values reported here, considering differences in methodology and sample purity.

Results shown in Figs. 3 and 4 indicate that curves relating dielectric constant and volume composition of samples are linear, although agreement between experimental and calculated values is poor, except in the solutions where dielectric constants equal 40 and 50. Moore (1) noted that deviations of dielectric constant from the direct proportionality predicted by mathematical computation should be more pronounced as polarity of the mixtures increases. Such is indeed the case in the two systems studied. The nature of the curves does indicate that dielectric constants in these systems are apparently some type of linear function of the concentration of the various components expressed on a volume basis; however, because of the various complexities of these systems, no simple relationship appears to exist between dielectric constants of the mixtures and those of the pure components which would allow computation by the simplified form of the Onsager-Kirkwood equation. There seems to be no major advantage to expressing concentrations on a weight basis; in fact, use of volume percentage appears to be of some benefit in regard to ease of fitting curves through the experimental points.

It has been our experience that the dielectric constant principle of blending solvent systems as outlined by Moore (1) sometimes fails to produce the desired results when used in actual practice. It is quite possible that some of these failures have been because of the large differences which can occur between calculated and actual dielectric constant values in these complex systems. We hope that the dielectric constant–composition relationships obtained as a result of our investigation can serve to place this useful technique of solvent blending on a more reliable basis. Experimental determinations of dielectric constants of other pharmaceutical systems and other important aspects of the relationships between solubility and dielectric constants are being continued and will be reported at a later date.

Preliminary Identification of the Antibacterial Principle "Madronin" from the Leaves of *Arbutus menziesii*

By BALACHANDRA KABADI and E. ROY HAMMARLUND

The antibacterially active compound "madronin" from the leaves of Pacific Madrona tree has been tentatively identified as a mixture of gallotannin and catechol tannin in addition to varying amounts of their degradation products, gallic acid, m-digallic acid, possibly trigallic acid, catechol, phloroglucinol, and glucose. Experimental evidence includes results of qualitative physical and chemical analyses, light absorption, paper chromatography, and microbiological fermentation tests. A simple modified laboratory extraction and purification procedure for the active principle is given. The previous observations made on madronin are explained according to its newly determined composition. Since tannin has been shown to be a rather potent antibacterial substance for many micro-organisms, its possible influence upon the various surveys for antibacterial agents in higher plants should be considered.

In 1952 HAMMARLUND, Pennington, and Rising (1) reported that the leaves of the Pacific Madrona tree (*Arbutus menziesii* Pursh., family *Ericaceae*) contained one or more antibacterial substances which were active *in vitro* mainly against Gram-positive and acid-fast bacteria. Their studies indicated the presence of several substances having similar chemical and antibacterial activities and the name "madronin" was given to the crude mixture of the active material (1, 2).

This current investigation was undertaken to characterize further and identify chemically the antibacterial principle by employing various improvements in the extraction and purification procedures.

Since light absorption studies made in this current investigation and most of the earlier qualitative tests indicated that madronin was probably a tannin although a few chemical tests reported earlier gave doubtful reactions for the presence of phenolic groups (1), numerous comparison tests were conducted with such substances as tannic acid N.F. (from *Quercus infectoria*), gallotannin (from *Rhus senialita*), and polyhydroxy phenolic compounds.

The active antibacterial substance prepared by using the present modified extraction and purification procedure, which is similar to that routinely used (3) for the preparation of tannins, is referred to in this presentation as "purified" madronin.

Received March 6, 1963, from the College of Pharmacy, University of Washington, Seattle.

Accepted for publication May 8, 1963.

This investigation was supported in part by funds provided for biological and medical research by the State of Washington Initiative Measure No. 171 and in part by Research Grant A1-04687-01 from the National Institute of Allergy and Infectious Diseases, U. S. Public Health Service, Bethesda, Md.

Abstracted from a thesis submitted by Balachandra Kabadi to the Graduate School, University of Washington, Seattle, in partial fulfillment of Master of Science degree requirements.

EXPERIMENTAL METHODS AND RESULTS

Modified Extraction Procedure.—Fresh leaves and stems were dried in a circulating hot air oven at 45° for about 48 hours. Six-hundred grams of the dried leaves were powdered and were repeatedly extracted in a Waring Blendor with 5 L. of distilled water. The aqueous extract was centrifuged, filtered, and dried under reduced pressure. The dried aqueous extract, weighing about 44 Gm., was repeatedly extracted in a large centrifuge tube by stirring with acetone in which sugar and other nonactive constituents were insoluble. The clear acetone solution was decanted following centrifugation and evaporated to dryness under reduced pressure. This yielded approximately 6.5 Gm. of material.

The residue from the acetone extract was dissolved in a minimal amount of water and filtered. This aqueous solution (approximately pH 3.7) was repeatedly extracted with ethyl ether to remove the coloring matter and gallic acid. To the aqueous solution 0.33 *M* phosphate buffer was added to raise the pH to 6.8, and the solution was extracted in several portions with 1 L. of ethyl acetate. The combined ethyl acetate solutions were air-dried and yielded about 4 Gm. of dried, antibacterially active residue.

Finally, the dried residue was dissolved in a minimal amount of water (approximately 15 ml.) and added to a 1 in. by 2-ft. chromatographic adsorption column packed with standard cellulose powder[1] prepared from a slurry in *n*-butanol (4). The chromatographic column was developed by the further addition of *n*-butanol, whereupon two colored bands formed. The lower band was eluted with *n*-butanol; the effluent was evaporated under reduced pressure and gave about 3.5 Gm. of yellow residue. The top purple band, which did not move with the butanol solvent, was eluted with water and rejected because it was antibacterially inactive.

The dried residue from the butanol effluent was dissolved in a minimal amount of acetone and poured slowly into 500 ml. of ethyl ether. A resultant white precipitate was filtered off and then immediately dried under reduced pressure. This was designated as "purified" madronin.

TABLE I.—ANTIBACTERIAL ACTION OF MADRONIN AND RELATED SUBSTANCES

Test Compd.	Minimal Inhibition Concn., mcg. per ml. of the Medium
Madronin	4.5 to 5.0
"Purified" madronin	3.3 to 4.3
Tannic acid N.F.	2.5
Gallotannin[a]	4.9
Gallic acid[b]	11.6

[a] Gallotannin extracted from Chinese galls using 85% ethanol and dried under reduced pressure. [b] Mallinckrodt Chemical Works, New York, N. Y.

Antibacterial Study.—Tests made for the determination of the antibacterial activity of "purified" madronin and related substances were similar to those of Hammarlund, *et al.* (1). These tests were a quantitative serial dilution method for determining the minimal inhibitory concentration and a qualitative filter paper disk diffusion agar plate method for the qualitative detection of the antibacterial substances. The test organism was *Staphylococcus albus* C_{87},[2] and the media used for the serial dilution tests and agar plates was identical with that previously reported (1). The antibacterial activity of madronin, "purified" madronin, and related substances is recorded in Table I.

Qualitative Analyses of Antibacterial Principle.—The following chemical reactions which are generally characteristic of tannins were given by both the aqueous madronin and "purified" madronin solutions. Madronin formed a precipitate with gelatin, albumin, or starch (5). Madronin and tannic acid N.F. exhibited identical tanning properties with the Goldbeater's skin test using fresh untanned cowhide (3). Madronin gave a bluish-green color with ferric chloride and ferric alum solutions. Madronin was precipitated by salts of the heavy metals of copper, mercury, silver, and lead. Madronin gave a positive Sanio-bichromate test. Madronin precipitated with the alkaloids or alkaloidal salts of atropine, berberine, brucine, caffeine, cinchonidine, cinchonine, hydrastine, and strychnine (3). It formed a precipitate with the organic bases pyridine and phenazone (6).

The following tests indicated the presence of a gallotannin and a catechol tannin. The formaldehyde test (7) gave the characteristic pink fluffy precipitate of a catechol tannin and upon the addition of solutions of ferrous hydroxide and sodium acetate the filtrate became violet, which further indicated the presence of gallotannin. When madronin was heated above 210° for 30 minutes, a gas evolved and a sublimate formed on the sides of the vessel. The gas gave a white precipitate when passed through lime water and the sublimate turned red with ferric chloride solution and blue with ferrous sulfate solution. These tests on the sublimate as well as a paper chromatogram indicated the presence of pyrogallol, resulting from the gallic acid of gallotannin. A precipitate formed upon the addition of ammonium sulfide and ammonium molybdate, which are positive tests for gallotannin. Likewise, madronin precipitated with bromine water, which is positive for catechol tannin. The precipitate which formed upon the addition of lead acetate solution was soluble in acetic acid; this is characteristic of a catechol tannin. Madronin gave a positive phlobaphene test (8), indicating the presence of catechol tannin. The pine wood test (lignin reaction) gave the characteristic pink (7), indicating the presence of phloroglucinol from catechol tannin.

Ultraviolet Absorption.—Although madronin was thought to be a mixture of several substances instead of a pure substance, its absorption spectra were examined for characteristic features and were compared to those of tannic acid N.F. The ultraviolet absorption spectrum of an aqueous solution containing 16 mcg./ml. madronin or tannic acid N.F. was determined from 210 mμ to 350 mμ at various pH from 4–11 using a Cary recording spectrophotometer. Acetate, phosphate, and boric acid–sodium hydroxide–potassium chloride mixtures were used as the corresponding buffer solutions to maintain the desired pH. The same conditions were followed as previously employed by Hammarlund, Pennington, and Rising (1). The positions of the peaks in the spectra obtained for tannic acid N.F. (Fig. 1) were nearly identical at each pH with those previously reported for madronin; however, their magnitudes were greater, as reported by Sohn (9). The only essential difference was the presence of a more distinct absorption peak at 230 mμ for tannic acid N.F. at pH 10. For simplicity in Fig. 1 only the spectra for tannic acid at pH 6, 8, and 10 are given.

Infrared Absorption.—The infrared spectrum of 2 mg. of madronin and "purified" madronin in a 400-mg. KBr pellet was measured with a Beckman infrared recording spectrophotometer (model IR-5A) from 2 μ to 16 μ. The position of the absorption peaks was practically identical to that of an equal quantity of tannic acid N.F. with only insignificant shifts in the peaks as seen in Fig. 2. The infrared absorption spectra for the two madronin samples were identical.

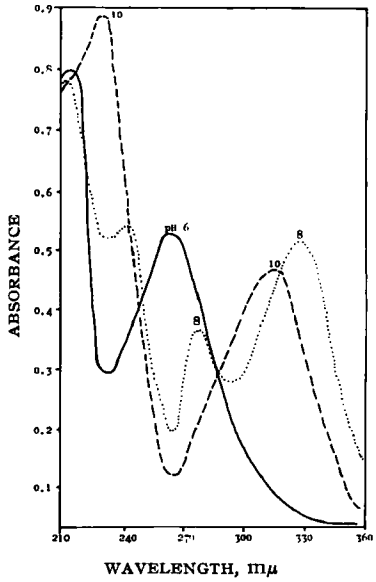

Fig. 1.—Ultraviolet absorption spectrum of tannic acid N.F. at various pH.

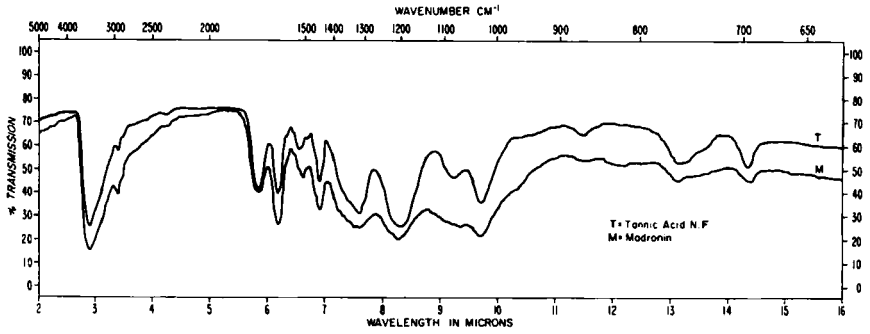

Fig. 2.—Infrared spectra of tannic acid N.F., madronin, and "purified" madronin. (The two madronin spectra are similar.)

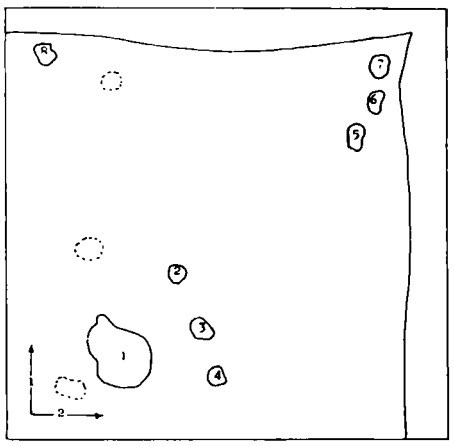

Fig. 3.—Two-dimensional chromatogram of madronin. Solvent system: first direction, 6% acetic acid; second direction, *n*-butanol:acetic acid:water (4:1:5). Reagent: 0.5% ammoniacal silver nitrate in methanol. Identified spots are (solid line): *1*, gallotannin; *2*, gallic acid; *3*, *m*-digallic acid; *4*, trigallic acid; *5*, catechin; *6*, phloroglucinol; *7*, catechol; *8*, glucose.

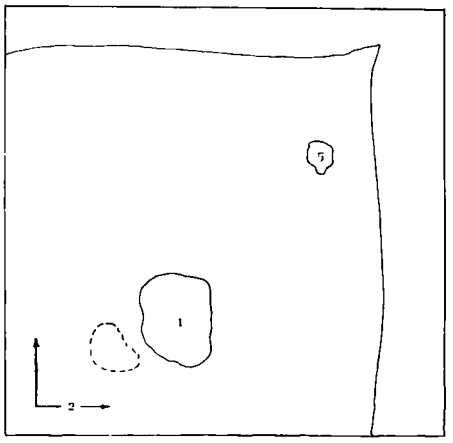

Fig. 4.—Two-dimensional chromatogram of "purified" madronin. Solvent system: first direction, 6% acetic acid; second direction, *n*-butanol:acetic acid:water (4:1:5). Reagent: 0.5% ammoniacal silver nitrate in methanol. Identified spots are: *1*, gallotannin; *5*, catechin.

Paper Chromatography.—The ascending filter paper partition chromatography of madronin using a water-saturated butanol solvent system on Whatman No. 1 paper previously reported by Hammarlund and associates (1) was repeated on tannic acid N.F. under identical conditions. Tannic acid also separated similarly into two antibacterially active spots.

The detailed chromatographic study of madronin and "purified" madronin was conducted on two-dimensional Whatman No. 1 chromatographic sheets, 14 in. square, by using the ascending method (4) and employing 6% acetic acid as the developing solvent in the first direction and *n*-butanol:acetic acid:water (4:1:5) in the second direction. The reagent employed for detecting the position of the spots was 0.5% ammoniacal silver nitrate in methanol (7, 10). The chromatogram of madronin is shown in Fig. 3, and the color of the spots of the various phenolic substances varied from brown to green-brown to blue-black. The following substances in madronin were identified by comparisons of the position and color of their spots with those given by known reagents used singularly or in combination: glucose, gallic acid, phloroglucinol, catechol, catechin, and tannic acid. In the case of gallotannin, *m*-digallic acid, and trigallic acid for which the pure reagents were not readily available, the relative position of the spots in each case were compared with similar chromatograms of tannins reported in the literature (4). This method likewise was used in determining the presence of protocatechuic acid and pyrogallol in the hydrolytic products. The spots encircled by dotted lines remain unidentified. Using the same method a chromatogram of "purified" madronin contained fewer spots (Fig. 4), showing only the presence of gallotannin and possibly catechin.

Hydrolysis of Madronin and Identification of the Hydrolytic Products.—One gram of madronin was acid-hydrolyzed by refluxing in 6% sulfuric acid for 20 hours. A two-dimensional paper chromatogram was made of the filtrate employing the same method described previously. The chromatogram is shown in Fig. 5 and the following spots were identified: gallic acid, catechin, phloroglucinol, catechol, glucose, and protocatechuic acid. A reasonably drastic acid treatment was made to obtain complete hydrolysis.

A 200-mg. sample of madronin was similarly alkali-hydrolyzed by dissolving it in an aqueous 5% sodium hydroxide solution which was shaken at room temperature for a few minutes. The resulting solution was chromatographed as previously described and the following spots were identified as shown in Fig. 6: gallotannin, gallic acid, *m*-digallic acid, trigallic acid, catechin, phloro-

glucinol, catechol, glucose, and protocatechuic acid. Since phloroglucinol and pyrogallol have the same R_f values for the two-dimensional solvents used, it was difficult to prove conclusively whether pyrogallol was there when phloroglucinol was present (10).

One-half gram of "purified" madronin was dissolved in 2% hydrochloric acid and kept at 95° for 1 hour. The resulting solution was then spotted on paper and two-dimensional chromatography was carried out (Fig. 7). By comparison with the chromatogram of "purified" madronin before hydrolysis (Fig. 4) which contained essentially

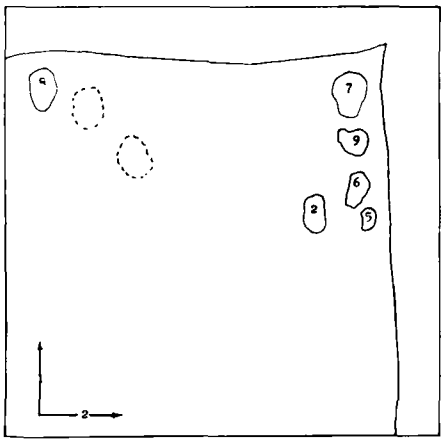

Fig. 5.—Two-dimensional chromatogram of acid-hydrolyzed madronin. Solvent system: first direction, 6% acetic acid; second direction, *n*-butanol:acetic acid:water (4:1:5). Reagent 0.5% ammoniacal silver nitrate in methanol. Identified spots are (solid line): *2*, gallic acid; *5*, catechin; *6*, phloroglucinol; *7*, catechol; *8*, glucose; *9*, protocatechuic acid. Length of hydrolysis: 20 hours with 6% sulfuric acid.

gallotannin and possibly catechin, the following additional hydrolytic products were obtained: gallic acid, *m*-digallic acid, trigallic acid, catechol, protocatechuic acid, and glucose. The hydrolysis was still incomplete because some gallotannin remained. Only a relatively mild acid treatment was required to show that "purified" madronin was hydrolyzable.

DISCUSSION

In the original study by Hammarlund, Pennington, and Rising (1) madronin was reported as being a mixture of unknown antibacterially active compounds. The current study revealed that the active principles were essentially gallotannin and catechol tannin in addition to some of the decomposition products of the tannins and that all of the results and observations made by the previous workers could be interpreted now on the basis of the newly determined composition of madronin.

The antibacterial activity of tannins has been extensively studied (11–16). In this present study madronin possessed slightly less antibacterial activity than tannic acid N.F. This might be due to the presence in madronin of the decomposition products of tannic acid, such as catechol, phloroglucinol, catechin, gallic acid, and glucose in addition to nonhydrolyzed gallotannin and catechol tannin. "Purified" madronin which did not contain the decomposition products showed greater antibacterial activity than did the original madronin but still not quite as much as did tannic acid N.F.

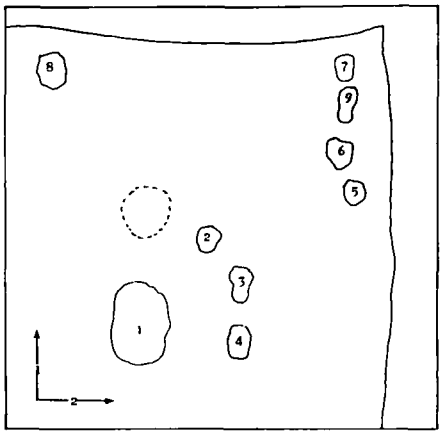

Fig. 6.—Two-dimensional chromatogram of alkali-hydrolyzed madronin. Solvent system: first direction, 6% acetic acid; second direction, *n*-butanol:acetic acid:water (4:1:5). Reagent: 0.5% ammoniacal silver nitrate in methanol. Identified spots are (solid line): *1*, gallotannin; *2*, gallic acid; *3*, *m*-digallic acid; *4*, trigallic acid; *5*, catechin; *6*, phloroglucinol; *7*, catechol; *8*, glucose; *9*, protocatechuic acid. Length of hydrolysis: 2 minutes with 5% sodium hydroxide solution.

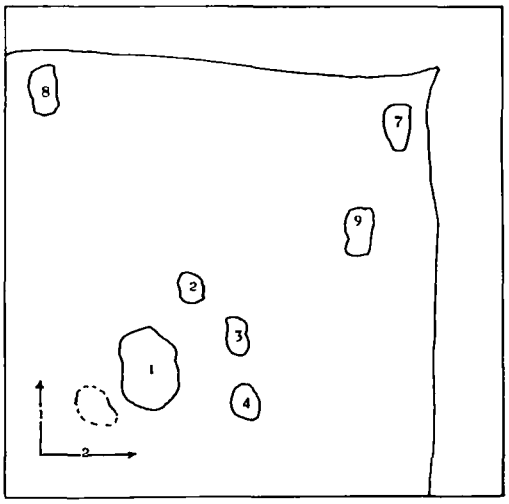

Fig. 7.—Two-dimensional chromatogram of acid-hydrolyzed "purified" madronin. Solvent system: first direction, 6% acetic acid, second direction, *n*-butanol:acetic acid:water (4:1:5). Reagent: 0.5% ammoniacal silver nitrate in methanol. Identified spots are (solid line): *1*, gallotanin; *2*, gallic acid; *3*, *m*-digallic acid; *4*, trigallic acid; *7*, catechol; *8*, glucose; *9*, protocatechuic acid. Length of hydrolysis: 1 hour with 2% hydrochloric acid.

The physical properties of madronin (yellow color, amorphous structure, and decomposition at 200°) are closely parallel to those of tannins. The levorotation of madronin is possibly due to the presence of catechol tannin which masked the usual dextrorotation of gallotannin. The loss of anti-

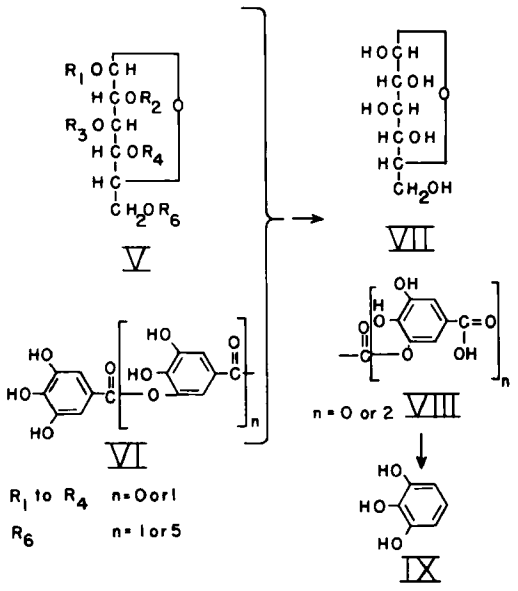

Fig 8—Degradation of gallotannin.

bacterial activity of madronin above pH 7 is due to the fact that tannins are less stable in alkaline solutions (3).

It was largely the fact that the qualitative chemical tests of madronin were similar to the reactions given by the various polyhydroxy phenolic constituents of tannic acid which led to the recognition that madronin was probably a tannin, particularly since no other antibacterial component was found present. Although various polyhydroxy compounds may give some of the individual chemical reactions, all the tests are given only by tannins (5).

The evidence that one of the tannins was gallotannin (V–VI, Fig. 8) was substantiated by the presence of gallic acid (VIII, n = 0) and glucose (VII). Tests for the presence of glucose in madronin, such as Molisch or yeast fermentation, were negative; however, glucose was identified from the hydrolytic products following purification (3) by both chemical and biological tests (positive osazones, Fehling's, Tollen's, yeast fermentation) and by paper chromatographic methods (Figs. 5, 6, and 7). Gallic acid and its decomposition product, pyrogallol (IX), were identified by their characteristic chemical tests and by paper chromatography.

