It is apparent from the vertical cut data in Table VII that the displacement of core along the vertical axis takes place in the upward direction for tablets prepared on the Manesty machine. In this tablet press, the core is transferred to the bottom bed of coating granulation by a transfer arm and deposited into the coating bed by a transfer pin, causing the tablet to fall into the bed center. Coating granulation is then added and the upper punch comes down to compress the tablet. Here it would be expected that the displacement of the core would be in the upward direction along the vertical plane.

For the tablets produced on the Kilian machine, the core shows a downward displacement when measured "along axis" and an upward displacement when measured "across axis" as shown by the data in Table IX. The vertical core displacement in the Kilian machine may be caused by the free fall action of the upper punch to imbed the core in the bottom bed of coating granulation before the upper layer of coating granulation is added. Since there is core displacement in both directions for this machine, the responsible factors are rather complex and will not be considered at this time.

As is apparent by comparing the data for the horizontal cuts, Tables III and IV with those of the vertical cuts, Tables VI to IX, the effect of the centrifugal and tangential forces are more pronounced on the dislocations of core on the horizontal cuts than the tilts of core on the vertical cuts.

From the data obtained for core dislocation along horizontal cuts and tilt and displacement along vertical cuts, there seems to be a definite relationship between degree of core off-centering and the size distribution of coating granulation. In addition, the machine design (Kilian and Manesty) appears to influence this effect.

On the basis of all the data for the Kilian and Manesty machines it is evident that coating granulations 100 and 50 yield tablets exhibiting the poorest core centration for the Manesty and Kilian machines, respectively. On the other hand, it appears that optimal core centration is obtained with coating granulation fraction 35 for the Manesty machine and with coating granulation fractions 8 or 100 for the Kilian machine. This relationship also holds when only the data from horizontal cuts are compared. However, a comparison of the data from the vertical cuts shows that for both the Manesty and Kilian machines, coating granulation fraction 35 gives the smallest displacement of core and coating granulation fraction 8 gives the least tilt of core. It becomes evident from these off-centering data that the dislocations of core from the horizontally determined cuts exert the predominant effect on the overall centration of core in tablet.

From the core expansion data reported in Table V, it is evident that the core expansion is smallest when coating granulation 100 is used. This has been found to hold for tablets produced on both the Manesty and Kilian machines. Since the sieve analysis on granulation 100 has shown it to have the smallest size distribution granules of the four coating granulations studied, it would be expected to cause the least core expansion. This may be explained on the basis that the smaller the particles, the less void space there is between particles and consequently, less space for the core to expand during the final compression step in the bed of coating granulation.

SUMMARY

The information obtained from this investigation may be summarized as follows:

1. A procedure has been developed for the determination of core dislocation in compressed coated tablets.

2. These factors appear to be responsible for core dislocation: (*a*) Two major forces which are acting tangentially and radially. (*b*) The bottom bed of coating granulation taking on a slanted shape due to die table rotation.

3. The data obtained in this study show that the core dislocation measured along the horizontal cuts have a more pronounced effect on the overall off-centering than the core tilt measured along the vertical cuts.

4. The results obtained indicate that the coating granulation size distribution influences core centration. In addition, this influence is not the same for the Manesty and Kilian machines.

5. Core expansion was observed to take place for each coating granulation, the least being with the coating granulation containing the smallest granules.

6. Using this procedure for determining core dislocation it should be readily possible to determine the optimal granule size distribution for a

particular coating granulation required to give optimal core centration.

7. Optimal core centration is desired for several reasons, the major ones being (*a*) Uniformity of dose, *i.e.*, if the tablets were to be broken along a center bisection, unequal doses would be obtained if the core is not in the center of the tablet. (*b*) Protective action of coating, *i.e.*, if the coating is used to improve the stability of the core ingredients, conceal the bitter taste of medicaments used in the core, and the like, the coating must completely cover the core tablet, otherwise the effectiveness of the coating is reduced. (*c*) Physical appearance, *i.e.*, if the core was to protrude out of the coating, either due to tilting or displacement in the vertical plane or horizontal dislocation, it would give an unsatisfactory aesthetic appearance.

Study of the Thermistor Bridge for the Measurement of Colligative Properties

By FRANK M. GOYAN and RICHARD D. JOHNSON

Further refinement of the apparatus described by Goyan and Reck has been studied, using thermistors. One variation described involves the use of intermittent power with simultaneous recording. Another variation treats the problem of using relatively high battery voltages in order to increase the sensitivity of the bridge without the use of amplifiers. The paper discusses the determination of molecular weights, as well as osmometry and isotonicity measurements. Results indicate that significant measurements can be made without minimizing the heating produced by the bridge current.

THERMISTORS may be used as resistance thermometers with high negative temperature coefficients. Because of their small size and low cost as compared to platinum resistance thermometers and their high coefficient; they seem to be ideally suited to the determination of temperature changes associated with freezing-point lowering and boiling-point elevation. One of the authors (1) has described an isotonicity meter based upon freezing-point measurements which includes a single thermistor in a Wheatstone bridge. The off-balance condition of the bridge is read on a vacuum-tube voltmeter. Ballard and Goyan (2) have shown that isotonicity in terms of per cent sodium chloride is a linear function of the usual colligative properties within the range of concentration and accuracy normally required.

Received March 26, 1962, from the University of California School of Pharmacy, San Francisco.
Accepted for publication July 16, 1962.
Presented to the Scientific Section, A.PH.A., Las Vegas meeting, March 1962.

It is quite proper to generalize that any osmometer, within the special limitations of each instrument, measures some approximately linear function of the colligative properties of solutions. The Hill-Baldes thermoelectric osmometer is no exception. In its original form it consisted of a thermocouple arranged in a constant temperature humidified air chamber (3). By placing a drop of solvent on one junction of the thermocouple and a drop of solution on the other, a temperature increase of the drop of solution relative to the drop of solvent develops measurable thermal E.M.F. This temperature difference and the resulting E.M.F. is proportional to the isotonicity or osmolal concentration of the solution.

With the advent of thermistors, many investigators (4–6) have modernized the Hill-Baldes osmometer by placing two thermistors in the chamber and connecting them as two arms of a Wheatstone bridge. This change has the advantage that the electric circuits are easier to

particular coating granulation required to give optimal core centration.

7. Study of the Thermistor Bridge for the Measurement of Colligative Properties

By FRANK M. GOYAN and RICHARD D. JOHNSON

Further refinement of the apparatus described by Goyan and Reck has been studied, using thermistors. One variation described involves the use of intermittent power with simultaneous recording. Another variation treats the problem of using relatively high battery voltages in order to increase the sensitivity of the bridge without the use of amplifiers. The paper discusses the determination of molecular weights, as well as osmometry and isotonicity measurements. Results indicate that significant measurements can be made without minimizing the heating produced by the bridge current.

THERMISTORS may be used as resistance thermometers with high negative temperature coefficients. Because of their small size and low cost as compared to platinum resistance thermometers and their high coefficient; they seem to be ideally suited to the determination of temperature changes associated with freezing-point lowering and boiling-point elevation. One of the authors (1) has described an isotonicity meter based upon freezing-point measurements which includes a single thermistor in a Wheatstone bridge. The off-balance condition of the bridge is read on a vacuum-tube voltmeter. Ballard and Goyan (2) have shown that isotonicity in terms of per cent sodium chloride is a linear function of the usual colligative properties within the range of concentration and accuracy normally required.

Received March 26, 1962, from the University of California School of Pharmacy, San Francisco.
Accepted for publication July 16, 1962.
Presented to the Scientific Section, A.PH.A., Las Vegas meeting, March 1962.

It is quite proper to generalize that any osmometer, within the special limitations of each instrument, measures some approximately linear function of the colligative properties of solutions. The Hill-Baldes thermoelectric osmometer is no exception. In its original form it consisted of a thermocouple arranged in a constant temperature humidified air chamber (3). By placing a drop of solvent on one junction of the thermocouple and a drop of solution on the other, a temperature increase of the drop of solution relative to the drop of solvent develops measurable thermal E.M.F. This temperature difference and the resulting E.M.F. is proportional to the isotonicity or osmolal concentration of the solution.

With the advent of thermistors, many investigators (4–6) have modernized the Hill-Baldes osmometer by placing two thermistors in the chamber and connecting them as two arms of a Wheatstone bridge. This change has the advantage that the electric circuits are easier to

deal with because of the higher voltage generated per degree of difference in temperature. However, the disadvantage of thermistors over thermocouples is that the former are heated by the current needed to operate them. This problem has been mentioned by most investigators. Their assumption that the heating effect may safely be neglected seems to be justified by their results. However, the present study has shown that good results can be obtained when the heating produced by the measuring current is greater than that produced by the phenomenon itself.

Goyan and Reck (7) made a radical modification of the Hill-Baldes osmometer by placing the two junctions of their thermocouple in separate tubes, each lined with platinum gauze for the purpose of holding solvent as close as possible to the junctions. This method gave good results and suggested the idea that the method is essentially a modification of the boiling-point method for determining colligative properties. Higuchi, *et al.* (8), followed this idea to its logical conclusion by evacuating the chamber after placing their solvent and solution in contact with thermistors. By means of mechanical stirring, they were able to simulate boiling-point work at room temperature and show that their results could be treated by classical thermodynamics.

When the need for accurate molecular weight determinations came to the attention of one of the authors, it was decided to modernize the Goyan-Reck apparatus by using thermistors. The present paper deals with this phase of molecular weight studies. It is obvious that any adequate measure of colligative properties will give a real or (in the case of dissociating or associating solutes) an apparent molal concentration. Since the weight of solute is known for some given quantity of solvent and the number of moles of solute in the same quantity of solvent is easily read from a suitable calibration chart of the instrument, it follows that the Goyan-Reck apparatus should be as effective in determining molecular weight as in determining isotonicity values.

This research began in an exploratory way. The first phase represents various attempts to minimize heating effects due to current through the thermistors. The second phase is a deliberate attempt to operate the thermistors at high current in order to take advantage of the greater sensitivity at the higher bridge voltages.

EXPERIMENTAL

Figure 1 shows the final modification of one of the sample cells using thermistors. During the first phase of this investigation, the tubes were 9.5 cm. long. Both were slipped through holes in a rubber stopper into water in a wide-mouth, 400-ml. Dewar filler having an internal diameter of 4.5 cm. The water in the Dewar flask was stirred vigorously with a stirring motor and a screw or propeller at the end of a free shaft. In the early part of the investigation it was thought desirable to adjust the temperature by changing the rate of stirring, but later a small coil of resistance wire (about 10 ohms) was wound inside a glass tube to serve as a heater. The heating was controlled manually by means of a variable transformer connected to a low-voltage transformer. When manual control of temperature became arduous, a thermocap relay was arranged to short an adjustable resistor in series with the heater. It was found that the value of this resistor should be such that the change in temperature was extremely gradual. Under these conditions, temperature corrections could be made for variations of 0.01–0.02°. Temperature was read on an 18–28° thermometer graduated in 0.01° marks. The same thermometer also served to operate the thermocap relay.

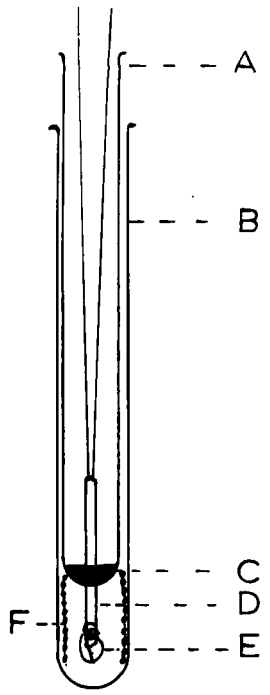

Fig. 1.—Thermistor assembly used in a constant temperature water bath maintained at 25° (about 5° above room temperature). A = glass tube supporting thermistor; B = glass tube selected so the thermistor support barely clears (7.5 mm. x 12 cm. I.D.); C = dental amalgam holding thermistor in place; D = thermistor as supplied at the end of a glass rod; E = platinum loop; F = platinum gauze.

The electrical circuit for the first phase of the investigation has been described previously (9). The thermistor[1] used for the sample had a temperature coefficient of −4.8% per degree and a resistance

[1] The thermistors were type 51A1 from the Victory Engineering Corp. of Union, N. J., although not specially selected.

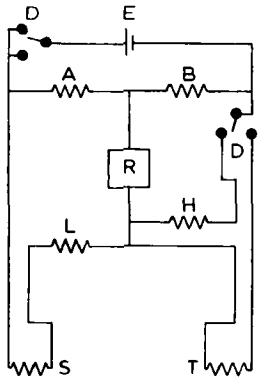

Fig. 2.—Circuit diagram of the bridge used for the high voltage work. A and B = ratio arm box; D = D.P.D.T. switch; E = battery (see text); H = Heathkit decade resistance box, 0–99,999 ohms; L = Leeds and Northrup box (see text); R = Leeds and Northrup Speedomax recording potentiometer 0–10 mv.; S = thermistor used for sample; T = thermistor used for reference.

of about 94,000 ohms at 25°. The ratio-arm box was used at the 1,000 settings. The switch built into the recorder for making and breaking external circuits was described in connection with incremental titration (9). This switch was used to open and close the battery circuit of the bridge at regular intervals, the closed condition lasting for a few seconds and the open condition about half a minute. Each time the battery circuit was closed the recorder would draw a horizontal line, the length of which was found to be a measure of the off-balance condition of the bridge. Consequently, the length of the lines for various known concentrations could be plotted against concentration in order to obtain a calibration chart.

Samples were added with a medicine dropper to the platinum loops surrounding the thermistor after removing the tube from the bath. A small piece of sheet brass was bent to form a channel to assist in removing the thermistors from the tubes without touching the sides. A slot was cut for the lip of the tube and the upper half above the slot built up with tape so that the surface of the tape was flush with the inner surface of the tube. The thermistor, after washing and filling, was replaced in the tube and the tube replaced in the water bath. During this operation the thermistors were connected but the battery circuit was open.

Figure 2 shows a circuit diagram of the bridge used in the second phase of the work. The positions of the battery and of the recorder were exchanged in developing this circuit from the one previously published (9). This was done in order to gain sufficient sensitivity without the amplifier. During a few experiments, a 10,000-ohm resistor was added to each ratio arm, but most of the work was done with the same 1,000-ohm ratio-arm resistors used previously.

It must not be assumed that the experimental details given above represent the authors' recommendation for a finished instrument. The object of the work was to study the design problem and to report significant information. For example, the switching arrangement designed to substitute a resistance box for the thermistor used as a reference resistor was a great convenience in measuring absolute temperature changes, but did not contribute to the functioning of the instrument as an osmometer.

All solutions used were prepared by weighing chemicals from good quality commercial samples on an analytical balance. All of the solutions were made with distilled water as the solvent and distilled water was always used on the reference thermistor.

RESULTS

Phase I

The first phase of the work showed that thermistors could be substituted for thermocouples in the Goyan-Reck apparatus without reducing sensitivity. The advantage of this substitution is that there is no need to take great pains to avoid parasitic thermal potential differences, thus eliminating the critical need for a constant-temperature air bath. It was further established that when the current from a $1^1/_2$-v. battery passed through the bridge for a few seconds at half-minute intervals, the line drawn by the recorder pen varied in length as a function of the off-balance condition of the bridge. Within limits, the length of these lines is a linear function of the concentration of solution on the sample thermistor. Figure 3 shows a typical recording and Fig. 4 shows the accumulated results of several measurements.

The feasibility of this intermittent method is interesting, but it failed to produce a dramatic improvement in results over what might be expected from a thermocouple and a good amplifier. It was discovered that the limit of accuracy was determined by the geometry of the drop with respect to the platinum gauze, the design of the water bath, rate of stirring, and freedom from rapid temperature changes in the bath. One important

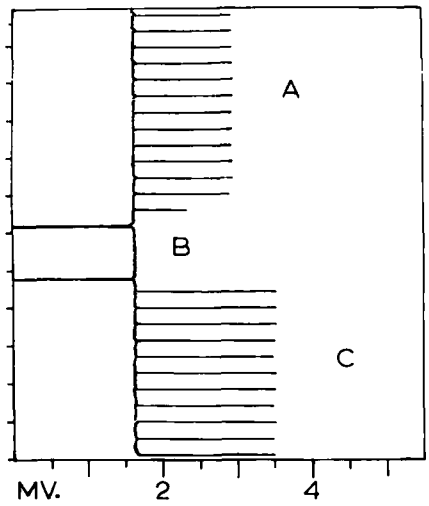

Fig. 3.—A typical recording using the intermittent method at $1^1/_2$ v. on the bridge. The graph shows millivolt values at regular time intervals. A = water; B = open circuit; C = 0.0435 *M* dextrose. Each division on the ordinate represents approximately 100 sec.

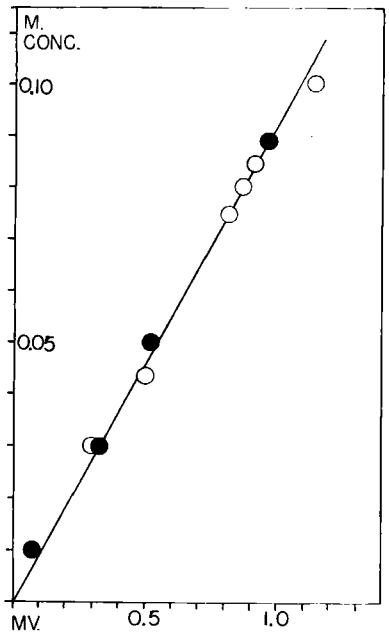

Fig. 4.—Calibration chart for the intermittent method: ●, sucrose; ○, dextrose. (Molar concentration *vs.* difference between mv. reading for water and solution.)

consideraton in the design of the water bath is that there should be an air space between the rubber stopper and the surface of the water, thus indicating that the use of a Dewar flask is important.

Phase II

The second phase of this study was suggested by the results of the first. Substitution of thermistors in place of thermocouples made it possible to simplify the electrical circuit. It seemed reasonable to explore the use of higher battery voltages across the bridge so as to obtain greater off-balance voltage for the same change in thermistor resistance. It is easy to show that, to a good approximation, for a balanced bridge of the type shown in Fig. 2

$$\Delta E = \Delta R(E/4R)$$

ΔE is the potential difference seen by the recorder; E is the battery voltage; R is the resistance of either thermistor arm; and ΔR is a small change in R. This equation was verified in practice. One-hundred ohms variation of the box in series with the sample thermistor showed 1.4 mv. for a 6-v. battery, 2.9 mv. for a 12-v. battery, and 5.9 mv. for a 24-v. battery.

The easy conversion from millivolt reading to ohms is a great help in reading the bridge. It is not necessary to balance except to the nearest 100-ohm setting. Two positions on the recorder chart separated by the voltage corresponding to 100 ohms are located to the right and left of the nul position by approximately balancing the bridge. The exact resistance required to balance is then easily calculated.

The use of the recording potentiometer as a nul instrument for a Wheatstone bridge would seem needlessly complex except for the fact that the equation given above is valid only when very little current is flowing through the nul instrument. Another and more essential use of the recorder is to establish final equilibrium values. Figure 5 shows a typical example of a slow and a moderately rapid rate of attainment of equilibrium after the sample had been exposed to the air of the room. Solutions seem to come to a steady state more slowly than pure water, indicating that in some cases diffusion of a film of condensed water is a problem when the drop was initially cooled by evaporation. The general behavior of the samples indicates the desirability of making a hole close to and parallel to the thermistor through the glass tubing support in order to insert a long hollow needle for washing and filling without removing the thermistor from the bath. This is an excellent feature of a commercial instrument (10). An innovation which seems to hasten equilibrium is to wait a few minutes before connecting the battery to the bridge. Convection caused by the heating of the thermistor probably provides some convection stirring which differs under different conditions.

The method used for placing the sample has some advantages, however. It is simple and makes it easy to wash and dry the thermistor before adding a sample, thus reducing the volume of solution required to about 0.1 ml. For exploratory work of the type reported, there is considerable advantage in frequent inspection. Several experiments with solutions of potassium permanganate showed that one of the platinum loops could be washed with 10–20 drops of new solution.

The most important conclusion that can be drawn from this work is shown in Fig. 6 and Table

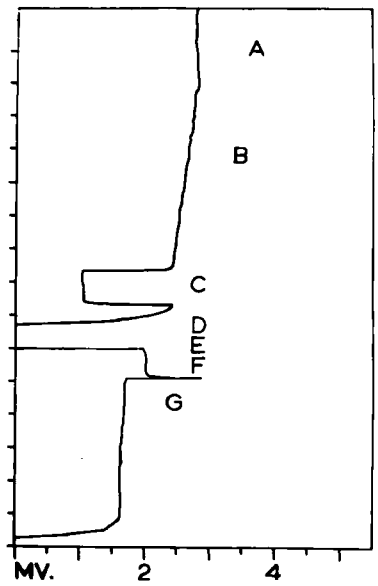

Fig. 5.—A typical recording using 6 v. across the bridge. (Time *vs.* mv.) A = final value for 0.1 *M* urea; B = slow attainment of steady state; *C* = change of decade box by 100-ohms; D = rapid approach to approximate equilibrium; E = thermistor first connected; F = battery circuit open; G = final equilibrium value for water. Each division on the ordinate represents approximately 100 sec.

I. It will be noted that high voltages across the bridge can be used without evidence of serious trends. The temperatures shown in Table I were

TABLE I.—A STUDY OF AQUEOUS SOLUTIONS OF UREA AT DIFFERENT BATTERY VOLTAGES[a]

	Resistance Change from Value with Water, ohms		
M	6 v.	12 v.	24 v.
0.1	72	69	82
0.2	159	167	160
0.4	319	337	371
0.8	685	676	650

[a] Temperature elevation due to current: 0.07° at 6 v., 0.20° at 12 v., 0.63° at 24 v.

calculated from data taken with the bath at 25° and the resistance box substituted for the standard thermistor. Water was placed on the sample thermistor and readings taken at different bridge voltages. The first reading at $1^1/_2$ v. was taken as the true resistance of the thermistor at 25°. As the voltage on the bridge was increased, the resistance went down. The differences were converted to temperature from the measured temperature coefficient and resistance of the thermistor.

Although there seems to be no evidence that the results obtained with high voltage across the bridge are invalid, there are some anomalous results that may indicate that the steady states developed on the thermistor are influenced by other factors. This has been recognized for some time (3), and it is possible that the excessively warm drops amplify this effect. Figure 6 displays the results obtained with sucrose. It will be noted that the points for this substance deviate from a straight line by an amount greater than can be attributed to experimental error.

DISCUSSION

This work is of value in the development of improved instrumentation based upon the Hill-Baldes principle, although the authors are not presenting a finished instrument. It is of special interest that high voltages can be used successfully even though the resulting heating of the thermistor amounts to a change of resistance of almost 3,000 ohms or nearly three-quarters of a degree.

Neither method was pushed to its fullest extent either with respect to accuracy or convenience. However, a study of the data used to plot Fig. 4 shows an average deviation of 1.5% for the three points above 0.01 *M*. All of the dextrose points show an average deviation in the calculated slope of a hypothetical straight line of 3.6%. It is safe to conclude that routine measurements could be made with less than 3% error for the intermittent method.

No attempt was made to refine the techniques used in obtaining data for Table I. Most of the values reported were obtained from duplicate determinations. The maximum difference was 14%, the minimum difference was 0.3%, and the average difference was 5%. This was sufficient to show a lack of significant trend as a function of battery voltage and indicated that the use of higher current might be expected to give satisfactory molecular weights. A systematic determination of the molecular weight of an unknown compound using a 6-v. supply showed an average deviation of 1.8% for nine readings. It is not to be assumed that this value necessarily represents the ultimate accuracy obtainable.

Chemistry of Guareschi Imides II. Enolic Character of β-Aryl Guareschi Imides

By ARNOLD A. LIEBMAN† and FRANK E. DIGANGI

The bicyclization and methylation reactions of β-aryl Guareschi-like imides were studied and the results indicate a favoring enolic structure that hindered these reactions in alkaline media.

With the successful lithium aluminum hydride reduction of β,β-dialkyl-bicyclo Guareschi imides I (1), it appeared that a series of β-alkyl-β-aryl-bicyclo Guareschi-like imides II might also be prepared which upon reduction would yield compounds having a potential analgesic structure III.

VI

Since the Guareschi reaction is limited to ketones having two methyl or methylene groups adjacent to the carbonyl, starting materials were prepared *via* the two step synthesis developed by Cope (2) for the preparation of ethyl-(1-arylalkylidene)-cyanoacetates followed by the Michael addition of sodium cyanoacetamide using McElvain's (3) procedure.

Treating the β-aryl Guareschi-like imides with sodium methoxide and methylene iodide in the same manner as the β,β-dialkyl Guareschi imides (1) resulted in the recovery of starting material only. Similar results were encountered when α,α′-dicyano-β-methyl-β-phenylglutarimide was converted into its sodio derivative and treated with 1,2-dibromoethane and 1,3-diiodopropane, respectively. The β-ethyl analog also failed to form a bicyclo product with methylene iodide in sodium methoxide solution.

Failure of these β-alkyl-β-aryl Guareschi-like imides IV to form bicyclo heptanes in a manner similar to the β,β-dialkyl Guareschi imides may be attributed to either steric hindrance or an enolic structure inhibiting the reaction. The former may be eliminated since, α,α′-dicyano-β-isobutyl-β-methyl-glutarimide has been synthesized and it readily underwent the expected bicyclization with methylene iodide (1). On the other hand, dissolving a β-aryl Guareschi-like imide IV in alkoxide solution could result in formation of the enolate anion V which could react with methylene iodide yielding the enol ether system VI. This would decompose to starting material when treated with aqueous acid.

Methylation of α,α′-dicyano-β-methyl-β-penyl-glutarimide indicated the enolic nature of this compound. When this imide was converted into its mono sodium salt and treated with one molecular equivalent of methyl iodide, reaction appeared to occur since the solution quickly became neutral to moist litmus paper. However, only starting material was isolated from the reaction mixture. When two equivalents of sodium ethoxide and two of methyl iodide were used, a monomethyl product resulted. The entering methyl group attached itself to the imide nitrogen as evidenced by the absence of N—H stretching bands in the infrared spectrum of this compound. A dimethyl compound was obtained when this imide was treated with three equivalents of sodium ethoxide and of methyl iodide. The dimethyl compound was also obtained when six equivalents of sodium ethoxide and of methyl iodide

were used. These results are for the most part consistent with those of Kon and Thorpe (4) obtained in methylation studies of β,β-dialkyl Guareschi imides.