The evidence that a catechol tannin (I, Fig. 9) was also present in madronin was obtained through the following series of reactions—the formation of a bluish-green color with iron compounds, the precipitation with bromine solution and formaldehyde solution, and formation of the red phlobaphene and a positive pine wood test which indicated the presence of phloroglucinol (II, Fig. 9). Finally, the identification by paper chromatography of protocatechuic acid (IV, Fig. 9) among the hydrolytic products of madronin is further evidence for the presence of catechol tannin.

Additional decomposition products of tannins such as catechol (III, Fig. 9), m-digallic acid (VIII, Fig. 8, n = 1), and trigallic acid possibly (VIII, Fig. 8, n = 2) were also identified by paper chromatography (Figs. 5, 6, and 7).

Because all evidence showed madronin to be a mixture of gallotannin and catechol tannin which hydrolyzed readily, the proportion of the various phenolic constituents and other hydrolytic products may vary greatly during extraction and purification. In addition, the normal seasonal variation could influence the concentration of the active tannin principle. Therefore, it is reasonable to assume that the yield of madronin and the antibacterial assays will show large variations depending upon the history of the sample tested.

One of the general observations which has resulted from this study is the reiteration of the importance of tannins as antibacterial substances in higher plants. Because of their natural wide occurrence in plants it is highly probable that in some cases the activity found in the higher plants during the course of the many surveys for antibacterial agents as reviewed recently by Nickell (17) might be due partly or entirely to the presence of tannins. Therefore, if antibacterial activity is found in extracts of higher plants, the extracts should be carefully tested for the presence of tannins.

SUMMARY AND CONCLUSIONS

A simple modified laboratory extraction and purification procedure was developed for the extraction of more antibacterially active madronin than was obtained previously.

Experimental evidence involving studies of light absorption, paper chromatography, qualitative chemical tests, and microbiological fermentation experiments shows that madronin is a mixture of gallotannin and catechol tannin and their various decomposition products of gallic acid, m-digallic

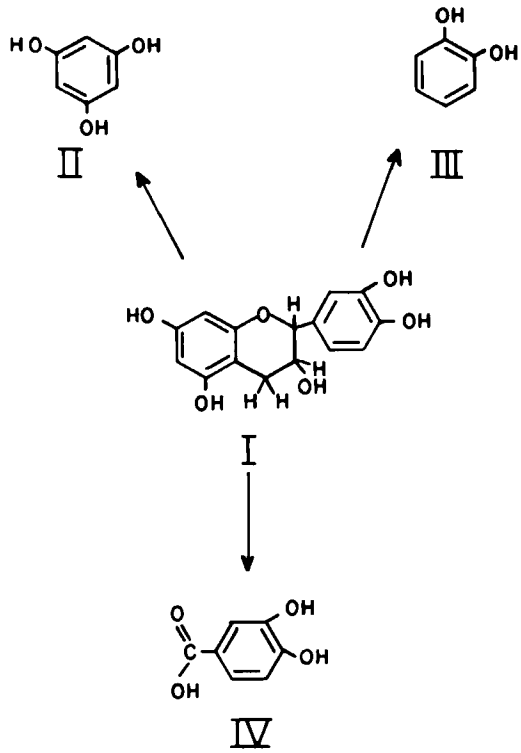

Fig. 9.—Degradation of catechol tannin (catechin).

acid, trigallic acid, catechol, phloroglucinol, and glucose.

Tannin has been shown to be a rather potent antibacterial substance; its possible influence upon the various surveys for the presence of antibacterial agents in higher plants should be investigated during the surveys.

Colorimetric Method for Determination of Uracil Mustard and Related Alkylating Agents

By H. G. PETERING and G. J. VAN GIESSEN

A colorimetric method for uracil mustard has been developed which is equally useful for other aromatic and aliphatic nitrogen mustard antitumor drugs. This method has been used to determine these drugs in plasma pools and for the study of their kinetics of hydrolysis and reactivity with nucleophilic reagents.

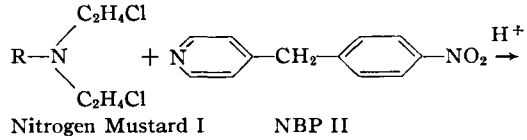
SEVERAL COLORIMETRIC methods for the determination of specific nitrogen mustards have been described by Klatt, Griffin, and Stahlin (1), Friedman and Boger (2) and Ausman, Crevar, Hagedorn, Bardos, and Ambrus (3). These methods all are based on the method for alkylating agents first reported by Epstein, Rosenthal, and Ess (4) which involves reaction of these agents with 4-(*p*-nitrobenzyl) pyridine. A photofluorometric method for ethylenimino and chloroethylamino groups has also been devised by Mellett and Woods (6). This latter method has the advantage of extreme sensitivity and thus may be useful for blood-level studies; it has the disadvantage of possible large losses because of involved and laborious manipulations.

The colorimetric methods are simpler than the fluorometric method and are useful in kinetic studies and in following the levels of these drugs when they are used in surgical perfusion studies. However, when we tried them with uracil mustard, 5-bis(2-chloroethyl) aminouracil, a number of difficulties were encountered. Since the method of Mellett and Woods was not found suitable for our purposes, we decided to attempt a modification of the colorimetric method of Klatt, Griffin, and Stahlin (1) so that a variety of nitrogen mustards could be determined.

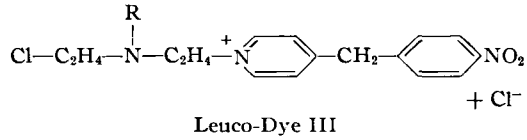
This method which is equally useful with aliphatic, aromatic, and heterocyclic nitrogen mustards and which can be conveniently used to determine these antitumor agents in perfusion blood pools, and on tissue extracts, is presented here.

EXPERIMENTAL

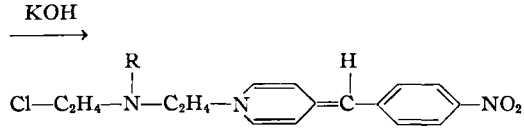
The reaction of alkylating agents with 4-(*p*-nitrobenzyl) pyridine (NBP) (II), which produces the chromophore, is carried out in our method under conditions similar to those originally described by Epstein, *et al.* (4). In the reaction formulated in Eq. 1, the solubility of the reaction product III is dependent on whether R is alkyl, aryl, or heterocyclic. Similarly the color formed from the chromophore IV when alkali is added will depend on the nature of R. In addition, Epstein, *et al.* (4), showed that the type of alkali used is of importance in the intensity of color formation. All of these matters were carefully considered in formulating the method outlined below.



Nitrogen Mustard I NBP II



Leuco-Dye III



Chromophore IV

The method worked out for uracil mustard (*Ia*) was found to give good results for dopan (*Ib*), chlorambucil (*Ic*), tris-chloroethylamine hydrochloride (*Id*), and HN-2 (Merck Mustargen) (*Ie*). The structures of these compounds, all of which are used as antitumor agents, are given in Table I.

acid, trigallic acid, catechol, phloroglucinol, and glucose.

Tannin has been shown to be a rather potent antibacterial substance; its possible influence upon the various surveys for the presence of antibacterial agents in higher plants should be investigated during the surveys.

Colorimetric Method for Determination of Uracil Mustard and Related Alkylating Agents

By H. G. PETERING and G. J. VAN GIESSEN

A colorimetric method for uracil mustard has been developed which is equally useful for other aromatic and aliphatic nitrogen mustard antitumor drugs. This method has been used to determine these drugs in plasma pools and for the study of their kinetics of hydrolysis and reactivity with nucleophilic reagents.

SEVERAL COLORIMETRIC methods for the determination of specific nitrogen mustards have been described by Klatt, Griffin, and Stahlin (1), Friedman and Boger (2) and Ausman, Crevar, Hagedorn, Bardos, and Ambrus (3). These methods all are based on the method for alkylating agents first reported by Epstein, Rosenthal, and Ess (4) which involves reaction of these agents with 4-(*p*-nitrobenzyl) pyridine. A photofluorometric method for ethylenimino and chloroethylamino groups has also been devised by Mellett and Woods (6). This latter method has the advantage of extreme sensitivity and thus may be useful for blood-level studies; it has the disadvantage of possible large losses because of involved and laborious manipulations.

The colorimetric methods are simpler than the fluorometric method and are useful in kinetic studies and in following the levels of these drugs when they are used in surgical perfusion studies. However, when we tried them with uracil mustard, 5-bis(2-chloroethyl) aminouracil, a number of difficulties were encountered. Since the method of Mellett and Woods was not found suitable for our purposes, we decided to attempt a modification of the colorimetric method of Klatt, Griffin, and Stahlin (1) so that a variety of nitrogen mustards could be determined.

This method which is equally useful with aliphatic, aromatic, and heterocyclic nitrogen mustards and which can be conveniently used to determine these antitumor agents in perfusion blood pools, and on tissue extracts, is presented here.

EXPERIMENTAL

The reaction of alkylating agents with 4-(*p*-nitrobenzyl) pyridine (NBP) (II), which produces the chromophore, is carried out in our method under conditions similar to those originally described by Epstein, *et al.* (4). In the reaction formulated in Eq. 1, the solubility of the reaction product III is dependent on whether R is alkyl, aryl, or heterocyclic. Similarly the color formed from the chromophore IV when alkali is added will depend on the nature of R. In addition, Epstein, *et al.* (4), showed that the type of alkali used is of importance in the intensity of color formation. All of these matters were carefully considered in formulating the method outlined below.

Accepted for publication May 4, 1963.

TABLE I.—STRUCTURE OF NITROGEN MUSTARDS INVESTIGATED WITH GENERAL FORMULA R—N $(CH_2—CH_2Cl)_2$

	Trade Name	Chemical Name	R Group
I*a*	Uracil mustard	5-Bis-(2-chloroethyl)-aminouracil	I*b*	Dopan	5-Bis-(2-chloroethyl)-amino-6-methyluracil	I*c*	Chlorambucil	4′-Bis-(2-chloroethyl)-amino-3-phenylbutyric acid	I*d*	HN-3	Tris-(2-chloroethyl)-amine - 1·HCl	$Cl—CH_2—CH_2—$
I*e*	HN-2	Bis-(2 chloroethyl)-methylamine · HCl	$CH_3—$

Apparatus.—A Beckman B spectrophotometer was used throughout this work, but any other suitable instrument can be used. The color developed in this method was most accurately determined at 600 mμ.

Reagents.—Five per cent of 4-(*p*-nitrobenzyl) pyridine (NBP) obtained from Aromil Chemical Co., Baltimore, Md., was dissolved in acetone and used as the chromophore-producing reagent. Potassium hydroxide (1*N*) in 90% ethanol was used as the base for color development.

Nitrogen Mustard Solutions.—Uracil mustard, dopan, chlorambucil, and HN-3 were synthesized in the Upjohn Laboratories; HN-2 was obtained as Mustargen from Merck and Co. Stock solutions of the first four compounds were prepared by dissolving 10 mg. of each drug in 5 ml. of dimethylacetamide (DMA) and diluting these solutions to 100 ml. with absolute ethanol or saline. (The drugs are more stable if the dilution is made in absolute ethanol.) A stock solution of Mustargen, which is a mixture of 10 mg. of HN-2 and 90 mg. of sodium chloride, was prepared by dissolving 100 mg. in 10 ml. of water and then diluting 1 ml. of this solution with 0.5 ml. of DMA and enough absolute ethanol or saline to bring the volume to 10 ml. Thus each stock solution contained the same weight concentration of drug and the same dilution of DMA. Aliquots of these stock solutions were used to obtain the standard curves and to explore the recovery of uracil mustard from plasma.

Buffer Solutions.—Phthalate buffer of pH 4.0 was prepared according to Clark (5), and the acetate buffer of pH 4.6 according to the directions of Friedman and Boger (2).

PROCEDURES

Standardization Curves.—An aliquot of stock solution of I*a*, I*b*, I*c*, I*d*, or I*e* in the range of 10–70 mcg. was placed in a 12-ml. centrifuge tube. To this was added 1.0 ml. of pH 4.0 phthalate buffer, 1.0 ml. of NBP reagent, 1.0 ml. of 0.9% saline, and enough absolute ethanol to bring the volume to 4.0 ml. This mixture with a boiling chip was then heated for 20 minutes in a water bath at 80°. A blank without the mustard but with 1.0 ml. of absolute ethanol was treated in the same way.

After the heating period, during which the condensation was completed, the tubes were plunged into an ice bath and after being cooled were individually treated for maximum color formation and subsequent spectrophotometric analysis at 600 mμ. The contents of each tube were carefully transferred to a 5-ml. volumetric flask, 0.1 ml. of 1.0 *N*

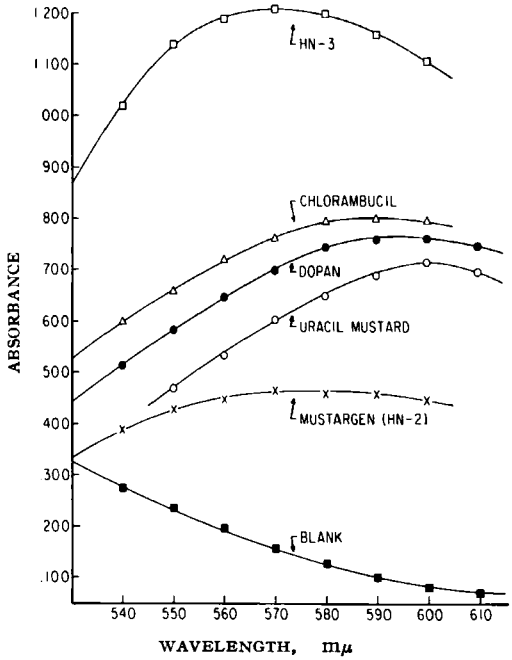

Fig. 1.—Ultraviolet absorption curves of chromophores produced by reaction of NBP reagent with several nitrogen mustards.

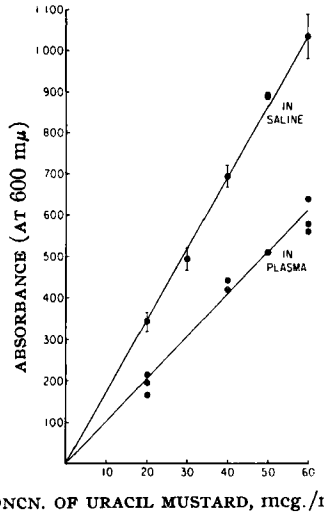

Fig. 2.—Beer's law plot of uracil mustard in saline compared with similar amounts extracted from plasma. These data indicate the extent of decomposition or binding of uracil mustard which can be expected in determining the concentration of this drug in blood.

KOH was added, and the volume brought to 5.0 ml. with ethanol. Each flask was thoroughly mixed, and placed in a cell for spectral analysis. The absorbance was observed to decrease at the rate of 1% per minute after the addition of the alkali, making it important to read the color at a designated time interval after mixing the reagents. All of our data for standard curves were obtained by making the readings within 2–3 minutes after the addition of alkali. Under these conditions a plot of absorbance *versus* concentration of drug gave a linear relationship (Beer's law) up to 70 mcg. in all instances.

Recovery of Uracil Mustard from Blood Plasma.—The following procedure was used to determine the recovery of uracil mustard (I*a*) from blood plasma. To heparinized rat plasma, uracil mustard was added from a DMA-saline stock solution in amounts so that 1.0 ml. of plasma contained 20–60 mcg. of I*a*. One milliliter of such plasma was immediately extracted with 2.0 ml. of acetone, making certain that thorough mixing and extraction occurred. The precipitated proteins were removed by centrifugation and the extract saved. The precipitate was extracted twice more with 1.0 ml. of acetone. The combined extract was then cooled in an ice bath and again centrifuged to remove residual protein. To this extract, in a 40-ml. centrifuge tube, was added 1.0 ml. of NBP reagent, 1.0 ml. of pH 4.0 phthalate buffer, and several milliliters of ethanol to control foaming.

This mixture was then heated at 60° for 5 minutes and at 80° for 20 minutes, during which the desired condensation occurred and acetone, which can react in the final color development, is removed. The resultant reaction product was then treated for color formation as described above. The chromophore produced from the drug extracted from plasma fades more rapidly than it did in the case of the standard curve investigation, probably because of the presence of unidentified soluble reactants. The rate of decrease of absorbance is about 5% per minute which makes it imperative that the readings be made quickly after the addition of alkali.

RESULTS

One of the important problems which must be resolved in the colorimetric determination of nitrogen mustards by the use of NBP reagent is the selection of the wavelength (or band) for maximum sensitivity of color determination. This varies enough for different nitrogen mustards that it accounts for some of the differences in the methods now in use. Our data in Fig. 1 indicate that the selection of 600 mμ, the maximum for the uracil mustard color, is satisfactory for the other compounds tested, although each has a somewhat different maximum. However, if 562 mμ had been selected as indicated in the work of Klatt, *et al.* (1), and 540 as indicated by Friedman and Boger (2), the results with uracil mustard (I*a*), dopan (I*b*), and chlorambucil (I*c*) would have been lower and thus decreased the sensitivity of the test.

Since excellent linear plots of optical density *versus* concentration (Fig. 2) were obtained in every case, the optical density constants for 10 mcg. per ml. are compared in Table II. These data indicate the applicability of the method to a wide variety of nitrogen mustards with comparable sensitivity in all cases except that of HN-2, which was obtained as Mustargen (Merck). Since Mustargen is a mixture of HN-2 and sodium chloride, no real basis for purity or lack of decomposition was available and it is likely that the lower results reflect less HN-2 available in the sample. Nevertheless, the method gave excellent agreement with Beer's law; thus the color with HN-2 by this method is consistent and determinable.

In all reports on the reaction of NBP with nitrogen mustards, the pH of the reaction mixture has been cited as critical; indeed it is important to have an acidic medium present as the reaction kinetics have shown. Epstein, *et al.* (4), indicated a phthalate buffer at pH 4.0 was the best for the original study. Klatt, *et al.* (1), stated that the pH should be between 4.5 and 5.0 and attempted to achieve this by adding acetic acid to the mixture before heating. Friedman and Boger (2) found acetate buffer at pH 4.6 to be better than phthalate buffer at the same

TABLE II.—ABSORBANCE OF CHROMOPHORES DEVELOPED WITH DIFFERENT NITROGEN MUSTARDS

	Mol. Wt.	Eq. Wt.	Absorbance at 600 mμ: Per 10 mcg. of Drug ± S.E.	Absorbance at 600 mμ: Per 0.1 μm. of Drug
Uracil mustard	252	126	0.173 ± 0.007	0.437
Dopan	266	133	0.185 ± 0.007	0.492
Chlorambucil	304	152	0.199 ± 0.006	0.605
HN-3 HCl	241	80	0.282 ± 0.014	0.679
HN-2 HCl (Mustargen)	192.5	96	0.117 ± 0.003	0.223

pH. We have compared the color developed with Ia and Id when acetate buffer of pH 4.6 and phthalate buffer of pH 4.0 are used. Our results show that the original work of Epstein, *et al.* (4), is valid, and that a phthalate buffer of pH 4.0 gives considerably higher values. We therefore held to the original buffer selection.

Potassium hydroxide (1.0 *N*) in 90% ethanol was used for final color development instead of either K_2CO_3 solutions or triethylamine as suggested by Epstein, *et al.* (4), and Klatt, *et al.* (1). Thereby we have avoided the problems of solubility of K_2CO_3 when acetone or ethanol are present and the critical nature of the water concentration as well as the difficulties which are inherent in safely handling triethylamine and in keeping it stabilized. This modification contributed greatly to the suitability of the method for both aqueous-soluble and aqueous-insoluble nitrogen mustard derivatives.

In other studies we found that DMA is not only a useful solvent for making up stock solutions of uracil mustard and other alkylating agents, but also that its presence at 2–5% in a saline solution of these drugs increase their stability. From our data DMA at levels up to 10% in the solutions of any of the mustards investigated does not affect the chromophore development or the subsequent color formation. Therefore, nitrogen mustard solutions containing DMA may be prepared for kinetic or biological studies without fear of altering the analytical data when this method is used.

The addition of uracil mustard in DMA-saline or ethanol-saline solutions to plasma and the immediate analysis of this mixture according to the method described above gave consistent values of about 60% recovery of the added drug. These data which are shown in Fig. 2 compared with the standard curve in the absence of plasma indicate the rapid inactivation of the drug or its complexing with plasma proteins. When trichloracetic acid precipitation of plasma protein and extraction of uracil mustard were attempted, no color development at all was obtained. Similarly when proteins were precipitated by boiling for 3 minutes in the presence of hydrochloric acid according to the method of Friedman and Boger (2) no evidence of uracil mustard in the extract was obtained. When, however, the method of Klatt, *et al.* (1), was used and the plasma was added directly to the reaction mixture, color development of intensity similar to that found by our method was obtained, although the consistency of the results was not satisfactory. Thus it is evident that uracil mustard is affected by the methods for removal of plasma protein.

DISCUSSION

Of the colorimetric methods mentioned earlier for the determination of nitrogen mustard drugs useful in cancer chemotherapy, only that of Klatt, Griffin, and Stahlin (1) has been shown to be suitable for both aromatic and aliphatic compounds. This method, however, has several shortcomings which the present method avoids. Since the pH of the reaction medium for the production of the chromophore is critical, we have chosen to use a definite buffer—phthalate buffer at 4.0—rather than adjusting the acidity with glacial acetic acid as Klatt, *et al.*, did. Furthermore, we have eliminated the use of triethylamine as the alkali for color development to avoid handling a highly toxic reagent which is unstable and requires frequent purification and have substituted instead ethanolic potassium hydroxide which is more readily available and easier to handle.

We have avoided the use of methods for extracting the drugs from plasma which will destroy the drug as Klatt, *et al.*, also attempted to do. We, however, prefer the extraction of the drug from plasma with acetone in which it is stable, although we have used the method of Klatt, *et al.*, with some success. We have found that uracil mustard is unstable when trichloracetic acid is used for extraction purposes or when the plasma is heated to boiling in the presence of hydrochloric acid as Friedman and Boger (2) recommended.

Only the method of Mellett and Woods (6) offers advantages over that described here in that it is more sensitive because of the use of a fluorometric method. Our experience with this method indicated to us that in its present form it was not suitable for routine use by laboratory technicians. In addition, we feel that the results with uracil mustard by this method as reported recently by Mellett and Woods (6) indicate very great losses during the laborious manipulations which involve the use of strong hydrochloric acid, known to cause destruction of uracil mustard. Nevertheless, if a more sensitive method is required than that described here, fluorometric methods of analysis should be investigated and developed.

Emulsifying Effects of Several Ionic Surfactants on a Nonaqueous Immiscible System

By J. D. McMAHON, R. D. HAMILL, and R. V. PETERSEN

The emulsifying effects of twelve anionic and five cationic surfactants on the nonaqueous immiscible system, glycerin and olive oil, were studied. Three anionic agents, dioctyl sodium sulfosuccinate, diamyl sodium sulfosuccinate, and calcium stearate, and two cationic agents, benzalkonium chloride and lauryltrimethylammonium bromide, failed to stabilize the system. On the other hand, four anionic agents, tetrasodium-N-(1,2-dicarboxyethyl)-N-octadecyl-sulfosuccinamate, sodium lauryl ether sulfate, sodium lauryl sulfate, and sodium stearate, and three cationic agents, stearyltrimethylammonium chloride, cetylpyridinium chloride, and stearyldimethylbenzylammonium chloride, produced stable emulsions. The anionic agents formed by the saponification of the fatty acids present in the olive oil with 2-amino-2-methyl-1,3-propanediol, tris (hydroxymethyl) aminomethane, triethanolamine, ethanolamine, or ammonia, yielded clear, stable emulsions. Emulsification occurred more readily, or preferentially, when the surfactant was first added to the glycerin. All of the emulsions formed were of the oil-in-glycerin type, except those containing sodium stearate or stearyltrimethylammonium chloride.

DURING RECENT YEARS rapid advances have been made in the technology of surface-active agents (surfactants). A multitude of new agents have been developed and their properties and actions studied. These studies have resulted not only in a vast expansion of the knowledge of the better known actions, but also in the discovery of new actions and new applications for these agents.