The enolic nature of Guareschi imides was further demonstrated by methylation of the ammonium salts of the imides obtained from the Guareschi reaction. Suspending the ammonium salt of α,α′-dicyano-β,β-dimethylglutarimide (VII) in an ethanol-

benzene mixture and adding a slight excess of dimethyl sulfate resulted in a clear solution which was subsequently diluted with water. Upon standing, the solution precipitated a mixture of products, apparently the free imide VIII and the N-methylimide IX. Significantly, the precipitated material consisted entirely of neither VIII nor of IX, indicating a starting mixture of amonium salts X, XI. Similar results were encountered when the ammonium salt of α,α′-dicyano-β,β-pentamethyleneglutarimide was treated with dimethyl sulfate.

EXPERIMENTAL[1]

Ethyl-(1-phenylethylidene)-cyanoacetate.—In a 1-L., three necked, round-bottom flask equipped with a stirrer and Dean-Stark water separator were placed 120 Gm. (1 mole) of acetophenone, 113 Gm. (1 mole) of ethyl cyanoacetate, 48 Gm. (0.8 mole) of glacial acetic acid, 15.4 Gm. (0.2 mole) of ammonium acetate, and 200 ml. of anhydrous benzene. The mixture was treated according to the procedure of Cope (2) and McElvain (3) and upon distillation yielded 117 Gm. (54%) of product boiling between 145–160°/0.7 mm. Reported (3) boiling range is 135–160°/0.35 mm.

α,α′ - Dicyano - β - methyl - β - phenylglutarimide.—According to the procedure of McElvain and Clemens (5), 0.5 mole of sodium cyanoacetamide was treated with 0.5 mole of ethyl-(1-phenylethylidene)-cyanoacetate. The dried product weighed 114.4 Gm. (90%) and melted at 272–278° (decompn). Reported (5) melting point is 274–278° (decompn).

Attempted Preparation of β-Alkyl-β-aryl-bicyclo Guareschi Imides.—In a 1-L., round-bottom flask fitted with a reflux condenser were placed 275 ml. of absolute methanol and 17.2 Gm. (0.75 Gm. atom) of sodium, added in small portions. When the sodium had dissolved, 63.3 Gm. (0.25 mole) of α,α′-dicyano-β-methyl-β-phenylglutarimide was added and the mixture heated under reflux for ½ hour during which time the imide dissolved. To the solution, 101.0 Gm. (0.38 mole) of methylene iodide was added and reflux continued for 3 hours during which time the methylene iodide dissolved. The solution was cooled and poured with stirring into 325 ml. of water containing 72 ml. of concentrated hydrochloric acid. When precipitation was complete, the solid was removed and washed repeatedly with ether. Recrystallization of this material from methanol and acetone yielded 39.1 Gm. of starting material. This experiment was repeated under extremely anhydrous conditions, using highly purified starting material and reagents. The solid that was obtained was recrystallized from absolute ethanol and melted at 282°. A mixed melting point with starting material caused no depression and the infrared spectrum was identical with that of starting material. Similar results were obtained when these β-aryl Guareschi-like imides were treated with 1,2-dibromoethane and 1,3-diiodopropane. In the latter instance, the above conditions were observed and in addition, the reaction was attempted in tetrahydrofuran using sodium hydride as the base.

Reaction of α,α′-Dicyano-β-methyl-β-phenylglutarimide with One Molecular Equivalent of Methyl Iodide.—A solution of sodium ethoxide was prepared by adding 0.92 Gm. (0.04 Gm. atom) of sodium to 50 ml. of absolute ethanol. To the solution, 20.1 Gm. (0.04 mole) of α,α′-dicyano-β-methyl-β-phenylglutarimide suspended in 200 ml. of absolute ethanol was added with stirring. The reaction mixture quickly became homogeneous and 6.0 Gm. (0.044 mole) of methyl iodide was added with stirring over a period of 10 minutes. The mixture was stirred and heated under reflux for 15 minutes when a sample was neutral to moist litmus paper. Reflux was continued for 1 hour after which time 150 ml. of ethanol was removed by distillation under reduced pressure. The remaining solution was cooled and poured into 300 ml. of water containing 25 ml. of concentrated hydrochloric acid. The precipitated material was collected, washed with ether and recrystallized from ethanol, melting at 282–285° (decompn). A mixed melting point with starting material gave no depression in the melting point. The infrared spectrum of this material was identical to that of starting material.

α,α′ - Dicyano - β - methyl - β - phenyl - N - methylglutarimide.—The conditions in the preceding experiment were followed using 12.7 Gm. (0.05 mole) of the imide, 2.3 Gm. (0.1 Gm. atom) of sodium and 15.6 Gm. (0.11 mole) of methyl iodide. The reaction mixture was neutral to moist litmus paper when the methyl iodide had all been added. The neutral solution was refluxed for an additional hour when it was evaporated under reduced pressure to a volume of 100 ml. and diluted with 300 ml. of water followed by 25 ml. of concentrated hydrochloric acid. An oil separated which was solidified with stirring and recrystallized from ethanol yielding 6.6 Gm. (49%) of the monomethyl product melting between 172–181°. The infrared spectrum of this compound differed with that of starting material in that no N—H bands were present.

[1] Melting points are uncorrected and were taken with a Thomas Hoover capillary tube melting point apparatus. Microanalyses were performed by the Microanalytical Laboratory of the University of Minnesota.

Anal.—Calcd. for $C_{15}H_{13}N_3O_2$: C, 67.40; H, 4.90. Found: C, 67.47; H, 5.04.

α,α' - Dicyano - α' - β - dimethyl - β - phenyl - N-methylglutarimide.—Using the above procedure, but using 0.15 Gm. atom of sodium and 0.165 mole of methyl iodide to 0.05 mole of the imide, yielded 10 Gm. (71%) of the product, m.p. 190–192°.

Anal.—Calcd. for $C_{16}H_{15}N_3O_2$: C, 68.32; H, 5.38. Found: C, 68.29; H, 5.37.

Similar results were obtained with a 2:1 ratio of methyl iodide to each active hydrogen and the solution refluxed for 21 hours. Assignment of the second entering methyl group to the α'-position rather than the α is an arbitrary one.

Reaction of the Ammonium Salt of α,α'-Dicyano-β,β-dimethylglutarimide with Dimethyl Sulfate.—The ammonium salt of α,α'-dicyano-β,β-dimethylglutarimide, 52.0 Gm. (0.25 mole), was suspended in a mixture of 100 ml. of anhydrous benzene and 100 ml. of absolute ethanol contained in a 500 ml., three necked, round-bottom flask equipped with a stirrer, dropping funnel, and reflux condenser. The mixture was stirred and heated under reflux for 1 hour after which time 37.8 Gm. (0.3 mole) of dimethyl sulfate was added with stirring. After the addition was completed, the mixture was stirred and heated under reflux for 2 hours. Within the first 15 minutes of this reflux period, the solid had all dissolved. The solution was cooled, diluted with an equal volume of water and refrigerated overnight. The solid that had separated (31.8 Gm.), was collected, and recrystallized from 60% ethanol. This material melted between 139–155°. A mixed melting point of α,α'-dicyano-β,β-dimethylglutarimide and α,α'-dicyano-β,β-dimethyl-N-methylglutarimide melted at 144–155°.

SUMMARY

1. β-Aryl Guareschi-like imides failed to undergo bicyclization with α,Ω-dihalides.

2. The failure of β-aryl Guareschi-like imides to undergo bicyclization is attributed to a favored enolic system in the presence of alkali which in turn resists the expected reaction.

Mercury(II) Complex of *d*-Cycloserine

By NICHOLAS G. LORDI

The apparent formation constant of the 2:1 complex of *d*-cycloserine and mercury (II) has been measured and found to be $10^{17.5}$ at 25° in solutions of ionic strength of ~0.4. Evidence is presented to substantiate the conclusion that chelation contributes little to the structure of the complex.

As PART of a study dealing with the influence of metal ions on the mode of degradation of the antibiotic *d*-cycloserine (*d*-4-amino-3-isoxazolidone) in aqueous solution, the apparent formation constant of the mercury(II) complex of cycloserine was measured. Neilands (1) and Neuzil and Breton (2) have indicated that cycloserine formed 1:1 and 2:1 complexes with copper(II), zinc(II), cadmium(II), cobalt(II), and nickel(II). No significant complex formation was observed with beryllium(II), magnesium(II), manganese(II), iron(II), and iron(III). It was of interest to compare the stability of the cycloserine–mercury(II) complex with the stabilities reported for similar complexes with other metal ions, as well as with several of the metal ion complexes of other ligands.

EXPERIMENTAL

A potentiometric technique was employed (3, 4). The potential of a mercury electrode in equilibrium with a solution of the mercury(II)–cycloserine complex in the presence of excess cycloserine was measured as a function of pH. Solutions were prepared containing from 0.01 to 0.05 *M* cycloserine, equimolar amounts of sodium hydroxide, from 0.0004 to 0.001 *M* mercuric acetate,[1] and sufficient potassium nitrate to adjust their ionic strength to 0.4. The potential of the mercury electrode (Sargent No. S-30438) *vs.* a saturated calomel electrode (S.C.E.) isolated from the solution through a 1.5 *M* potassium nitrate agar salt bridge was measured using a Fisher student potentiometer. The pH of the solution was varied by titration under nitrogen with 1 *M* perchloric acid. The resulting volume changes amounted to less than 8 per cent of the initial volume at the end of the titration. Corrections were made for concentration changes owing to dilution when significant. A Beckman model G pH meter was employed, using an external glass electrode (type 1190-80) to measure the pH. Since the complex was observed to precipitate at pH values greater than 8, the potential measurements were restricted to the pH range 2–8. The temperature of the solution and calomel electrode was maintained at 25 ± 0.5°.

The apparent dissociation constants of the cycloserine were also measured in 0.4 *M* potassium

Mercury(II) Complex of *d*-Cycloserine

By NICHOLAS G. LORDI

The apparent formation constant of the 2:1 complex of *d*-cycloserine and mercury (II) has been measured and found to be $10^{17.5}$ at 25° in solutions of ionic strength of ~0.4. Evidence is presented to substantiate the conclusion that chelation contributes little to the structure of the complex.

As PART of a study dealing with the influence of metal ions on the mode of degradation of the antibiotic *d*-cycloserine (*d*-4-amino-3-isoxazolidone) in aqueous solution, the apparent formation constant of the mercury(II) complex of cycloserine was measured. Neilands (1) and Neuzil and Breton (2) have indicated that cycloserine formed 1:1 and 2:1 complexes with copper(II), zinc(II), cadmium(II), cobalt(II), and nickel(II). No significant complex formation was observed with beryllium(II), magnesium(II), manganese(II), iron(II), and iron(III). It was of interest to compare the stability of the cycloserine–mercury(II) complex with the stabilities reported for similar complexes with other metal ions, as well as with several of the metal ion complexes of other ligands.

EXPERIMENTAL

A potentiometric technique was employed (3, 4). The potential of a mercury electrode in equilibrium with a solution of the mercury(II)–cycloserine complex in the presence of excess cycloserine was measured as a function of pH. Solutions were prepared containing from 0.01 to 0.05 *M* cycloserine, equimolar amounts of sodium hydroxide, from 0.0004 to 0.001 *M* mercuric acetate,[1] and sufficient potassium nitrate to adjust their ionic strength to 0.4. The potential of the mercury electrode (Sargent No. S-30438) *vs.* a saturated calomel electrode (S.C.E.) isolated from the solution through a 1.5 *M* potassium nitrate agar salt bridge was measured using a Fisher student potentiometer. The pH of the solution was varied by titration under nitrogen with 1 *M* perchloric acid. The resulting volume changes amounted to less than 8 per cent of the initial volume at the end of the titration. Corrections were made for concentration changes owing to dilution when significant. A Beckman model G pH meter was employed, using an external glass electrode (type 1190-80) to measure the pH. Since the complex was observed to precipitate at pH values greater than 8, the potential measurements were restricted to the pH range 2–8. The temperature of the solution and calomel electrode was maintained at 25 ± 0.5°.

The apparent dissociation constants of the cycloserine were also measured in 0.4 *M* potassium

[1] The acetate and nitrate ions present in the system would have a negligible effect (other than that due to alteration in ionic strength) on the measured potential, owing to the much greater concentration of cycloserine than acetate and the very weak tendency of mercury(II) to complex nitrate.

nitrate, by titration with sodium hydroxide and perchloric acid.

The cycloserine[2] had a melting point of 155° (decompn.) after recrystallization from alcohol. The other chemicals used were of reagent grade.

CALCULATIONS AND RESULTS

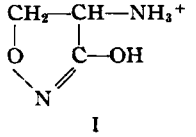
Table I summarizes the equilibria describing the state of a solution containing cycloserine and

TABLE I.—SUMMARY OF EQUILIBRIA AND APPARENT EQUILIBRIUM CONSTANTS DESCRIBING THE MERCURY(II)–CYCLOSERINE SYSTEM[a]

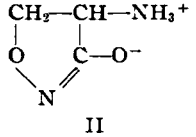
Equilibria	K′	Log K′
$H_2L^+ = HL + H^+$	K_{a1}	−4.57
$HL = L^- + H^+$	K_{a2}	−7.40
$Hg^{++} + HL = HgL^+ + H^+$	K_{10}	...
$Hg^{++} + HL = Hg(HL)^{++}$	K_{11}	...
$Hg^{++} + 2HL = HgL_2 + 2H^+$	K_{20}	2.73
$Hg^{++} + 2HL = HgL(HL)^+ + H^+$	K_{21}	8.67
$Hg^{++} + 2HL = Hg(HL)_2^{++}$	K_{22}	14.07
$Hg^{++} + HL + L^- = HgL(HL)^+$	$K_{23} = K_{21}/K_{a2}$	16.06
$Hg^{++} + 2L^- = HgL_2$	$\beta_2 = K_{20}/(K_{a2})^2$	17.53
$HgL(HL)^+ = HgL_2 + H^+$	$K_{31} = K_{20}/K_{21}$	−5.93
$Hg(HL)_2^{++} = HgL(HL)^+ + H^+$	$K_{32} = K_{21}/K_{22}$	−5.44

[a] In aqueous solution at 25°C. and $\mu \sim 0.4$.

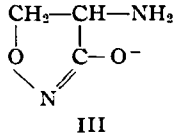
mercury(II) and the equilibrium constants computed from the experimental data. In aqueous solution cycloserine may exist as a cation (H_2L^+), dipolar ion (HL), or anion (L^-), as indicated by structures I, II, and III. The observed values of K_{a1}' and K_{a2}', describing the equilibria between these forms, agreed with those reported by Neilands (1).



I



II



III

The experimental data were analyzed in a manner similar to that described by Brooks and Davidson (5). In order to simplify the calculations, it was assumed that the 1:1 complexes (equilibria 3 and 4) did not significantly contribute to the complexation of mercury(II) by cycloserine. This assumption was justified since measurements were made in the presence of excess ligand. It was substantiated by the subsequent analysis. K_{10} and K_{11} were not measurable under the conditions employed in this study.

[2] The cycloserine employed in this study was a sample of Seromycin, Lot No. 61, generously supplied by Eli Lilly & Co.

The total concentration of ligand species, therefore, is

$$\Sigma L = [L^-] + [HL] + [H_2L^+] + 2[HgL_2] + 2[HgL(HL)^+] + 2[Hg(HL)_2^{++}] \quad \text{(Eq. 1)}$$

while the total concentration of mercury(II) species is

$$\Sigma Hg(II) = (Hg^{++}) + [HgL_2] + [HgL(HL)^+] + [Hg(HL)_2^{++}] \quad \text{(Eq. 2)}$$

Since Σ Hg(II) $\gg$ (Hg^{++}), the concentration of uncomplexed ligand species, $[L^-] + [HL] + [H_2L^+]$, may be taken as $\Sigma L - 2\Sigma Hg(II)$. It is convenient to define the following function which may be derived from Eq. 2 and equilibria 5, 6, and 7

$$\frac{\frac{Hg(II)}{(Hg^{++})} - 1}{[HL]^2} = \frac{K_{20}}{(H^+)^2} + \frac{K_{21}}{(H^+)} + K_{22} = \bar{K} \quad \text{(Eq. 3)}$$

Also

$$[HL] = \frac{\Sigma L - 2\Sigma Hg(II)}{\alpha} \quad \text{(Eq. 4)}$$

where

$$\alpha = 1 + \frac{(H^+)}{K_{a1}} + \frac{K_{a2}}{(H^+)}$$

The mercuric ion activity was calculated from the measured potential of the mercury electrode *vs.* the S.C.E. using the Nernst equation (3)

$$E = 0.612 - 0.0296 \log (Hg^{++}) \quad \text{(Eq. 5)}$$

where 0.612 volts[3] is the standard potential of the Hg/Hg^{++} couple *vs.* the S.C.E. Corrections owing to the reduction of Hg^{++} by Hg^0 to Hg_2^{++} were negligible because of the excess ligand present. The mercury (I) complex of cycloserine is not stable, readily disproportionating.

Equation 3 was used to evaluate the constants K_{20}, K_{21}, and K_{22}. Values of the function $(\bar{K})$ between pH 6.5–8 were used to compute K_{20}; values between pH 4.5–6.5 were used to compute K_{21}; and values between pH 4.5–2 were used to compute K_{22}. The consistency of the experimental data with the proposed model is illustrated by Fig. 1 which shows a plot of log $\bar{K}$ as a function of pH. Values of the function on the left-hand side of Eq. 3 computed from the experimental data are compared to $\bar{K}$ calculated using the tabulated values of K_{20}, K_{21}, and K_{22}.

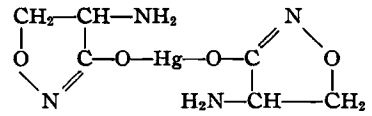
The apparent formation constant (β_2') and dissociation constants (K_{31}' and K_{32}') of the complex were calculated as indicated in Table I.

DISCUSSION

A comparison of the apparent formation constants reported for some metal ion (1, 6) complexes of *dl*-serine and *d*-cycloserine is made in Table II. As expected, the stability of the 2:1 cycloserine–mercury(II) complex is considerably greater than

[3] No attempt was made to correct the standard potential to a value corresponding to $\mu \sim 0.4$, because of a lack of information concerning the effect of ionic strength on the potential of the Hg/Hg^{++} couple. This meant that the value of the computed formation constant was high, probably by not more than 0.3 log K unit.

that observed for other metals. The known tendency of cycloserine to chelate copper(II), zinc(II), and cobalt(II) is a great deal less than that observed for serine. Neilands (1) has pointed out that this is probably due to the less favorably fixed positions of the potential chelating groups in cycloserine as contrasted to the flexibility of the amino acid molecule. On the other hand, the stabilities of the mercury(II) complexes are of the same order of magnitude. This observation, as well as the experimental data, supports the view that chelation does not significantly contribute to the structure of the complex, which may be represented at pH ~8 as



The dissociation constants of the mercury(II) complex (K_{31}' and K_{32}') are on the order of 10^2 greater than the corresponding ionization constant (K_{a2}') of cycloserine. If chelation through the amino-group was significant, a much greater increase should have been observed. The fact that the formation constants K_{22}', K_{23}', and β_2' increase successively in value may be accounted for by charge effects as well as by chelation. Similar observations were made by Brooks and Davidson (5) in their analysis of the histidine–mercury(II) system.

Some observations have been made concerning the stability of the cycloserine–metal complexes to hydrolysis. They appear to degrade by a mechanism different from that involved in the decomposition of cycloserine (7). Particularly striking changes may be observed in a solution of the copper (II) chelate upon aging. The solution changes from a green to a deep blue color and deposits a violet precipitate. These observations are the subject of studies now in progress and will be reported on in more detail at a later date.

TABLE II.—COMPARISON OF APPARENT FORMATION CONSTANTS (LOG β_2') OF *d*-CYCLOSERINE AND *dl*-SERINE METAL COMPLEXES

Ligand	Temp., °C.	Hg(II)	Cu(II)	Zn(II)	Co(II)
d-Cycloserine	25	17.5	9.7	6.0	5.7
dl-Serine	20	17.5	14.6	8.6	8.0

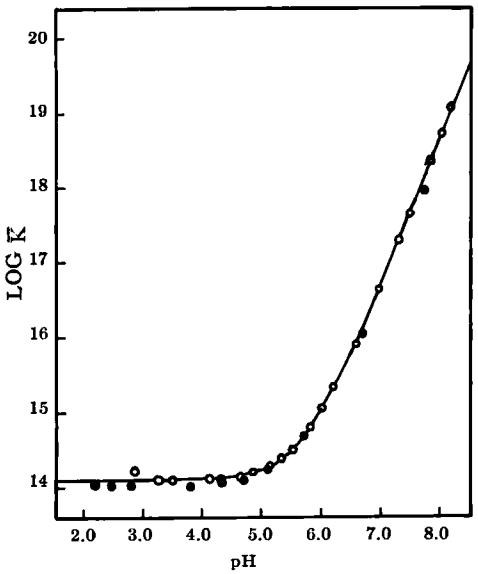


Fig. 1.—Log $\bar{K}$ *vs.* pH: the solid line represents $\bar{K}$ calculated from Eq. 5 using values of $K_{20} = 10^{2.73}$, $K_{21} = 10^{8.67}$, and $K_{22} = 10^{14.07}$; the open circles represent values calculated from measured mercuric ion activities where ΣL is 0.04 *M* and Σ Hg(II) is 0.0004 *M*; the solid circles represent values calculated from measured mercuric ion activities where ΣL is 0 01 *M* and Σ Hg(II) is 0.001 *M*.

Basis of Hydrogen Ion Binding Curves Deduced from Differences in Solution and Solvent Titrations

By EDWARD R. GARRETT†

A hydrogen ion binding curve may be constructed by plotting the difference in titers of samples and blanks against pH. The theoretical bases for the determination of pKa and stoichiometry for weak acids and bases by such curves is investigated. The assumptions and limitations of such methods are specified. The nature and degree of the difference in the titration curve and the hydrogen ion binding curve is shown for changes in pK and concentration of solute.

IN A PAPER discussing the use of apparent dissociation constants (Ka′) in qualitative organic analysis, Parke and Davis (1) had proposed the use of hydrogen ion binding curves for estimation of pKa′. Their procedures involved the titration of two solutions, one including and one omitting the sample, with titrant of the same high normality. The amount of titer necessary to achieve a given pH for the blank is subtracted from the amount necessary to achieve the same pH for the solution. These titer differences may be calculated in an acidic or basic direction using the amount of titrant at pH 7 as zero for blank and solution. For example, a method would be to subtract the volume of standard acid necessary to bring the blank solution (initially at pH 7) to a given pH, *e.g.*, pH_1, which is less than 7, from the volume of standard acid necessary to change the pH of the sample solution from 7 to that same pH_1. Similarly, the volume of standard alkali necessary to bring the blank solution to a given pH, *e.g.*, pH_2, which is greater than 7, would be subtracted from the volume of standard alkali necessary to change the pH of the sample solution from 7 to that same pH_2.

The titer differences when divided by the total stoichiometric titer for a single titratable function (α) were plotted against the pH and are presumably related to the expression

$$pH = pKa' + \log [\alpha/(1 - \alpha)] \quad \text{(Eq. 1)}$$

where α is the degree of dissociation. The pKa′ was estimated from the pH value at $\alpha = 0.5$ (2).

It should be informative to investigate the basic principles validating this technique and to evaluate its limitations.

The general equation for equilibria during titration of a weak acid (HA) by a base (MOH) on the Parke-Davis assumptions of concentrations equal to activities [or for neutralization of a salt (MA) by a strong acid (HX)] (2) is

$$[H^+] = Ka' \frac{[HA]}{[A^-]} = Ka' \frac{(a - b) - [H^+] + [OH^-]}{b + [H^+] - [OH^-]} \quad \text{(Eq. 2)}$$

where the total concentrations of weak acid and weak acid anion is

$$a = [HA] + [A^-] \quad \text{(Eq. 3)}$$

where the concentration of the anion given as the salt is

$$b = [M^+] \quad \text{(Eq. 4)}$$

and since the solution is electrically neutral

$$[M^+] + [H^+] = [A^-] + [OH^-] \quad \text{(Eq. 5)}$$

Titration of a Salt of a Weak Acid in Acid Region With a Strong Acid.—When pH < 7, $[H^+] \gg [OH^-]$ so that Eq. 2 reduces to

$$[H^+] = Ka' \frac{(a - b) - [H^+]}{b + [H^+]} \quad \text{(Eq. 6)}$$

If x is the number of milliequivalents of MA before titration in L ml. of solution titrated with M ml. of strong acid of y normality, and if M_x is the stoichiometric acid titer for x meq. of MA, then

$$a = x/(L + M) = M_x y/(L + M) \quad \text{(Eq. 7)}$$

and

$$b = (M_x - M)y/(L + M) \quad \text{(Eq. 8)}$$

If M' is the ml. of strong acid titer necessary to achieve the same pH or $[H^+]$ with the same equipment for L' ml. of a blank as M ml. does for L ml. of sample solution, then

$$[H^+] = M' y/(L' + M') \quad \text{(Eq. 9)}$$

Equations 7, 8, and 9 may be substituted into Eq. 6, and since the y values cancel

$$[H^+] = Ka' \frac{\alpha'}{(1 - \alpha')} \quad \text{(Eq. 10)}$$

where

$$\alpha' = \left\{ M - M' \left(\frac{L + M}{L' + M'} \right) \right\} \Big/ M_x \quad \text{(Eq. 11)}$$

The logarithmic form of Eq. 10 is the same as Eq. 1 except for the sign of the log term. The α' values may be calculated for a given pH from knowledge of the ml. of titer (M and M') necessary to achieve that pH in L ml. of sample and L' ml. of the blank.

If the initial volumes of sample and blank solutions are the same ($L = L'$) and the concentration of the acid titer is great with respect to that of the sample solution ($L \gg M > M'$) then the logarithmic form of the simplified expression is

$$pH = pKa' - \log \frac{(M - M')/M_x}{1 - (M - M')/M_x} = pKa' - \log \frac{\alpha''}{1 - \alpha''} \quad \text{(Eq. 12)}$$

Addition of a Strong Acid to a Weak Acid in Acid

Received August 13, 1962, from the Upjohn Co., Kalamazoo, Mich.