Surfactants exhibit many properties, among which are included emulsifying, demulsifying, wetting, foaming, antifoaming, dispersing, solubilizing, detergent, and spreading actions. Many of these actions are interrelated and all are manifestations of the thermodynamic function of surfactants in effecting a reduction in the surface or interfacial tension between a liquid and an adjoining phase. The amphiphilic nature of surfactant molecules results in a simultaneous attraction for both polar and nonpolar substances which accounts for some of their actions.

The actions enumerated above find applications in a large number of industries, including the pharmaceutical and cosmetic industries. Many pharmaceutical applications have been extensively investigated. For example, the use of surfactants as emulsifying agents for oil-water systems, as detergents, dispersing agents, suppository bases, disinfectants, preservatives, and fecal softeners, is well established. There are also reports in the literature regarding the use of surfactants as solubilizing agents for volatile oils (1), phenobarbital in a nonalcoholic vehicle (2), reserpine (3), benzoic acid derivatives (4), hexachlorophene (5, 6), and many other substances for internal and external application. Many studies also have been performed and reviewed on the effects of surfactants on gastrointestinal absorption of drugs (7–9), absorption of fats (7), and percutaneous absorption (10). Despite the abundant literature regarding the effects of surfactants on aqueous and aqueous-oil systems, relatively little is mentioned on nonaqueous, binary, immiscible systems, such as glycerin and olive oil. For this reason, and because these solvents are pharmaceutically useful, these agents were selected as a model for the study of the effects of surfactants on such a system. The results obtained in the descriptive phase of this investigation provide the basis for this report.

METHODS

The system employed in each experiment consisted of equal weights of glycerin and olive oil with a variable concentration of surfactant. The glycerin and olive oil used were U.S.P. grade. Every reasonable precaution was taken to avoid undue exposure of these reagents to the atmosphere, except during actual manipulation; although, due to the hygroscopicity of glycerin, anhydrous conditions would have been almost impossible to achieve and maintain under the experimental conditions employed.

Two methods of mixing were used. In Method I the surfactant was weighed and added directly to a weighed quantity of glycerin. This mixture was then transferred to a glass mortar. The oil was added slowly in small portions, with rapid trituration after each addition. In Method II the requisite quantity of surfactant was added to the oil. The oil and surfactant were then transferred to a glass mortar and the glycerin was added slowly, in small portions, with vigorous trituration after each addition.

Liquid surfactants were weighed directly into a tared beaker which contained the requisite weight

example, to expedite the use of ammonia as a saponifying agent, stock solutions were prepared by bubbling the anhydrous gas into weighed quantities of glycerin and of olive oil. Requisite quantities of these stock solutions were used for the preparation of solutions of various concentrations.

Hand methods of trituration were employed throughout the experiment. A colloid mill and a hand homogenizer were used to compare the results obtained by hand methods, but these devices did not improve significantly the products obtained by hand trituration.

Three criteria were used to evaluate the results of manipulations by Methods I and II. The product was considered to be *stable* if emulsification occurred and there was no separation into layers for at least 7 days. The term *emulsions* is used to designate those products which did not separate into distinct layers, although solubilization may have contributed to the overall phenomenon. Figure 1 depicts the appearance of a completely separated product, a partially separated product, a clear emulsion, an opaque emulsion and a semisolid emulsion, all of which were aged for at least 1 week. Only the latter three examples were considered as emulsions. Another criterion was based on the *miscibility* of the emulsion with added olive oil or glycerin upon gentle stirring. This procedure was employed to determine emulsion type, based on the assumption that additional liquid of the external phase, but not of the internal phase, could easily be mixed with the emulsion. Finally, *microscopic* determination of emulsion type was facilitated by the preparation of a 1.0% solution of D & C red No. 18 dye in olive oil. Heat was applied to effect solution. The cooled oil, containing the dye, was subsequently mixed with glycerin and surfactants in the usual manner and the resulting emulsions examined microscopically.

To determine the influence of temperature on the miscibility of olive oil and glycerin, mixtures of these agents were prepared in increments of 5.0% ranging from 5.0% olive oil and 95.0% glycerin to 95.0% olive oil and 5.0% glycerin. Miscibility was not effected in any of these mixtures at temperatures up to 180°, at which point there was evidence of decomposition.

RESULTS

Anionic Agents.—Table I summarizes the results obtained using the anionic surfactants and the saponifying amines.

Cationic Agents.—Table II summarizes the results obtained using the cationic agents.

An examination of Table I reveals that stable emulsions were obtained from the use of tetrasodium - N - (1,2 - dicarboxyethyl) - N - octadecylsulfosuccinamate, sodium lauryl ether sulfate, sodium lauryl sulfate, sodium stearate, and from the saponifying amines, 2-amino-2-methyl-1,3-propanediol, tris(hydroxymethyl) aminomethane, triethanolamine, ethanolamine, and ammonia. Other agents produced emulsions which remained stable for several hours or days, but separated partially or completely on standing. For example, emulsification was observed immediately after manipulation of products containing dioctyl sodium sulfosuccinate, diamyl sodium sulfosuccinate, the lower concentrations of 2-amino-2-methyl-1,3-propanediol, or triethanolamine. Negative results are reported, however, because detectable separation occurred within the arbitrary 7-day period.

Microscopic examination of the products containing D & C red No. 18 dye, predissolved in the oil, confirmed the fact that emulsification had occurred. Figures 2 and 3 illustrate this observation. In all cases, except that of sodium stearate, the oil appeared in the internal phase, although evidence of

mixed emulsification was observed in a number of instances. Figure 4 is a photomicrograph of a sodium stearate emulsion wherein the oil (dark area) is seen in the external phase. Mixed emulsification can be detected by close observation of this figure.

When sodium lauryl sulfate, sodium stearate, or ethanolamine was used, the resulting preparations had a very thick consistency. Indeed, the higher concentrations resulted in semisolid preparations. Consequently, any separation in these products occurred very slowly, usually over several weeks.

With the exception of ethanolamine, the saponifying amines produced very stable emulsions, even in very low concentrations. The resulting products were clear or only faintly cloudy. Several of them exhibited opalescence. Some darkening was noted in emulsions containing triethanolamine or ammonia on standing. However, some of these preparations have remained stable for over 2 years. It is interesting that the use of preformed triethanolammonium oleate, prepared by reacting equivalent amounts of triethanolamine and oleic acid, aided by mild heating, produced the same results as did the corresponding amount of triethanolamine.

Table II reveals that stable emulsions were obtained from the use of the cationic agents, cetylpyridinium chloride, stearyltrimethylammonium chloride, and stearyldimethylbenzylammonium chloride. Emulsions were formed also when benzalkonium chloride or lauryltrimethylammonium bromide were used; however, these emulsions separated, partially or completely, within 7 days. That emulsification occurred in these preparations was confirmed by microscopic examination of the dyed emulsions.

An inversion in emulsion type was observed when stearyltrimethylammonium chloride was employed in concentrations of 0.5 and 1.0% by Method I. Preparations containing 0.5% of this agent formed oil-in-glycerin emulsions until the proportion of oil reached approximately 42% of the total composition, at which point an inversion to the glycerin-in-oil type occurred. Partial separation of this emulsion was detectable after standing for 7 days. Preparations containing 1.0% stearyltrimethylammonium chloride, prepared by Method I, formed oil-in-glycerin emulsions until the proportion of oil reached approximately 48%, at which point inversion occurred. No separation of these emulsions was detectable after 7 days. At the 5.0% level of surfactant inversion to the glycerin-in-oil type did not occur, even when the oil concentration was increased to approximately 78–80%. At this point the emulsions "cracked."

The use of stearyltrimethylammonium chloride by Method II produced emulsions of the glycerin-in-oil type at concentrations of 0.5, 1.0, and 5.0%, although at the two lower concentrations partial separation occurred on standing for 7 days.

A comparison of the results obtained with Method I and Method II reveals that the former was superior in its ability to produce stable emulsions with either anionic or cationic surfactants. Method II was successful only in the case of ammonia, in one preparation containing 1.0% triethanolamine which had been aged for several days (not included in Table I), and in preparations containing stearyltrimethylammonium chloride.

DISCUSSION

The data presented in Table I indicate that certain anionic agents are useful for emulsifying the glycerin-olive oil system employed in these studies. This interpretation is supported by macroscopic and microscopic examination and by testing the products for miscibility with added olive oil or glycerin. Except for sodium stearate emulsions, all of the emulsions prepared from anionic agents were of the oil-in-glycerin type. Emulsions containing sodium stearate were of the glycerin-in-oil type. The sodium stearate–induced emulsions exhibited a degree of mixed emulsification, as did a number of other emulsions. This can be observed in Fig. 4. The glycerin-in-oil nature of emulsions containing sodium stearate was further substantiated by the fact that only a limited quantity of glycerin could be added to these emulsions, whereas olive oil was readily miscible with them. In all other instances glycerin, but not olive oil, mixed readily with the emulsions.

Emulsions obtained with 2-amino-2-methyl-1,3-propanediol, tris(hydroxymethyl) aminomethane, triethanolamine, ethanolamine, or ammonia, using Method I, formed rapidly with a minimum of agitation. Evidently, saponification occurred readily. The great capacity of these agents to emulsify the oil is remarkable, since, in one case, as little as 0.01% of the saponifying amine was used to produce a stable emulsion. Still lower concentrations may be effective for this purpose.

The value of the cationic surfactants as emulsifying and solubilizing agents has not been unequivocally established. The solubilizing effects of dodecylamine hydrochloride (11) and cetylpyridinium chloride (12) in aqueous preparations have been reported. The results presented herein indicate that cetylpyridinium chloride, stearyltrimethylammonium chloride, and stearyltrimethylbenzylammonium chloride are effective agents for the emulsification of olive oil and glycerin under the conditions of this experiment and may be of value in this application. These observations should be extended before categorical statements can be made regarding

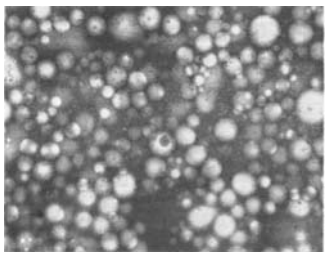

Fig. 4.—Photomicrograph of an emulsion containing 2.0% sodium stearate in equal weights of glycerin and olive oil stained with D & C red No. 18 dye.

the usefulness of these agents in solubilizing or emulsifying aqueous or nonaqueous systems.

The results reported in Table II on the cationic agents were substantiated by microscopic and macroscopic examination and by testing the products for stability and for miscibility with added olive oil or glycerin.

The fact that both types of emulsions, oil-in-glycerin and glycerin-in-oil, were induced by one agent, stearyltrimethylammonium chloride, lends support to the well known theories which imply that an emulsion forms in such a way that the higher proportion of surfactant is in the external phase. Indeed, with this agent, Method I (in which the surfactant was first dissolved in glycerin) favored the formation of oil-in-glycerin emulsification, whereas the reverse was true of Method II. The inversions observed during manipulation by Method I did not occur until substantial quantities of oil had been incorporated into the internal phase.

The viscosity of emulsions resulting from the use of either anionic or cationic agents was obviously much higher than that of either of the constituents, although accurate viscosity measurements have not yet been made. Even when emulsification was not effected, an increase in viscosity and slower rates of separation, compared to olive oil and glycerin alone, frequently were noted.

It was observed that in many instances where negative results are indicated, emulsification resulted until the proportion of oil exceeded a maximum concentration at which point separation occurred. This point was frequently very sharp, occurring on addition of only 1 or 2 ml. of oil and detectable by a sudden decrease in viscosity. This phenomenon was particularly noticeable with the lower concentrations of saponifying amines. For such cases it is assumed that the concentration in internal phase exceeded the capacity of the surfactant to maintain a stable emulsion. It is realized that greater variation in the concentrations of surfactants or in the proportion of glycerin and/or olive oil may have produced positive results where emulsification otherwise did not occur.

The addition of an oil soluble dye (D & C red No. 18) or a glycerin soluble dye (methylene blue) to the *finished emulsion* was unsatisfactory for microscopic observation and led to some early erroneous conclusions. The fact that most of the nondyed emulsions were translucent and failed to show emulsification on microscopic examination led to the initial belief that solubilization was the primary action of the surfactants in this system. This is understandable in view of the similar refractive indices of the reagents (glycerin n_D^{25} 1.4730; olive oil n_D^{25} 1.466–1.468). This also may account for the fact that most of the emulsions were clear or only faintly cloudy.

Technique played an important role in the successful formation of emulsions. Vigorous trituration and slow addition of the oil enhanced the chances of effecting emulsification. Microscopic examination of the dyed emulsions revealed that those prepared by this technique exhibited smaller globule sizes than those prepared by less vigorous agitation and more rapid addition of the oil. It should be mentioned, however, that the surfactant also had a pronounced influence on the size of the globules contained in the emulsion.

Why is Method I superior to Method II in its capacity to produce stable emulsions? The answer to this question is not obvious. However, based on the assumption that micelle formation is responsible for eventual emulsification, an explanation might be proposed. McBain (13) has suggested that emulsification results when the saturation point of micelles is exceeded and further states: "The apparent density of liquid solubilized by a micelle is the same or nearly the same as that of the pure oil at the limit of saturation (as may easily be seen on reflecting that when the micelle becomes saturated the addition of still more liquid results in a *transition from solution to emulsion*)." The existence of micelles in nonaqueous systems has been reported by several investigators (14–20). Hall (21), on the other hand, has evidence that micelles are not present in benzene solutions of the nonionic agent, polyoxyethylene lauryl ether 30,[1] but has evidence supporting the existence of micelles in benzene solutions of anionic and cationic surfactants. The fact that glycerin is a polar substance and has solvent properties quite similar to those of water would lead one to suspect that micelles form in glycerin in a manner similar to the micelle formation in water. The assumption that micelles do exist and that the oil is dissolved within the hydrocarbon interior of the micelle appears logical. The fact that emulsions formed quickly and easily by use of the saponifying amines indicates that micellar formation was rapid. It would further appear that once a micelle forms, the orientation is highly stable and a reversion in type does not readily occur. Thus, the micellar orientation within the system employed in these studies which leads to stable emulsions must, in most instances, be that present in glycerin.

SUMMARY

The effects of various surfactants on the system, olive oil and glycerin, were studied. The anionic agents, dioctyl sodium sulfosuccinate, diamyl sodium sulfosuccinate, and calcium stearate failed to produce stable emulsions under the conditions of this study. The cationic agents, benzalkonium chloride and lauryltrimethylammonium bromide, likewise failed to stabilize the system.

Some anionic agents were effective in producing emulsification of glycerin, and olive oil. Tetrasodium - N - (1,2 - dicarboxyethyl) - N - octadecylsulfosuccinamate, sodium lauryl ether sulfate, and sodium lauryl sulfate produced stable, somewhat opaque, preparations. The amines, 2-amino-2-methyl-1,3-propanediol, tris(hydroxymethyl) amino-

[1] Marketed as Brij 30 by the Atlas Powder Co., Wilmington, Del.

methane, ethanolamine, triethanolamine, and ammonia gas, at very low concentrations, formed saponification products which resulted in clear, stable emulsions. Three cationic agents, cetylpyridinium chloride, stearyltrimethylammonium chloride, and stearyldimethylbenzylammonium chloride, likewise produced stable emulsions of this system.

Method I, in which the surfactant was added to the glycerin, was effective in all of the cases mentioned; whereas Method II, in which the surfactant was added to the oil, was effective in only a few isolated cases—namely, with ammonia, triethanolamine, and stearyltrimethylammonium chloride. All of the emulsions formed were of the oil-in-glycerin type, with the exception of emulsions containing sodium stearate or stearyltrimethylammonium chloride.

Comparative Activities of Maleyl, Fumaryl, and Succinyl Dicholine

A Correction of the Literature

By JOHN F. McCARTHY, JOSEPH G. CANNON†, and JOSEPH P. BUCKLEY

A reinvestigation of the synthesis and structure of "dicholine maleate" reported by an earlier worker has shown that the *cis*-double bond was isomerized to the *trans*-form. An alternate synthesis for dicholine maleate has been repeated and has been found to give rise to the correct structure. Contrary to literature reports, there are marked differences in biological potency between maleyl and fumaryl dicholines compared with succinyl dicholine.

In considering structure-activity relationships of succinyl dicholine, conformations of the succinic acid portion of the ester assume some importance. If one considers possible conformations of a succinate ester, it would be expected that a staggered conformation of the acid would be favored over eclipsed or gauche forms. Inspection of Dreiding models of maleic and fumaric acids reveals that the carboxyl groups of these acids are oriented in space in a manner which closely resembles the orientation in space of the eclipsed and the staggered conformations, respectively, of succinic acid. The question then arises as to whether the staggered conformation would be favored for adsorption at a biological receptor surface.

Dicholine esters of maleic and fumaric acids offer special interest in that they are unsaturated analogs of succinyl dicholine. The double bond confers some degree of rigidity upon the acid portion of the system; thus the quaternary groups are held in a somewhat fixed, rigid relationship to each other, being relatively close together in the *cis*-maleate ester, and relatively far apart in the *trans*-fumarate ester. If the concept that both quaternary heads of succinyl dicholine attach in some specific manner to receptor sites and/or to "anchoring" sites is valid, there should be considerable difference in biological potency between the dicholine esters of the two isomeric unsaturated acids. Cavallito and Gray (1) stated that the fumaryl and the maleyl esters of choline

Comparative Activities of Maleyl, Fumaryl, and Succinyl Dicholine

A Correction of the Literature

By JOHN F. McCARTHY, JOSEPH G. CANNON†, and JOSEPH P. BUCKLEY

A reinvestigation of the synthesis and structure of "dicholine maleate" reported by an earlier worker has shown that the *cis*-double bond was isomerized to the *trans*-form. An alternate synthesis for dicholine maleate has been repeated and has been found to give rise to the correct structure. Contrary to literature reports, there are marked differences in biological potency between maleyl and fumaryl dicholines compared with succinyl dicholine.

In considering structure-activity relationships of succinyl dicholine, conformations of the succinic acid portion of the ester assume some importance. If one considers possible conformations of a succinate ester, it would be expected that a staggered conformation of the acid would be favored over eclipsed or gauche forms. Inspection of Dreiding models of maleic and fumaric acids reveals that the carboxyl groups of these acids are oriented in space in a manner which closely resembles the orientation in space of the eclipsed and the staggered conformations, respectively, of succinic acid. The question then arises as to whether the staggered conformation would be favored for adsorption at a biological receptor surface.

Dicholine esters of maleic and fumaric acids offer special interest in that they are unsaturated analogs of succinyl dicholine. The double bond confers some degree of rigidity upon the acid portion of the system; thus the quaternary groups are held in a somewhat fixed, rigid relationship to each other, being relatively close together in the *cis*-maleate ester, and relatively far apart in the *trans*-fumarate ester. If the concept that both quaternary heads of succinyl dicholine attach in some specific manner to receptor sites and/or to "anchoring" sites is valid, there should be considerable difference in biological potency between the dicholine esters of the two isomeric unsaturated acids. Cavallito and Gray (1) stated that the fumaryl and the maleyl esters of choline

are equally and fairly active. Brücke (2) cited literature reports that fumaryl dicholine is approximately one-half as potent as succinyl dicholine in the rabbit head-drop test. This author, while listing maleyl dicholine in his tables, recorded no biological data for it. Glick (3) reported synthesis of maleyl dicholine by condensing maleic anhydride with ethylene bromohydrin using heat but no solvent or catalyst, followed by treatment of the resulting bis-(2-bromoethyl) maleate with an excess of trimethylamine. Glick did not report test data of succinyl dicholine-like activity for this ester; hydrolysis rates for the compound which were reported by Glick were extremely similar to those reported by other workers for analogous fumarate esters. Synerholm and Hartzell (4) reported the preparation of bis-(2-chloroethyl) maleate by reacting 2-chloroethanol with maleic anhydride. When the experiments of Glick and of Synerholm and Hartzell leading to bis-(2-haloethyl) maleates were repeated in this laboratory, products were obtained which corresponded in melting points and in other physical characteristics to those reported by the original workers; however, these products were identical (evidenced by infrared spectral studies and by mixed melting points) to fumarate esters which were prepared in an unumbiguous manner. Therefore, it would appear that the hydrogen halide, formed in small amounts during the reaction of maleic anhydride with the halohydrin, catalyzed isomerization of the *cis* double bond to the more stable *trans*. It is well established (5) that maleates are rapidly converted to fumarates in the presence of hydrohalic acids. It would appear that Glick's "maleyl dicholine" was actually fumaryl dicholine.

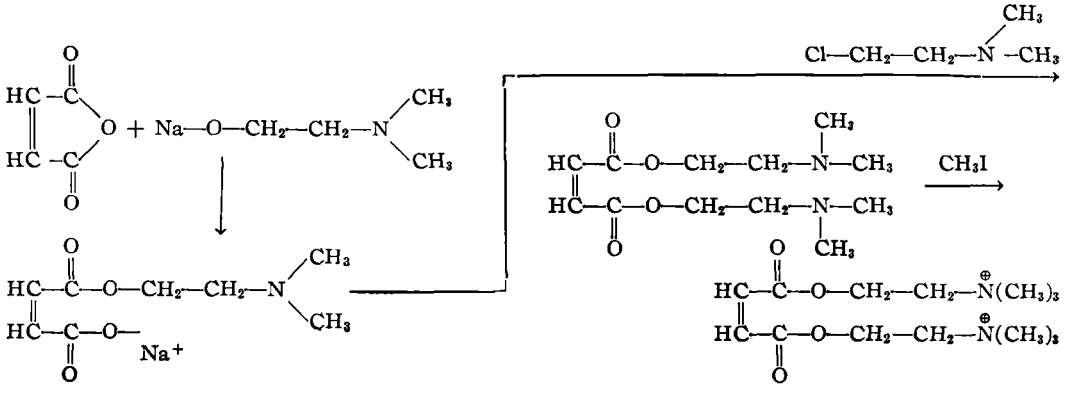
The only other recorded synthesis of maleyl dicholine is that of Christiansen and co-workers (6), who reported no data to support the structure of the material claimed to be maleyl dicholine. Hence, their synthesis was repeated in this laboratory as outlined

Mayo and Walling (7) have stated that primary and secondary amines will cause isomerization of maleates to fumarates. However, these authors pointed out that tertiary amines (except for pyridine) are known not to effect this isomerization. Hence, it was expected that no change in the configuration about the double bond would occur in the preparation of the bis-(2-dimethylaminoethyl) ester of maleic acid. Confirmation of this was obtained when the infrared spectrum of bis-(2-dimethylaminoethyl) fumarate (prepared from bis-(2-bromoethyl) fumarate and dimethylamine) was found to be significantly different from that of bis-(2-dimethylaminoethyl) maleate prepared by the method of Christiansen and co-workers (6).

Application of classical methods to prove that treatment of bis-(2-dimethylaminoethyl) maleate with excess methyl iodide did not result in isomerization of the double bond and that the final product of the reaction sequence was indeed dicholine maleate led to inconclusive results. When dicholine maleate, prepared in this laboratory by the method of Christiansen and co-workers (6), was hydrolyzed with base, only fumaric acid could be isolated following acidification. This result is not necessarily significant, since the iodide ions present in the solution will be converted into hydriodic acid on acidification of the reaction mixture with sulfuric acid. In addition, air oxidation could form small amounts of free iodine which is known (5) rapidly to isomerize maleic to fumaric acid. The fact that the acidic solution from which the fumaric acid was isolated assumed the color of a dilute solution of iodine supports this contention.

A comparison of the decomposition points of an authentic sample of dicholine fumarate and of dicholine maleate prepared by Christiansen's method revealed that the two products melted with decomposition at the same temperature (252–253°) when determined under identical conditions, individually, and when mixed. Generally, these data are taken as proof that two samples from different sources are identical. However, it has been reported (8) that maleic acid is converted to the higher melting fumaric acid when it is heated slightly above its melting point; hence, it could be argued that at such high temperatures, dicholine maleate might be expected to isomerize to dicholine fumarate.