Accepted for publication September 10, 1962.

† Present address: College of Pharmacy, Univerity of Florida, Gainesville.

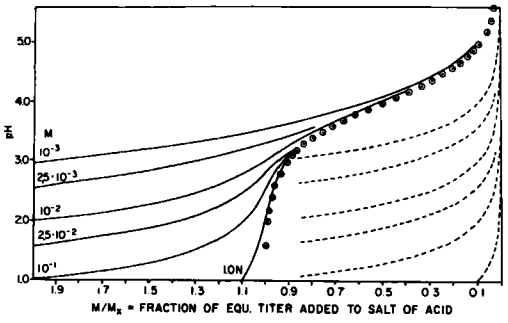

Fig. 1.—Titration and hydrogen ion binding curves for various concentrations of an acid of pKa 4.0; ———, acid titration curves for the weak acid salt on the assumption of no change in concentration of the solution during the titration; – – –, comparable titrations of blank of the same volume; ⊙⊙⊙, difference in titer at any pH for the titration of a sample and blank. It should be noted that the circles give the same S-shaped curve for any concentration of the acid when the titrations are thus corrected for the titration of the blank.

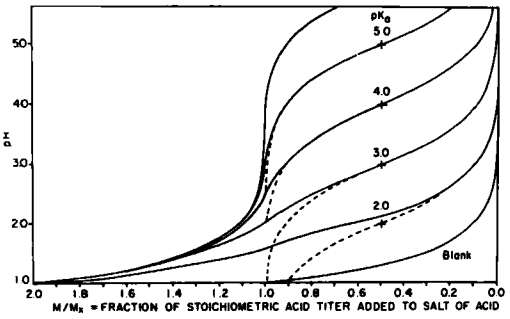

Fig. 2.—Titration and hydrogen ion binding curves for 0.1 *M* solutions of acids of various pKa; ———, acid titration curves for the weak acid salt on the assumption of no change in concentration of the solution during the titration; – – –, difference in titer at any pH for the titrations of sample and blank. The blank is of the same volume as the sample.

Region.—At any time during the addition of a strong acid (HX) to a weak acid (HA), the hydrogen ion concentration $[H^+]$ should be equal to the sum of those ions from the completely dissociated strong acid $[H_s^+]$ and the incompletely dissociated weak acid $[H_w^+]$

$$[H^+] = [H_w^+] + [H_s^+] \qquad \text{(Eq. 13)}$$

However, the acid anion concentration is

$$[A^-] = [H_w^+] = [H^+] - [H_s^+] \qquad \text{(Eq. 14)}$$

and thus,

$$[HA] = a - [H_w^+] = a - [H^+] + [H_s^+] \qquad \text{(Eq. 15)}$$

$$[H^+] = Ka\,\frac{a - [H^+] + [H_s^+]}{[H^+] - [H_s^+]} \qquad \text{(Eq. 16)}$$

Substitution of Eqs. 7, 9 and

$$[H_s^+] = (M - M_x)y/(L + M) \qquad \text{(Eq. 17)}$$

into Eq. 16 results in Eq. 10, 11, and on simplification. to Eq. 12.

Similar equations result for the same assumptions although the sign of the log term in Eqs. 10 and 12 would differ, if the titrations of both blank and sample were carried out in the alkaline range where $[OH^-] \gg [H^+]$, where the undissociated weak acid of the sample is neutralized by strong base and where the pH of the blank is increased by strong base and from Eq. 2

$$[H^+] = Ka'\,\frac{[HA]}{[A^-]} = Ka'\,\frac{(a - b) + [OH^-]}{b - [OH^-]} \qquad \text{(Eq. 18)}$$

Applications of the Derived Equation.—The simplified expression (Eq. 12) states that a difference in titer necessary to achieve the same pH for a sample and a blank solution when divided by the total ml. of stoichiometric titer may be plotted against pH to give an S-shaped curve that is always of the same form.

A series of curves are given in Fig. 1 for the strong acid titrations of various concentrations of a weak acid salt (pKa = 4.0) and their corresponding blanks. The circles represent the ideal S shape calculated for all concentrations on the basis of the assumptions of Eq. 12. The solid lines represent the titration curves of the sample, and the dashed lines the titration curves of the blanks. The estimates of pKa' at $\alpha'' = 0.5$ are practical in a manner equivalent to the use of the pH at half-neutralization as the pKa' (2). This presupposes that the purity and stoichiometry are known for all concentrations of the anion of the acid of pKa 4.0. It must be realized, however, that the assumptions of $M \ll L$, and activity equal to concentration will not hold for very concentrated solutions of the sample.

At low sample concentrations, the error in calculated titer differences will be large.

A series of theoretical curves are also given in Fig. 2 for the strong acid titrations of 0.1 *M* solutions of weak acid salts of various pKa's and a corresponding blank. The dashed lines represent the ideal S shapes calculated on the basis of the assumptions of 12 from the differences in titer of sample and blank solutions where the abscissa for the dashed lines now becomes $(M - M'/M_x)$. The method has no advantage over the traditional techniques of determining pKa' at half neutralization for pKa's generally in the range 4–10, unless solubilities of material are low and the inflections are not sharp. The pKa's of material with $2 < pKa < 4$ may be estimated but the error in subtraction of volumes and in pH readings at pH <2.0, and the failure of the assumptions underlying Eq. 12 invalidate the techniques in those regions, especially for estimates of stoichiometry.

The above discussion considers aqueous solutions. Titrations in nonaqueous solvents are special cases and must be considered separately. For example, a pKa' calculated from the apparent pH at half neutralization in nonaqueous solvent is highly concentration dependent (3).

Method for Isolation and Determination of α-Methyl DOPA Ethyl Ester in Aqueous Solution

By ARNOLD D. MARCUS and JOSEPH D. DEMARCO

The ethyl ester of α-methyl-3,4-dihydroxyphenylalanine can be quantitatively separated from the free acid by column partition chromatography. Best results have been achieved by using a pH 4.5, 0.1 *M* citrate buffer adsorbed on powdered cellulose as the stationary phase and *n*-butanol as the mobile phase. If the eluate is analyzed colorimetrically using a reagent specific for intact catechol nuclei, interference by any oxidized ester is avoided. The method has been found useful for accelerated stability studies and provides recoveries averaging 99 per cent of theory.

IN AQUEOUS solution the ethyl ester of α-methyl-3,4-dihydroxyphenylalanine (α-methyl DOPA ethyl ester) is subject to two modes of degradation. The ester function may hydrolyze to yield the free amino acid, and the catechol nucleus is, as would be expected, quite prone to oxidation. In view of the two degradative pathways, initial study of the stability of the ester in aqueous solution did not seem amenable to straightforward functional group analysis. Instead, it seemed most desirable to attempt to preferentially isolate the totally intact ester and to conveniently determine its concentration by simple ultraviolet spectrophotometry.

In the event that such complete separation was found too difficult or time consuming, it was felt that isolation of the oxidized and unoxidized ester *together* would be entirely satisfactory if followed by an analytical procedure specific for the intact catechol nucleus.

The main problem, then, concerned separation of the intact or oxidized ester from any hydrolysis products. Toward this end, partition chromatography using suitably buffered and stabilized columns seemed a desirable approach.

Preliminary experiments indicated that successful separation of the ester could be achieved by using columns buffered at a pH of about 5. It was quite evident that the stationary phase should preferably contain both sodium bisulfite and ethylenediamine tetraacetic acid to prevent oxidation of the ester during column residence. Separation of the ester was most easily achieved by elution with *n*-butanol saturated with buffer.

The choice of a holding material was somewhat vexing in that silicic acid columns gave a very slow rate of flow. While columns prepared with Celite 545[1] seemed quite suitable, it was soon apparent that the trace metal contaminants in the Celite promoted oxidation of the ester. Fortunately, columns prepared with powdered cellulose were found entirely acceptable if stored no longer than one week prior to use.

EXPERIMENTAL

Reagents.—pH 4.5, 0.1 *M* citrate buffer; chloroform, Merck reagent; *n*-butanol, Merck reagent; sodium bisulfite; ethylenediamine tetraacetic acid; and powdered cellulose, chromatography grade.

Apparatus.—Chromatographic columns, 40 cm. long × 2 cm. i.d., constricted at the end and provided with a delivery tube to fit into the neck of a 100-ml. volumetric flask.

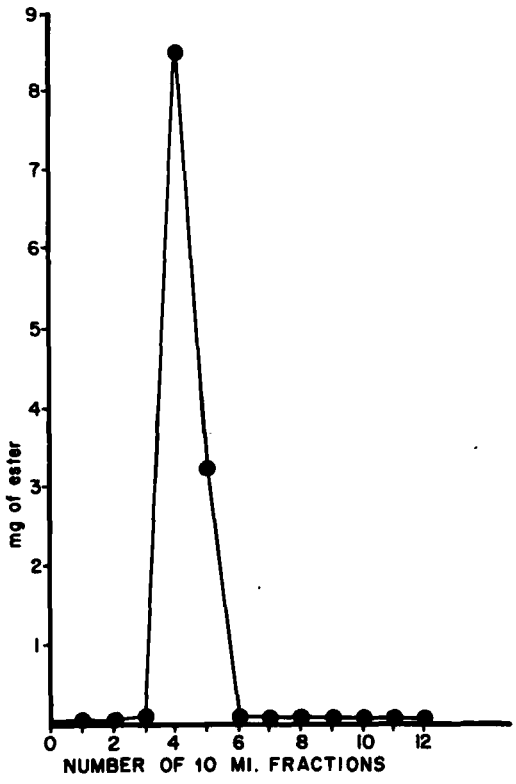

Fig. 1.—Chromatogram showing the elution of α-methyl DOPA ethyl ester from a cellulose column with *n*-butanol.

Procedure.—Sixteen grams of powdered cellulose was mixed mechanically with *ca.* 150 ml. chloroform. Twelve milliliters of buffer previously equilibrated against *n*-butanol and containing 0.35% sodium bisulfite and 0.05% ethylenediamine tetraacetic acid was then added to the cellulose-chloroform mixture with vigorous agitation. The

Received April 25, 1962, from the Pharmaceutical Research Department, Merck Sharp and Dohme Research Laboratories, West Point, Pa.

Accepted for publication August 29, 1962.

The authors wish to express their thanks to Mr. Donald Rodgers for making the details of the colorimetric method available and for supplying the reagent.

[1] Tradename for mineral filler marketed by Johns-Manville Sales Corp., New York, N. Y.

resulting slurry was packed into a column incrementwise using moderate pressure.

Prior to adding the sample, the column was washed with 50 ml. *n*-butanol previously equilibrated against buffer. When the last traces of butanol had entered the column, 1 ml. of a solution of α-methyl DOPA ethyl ester (5–10 mg./ml.) in water or buffer was added to the column and allowed to drain into the body of material. Five milliliters of *n*-butanol was then added to wash the walls of the column and followed by a second 5 ml. of *n*-butanol.

Twenty-five milliliters of *n*-butanol saturated with buffer was then added, and a constant head maintained on the column. At this point, collection of the effluent was started and either small fractions or gross volumes were collected.

Initially all assays were done spectrophotometrically by diluting the effluent with 0.1 *N* methanolic hydrochloride. Subsequently, when it appeared that small amounts of oxidation products were being eluted, all determinations were made by a modification of the procedure of Heinrich and Schuler (1). The procedure used was: the eluate, collected in a volumetric flask, was diluted with 5 *M* acetic acid to provide a concentration of 10 to 15 mcg. of ester per ml. A 5-ml. aliquot of this dilution was transferred to a 25-ml. volumetric flask along with 5 ml. of a 0.6% solution of 4-nitro-2-chloro-1-diazophenyl-β-naphthylsulfonic acid in 5 *M* acetic acid. The mixture was brought to volume with 5 *M* acetic acid and heated at 35° for 1 hour. The flasks were removed from the constant temperature bath, cooled rapidly, and read at 410 mμ *vs.* a suitable reagent blank. In the concentration range employed, all colors showed excellent adherence to Beer's law.

The reagent in 5 *M* acetic acid is stable for at least a week if kept cold. The partition columns should not be kept longer than 1 week.

DISCUSSION OF EXPERIMENTAL RESULTS

When 10 mg. each of α-methyl DOPA ethyl ester and the free amino acid were applied to separate cellulose columns and the effluent collected in 10-ml. fractions, no elution of the free acid could be detected after a total of 25 fractions had been assayed (ultraviolet). In contrast, elution of the ethyl ester was very easily accomplished in a reasonably narrow band as shown in Fig. 1. Although it has been found consistently that all of the ester is eluted in the third through the sixth fraction, we found it simpler to initiate collection of the effluent in a 100-ml. volumetric flask and to collect a total of 100-ml. of effluent. The slight dilution caused by collection of the larger volume is insignificant in view of the high sensitivity of the colorimetric method.

The recoveries of α-methyl DOPA ethyl ester obtained by the method outlined are given in Table I. It is evident from these data that recoveries are well within the limits desired for stability studies and that both the precision and accuracy are satisfactory.

TABLE I.—RECOVERY OF α-METHYL DOPA ETHYL ESTER AFTER PARTITION CHROMATOGRAPHY AND COLORIMETRIC ASSAY

Mg. Added	Mg. Found	% Theory Found[a]
2.56	2.60	102
5.05	4.95	98
9.84	9.84	100
10.00	9.95	99.5
10.67	10.13	95

[a] Average recovery = 98.9% of theory.

Subsequent experiments, in which known quantities (*ca.* 5 mg. each) of α-methyl DOPA ethyl ester and the free acid were chromatographed on single columns, showed the amino acid to have no effect on elution of the ester. Similarly, artificially degraded solutions of α-methyl DOPA ethyl ester (air oxidation at 60°) showed substantial loss after chromatography and colorimetric assay.

Thin-Layer Chromatography in Drug Analysis II. Procedure for the Identification of Various N^4-Substituted Sulfonamides

By B. T. KHO and SHELDON KLEIN†

A thin-layer chromatographic procedure using the step technique is described for the separation and identification of various N^4-acylated and N^4-aroylated sulfonamides. The test has been successfully applied to mixtures of (*a*) phthalylsulfacetamide, phthalylsulfathiazole, and succinylsulfathiazole and (*b*) phthalylsulfanilamide, succinylsulfacetamide, and succinylsulfanilamide. Detection was accomplished by use of ultraviolet observation and an 0.05% alcoholic bromcresol purple solution. The procedure can be completed within two and one-half hours.

A METHOD for the detection of N^4-acylated and N^4-aroylated sulfonamides alone or when present in mixtures along with N^4-unsubstituted compounds has not yet been reported in the thin-layer chromatography (TLC) literature. Sophoulis (1) has reported a paper chromatographic procedure for various sulfonamides including phthalylsulfacetamide, phthalylsulfathiazole, and succinylsulfathiazole, which required 6 hours for development. The procedure gave R_f values which were too close to provide separation of phthalylsulfacetamide and succinylsulfathiazole

The usual color reactions for the detection of the unsubstituted sulfonamide spots are based on the reaction of the free aromatic NH_2 group. The standard procedure for the detection of N^4-substituted sulfonamides on paper is by use of acid-base indicators (2). In developing the TLC procedure described in this paper, it was found that for certain substituted compounds, bromcresol purple gave the best results when silica gel G was used. For others, detection by ultraviolet fluorescence was necessary.

This paper deals with the separation and identification, by TLC, of the N^4-acylated and N^4-aroylated sulfonamides together or in combination with N^4-unsubstituted sulfonamides. A successful procedure was obtained using the step technique (3). This necessitated the use of two chambers. One of the two was lined with filter paper that was saturated with the solvent system. This was necessary to avoid the edge phenomenon (3). Unsubstituted sulfonamides are detected on the same plates using the Bratton-Marshall reagent. The identification of these was accomplished according to a previously described method (4).

The procedure is useful in the identification of the N^4-substituted sulfonamides present in the U.S.P. XVI (5) and N.F. XI (6). It also provides a means for the detection of the corresponding unsubstituted sulfonamides, if present.

EXPERIMENTAL

Apparatus.—Glass plates (200 × 200 mm.). An unlined tank ($8^1/_2$ in. × 4 in. × $8^1/_2$ in.) for solvent A. A second tank similar to A but containing solvent B and lined with solvent-saturated filter paper.

Preparation of Plates.—The plates were coated according to the procedure described in the previous paper (4).

Solvent A.—Methanol-ethanol (1:1). Prepared by mixing 60 ml. each of anhydrous ethanol and A.C.S. reagent methanol.

Solvent B.—*n*-Propanol–0.05 *N* hydrochloric acid (4:1). Prepared by mixing 100 ml. of *n*-propanol, 25 ml. of water, and 0.1 ml. of concentrated hydrochloric acid.

Adsorbant.—Silica gel G.

Standards.—Twenty-five mg. dissolved in 50 ml. acetone. These were freshly prepared. The compounds used were: phthalylsulfacetamide (I),[1] phthalylsulfathiazole (II), succinylsulfathiazole (III), phthalylsulfanilamide (IV),[1] succinylsulfanilamide (V),[1] and succinylsulfacetamide (VI)[1].

Preparation of Samples.—An equivalent of 25 mg. of sulfonamide was extracted with 50 ml. of acetone. For suspensions, 1 ml. of water was added before extraction. If necessary, the solutions were centrifuged and the clear supernatant liquid used.

Observation.—Short wave U.V. lamp (254 mμ)[2] and 0.05% alcoholic solution of bromcresol purple.

Quantity of Sulfonamide Applied.—One mcg. for compounds I to IV inclusive, 3 mcg. for compounds V and VI.

Using the Desaga apparatus,[3] the adsorbant was applied to the plates as described in the previously published paper (4). The tanks were allowed to equilibrate overnight. In addition to a finish line at 100 mm. from the start, a small notation was made at the 50-mm. level.

Samples (2 μl.) and standard (2 μl.) solutions representing compounds I to IV inclusive were applied on the plates along an imaginary line 15 mm. from the starting edge. For compounds V and VI, 6 μl. was applied. Two microliters of a standard solution containing 1 mg. per 2 ml. and representing a possible unsubstituted hydrolysis product were also applied.

Development was started in tank A. When the front reached 50 mm., the plates were removed, dried at 100° for 5 minutes, allowed to cool, and then placed into tank B. When final development to 100 mm. was completed, the plates were removed and again dried at 100° for 5 minutes. Observation was begun using a short wave U.V. lamp.

Phthalylsulfacetamide (I), Phthalylsulfathiazole

Received September 5, 1962, from the Quality Control Section, Merck Sharp & Dohme, Division of Merck & Co., Inc., West Point, Pa.

Accepted for publication September 14, 1962.

The authors gratefully acknowledge the cooperation of Dr. L. Paul Sinotte and Mr. Theodore P. Michaels in carrying out this project. The authors also wish to thank the Technical Services Unit for helpful suggestions and Miss Kathleen Smith for her secretarial assistance.

[3] Obtainable from C. Desaga, Heidlberg, Germany, through Brinkmann Instruments, Inc., Great Neck, L. I., N. Y.

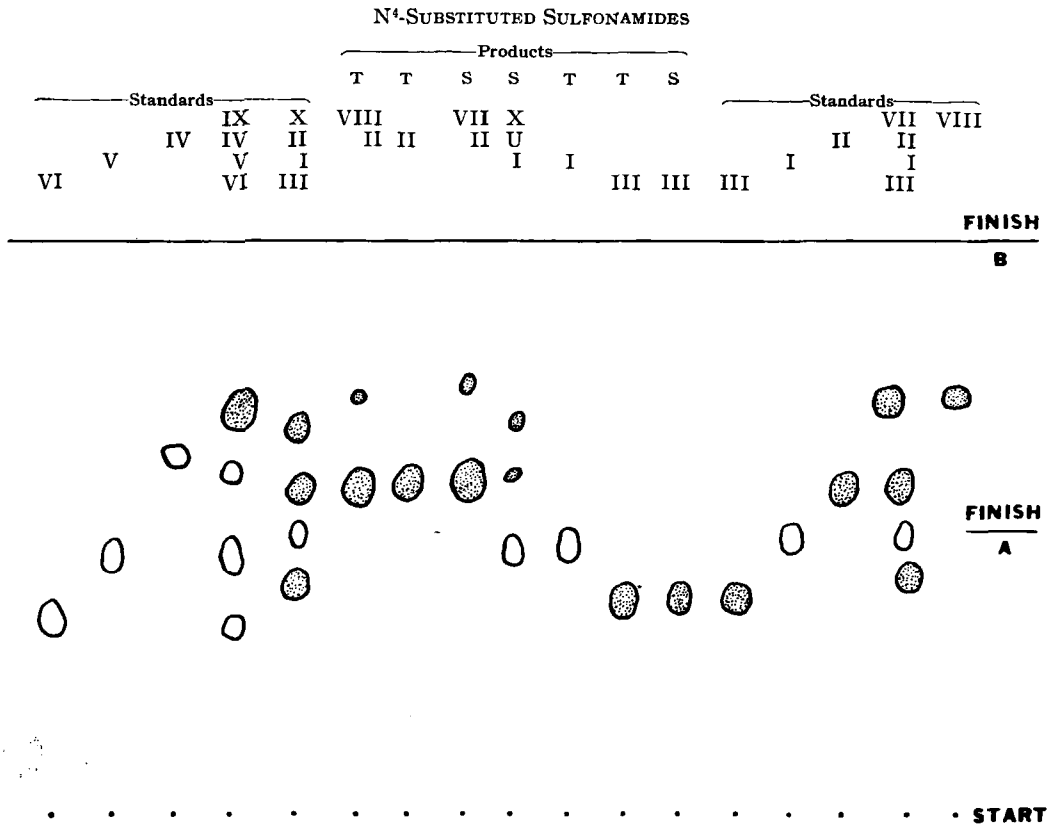

Fig. 1.—I = Phthalylsulfacetamide; II = phthalylsulfathiazole; III = succinylsulfathiazole; IV = phthalylsulfanilamide; V = succinylsulfanilamide; VI = succinylsulfacetamide; VII = sulfathiazole; VIII = sulfamethazine; IX = sulfanilamide; and X = sulfacetamide. U, unknown; A, solvent A; B, solvent B; T, tablet; and S, suspension. The clear spots refer to areas detected by use of ultraviolet lamp. The shaded spots refer to areas detected by use of bromcresol purple indicator.

(II), and Succinylsulfathiazole (III).—Compound I appeared as a bright blue fluorescent area which was marked, if present. Compounds II and III sometimes appeared faintly blue. Spraying with 0.05% alcoholic solution of bromcresol purple showed blue or purple spots on a yellow background in the presence of II and III or any unsubstituted sulfonamide produced by hydrolysis. Compound I appeared blue when first sprayed, but the color faded with either continued spraying or within a short period after the spraying was completed. On first application, the entire plate appeared blue. The background rapidly faded, leaving only areas of II, III, and the unsubstituted sulfonamides visible.

A reproduction of a developed plate is shown in Fig. 1. The copy was obtained using a Xerox 914 copier and a modified procedure of Hilton and Hall (7).

Phthalylsulfanilamide (IV), Succinylsulfanilamide (V), and Succinylsulfacetamide (VI).—The sensitivity of the U.V. detection method for observing V and VI is less than for any of the other four compounds tested. A 3 mcg. sample was the smallest amount easily detected. Compounds V and VI appeared as blue fluorescent areas after exposure of the plates to the ultraviolet lamp for a period of two or three minutes. Spraying with the indicator gave rapidly fading blue or purple spots.

A summary of approximate R_f values for the various sulfonamides tested is shown in Table I.

TABLE I.—APPROXIMATE R_f VALUES OBTAINED FOR VARIOUS N⁴-SUBSTITUTED SULFONAMIDES

Sulfonamide	Av. R_f[a]	Observation
Succinylsulfacetamide	0.37	UV
Succinylsulfathiazole	0.43	Indicator
Succinylsulfanilamide	0.49	UV
Phthalylsulfacetamide	0.51	UV
Phthalylsulfathiazole	0.61	Indicator
Phthalylsulfanilamide	0.66	UV

[a] Data obtained from seven or more plates.

RESULTS AND DISCUSSION

For the samples tested, separation and identification of the N⁴-substituted sulfonamides was accomplished by use of the step technique (3). The substituted compounds were easily separated from the free sulfonamides. Verification of the presence of any unsubstituted sulfonamides can be made using diazotization and the Bratton-Marshall reagent. For identifying the unsubstituted sulfon-

amide, the method described in the previously published paper (4) was used.

The R_f values for the N^4-substituted sulfonamide official in the U.S.P. XVI (5) and N.F. XI (6), namely I, II, and III were sufficiently different to permit identification

The R_f values for IV, V, and VI were also sufficiently different to allow separation from each other. Of the six compounds tested, all can be separated either by R_f values or fluorescent observation, except I and V. At equal concentrations of 1 mcg. per spot, V is not visible. Though II and IV give close R_f values, II changes the indicator color to blue or purple whereas IV does not. Compound IV gives a bright blue fluorescence and II does not.

After two days the standard solutions showed the presence of the free form.

Due to the uncertainty of reproducing R_f values from one plate to another, it is important to use standards along with the samples.

The total development time is approximately two and one-half hours.

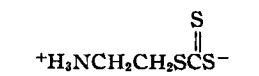
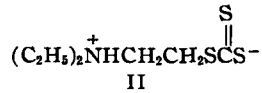
Structure of the Carbon Disulfide Adduct of β-Mercaptoethylamine

Sir:

We have recently reported (1, 2) the preparation of a compound from the reaction of β-mercaptoethylamine (MEA) and carbon disulfide, in either aqueous or alcoholic ammonia, which gave good protection to animals against an otherwise lethal dose of X-irradiation. This compound was believed to be 2-mercaptoethyldithiocarbamic acid on the basis of elemental analysis, its reaction with acylating agents, and a characteristic dithiocarbamate absorption peak (3) in the ultraviolet at 248 mμ (log ε max. = 3.03) (C_2H_5OH). Other characteristic absorption peaks for dithiocarbamates at 290–310 mμ and 340–360 mμ were absent, however, and further examination of the ultraviolet absorption characteristics of dithiocarbamate and trithiocarbonate zwitterions has shown the product in question to be a trithiocarbonate zwitterion I. A previous example of a trithiocarbonate zwitterion has not appeared in the literature.



I



II

Trithiocarbonate zwitterion II of unquestioned structure was prepared from 2-diethylaminoethanethiol hydrochloride (Evans Chemetics, Inc.) and carbon disulfide in ammoniacal solution, analogously to the preparation of I, m.p. 114–115° with effervescence, (90% yield).

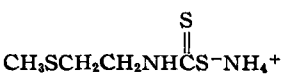
Anal.—Calcd. for $C_7H_{15}NS_3$: C, 40.16; H, 7.22; N, 6.70; S, 45.94. Found: C, 40.74; H, 7.20 N, 6.96; S, 46.13.

The compound reduced iodine, and it showed definite trithiocarbonate absorption peaks (4) in the ultraviolet at 226 mμ (log ε max. = 4.07) and 303 mμ (log ε max. = 4.18) in alkaline C_2H_5OH. Compound I, quite similar in color and physical appearance, showed ultraviolet absorption peaks at 226 mμ (log ε max. = 3.96) and 304 mμ (log ε max. = 4.15), when observed in the same solvent.

Furthermore, compound III, possessing definite dithiocarbamate absorption characteristics in the ultraviolet, was prepared from the S-methyl ether of MEA [prepared by the procedure of Gonick (5)] and carbon disulfide in ammoniacal solution, and was isolated as an unstable ammonium salt, m.p. 104–106°, (70% yield).

Anal.—Calcd. for $C_4H_{12}N_2S_3$; N, 15.27; S, 52.17. Found: N, 15.06; S, 51.38.

Loss of ammonia and carbon disulfide was evident within 24 hours. Characteristic dithiocarbamate absorption was observed at 257 mμ (log ε max. = 3.92), 292 mμ (log ε max. = 4.06), and 345 mμ (log ε max. = 1.95) in alkaline C_2H_5OH.



III

Because of the remarkable agreement in physical properties and ultraviolet absorption between the carbon disulfide adduct I of MEA and a similarly constituted trithiocarbonate

amide, the method described in the previously published paper (4) was used.

The R_f values for the N^4-substituted sulfonamide official in the U.S.P. XVI (5) and N.F. XI (6), namely I, II, and III were sufficiently different to permit identification

The R_f values for IV, V, and VI were also sufficiently different to allow separation from each other. Of the six compounds tested, all can be separated either by R_f values or fluorescent observation, except I and V. At equal concentrations of 1 mcg. per spot, V is not visible. Though II and IV give close R_f values, II changes the indicator color to blue or purple whereas IV does not. Compound IV gives a bright blue fluorescence and II does not.

After two days the standard solutions showed the presence of the free form.

Due to the uncertainty of reproducing R_f values from one plate to another, it is important to use standards along with the samples.

The total development time is approximately two and one-half hours.

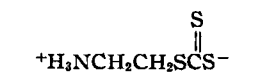
Communications

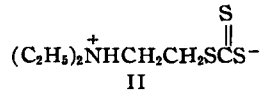
Structure of the Carbon Disulfide Adduct of β-Mercaptoethylamine

Sir:

We have recently reported (1, 2) the preparation of a compound from the reaction of β-mercaptoethylamine (MEA) and carbon disulfide, in either aqueous or alcoholic ammonia, which gave good protection to animals against an otherwise lethal dose of X-irradiation. This compound was believed to be 2-mercaptoethyldithiocarbamic acid on the basis of elemental analysis, its reaction with acylating agents, and a characteristic dithiocarbamate absorption peak (3) in the ultraviolet at 248 mμ (log ε max. = 3.03) (C_2H_5OH). Other characteristic absorption peaks for dithiocarbamates at 290–310 mμ and 340–360 mμ were absent, however, and further examination of the ultraviolet absorption characteristics of dithiocarbamate and trithiocarbonate zwitterions has shown the product in question to be a trithiocarbonate zwitterion I. A previous example of a trithiocarbonate zwitterion has not appeared in the literature.



I



II

Trithiocarbonate zwitterion II of unquestioned structure was prepared from 2-diethylaminoethanethiol hydrochloride (Evans Chemetics, Inc.) and carbon disulfide in ammoniacal solution, analogously to the preparation of I, m.p. 114–115° with effervescence, (90% yield).

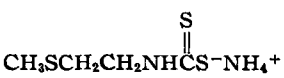
Anal.—Calcd. for $C_7H_{15}NS_3$: C, 40.16; H, 7.22; N, 6.70; S, 45.94. Found: C, 40.74; H, 7.20 N, 6.96; S, 46.13.

The compound reduced iodine, and it showed definite trithiocarbonate absorption peaks (4) in the ultraviolet at 226 mμ (log ε max. = 4.07) and 303 mμ (log ε max. = 4.18) in alkaline C_2H_5OH. Compound I, quite similar in color and physical appearance, showed ultraviolet absorption peaks at 226 mμ (log ε max. = 3.96) and 304 mμ (log ε max. = 4.15), when observed in the same solvent.

Furthermore, compound III, possessing definite dithiocarbamate absorption characteristics in the ultraviolet, was prepared from the S-methyl ether of MEA [prepared by the procedure of Gonick (5)] and carbon disulfide in ammoniacal solution, and was isolated as an unstable ammonium salt, m.p. 104–106°, (70% yield).

Anal.—Calcd. for $C_4H_{12}N_2S_3$; N, 15.27; S, 52.17. Found: N, 15.06; S, 51.38.

Loss of ammonia and carbon disulfide was evident within 24 hours. Characteristic dithiocarbamate absorption was observed at 257 mμ (log ε max. = 3.92), 292 mμ (log ε max. = 4.06), and 345 mμ (log ε max. = 1.95) in alkaline C_2H_5OH.



III

Because of the remarkable agreement in physical properties and ultraviolet absorption between the carbon disulfide adduct I of MEA and a similarly constituted trithiocarbonate

zwitterion on the one hand, and the marked disparity in these properties with the dithiocarbamate of the methyl thioether of MEA on the other, it is concluded that I is a trithiocarbonate zwitterion.

Alkaloids of *Vinca rosea* Linn. (*Catharanthus roseus* G. Don) XVIII. Root Alkaloids

Sir:

A number of crude amorphous alkaloidal fractions from root extracts had demonstrable anti-P-1534 leukemia activity in DBA/2 mice, and it was deemed necessary to determine whether this oncolytic activity was caused by any of the four known dimeric alkaloids or by any new entities. While the roots had been examined previously by other investigators (1), they had not been looked at utilizing the method of selective extraction, followed by column chromatography and gradient pH techniques as devised in this laboratory (2, 3).

The *A* fraction yielded two new alkaloids, vinosidine and lochnerivine, as well as mitraphylline (the oxindole of ajmalicine)—first reported as being obtained from *Mitragyna macrophylla* Hiern (4)—along with varying amounts of the known alkaloids ajmalicine, leurosine, virosine, perivine, VLB (obtained as both base and sulfate), leurosidine, carosidine, sitsirikine (as sulfate), and trace amounts of leurocristine (as sulfate) (5). Two other new alkaloids, leurosivine and cavincine, were obtained only as sulfates.

The *B* fraction gave three new alkaloids, ammocalline,[1] pericalline, and ammorosine, as well as akuammicine [first reported as being obtained from *Picralima klaineana* Pierre (6)], along with lochnerivine, leurosine, perivine, virosine, and lochnerine.

Pertinent physical data of these new alkaloids are as follows:

Vinosidine crystallized from methanol, m.p. 253–257° dec.; pK'a = 6.80 (33% DMF).

Anal.—Calcd. for $C_{22}H_{26}N_2O_5$: C, 66.31; H, 6.58; N, 7.03; O, 20.08. Found: C, 66.26; H, 6.72; N, 6.75; O, 20.51.

The ultraviolet spectrum in ethanol is characterized by maxima at 226, 254, 259, and 300 mμ, with a shoulder at 330 mμ; log E (1%, 1 cm.) = 3.01, 2.46, 2.46, 2.20, and 1.90, respectively. The infrared spectrum of a $CHCl_3$ solution exhibits the following 11 characteristic bands, listed in the order of decreasing intensities (as in all following examples): 1220, 1299, 1266, 1282, 1538, 1695, 1149, 1136, 1724, 1471, and 1087 $cm.^{-1}$

Lochnerivine crystallized from methanol, m.p. 278–280°; no titratable groups were found between pH 3.0–11.0.

Anal.—Calcd. for $C_{24}H_{28}N_2O_5$: C, 67.90; H, 6.65; N, 6.60; O, 18.85. Found: C, 67.91; H, 6.48; N, 7.01.

The ultraviolet spectrum in ethanol is characterized by maxima at 296 and 329 mμ, with a shoulder at 236 mμ; log E (1%, 1 cm.) = 2.52, 2.61, and 2.39, respectively. The infrared spectrum of a Nujol mull shows the following bands: 1666, 1615, 1685, 1464, 1640, 1453, 1200, 1380, 1113, 1168, and 1369 $cm.^{-1}$

Leurosivine crystallized as the sulfate from ethanol, m.p. > 335° dec.; pK'a = 4.8, 5.8 (33% DMF).

Anal.—Calcd. for $C_{41}H_{54}N_3O_9 \cdot H_2SO_4$:[2] C, 59.26; H, 6.79; N, 5.06; S, 3.86; O, 25.03. Found: C, 59.00; H, 6.85; N, 5.09; S, 3.71; loss on drying, 4.5.

The ultraviolet spectrum in ethanol is characterized by maxima at 214 and 265 mμ, with shoulders at 286, 295, and 310 mμ; log E (1%,

1 cm.) = 2.73, 2.23, 2.09, 2.03, and 1.78, respectively. The infrared spectrum of a Nujol mull shows the following bands: 1455, 1736, 1031, 1747, 1229, 1369, 1253, 1100, 1088, 1129, and 1001 cm.$^{-1}$.

The base, isolated from the sulfate, would not yield to crystallization from any of the solvents used. Its ultraviolet spectrum in ethanol is identical to that of the sulfate. The infrared spectrum of a $CHCl_3$ solution shows the following bands: 1231, 1738, 1456, 1041, 1427, 1495, 1168, 1612, 1366, 1143, and 1001 cm.$^{-1}$.

Cavincine crystallized as the sulfate from ethanol, m.p. 275–277° dec.; pK'a = 6.90 (33% DMF). The ultraviolet spectrum in ethanol is characterized by maxima at 224, 281, and 288 mμ; log E (1%, 1 cm.) = 2.86, 2.17, and 2.08, respectively. The infrared spectrum of a Nujol mull shows the following bands: 1453, 1725, 1088, 1022, 1029, 1371, 1051, 1132, 746, 1143, 1131, and 1160 cm.$^{-1}$.

The base, isolated from the sulfate, could not be crystallized. Its ultraviolet spectrum in ethanol is identical to that of the sulfate. The infrared spectrum of a Nujol mull shows the following bands: 1449, 1708, 1372, 737, 1162, 1198, 1222, 1258, 1321, 1348, and 1058 cm.$^{-1}$.

Ammocalline crystallized from acetone, m.p. > 335° dec.; pK'a = 7.30 (33% DMF).

Anal.—Calcd. for $C_{19}H_{22}N_2$: C, 81.97; H, 7.97; N, 10.06. Found: C, 81.63; H, 7.69; N, 9.93.

The ultraviolet spectrum in ethanol is characterized by maxima at 218 and 288 mμ; log E (1%, 1 cm.) = 3.09 and 2.61, respectively. The infrared spectrum of a Nujol mull shows the following bands: 1467, 748, 1435, 737, 1330, 906, 1381, 1340, 1298, 1144, and 1320 cm.$^{-1}$.

Pericalline crystallized from acetone, m.p. 196–202°; pK'a = 8.05 (33% DMF). The ultraviolet spectrum in ethanol is characterized by maxima at 207 and 304 mμ, with shoulders at 230 and 240 mμ; log E (1%, 1 cm.) = 2.98, 2.80, 2.84, and 2.75, respectively. The infrared spectrum of a $CHCl_3$ solution shows the following bands: 1322, 1458, 1120, 1441, 1420, 1230, 1601, 885, 820, 661, and 1300 cm.$^{-1}$.

Ammorosine crystallized from methanol, m.p. 221–225°; pK'a = 7.30 (33% DMF).

Anal.—Found: C, 68.73; H, 7.70; N, 7.87; O, 15.46.

The ultraviolet spectrum in ethanol is characterized by maxima at 227 and 280 mμ, with shoulders at 295 and 305 mμ; log E (1%, 1 cm.) = 2.88, 2.36, 2.26, and 2.03, respectively. The infrared spectrum of a Nujol mull shows the following bands: 1028, 1458, 1146, 1217, 790, 1119, 1166, 1327, 1438, 1489, 1103, and 835 cm.$^{-1}$. The infrared spectrum of a $CHCl_3$ solution of the acetone-recrystallized base shows the following bands: 1148, 1137, 1486, 1026, 1330, 1462, 872, 1115, 1109, 1355, and 1174 cm.$^{-1}$.

Mitraphylline and akuammicine were both obtained by crystallization from acetone. They were identified by comparison of melting points, X-ray powder diffraction patterns, and infrared and ultraviolet spectra with those of authentic samples.

Detailed methods of obtaining these alkaloids, along with their preliminary characterization, will be discussed at a later date.

Structure of "2-Mercaptoethyldithiocarbamic Acid"

Sir:

Recently Foye, Duvall, and Mickles (1, 2) have assigned the 2-mercaptoethyldithiocarbamic acid structure to the significantly radioprotective compound derived from reaction of equimolar amounts of 2-mercaptoethylamine (MEA) hydrochloride and carbon disulfide in ammoniacal solution. The chemical and physical properties reported for this material suggested reaction had occurred at the thiol end of the MEA molecule, rather than the amino end, producing the zwitterion of 2-aminoethyltrithiocarbonic acid.

$$HSCH_2CH_2NH_3^+Cl^- + CS_2 + NH_3 \rightarrow {}^-SC(=S)SCH_2CH_2NH_3^+ + NH_4^+Cl^-$$

Repetition of Foye's procedure (1) gave a yellow solid in about 75% yield. Like his material, it was insoluble in most common solvents and unstable in air. When isolated without washing (Foye's procedure) it melted at 80–82° dec. in a capillary. Washing with substantial quantities of water or ethanol raised the melting point without appreciably diminishing the yield or changing the infrared spectrum. In a capillary our test preparation melted at 86–88° dec., but on a block the melting point was much lower, 80–82°, and decomposition was not apparent. Foye reported a melting point of 76–78°, taken on a block. From the method of preparation, solubility behavior, and melting point data we conclude that our compound was identical with that reported by Foye. Our best washed sample (analysis below) was probably somewhat purer than his material.

Anal.—Calcd. for $C_3H_7NS_3$: C, 23.51; H, 4.61; N, 9.14; S, 62.75. Found: C, 23.15; H, 4.67; N, 9.48; S, 62.77.

To obtain physical and chemical evidence bearing on the structure problem it was necessary to find solvents for the compound. The zwitterion hypothesis suggested that highly polar solvents would be most suitable, and indeed the compound was found to be very soluble in dimethyl sulfoxide and dimethylformamide.

The proton nuclear magnetic resonance spectrum, taken in deuterated dimethyl sulfoxide with tetramethylsilane as standard, showed a broad absorption band at 7.00 p.p.m., assignable to $-NH_3^+$, and a multiplet at 3.28 p.p.m., assignable to $-CH_2-$, with relative areas almost exactly 3:4. If present, —SH should have appeared as a well defined triplet at about 1.75 p.p.m., and no such absorption was noted. The n.m.r. spectrum is thus completely consistent with the 2-aminoethyltrithiocarbonic acid zwitterion structure and totally inconsistent with the 2-mercaptoethyldithiocarbamic acid structure.

A solution of the compound in dimethylformamide reacted exothermically with benzyl chloride, and the product, obtained in low yield because of isolation difficulties, was shown by analysis to be the hydrochloride of 2-aminoethyl benzyl trithiocarbonate. This reaction and product are obviously possible only if the starting material is the zwitterion of 2-aminoethyltrithiocarbonic acid.

$${}^-SC(=S)SCH_2CH_2NH_3^+ + C_6H_5CH_2Cl \rightarrow C_6H_5CH_2SC(=S)SCH_2CH_2NH_3^+ Cl^-$$

Anal.—Calcd. for $C_{10}H_{14}NS_3Cl$: C, 42.92; H, 5.04; N, 5.01; S, 34.37; Cl, 12.67. Found: C, 42.66; H, 4.95; N, 5.12; S, 34.12; Cl, 12.61.

Finally, it was reasoned that if reaction had occurred at the thiol end of MEA, it should also be possible with mercaptoamines completely substituted on the nitrogen atom; if it had taken place at the amino end, no reaction should be possible with completely substituted mercaptoamines. To test this concept, equimolar amounts of 2-dimethylaminoethanethiol hydrochloride and carbon disulfide were reacted in the presence of excess aqueous ammonia under Foye's conditions. A yellow solid, m.p. 128–129.5° dec., was obtained in about 70% yield. The physical properties of this material were very similar to those of the MEA-CS_2 product, and its elemental analysis indicated that it resulted from combination of 1 mole of mercaptoamine with 1 mole of carbon disulfide. Since this compound can be formulated *only* as the zwitterion of 2-dimethylaminoethyltrithiocarbonic acid, its ready formation under Foye's conditions lends support to the belief that the MEA-CS_2 product is similarly constituted.

$$HSCH_2CH_2NH^+(CH_3)_2Cl^- + CS_2 + NH_3 \rightarrow {}^-SC(=S)SCH_2CH_2NH^+(CH_3)_2 + NH_4^+Cl^-$$

Anal.—Calcd. for $C_5H_{11}NS_3$: C, 33.12; H, 6.12; N, 7.73; S, 53.04. Found: C, 33.37; H, 6.14; N, 7.49; S, 52.89.

From all this evidence we conclude that the

compound reported by Foye, *et al.* (1, 2), as 2-mercaptoethyldithiocarbamic acid is actually the zwitterion of 2-aminoethyltrithiocarbonic acid. This structure is consistent also with the radioprotective activity shown by the material, since the very similar zwitterions of 2-aminoethylthiosulfuric acid and related compounds also are known to possess significant activity as radioprotectants (3, 4).

Inorganic Chemistry. By LOUIS K. SHARP. The Williams and Wilkins Co. (exclusive U. S. agent), 428 East Preston St., Baltimore 2, Md., 1962. viii + 339 pp. 15 × 23 cm. Price $8.

The author has designed this book to meet the requirements of students of pharmacy, medicine, and allied sciences by limiting the discussions of elementary chemistry and concentrating on those subjects of particular importance to medicinal and pharmaceutical chemistry students. The author has increased the treatment of inorganic compounds handled by workers engaged in research and analytical procedures, though not actually used as medicaments, which have particular methods of preparation and purification or peculiar hazards or disposal problems associated with them. The volume is divided into two parts: Part I is concerned with fundamental material and Part II contains factual material on the elements and compounds used as medicaments or as tools in analysis and research.

Elements of General and Biological Chemistry. An Introduction to the Molecular Basis of Life. By JOHN R. HOLUM. John Wiley & Sons, Inc., 440 Park Avenue South, New York 16, N. Y., 1962. ix + 470 pp. 14.5 × 23 cm. Price $5.95.

The molecular basis of life is the general theme of this textbook designed for students who, though not intending to become chemists, will profit from an awareness of the molecular basis of life in their chosen occupations. This book is not a general introductory view of general chemistry; it singles out certain processes of life at the molecular level and treats the selected topics in some depth.

Scientific Research in British Universities and Colleges 1961–62. Department of Scientific and Industrial Research, State House, High Holborn, London, W.C. 1, 1962. U. S. agents: British Information Services, 45 Rockefeller Plaza, New York 20, N. Y. xvii + 622 pp. 13 × 21.5 cm. Price $6.50.

This paperbound volume provides an extensive listing of scientific research in progress in British universities, university colleges, and associated institutions as well as research being conducted in the colleges of advanced technology in England, Wales, Scotland, and Northern Ireland during the 1961–1962 academic year. One hundred and sixteen institutions are included. Under the listing for each institution are brief, title-like descriptions of the projects under study in the various departments along with a list of workers supervising the research. The book is well indexed—a name index, a topic index, and a subject index. In all, the indexes cover about 165 pages of the volume.

Immunoassay of Hormones. Edited by G. E. W. WOLSTENHOLME and MARGARET P. CAMERON. Little, Brown and Co., 34 Beacon St., Boston 6, Mass., 1962. xii + 419 pp. 14 × 20 cm. Price $10.75.

This book is volume 14 of the Ciba Foundation Colloquia on Endocrinology covering a symposium in which 28 scientists, representing both immunologic and endocrinologic thought, participated. The symposia dealt with the complex problem of detection and assay of hormones by immunochemical means. Major topics included in the contents of the volume are: Growth hormone, Insulin, Glucagon, Thyrotropin, Corticotropin, Gonadotropins, and Prolactin. The papers presented and the general discussion which followed the papers should represent an up-to-date review of the status of work in this area. As with previous volumes, author and subject indexes are included.

The Opium Alkaloids. By DAVID GINSBURG. John Wiley & Sons, Inc., Interscience Division, 440 Park Ave. South, New York 16, N. Y., 1962. 111 pp. 15 × 23 cm. Price $6.50.

This book covers selected topics in the field of opium alkaloids and is written to be particularly useful in teaching graduate students. It gives examples of how complex structural problems and extraordinary chemical transformations are solved. In addition, it gives pertinent data regarding structural elucidation and the chemistry of the alkaloids. The book is divided into six major groupings entitled Morphine and codeine, Thebaine, The synthesis of morphine, Sterochemical considerations, The biogenesis of morphine, and Papaverine. A subject index is appended permitting ready access to the contents.

compound reported by Foye, *et al.* (1, 2), as 2-mercaptoethyldithiocarbamic acid is actually the zwitterion of 2-aminoethyltrithiocarbonic acid. This structure is consistent also with the radioprotective activity shown by the material, since the very similar zwitterions of 2-aminoethylthiosulfuric acid and related compounds also are known to possess significant activity as radioprotectants (3, 4).

Inorganic Chemistry. By LOUIS K. SHARP. The Williams and Wilkins Co. (exclusive U. S. agent), 428 East Preston St., Baltimore 2, Md., 1962. viii + 339 pp. 15 × 23 cm. Price $8.

The author has designed this book to meet the requirements of students of pharmacy, medicine, and allied sciences by limiting the discussions of elementary chemistry and concentrating on those subjects of particular importance to medicinal and pharmaceutical chemistry students. The author has increased the treatment of inorganic compounds handled by workers engaged in research and analytical procedures, though not actually used as medicaments, which have particular methods of preparation and purification or peculiar hazards or disposal problems associated with them. The volume is divided into two parts: Part I is concerned with fundamental material and Part II contains factual material on the elements and compounds used as medicaments or as tools in analysis and research.

The Editor comments

EXCELLENCE IN TEACHING

Each year at about this time we read of various awards being made to university professors or instructors for *excellence in teaching*. This type of award is a relative newcomer among the longer established and more widely known categories of honors. Such awards are intended to single out dedicated teachers, who—through their special classroom technique and personal inspiration—make a significant, favorable impression on their students. And, in so doing, they are able to contribute in a positive and enduring manner to the education and motivation of those students. Selection of the award recipients, at least in part, is often made by those in the best position to judge the teacher's ability—namely, the students themselves.

We have been pleased to note that the number of these annual awards appears to be increasing, and particularly that the number of pharmacy school faculty recipients is growing at perhaps an even faster rate.

Our pleasure in large part stems from the fact that these awards serve to recognize and encourage the many devoted and deserving faculty people who for years were virtually ignored while the spotlight of attention almost exclusively was beamed solely on the research professors and the more dramatic discoveries issuing from their laboratories. It is certainly not our intention to suggest that the tribute paid in recognition of research activities has been either inappropriate or excessive. However, similar attention to the beneficial value of the contributions being made by teachers of outstanding ability has been long overdue. It is gratifying to many of us that this unfortunate neglect is being corrected.

Metabolism of Phenothiazine Drugs

By JOHN L. EMMERSON† and TOM S. MIYA

OVER A PERIOD of years beginning in 1944, the research workers of the Rhône-Poulenc Research Laboratories in France synthesized a number of amine derivatives of phenothiazine. One of the most important of these was chlorpromazine prepared by Charpentier in 1950. This compound was found to exert a remarkable number of pharmacological effects involving the central and autonomic nervous systems. Courvoisier, *et al.* (1), have published an extensive report on the pharmacological activity of chlorpromazine in animals. The most striking aspect of this drug, however, was its therapeutic value in patients with certain emotional disturbances. This discovery provided the initial stimulus for the development and use of phenothiazine drugs in psychiatric practice.

The search for new drugs to treat specific mental disorders and the attempts to isolate a particular pharmacological effect by chemical alteration of the phenothiazine molecule has resulted in the introduction of several useful phenothiazine drugs of varying actions and potencies. These developments offer a unique opportunity, not only for the study of structure-activity relationships, but also for the examination of the effect of different chemical substituents on the biological fate of these compounds, their metabolism, distribution, and excretion.

Following oral or parenteral administration, most of the phenothiazine derivatives are extensively localized in body tissues. This property of the parent compound and/or its metabolites is probably responsible for the unusually prolonged excretion which has been observed (2, 3). The possibility that metabolites may be present in the body for long periods of time underscores the importance of the identification of these compounds and the role they play in the effectiveness of the phenothiazine drugs.

Results of studies on model compounds strongly suggest that the metabolites contribute to the action of the parent drug (4). Clinical changes in psychotic patients, the type of psychiatric disorder, or the rate of regression after drug withdrawal may be correlated with the nature and quantity of the metabolic products found in the urine. These factors have tended to focus attention on the biological fate of the phenothiazine drugs.