Infrared spectroscopy would not be expected to furnish conclusive results; the dicholine esters are completely insoluble in solvents used for infrared studies. Hence, it would be necessary to determine



their spectra in the solid state. Differences in spectra of closely related compounds taken in the solid state can be due to differences in crystalline forms rather than to differences in molecular structure. Stafford and his co-workers (9) have stated that the absorption maxima of maleates and of fumarates in the ultraviolet occur at the same wavelength (210 mμ region), but that the extinction coefficient of fumarates is greater than that of maleates. When the ultraviolet spectra of dicholine maleate diiodide and of dicholine fumarate diiodide were recorded in methanol, an absorption maximum appeared at 219 mμ, with an extinction coefficient of 15,000 in both cases. This maximum is probably not due to the unsaturated chromophore but to the iodide ion. Knight and co-workers (10) have reported that the ultraviolet spectrum of tetramethylammonium iodide contains an absorption maximum at 226 mμ with an extinction coefficient of 13,300. These workers attributed this absorption to iodide ion.

Support for the structure of dicholine maleate was obtained by paper chromatographic analysis (see Table I). Goldenberg and Spoerri (11) found that esters of dicarboxylic acids in which the two ester groups were in close proximity, such as diesters of maleic and phthalic acids, reacted more slowly with aqueous alkaline hydroxylamine to give hydroxamic acids than did diesters of fumaric acid or diesters in which the ester groups were separated by more than two carbons. Also, a much less intense color was produced in the case of maleic and phthalic acids on addition of ferric chloride reagent. The fact that the di-quaternary compound arising from bis-(2-N,N-dimethylaminoethyl) maleate failed to develop a color when paper chromatograms were treated with the hydroxylamine–ferric chloride reagent was interpreted as evidence that no isomerization of the double bond had occurred.

The differences which were noted in biological activities of the dicholine esters of maleic and fumaric acids further substantiated the structure of the dicholine maleate prepared by the method of Christiansen and co-workers.

Schilling and Pedersen (14) reported that maleyl dicholine prepared by Christiansen and co-workers (6) had some ability to paralyze skeletal muscle. However, these workers did not compare similar dose levels of maleyl dicholine and of succinyl dicholine, and they did not report tests on fumaryl dicholine. A search of the literature has not revealed that any group has prepared authentic maleyl dicholine and carried out parallel tests on it, on fumaryl dicholine, and on succinyl dicholine. The importance of steric factors in structure-activity relationships of quaternary compounds indicates the desirability of concurrent tests of these three esters.

TABLE I.—PAPER CHROMATOGRAPHIC ANALYSIS OF DICHOLINE MALEATE AND OF DICHOLINE FUMARATE[a]

Dicholine Ester	Reaction to Iodine (12)	Reaction to Hydroxylamine-ferric chloride (13)	R_f Value
Maleate	+	−	0.18
Fumarate	+	+	0.18

[a] The paper chromatographic system used was that of Augustinsson, K. B., and Grahn, M., *Acta Chem. Scand.*, 7, 906(1953).

The threshold dose of succinyl dicholine, determined in 13 cats, was approximately 0.04 to 0.05 mg./Kg., with a duration of action between 2 and 14 minutes.

Fumaryl dicholine produced a blockade of skeletal muscle contraction at a threshold dose of approximately 0.12 mg./Kg. Doses ranging between 0.06 and 2.32 mg./Kg. were administered to four cats. The compound did not produce significant changes in blood pressure below this threshold dose; however, doses above 0.2 mg./Kg. produced pressor effects and marked respiratory depression.

Maleyl dicholine was much less effective than either fumaryl dicholine or succinyl dicholine, and the threshold dose was approximately 2.0 mg./Kg. Doses ranging between 0.1 and 4.38 mg./Kg. were administered to four cats. The compound also produced transient hypotensive effects in the lower dose range (0.1 to 2.0 mg./Kg.) and marked hypotensive effects in doses in excess of 2.0 mg./Kg.

EXPERIMENTAL[1]

Chemical

Bis-(2-bromoethyl) Fumarate.—*A. From Fumary Chloride.*—Sodium dried, thiophene-free benzene (125 ml.), 17 Gm. (0.175 mole) of anhydrous reagent grade potassium carbonate, and 20 ml. (34.5 Gm., 0.276 mole) of 2-bromoethanol were mixed in a 500-ml. three-neck flask equipped with a mechanical stirrer, dropping funnel, and a condenser topped with a drying tube. A 14.5-Gm. (0.095 mole) quantity of fumaryl chloride (15) in 125 ml. of benzene was added over a 15-minute period to the rapidly stirred contents of the flask. Stirring was continued for 3 to 4 hours; then 100 ml. of chloroform was added, and the insoluble inorganic material was removed by filtration. The filtrate was washed successively with 100 ml. of water, two 100-ml. portions of saturated sodium bicarbonate solution, and 100 ml. of water. Removal of the solvent under reduced pressure (after drying with sodium sulfate) gave 22.1 Gm. (70%) of a white solid, which was recrystallized twice from Skelly B; m.p. 66–67°.

Anal.—Calcd. for $C_8H_{10}Br_2O_4$: C, 29.12; H, 3.05; Br, 48.44. Found: C, 29.76; H, 3.17; Br, 47.45.

B. From Maleic Anhydride.—A 10.65-Gm. (0.11 mole) quantity of freshly sublimed maleic anhydride (or Eastman white label grade, without sublimation) and 14.3 ml. (25 Gm., 0.2 mole) of 2-bromoethanol were placed in a 250-ml. round bottom flask equipped with a condenser and drying tube. The mixture was heated at 100° for 9 hours, cooled, and 200 ml. of chloroform was added. The insoluble material (4.8 Gm.) was removed by filtration; the filtrate was washed successively with 50 ml. of water, two 50-ml. portions of saturated sodium bicarbonate solution, and two 50-ml. portions of water. The chloroform solution was dried over sodium sulfate; the solvent was removed on a steam bath giving 14.5 Gm. (40%) of a solid which was recrystallized from Skelly B; m.p. 65–66°. [Glick (3) reported m.p. 66° for the neutral product of this reaction. Synerholm and Hartzell (4) reported m.p. 66.5 to 68°.] The infrared spectrum (8% in chloroform) was identical

[1] All melting points are uncorrected. Elemental analyses were performed by Huffman Microanalytical Laboratories, Wheatridge, Colo.

in all respects with that of the product from *A* (8% in chloroform). Also, a mixed melting point determination with the product from *A* showed no depression.

Bis-(2-N,N-dimethylaminoethyl) Maleate.—This compound was prepared in 4% yield by the method of Christiansen and co-workers (6); b.p. 109–110° (0.1 mm.); literature (6) b.p. 145° (1.5 mm.).

Bis-(2-N,N-dimethylaminoethyl) Fumarate.—A 6.0-Gm. (0.018 mole) quantity of bis-(2-bromoethyl) fumarate and 3.6 Gm. (0.08 mole) of dimethylamine were added to 100 ml. of sodium-dried toluene in a 125-ml. Erlenmeyer flask fitted with a ground-glass stopper. The flask was stoppered and allowed to stand at room temperature for 1 month. The insoluble material was removed by filtration, the toluene was removed from the filtrate under reduced pressure, and the residue was distilled, whereupon 4.3 Gm. (90%) of material boiling at 105–106° (0.02 mm.) was collected; literature (16) b.p. 138° (2 mm.).

Dicholine Maleate and Dicholine Fumarate.—These compounds were prepared by the procedure described by Christiansen and co-workers (6) for the preparation of methiodides. Reagent grade acetone was employed; it was stored over anhydrous potassium carbonate. The methyl iodide was Eastman white label grade, and it was redistilled immediately before use. Both dicholine ester diiodides were recrystallized from methanol-water (5:1). Melting point determinations were performed in an open capillary tube which was placed in a rapidly stirred bath preheated to 230°, and the temperature was increased at the rate of 2° per minute. The melting points of the two esters were determined simultaneously, and they were both 252–253° with decomposition. A mixture of equal parts of the two esters melted at 252–253° with decomposition under conditions described above. Bovet and co-workers (16) reported 253° for dicholine fumarate and Christiansen and co-workers (6) reported 264° for dicholine maleate.

Pharmacology

Cats of each sex were anesthetized with α-chloralose and urethan (30 mg./Kg. in a 25% urethan solution). The dose utilized was calculated on α-chloralose as 55 mg./Kg.

After cannulating the trachea, the ipsilateral femoral nerve was severed. The posterior tibial nerve was separated from the peroneal nerve for a distance of 2 or 3 cm. The tibial nerve was ligated at a distance of 4 to 5 cm. from its union with the peroneal nerve and cut distal to the ligature. If bleeding occurred from the small vessels in the neural sheath, a piece of surgical gauze soaked in thrombin (100 NIH units/ml.) was applied to the nerve to aid in coagulation. The bony tubercle on the medial edge of the foot between the heel and toe was detached with bone clippers and the tendon of the tibialis anticus muscle ligated just above the tubercle with a strong thread. The distal end of the thread was attached to a muscle pulley lever system. The recordings of the contractions of the tibialis anticus muscle were made on a slowly moving smoked kymograph. Platinum tipped electrodes were fixed around the intact peroneal nerve. The nerve was bathed in warm heavy mineral oil maintained at 35 to 38°. A Grass stimulator (SD5) was used to deliver 0.8 to 1.0 volt square wave impulses every 6 seconds. The threshold for the peroneal nerve was determined for each preparation and control contractions recorded for a 30-minute period. A carotid artery was cannulated, and the blood pressure was recorded by means of a glass cannula and mercury manometer system. The glass cannula was connected to its respective pressure recording device through a normal saline (0.1% sodium chloride solution) bridge. Coagulation was prevented by injecting 0.2 ml. of heparin (1000 U.S.P. units/ml.) into the tip of the glass cannula. The experimental compound was administered *via* the femoral vein and the effects on contraction of the tibialis anticus muscle and blood pressure recorded. Succinyl dicholine was administered to each preparation.

Chemical and Pharmacological Studies on *Argemone mexicana*

By B. C. BOSE, R. VIJAYVARGIYA, A. Q. SAIFI, and S. K. SHARMA

Chemical and pharmacological studies of Argemone mexicana have been carried out. Chemical analysis revealed the presence of total alkaloids 0.125 per cent, consisting of protopine 0.084 per cent and berberine 0.041 per cent, tannin 1.10 per cent, resin 1.75 per cent, and a toxic principle in argemone oil. The main activity was related to the alkaloids, the protopine fraction stimulating heart, respiration, skeletal muscles, and blood pressure. The total alkaloidal fraction stimulated all the smooth muscles and antagonized the actions of acetylcholine, histamine, and 5-hydroxytryptamine. Its oxytocic action resembled that of pitocin. Atropine, adrenergic blocking agents, and antihistaminics did not modify the response on blood pressure. The carotid occlusion reflex was inhibited, but responses to acetylcholine and catecholamines remained unaffected. It antagonized barbiturate-induced depression and potentiated methamphetamine stimulation of spontaneous motility in mice. It produced a mild neuromuscular block of the diaphragm and showed antiacetylcholine action on the frog rectus.

ARGEMONE MEXICANA (*Papaveraceae*), an American plant naturalized in India, grows widely and is commonly known as a pivla dhatura or satyanashi. The yellow, milky juice has long been used in indigenous systems of medicine for dropsy, jaundice, skin diseases, indolent or syphilitic ulcers, eye conditions, respiratory disorders, and constipation. Schlotterbeck (1) isolated and identified two alkaloids, berberine and protopine, from the plant. Berberine was tried by the early physicians in malaria and leishmaniasis (2–4). The seeds of this plant yield a fixed oil, argemone oil (22 to 36%), which, when consumed in adulterated mustard oil for cooking, was found responsible for the epidemic dropsy in certain areas (2). Mukerji (5) isolated a toxic substance, with an empirical formula $C_{19}H_{15}NO_4$, responsible for this. Pharmacological actions of berberine, obtained from the berberis family, have been reported (6, 7). Since no investigations on the effects of total alkaloids, and especially the protopine fraction of this plant have so far been reported, the present study was undertaken.

EXPERIMENTAL

The air-dried powdered roots and stems of the plant were subjected to successive extractions with the following solvents in a soxhlet apparatus and the residues found to be: alcohol—10.5, chloroform—2.1, petroleum ether—2.7, benzene—0.9, ether—1.7, acetone—3.3, and ethylacetate—1.6%.

On incineration, the total, acid soluble, acid insoluble, and water soluble ashes were found to be 8.56, 85.3, 14.7, and 50.8%, respectively. Inorganic constituents detected were potassium, calcium, sodium, aluminum, sulfates, nitrates, and carbonates.

Received October 23, 1962, from the Department of Pharmacology, M. G. M. Medical College, Indore (M. P.), India.
Accepted for publication May 27, 1963.

The paper chromatographic studies of alcohol and chloroform extracts, using Whatman No. 1 filter paper and water-saturated *n*-butanol:glacial acetic acid (25:1) as solvent, gave two distinct spots with R_f values of 0.35 and 0.23 and golden yellow and bluish fluorescence, respectively. The chromatograms, when sprayed with modified Dragendorff's reagent, showed them to be due to alkaloids. These were found to agree with berberine and protopine, respectively.

The plant was also found to contain tannins (1.10%) and resin (1.75%) by potassium permanganate titration and water precipitation methods, respectively. All the extracts gave a positive Libermann-Burchard's test for sterol bodies which was later found to be due to the alkaloids themselves.

The alkaloids were quantitatively estimated by the method described by Alfredo Santos (8). Much variation was observed from sample to sample, but the average total alkaloidal content was 0.125%. Of these, protopine formed 0.084%. The presence of these alkaloids was confirmed by the melting points and maximum light absorption spectra.

The toxic principle from the seed was separated and identified from the oil according to the method described by Mukerji (5).

Most of the pharmacological experiments were conducted with a total alkaloidal solution with the hydrochloride salt. In a few cases, both berberine and protopine were used for comparative evaluation of differences in actions.

Ten dogs, (five anaesthetized with urethane, 1.8 Gm./Kg., and five with diallyl barbituric acid, 0.7 ml./Kg.), weighing between 6–13 Kg., were utilized in the present study for observations on the effects of alkaloids on blood pressure, respiration, auriculo-ventriculogram, and intestine by the usual techniques.

Blood Pressure.—The total alkaloidal fraction was studied in a dose range of 0.05 to 5.0 mg./Kg. Smaller doses either had no effect or occasionally produced a slight rise, but a dose above 0.1 mg./Kg. produced a definite fall in blood pressure (Fig. 1). Atropine, adrenergic blocking agents, or antihistaminics did not modify the response. The hypotensive effect was more marked in experimentally induced hypertension with norepinephrine.

The sinus response due to carotid occlusion was inhibited by this fraction, but responses due to acetylcholine, epinephrine, or norepinephrine remained unaltered (Fig. 2). With smaller concentrations, a potentiation of acetylcholine-induced fall in blood pressure was observed.

Protopine fraction produced a rise in the blood pressure in smaller concentrations and a fall in doses greater than 1 mg./Kg. Berberine produced a fall in all the concentrations tried.

Heart.—The total alkaloidal fraction (1.0 mg./Kg.) inhibited both auricles and ventricles *in situ* in dogs. Rabbit heart, both *in situ* and isolated, was also depressed by the alkaloids in a concentration of 1×10^{-5} to 4×10^{-4}. Isolated amphibian heart was depressed even in a concentration of 1×10^{-6}. It also antagonized acetylcholine and epinephrine responses in a concentration of 1×10^{-5} to 2×10^{-4} (Fig. 3). Whereas the protopine fraction produced a slight stimulation even in a dose of 25 mcg./Kg., the berberine fraction was consistently found to be a myocardial depressant.

Respiration.—The total alkaloidal fraction, when given intravenously, stimulated respiration. It antagonized barbiturate-induced respiratory depression at higher concentrations (Fig. 4). The protopine fraction was very potent in this respect, whereas berberine produced an initial stimulation followed by depression. Both atropine and dihydroergotamine did not affect these actions.

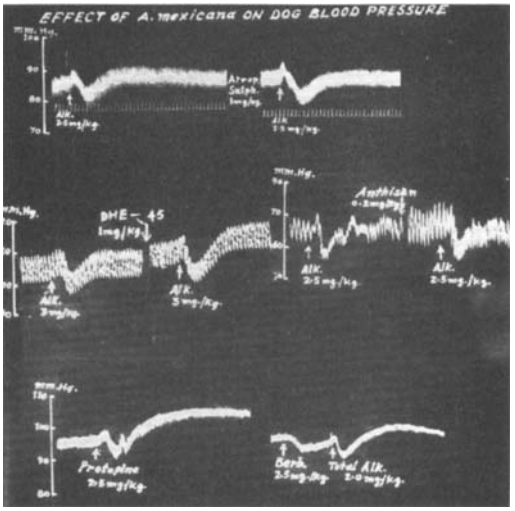

Fig. 1.—Effect of total alkaloid, protopine and berberine on blood pressure in the dog.

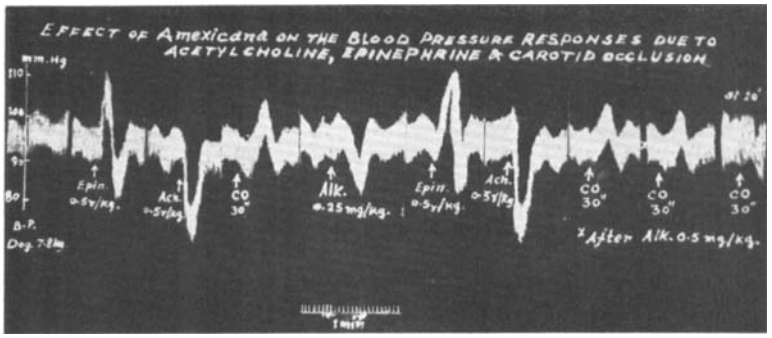

Fig. 2.—Effect of *A. mexicana* on the blood pressure responses to acetylcholine, epinephrine, and carotid occlusion responses.

Intestine.—In anesthetized dog and rabbit, both total and individual alkaloidal fractions produced an immediate stimulation of tone and peristaltic movements of the gut in a dose of 0.05 mg./Kg. Atropine inhibited the increase in tone but did not affect the augmentory action of the alkaloid on peristalsis.

Segments of ileum and uterus from freshly killed rats, guinea pigs, and rabbits, were mounted in an isolated organ bath and the effect of the alkaloids studied by the usual method. The intestine was stimulated in a concentration of 1×10^{-7} to 2×10^{-6}, with a concentration of 5×10^{-5}, though tone was increased; but there was a decrease in the amplitude of rhythmic contractions. In a concentration of 2×10^{-6} to 1×10^{-5} the total alkaloidal fraction administered half a minute before or simultaneously with spasmogens produced antiacetylcholine, antihistamine, and anti-5-hydroxytryptamine actions, even though it produced stimulation of its own. But when these spasmogens were allowed to remain in contact for some time and a persistent increased tone level obtained, the alkaloid produced an immediate relaxation. In atropinized tissue preparations the alkaloid still produced stimulation, though not markedly.

Other Smooth Muscles.—*In situ* experiments with rabbit uterii and isolated rat and guinea pig uterii showed that the alkaloid possessed a significant oxytocic activity in a concentration exceeding 5×10^{-7}; concentration of 5×10^{-6} produced, qualitatively, an effect similar to that of pitocin, 0.05 units/ml. (Fig. 5).

With frog blood vessel perfusion experiments, it was observed that the alkaloid produced vasodilatation in a concentration of 1×10^{-7} to 6×10^{-5}.

The effect on bronchioles was studied by both tracheal chain and lung perfusion experiments by the techniques detailed earlier (9). It was observed that though the total alkaloidal fraction produced a bronchoconstriction it exhibited antiacetylcholine and antihistaminic actions in a concentration of 5×10^{-6} to 3×10^{-4}.

Skeletal Muscle.—The protopine fraction, in a dose of 2.5 mg./Kg. or above, produced generalized muscle twitchings, more predominant in the neck and limb muscles, lasting for 2–5 minutes in dogs. This response usually corresponded with the respiratory stimulation. In a concentration of 2×10^{-5} to 2×10^{-4}, the total alkaloidal fraction showed an antiacetylcholine activity on frog rectus abdominis muscle studied in a leech muscle apparatus. A concentration of 2×10^{-4} evoked muscle twitchings. With experiments on a rat phrenic nerve diaphragm preparation by the method of

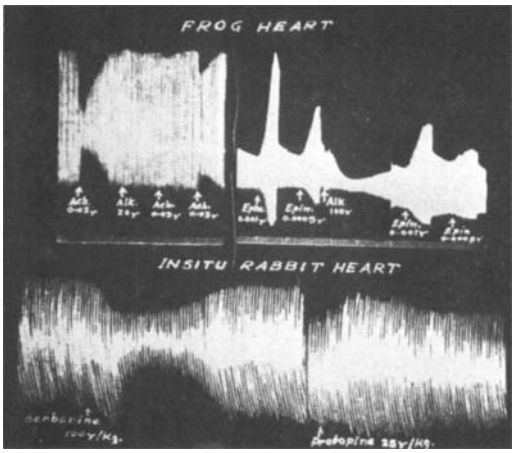

Fig. 3.—Effect of *A. mexicana* on frog and rabbit hearts.

Bulbring (10) it was observed that total alkaloidal fraction, in a concentration of 2×10^{-4}, produced a mild neuromuscular blocking effect which was partially antagonized by prostigmine. Concentrations of 2×10^{-5} or above produced muscle twitchings.

Effect of the total alkaloidal fraction on spontaneous motility was studied in mice (in groups of two each) with a simple instrument. It antagonized barbiturate-induced narcosis and potentiated the methamphetamine-induced hypermotility. The total alkaloidal fraction had no effect on rabbit cornea, conjunctival reflexes, or at the site of local injection in rats. But crude chloroform and petroleum ether extracts, suspended in normal saline, produced edema and necrosis at the site of injection in 80% of the cases within 2–3 days.

A few experiments conducted with the toxic substance isolated from argemone oil, showed hypotension, myocardial, respiratory, and intestinal inhibition. There was always a local action at the site of parenteral administration in rats.

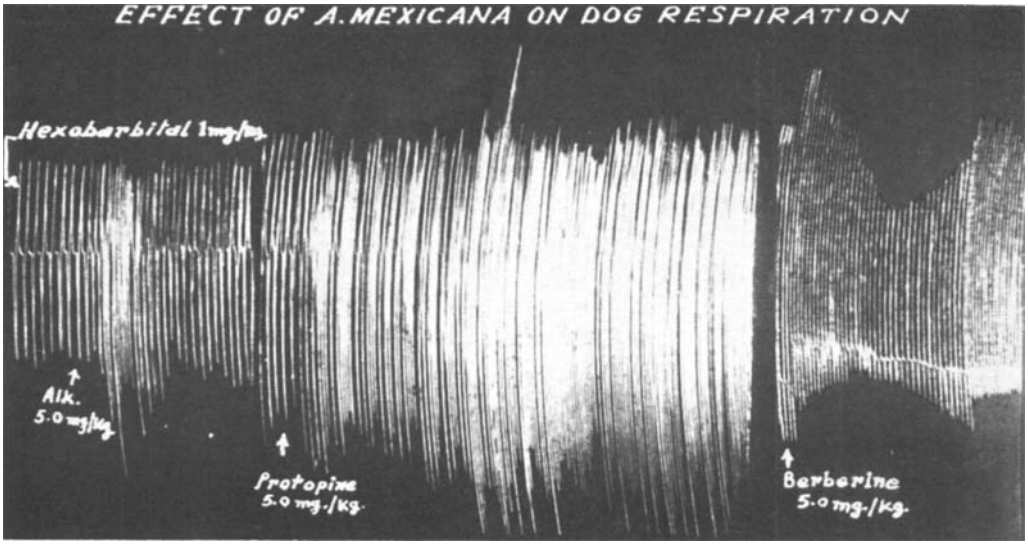

Fig. 4.—Effect of protopine and berberine on hexobarbital-depressed respiration of dog.