This review of the literature and summary of the present state of knowledge concerning the metabolism of the phenothiazine drugs deals primarily with the biological transformation of phenothiazine derivatives currently used as psychotherapeutic agents. The equally important topics of absorption, tissue distribution, and excretion will be considered in a subsequent report. A substantial part of the present review is devoted to the discussion of chlorpromazine metabolism. Chlorpromazine has been used as a representative compound for the following reasons: 1. the preponderance of the relevant literature concerns chlorpromazine; 2. chlorpromazine data have, in many cases, been independently verified; 3. chlorpromazine was the first compound of this series to be examined for metab-

olism. A recent review by Bousquet (5) may be consulted for current information in the general area of drug metabolism. The reader is also referred to a review of the metabolism of psychoactive drugs by Carr (6) and an excellent review of the pharmacology of the tranquilizer drugs by Domino (7). The latter paper also discusses the metabolic fate of these compounds. Harwood (8) has reviewed the metabolism of phenothiazine.

In order to facilitate the presentation of data, the literature is discussed under subject headings which relate to a particular type of metabolic reaction. For the sake of brevity and continuity, the generic names of the phenothiazine drugs have been used. Table I lists the generic names and chemical structures. The structural formulas of several known and hypothesized metabolites are given in Table II. Although some later papers are included, this review is chiefly concerned with the literature through August 1962.

SULFOXIDATION

Prior to 1950, the oxidation of organic sulfur compounds to sulfoxides was a rather novel type of biological transformation. Other than the work of Clare, *et al.* (9), on the metabolism of phenothiazine, little was known of this metabolic reaction. Phenothiazine-5-oxide was found in the blood and aqueous humor of the eye in calves which had been treated with the anthelmintic, phenothiazine. Today the accumulated evidence indicates that the formation of the sulfoxide (5-oxide) is a metabolic reaction common to all the phenothiazine derivatives in current use.

Salzman, *et al.* (10), reported in 1955 that they were able to isolate, by counter-current methods, a major metabolite of chlorpromazine and to identify this compound as the sulfoxide. In studies of urinary excretion (11), this form was found to comprise from 10–14% of the administered dose of chlorpromazine in dogs and about 5% of the dose in man. Only very small amounts of the drug were excreted unchanged by either species. In a study of the urinary excretion patterns of patients receiving daily chlorpromazine medication, Huang and Kurland (12) have shown that the average urinary excretion (*per diem*) of chlorpromazine and its sulfoxides varied from 1–20% of the daily dose. Sulfoxide excretion ranged from 1–18%, while the amount of free chlorpromazine in the urine was usually less than 1% of the dose. The average ratio of free chlorpromazine to its sulfoxides was found to be approximately 1:16.

Fishman and Goldenberg (13), by chromatographic studies, were able to show ten metabolites of chlorpromazine which were extractable at an alkaline pH from human urine. Six of these compounds gave ultraviolet spectra characteristic of sulfoxides. In addition to chlorpromazine sulfoxide, two demethylated sulfoxides were shown by chromatography. In subsequent

studies, these workers were able to quantify some of the urinary metabolites of chlorpromazine in man and dog (14). Values for total sulfoxide excretion were given as 5.9% of the dose in man and 11.3% in the dog. These figures agree closely with the earlier findings of Salzman and Brodie (11). It should be pointed out that excretion data for sulfoxides, as reported by Goldenberg and Fishman (14), were calculated as the sum of three different sulfoxides separated by chromatography and determined individually. Since the colorimetric assays in earlier reports gave no indication of an alteration in the side chain, the quantities given for a sulfoxide metabolite probably represented some demethylated products.

Sulfoxides have been found to be the principal metabolic products of chlorpromazine in the mouse. Upon administration of S^{35}-labeled chlorpromazine to mice, the radioactivity in the

urine was found in the forms of free sulfate (3–5%), "combined sulfate" (23–48%), and the sulfoxide of chlorpromazine (49–73%) (15). In the rat, Ogawa, *et al.* (16), found that 27% of the dose of chlorpromazine appeared in the urine within 72 hours. The unchanged drug accounted for 8.1% of the dose while 18.9% was present as the sulfoxide. Other studies have shown that approximately 40% of the administered radioactivity is excreted by the rat in the urine when S^{35}-chlorpromazine is given (17, 18). Emmerson and Miya (18) were able to account for 12% of the dose in the urine as unmetabolized drug and a similar amount as sulfoxides of chlorpromazine.

Tissue homogenates have been used to study the oxidation of chlorpromazine *in vitro*. Chlorpromazine sulfoxide has been isolated from the incubation media. The ability to metabolize chlorpromazine is apparently centered in the liver, for other tissues have shown little activity in this respect (19, 20).

By intravenous administration of chlorpromazine sulfoxide to dogs, it has been shown that the sulfoxide itself is metabolized. Less than one-quarter of the original dose was excreted unchanged, and chromatography of the urine revealed a further metabolic product of the sulfoxide (11). Similar results have been reported in man (21). The biological half-life of the sulfoxide in human plasma has been calculated to be about 3 hours. The duration of its sedative effect was short; it usually lasted not more than 1 hour. Following an intravenous dose to patients, only 2–3% of the dose could be recovered as unchanged drug during the subsequent 24 hours (21).

In vitro studies have provided further evidence that chlorpromazine sulfoxide undergoes additional metabolism (19, 20). It has been postulated that chlorpromazine sulfone (chlorpromazine-5-dioxide) may be one of the *in vitro* products (20). Chlorpromazine sulfone has not been encountered in the investigations involving the urinary metabolites (13, 18, 22). However, Zehnder, *et al.* (23), have, by the use of S^{35}-thioridazine and inverse-isotope dilution techniques, shown that thioridazine disulfone is a metabolite which is found in the bile and urine of the rat. The metabolism of thioridazine is complicated by the presence of another oxidizable sulfur atom in the 2-methylmercapto group of the phenothiazine ring. By inverse dilution analysis, the ring sulfoxide metabolite (the 5-oxide), the side-chain sulfoxide metabolite (oxidation of the methylmercapto sulfur atom), and the disulfoxide metabolite of thioridazine were demonstrated and quantified in addition to the previously mentioned disulfone. The disulfoxide was excreted in the largest quantities. However, all of the metabolites which were determined in the urine represented only 1–2% of the administered radioactivity. These metabolites made up approximately 20% of the radioactive substances in the bile of the rat. Only traces of unchanged thioridazine were excreted in either bile or urine.

Walkenstein and Seifter (24) recovered 70–80% of the radioactivity in the urine and 20–30% in the feces of the dog following a single intraperitoneal injection of S^{35}-promazine. From 3–5% was shown to be the sulfoxide, 2–3% was excreted unchanged, and 3–4% of the dose was comprised of monomethyl promazine and the monomethyl sulfoxide of promazine.

By paper chromatography of urine, Hoffmann, *et al.* (25), have isolated the sulfoxide as a metabolite of mepazine in the rat. Evidence has been given which indicates that a metabolite of perphenazine in liver tissue of the rat is the sulfoxide of this drug (26). Up to one-third of the dose of methoxypromazine is excreted in the urine by man, almost wholly in the sulfoxide form (27). After parenteral administration of promethazine-S^{35} to rats, the largest portion of the radioactive dose appeared in the urine. The sulfoxide of this phenothiazine derivative was found to be an important urinary metabolite in the rat (28). Chlorprothixene [2-chloro-10-(3-dimethylaminopropylidene)thiaxanthene HCl] is subject to biological oxidation in the same manner as the phenothiazine derivatives. A sulfoxide metabolite of this compound has been shown to be formed by man and the rat with the aid of paper chromatography and ultraviolet absorption analysis (29).

The sulfur atom of the phenothiazine ring is particularly subject to oxidation. Apparently the initial stages involve electron transfer and free radical formation. This phenomenon will be discussed later. In studies with mepazine, Block (30) found that sulfoxide formation can occur due to the presence of peroxide contamination of ethyl ether. More recently, Ross, *et al.* (31), have noted *in vitro* sulfoxidation of desmethyl chlorpromazine which occurred during ether extraction or subsequent chromatography. These findings emphasize the care which must be taken in experiments with the phenothiazine compounds in order to prevent (and recognize) the formation of artificial metabolites.

DEMETHYLATION

Ross, *et al.* (32), using chlorpromazine-(N-methyl)-C^{14}, have found that 12–16% of the label is expired as $C^{14}O_2$ by the rat during the first 6 hours. Animals maintained for 12 hours continued to expire 0.7–2.0% of the radioactive dose each hour throughout the observation period. An active system which demethylates drugs has been shown to be present in the liver (33). Upon incubation of chlorpromazine with rabbit-liver homogenates, prepared according to the method of La Du, *et al.* (33), Salzman and Brodie (11) reported that no demethylation occurred. After *in vivo* demethylation of chlorpromazine had been shown (32), Young, *et al.* (34), demonstrated that properly fortified homogenates could demethylate the drug. After a 1-hour incubation, approximately 40% of the substrate carbon-14 could be recovered as liberated CO_2.

The metabolic fate of S^{35}-promazine has been studied in dogs by Walkenstein and Seifter (24). From 70–80% of the administered radioactivity was eventually excreted in the urine. By the use of chromatography and the authentic compounds as non-labeled carriers, several metabolites of promazine were identified: promazine sulfoxide (3–5%); desmethyl promazine sulfoxide (2.5–3.5%); unchanged promazine (2–3%); and desmethyl promazine (0.75–1%). Injection of either desmethyl promazine or promazine sulfoxide gave rise to desmethyl promazine sulfoxide. Thus it appears that neither monodemethylation nor sulfoxidation (as the initial reaction) prevents the second metabolic change resulting in the desmethyl sulfoxide of promazine.

Demethylated derivatives were found to account for at least two of the sulfoxide metabolites noted by Fishman and Goldenberg (13). Additional evidence was given in a later report to substantiate the formation of the desmethyl and desdimethyl sulfoxide metabolites of chlorpromazine (14). The desdimethyl sulfoxide, a primary amine, is suggested to be the major "non-polar" metabolite of chlorpromazine in human urine. Their results may be summarized as follows: 1. Man—desdimethyl chlorpromazine sulfoxide, 3.7%; desmethyl chlorpromazine sulfoxide, 1.8%; chlorpromazine sulfoxide, 0.4%; unchanged chlorpromazine, 0.2%; 2. Dog—desdimethyl chlorpromazine sulfoxide, 1.1%; desmethyl chlorpromazine sulfoxide, 5.1%; chlorpromazine sulfoxide, 5.1%; unchanged chlorpromazine, 2.8%. Huang and Kurland (12) observed the same metabolites by two-dimensional paper chromatography. An additional metabolite of chlorpromazine, believed to be desmethyl chlorpromazine, was noted by Goldenberg and Fishman in the urine of the dog, but not of man. Desmethyl chlorpromazine has been shown to be an *in vitro* metabolite of chlorpromazine (31). Desdimethyl chlorpromazine sulfoxide is a more prominent metabolite of chlorpromazine in man than in the dog. It is possible, considering the fact that the dimethylaminopropyl side chain is common to both promazine and chlorpromazine, that a desdimethyl metabolite of promazine could be demonstrated in man.

With the exception of the unchanged drug in the urine, the excretion patterns are very similar in the rat (18) and the dog (14) after one dose of chlorpromazine. The rat excretes as much as 12% of the dose of chlorpromazine in the urine as unmetabolized drug. Fedorov (17) has reported that urinary excretion of unchanged chlorpromazine by the rat accounts for 25% of the dose given.

The N-demethylation of thioridazine was studied by using the $\diagdown N—C^{14}H_3$ form of the drug (23). Measurement of $C^{14}O_2$ excretion in the respired air indicated that the rat demethylates 30–40% of a dose of this drug. In light of the extensive demethylation of this compound, it is likely that desmethyl analogs of the sulfoxide and sulfone metabolites are also formed. The number of theoretical metabolites is formidable.

Imipramine [N-(3-dimethylaminopropyl)-imino bibenzyl HCl], a compound similar in structure to promazine, is demethylated and hydroxylated. Herrmann, *et al.* (35, 36), found both monomethyl and completely demethylated derivatives of imipramine in rabbit urine. The metabolism of this compound in rabbits is extensive, whereas man excretes much of the ingested imipramine in unmetabolized form.

N-OXIDE FORMATION

As part of their continuing studies on the metabolism of chlorpromazine by man, Fishman, *et al.* (37), have recently reported the isolation of an N-oxide metabolite from urine. The presence of an oxygen atom attached to the nitrogen of the side chain was found to cause minor but detectable differences in the chemical properties of chlorpromazine. It should be noted that the ultraviolet spectra of chlorpromazine and chlorpromazine-N-oxide were indistinguishable. Chlorpromazine-N-oxide was not a major urinary excretion product of chlorpromazine in man or in the dog. In patients receiving chlorpromazine orally, the N-oxide accounted for

0.7% of the daily dose. The corresponding figure for dogs was somewhat higher, as much as 2–3.5%. This work has been extended (38) to include imipramine, which has the same side chain as chlorpromazine. Patients on imipramine therapy excreted approximately 2% of the administered drug as imipramine-N-oxide.

HYDROXYLATION

Upon fractionation of urine from patients receiving chlorpromazine, three polar metabolites were observed by Lin, *et al.* (39). Treatment with β-glucuronidase gave rise to free glucuronic acid and three new phenothiazines. These compounds were not chlorpromazine or chlorpromazine sulfoxide. A fourth metabolite showed an ultraviolet spectrum similar to that of chlorpromazine with an additional absorption peak at 284 mμ, a property suggestive of a ring-hydroxyl function. Following enzymatic hydrolysis, the released phenothiazines became extractable with ethyl ether from an acid medium. This group believes that the products isolated were phenolic metabolites and that hydroxylation constitutes an important aspect of chlorpromazine metabolism in man. Posner (40) has drawn the same conclusion from his chromatographic studies. He had proposed, as have others (2, 12, 14), that glucuronides are the major excretory products in man rather than sulfoxides.

In a study comparing the metabolism of chlorpromazine in man and dog, Goldenberg and Fishman (14) noted both qualitative and quantitative differences in the urinary metabolic patterns. Man excreted predominantly phenolic metabolites of chlorpromazine, and the urine was found to contain one series of phenolic metabolites which were entirely absent in dog urine. These workers estimate that there may be as many as 24 different metabolites of chlorpromazine. Huang and Kurland (2, 12, 41) also reported that hydroxylated products and their glucuronides constitute the chief metabolites of chlorpromazine in man. The glucuronides could be detected for several weeks after discontinuation of treatment.

It was concluded from studies involving β-glucuronidase and paper chromatography that thioridazine is excreted into rat bile primarily as hydroxylated metabolites conjugated with glucuronic acid (23). Thioridazine and its products are excreted primarily in the feces. Studies by Herrmann, *et al.* (35, 36), have shown conclusively that ring hydroxylation occurs in the metabolism of imipramine. The 2-hydroxylated derivative of imipramine has been synthesized and shown to be identical with one of the metabolites in rabbit urine. This metabolite is also excreted as a conjugate with glucuronic acid.

Nadeau and Sobolewski (42, 43) have investigated the excretion products in daily urine samples from patients receiving chlorpromazine over a period of many months. More than half of the compounds excreted in the urine were shown to be present as conjugates, apparently involving glucuronic acid. It was found that the capacity for this conjugation was not altered by massive dosage or prolonged administration of the drug.

In a discussion of the absorption spectra of some metabolites of chlorpromazine, Kinbergen (44) postulated that a certain shift in absorption maxima pointed to the presence of one or two hydroxyl groups on the phenothiazine nucleus. References to conjugated, polar, or possible phenolic metabolites of the phenothiazine derivatives are common (13, 14, 23, 45–47).

Interest in possible hydroxylated metabolites of the amine substituted phenothiazines has been spurred by the knowledge that mono- and di-hydroxylated derivatives of phenothiazine are formed by a number of animals (48–50). The hydroxylated metabolites of phenothiazine are of two basic types—leucophenothiazone (3-hydroxy phenothiazine) and leucothionol (3,7-dihydroxyphenothiazine)—each of which also occurs in an enolic form, phenothiazone (phenothiaz-3-one) and thionol (7-hydroxyphenothiaz-3-one), respectively. Berti and Cima (51) have stated that chlorpromazine compounds of the phenothiazone type are rather improbable. They feel that the substituted nitrogen in chlorpromazine would prevent the shift in double bonds necessary for phenothiazone formation. They also refer to the absence of color in the urine of animals after chlorpromazine treatment. The phenothiazone metabolites impart a red color to the urine of animals treated with phenothiazine. This does not exclude, however, the possibility that certain metabolites of the substituted phenothiazines may be in the leuco or colorless forms analogous to those found with phenothiazine.

OTHER METABOLIC CHANGES

A ferric chloride-sulfuric acid reagent has been developed to yield a color with the metabolites in the urine of a patient which is proportional in intensity to the amount of chlorpromazine ingested daily (52). It was hypothesized that the violet color observed was due to the reaction of

the reagent with a relatively unstable metabolite which is intermediary between chlorpromazine and chlorpromazine sulfoxide. A compound that gives the same violet color can be prepared by irradiation of an aqueous solution of chlorpromazine with ultraviolet light (53). Forrest, *et al.* (53), using electron spin resonance and absorption spectra, tentatively characterized the intermediate as a thionium hydroxide with one or two hydroxyl groups attached to the sulfur atom. The first products in the oxidation of phenothiazine drugs have been shown to be ion radicals (54). There is good evidence that these radicals are responsible for the color reactions observed. The intermediate form of chlorpromazine produced by ultraviolet irradiation is apparently the same as that of the metabolite(s) occurring in the urine of treated patients. It is of interest that small amounts of these compounds are excreted for many weeks following discontinuation of treatment with a phenothiazine drug (3). A free-radical intermediary form of the phenothiazines has also been postulated by Laborit, *et al.* (55). There are several other papers demonstrating the lability of chlorpromazine in the presence of acids, bases, or light (56–59). One analytical method, designed for phenothiazine derivatives, has an end point governed by color changes during titration. A red free-radical is formed immediately upon the loss of one electron. Decoloration occurs at the equivalence point when a second electron is lost (60).

Both the chlorine atom and the side chain of chlorpromazine remain firmly attached to the phenothiazine nucleus during the passage of the drug through the animal body (51). The stability of the halogen atoms of trifluoperazine has also been demonstrated (61).

There is evidence that the thiazine ring can be degraded by the mouse. Christensen and Wase (15) recovered small quantities of the administered radioactivity as labeled sulfate after injection of S^{35}-chlorpromazine. Walkenstein and Seifter (24) have reported that 10% of the sulfur from S^{35}-phenothiazine is excreted by the dog as inorganic sulfate. This type of breakdown did not occur with promazine, however. This provides further evidence that the side chain is not metabolically removed.

Acetylfluphenazine can be enzymatically hydrolyzed *in vitro* to fluphenazine. Smith (62) has hypothesized that the same reaction may take place *in vivo* and that fluphenazine is the active agent.

The biological fate of two quaternary phenothiazine compounds has been studied in rats by the use of sulfur-35 and tracer techniques (28, 63). After oral administration, these compounds are excreted mainly in the feces. One was largely excreted as the unchanged drug with only traces of possible metabolites. Although the sulfoxide was observed with the other compound, only a small portion of the dose appeared in this form. Apparently neither compound undergoes extensive metabolism. Access to the metabolizing enzymes may be prevented by the chemical influence of the quaternary nitrogen of the side chain in these compounds.

PHARMACOLOGICAL EFFECTS OF METABOLITES

Although chlorpromazine sulfoxide exhibits pharmacological effects which are qualitatively similar to those of chlorpromazine, the latter compound has a much greater potency and a more rapid onset of action (64). Chlorpromazine sulfoxide has been shown to have a weak sedative action of short duration in man (21). For these reasons it is considered unlikely that the effects of chlorpromazine are mediated through the sulfoxide. Moran and Butler (64) have shown that chlorpromazine sulfoxide is not equally active in all species. The sulfoxide was found to be about one-tenth as active as chlorpromazine in potentiating hexobarbital anesthesia and one-eighth as active as chlorpromazine in producing sedation in the dog. Cats exhibited similar effects. In mice and rabbits, however, chlorpromazine sulfoxide was almost devoid of sedative action and had very little potentiating effect on hexobarbital sleeping time in mice. This is in marked contrast to chlorpromazine which is about equally potent, in these respects, in all of the forenamed species. The pharmacological activity of mepazine shows a decrease corresponding to that seen with chlorpromazine upon sulfoxidation (25).

Posner, *et al.* (4), have compared, in a series of behavioral and pharmacological tests, several known and model metabolites of chlorpromazine and promazine. Their results confirmed those of previous reports concerning the decreased activity of chlorpromazine sulfoxide. Of greatest interest, however, was the remarkable degree of activity shown by demethylated and hydroxylated compounds. Desmethyl chlorpromazine was only slightly less active than chlorpromazine. While the activity of chlorpromazine-N-oxide was less than desmethyl chlorpromazine, all of these chlorpromazine analogs were far more active than chlorpromazine sulfoxide. The ac-

tivity of 4-hydroxypromazine approached that of promazine, but the 2-hydroxy derivative was generally much less active. Although these phenolic derivatives of promazine are only model compounds and are definitely not metabolites of the drug (40), other phenolic metabolites are known to be formed. The studies on model compounds clearly demonstrate that activity could reside in a metabolite resulting from ring hydroxylation. The possibility that demethylated or N-oxide metabolites contribute to the action of chlorpromazine or promazine is equally intriguing.

In chemical studies chlorpromazine was found to be a powerful electron donor. This property was attributed to the phenothiazine portion of the molecule. Karreman, *et al.* (65), have suggested that the therapeutic effect of the drug is related to this phenomenon.

Investigators have shown that desmethylimipramine, a known metabolite of imipramine is more potent in some respects than its parent compound (66). There is good evidence to indicate that the antidepressant action of imipramine is actually due to its demethylated metabolite (67, 68). It is more remarkable, however, that imipramine appears to antagonize the effectiveness and delay the onset of action of desmethylimipramine (68). These results serve to emphasize the problems which may also be encountered in studies on the phenothiazine derivatives concerning the evaluation of the pharmacological actions and interactions of parent compound and metabolites.

SUMMARY

Consideration has been given to the literature associated with the metabolism of modern phenothiazine drugs. Several important pathways have been elucidated. A particularly characteristic reaction of this class of compounds is sulfoxidation. Further oxidation of the sulfur atom to a sulfone has been observed only with thioridazine. A number of other metabolic reactions have been demonstrated with the phenothiazine drugs. Among these are: demethylation, N-oxide formation, and conjugation with glucuronic acid. Although the isolation and identification of an actual phenolic metabolite of a N-substituted phenothiazine has not yet been accomplished, the analysis of glucuronic acid conjugates leaves little doubt that the phenothiazine components are phenolic in nature. Evidence indicates that aromatic hydroxylation followed by conjugation with glucuronic acid is the dominant metabolic pathway for the phenothiazine drugs in man. Studies have shown that it is possible for a phenolic metabolite to contribute to the action of its parent drug, *e.g.*, aromatic hydroxylation does not necessarily result in loss of pharmacological activity. Thus, the identification of the phenolic metabolites of the phenothiazine derivatives should be considered a task of prime importance.

In view of the number of known and theoretical metabolites of the phenothiazine drugs, the species differences in the metabolism of these compounds, and the inherent lability of the phenothiazine nucleus, one must conclude, in retrospect, that the progress in elucidating the metabolic fate of these compounds has been quite remarkable. However, much work remains to be done in this area, since with the metabolites identified to date it is not possible to account for more than 8–10% of the dose of a phenothiazine drug in man.

Quantitative Determination of Serotonin in *Panaeolus* Species

By J. K. WIER† and V. E. TYLER, JR.

A method was developed for the quantitative estimation of serotonin (5-hydroxytryptamine) in mushrooms, especially species of the genus *Panaeolus*. The procedure involves extraction of the dried, finely powdered carpophores with acidified alcohol, application of the extract to filter paper strips, formation of these chromatograms with *n*-propanol : 1 *N* ammonium hydroxide (5:1), development of colored serotonin spots with a modified Pauly's reagent, determination of the total color of these spots with an automatic recording electronic densitometer, and calculation of the serotonin content from a standard curve. Each step in the procedure was evaluated to determine the influence of certain variables, and the results obtained by the final method were subjected to statistical evaluation.

SEROTONIN (5-hydroxytryptamine) has received considerable attention recently due to its interesting physiological properties (1). In addition to its occurrence in certain animal tissues, the compound has been found in a number of plants (2), including carpophores of *Panaeolus* species. Several cases of cerebral mycetism reputedly have been caused by ingestion of certain species of this genus (3). Although *P. campanulatus* (Fr.) Quél. has been reported (4) to be devoid of psychotomimetic activity in the rat and in man, Tyler and Smith (5) have reported the presence of serotonin in it and in several other species of *Panaeolus*. It was of interest, therefore, to determine the concentration of serotonin in these mushrooms.

Serotonin and related indole derivatives have been quantitated by determination of their physiological effects on certain animal tissues,

such as isolated intestinal strips (6), and on grass coleoptiles (7). Other methods involving absorption of ultraviolet light, fluorescence, and colorimetry (8) have also been utilized. Difficulties involved in separating serotonin from the closely related compounds with which it frequently occurs, render all existing procedures somewhat tedious to employ and more or less nonspecific. These considerations prompted us to undertake the development of a new quantitative procedure for the determination of serotonin in mushroom tissues. Consequently, a quantitative paper chromatographic assay procedure was designed and critically evaluated.

The general procedure followed in the estimation of serotonin was to extract the serotonin from dried carpophores of *Panaeolus* species by suitable means, to spot these extracts and known serotonin solutions on filter paper strips, to prepare chromatograms on these strips with suitable developing solvents and color-forming reagents, to determine the total color of the serotonin chromatographic spots with an automatic recording electronic densitometer, and to estimate the serotonin content of the mushrooms by comparison of the total color determinations of the extract spots with those produced by known quantities of serotonin.

During the course of this investigation, a preliminary communication appeared which called attention to the possibility of quantitation of serotonin and other 5-hydroxyindoles by similar paper chromatographic methods (9). This publication did not give experimental details regarding the influence of the numerous variables involved, nor did it apply the method to extracts of natural products. Preliminary experimental evidence available at the time this work came to our attention revealed that the accurate paper chromatographic determination of serotonin was by no means as simple as the publication of Carcasona, Unterharnscheidt, and Cervos-Navarro would seem to indicate. This fact was supported by continued studies.