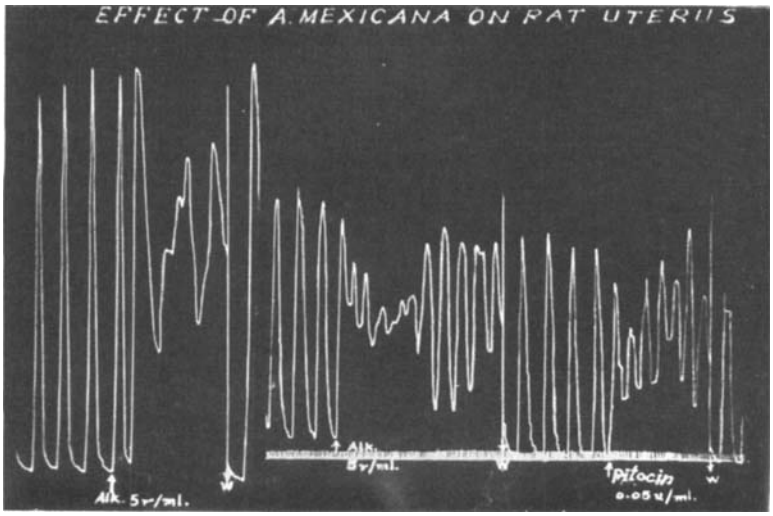

Fig. 5.—Effect of total alkaloid on isolated rat uterus.

Our findings with berberine on the gastrointestinal, cardiovascular, and respiratory systems are in agreement with those of other workers (6).

Behavior of Erythrocytes in Various Solvent Systems I

Water-Glycerin and Water-Propylene Glycol

By DONALD E. CADWALLADER

The hemolytic behavior of rabbit and human erythrocytes in water–glycerin and water–propylene glycol solutions was investigated. Complete hemolysis of erythrocytes took place in all propylene glycol solutions and most glycerin solutions. Aqueous solutions containing 50, 60, and 70 per cent glycerin prevented complete hemolysis of rabbit erythrocytes but not human erythrocytes. The addition of sodium chloride to various glycerin solutions prevented hemolysis. The addition of sodium chloride to propylene glycol solutions prevented hemolysis of rabbit erythrocytes in 5–30 per cent solutions and of human erythrocytes in 5–40 per cent solutions. When possible, the data were used to calculate van't Hoff *i* values for sodium chloride in various water-glycerin and water–propylene glycol solutions. Unusual behavior was displayed by erythrocytes in 40–50 per cent propylene glycol solutions. The addition of sodium chloride to solutions containing 50 per cent or more of propylene glycol did not prevent complete laking of red blood cells.

SINCE THE DEVELOPMENT of the hemolytic method by Husa and co-workers (1, 2), many investigations have been carried out (3–12) to study the behavior of erythrocytes to various compounds. In the aforementioned investigations, water was used as the solvent for all of the substances studied. Water, however, is not the only solvent used for intravenous preparations. To prepare a safe, stable, and efficacious injection, it is sometimes necessary to employ a mixed solvent system consisting of water and a nonaqueous co-solvent. Two nonaqueous solvents that are used in the formulation of parenteral preparations are glycerin and propylene glycol.

Husa and Adams (1) showed that glycerin and propylene glycol did not prevent hemolysis at concentrations which were calculated to be isotonic according to physicochemical data. They also reported that 0.3 to 0.5% sodium chloride would prevent hemolysis when added to hypo-osmotic concentrations of the polyhydric alcohols in water. Hammarlund and Pedersen-Bjergaard (13) demonstrated that complete hemolysis of blood takes place in iso-osmotic concentrations of glycerin and propylene glycol.

Hemolytic studies with glycerin and propylene glycol solutions were carried out by Zanowiak and Husa (8). They found that complete hemolysis took place in each 10% polyhydric alcohol–water solution, even though this concentration was well above the iso-osmotic concentration of each substance. They also reported that the addition of 0.2% sodium chloride did not prevent hemolysis of blood in the 10% glycerin or propylene glycol solutions. The presence of 0.6% sodium chloride, however, in these 10% solutions did prevent hemolysis. The purpose of this investigation was to conduct experiments to study further the behavior of red blood cells in aqueous glycerin and propylene glycol solutions. The hemolytic method was employed, and the experiments were designed so that standard hemolysis curves of human and rabbit blood obtained from experiments using sodium chloride–water solutions could be compared to hemolysis curves obtained from experiments using sodium chloride–water–polyhydric alcohol solutions. From these

data it was possible to calculate *hemolytic* isotonic coefficients for sodium chloride in various water–polyhydric alcohol solutions (*e.g.*, *i* values for NaCl in 5, 10, 20% propylene glycol).

EXPERIMENTAL

Materials.—Propylene glycol U.S.P. and reagent grade glycerin and sodium chloride were used.

Preparation of Solutions.—All of the polyhydric alcohol solutions were weight-in-volume percentage preparations. The sodium chloride solutions were prepared in the same manner described by other workers (1–10).

Collection of Blood.—The blood was collected and defibrinated in the same manner reported by Husa and co-workers (1–10). The human blood used in these experiments was obtained from the forearm veins of a 31-year-old white male.

Quantitative Determination of Per Cent Hemolysis.—The method used to determine the degree of hemolysis of erythrocytes in the various solutions involved in this investigation was essentially that described by Grosicki and Husa (2). The laking of blood in distilled water was used as the standard for 100% hemolysis. Because of the viscosity of the polyhydric alcohol solutions, especially in high concentrations, it was necessary to use centrifuge speeds of 2000–3000 r.p.m. to bring about complete settling of intact cells.

Water-glycerin and water–propylene glycol solutions absorbed a small amount of light, and this absorbance increased with an increase in polyhydric alcohol content. This absorbance was determined for the various concentrations of polyhydric alcohols used in experiments, and these blank readings were subtracted from the Klett-Summerson colorimeter readings obtained at the end of hemolysis experiments.

After several experiments, complete hemolysis of blood in polyhydric alcohol solutions gave absorbance readings indicating greater than 100% hemolysis. These higher readings appeared to be because of the darkening of the color of the oxyhemoglobin solutions. Experiments were carried out to determine to what extent this darkening took place in various glycerin and propylene glycol solutions. A solution representing 100% hemolysis was prepared by adding 1 ml. of blood to 100 ml. of distilled water. The resulting oxyhemoglobin solution was added in like amounts to each of two colorimeter tubes, one containing a measured amount of distilled water and the other containing a like amount of water–polyhydric alcohol solution. The colorimeter readings of these solutions were compared. After correcting for the absorbance of the polyhydric alcohol, per cent hemolysis readings were 2–3% higher for the water–polyhydric alcohol–blood solutions than water–blood solutions. This increase in hemolysis readings was attributed to a darkening of the red color by the polyhydric alcohols. The necessary corrections were made by subtracting this excess colorimetric reading, expressed as per cent, from the per cent hemolysis readings obtained for various glycerin and propylene glycol solutions.

Calculation of *i* Values.—When the concentrations of sodium chloride and any other compound causing the same degree of hemolysis are known, the value of *i* (isotonic coefficient) for the other compound can be calculated according to the osmotic equation used by Grosicki and Husa (2)

$$\frac{\left(\begin{matrix}i\text{ value}\\ \text{for NaCl}\end{matrix}\right)\left(\begin{matrix}\text{Gm. of NaCl}\\ \text{in 100 ml. of}\\ \text{solution}\end{matrix}\right)}{(\text{Gm.–molecular wt. of NaCl})} = \frac{\left(\begin{matrix}i\text{ value}\\ \text{for other}\\ \text{compound}\end{matrix}\right)\left(\begin{matrix}\text{Gm. of other}\\ \text{compound in 100}\\ \text{ml. of solution}\end{matrix}\right)}{\left(\begin{matrix}\text{Gm.—molecular wt. of other}\\ \text{compound}\end{matrix}\right)} \quad \text{(Eq. 1)}$$

The objective of this paper, however, was to calculate *apparent* *i* values for sodium chloride when the salt was present in a water–polyhydric alcohol system, *e.g.*, sodium chloride in 10% glycerin. In these calculations, it was necessary to assume that glycerin and propylene glycol did not contribute to the osmotic behavior of the solutions and that the sodium chloride was solely responsible for the

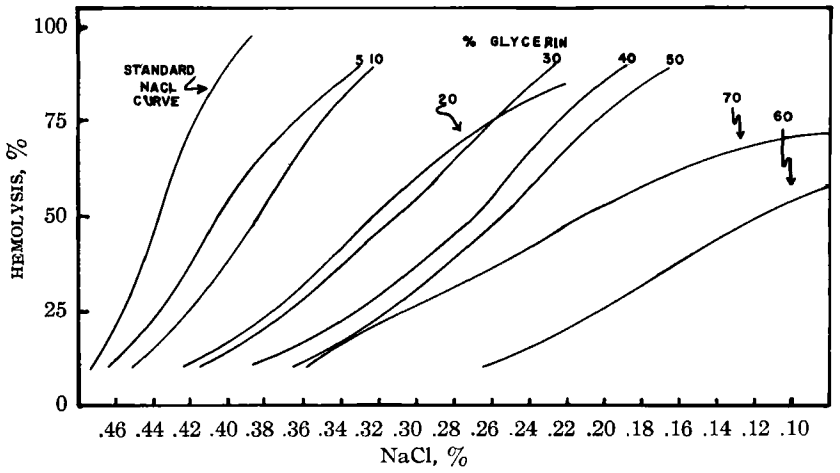

Fig. 1.—Per cent hemolysis of rabbit erythrocytes after 45 minutes at 25° in various glycerin – saline solutions.

tonicity of the solutions. Since the calculations were concerned with i values of only sodium chloride in different solvents, the molecular weights in Eq. 1 are identical and the equation becomes

$$\begin{pmatrix} i \text{ value for} \\ \text{NaCl in water} \end{pmatrix} \begin{pmatrix} \text{Gm. of NaCl} \\ \text{in 100 ml.} \\ \text{water} \end{pmatrix} = \begin{pmatrix} i \text{ value for} \\ \text{NaCl in other} \\ \text{solution} \end{pmatrix} \begin{pmatrix} \text{Gm. of NaCl} \\ \text{in 100 ml.} \\ \text{other solution} \end{pmatrix} \quad \text{(Eq. 2)}$$

The value of i for sodium chloride was taken as 1.86, which is the accepted value of i for 0.9% sodium chloride in water (2).

Curves showing the degree of hemolysis in sodium chloride–water solutions and sodium chloride–water–polyhydric alcohol solutions were plotted on rectangular coordinate paper. From these curves the concentrations of sodium chloride in Gm./100 ml. of water and the other solvent, causing 25, 50, and 75% hemolysis were determined. These values were inserted into Eq. 2, and the values of i for sodium chloride in a particular water–polyhydric alcohol solution, at concentrations giving 25, 50, and 75% hemolysis were determined. The various i values for sodium chloride in aqueous glycerin and propylene glycol solutions are shown in Tables I and II.

Preparation of Hemolysis Curves.—Fourteen experiments employing rabbit blood were carried out. The average readings of these experiments were used to construct a standard hemolysis curve (left hand side of Figs. 1 and 3). In constructing the hemolysis curves of the various polyhydric alcohol solutions, the grams of NaCl per 100 ml. of solution causing 25, 50, and 75% hemolysis were calculated with reference to the standard hemolysis curve. By utilizing Eq. 2, the Gm. of NaCl per 100 ml. in polyhydric alcohol solution causing 25% hemolysis was calculated as

$$X = \frac{A \times B}{C} \quad \text{(Eq. 3)}$$

where X = Gm. of NaCl in 100 ml. polyhydric alcohol solution causing 25% hemolysis, A = 1.86 as the i value for NaCl in water, B = Gm. of NaCl in 100 ml. of water causing 25% hemolysis (obtained from standard hemolysis curves in Figs. 1 and 3), and C = i value for NaCl in appropriate polyhydric alcohol solution (obtained from Tables I and II). Similar calculations were carried out to obtain i values at 50 and 75% hemolysis. With these three i values at 25, 50, and 75% hemolysis, the hemolysis curves for the various glycerin and propylene glycol solutions were plotted. In this manner, Figs. 1 and 3 are a compilation of the experiments run with rabbit blood, and all the curves have in common a standard hemolysis curve.

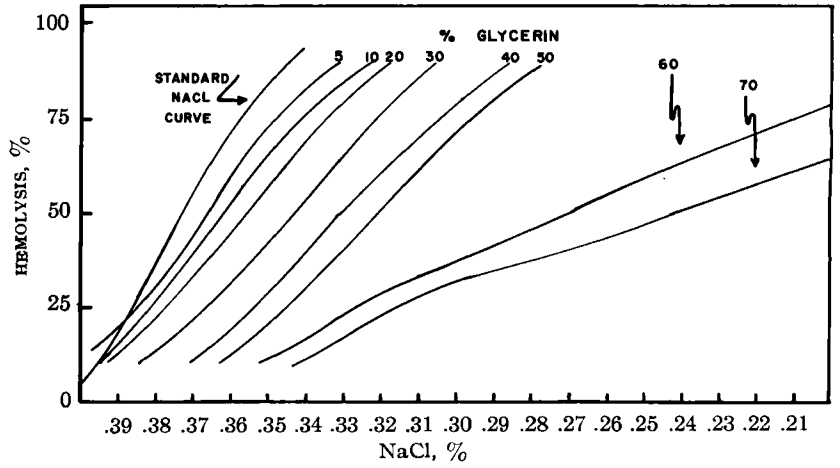

Fig. 2.—Per cent hemolysis of human erythrocytes after 45 minutes at 25° in various glycerin – saline solutions.

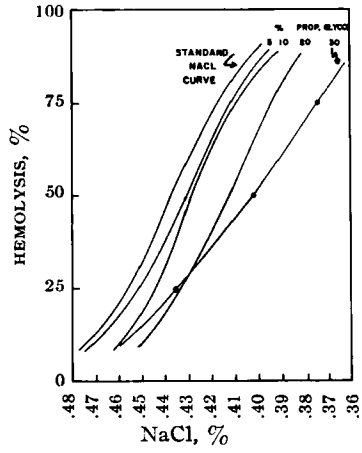

Fig. 3.—Per cent hemolysis of rabbit erythrocytes after 45 minutes at 25° in various propylene glycol–saline solutions.

Twelve similar experiments employing human blood were carried out. The average readings of these experiments were used to construct a standard hemolysis curve (left hand side of Figs. 2 and 4). The hemolysis curves for human blood in various polyhydric alcohol solutions were constructed in the manner previously described for the rabbit blood hemolysis curves. Figures 2 and 4 are a compilation of the experiments run with human blood.

RESULTS

Water-Glycerin Solutions.—The hemolysis of rabbit erythrocytes after 45 minutes at 25° in various water-glycerin solutions is shown in Fig. 5. All of the glycerin solutions void of sodium chloride caused complete hemolysis of rabbit erythrocytes except the 50, 60, and 70% solutions in which a small decrease in hemolysis was noticed.

Complete hemolysis of human erythrocytes took place in aqueous solutions containing 0.0 to 100% glycerin.

The fragility of rabbit and human erythrocytes in various water-glycerin solutions was modified or corrected by the addition of sodium chloride. It was possible to calculate *i* values for sodium chloride in various water-glycerin solutions. The average *i* values for sodium chloride in various glycerin solutions are given in Table I. In all cases, the *i* values for sodium chloride in water-glycerin solutions were greater than 1.86, the accepted value for 0.9% sodium chloride in water. This increase in *i* values can probably be attributed to some effect of glycerin on erythrocytes rather than increased activity of sodium chloride in the binary solvent. The higher *i* values for sodium chloride for rabbit blood than for human blood indicate that glycerin renders rabbit erythrocytes more resistant toward osmotic hemolysis. The sodium chloride *i* values increased with an increase in glycerin concentration which meant that less sodium chloride needed to be added to a more concentrated glycerin solution in order to make the solution isotonic to blood. The only exception to this was the higher *i* values for sodium chloride in 60% glycerin than in 70% glycerin solution when rabbit blood was employed. This can be accounted for by the fact that the least amount of hemolysis in water-glycerin solutions *sans* sodium chloride took place in 60% glycerin solution as shown in Fig. 5.

Values of *i* for sodium chloride in water-glycerin solutions containing more than 70% glycerin were not calculated because of inadequate data. Rabbit or human blood was placed in 80 and 90% glycerin solutions containing 0.2 to 0.4% sodium chloride. The opacity of these mixtures indicated that sodium chloride prevented complete hemolysis of rabbit and human erythrocytes in 80–90% glycerin solutions. The high viscosity of these solutions made it difficult to spin down the unhemolyzed cells which

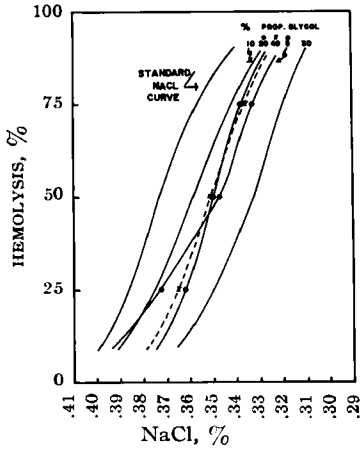

Fig. 4.—Per cent hemolysis of human erythrocytes after 45 minutes at 25° in various propylene glycol–saline solutions.

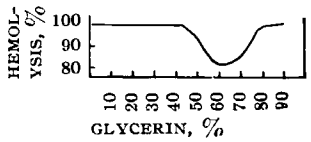
Fig. 5.—Per cent hemolysis of rabbit erythrocytes after 45 minutes at 25° in various glycerin solutions.



resulted in inaccurate colorimeter readings. After prolonged high speed centrifugation, these solutions retained a slight opaqueness.

Hemolysis curves showing the amount of laking that occurred when rabbit and human blood were added to various water–glycerin–sodium chloride solutions are shown in Figs. 1 and 2. These curves were constructed in the manner described in the *Experimental* section of this report utilizing the data presented in Table I. The addition of 0.48 to 0.28% sodium chloride to various water-glycerin solutions prevented osmotic hemolysis of rabbit erythrocytes. Hemolysis of human erythrocytes was prevented in water-glycerin solutions by the addition of 0.42 to 0.35% sodium chloride.

The average *i* values for human blood (Table I) were used to calculate the amount of sodium chloride that should be added to various water-glycerin solutions to make them isotonically equivalent to 0.9% sodium chloride solution. It was found that between 0.89 and 0.80% sodium chloride should be added to solutions containing 5–40% glycerin. The 50, 60, and 70% glycerin solutions would be made equivalent to isotonic saline solution by the addition

of 0.75, 0.63, and 0.55% sodium chloride, respectively. These data are shown in Fig. 6.

Water–Propylene Glycol Solutions.—All aqueous propylene glycol solutions ranging in concentration from 0.0 to 100% caused complete hemolysis of rabbit and human erythrocytes.

The addition of sodium chloride to water-propylene glycol solutions prevented hemolysis of rabbit erythrocytes in those solutions containing up to 30% propylene glycol. The *i* values for sodium chloride in these solutions were determined; the average values are given in Table II. The *i* values were slightly greater than 1.86. The hemolysis curves plotted from the data obtained after the addition of rabbit blood to various water–propylene glycol–sodium chloride solutions are shown in Fig. 3. Hemolysis of rabbit erythrocytes was prevented by the addition of 0.49 to 0.46% sodium chloride to 5–30% propylene glycol solutions. Peculiar hemolytic behavior of rabbit erythrocytes was noticed in 40% propylene glycol solutions. Complete protection of rabbit erythrocytes could not be achieved by the addition of sodium chloride up to concentrations of 6.0%. As the sodium chloride content increased from 0.4 to 1.0%, there was a decrease in hemolysis to a minimum of 15%; higher concentrations of sodium chloride caused an increase in hemolysis. This unusual behavior of rabbit erythrocytes in 40% propylene glycol is shown in Fig. 7. The complete hemolysis of rabbit erythrocytes in aqueous solutions containing 45% and more propylene glycol could not be prevented by the addition of up to 10.0% sodium chloride.

Hemolysis of human erythrocytes was prevented by the addition of 0.41 to 0.37% sodium chloride to 5–40% propylene glycol solutions. The *i* values for sodium chloride in these solutions were determined; the average values are given in Table II. The hemolysis curves prepared from the data obtained after the addition of human blood to various water–propylene glycol–sodium chloride solutions are illustrated in Fig. 4. Interesting behavior of human erythrocytes occurred in 45% propylene glycol solutions. There was a decrease in hemolysis in solutions containing 0.40 to 0.75% sodium chloride. Higher concentrations of sodium chloride resulted in increases in hemolysis. Complete hemolysis of human erythrocytes took place in 45% propylene glycol solutions containing 3.0% and more sodium chloride. This behavior is depicted in Fig. 8. The addition of various amounts of sodium chloride (up to 10.0%) did not prevent complete hemolysis of human erythrocytes in aqueous solutions containing 50% or more propylene glycol.

The average *i* values for human blood (Table II) were used to calculate the amount of sodium chloride that should be added to various water–propylene glycol solutions to make these solutions isotonically equivalent to 0.9% sodium chloride solution. Between 0.87 to 0.80% sodium chloride should be added to aqueous solutions containing 5–40% propylene glycol.

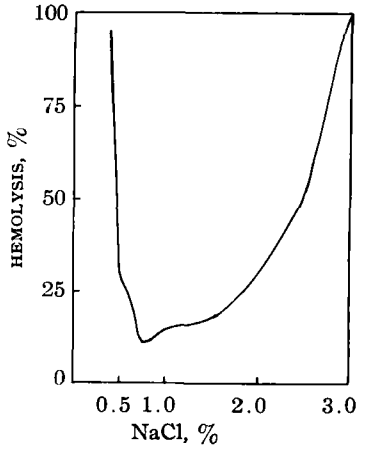

Fig. 8.—Per cent hemolysis of human erythrocytes after 45 minutes at 25° in various saline solutions containing 45% propylene glycol.

DISCUSSION

The concentrations of glycerin and propylene glycol in water that are iso-osmotic to 0.15 *M* sodium chloride and human blood, according to osmotic calculations, are 2.6 and 2.0%, respectively. The polyhydric alcohol content of aqueous solutions studied in this paper exceeded those concentrations having the same osmotic pressure as rabbit and human blood. Previous workers (1, 13) have shown that aqueous glycerin and propylene glycol solutions having concentrations that are hypo- and iso-osmotic to 0.15 *M* sodium chloride cause complete hemolysis of rabbit and human erythrocytes. Regardless of the polyhydric alcohol content, water-glycerin and water–propylene glycol solutions failed to prevent hemolysis of rabbit and human erythrocytes. These experimental data point out that when water-glycerin or water–propylene glycol are used as vehicles for intravenous solutions, the finished

product should not be assumed hypertonic with respect to blood. All aqueous glycerin and propylene glycol solutions studied in this investigation were hypotonic with respect to rabbit and human erythrocyte membranes.

Sodium chloride is effective in preventing hemolysis of rabbit and human erythrocytes in glycerin and propylene glycol solutions when the alcohols were in hypo-osmotic concentrations (1). Zanowiak and Husa (8) reported that 0.6% sodium chloride present in 10% glycerin and propylene glycol solutions prevented hemolysis of rabbit and human erythrocytes. The present investigation shows the presence of sodium chloride will prevent hemolysis of rabbit and human erythrocytes in aqueous solutions containing 5–90% glycerin. Sodium chloride prevented hemolysis of rabbit and human erythrocytes in aqueous propylene glycol solutions as long as the glycol concentration did not exceed 40–45%. Water–propylene glycol solutions containing more than 40–45% propylene glycol could not be made isotonic to rabbit and human erythrocyte membranes by the addition of sodium chloride. These data demonstrate that propylene glycol has greater hemolytic activity than glycerin. Jacobs, *et al.* (14), reported that each successive hydroxyl group added to the propane molecule decreased the rate of penetration of the alcohol into ox and rabbit erythrocytes.

Brittain and D'Arcy (15) have reported on the *in vivo* hematological effects in the rabbit following the intravenous injection of aqueous solutions containing different concentrations of propylene glycol in normal saline. Although the fragility of the red blood cells was not affected by different concentrations of propylene glycol, there was a marked decrease in blood clotting time with a corresponding increase in platelet count after the injection of 50% propylene glycol. The effect of 25% propylene glycol was considerably less. In this investigation the addition of sodium chloride to 30–40% propylene glycol solutions prevented hemolysis of rabbit and human erythrocytes, while the addition of sodium chloride to 50% propylene glycol solutions did not prevent complete hemolysis of these erythrocytes.

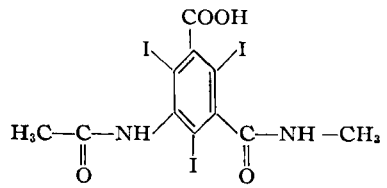
5 - Acetamido - 2,4,6 - triiodo - *N* - methylisophthalamic acid, $C_{11}H_9I_3N_2O_4$; M.W. 613.92; 62.01% iodine. The structural formula of iothalamic acid may be represented as follows:



Received August 27, 1963, from the Drug Standards Laboratory, American Pharmaceutical Association Foundation, Washington, D. C. 20037.
Accepted for publication October 2, 1963.
This monograph was developed by Robert R. Stark. Mallinckrodt Chemical Works has cooperated by furnishing samples and data to aid in its development and preparation.

Physical Properties.—Iothalamic acid occurs as a white, odorless, bulky crystalline powder. In a

melting point capillary it darkens at about 275° and decomposes with evolution of iodine fumes at 281–285° (U.S.P. XVI Class Ia). It is slightly soluble in water and in alcohol, and is practically insoluble in chloroform. It is soluble in solutions of alkali hydroxides.

Identity Tests.—Heat about 500 mg. of iothalamic acid in a porcelain crucible over a free flame: violet vapors of iodine are evolved.

A 1:100,000 solution of iothalamic acid in alcohol exhibits an ultraviolet absorbance maximum at about 242 mμ [absorptivity (1%, 1 cm.) about 530]. The spectrum is shown in Fig. 1.

The infrared spectrum of a 0.5% dispersion of iothalamic acid in potassium bromide, in a disk of about 0.82-mm. thickness is shown in Fig. 2.

Purity Tests.—Dry about 1 Gm. of iothalamic acid, accurately weighed, at 105° for 18 hours: it loses not more than 1.0% of its weight.

Char about 1 Gm. of iothalamic acid, accurately weighed, cool the residue, add 1 ml. of sulfuric acid, heat cautiously until evolution of sulfur trioxide ceases, ignite, cool, and weigh: the residue does not exceed 0.1%.

Add about 200 mg. of iothalamic acid to a mixture of 2 ml. of water and 2 ml. of chloroform, shake vigorously, and allow the layers to separate: the chloroform layer remains colorless (absence of free iodine).

Dissolve 500 mg. of iothalamic acid in 20 ml. of water containing 2–3 drops of stronger ammonia

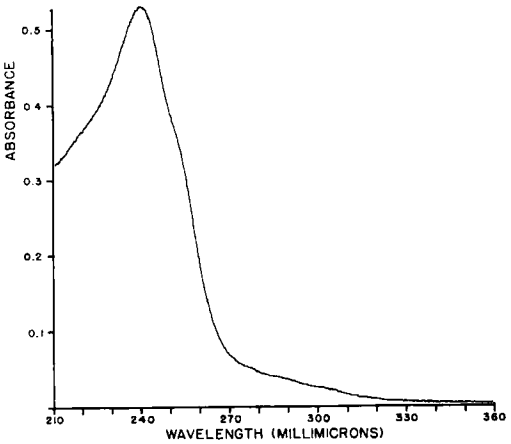

Fig. 1.—Ultraviolet absorption spectrum of iothalamic acid in alcohol (10 mcg. per ml.); Beckman model DK-2A spectrophotometer.

water contained in a 150-ml. glass-stoppered flask. Add 5 ml. of diluted nitric acid, shake vigorously, and filter the mixture through chloride-free paper. Add 2 ml. of silver nitrate T.S. to the filtrate: the solution shows no more turbidity than that produced by 0.01 mg. of chloride ion (Cl) in an equal volume of solution containing 5 ml. of diluted nitric acid and 2 ml. of silver nitrate T.S. (about 20 parts per million).

Transfer 1 Gm. of iothalamic acid to a 250-ml. beaker, add 15 ml. of nitric acid, and evaporate almost to dryness on a hot plate. Cool, add 10 ml. of nitric acid and 5 ml. of perchloric acid, and evaporate to dryness. Cool, add 2 ml. of hydrochloric acid, and rinse down the inner walls of the beaker with a few milliliters of water. Evaporate to dryness, cool, add another 2 ml. of hydrochloric acid, and again rinse down the inner walls of the beaker with a few milliliters of water. Evaporate to dryness, and bake the residue for a few minutes. Cool, add 10 ml. of water, 1 drop of phenolphthalein T.S., and sodium hydroxide T.S., dropwise, until the solution just turns pink. Add 1*N* hydrochloric acid dropwise until the color is discharged, add 1 ml. of diluted acetic acid, and dilute to 25 ml. with water. Prepare a control containing 20 mcg. of lead (Pb) and 1 ml. of diluted acetic acid in 25 ml. Add a small amount of activated charcoal (Darco G-60 is satisfactory) to each solution, and filter through retentive paper into 50-ml. color comparison tubes. Wash with a few ml. of water, dilute the solutions to 40 ml., and add 10 ml. of hydrogen sulfide T.S. to each solution: any brown color produced in the sample solution is not darker than that in the control solution: the heavy metals limit for iothalamic acid is 20 parts per million.

Assay.—(*Iodine*).—Transfer about 300 mg. of iothalamic acid, previously dried at 105° for 18 hours and accurately weighed, to a glass-stoppered 250-ml. flask, add 30 ml. of sodium hydroxide solution (1 in 20) and 500 mg. of powdered zinc. Connect the flask to a reflux condenser and reflux the mixture for 30 minutes. Cool to room temperature, and wash the condenser with 20 ml. of water. Filter the mixture and wash the flask and the filter with small portions of water, adding the washings to the filtrate. Add to the filtrate 5 ml. of glacial acetic acid and 1 ml. of a 1 in 1000 solution of tetrabromophenolphthalein ethyl ester in glacial acetic acid, and titrate with 0.05 *N* silver nitrate until the color of the yellow precipitate just changes to green. Each milliliter of 0.05*N* silver

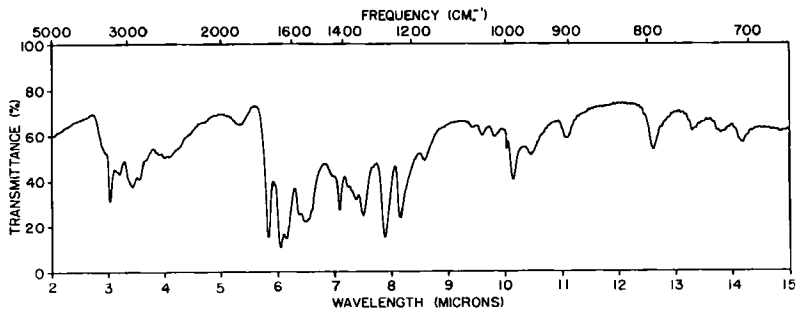

Fig. 2.—Infrared spectrum of iothalamic acid in potassium bromide disk (0.5%); Perkin-Elmer model 21 spectrophotometer, sodium chloride prism.

nitrate is equivalent to 6.345 mg. of iodine (I). The amount of iodine found is not less than 61.2% and not more than 62.8% of the weight of the sample taken.

(*Iothalamic Acid*).—Transfer about 2 Gm. of iothalamic acid, previously dried at 105° for 18 hours and accurately weighed, to a 250-ml. conical flask, and add 50.0 ml. of 0.1*N* sodium hydroxide. Swirl the flask to dissolve the sample, add 3 drops of phenolphthalein T.S., and titrate the excess base with 0.1 *N* hydrochloric acid. Each ml. of 0.1 *N* sodium hydroxide consumed is equivalent to 61.39 mg. of $C_{11}H_9I_3N_2O_4$. The amount of iothalamic acid found is not less than 99.0% and not more than 101.0% of the weight of the sample taken.

DOSAGE FORMS OF IOTHALAMATE SALTS

Meglumine Iothalamate Injection

A sterile solution of iothalamic acid in water for injection, prepared with the aid of meglumine (*N*-methylglucamine); $C_{18}H_{26}I_3N_3O_9$; M.W. 809.14.

Physical Properties.—Meglumine iothalamate injection is a clear, pale yellow, slightly viscous liquid. The pH is between 6.8 and 7.5.

Identity Tests.—Dilute a volume of meglumine iothalamate injection, equivalent to about 2 Gm. of meglumine iothalamate, with water to 100 ml., add 5 ml. of dilute hydrochloric acid, mix, and filter off the precipitated iothalamic acid. Wash the precipitate with four 10-ml. portions of water, and dry at 105° for 4 hours: the dried residue responds to the chemical and infrared identity tests for iothalamic acid.

Purity Tests.—Transfer a volume of meglumine iothalamate injection, equivalent to 1 Gm. of meglumine iothalamate, to a 250-ml. beaker. Proceed as directed in the heavy metals test in the monograph for iothalamic acid, beginning with ". . .add 15 ml. of nitric acid. . . ." The heavy metals limit for meglumine iothalamate is 20 parts per million.

To about 2 ml. of meglumine iothalamate injection add a few drops of starch T.S.: no blue color is produced (absence of free iodine).

Assay.—(*Meglumine Iothalamate*).—Pipet a volume of meglumine iothalamate injection, equivalent to about 3 Gm. of meglumine iothalamate, into a 100-ml. volumetric flask, add water to volume, and mix. Pipet 10 ml. of the solution into a 250-ml. glass-stoppered flask and proceed as directed in the *Assay for Iodine* under iothalamic acid, beginning with ". . .add 30 ml. of sodium hydroxide solution (1 in 20). . . ." Each milliliter of 0.05 *N* silver nitrate is equivalent to 13.49 mg. of $C_{18}H_{26}I_3N_3O_9$. The amount of meglumine iothalamate found is not less than 96.0% and not more than 104.0% of the labeled amount.

Sodium Iothalamate Injection

A sterile solution of iothalamic acid in water for injection, prepared with the aid of sodium hydroxide.

Physical Properties.—Sodium iothalamate injection is a clear, pale yellow, slightly viscous liquid. The pH is between 6.8 and 7.5; $C_{11}H_8I_3N_2NaO_4$; M. W. 635.90.

Identity Tests.—The solution responds to the identity tests for meglumine iothalamate injection and to the U.S.P. XVI flame test for sodium.

Purity Tests.—Determine the heavy metals content by the procedure for meglumine iothalamate injection. The heavy metals limit for sodium iothalamate is 20 parts per million.

To about 2 ml. of sodium iothalamate injection add a few drops of starch T.S.: no blue color is produced (absence of free iodine).

Assay.—(*Sodium Iothalamate*).—Assay sodium iothalamate injection by the procedure for meglumine iothalamate injection. Each milliliter of 0.05 *N* silver nitrate is equivalent to 10.60 mg. of $C_{11}H_8I_3N_2NaO_4$. The amount of sodium iothalamate found is not less than 97.5% and not more than 102.5% of the labeled amount.

DISCUSSION

U.S.P. and N.F. terminology for solubility, melting range, reagents, etc., have been used wherever feasible.

Iothalamic acid, synthesized by Hoey, *et al.* (1), is a radiographic contrast medium. Solutions of its salts are used for intravenous urography (meglumine iothalamate)[1] and for intravascular angiocardiography and aortography (sodium iothalamate).[2] Chemically, these solutions are similar to methylglucamine diatrizoate injection U.S.P. XVI, and sodium diatrizoate injection U.S.P. XVI, respectively, and the tests and standards in the above monographs are also similar to those in the official monographs.

Identity Tests.—Because of similarity of structure, identity tests based upon evolution of iodine vapor and comparison of the ultraviolet absorption spectrum with that of a reference standard are not sufficient to identify iothalamic acid or its salts. Comparison of the infrared spectrum with that produced by reference material under identical conditions provides a satisfactory test.

Quantitative Methods.—The quantitative methods provided are simple enough to perform and possess sufficient accuracy and precision for their intended purposes. Acidimetric determination of iothalamic acid gave an average value of 100.3 ± 0.2%.[3] Argentimetric determination of this compound gave an average value equivalent to 61.1 ± 0.1% iodine. Analysis of commercial preparations gave average values of 98.3 ± 0.1% and 97.7 ± 0.1% for meglumine iothalamate and sodium iothalamate injections, respectively.

Dosage Variation in Compressed Tablets

By C. D. SMITH, T. P. MICHAELS, M. J. CHERTKOFF, and L. P. SINOTTE

A study was undertaken to evaluate the intertablet dosage variation in a number of different products by the use of automated instrumentation. Representative samples of actual production runs were used; an analysis of the data is presented.

ALTHOUGH PRODUCT DOSAGE is expressed on an individual compressed tablet basis, potency testing utilizes an analytical sample which is a composite of many tablets. An assay procedure will often read: "Weigh and finely powder not less than 20 ——— tablets. Weigh accurately a portion of the powder, equivalent to about . . ." (1). Such procedures give information on the average tablet assay; however, they give no information on the individual tablets. For example, if half of the tablets were 50% high in potency and half 50% low, the composite sample would still assay satisfactorily.

Considerable interest has recently been shown in studying this topic as exemplified in reports by Moskalyk, *et al.* (2), Garrett (3), and Evers (4). Suggestions have been made to modify the presently accepted practice of assaying a composite sample and to assay individual tablets (5, 6). Because of the difficulty of performing large numbers of assays, these studies have been limited to a relatively small sample, usually less than 100, which may not be representative of modern large scale production lots. For this reason, the nature of the distribution of individual tablet assays has not been established. Such information is necessary before the need for a change in existing procedures can be established and corrective action devised.

Recent work in this laboratory has made available automated chemical instrumentation (7–9) capable of automatically analyzing 20 tablets per hour. This facilitates the collection of a large number of assays. This paper presents assay and weight variation data on round, discoid, individual tablets—selected to be representative of different production batches of several products—in an attempt to define the nature of the distribution of dosage variation in commercially available compressed tablets.

Received June 4, 1963, from the Quality Control Section, Merck Sharp and Dohme, Division of Merck and Co., Inc., West Point, Pa.

Accepted for publication June 21, 1963.

The authors acknowledge the assistance of Mr. W. Holl and M. K. Wrightman for laboratory assistance, and Mr. J. L. Ciminera and Mr. A. G. Itkin for advice on statistical evaluation.

EXPERIMENTAL

Chemical assays were performed with modified AutoAnalyzer[1] as described by Michaels and Sinotte (7) and Holl and Walton (8). Individual tablets, taken at approximately uniform intervals throughout the compression of a lot, were assayed automatically. The assay procedures employed were colorimetric as described by Wrightman and Holl (9). The individual tablet weights were obtained by standard analytical balances or the Mettler automatic tablet weigher.[2] All curves in the figures are fitted by eye.

RESULTS AND DISCUSSION

Variation Range of Individual Tablet Assays.—Table I summarizes the assay results obtained on two batches of each of five different products. These data are typical of other products and batches studied over a 1-year period. These results were tested for conformance with the presently accepted composite limits of ±10% (1) and against somewhat wider limits of ±15%, as recently suggested (5). Over 99% of the tablets conform to presently accepted composite limits; only a few minor deviations were found. All tablets conform to the wider limits.

Distribution of Individual Tablet Assay.—To define the distribution of individual tablet assays

	C		49	100	4.5	[−1.00]	3.42	Skewed—low side
	D		100	99	1.7	−0.14	3.02	Normal

[a] Tested for significance by student "t" test at 0.05 level; significant values indicated by brackets.

further lots were studied. The curves are described numerically by $\bar{X}$ (average assay), σ (standard deviation), α_3 (a measure of skewness), and α_4 (a measure of kurtosis).

The expected value for α_3 is zero for a normal distribution. A negative value indicates distribution skewed to the left; a positive value indicates a distribution skewed to the right. The expected value for α_4 is 3 for a normal distribution. A value greater than 3 indicates a leptokurtic distribution (more peaked than normal); a value less than 3 indicates a platykurtic distribution (flatter than normal)(10).

It is obvious from the data in Table II that the average assays are very close to label claims. The standard deviations are small which confirms the information reported in Table I and, with few exceptions, the curves are essentially normal. The significance of the α_3 and α_4 values were determined (11), and the type of curve is indicated.

Examination of the data indicates a relationship between standard deviation and per cent of active ingredient in the tablet. Figure 1 shows that as the per cent of active ingredient increases, the variation in individual assays decreases.

The standard deviation of 4.5 (Product 7, Lot C) is an aberrant value and may be due to experimental errors. To confirm that this is not a normal situation, nine more lots of Product 7 were investigated (see Table III). The average standard deviation of these nine lots is 1.7, which lies very close to the estimated line.

Distribution of Individual Tablet Weights.—To define the distribution of individual tablet weights 13 lots representing six different products were studied. The data in Table IV are typical of many other products and lots studied.

Examination indicates that the data are essentially normal as discussed above. The average weights are close to the target weight and the standard deviations are small. These standard deviations in milligrams vary directly with tablet weight as shown in Fig. 2. However, when the relative per cent error ($\sigma/\bar{X} \times 100$) is plotted against average weight (Fig. 3) it is evident that the relative per cent error remains constant at about 1.4 for tablets weighing more than 300 mg. Further work is indicated to study the rise in relative per cent error for tablets weighing less than 300 mg.

Correlation Between Individual Tablet Weight and Assay.—To study the relationship between the two variables, individual tablets from 12 lots representing six different products were weighed and then assayed. The distribution of these two variables have been previously shown in Tables II and IV. The relationship of these two variables is expressed as correlation coefficients. There is no relationship when the value is zero, whereas perfect

positive correlation exists when the value is one. The results in Table V show a significant correlation in 10 out of 12 lots at a low level, in the range studied. In the range studied there seems to be no relationship between weight-assay correlations and per cent of active ingredient in the tablet.

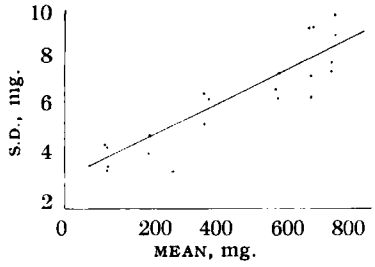

Fig. 2.—Standard deviation (weights) *vs.* mean.

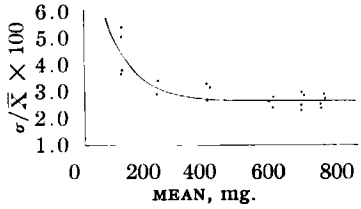

Fig. 3.—Relative error (weights) *vs.* mean.

CONCLUSIONS

It was found from the sample studied in our laboratories that (*a*) the spread of dosage variation in individual compressed tablets was very small, (*b*) the distribution of individual tablet weights and assays was essentially normal; and (*c*) a correlation existed between tablet weight and assay, at a low level, in the range studied.

In this type of situation where extensive research.

considerable production experience, and sufficient in-process controls exist, low dosage variation in individual compressed tablets may be achieved. Modern quality control concepts emphasize that quality should be built into the product rather than tested in. The results of this study indicate what can be achieved by following this concept.

It should be noted that the tablets studied were round, discoid shape, containing more than 20% active ingredient, and the assay procedures involved have a high degree of reliability. Further studies should be performed with tablets of irregular shapes and lower percentage of active ingredient. It would also be interesting to examine the effects of assay procedures of greater variability on this type of study.

Notes

Synthesis of Selected Amides of Mono- and Bis(carboxypiperidino)alkanes

By RONALD P. QUINTANA and WAYNE A. SHRADER

The synthesis of selected amides of mono- and bis(carboxypiperidino)alkanes is reported.

THE SYNTHESIS of selected amides of mono- and bis(carboxypiperidino)alkanes has been undertaken to expand significantly those series of compounds previously reported (1–4). The compounds described in this communication were chosen on the basis of enzymodynamic studies, wherein particularly interesting variations in biochemical response relative to modifications in chemical constitution were noted and parallel effects upon surface and interfacial tension were observed. The fact that in some instances, among the monomethyl-, dimethyl-, monoethyl-, and diethylcarboxamido derivatives, the latter was the only one effecting appreciable or even significant inhibition in isolated human plasma "pseudo"-cholinesterase systems (5), prompted us to explore variations in the amide group in terms of steric factors and the electrophilic character of the carbonyl carbon. Since the mono- and bis[3-(N,N-diethylcarboxamido)piperidino]-ethanes and decanes reflected perhaps the most interesting relationships between molecular constitution, cholinesterase inhibition (5), and surface and interfacial tension (6), these four analogs were selected as model molecules for this study.

In general, the synthetic procedures employed in this investigation were those utilized by Lassio and co-workers (1, 2, 4). The compounds 1-ethyl-3-(N,N-diethylcarboxamido)-1,2,5,6-tetrahydropyridine hydrochloride (XVIII) and 1-decyl-3-(N,N-diethylcarboxamido)-1,2,5,6-tetrahydropyridine hydrochloride (XIX) were synthesized by sodium borohydride reduction of the appropriate pyridinium salts, a method employed by Lyle and co-workers (7) in the preparation of arecoline (methyl 1-methyl-1,2,5,6-tetrahydronicotinate) and methyl 1-methyl-1,2 5,6-tetrahydroisonicotinate.

The position of the double bond in compounds XVIII and XIX was confirmed by a comparison of the ultraviolet and infrared spectra of these compounds with the corresponding spectra of 1-methyl-3-(N,N-diethylcarboxamido)-1,2,5,6-tetrahydropyridine hydrochloride (XX) (1), prepared from arecoline (see Table I). Lyle's recent interpretation (8) of the mechanism involved in the sodium borohydride reduction of pyridinium ions provides further substantiation in this regard.

Synthesis of Selected Amides of Mono- and Bis(carboxypiperidino)alkanes

By RONALD P. QUINTANA and WAYNE A. SHRADER

The synthesis of selected amides of mono- and bis(carboxypiperidino)alkanes is reported.

THE SYNTHESIS of selected amides of mono- and bis(carboxypiperidino)alkanes has been undertaken to expand significantly those series of compounds previously reported (1–4). The compounds described in this communication were chosen on the basis of enzymodynamic studies, wherein particularly interesting variations in biochemical response relative to modifications in chemical constitution were noted and parallel effects upon surface and interfacial tension were observed. The fact that in some instances, among the monomethyl-, dimethyl-, monoethyl-, and diethylcarboxamido derivatives, the latter was the only one effecting appreciable or even significant inhibition in isolated human plasma "pseudo"-cholinesterase systems (5), prompted us to explore variations in the amide group in terms of steric factors and the electrophilic character of the carbonyl carbon. Since the mono- and bis[3-(N,N-diethylcarboxamido)piperidino]-ethanes and decanes reflected perhaps the most interesting relationships between molecular constitution, cholinesterase inhibition (5), and surface and interfacial tension (6), these four analogs were selected as model molecules for this study.

In general, the synthetic procedures employed in this investigation were those utilized by Lassio and co-workers (1, 2, 4). The compounds 1-ethyl-3-(N,N-diethylcarboxamido)-1,2,5,6-tetrahydropyridine hydrochloride (XVIII) and 1-decyl-3-(N,N-diethylcarboxamido)-1,2,5,6-tetrahydropyridine hydrochloride (XIX) were synthesized by sodium borohydride reduction of the appropriate pyridinium salts, a method employed by Lyle and co-workers (7) in the preparation of arecoline (methyl 1-methyl-1,2,5,6-tetrahydronicotinate) and methyl 1-methyl-1,2 5,6-tetrahydroisonicotinate.

The position of the double bond in compounds XVIII and XIX was confirmed by a comparison of the ultraviolet and infrared spectra of these compounds with the corresponding spectra of 1-methyl-3-(N,N-diethylcarboxamido)-1,2,5,6-tetrahydropyridine hydrochloride (XX) (1), prepared from arecoline (see Table I). Lyle's recent interpretation (8) of the mechanism involved in the sodium borohydride reduction of pyridinium ions provides further substantiation in this regard.

compound was prepared from isonicotinic acid. The product distilled at 94°/0.15 mm. Hg, uncorrected (lit. (9) b.p. 123 to 123.5°/3 mm. Hg, corrected; lit. (10) b.p. 109°/0.5 mm. Hg, uncorrected).