EXPERIMENTAL

The mushrooms utilized in this investigation were specimens of the dried carpophores of *Panaeolus campanulatus* (Fr.) Quél. and *P. foenesecii* (Fr.) Kühn. which were collected in the Puget Sound region of the state of Washington. Samples of both species were authenticated by Prof. Alexander H. Smith, University Herbarium, University Museums, University of Michigan. Since fresh carpophores could not be preserved for extended periods of time, they were dried for 48 hours in a forced-air drying oven at approximately 45°. This procedure resulted in an average loss in weight (water) corresponding to 93.5% of the fresh tissue.

Serotonin creatinine sulfate[1] (California Corporation for Biochemical Research) was used as a reference standard. Standard solutions of this serotonin complex were prepared in 0.1 *N* hydrochloric acid in diluted alcohol, U.S.P. XVI, and were preserved at room temperature in the dark. Under these conditions, the solutions were found to be stable for several weeks.

Extracts of mushroom carpophores were prepared by homogenizing for 20 minutes an accurately weighed quantity (approximately 1 Gm.) of a No. 200 powder of the tissues in about 7–8 ml. of 0.1 *N* hydrochloric acid in diluted alcohol, U.S.P. XVI, by means of a glass homogenizing tube fitted with a Teflon pestle. The particulate matter was separated by centrifugation. Portions of the supernatant liquid, representing the extract of a known tissue weight, were applied by means of a micropipet to 1-in. wide strips of Whatman No. 1 filter paper (designated for chromatographic use). The solutions were applied in 2–3 μl. portions, with drying between applications, to a maximum volume of 50 μl. It was found that while serotonin in the standard solutions was not affected by hot air drying, approximately 25% of the serotonin in the homogenate supernatant liquid was destroyed when the temperature of the drying air was approximately 65–70° (Table I). Consequently, forced air at room temperature was used for drying the spotted solutions.

TABLE I.—EFFECT OF HOT AIR DRYING ON PURE SEROTONIN COMPLEX AND SEROTONIN IN MUSHROOM EXTRACT

Compound on Strips	Blower Temperature	No. of Strips	Mean Serotonin Spot Size, in.²	95% Confidence Limits, in.²
Serotonin complex	cold	10	3.96	±0.116
Serotonin complex	hot	10	3.93	±0.195
Mushroom extract	cold	8	2.02	±0.079
Mushroom extract	hot	8	1.54	±0.053

Chromatograms were formed by the ascending method employing solvent systems of either the butanol phase of *n*-butanol : glacial acetic acid: water (4:1:5) or *n*-propanol : 1 *N* ammonium hydroxide (5:1). After drying for 2 hours at room temperature, the formed chromatograms were sprayed with either *p*-dimethylaminobenzaldehyde (2%) in hydrochloric acid : water (1:9), or with a diazotized sulfanilamide solution followed by an alkaline spray (Pauly's reagent) (10). In this investigation, 1 *N* ammonium hydroxide was substituted for the sodium carbonate solution usually employed in Pauly's reaction because carbonate left a residue on the paper strips which made the rate of feed of those strips through the scanning apparatus very uncertain. Chromatographic strips were sprayed while in a horizontal position to minimize the eluting effect of the spray solutions.

[1] A quantity of the compound equal to that purchased was supplied through the courtesy of Vismara Terapeutica, Casatenova brianza (Como), Italy.

The color formed by serotonin and the Pauly-ammonium hydroxide reagent was extremely stable. No appreciable loss of color could be detected after 6 hours; approximately 5% of the color intensity was lost after one week. The color formed with the *p*-dimethylaminobenzaldehyde reagent was very unstable; approximately 11% of this color was lost after only 2 hours.

Total color of the serotonin-reagent spots was determined with a Photovolt automatic recording electronic densitometer. This apparatus consisted of the following: (*a*) photometer, model 501-A with phototube C and a 485 mμ (Pauly reaction spots) narrow-band color filter; (*b*) transmission density unit, model 52C, with a 1 × 25 mm. aperture slit, a guide for the paper strips, and a synchronous motor drive assembly to advance the paper strips; (*c*) varicord, variable response recorder model 42. This apparatus moved the strips past the 1 × 25 mm. aperture which was located between the light source and the photoelectric cell. The chart paper of the recorder was moved in synchronization with the movement of the chromatographic strip past the aperture. The excursion of the pen on the recorder chart paper was proportional to the total absorption of light across the width of the paper strip. The area under the generally triangular-shaped curves traced by the recorder was a measure of the total color of the chromatographic spots scanned. This area was measured with a polar planimeter.

Because the density of the filter paper strips along their length was quite variable, it was necessary, for greatest precision, to apply a correction for this variation to the recorder chart base line. This was prepared by passing the blank strips through the densitometric apparatus before solutions were spotted on them and using the recording thus obtained as a base line for the curves produced from the finished chromatograms. A typical series of ten strips examined in this way, and the total spot size calculated using the variable base line, gave a mean result (95% confidence limits) of 5.35 ± 0.180 in.² in comparison to a mean of 5.20 ± 0.333 in.² when a straight base line was employed.

Standard curves were prepared for serotonin (standard solutions of serotonin creatinine sulfate) in both the *n*-butanol : glacial acetic acid : water and the *n*-propanol : 1 *N* ammonium hydroxide solvent systems, using the Pauly-ammonium hydroxide spray reagent. Table II and Fig. 1 present the data for the latter solvent system.

TABLE II.—TOTAL COLOR DETERMINATIONS OF SEROTONIN EMPLOYING *n*-PROPANOL : 1 *N* AMMONIUM HYDROXIDE CHROMATOGRAPHIC SYSTEM AND MODIFIED PAULY SPRAY

Serotonin, mcg.	No. of Strips	Mean Area, in.²	95% Confidence Limits, in.²
1	18	0.81	±0.046
2.5	18	1.98	±0.077
4	18	3.04	±0.058
5	18	3.59	±0.061
7.5	12	4.61	±0.155

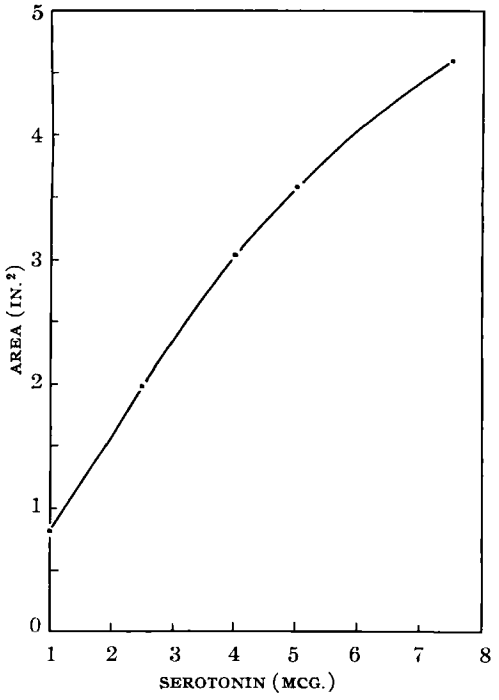

Fig. 1.—Standard curve prepared from total color determinations of serotonin spots following chromatography in *n*-propanol : 1 *N* ammonium hydroxide system and treatment with modified Pauly spray.

RESULTS AND DISCUSSION

As seen in Fig. 1, the relation of total color of chromatographic spots to the concentration of serotonin in those spots is not linear, nor does a simple logarithmic relationship exist between these two quantities. This is not an unexpected result, since the effect of the paper strip, the nature of the color-forming reaction, and the quantities of substance required in the spots for satisfactory determination of total area may all act to cause such a nonlinear relationship. The slight curvature of this line imposes no impediment to reliable assay determinations.

In order to determine the efficiency of the extraction procedure and the accuracy of the total color densitometric assay method, known amounts of serotonin were added to carpophore tissue, extracted, and quantitated by both ultraviolet light absorption and the chromatographic procedure. In addition, serotonin content of carpophore tissue was determined by a nitrosonaphthol colorimetric assay (8).

The ultraviolet absorption technique revealed approximately 95% recovery of added serotonin; the total color densitometric procedure gave a similar value for chromatograms formed in the *n*-propanol:1 *N* ammonium hydroxide solvent system. However, this procedure when applied to chromatograms formed in the *n*-butanol:glacial acetic acid:water solvent system, showed approximately only 62% recovery of added serotonin; and the value of mushroom tissue serotonin determined from such chromatograms was approximately 62% of that indicated by chromatograms formed in the *n*-propanol:1 *N* ammonium hydroxide solvent system. Since the only difference between the two cases was in the solvent systems employed, this apparent difference in mushroom tissue serotonin

content must have been due to a difference in interaction between those two solvent systems with the substances present in the mushroom extract.

Tyler and Smith (5) have shown, by the use of two-dimensional chromatographic procedures applied to extracts of *P. campanulatus*, that the serotonin spot formed in the *n*-propanol:1 *N* ammonium hydroxide solvent system is not separable into other Pauly reagent-positive spots. Therefore, the low concentration of serotonin indicated by the chromatograms formed in the *n*-butanol:glacial acetic acid:water solvent system must have been due to a failure of a portion of the serotonin present in the extracts to migrate to the normal serotonin position on the chromatograms. As Stowe has suggested (11), such failure could be due to the existence of serotonin as more than one ionic species in the presence of this solvent system and other substances present in the extracts.

Serotonin content of mushroom tissues estimated by the total color densitometric system from chromatograms formed in the *n*-propanol:1 *N* ammonium hydroxide solvent system agreed reasonably well with that determined by the nitrosonaphthol colorimetric procedure, but consistently averaged approximately 10% higher. This would seem to indicate a lower efficiency of serotonin extraction by the procedure used for the nitrosonaphthol determination. Davis (12) has indicated that this procedure gives a low value of blood serotonin due to oxidation occurring during the extraction process.

The mean serotonin content of five samples of *P. campanulatus* determined by the total color procedure presented here was 1234 ± 39.0 mcg./Gm. (Table III). Correction for the mean water content

TABLE III.—SEROTONIN CONTENT OF DRIED CARPOPHORES OF *Panaeolus campanulatus*[a]

Sample No.	Serotonin Content, mcg./Gm.
1	1211
2	1266
3	1240
4	1193
5	1260
Mean[b]	1234 ± 39.0

[a] Extracted by homogenization in acidic diluted alcohol, U.S.P. XVI. Assayed by total color method using *n*-propanol:1 *N* ammonium hydroxide (5:1) solvent system and modified Pauly spray reagent. [b] Mean ±95% confidence limits.

gives a value of 80 mcg. of serotonin per gram of fresh mushroom tissue (0.008%). The serotonin content of *P. foenesecii*, similarly established, was 3728 ± 45.8 mcg./Gm. (dry weight) or 240 mcg./Gm. of fresh tissue (0.024%). Only one plant material, the kernel of the English walnut, *Juglans regia*, has been reported to have a higher serotonin content (170–340 mcg./Gm.–fresh weight) (13).

SUMMARY

A summary of the total color densitometric assay procedure is as follows:

1. Homogenization of a No. 200 powder of dried mushroom carpophores with 0.1 *N* hydrochloric acid in diluted alcohol, U.S.P. XVI.

2. Quantitative application of these carpophore extracts to filter paper strips with forced air drying of the spots at room temperature.

3. Formation of chromatograms by the ascending method employing an *n*-propanol:1 *N* ammonium hydroxide (5:1) solvent system.

4. Formation of colored serotonin spots with Pauly-ammonium hydroxide reagent.

5. Determination of total color of serotonin spots with an automatic recording electronic densitometer.

6. Calculation of mushroom serotonin from a standard curve prepared by chromatographing known quantities of serotonin creatinine sulfate.

The extraction procedure outlined here is rapid and simple. Although the determination of total color of the chromatographic spots is time consuming, the extreme stability of the serotonin-Pauly reagent color lends itself well to such a technique. Inspection of the 95% confidence limit values presented in Tables II and III shows that the precision of the method is quite acceptable, rendering it a useful procedure for the specific determination of serotonin in plant tissues.

Investigation of the Cardiovascular Response of the Dog to 1-Phenyl-2-hydrazinopropane

By STUART BOYER, HOWARD J. JENKINS, and SUMNER M. ROBINSON

Results of a further attempt to determine a basis for the qualitative difference in blood pressure response of the human and the dog to 1-phenyl-2-hydrazinopropane are reported. Elimination of arterial pressure level as a factor influencing the circulatory response of the dog to this compound removes the last possibility for a circumstantial basis for the difference. Mechanism studies indicate that the canine pressor response is a neurotropic, sympathetic effect mediated, for the most part, as a direct action on myoneural junction receptor sites with a lesser component of indirect action on these sites related to MAO inhibition or the peripheral release of catecholamines from blood vessel walls. Evidence presented by certain clinical investigators points to either a ganglionic or an adrenergic block as responsible for the human antihypertensive effect.

WHILE 1-phenyl-2-hydrazinopropane[1] has been reported to produce marked orthostatic hypotension in humans with elevated blood pressure, it would appear to elicit only an inconstant and relatively weak depressor response in the supine hypertensive (1, 2). Certain clinical studies have indicated that this hydrazine analog of amphetamine exhibits only a slight hypotensor activity in normotensive individuals. These findings are in sharp disagreement with the pressor activity demonstrated in both pentobarbital-anesthetized and conscious dogs by Groves (3) and in the present work with conscious dogs in the orthostatic position.

The goal of this and a previous investigation was the establishment of a basis for the apparent species difference in the responses of the human and the dog to 1-phenyl-2-hydrazinopropane. Realization of this goal was attempted first through the stepwise elimination of species differences pertaining to the conditions surrounding the administration of the drug on the one hand, and the measurement of blood pressures on the other. A second attempt at goal achievement involved a study of the mechanism of the hypertensive response of the dog to this compound. Information provided in the latter study together with that relating to the mechanism of the hypotensive response of the human to this drug might provide the explanation for a true species difference in response.

EXPERIMENTAL

Methods.—Since the work of Groves served to eliminate route of administration, anesthesia and recording position of the individual as bases for the difference in the response of the human and the dog to 1-phenyl-2-hydrazinopropane, the first concern of this work was to examine the influence of blood pressure level on the canine response to this compound. Accordingly, Page's method was employed for the production of chronic renal hypertension in dogs (4). Work with 1-phenyl-2-hydrazinopropane was begun only after significant sustained elevation in blood pressure was observed, usually about 4 to 5 weeks after the encapsulation of the kidneys.

Blood pressure recordings were obtained in these renal hypertensive animals both in the conscious and pentobarbital-anesthetized state by means of a femoral artery puncture. In conscious dogs the puncture area was previously anesthetized with 2% ethyl chloride. A continuous flow of a 0.02% heparin solution in saline (5 ml./hour) from the infusion pump prevented clotting in the artery. The infusion pump was connected to a Sanborn recorder through a transducer and amplifier. Changes in respiratory rate and depth were recorded by means of a bellows-type pneumograph which was connected through another transducer and another amplifier to the same recorder.

All injections of this compound were made in the femoral vein through an 18-gauge indwelling needle which was connected by rubber tubing to a saline-filled buret. The injection volume was flushed in each time at the same rate with the same saline volume.

Results.—Prior to the actual testing of the compound in hypertensive dogs, work was carried out in normotensive animals, both conscious and pentobarbital-anesthetized (see Table I). The data obtained were qualitatively similar to but quantitatively different from comparable results appearing in the literature. The cardiac rate decrease generally took place in normotensive dogs at the beginning of blood pressure elevation rather than at or after the peak response was reached. In a few instances, a cardiac rate increase rather than a decrease followed administration of the compound, and when this occurred the pressor response was more marked than when a decrease in rate resulted. Work with atropinized dogs indicated that the cardiac rate decrease usually seen in normotensive dogs is reflex-ordered.

The peak blood pressure response in both con-

scious and anesthetized normotensive dogs was attained, in every case, within $^1/_2$ to $2^1/_2$ minutes subsequent to administration of the compound. The respiratory rate was usually increased when initially low and decreased when initially high. In most instances, the depth of respiration was decreased when blood pressure reached peak response, but the effect was of short duration only.

A pressor activity, corresponding in extent and duration to that evidenced in normotensive dogs, was exhibited by 1-phenyl-2-hydrazinopropane in hypertensive dogs (see Table II). Elevation of blood pressure usually began immediately after administration of the compound to either normotensive or hypertensive dogs. In most instances a decrease in cardiac rate, beginning with blood pressure rise and continuing until return of pressure to preinjection levels, occurred in both animals. Peak pressures were reached in hypertensive dogs within the same time interval as in normotensive dogs. Respiratory changes were similar in both animals, the rate being increased if previously low and decreased if previously high, and depth being decreased fleetingly during the zenith of the blood pressure response.

Tolerance to the compound was reflected in the tachyphylaxis associated with pressor responses to repeated doses in a given test run. Also a distinct sedating effect, related in magnitude to dose, accompanied other manifestations of activity. The latter effect had a duration similar to that of the blood pressure response. Salivation occurred intermittently, and tachycardia and mydriasis were occasionally encountered following the administration of 1-phenyl-2-hydrazinopropane. Ataxia was noted in hypertensive dogs after two injections of 2.0 mg./Kg. Cardiac arrhythmias usually became more marked as the dosage level was increased. Soft stools and emesis were observed after repeated administration of the compound.

With the elimination in the portion of the work of the influence of pre-existing blood pressure as a factor in the response to 1-phenyl-2-hydrazinopropane in the dog, the last of the circumstantial bases for an apparent species difference in the response of the human and the dog to this compound was removed.

Since the mode of action involved in the pressor response to 1-phenyl-2-hydrazinopropane in the dog is not generally agreed upon by investigators, it was considered advisable to pursue this area further in an effort to uncover a mechanistic basis for the compound's species response difference. If there is a definitive difference in the pharmacology of this compound at the action level in the human and in the dog, as indicated by this and comparable clinical studies, this would, of course, account for the response difference in the two species. A number of dogs were used in this portion of the investigation, but in a given series, to avoid animal variation, the same dog was employed repeatedly.

Results of experiments by Eltherington and Horita in intact dogs demonstrate the ability of dibenzyline to block completely the pressor response to 1-phenyl-2-hydrazinopropane (5). These findings support the likelihood of a neurotropic, rather than a musculotropic, activity in the dog's pressor response to this compound. That this neurotropic activity is not concerned with a block of parasympathetic pathways is supported by other findings of these investigators in intact dogs. Previous administration of the compound to such animals was shown to cause no significant changes in the pressure responses elicited by acetylcholine chloride (10 mcg./Kg.).

The possibility that the neurotropic activity is an active proposition involving sympathetic pathways, either the ganglia or the myoneural junction, was contemplated. The appraisal of this possibility comprises the latter portion of this investigation. The postulation of ganglionic stimulation as the mechanism of action of 1-phenyl-2-hydrazinopropane was examined with the use of the ganglionic blocking agent hexamethonium. The latter was administered by intravenous injection (2 mg./Kg.) to anesthetized normotensive and conscious hypertensive dogs prior to the administration of 1 and 2 mg./Kg. doses of 1-phenyl-2-hydrazinopropane by the same route. Hexamethonium did not exert any observable effect on the pressor response of either animal to 1-phenyl-2-hydrazinopropane. Actually, the reverse was true, *i.e.*, following the

former, the pressor response to the latter appeared enhanced. The effectiveness of the hexamethonium block was confirmed by the subsequent injection of 1-dimethyl-4-phenylpiperazine iodide (DMPP).

With ganglion stimulation thus ruled out of sympathetic involvement, a next step was to test the postulation of adrenergic receptor site stimulation. This was done by administering 25 mg./Kg. of phentolamine[2] (methanesulfonate) intravenously prior to the compound to block these receptor sites at the sympathetic myoneural junction. The administration of 1-phenyl-2-hydrazinopropane in amounts which, in the absence of phentolamine, had been effective in eliciting a marked elevation of blood pressure, failed to evoke a significant pressor response (see Table I). Confirmation of the adrenergic blockade was provided by a fall in blood pressure following intravenous administration of 4 mg. of epinephrine hydrochloride. The intravenous administration of RA-1226,[3] a compound which has been demonstrated to possess both neurotropic and musculotropic spasmogenic activity (6), was found effective in elevating canine blood pressure following doses of 1 to 25 mg./Kg. of phentolamine. This latter finding corroborates the discovery by Eltherington and Horita of the lack of a musculotropic spasmogenic component in the pharmacologic makeup of 1-phenyl-2-hydrazinopropane.

Since the previous work had thus limited the action site of the pressor response to 1-phenyl-2-hydrazinopropane in the dog to the sympathetic myoneural junction, a distinction had to be drawn among the three conceivable types of action at this point: direct stimulation of junctional receptor sites, indirect stimulation of these sites through peripheral release of catecholamines stored in the blood vessel walls (7) and monoamine oxidase (or similar enzyme) inhibition (8). It was thought that one or a combination of these types actually occurs. In an effort to determine which, 1-phenyl-2-hydrazinopropane was administered to normotensive dogs previously reserpinized (chemical sympathectomy) by the subcutaneous injection of 0.05 mg./Kg. for 5 to 7 consecutive days (see Table III). The pressor response to the compound in such animals was not so great by some 40% as in the nonreserpinized dogs, these results indicating that the major part of the compound's pressor activity is exerted by direct stimulation of adrenergic receptor sites, the remainder through either MAO inhibition or the peripheral release of catecholamines stored in blood vessel walls. Studies conducted in dogs pretreated with 15 mg./Kg. of guanethidine for periods of 24 to 48 hours prior to the administration of 1-phenyl-2-hydrazinopropane support the above results.

DISCUSSION

The discovery in the first portion of this work that the arterial blood pressure level of the dog receiving 1-phenyl-2-hydrazinopropane does not materially affect his blood pressure response to this compound served to remove the last possibility for a circumstantial basis for the difference in its effect upon human and canine circulatory systems. There remained then the task of uncovering, from a mode of action study, a possible mechanistic basis for the species response difference.

The data of Eltherington and Horita demonstrating the ability of dibenzyline to block effectively the pressor response to this compound in the anesthetized dog point to the lack of a musculotropic component in its activity makeup. Support for the lack of musculotropic activity on the part of 1-phenyl-2-hydrazinopropane is provided by that portion of this study in which phentolamine (25 mg./Kg.) was shown capable of preventing the effect of this compound while RA-1226, an agent possessing both neurotropic and musculotropic activity, was only partially blocked by the same dose of adrenergic blocker. Eltherington and Horita also maintained that the neurotropic action of 1-phenyl-2-hydrazinopropane is not involved with the parasympathetic pathway, since previous administration of the compound caused no alteration in the blood pressure response to acetylcholine. In the current study, it was shown that the previous administration of blocking doses of hexamethonium does not alter the ability of the compound to elevate pressure. From this information, it would appear that stimulation along sympathetic pathways does not occur at the ganglia nor is it of central origin. Data of similar investigations with tetraethylammonium by Eltherington and Horita concur in these findings.

The rise in blood pressure following 1 mg./Kg. doses of 1-phenyl-2-hydrazinopropane was completely blocked by phentolamine (1 and 25 mg./Kg.), partially blocked by guanethidine (15 mg./Kg.), and reserpine (0.05 mg./Kg. for 5 days). These results point to four action possibilities with respect to the compound's pressor effect in dogs. These possibilities include direct stimulation of effector cell receptor sites at the sympathetic myoneural junction, indirect stimulation of these sites through MAO inhibition, indirect stimulation through the peripheral release of catecholamines stored in the blood vessel walls and, finally, a combination of two or more of these.

The results in dogs pretreated with reserpine and guanethidine indicate that the major component of the pressor activity of this agent, some 60%, is exerted through direct stimulation of adrenergic receptors. The lesser activity component, the 40% blocked by reserpine and guanethidine, is achieved through either MAO (or other enzyme) inhibition or the peripheral release of catecholamines stored in the walls of the blood vessels. In the human, the compound may act like a ganglionic blocker (9) or an adrenergic blocker (10).

SUMMARY

The pressor response to 1-phenyl-2-hydrazinopropane is essentially the same in hypertensive as in normotensive dogs.

The cardiac rate decrease which accompanies the blood pressure elevation following the administration of this compound does not occur in atropinized dogs.

The pressor response to 1-phenyl-2-hydrazinopropane is completely blocked by phentolamine, indicating the absence of a musculotropic component and the involvement of the sympathetic pathway in the response.

The pressor response to this compound is not affected by the prior administration of hexamethonium, making unlikely the possibility of ganglion and central stimulation.

The diminution of the pressor response to 1-phenyl-2-hydrazinopropane in reserpinized dogs and those which had received guanethidine gives support to the combined mechanism at the myoneural junction of direct and indirect effector cell receptor site stimulation, the latter by MAO (or other enzyme) inhibition or by the peripheral release of catecholamines in the blood vessel walls.

Phase Solubility Study of Solid Species Formed by Magnesium Aluminate from Aqueous Solutions Containing Sulfate Ions

By TAKERU HIGUCHI and FOO SONG HOM†

A phase solubility technique has been used to detect and establish the nature of several hydrated solid species formed by sulfated magnesium aluminate. The most stable form at lower magnesium level appears to correspond to a hydrate of 4MgO : Al_2O_3:SO_3. Equilibrium behavior of this substance is such as to obey the solubility product principle with regards to both magnesium and sulfate. Under other conditions species corresponding to MgO:Al_2O_3, 3MgO : Al_2O_3 : SO_3, and 8MgO:Al_2O_3 : SO_3 seem to be produced. The results demonstrate the great value of the phase solubility technique in studying complex inorganic systems.

SERIOUS INVESTIGATIONS of the physical states of precipitated hydrous oxides and mixed hydrous oxides have been severely limited by the instability of these inorganic systems and by the difficulty in establishing their true states and compositions without washing or drying. For this reason, despite wide pharmaceutical usage of many of these compounds as bases for antacids, no detailed physical-chemical studies on these systems have been published in recent years. The present report is concerned with the results of an investigation on a hydrous sulfated magnesium aluminate system which makes use of a phase solubility technique developed earlier for studies on formations of organic complexes. The data presented show that the $m\text{MgO}\cdot n\text{Al}_2\text{O}_3\cdot p\text{SO}_3\cdot x\text{H}_2\text{O}$ systems could exist in a number of different stoichiometric ratios.