3-(Pyrrolidinoformyl)pyridine (II).—This compound was prepared from nicotinic acid. The product distilled at 114°/0.04 mm. Hg, uncorrected (lit. (10) b.p. 131–133°/0.3 mm. Hg, uncorrected).

The compounds listed in Table II were prepared by the following procedures.

Procedure A: **1-Ethyl-3-(N,N-dimethylcarboxamido)piperidine Hydrobromide** (III).—N,N-Dimethylnicotinamide (25 Gm., 0.167 mole) (IV) and ethyl bromide (48.3 Gm., 0.443 mole) were dissolved in 200–300 ml. anhydrous benzene and refluxed for 48–60 hours. The precipitate formed in the reaction was separated and was dissolved in 150–200 ml. distilled water. The aqueous solution was washed with benzene, treated with charcoal, and filtered. The filtrate was subjected to hydrogenation (aqueous or hydroalcoholic solution) in the presence of 1.0 Gm. platinum oxide (Adams' catalyst) at maximum pressures of 45–50 p.s.i. After absorption of hydrogen ceased, the platinum oxide was filtered off and the solvent was removed by azeotropic distillation under reduced pressure with absolute ethanol and anhydrous benzene. The product was purified by recrystallization.

Procedure B: **1,2-Bis[3-(N,N-dimethylcarboxamido)piperidino]ethane Dihydrobromide** (VI).—N,N-Dimethylnicotinamide (52.1 Gm., 0.347 mole) (IV) and 1,2-dibromoethane (32.6 Gm., 0.174 mole) were dissolved in 200 ml. anhydrous benzene and refluxed for 53–62 hours. The precipitate formed during the reaction was then treated as described under *Procedure A*.

Procedure C: **1-Ethyl-3-(N,N-diethylcarboxamido)-1,2,5,6-tetrahydropyridine Hydrochloride** (XVIII).—1 - Ethyl - 3 - (N,N - diethylcarboxamido)pyridinium bromide (XVII) (2) was prepared by refluxing N,N-diethylnicotinamide (40 Gm., 0.224 mole) (XVI) and ethyl bromide (61 Gm., 0.560 mole) in 250 ml. anhydrous benzene for 48 hours. Excess alkyl halide and solvent were removed by decantation. The residual oil was dissolved in 150 ml. water, the aqueous solution was washed with benzene, and the water was removed under reduced pressure. Last traces of moisture were removed by azeotropic distillation with benzene. The oily product (60 Gm., 0.209 mole) was dissolved in 400 ml. dry methanol and cooled in an ice bath. Sodium borohydride (31.7 Gm., 0.838 mole) was added with stirring to the cold solution over 30 minutes; subsequently the solution was stirred an additional 30 minutes. Methanol was removed by distillation under reduced pressure to give a spongy yellow residue which was dissolved in 230 ml. water and saturated with potassium carbonate. The mixture was extracted with ether, the combined ether extracts were dried over anhydrous potassium carbonate, filtered, and the ether was removed by distillation. The oily residue was purified by conversion to the hydrochloride (anhydrous HCl in anhydrous ether) with or without prior fractionation under reduced pressure. Residual traces of moisture were removed from the oily hydrochloride by azeotropic distillation with benzene. The salt was then purified by recrystallization from ethanol-ethyl acetate.

Sensitive and Reproducible Assay Method for Chymotrypsin

By B. L. KABACOFF, M. UMHEY, A. WOHLMAN, and S. AVAKIAN

A new assay method for chymotrypsin was developed. This method, based on N-acetyl-L-tyrosine ethyl ester (ATEE), was found to be ten times as sensitive as the proposed N.F. assay method for chymotrypsin. In the new method described, the residual substrate is measured by a single colorimetric determination. The method is convenient and highly reproducible.

THE CLASSICAL assay methods for proteolytic activity such as hemoglobin digestion, casein digestion, and milk clotting, although convenient and simple, lack specificity. N-acetyl-L-tyrosine ethyl ester (ATEE) is a specific substrate for chymotrypsin. The proposed N.F. method for the analysis of chymotrypsin, based on the work of Schwert and Takenaka (1), utilizes ATEE as the enzyme substrate. The rate of hydrolysis of this substrate in pH 7.0 buffer is followed spectrophotometrically at 237 mμ. Readings are taken every 30 seconds for a period of 4 minutes. The temperature must be kept within ±0.1° of 25.0°.

The above method has certain drawbacks which limit its practical application. Elaborate equipment is required to maintain the cell compartment of the spectrophotometer at the exact temperature speci-

Sensitive and Reproducible Assay Method for Chymotrypsin

By B. L. KABACOFF, M. UMHEY, A. WOHLMAN, and S. AVAKIAN

A new assay method for chymotrypsin was developed. This method, based on N-acetyl-L-tyrosine ethyl ester (ATEE), was found to be ten times as sensitive as the proposed N.F. assay method for chymotrypsin. In the new method described, the residual substrate is measured by a single colorimetric determination. The method is convenient and highly reproducible.

THE CLASSICAL assay methods for proteolytic activity such as hemoglobin digestion, casein digestion, and milk clotting, although convenient and simple, lack specificity. N-acetyl-L-tyrosine ethyl ester (ATEE) is a specific substrate for chymotrypsin. The proposed N.F. method for the analysis of chymotrypsin, based on the work of Schwert and Takenaka (1), utilizes ATEE as the enzyme substrate. The rate of hydrolysis of this substrate in pH 7.0 buffer is followed spectrophotometrically at 237 mμ. Readings are taken every 30 seconds for a period of 4 minutes. The temperature must be kept within ±0.1° of 25.0°.

The above method has certain drawbacks which limit its practical application. Elaborate equipment is required to maintain the cell compartment of the spectrophotometer at the exact temperature speci-

Fig. 2.—Effect of variation of initial ATEE concentration on the assay.

fied. The manipulations involved make readings at intervals of exactly 30 seconds difficult. Variable results may often be obtained when ATEE from different sources is used. Even when the variables are carefully controlled, results are often erratic. The present study was undertaken to devise a new assay method for chymotrypsin based on ATEE and to evaluate its reproducibility and convenience. In this method, the residual ATEE after incubation with the enzyme is measured by reacting it with alkaline hydroxylamine, thus forming the hydroxamic acid (2). The hydroxamic acid is then acidified and reacted with ferric ion to produce a color which is read on a spectrophotometer.

EXPERIMENTAL

The chymotrypsin used in the study was obtained from Princeton Laboratories, Princeton, N. J., and the Worthington Biochemical Corporation, Freehold, N. J. The enzymes from both sources were crystallized. The ATEE was obtained from Mann Research Laboratories, New York, N. Y., Calbiochem, Los Angeles, Calif., and K & K Laboratories, Jamaica, N. Y. The chymotrypsin used as the standard had an assay of 1290 proposed N.F. units/mg. All of the samples utilized in this study were assayed against this standard.

Reagents.—All solutions were prepared with distilled water and reagent grade materials. Hydroxylamine hydrochloride, 139 Gm./L., and sodium hydroxide, 140 Gm./L., were used. Alkaline hydroxylamine solution is prepared by mixing equal volumes of the above solutions just prior to use. Hydrochloric acid (0.001 *N* and 4.0 *N*), phosphate buffer of 1.09 Gm. anhydrous potassium dihydrogen phosphate, and 2.27 Gm. anhydrous disodium hydrogen phosphate diluted to 100.0 ml. (the pH of this solution should be 7.0 ±0.1) were employed. The substrate solution was 115 mg. of N-acetyl-L-tyrosine ethyl ester in 50.0 ml. of phosphate buffer. Shake well to dissolve and filter through Whatman No. 42 filter paper (prepare fresh daily). Ferric chloride (hexahydrate), 189 Gm./L.

Table I.—Comparison of ATEE from Different Sources

	Chymotrypsin Activity, Proposed N.F. Units/mg.		
	Mann	Calbiochem	K & K
CTD-5	1250 ± 41 (4)[a]	1290 ± 69 (4)[a]	1230 ± 43 (2)[a]
CTD-7	1340 ± 13 (4)[a]	1340 ± 26 (4)[a]	1330 ± 20 (2)[a]

[a] Number of determinations.

Method.—A solution of chymotrypsin sample in 0.001 *N* hydrochloric acid is prepared so that it contains 1.5 to 2.0 proposed N.F. units (1.2 to 1.6 mcg.) of chymotrypsin per ml. A solution using chymotrypsin of known potency (standard) is also prepared.

One-milliliter aliquots of the substrate solution are placed into each of three test tubes immersed in a water bath maintained at 25 ±0.5°. To one tube, 0.5 ml. of the sample solution is added. To the second tube, 0.5 ml. of the standard is added. To the third tube, 0.5 ml. of 0.001 *N* HCl is added. The exact time of each addition is noted. It is advisable to stagger the additions 1 minute apart.

Exactly 50 minutes after the addition of enzyme solution or 0.001 *N* HCl to the test tubes, the reaction is stopped by the addition of 2.0 ml. of alkaline hydroxylamine solution. Two minutes later, 1.0 ml. of 4 *N* hydrochloric acid is added to each tube.

The color is then developed by the addition of 1.0 ml. of ferric chloride solution to each tube. The absorbances of the solutions (unknown, standard, 0.001 *N* HCl) are read against distilled water at 540 mμ in a 1-cm. cell. These readings should be made within 20 minutes after the ferric chloride addition. The absorbances of the unknown and standard solutions are each subtracted from that of the 0.001 *N* hydrochloric acid. These differences in absorbance are proportional to the activities of the enzyme solutions. Samples should be run in duplicate or triplicate.

After the addition of each reagent, the tubes should be agitated vigorously. If this precaution is not taken, the absorbance may be erroneously high. The quality of the substrate may be checked prior to the assay by adding all the reagents as stated above using 0.001 *N* hydrochloric acid instead of

chymotrypsin solution. Do not incubate but read the absorbance immediately. The absorbance should be between 0.400 and 0.650.

RESULTS

Dependence of ATEE Hydrolysis on Chymotrypsin Concentrations.—Figure 1 gives the absorbance obtained after incubation of varying concentrations of chymotrypsin with substrate solution in two typical experiments. Each point on the curves represents duplicate determinations. It can be seen that the relationship is linear up to 1.2 mcg./0.5 ml. Since the absorbance, which is a measure of ATEE present, fell from approximately 0.55 to 0.06, we may say that about 90% of the substrate was hydrolyzed by this concentration of enzyme.

Effect of Variation of Initial ATEE Concentration on the Assay.—Eight solutions of ATEE (from three different suppliers) were made up at various times and were used in assaying lot CTD-7 of chymotrypsin. Although the same amount of ATEE was weighed out, the resulting solution contained variable concentrations of intact ester as evidenced by differences in the absorbances obtained after ferric chloride addition. Because of the slow solubility of ATEE, varying amounts of the ester remained undissolved and were filtered out. Prolonged attempts to effect complete solution of ATEE may result in a variable degree of hydrolysis of the ester.

It can be seen from Fig. 2 that a wide variation of initial ATEE concentration produces no appreciable effect on the assay.

Effect of ATEE from Different Sources on the Assay.—Substrates from three sources were compared using two lots of chymotrypsin (Table I). The greatest variation obtained was that between the Mann and K & K product using CTD-5. This difference was not statistically significant ($P>0.2$).

Variation Within a Single Assay.—Four lots of chymotrypsin were assayed in triplicate. In each case, three aliquots from a single dilution were incubated against the same substrate solution. The results given in Table II are typical. It can be seen that the reproducibility is quite satisfactory.

Variation Among Several Assays.—Four lots of chymotrypsin were assayed in duplicate or triplicate at various times over a period of a few weeks. The results are given in Table III. The average error (deviation from the mean) ranges from 1.0 to 3.1%.

DISCUSSION

In the proposed N.F. assay method for chymotrypsin, the ratio of substrate to enzyme is relatively small (2.5×10^4 on a molar basis). The resulting reaction is frequently not zero order with respect to substrate. As a result, the fall in absorbance is often not linear. In the present study, the ratio of substrate to enzyme is ten times that found with the N.F. method. Therefore, the variable hydrolysis which occurs during the preparation of ATEE solutions is negligible. As was shown in Fig. 2, the initial concentration of ATEE may vary over a wide range without affecting the accuracy of the results. In addition, we found that during the enzymatic reaction, linearity exists even when 90% of the ATEE has been hydrolyzed.

The separate 4-minute incubation required for each sample analyzed by the proposed N.F. method, requires special equipment to preclude temperature variations greater than $\pm 0.1°$. It was found that since with our method, the standard and sample are incubated together for 50 minutes, an ordinary water bath (which may fluctuate within a range of $\pm 0.5°$) was adequate.

In the method under consideration, the absorbance of each sample must be read only once, within 20 minutes after the color development. This is in direct contrast to the repeated 30-second interval readings required with the proposed N.F. method. Additionally, any instability in the spectrophotometer, which is insufficient to interfere with the usual type of assay, will result in a significant error in results obtained by the N.F. method.

The sensitivity of the hydroxamate method as described here is approximately ten times that of the proposed N.F. method. Therefore, any possible interference resulting from other ingredients in chymotrypsin formulations would be greatly minimized by the dilution. At the concentrations utilized in this study, it was found that a 50-minute incubation period provided accurate and reproducible results. When working with lower concentrations, a longer period of incubation may be desirable. Conversely, with larger concentrations, an incubation period of less than 50 minutes may prove satisfactory.

N-Substituted Cyclopropylamines

By M. FREIFELDER and BRUCE W. HORROM

A NEED IN this laboratory for some *N*-substituted cyclopropylamines of type A prompted an in-

$$\Delta NHCH\overset{\frown}{(CH_2)_n} \quad n = 2 \text{ to } 6$$

A

vestigation of their synthesis. All but dicyclopropylamine were readily obtained by reductive alkylation of cyclopropylamine with the corresponding cyclic ketone in the presence of platinum oxide. Since cyclopropanone was not available, acetone was substituted to give the structurally related *N*-isopropylcyclopropylamine.

Attempts to isolate and distill *N*-cycloheptylidenecyclopropylamine gave a mixture of products of constantly rising boiling points and changing refractive indices. The inability of the product of condensation of amine and ketones to withstand heating in the course of solvent removal discouraged any further effort to isolate and characterize the other intermediate Schiff bases. Each intermediate, however, was identified in solution by means of its infrared spectrum.[1] The amine and ketone (excluding acetone) were mixed in thiophene free benzene. Water separated from the mixture upon standing and anhydrous magnesium sulfate was added. After removal of drying agent, a sample of the solution showed the presence of C=N function by the characteristic band at 6.1 μ. The remainder of the benzene solution was then hydrogenated in the presence of platinum oxide. In the reaction with acetone, equimolar amounts of amine and acetone were mixed, allowed to stand, and then hydrogenated in the presence of platinum oxide.

EXPERIMENTAL

The following is characteristic of the preparation of the *N*-cycloalkylcyclopropylamines listed in Table I.

N-Cyclobutylcyclopropylamine.—A 10-Gm. (0.1428 mole) quantity of cyclobutanone[2] was added to 8.14 Gm. (0.1428 mole) of cyclopropylamine[2] in 50 ml. of anhydrous thiophene free benzene and allowed to stand for 1 hour. Slight warming occurred, and water began to separate. Then 10.0 Gm. of anhydrous magnesium sulfate was added and the mixture allowed to stand for an additional hour. The drying agent was filtered and washed with 25–50 ml. of thiophene free benzene. The filtrate was hydrogenated under 2 atm. pressure in the presence of 0.3 Gm. of platinum oxide. When the uptake of hydrogen was complete (1.5 hours), the benzene solution was filtered from the catalyst. The solvent was distilled off and the residue fractionated. The benzene distillate contained a considerable amount of I. Additional yield as hydrochloride salt was obtained by treating the distillate with alcoholic hydrogen chloride, concentrating the solution to dryness, and recrystallizing the salt from hot acetone.

[a] The yield consisted of 46% of material as base and 30% as hydrochloride salt. [b] Rapid absorption of carbon dioxide by the bases made satisfactory analytical values for carbon and hydrogen difficult to obtain. In some instances when the analyses were carried out immediately after distillation good values resulted. In others it was necessary to characterize the compound by means of its hydrochloride salt. [c] Microanalyses carried out by Mr. O. Kolsto and his group in this laboratory.

Received March 4, 1963, from the Organic Chemistry Department, Research Division, Abbott Laboratories, North Chicago, Ill.

Accepted for publication August 23, 1963.

[1] Work done in this laboratory by Mr. A. Kammer and Mr. W. Washburn.

[2] The cyclic ketones and cyclopropylamine are available from the Aldrich Chemical Co., Milwaukee, Wis.

In the preparation of the higher homologs, a slight excess of cyclopropylamine was used. Distillation of the resultant products of reduction was uncomplicated.

N-Isopropylcyclopropylamine.—Cyclopropylamine (28.5 Gm., 0.5 mole) and 31.8 Gm. (0.5 mole) of acetone were mixed and allowed to stand for 1 hour, then hydrogenated under 2–3 atm. pressure in the presence of 1.0 Gm. of platinum oxide. After uptake of hydrogen was complete (6 hours), the mixture was allowed to stand until the catalyst settled. The solution was decanted from the catalyst in a nitrogen atmosphere. *Caution!* In air the catalyst may ignite the vapors of the low boiling liquid. The base, which contained some water, was treated with solid potassium hydroxide. It was separated and distilled. A hydrochloride salt was prepared for identification.

In another experiment the reduction was carried out in alcohol. The filtered solution was treated with an equivalent of alcoholic hydrogen chloride and the salt obtained after concentration.

Synthesis of the Diuretic 8-Chloroalloxazine-5,10-dioxide

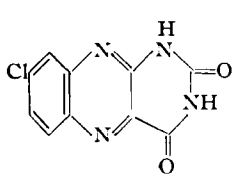
By H. G. PETERING and G. J. VAN GIESSEN

The synthesis of 8-chloroalloxazine-5,10-dioxide, a new diuretic, is described. It has advantages over 8-chloroalloxazine in that it is readily solubilized in aqueous media containing arginine or tris-buffer (THAM).

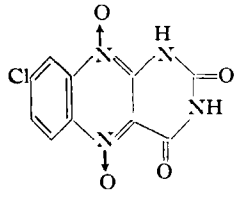
RECENTLY Petering and Van Giessen (1) reported the synthesis of a new diuretic, 8-chloroalloxazine (I) and of several related alloxazines and quinoxalines. In extending the study of the relationship of diuretic activity to chemical structure in this series of compounds, 8-chloroalloxazine-5,10-dioxide (II) has now been prepared. It was found by B. E. Graham in this laboratory (2) to be the only one with diuretic activity comparable to I. Moreover, II can be readily solubilized in water by the addition of arginine or tris-hydroxymethylaminomethane (tris or THAM). Because of the biological potentialities of this compound, its synthesis is presented here.

EXPERIMENTAL

Synthesis.—8-Chloroalloxazine (2.5 Gm.) was suspended in a mixture of 100 ml. 88% formic acid and 10 ml. 30% hydrogen peroxide. The mixture was warmed to 65° on a water bath. The heat was removed as the exothermic reaction began. The reaction temperature was allowed to rise to 95°. (An ice bath was kept on hand to permit rapid cooling in case the reaction became violent.) A rapid evolution of gas occurred when the temperature reached 75–80°, all of the insoluble material went into solution, and the color deepened from pale yellow to orange. Shortly thereafter, crystals of II began to form. After the evolution of gas had ceased, the mixture was allowed to cool to room temperature and was refrigerated at 5° for 48 hours.



8-Chloroalloxazine (I)



8-Chloroalloxazine-5,10-dioxide (II)

The orange crystals were collected and washed with small amounts of cold water, ethanol, and acetone. The yield of air-dried product was 2.4 Gm. or 85% of theory, m.p. 285–292°.

When glacial acetic acid was used as the solvent, II was obtained in 81% yield, m.p. 293–295°.

Recrystallization of II from methylcellosolve raised the melting point to 297–298° (Product A). Recrystallization from a mixture of 88% formic acid containing 10% of hydrogen peroxide (30%) gave 80% yield of II, m.p. 300–301° (Product B). Recrystallization can also be effected from 95% ethanol.

Anal.—Calcd. for $C_{10}H_5ClN_4O_4$: C, 42.8; H, 1.8; Cl, 12.6; N, 20.0; O, 22.8. Found: Product A—C, 43.4; H, 2.4; Cl, 11.7; N, 19.7; O, 23.8. Product B—C, 43.6; H, 1.2; Cl, 12.0; N, 19.2; O, 20.9.

Infrared Spectrum.—The I.R. spectral analyses of Products A and B mentioned above were identical and showed the required bands for the structure proposed for II. N—H, 3140 (sh) and 3050 $cm.^{-1}$; C = 0, 1715–1708 $cm.^{-1}$; C = C/C N, 1608, 1580–1572, 1500(sh), 1480(sh) $cm.^{-1}$; N→0, 1340, 1246, and 1235 (sh) $cm.^{-1}$.

Ultraviolet Spectrum.—The U.V. spectral analyses showed no evidence of the presence of I, but distinctive bands characteristic of II. The ϵ values are as follows: 281.5 mμ, 62,600; 346 mμ, 6150; 459 mμ, 9100.

Chromatography on circular disk paper using as solvent *n*-butanol 6, pyridine 4, water 3 (v/v/v), showed one ultraviolet fluorescing band at R_f 0.48, with a very faint trace of fluorescence at 0.66 which was not identified. The R_f of I in this solvent is 0.81.

8-Chloroalloxazine-5,10-dioxide is soluble to the extent of 12.5 mg. per 100 ml. of water and 6 mg. per 100 ml. of physiological saline. This solubility is raised to 830 mg. per 100 ml. of 0.1 *M* arginine and to 625 mg. per 100 ml. of 0.1 *M* tris-buffer (THAM), with resulting pH values of 7.0 in each case. The dioxide is also solubilized by sodium and potassium bicarbonate.

Sensitive Ultraviolet Spectrophotometric Determination of Some Phenethanolamine Drugs

By LESTER CHAFETZ

The ultraviolet determination of phenylpropanolamine as benzaldehyde after periodate oxidation reported (12) was the basis of a study using a modified procedure for the assay of other phenethanolamine derivative drugs in dosage forms. Quantitative recoveries of aryl aldehyde after periodate oxidation of ephedrine, phenylpropanolamine, phenyramidol, and phenylephrine were demonstrated.

THE UTILITY of ephedrine, phenylpropanolamine, phenylephrine, and other compounds which may be considered phenethanolamine derivatives has led to the publication of a large number of methods for their determination in pharmaceutical dosage forms and other environments (1). Among the methods described for the nonphenolic members of the group are titrations of the base function (2), gravimetric determination *via* the hydrochloride salt (3) or tetraphenylboron salt (4), condensation with chromogens (5), dye-complex colorimetry (6), and absorption spectrometry (7). The monophenolic members of the group have also been determined by methods depending on the presence of that group; among these are bromination (8), coupling with a diazonium salt (9) or 4-aminoantipyrine (10), and the Millon reaction (11). Many other assay methods have been reported for this chemical class, attesting both to their importance and the limitations of sensitivity and selectivity which must be reckoned with in solving each analytical problem.

One of the more selective analytical procedures for a phenethanolamine drug was that described by Heimlich and his co-workers (12) in 1961. They determined phenylpropanolamine in urine by oxidizing the drug to benzaldehyde with periodate and measuring the ether extracted aldehyde spectrophotometrically. The possible application of the periodate oxidation procedure to the assay of ephedrine and related drugs in dosage forms led to the modifications and extensions reported here. The availability of a series of phenethanolaminoheterocyclic compounds synthesized in these laboratories (13) afforded an opportunity to test the procedure on analogs of differing base strength. The chemical structures of the compounds are described in Table I.

EXPERIMENTAL

Reagents.—Two per cent sodium metaperiodate, concentrated hydrochloric acid, approximately 0.05 *N* hydrochloric acid, 0.05 *N* sodium hydroxide, hexane (Phillips high purity grade or equivalent), chloroform A.C.S., and saturated sodium bicarbonate were employed.