Results of the present studies suggest that formations of distinct solid species having the following approximate compositions are favored by hydrated aluminum and magnesium oxides in contact with aqueous solutions containing sulfate ions: (*a*) $3\text{MgO}\cdot\text{Al}_2\text{O}_3\cdot\text{SO}_3\cdot x\text{H}_2\text{O}$, (*b*) $4\text{MgO}\cdot\text{Al}_2\text{O}_3\cdot\text{SO}_3\cdot y\text{H}_2\text{O}$, and (*c*) $8\text{MgO}\cdot\text{Al}_2\text{O}_3\cdot\text{SO}_3\cdot z\text{H}_2\text{O}$. The presence of sulfate in the structure appears to be necessary. These systems appear to possess distinct solubility products based on the concentrations of the three components.

These findings also attest to the value of phase solubility determinations in the detection and

Phase Solubility Study of Solid Species Formed by Magnesium Aluminate from Aqueous Solutions Containing Sulfate Ions

By TAKERU HIGUCHI and FOO SONG HOM†

A phase solubility technique has been used to detect and establish the nature of several hydrated solid species formed by sulfated magnesium aluminate. The most stable form at lower magnesium level appears to correspond to a hydrate of 4MgO : Al_2O_3:SO_3. Equilibrium behavior of this substance is such as to obey the solubility product principle with regards to both magnesium and sulfate. Under other conditions species corresponding to MgO:Al_2O_3, 3MgO : Al_2O_3 : SO_3, and 8MgO:Al_2O_3 : SO_3 seem to be produced. The results demonstrate the great value of the phase solubility technique in studying complex inorganic systems.

SERIOUS INVESTIGATIONS of the physical states of precipitated hydrous oxides and mixed hydrous oxides have been severely limited by the instability of these inorganic systems and by the difficulty in establishing their true states and compositions without washing or drying. For this reason, despite wide pharmaceutical usage of many of these compounds as bases for antacids, no detailed physical-chemical studies on these systems have been published in recent years. The present report is concerned with the results of an investigation on a hydrous sulfated magnesium aluminate system which makes use of a phase solubility technique developed earlier for studies on formations of organic complexes. The data presented show that the $m\text{MgO}\cdot n\text{Al}_2\text{O}_3\cdot p\text{SO}_3\cdot x\text{H}_2\text{O}$ systems could exist in a number of different stoichiometric ratios.

Results of the present studies suggest that formations of distinct solid species having the following approximate compositions are favored by hydrated aluminum and magnesium oxides in contact with aqueous solutions containing sulfate ions: (*a*) $3\text{MgO}\cdot\text{Al}_2\text{O}_3\cdot\text{SO}_3\cdot x\text{H}_2\text{O}$, (*b*) $4\text{MgO}\cdot\text{Al}_2\text{O}_3\cdot\text{SO}_3\cdot y\text{H}_2\text{O}$, and (*c*) $8\text{MgO}\cdot\text{Al}_2\text{O}_3\cdot\text{SO}_3\cdot z\text{H}_2\text{O}$. The presence of sulfate in the structure appears to be necessary. These systems appear to possess distinct solubility products based on the concentrations of the three components.

These findings also attest to the value of phase solubility determinations in the detection and

characterization of complex inorganic species. No other technique at the moment can give such unequivocal evidence of formation of these discrete phases.

PAST WORK

Interactions of aluminum and magnesium oxides in more or less their hydrated state to form complex species have received serious attention by numerous previous workers (1–17). In many instances no more was claimed than that an amorphous mixture of improved therapeutic value as an antacid was claimed. In other cases there were evidences for formation of discrete solid phases.

The work of Hallman (12) is of particular interest because of its close relationship to the present study. He claimed preparation of a hydrated magnesium aluminate species from strongly alkaline aluminate solution (pH 12–13) and magnesium sulfate having the following formula

$$[Mg(OH)]_4\ [(HO)_4Al \overset{OH}{\underset{OH}{}} Al(OH)_4]$$

The work of Cole and Hueber (11) indicated that aluminate concrete long exposed to sea water formed $4MgO \cdot Al_2O_3 \cdot xH_2O$ and $4MgO \cdot 2Al_2O_3 \cdot MgSO_4 \cdot xH_2O$.

In general, the past studies suffered from the fact that compositional determinations were based on analysis of washed samples of the precipitated phases. Since many of these systems were subject to hydrolytic changes during washing, these analytical findings did not reflect the actual composition of the precipitates. For the present investigations, use was made of the phase solubility technique developed earlier for systems of this type (18) which permitted determination of the true nature of the precipitated phase.

EXPERIMENTAL

Reagents

Only reagent grade chemicals were used except for the indicators which were utilized as received. The water used in these studies was made by distillation from all borosilicate still of ordinary distilled water. For phase solubility studies this was boiled and cooled under nitrogen prior to use.

Preparation of Sodium Aluminate Solution.—The formula used for 0.2 *M* stock solution was: $Al(OH)_3 \cdot nH_2O$ (Fisher Scientific Co.), 15.22 Gm., sodium hydroxide, reagent grade, 25.00 Gm., and enough distilled water to make 1000 ml.

Procedure.—The sodium hydroxide was heated in a nitrogen atmosphere to a melt in a large nickel crucible. Aluminum hydroxide was added with stirring to the melt in small divided portions with a nickel spatula. After completion of the addition, the mixture was stirred thoroughly and cooled to room temperature under nitrogen. About 100 ml. of distilled water was added to the resulting sodium aluminate and heated to effect complete solution. The solution was allowed to cool and was made to one liter with distilled water and stored in a polyethylene bottle.

Methods of Analysis

Gravimetric Determination of Aluminum (19) and Magnesium.—The method is based on the fact that aluminum forms an insoluble complex (pK_{sp} = 29.0) with 8-hydroxyquinoline quantitatively in the pH range of 5 and 10, whereas the magnesium complex is insoluble and forms only in alkaline pH, preferably 10. Thus, this method can be used to determine aluminum, in the presence of magnesium, and magnesium as well.

Procedure.—The sample containing aluminum and magnesium (10 to 50 mg. of each) was acidified with hydrochloric acid in a 400-ml. beaker. To this solution was added 5 to 10 ml. of 10% tartaric acid solution (10 × wt. of aluminum) to keep the aluminum in solution, followed by 15 ml. of a 30% ammonium acetate solution. After dilution with distilled water to 300 ml., the pH was adjusted with 2 *N* ammonia to 5.2 to 6.8 with the aid of 3 drops of a bromocresol purple indicator solution. The solution sample was warmed, and then 5 ml. of a 50% 8-quinolinol in glacial acetic acid was pipetted into the beaker with stirring. Four or five milliliters of isopropanol was added in some instances to help contain the precipitate in the beaker. The system was heated to nearly boiling and allowed to digest from 0.5–1.0 hour at the temperature of the steam bath, or until the precipitate had become hard and crystalline. During the process of digestion, if the supernatant solution turned pale greenish yellow, more precipitant was added until it turned a definite yellowish orange. At this time the system was cooled to 60° and filtered into a tared 30-ml. glass crucible fitted with a fritted disk of medium porosity. The precipitate was washed with about 75 ml. of distilled water and dried at 135–145° to constant weight (about 2–4 hours). After cooling for one hour in a desiccator, the precipitate was weighed as the anhydrous complex with a molecular weight of 459.42 Gm. per mole.

The determination of magnesium was carried out by collecting the filtrate and the washings from the aluminum determination and placing it into a 600-ml. beaker to which were added 25 ml. of strong ammonia (to give pH 10) and 5–15 ml. of saturated 8-quinolinol in isopropanol. The remaining procedure was the same as given above, except that the precipitate was washed with a 30% isopropanol solution containing 1% ammonia. The precipitate was weighed as the anhydrous complex with a molecular weight of 312.60 Gm. per mole.

EDTA Titration of Magnesium.—The direct titration of magnesium in solution presented no difficulties except that the rate of reaction between EDTA and magnesium-Eriochrome Black T complex (20, 21) and magnesium-Calmagite complex was rather low at room temperature. To overcome this difficulty, the titration was carried out at 60°. Even though Lindstrom and Diehl (22) claimed that Calmagite was more stable than Eriochrome Black T when both were 0.1% aqueous solutions, these indicators were best used as 1% triturations in either sodium chloride or potassium chloride and stored in well stoppered bottles.

Lewis and Melnick (23) studied the accuracy in the determination of calcium and magnesium with EDTA and found that the magnesium titration at pH 10 was complete when a permanent blue color developed. When this end point was used, a satisfactory agreement was obtained for EDTA solutions standardized separately with four different

elements, the results agreeing within about one part per thousand.

Procedure.—A 5.0- to 25.0-ml. sample of the magnesium solution was pipetted into a 125-ml. Erlenmeyer flask and sufficient double distilled water was added to give a 45-ml. total volume. This was followed by 5 ml. of 0.1 *M* borate pH 10 buffer solution and heating on steam bath to 60°. After addition of an estimated 10–15 mg. of the indicator trituration, the sample was titrated slowly until all traces of the red tint had just disappeared and a permanent blue color appeared. The amount of magnesium was calculated: one ml. 0.0100 *M* EDTA = 0.2432 mg. of magnesium.

Precipitation of Sulfate as Barium Sulfate.—The method was that described by Blaedel and Meloche (24), but was tested for accuracy and precision in the experimental concentration range. The result for the average of four determinations of a 5.000×10^{-3} mole per liter of sodium sulfate solution was $4.99 \pm 0.05 \times 10^{-3}$ *M*.

Special Equilibration Procedure Used in the Phase Studies

Short Equilibration Procedure—Beaker Method for Determining Acetic Acid Requirements.—A twenty-milliliter aliquot of the 0.1 *M* sodium aluminate solution was pipetted into a 150-ml. beaker containing a teflon encased magnetic bar and distilled water (sufficient to make up to approximately 100 ml. final volume) in a nitrogen atmosphere. To this was added with constant stirring 8.71 ml. of 1.042 *N* acetic acid containing varying amounts of 0.2 *M* magnesium sulfate. The final pH was measured after the system had apparently approached a steady value (about one-half hour). The precipitate was then quantitatively transferred onto a 60-ml. fritted disk glass filter, and washed with 75 ml. of distilled water. The precipitate was dissolved with sufficient concentrated hydrochloric acid and followed by several portions of distilled water. The filtrate was collected in a 400-ml. beaker. The aluminum and magnesium contents of the filtrate were determined by the 8-quinolinol precipitation method.

Long Equilibration Procedure Bottle Method for Determining Acetic Acid (or Sodium Hydroxide) Requirement.—Preliminary potentiometric titrations served as guides in spacing the amount of 0.1 *M* acids or acidic compounds to be used. The preselected volume of 0.1 *M* titrant was accurately measured into a 120-ml. wide mouth bottle equipped with a polyethylene lined screw cap. Sufficient distilled water was added to give 95.0 ml. before 5.0 ml. of the 0.1 *M* sodium aluminate solution was added from a 10-ml. autoburet to give the 100-ml. final volume. After the cap was secured on tightly, the system was equilibrated by slow rotation in a constant temperature bath set at 30° for two days or longer. At the end of this period the bottles were allowed to stand overnight in the bath to permit the fine precipitates to settle leaving a clear supernatant liquid. The screw cap was removed after careful drying and the pH of the supernate was measured.

Bottle Method—Phase Study of Unbuffered Systems.—The predetermined amounts of distilled water, 0.1 *M* sodium sulfate, 0.1 *M* acetic acid, or 0.1 *N* sodium hydroxide (as necessary to yield the approximate final desired pH value), 0.1 *M* magnesium acetate, and 0.1 *M* sodium aluminate solution were measured accurately in order as listed into a 120-ml. bottle to give a total final volume of 100 ml. A series of such bottles was prepared at one time. These prepared samples were rotated at 30° for a period of five days or longer at 30 r.p.m., after which time the same procedure was followed as given in the preceding section. Mixtures containing definite precipitates were filtered through sintered glass filters, whereas those containing colloidal particles were filtered through membrane filters of appropriate pore sizes. The highest pH value attainable after a little agitation was recorded as indicated by a glass electrode. Aliquot portions of the solutions were taken for chelometric determination of magnesium and gravimetric analysis of sulfate.

Bottle Method—Phase Study of Buffered Systems.—The procedure used was essentially the same as for unbuffered systems except that part of the distilled water was replaced by a buffer solution. Either 0.1 *M* acetic acid or 0.1 *N* sodium hydroxide solution was used to adjust the system approximately to the desired pH before buffering at this pH. The volume of the buffer was such that when diluted to the final volume of 100 ml. the resulting solution gave the desired pH reading. The buffers consisted of either 0.2 *M* of ammonia or 0.2 *M* of tris-(hydroxymethyl)-aminomethane with various amounts of 0.2 *M* hydrochloric acid.

EXPERIMENTAL OBSERVATIONS

Results of experimental studies on hydrous magnesium aluminate systems formed in the presence of sulfate, acetate, and sodium ions are reported. In general, the methods of investigations utilized solu-

tions of sodium aluminate, magnesium sulfate, magnesium acetate, and acetic acid to achieve the desired end states. Preliminary investigations necessary in obtaining the proper ratios of reactants to yield systems having comparable end pH values are reported initially.

pH and Acid-Base Relationship

Changes in pH of Sodium Aluminate Solution Elicited by Slow Addition of Acids and Acidic Salts.—Because of its amphoteric nature, aluminum can exist in solution under either highly alkaline or acidic conditions. If a highly alkaline aluminate solution is progressively made acidic by additions of acids or acidic salts such as magnesium sulfate, magnesium chloride, magnesium acetate, or calcium chloride, aluminum is precipitated simultaneously as the pH decreases. Hence, a considerable insight into the mechanism of the precipitation process can be gained from such potentiometric titration plots.

Figure 1 shows the titration characteristics of a sodium aluminate solution (containing an excess of sodium hydroxide with a mole ratio of NaOH:Al $(OH)_3$ of approximately 3.9) when titrated with hydrochloric acid, acetic acid, sulfuric acid, magnesium sulfate, magnesium acetate, and calcium chloride. The bottle technique for potentiometric titration under equilibrium conditions was utilized in obtaining these results. Each bottle contained 0.51 mmole of aluminate plus a definite quantity of titrant (varying in the series of bottles) in a total volume of 100 ml. The systems were equilibrated at 30° for two days, after which the pH of the supernatant liquid was determined by use of an alkaline range glass electrode.

Potentiometric titration at a normal rate of addition of 0.1 *N* sulfuric acid under a nitrogen atmosphere produced erratic pH readings with considerable drift in values. This phenomenon may be explained by the fact that aluminum can exist in aqueous solutions, depending on the medium, in several different forms of aquo-hydroxy species. A change in the medium necessitates a readjustment of the involved equilibria in accordance with the mass law. For this reason the potentiometric readings were obtained under at least pseudoequilibrium conditions.

From the plots depicted in Fig. 1 it is evident that in the highly alkaline pH range both acids and magnesium salts were effective in depressing the pH and in precipitating the aluminate solution. The maximum pH values at which the solid phase just appeared in each system are given in Table I.

Change in pH Produced by Fast Addition of Magnesium Sulfate to Sodium Aluminate Solution.—The effect on the hydrogen ion concentration elicited by different rates of incremental addition of magnesium sulfate to the sodium aluminate solution is clearly evident in Fig. 2. In the beaker method potentiometric readings were taken approximately thirty minutes following the addition. In the bottle method, pH determination was made after two days of equilibration under constant agitation. In all cases the system contained a total of four mmoles of aluminum.

The longer equilibration period gave a much sharper potentiometric break. It also produced markedly greater degrees of precipitation of aluminum at higher pH values, nearly all of the trivalent element being removed from solution by the bottle procedure at pH 11, whereas very little precipitation occurred at this pH by the beaker method. This difference may be due to several factors, one of which is the gradual hydrolysis of the aluminate ion (which hydrolyzes slowly in aqueous alkaline solutions). Another possibility is that the sulfate ions may slowly exchange with the hydroxyl ions in forming a new solid phase, thus raising the pH. By both procedures, however, it would appear that nearly all aluminum is precipitated at pH of 8.5.

Acetic Acid Required to Attain Fixed pH in Formation of Hydrous Magnesium Aluminate in Presence of Sulfate.—In forming hydrous magnesium aluminate in presence of sulfate ions from sodium aluminate, acetic acid was used to neutralize the excess sodium hydroxide and to adjust the system to give an essentially constant final solution

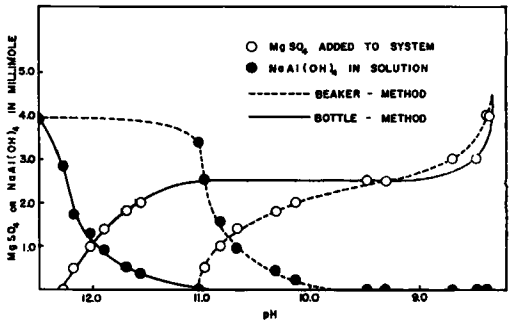

Fig. 2.—Difference in behavior between the beaker and the bottle methods for the precipitation of aluminate by magnesium sulfate as a function of pH.

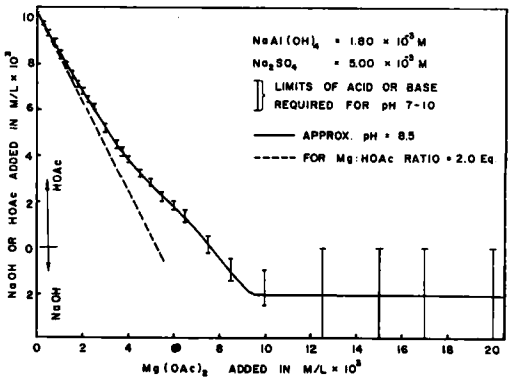

Fig. 3.—Acetic acid or sodium hydroxide–magnesium acetate relationship in systems containing aluminate and sulfate.

pH. It was desirable to maintain the hydrogen ion concentration by addition of acetic acid somewhat above that necessary to prevent precipitation of a discrete magnesium hydroxide phase (*ca.* pH = 10). For this purpose the amount of the acid needed to attain an approximate pH of 8.5 was determined for a system containing a fixed amount of sodium aluminate, sodium sulfate, and varying amounts of magnesium acetate. The bottle method was used, and the system was equilibrated for five days or longer at 30° before the pH of the clear supernatant liquid was determined.

Figure 3 gives the amount of acetic acid or sodium hydroxide added in moles per liter to yield an approximate final pH of 8.5 for various amounts of added magnesium acetate in a system containing 1.80×10^{-3} moles per liter of aluminate. It is evident again that in this pH range the amount of required acid is progressively decreased by addition of magnesium ions. The dotted line corresponds to a stoichiometric ratio of magnesium ion to acetic acid of 2.0. Although magnesium hydroxide is not precipitated as such, it would appear that at low magnesium ion concentration it becomes bound effectively as the oxide to the aluminum system to release two equivalents of hydrogen ions. The same intensity of magnesium ion binding appears to persist up to about two molar equivalents of aluminum present ($2 \times 1.80 \times 10^{-3}\ M = 3.60 \times 10^{-3}\ M$). Beyond this point the binding tendency appears to decrease but still persists noticeably until approximately 12.6×10^{-3} moles per liter of hydrogen ions are released from 1.80×10^{-3} moles per liter of aluminate in the presence of excess magnesium ions $\left(\frac{H^+}{Al} = 7.0\right)$.

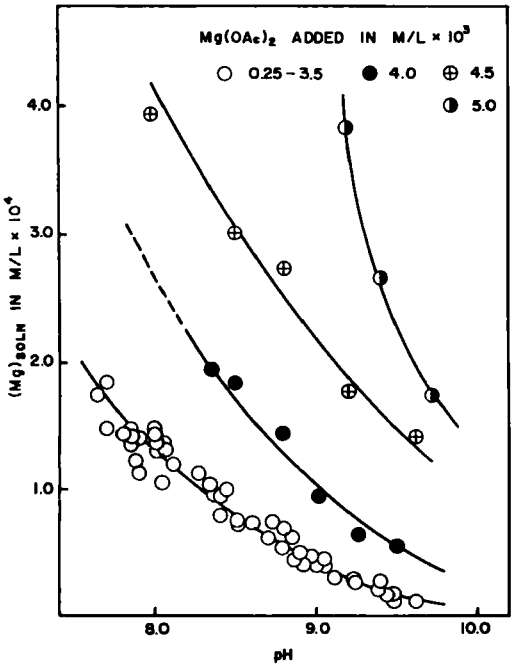

Fig. 4.—Changes in residual magnesium ion concentration in solution elicited by $1.80 \times 10^{-3}\ M$ aluminate as a function of pH for several values of added magnesium acetate in presence of $5.0 \times 10^{-3}\ M$ sodium sulfate.

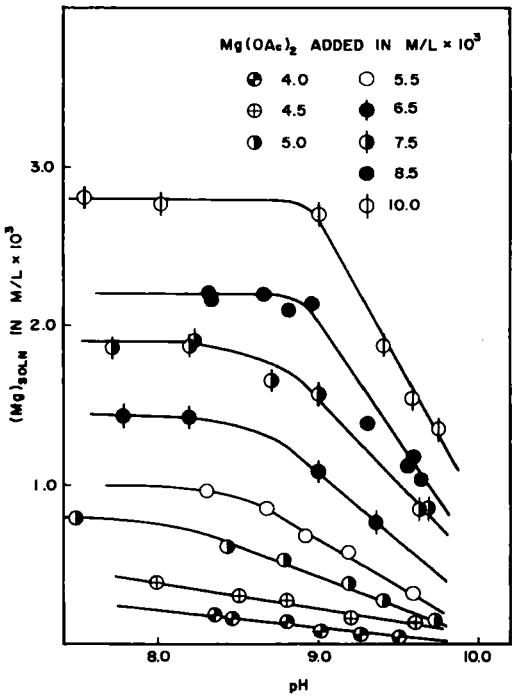

Fig. 5.—Changes in residual magnesium ion concentration in solution elicited by $1.80 \times 10^{-3}\ M$ aluminate as a function of pH for several values of added magnesium acetate in presence of $5.0 \times 10^{-3}\ M$ sodium sulfate.

Phase Solubility Studies on Unbuffered Systems

For the system involving formation of complex crystalline hydrated magnesium aluminate species from solutions of sodium aluminate, magnesium acetate, sodium sulfate, and acetic acid (or sodium hydroxide), considerable information relative to the roles played by each component can be obtained from phase solubility diagrams of various types. In the succeeding sections the influence of concentration of individual components on the extent of reaction of others are reported. All of the studies were carried out under conditions permitting establishment of equilibrium or pseudoequilibrium relationships.

pH and Degree of Magnesium Ion Binding.—Figures 4, 5, and 6 show the extent of magnesium ion binding exhibited by $1.80 \times 10^{-3}\ M$ aluminate solution containing $5.0 \times 10^{-3}\ M$ sodium sulfate. Figure 4 covers the range of added magnesium acetate of $0.25\text{–}5.0 \times 10^{-3}\ M$; Fig. 5 from 4.0–10.0 $\times 10^{-3}\ M$ and Fig. 6 from $12.5\text{–}20.0 \times 10^{-3}\ M$. The pH values were those obtained by the addition of appropriate amounts of acetic acid or sodium hydroxide. Any reduction in solution concentration below the slope of one is, of course, due to binding in these plots.

The data interpolated from the plots were used to construct Figs. 7 and 8. These phase solubility diagrams can be interpreted in terms of the classical phase rule. According to Fig. 7, the presence of less than the atomic ratio of Mg:Al of 2.0 led to essentially an invariant concentration of magnesium ion in the supernatant liquid, suggesting the presence of two discrete solid phases over this plateau

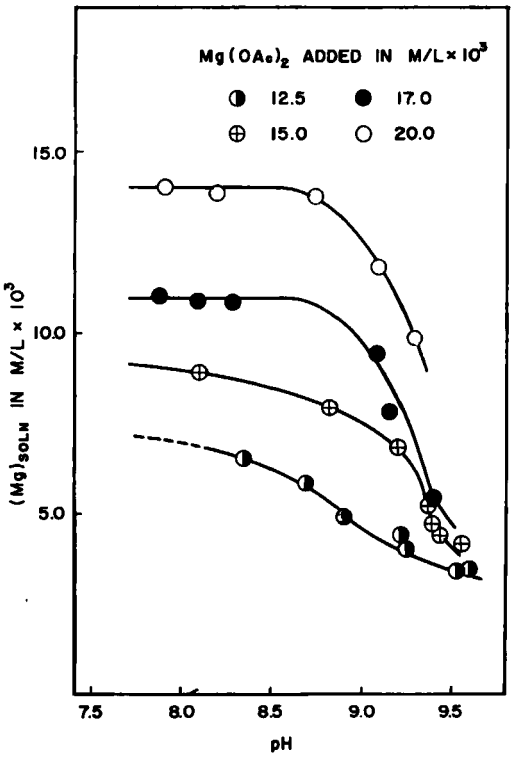

Fig. 6.—Changes in residual magnesium ion concentration in solution elicited by 1.80×10^{-3} M aluminate as a function of pH for several values of added magnesium acetate in presence of 5.0×10^{-3} M sodium sulfate.

range. An increase in the added magnesium concentration above this point (3.60×10^{-3} M) resulted in a sharp rise in the magnesium ion concentration in solution. The slope at this point was, however, well below one. Further increase in the amount of added magnesium ion eventually caused a corresponding rise in solution concentration as shown in Fig. 8. Each dotted line extrapolated to a solid phase with an atomic composition of four magnesium to one of aluminum.

The influence of pH on the phase solubility diagrams was noticeable but surprisingly small. This was particularly true at pH values below 9 and with higher added magnesium acetate concentrations.

The results presented were obtained by use of the bottle method as described in the section on experimental procedure for phase solubility studies in unbuffered systems. Predetermined amounts of the components were added to each bottle in a definite order. The aluminate solution used contained a large excess of sodium hydroxide with a sodium hydroxide to aluminum hydroxide molar ratio of approximately 5.7. The systems were equilibrated at 30° for five days or longer after which the pH and the magnesium concentration in the supernatant liquid were determined.

In summary, the phase solubility diagrams obtained have indicated formations of at least two crystalline forms of $m\mathrm{MgO}\cdot n\mathrm{Al_2O_3}\cdot p\mathrm{SO_3}\cdot x\mathrm{H_2O}$. The first had an atomic ratio of Mg:Al of 2.0 and the second had a ratio of 4.0. The very flat plateau corresponding to the formation of the first suggested that the structure of this species was such as to permit ready formation of well-defined crystals. On the other hand, the second corresponded possibly to a limiting structure where definite crystals formed but might have permitted partial replacement by magnesium ions. Only in the limiting case would the ratio of 4.0 be achieved.