Equipment.—A Beckman DU spectrophotometer or equivalent instrument equipped for ultraviolet measurements, Bausch and Lomb spectronic 505 or equivalent recording ultraviolet spectrophotometer (optional), and standard volumetric laboratory glassware were used.

Estimation of Phenethanolamines as Benzaldehyde.—Transfer 5.0 ml. of an approximately 0.12 *M* solution of the nonphenolic phenethanolamine salt to a glass-stoppered tube of about 40-ml. capacity. Add 1.0 ml. of saturated sodium bicarbonate and 0.5 ml. of 2% sodium metaperiodate, and shake 10 minutes. Add 1–2 drops of concentrated hydrochloric acid. (The acid serves to convert amines which are not oxidized by periodate to their nonextractable salts.) Shake the mixture for 30 seconds with exactly 20.0 ml. of hexane, and filter the hexane layer through Whatman No. 1 paper. Determine the absorbance of the hexane extract at 242 mμ *versus* hexane in a 1-cm. silica cell or scan the ultraviolet spectrum in a recording instrument.

Estimation of Phenylephrine as *m*-Hydroxybenzaldehyde.—Transfer 5.0 ml. of an approximately 0.11 *M* solution of phenylephrine hydrochloride to a 60-ml. separator. Add 1.0 ml. of saturated sodium bicarbonate and 0.5 ml. of 2% sodium metaperiodate, and shake mechanically 10 minutes. Add 1–2 drops of concentrated hydrochloric acid. Extract the solution with five 5-ml. volumes of chloroform, and collect the extracts through cotton in a 25.0-ml. volumetric flask. Adjust the solution to the mark, and shake 15.0 ml. with exactly 10.0 ml. of 0.05 *N* sodium hydroxide. Filter the alkali extract through Whatman No. 1 paper, and determine its absorbance at 237 mμ in a 1-cm. cell against 0.05 *N* alkali or scan its spectrum.

RESULTS

Quantitation.—All of the phenethanolamines in Table I gave quantitative amounts of aryl aldehyde, except for the pyrimidine and *s*-triazine derivatives. Unoxidized fenyripol was recovered practically quantitatively and identified by its ultraviolet spectrum. Since the phenethanolamine derivative furnishes an equimolar quantity of aryl aldehyde, a close approximation of the extent of conversion can be made by comparing log molar extinction coefficients of the oxidized phenethanol-

amines with those of the aryl aldehydes. The absorptivity values ($E_{1cm.}^{1\%}$) of the phenethanolamines as aldehydes are listed in Table II, furnishing another indication of the sensitivity of the analytical method.

To test the feasibility of employing absorptivity values in dosage form assays, the periodate oxidation of ephedrine hydrochloride was replicated over a period of several days. The precision obtained is shown in Table III.

Assays of Ephedrine in Dosage Forms.—The assay procedure was applied to the determination of ephedrine hydrochloride in tablets declaring 1/4 gr. (16.2 mg.) of the drug along with aminophylline, pentobarbital sodium, ethyl aminobenzoate, and aluminum hydroxide, as well as excipients (starch, stearic acid, iron oxide, talc, calcium carbonate, gelatin). A weighed quantity of pulverized tablet representing about 2 mg. of declared ephedrine hydrochloride was shaken with exactly 100.0 ml. of distilled water for 10 minutes in a glass-stoppered 250-ml. conical flask. The mixture was filtered through Whatman No. 1 paper and the first 10–15 ml. filtrate discarded. A 5.0-ml. aliquot was run through the procedure. A scan of the spectrum of the hexane extract showed the characteristic spectrum of benzaldehyde. Using the mean absorptivity value of 716.1, a recovery of 16.5 mg. of ephedrine hydrochloride was obtained, which represents 101.8% of the declared amount. Potassium iodide in a similar formulation interferred with the direct determination of ephedrine by reducing periodate.

Assay of Phenylephrine Hydrochloride in a Dosage Form.—Phenylephrine hydrochloride was assayed in a commercial tablet declaring 2.5 mg. of the drug and 5.0 mg. prophenpyridamine maleate, 194.4 mg. salicylamide, 129.6 mg. of acetophenetidin, 97.2 mg. of aluminum hydroxide, and excipients (starch, talc, magnesium stearate, methyl cellulose, colorant). A quantity of pulverized tablet equivalent to 2 mg. of phenylephrine hydrochloride was shaken mechanically for 10 minutes with exactly 100.0 ml. of 0.05 *N* sulfuric acid and about 25 ml. of chloroform. The acid layer was filtered through paper and two 5.0-ml. aliquots of filtrate were treated as described in the phenylephrine procedure above, omitting addition of periodate for one used as the blank. Using the absorptivity value of 1073, a result of 2.41 mg. of phenylephrine hydrochloride, corresponding to 96.5% of the declared amount, was obtained. A scan of the spectrum showed it to be *m*-hydroxybenzaldehyde.

DISCUSSION

Periodate cleaves carbon-carbon bonds of vic-glycols, α-aminoalcohols where the amine is primary or secondary, and α-hydroxyketones (16). The reaction does not distinguish between *threo* and *erythro* isomers, although the observation that *cis* glycols cleave faster than *trans* (17) with periodate and the use of a difference in cleavage rate of *threo* and *erythro* α-aminoalcohols by lead tetra-acetate (18) suggests that a rate difference might be used as a basis for an analytical method in periodate reactions. The failure of the reaction to proceed with the pyrimidine and *s*-triazine analogs of phenyramidol suggests that the availability of electrons on the exocyclic nitrogen is a factor in the reaction.

Although the data given by Heimlich, *et al.* (12), show a quantitative extraction of benzaldehyde by ether, hexane has advantages in the procedure, since it dissolves compounds having a narrower range of polarity and fewer interferences are possible. Addition of acid before extraction eliminates interference from amine bases. It has been found that iodide causes difficulties, but this and similar interferences might be removed by rational separation techniques (19). The general procedure appears to be applicable with little or no modification to the assays of ephedrine, racephedrine, and phenylpropanolamine and their preparations in the compendia official in the United States.

The sensitivity afforded by the procedure is adequate for its use in dosage form assay. It could be increased by manipulating the volumes employed or by derivatization of the aryl aldehyde formed in a manner analogous to that of McChesney and his co-workers (20).

SUMMARY

Periodate oxidation of phenethanolamine drugs followed by ultraviolet spectrophotometry of the aryl aldehyde formed was shown to be quantitative. It affords a convenient, sensitive, and selective means for the assay of ephedrine in dosage forms,

and it appears applicable to the determination of phenylpropanolamine, phenyramidol, and phenylephrine.

The limitations in selectivity of the periodate procedure and interferences in the method are discussed.

Book Notices

Annual Review of Pharmacology. Edited by WINDSOR C. CUTTING, ROBERT H. DREISHBACH, and HENRY W. ELLIOTT. Annual Reviews, Inc., Palo Alto, Calif., 1963. vi + 486 pp. 22 × 14½ cm. Price $8.50.

The 1963 edition of this respected series presents sections entitled enzymes as primary targets of drugs, metabolic fate, drugs in lipid metabolism, interactions of drugs with endocrines, drugs and nerve conduction, effects of drugs on behavior, electrolyte and mineral metabolism, cellular effects of anticancer drugs, as well as others. Also included is a prefatory chapter by Henry H. Dale on pharmacology during the past 60 years. Cumulative indexes of authors and chapter titles for volumes 1 through 3 are appended.

British Pharmacopoeia. General Medical Council. Pharmaceutical Press, 17 Bloomsbury Square, London, 1963. xxviii + 1210 pp. 13½ × 22 cm. Price $22.50.

The General Medical Council of England has released the tenth edition of the British Pharmacopoeia which contains nearly 1000 monographs —some 211 of which did not appear in the previous edition. Additionally, the monographs for this edition employ the metric system throughout. This edition also includes 278 pages of appendices which give reagent specifications and information on nonaqueous titration, the oxygen flask method, chromatographic analysis, infrared absorption spectra, biological assays, and other useful information and procedures. The edition will become official on January 1, 1964.

Biochemical Systematics. By R. E. ALSTON and B. L. TURNER. Prentice-Hall, Inc., Englewood Cliffs, N. J., 1963. xii + 404 pp. 14½ × 22½ cm. Price $13.25.

By integrating data from biochemistry, plant chemistry, plant genetics, and systematics, the authors present a work oriented towards botanical systematics in what appears to be an unprecedented effort. The book is organized around major groups of chemical constituents rather than taxonomic systems of categories and the authors indicate that they do not now feel that available chemical correlations justify the construction of a phylogenetic tree. The main body of the book is devoted to the examination of the chemical nature of specific groups of plant constituents with a view to their actual and potential contributions to systematics.

Essentials of Biological Chemistry. By JAMES L. FAIRLEY and GORDON L. KILGOUR. Reinhold Publishing Corp., 430 Park Ave., New York 22, N. Y., 1963. xiii + 287 pp. 14½ × 22¼ cm. Price $7.50.

An undergraduate text book designed for an introductory course in biochemistry is presented for students who require some familiarity with biochemical principles in their chosen fields. Emphasis is placed on relating chemical structure to biological function. The volume pares the basics to a minimum and builds this foundation with materials in considerable depth. The volume gets progressively more complex beginning with the organic chemistry of the cellular constituents and working towards basic metabolic reaction sequences.

The Dictionary of Chemical Names. By W. E. FLOOD. Philosophical Library, Inc., 15 East 40th St., New York 16, N. Y., 1963. xxi + 238 pp. 13 × 20 cm. Price $7.50.

A glossary of the origin and history of chemical names is presented. An introductory section describes the development of the main branches of chemistry and the evolution of systematic nomenclature. The principal glossary is composed of two parts—one dealing with the chemical elements and the other dealing with chemical compounds, minerals, and other substances of chemical interest. An appendix provides brief biographical notes on about 50 of the more prominent chemists referred to in the glossary's text.

and it appears applicable to the determination of phenylpropanolamine, phenyramidol, and phenylephrine.

The limitations in selectivity of the periodate procedure and interferences in the method are discussed.

Biochemical Systematics. By R. E. ALSTON and B. L. TURNER. Prentice-Hall, Inc., Englewood Cliffs, N. J., 1963. xii + 404 pp. 14½ × 22½ cm. Price $13.25.

By integrating data from biochemistry, plant chemistry, plant genetics, and systematics, the authors present a work oriented towards botanical systematics in what appears to be an unprecedented effort. The book is organized around major groups of chemical constituents rather than taxonomic systems of categories and the authors indicate that they do not now feel that available chemical correlations justify the construction of a phylogenetic tree. The main body of the book is devoted to the examination of the chemical nature of specific groups of plant constituents with a view to their actual and potential contributions to systematics.

Essentials of Biological Chemistry. By JAMES L. FAIRLEY and GORDON L. KILGOUR. Reinhold Publishing Corp., 430 Park Ave., New York 22, N. Y., 1963. xiii + 287 pp. 14½ × 22¼ cm. Price $7.50.

An undergraduate text book designed for an introductory course in biochemistry is presented for students who require some familiarity with biochemical principles in their chosen fields. Emphasis is placed on relating chemical structure to biological function. The volume pares the basics to a minimum and builds this foundation with materials in considerable depth. The volume gets progressively more complex beginning with the organic chemistry of the cellular constituents and working towards basic metabolic reaction sequences.

The Dictionary of Chemical Names. By W. E. FLOOD. Philosophical Library, Inc., 15 East 40th St., New York 16, N. Y., 1963. xxi + 238 pp. 13 × 20 cm. Price $7.50.

A glossary of the origin and history of chemical names is presented. An introductory section describes the development of the main branches of chemistry and the evolution of systematic nomenclature. The principal glossary is composed of two parts—one dealing with the chemical elements and the other dealing with chemical compounds, minerals, and other substances of chemical interest. An appendix provides brief biographical notes on about 50 of the more prominent chemists referred to in the glossary's text.

and it appears applicable to the determination of phenylpropanolamine, phenyramidol, and phenylephrine.

The limitations in selectivity of the periodate procedure and interferences in the method are discussed.

Book Notices

Annual Review of Pharmacology. Edited by WINDSOR C. CUTTING, ROBERT H. DREISHBACH, and HENRY W. ELLIOTT. Annual Reviews, Inc., Palo Alto, Calif., 1963. vi + 486 pp. 22 × 14½ cm. Price $8.50.

The 1963 edition of this respected series presents sections entitled enzymes as primary targets of drugs, metabolic fate, drugs in lipid metabolism, interactions of drugs with endocrines, drugs and nerve conduction, effects of drugs on behavior, electrolyte and mineral metabolism, cellular effects of anticancer drugs, as well as others. Also included is a prefatory chapter by Henry H. Dale on pharmacology during the past 60 years. Cumulative indexes of authors and chapter titles for volumes 1 through 3 are appended.

British Pharmacopoeia. General Medical Council. Pharmaceutical Press, 17 Bloomsbury Square, London, 1963. xxviii + 1210 pp. 13½ × 22 cm. Price $22.50.

The General Medical Council of England has released the tenth edition of the British Pharmacopoeia which contains nearly 1000 monographs —some 211 of which did not appear in the previous edition. Additionally, the monographs for this edition employ the metric system throughout. This edition also includes 278 pages of appendices which give reagent specifications and information on nonaqueous titration, the oxygen flask method, chromatographic analysis, infrared absorption spectra, biological assays, and other useful information and procedures. The edition will become official on January 1, 1964.

The Dictionary of Chemical Names. By W. E. FLOOD. Philosophical Library, Inc., 15 East 40th St., New York 16, N. Y., 1963. xxi + 238 pp. 13 × 20 cm. Price $7.50.

A glossary of the origin and history of chemical names is presented. An introductory section describes the development of the main branches of chemistry and the evolution of systematic nomenclature. The principal glossary is composed of two parts—one dealing with the chemical elements and the other dealing with chemical compounds, minerals, and other substances of chemical interest. An appendix provides brief biographical notes on about 50 of the more prominent chemists referred to in the glossary's text.

Steroid Reactions, An Outline for Organic Chemists. Edited by CARL DJERASSI. Holden-Day, Inc., 728 Montgomery St., San Francisco 11, Calif., 1963. vi + 657 pp. 19 × 26 cm. Price $9.75.

Designed as a tool for graduate students and research chemists to permit ready reference to the details for appropriate conditions to accomplish a certain reaction, this volume will undoubtedly provide an excellent bridge for many workers. Textual statements are sparse but the organic reaction schemes are numerous with conditions and yields specified. Literature references are included and brief textual notes are inserted where appropriate.

Molecular Rearrangements, Part I. Edited by PAUL DE MAYO. Interscience Publishers, 605 Third Ave., New York 16, N. Y., 1963. xii + 706 pp. 15 × 23.5 cm. Price $25.

A thorough and detailed treatment on the rearrangements of organic molecules is presented in this two-part work prepared by group of outstanding chemists from the United States and other countries. The two volumes cover most of the well-known molecular rearrangements. The various rearrangements are divided into classes and discussed on the basis of mechanism of action in Part I. Rearrangements that occur in the most important classes of natural products are discussed in Part II.

The Specificity of Serological Reactions. By KARL LANDSTEINER. Dover Publications, Inc., 180 Varick St., New York 14, N. Y., 1962. xviii + 330 pp. 13.5 × 21.5 cm. Price $2. Paperbound.

Reports of studies by Dr. Karl Landsteiner, a 1930 Nobel Prize recipient, on antigens and serological reactions with simple compounds is presented. The work concentrates on the chemical aspects of immunological reactions and provides a concise survey of the basic concepts of immunology. An extensive bibliography of Dr. Landsteiner's writings is appended.

Fatty Acid Metabolism in Microorganisms. By KLAUS HOFMANN. John Wiley & Sons, Inc., 605 Third Ave., New York 16, N. Y., 1963. xii + 78 pp. 12.5 × 19 cm. Price $3.25.

A summarization of recent developments and studies with certain phases of fatty acid metabolism in microorganisms is presented. The volume treats the discovery and chemistry of cyclopropane fatty acids, the chemical nature of monounsaturated fatty acids in bacteria, the quantitative estimation of fatty acids in bacterial lipids, the biosynthesis of the cyclopropane ring, and the anaerobic biosynthesis of monosaturated fatty acids in microorganisms. The necessary experimental work was done in the chemistry and biochemistry departments of the University of Pittsburgh by the author.

British Pharmaceutical Codex 1963. COUNCIL OF THE PHARMACEUTICAL SOCIETY OF GREAT BRITAIN. The Pharmaceutical Press, 17 Bloomsbury Square WC 1, London, England, 1963. xxxvi + 1433 pp. 14 × 22 cm. Price $23.75.

This edition of the *Codex* again presents authoritative and useful therapeutic information as well as recognized and accepted standards for many pharmaceuticals and dosage forms not included in the *British Pharmacopoeia* in the usual high tradition of this compendium. The general format and arrangement found so popular and convenient with prior editions has been retained but the publication schedule has been accelerated to parallel that of the B. P. Several of the monographs incorporate infrared identification procedures; appropriate authentic specimens for the infrared procedures have been established. Over 200 new admissions are included in this edition and, as in the past, Parts II through VI provide monographs on immunological products, human blood preparations, surgical sutures, surgical dressings, and formulary preparations. In addition, several new appendixes have been added covering aerosol propellants, a system for the classification of powders, a table of standard wire gauges, and additional analytical information to aid the examination of various pharmaceutical products. Undoubtedly, pharmaceutical and medical practitioners in the United Kingdom will continue to place heavy reliance upon the *Codex* for the most concise and reliable information on today's leading pharmaceutical products and pharmaceutical scientists in the United States will find this edition a useful reference.

Alternating Current Polarography and Tensammetry. By B. BREYER and H. H. BAUER. Interscience Publishers, 605 Third Ave., New York 16, N. Y., 1963. xix + 288 pp. 15 × 23.5 cm. Price $12.

This thirteenth volume in the "Chemical Analysis" series presents a monograph on what is probably the most active area of electrochemical techniques. The work includes a chapter which provides a historical introduction to a.c. polarography and tensammetry, another giving a connected account of quantitative theoretical treatments of electrode processes under the influence of small superposed alternating voltages, another describing the necessary apparatus in detail. In addition, other chapters discuss the main results which have been obtained in the study of various organic and inorganic substances and mechanisms of electrode processes. While the book would serve best to acquaint the reader with the essentials of this technique, the presentation has been arranged so that relevant information on the analytical uses of the a.c. technique is readily accessible.

Handbook of Ocular Therapeutics and Pharmacology. Edited by PHILIP P. ELLIS and DONN L. SMITH. The C. V. Mosby Co., 3207 Washington Blvd., St. Louis 3, Mo., 1963. 193 pp. 17 × 24.5 cm. Price $8.50.

An encyclopedia-like handbook on ocular therapy and therapeutics is presented in this brief volume. One section covers the therapeutic aspects of the more common ocular diseases in summary form and another discusses the pharmacology of therapeutic agents employed. The pharmacology section discusses aspirin to zinc sulfate as related to ocular therapy quite adequately.

Steroid Reactions, An Outline for Organic Chemists. Edited by CARL DJERASSI. Holden-Day, Inc., 728 Montgomery St., San Francisco 11, Calif., 1963. vi + 657 pp. 19 × 26 cm. Price $9.75.

This thirteenth volume in the "Chemical Analysis" series presents a monograph on what is probably the most active area of electrochemical techniques. The work includes a chapter which provides a historical introduction to a.c. polarography and tensammetry, another giving a connected account of quantitative theoretical treatments of electrode processes under the influence of small superposed alternating voltages, another describing the necessary apparatus in detail. In addition, other chapters discuss the main results which have been obtained in the study of various organic and inorganic substances and mechanisms of electrode processes. While the book would serve best to acquaint the reader with the essentials of this technique, the presentation has been arranged so that relevant information on the analytical uses of the a.c. technique is readily accessible.

Handbook of Ocular Therapeutics and Pharmacology. Edited by PHILIP P. ELLIS and DONN L. SMITH. The C. V. Mosby Co., 3207 Washington Blvd., St. Louis 3, Mo., 1963. 193 pp. 17 × 24.5 cm. Price $8.50.

An encyclopedia-like handbook on ocular therapy and therapeutics is presented in this brief volume. One section covers the therapeutic aspects of the more common ocular diseases in summary form and another discusses the pharmacology of therapeutic agents employed. The pharmacology section discusses aspirin to zinc sulfate as related to ocular therapy quite adequately.

Steroid Reactions, An Outline for Organic Chemists. Edited by CARL DJERASSI. Holden-Day, Inc., 728 Montgomery St., San Francisco 11, Calif., 1963. vi + 657 pp. 19 × 26 cm. Price $9.75.

Designed as a tool for graduate students and research chemists to permit ready reference to the details for appropriate conditions to accomplish a certain reaction, this volume will undoubtedly provide an excellent bridge for many workers. Textual statements are sparse but the organic reaction schemes are numerous with conditions and yields specified. Literature references are included and brief textual notes are inserted where appropriate.

Molecular Rearrangements, Part I. Edited by PAUL DE MAYO. Interscience Publishers, 605 Third Ave., New York 16, N. Y., 1963. xii + 706 pp. 15 × 23.5 cm. Price $25.

A thorough and detailed treatment on the rearrangements of organic molecules is presented in this two-part work prepared by group of outstanding chemists from the United States and other countries. The two volumes cover most of the well-known molecular rearrangements. The various rearrangements are divided into classes and discussed on the basis of mechanism of action in Part I. Rearrangements that occur in the most important classes of natural products are discussed in Part II.

The Specificity of Serological Reactions. By KARL LANDSTEINER. Dover Publications, Inc., 180 Varick St., New York 14, N. Y., 1962. xviii + 330 pp. 13.5 × 21.5 cm. Price $2. Paperbound.

Reports of studies by Dr. Karl Landsteiner, a 1930 Nobel Prize recipient, on antigens and serological reactions with simple compounds is presented. The work concentrates on the chemical aspects of immunological reactions and provides a concise survey of the basic concepts of immunology. An extensive bibliography of Dr. Landsteiner's writings is appended.

Fatty Acid Metabolism in Microorganisms. By KLAUS HOFMANN. John Wiley & Sons, Inc., 605 Third Ave., New York 16, N. Y., 1963. xii + 78 pp. 12.5 × 19 cm. Price $3.25.

A summarization of recent developments and studies with certain phases of fatty acid metabolism in microorganisms is presented. The volume treats the discovery and chemistry of cyclopropane fatty acids, the chemical nature of monounsaturated fatty acids in bacteria, the quantitative estimation of fatty acids in bacterial lipids, the biosynthesis of the cyclopropane ring, and the anaerobic biosynthesis of monosaturated fatty acids in microorganisms. The necessary experimental work was done in the chemistry and biochemistry departments of the University of Pittsburgh by the author.

British Pharmaceutical Codex 1963. COUNCIL OF THE PHARMACEUTICAL SOCIETY OF GREAT BRITAIN. The Pharmaceutical Press, 17 Bloomsbury Square WC 1, London, England, 1963. xxxvi + 1433 pp. 14 × 22 cm. Price $23.75.

This edition of the *Codex* again presents authoritative and useful therapeutic information as well as recognized and accepted standards for many pharmaceuticals and dosage forms not included in the *British Pharmacopoeia* in the usual high tradition of this compendium. The general format and arrangement found so popular and convenient with prior editions has been retained but the publication schedule has been accelerated to parallel that of the B. P. Several of the monographs incorporate infrared identification procedures; appropriate authentic specimens for the infrared procedures have been established. Over 200 new admissions are included in this edition and, as in the past, Parts II through VI provide monographs on immunological products, human blood preparations, surgical sutures, surgical dressings, and formulary preparations. In addition, several new appendixes have been added covering aerosol propellants, a system for the classification of powders, a table of standard wire gauges, and additional analytical information to aid the examination of various pharmaceutical products. Undoubtedly, pharmaceutical and medical practitioners in the United Kingdom will continue to place heavy reliance upon the *Codex* for the most concise and reliable information on today's leading pharmaceutical products and pharmaceutical scientists in the United States will find this edition a useful reference.

Alternating Current Polarography and Tensammetry. By B. BREYER and H. H. BAUER. Interscience Publishers, 605 Third Ave., New York 16, N. Y., 1963. xix + 288 pp. 15 × 23.5 cm. Price $12.