Effect of Sulfate Concentration on the Degree of Magnesium Binding.—A review of Table I indicates that sulfate was necessary in the formation of solid phases in reactions of magnesium ion with aluminate. The reaction between magnesium acetate and sodium aluminate invariably produced a colloid which could be coagulated, besides sulfate, by many other polyvalent anions. For this reason sulfate was used in excess but constant amount (5.0×10^{-3} M) in the previous phase solubility studies.

Some experimental data to show the effect of added sulfate concentration on the degree of magnesium binding exhibited by 1.80×10^{-3} M aluminate for three initial magnesium acetate values have been compiled in Table II. Figure 9 gives the plot of magnesium solution concentration *vs.* the amount of added sodium sulfate and the colloid–precipitation range as well. Figure 10 shows the reciprocal relationship of added sodium sulfate concentration on the degree of magnesium binding for three values of added magnesium acetate. Although the pH values of these systems ranged rather widely, the averages were 8.6, 8.7, and 8.6 for the

[a] pH on this run was allowed to rise considerably above those of the others. Added aluminate = 18.0×10^{-4} M, pH adjusted to the average values of 8.6, 8.7, and 8.6 with either acetic or sodium hydroxide for the systems of added magnesium acetate 36.0, 75.0, and 150.0×10^{-4} M, respectively.

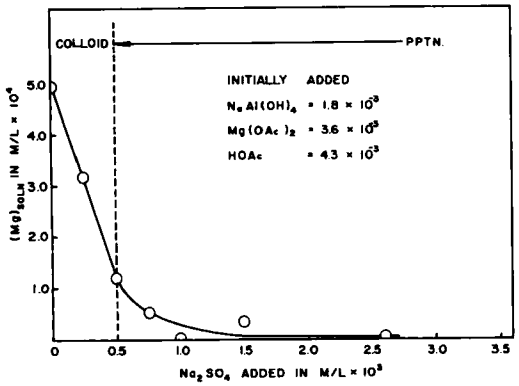

Fig. 9.—Changes in residual magnesium ion concentration exhibited by aluminate as a function of added sodium sulfate concentration in systems with an average pH value of 8.6.

added magnesium acetate of 3.60, 7.50, and 15.0×10^{-3} M, respectively.

With respect to the amount of magnesium bound in the precipitate, Fig. 10 shows that in the presence of excess sulfate ions the maximum atomic ratio of Mg:Al in the solid phase varied with added magnesium acetate as follows: magnesium acetate added in $M/L \times 10^3$, 3.60, 7.50, and 15.0, maximum Mg:Al atomic ratio in solid phase, 2.0, 3.3, and 3.9.

pH and Degree of Sulfate Binding.—The experimental values showing the effect of pH on the degree of sulfate binding as exhibited by 1.80 and 3.60×10^{-3} M of aluminate for various amounts of added magnesium acetate have been plotted in Figs. 11 and 12. The former covers the pH range of 7.5–10.0 and the latter from 9.0–14. The pH values were those elicited by the addition of appropriate amounts of acetic acid or sodium hydroxide.

Figure 11 indicates that pH had no apparent effect on the degree of sulfate binding in this range. The degree of sulfate binding seemed to approach a limiting value (*ca.* $0.8–0.9 \times 10^{-3}$ M) when the added magnesium acetate concentration was equal to or greater than 4.0×10^{-3} M in a system that contained 1.80×10^{-3} M of aluminate. This corresponds roughly to Al:sulfate ratio of 2.0. Figure 12 shows essentially the same effect for pH values below 11.0 with the exception that the degree of sulfate binding had not reached a limiting value. At pH values greater than 11.0 the degree of sulfate binding decreased until no binding was exhibited at pH 12.5 or greater for a system containing 3.60×10^{-3} M of aluminate.

Effect of Sulfate Concentration on the Degree of Sulfate Binding.—The effect of increasing sulfate concentration on the amount of sulfate bound by the hydrous magnesium aluminate system is evident from Fig. 13. The apparent extent of sulfate binding appears to be essentially independent of the sulfate concentration when even a slight excess of the divalent ion was present. The amount of binding appears to correspond to slightly less than that expected on the basis of Al:sulfate ratio of two, particularly at low initial aluminate concentration.

The open circles in Fig. 13 represent systems containing 1.80×10^{-3} M aluminate and added magnesium acetate equal to or greater than 5.0×10^{-3} M. The half circles represent systems containing 3.60×10^{-3} M aluminate and added magnesium acetate equal to or greater than 8.0×10^{-3} M. The solid circles represent systems containing 5.10×10^{-3} M aluminate and added magnesium acetate (or magnesium sulfate) equal to or greater than 12.0×10^{-3} M. The technique described in the experimental procedure for phase solubility studies on buffered systems was utilized in this series of experiments. The exceptions were that the sulfate (added either as sodium or magnesium salt) concentration was the variable and that

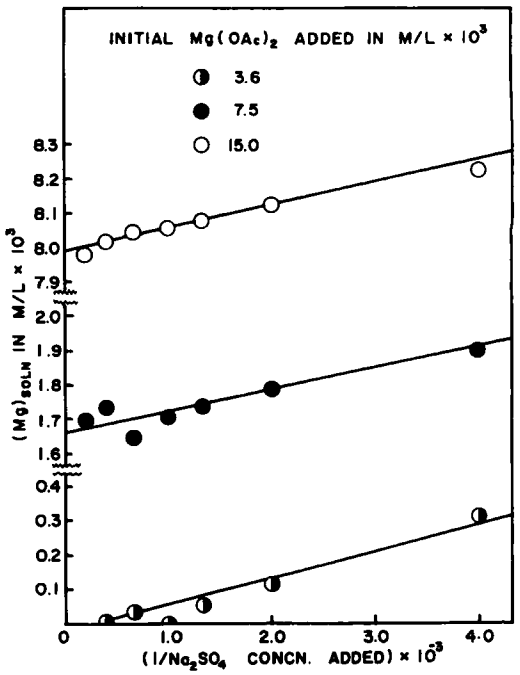

Fig. 10.—Changes in residual magnesium ion concentration exhibited by 1.80×10^{-3} M aluminate as a reciprocal function of added sulfate concentration for three values of added magnesium acetate in systems with average pH values of 8.6–8.7.

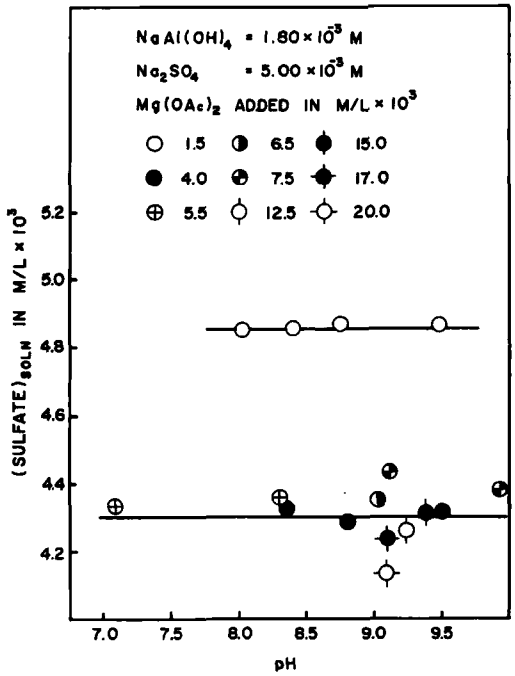

Fig. 11.—The effect of pH on the residual sulfate concentration in solution in systems containing aluminate and different values of magnesium acetate.

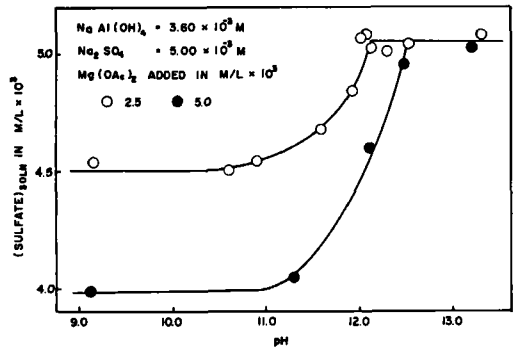

Fig. 12.—The effect of pH on the residual sulfate concentration in solution in systems containing aluminate and different values of magnesium acetate.

the system contained an excess amount of magnesium ions. At the end of the specified duration and conditions of equilibration, a 50-ml. aliquot sample of the filtered supernatant liquid was analyzed for the residual sulfate concentration according to the gravimetric method given earlier.

A study of Fig. 13 shows that the slopes of the three straight lines are all essentially in unity, indicating that further addition of sodium sulfate to the system caused only a corresponding increase in solution concentration. Under these experimental conditions the intercepts obtained by extrapolation of the linear portion of each curve provided the necessary composition information for the case of sulfate binding in the presence of excess of magnesium ions in solution. The results, when expressed as the atomic Al:sulfate ratios, are 2.5, 2.1, and 1.9, respectively, for the given aluminate concentrations.

Effect of Magnesium Concentration on the Degree of Sulfate Binding.—Figure 14 shows the extent of binding of sulfate ions as a function of the added magnesium acetate concentration by systems containing 1.80, 2.55, 3.60, 5.10 × 10^{-3} *M* of aluminate, and 0–20.0 × 10^{-3} *M* of added magnesium acetate. These results are shown plotted for three initial concentrations of added sodium sulfate (2.5, 5.0, and 10.0 × 10^{-3} *M*).

Even a cursory examination of Fig. 14 reveals that all the curves appear to have several manifestations in common, chiefly in the form of linear dependency portions sandwiched between initial and final invariant plateaus relating the effects of added magnesium acetate concentration on sulfate binding.

The addition of small amounts of magnesium ions apparently did not produce sulfate binding. This region probably corresponds to the initial rise in magnesium concentration in solution as shown in Fig. 7. As more magnesium acetate was added, the sulfate ions reacted in the stoichiometric ratio of 4 Mg:1 sulfate, the linear dependency finally leveling off into an invariant plateau. This strongly suggests

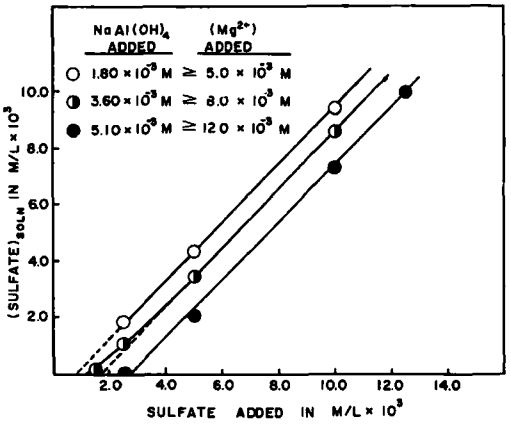

Fig. 13.—A phase solubility diagram showing the extent of sulfate binding exhibited by three concentrations of aluminate in the presence of excess of magnesium ions.

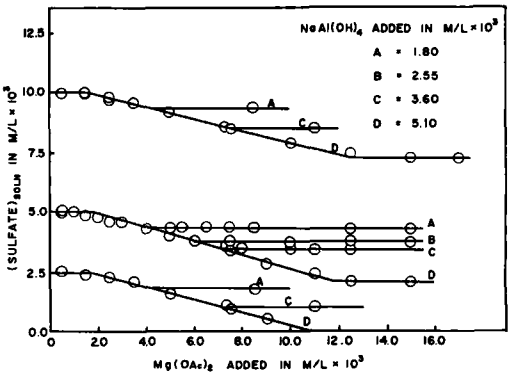

Fig. 14.—Changes in residual sulfate concentration in solution exhibited by several values of aluminate as a function of added magnesium acetate concentration for three added sodium sulfate concentrations.

that after the breakpoint sulfate was not being bound upon further addition of magnesium acetate. Figure 14 shows that these breakpoints depended mainly on the initially added sodium aluminate concentration. The stoichiometry at this point was approximately $4MgO \cdot Al_2O_3 \cdot SO_3 \cdot yH_2O$.

It should be kept in mind, however, that as indicated in Fig. 8, additional magnesium was taken up beyond the breakpoint. Eventually the final stoichiometry, as obtained in the presence of the large excess of magnesium ions indicated in a previous section, corresponds to $8MgO \cdot Al_2O_3 \cdot SO_3 \cdot zH_2O$. Since the Al:sulfate ratio is the same for both forms, Fig. 14 does not show further change in sulfate uptake beyond the breakpoint.

Phase Solubility Studies on Buffered Systems

The results reported in the preceding sections were obtained on systems initially containing only aluminate, acetate, sodium, magnesium, and sulfate ions, other than those contributed by water. Studies were also carried out with the addition of ammonium and chloride ions and ammonia particularly, since their presence permitted closer control of the relative basicity of the aqueous solutions. The behavior of the resulting and similar systems are substantially different from those of the unbuffered mixture and are reported in detail in this section.

Magnesium Binding and Effect of Buffer.—Figures 15 and 16 show the extent of magnesium ion binding exhibited by 1.80×10^{-3} *M* of aluminate containing 5.0×10^{-3} *M* sodium sulfate in presence of a relatively low buffer concentration of 1.0×10^{-2} *M* ammonia buffer (adjusted with hydrochloric acid). Figure 15 covers the range of added magnesium acetate of $0.5\text{–}3.0 \times 10^{-3}$ *M*, and Fig. 16 from $3.5\text{–}8.5 \times 10^{-3}$ *M*. The pH values given were obtained by use of predetermined amounts of acetic acid or sodium hydroxide and the appropriate buffer. The data interpolated from the two plots were then used to construct Fig. 17. The four curves designated in Fig. 17 by open, half solid, and quarter circles represent systems with pH values of 8.50, 8.75, 9.00, and 9.25, respectively. These results were obtained by use of the bottle method as described in the experimental section. Predetermined volumes of solutions of the components were measured into each bottle in a definite order. The addition of buffer simply replaced part of the distilled water so that the final volume remained 100 ml. The aluminate solution used had a sodium hydroxide to aluminum hydroxide mole ratio of approximately 5.7. Other than the specified cases, these systems were equilibrated at 30° for five days or longer, after which the pH and the magnesium concentration in the supernatant liquid were determined.

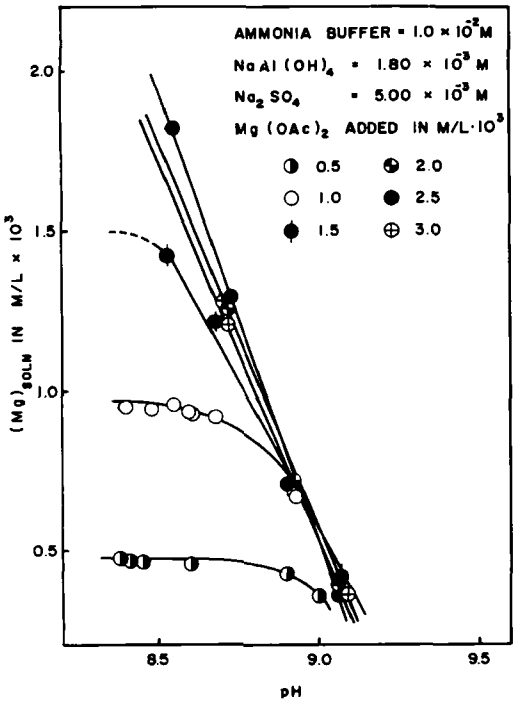

Fig. 15.—Changes in residual magnesium ion concentration in solution elicited by aluminate as a function of pH for several values of added magnesium acetate in buffered systems containing sulfate ions.

The binding behaviors exhibited in the presence of 0.01 *M* ammonia buffer as shown in Fig. 17 differ largely from the unbuffered systems in the significantly higher magnesium concentrations required to form the insoluble species. The analysis of the straight line portions of the plots at high magnesium concentrations yield the relationships

System with pH	Slope of final portion of curve	Extrapolated Mg:Al atomic ratio
8.50	0.98	1.66
8.75	0.93	1.72
9.00	0.88	1.81
9.25	0.77	1.92

The influence of pH is obvious in that a change from 9.25 to 8.50 caused the slopes to approach unity and the extrapolated Mg:Al ratio to assume a lower value. The data shown above suggest that at higher pH values the system behaved much like the unbuffered, whereas at lower pH there is suggestive evidence of formation of another species corresponding possibly to an atomic ratio of three magnesium to two aluminum (or Mg:Al of 1.50). Similar results were also obtained with substantially higher (5×) buffer concentration, as shown in Fig. 18.

The data shown in Fig. 19 also suggest this type of relationship. The determinations in this instance were made with magnesium sulfate instead of the acetate, and variable amounts of the buffer were used. At lower buffer concentrations the results again resemble those from the unbuffered runs. At a higher buffer concentration, particularly with a shorter time of equilibration, the precipitated species correspond to three magnesium to two aluminum (7.6×10^{-3} *M* magnesium to 5.1×10^{-3} *M* aluminum). This suggests that the 3:2 species may be metastable relative to the 2:1 form.

Similar response to pH was exhibited when another buffer species was employed. Figure 20 shows the relation obtained when tris-(hydroxymethyl)-aminomethane (THMAM) was used as the buffering agent with two days of equilibration period. In Fig. 21 the corresponding plots of precipitated magnesium *vs.* the amount added in the form of magnesium sulfate is shown. At lower pH values it appears

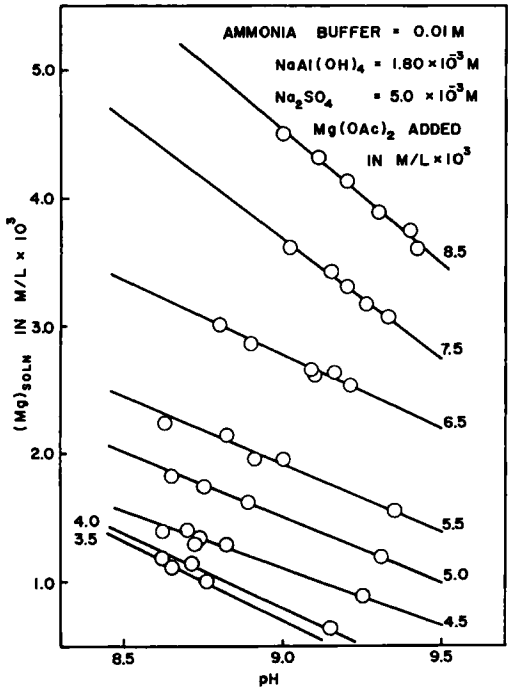

Fig. 16.—Changes in residual magnesium ion concentration in solution elicited by aluminate as a function of pH for several values of added magnesium acetate in buffered systems containing sulfate ions.

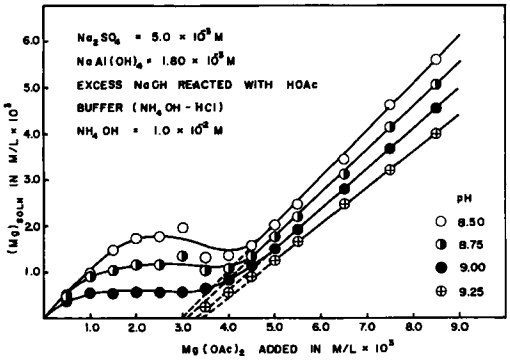

Fig. 17.—A phase solubility diagram showing the extent of magnesium ion binding exhibited by aluminate in buffered systems containing sulfate ions for four pH values.

that the break in the bound magnesium occurs at around 7.5×10^{-3} *M* corresponding again to 3:2 ratio. There appears to be another break at 1:2 ratio (2.5:5.1) which was not indicated in the ammonia systems. At higher pH there seems to be again the 2:1 relationship in presence of excess magnesium.

Sulfate Participation in the Buffered Systems.—It is evident from Figs. 19 and 20 that increasing the sulfate concentration reduces the amount of unbound magnesium ions in these systems. Thus, the species formed must again require sulfate ion in their formations. This is particularly evident in the data presented in Fig. 22, where the residual concentration of magnesium has been plotted against the amount of sulfate added.

The influence of the buffer on the sulfate participation is also shown in Fig. 23, where the residual sulfate has been plotted as a function of added magnesium ions. The amount of bound sulfate (the difference between the added and the sulfate in solution) appears to be somewhat less (approximately 16 per cent) than that in the unbuffered system.

Since the formation of the solid species required sulfate, the effect of sulfate concentration in solution on the residual magnesium concentration in solution may be expected to follow the solubility product principle.

As shown in Fig. 24, a logarithmic plot of data given in Fig. 22 indicates that the sulfate concentration varied inversely as the third power of the magnesium ions. In the limit in presence of excess sulfate ions this also suggests that the solid species corresponds to the composition, 3 Mg:2 Al:1 sulfate for this system.

Properties of the Solid Species

X-Ray Diffraction Patterns.—Figure 25 shows the Debye-Scherrer patterns (25) of relative intensities of some of the stronger lines along with their angles of diffraction. The relative intensity was defined

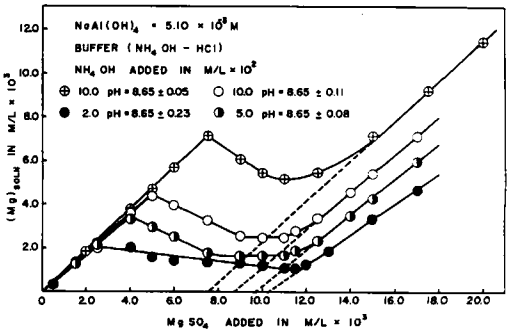

Fig. 19.—A phase solubility diagram showing the extent of magnesium binding exhibited by aluminate at various values of sulfate and three buffer concentrations, equilibration at five days (⊕ = two days).

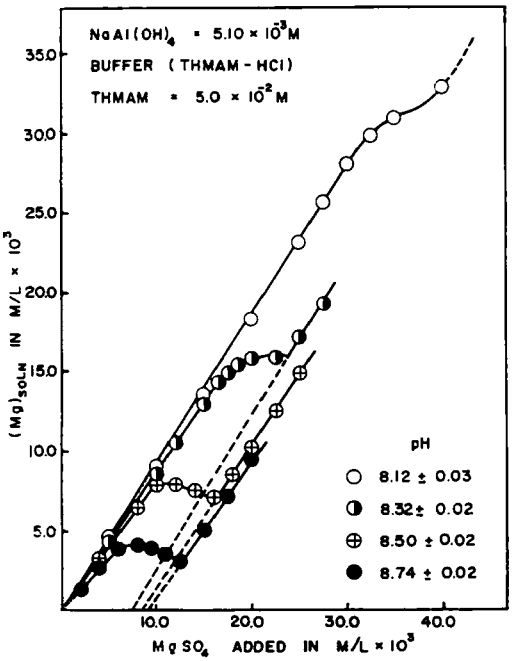

Fig. 20.—A phase solubility diagram showing the extent of magnesium binding exhibited by aluminate in buffered systems at various values of sulfate and pH with two days of equilibration.

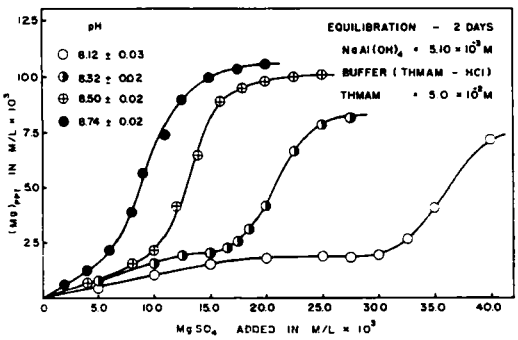

Fig. 21.—The amount of magnesium incorporated in the solid phase as a function of added magnesium sulfate concentration at four pH values in buffered systems containing aluminate with two days of equilibration.

as I/I_1, where I was the peak intensity of a diffraction line as estimated from per cent transmittance of the photographic negative corrected for background, and I_1 was the intensity of the strongest line of the particular phase in question. The diffraction patterns were developed by the use of filtered CuKα(λ = 1.5418 Å.) radiation on dried powdered samples (ground to about 200 mesh) with one hour exposure time on a camera film of 57.3 mm. in diameter. The relative information on the source and state of the powder samples is compiled in Table III. Samples A to E were isolated from phase solubility runs, washed with distilled water, and dried at room temperature and atmospheric pressure. Sample F was made batchwise, washed with distilled water, and dried over concentrated sulfuric acid at a reduced pressure for two weeks.

The effect of composition on the diffraction pattern as shown in Fig. 25 is of some interest. In particular the lines diffracted in the neighborhood of 30 and 33 degrees seemed to be shifted closer toward 30 degrees as the Mg:Al ratios increased. Another significant feature in these several patterns is the presence of an intense doublet at or close to the ten degree angle in samples A, B, and C, but which is either diffused or absent in the remaining samples.

All the samples indicated by the Debye-Scherrer patterns appeared at least partially crystalline and gave similar but significantly different X-ray diffraction patterns. For the series with Mg:Al ratios of 0.5 (A), 1.5 (B), 1.8 (C), and 4.0 (D), the line intensities as a whole increased as the ratios increased with the greatest distortion of lines in sample D (*cf.* Fig. 25).

Although the solid samples subjected to X-ray analysis were recovered directly from phase solubility runs, they were unfortunately subjected to varying degrees of washing with distilled water to remove the residual solution phase, as mentioned. This procedure probably produced significant alterations both in the crystal structures and the chemical compositions of the recovered dried products. Any serious attempts to derive structural information from the diffraction patterns should take this factor into account. The data presented in this section should, therefore, be considered as being indicative rather than conclusive, relative to the true structure of the precipitated species.

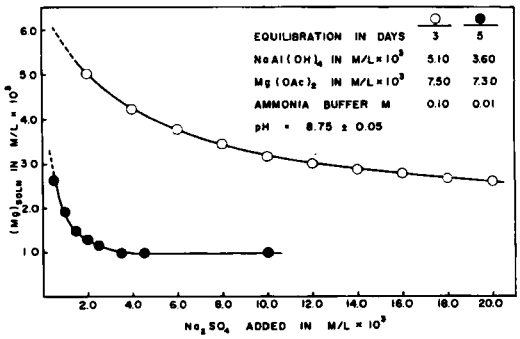

Fig. 22.—Changes in residual magnesium concentration in solution elicited by aluminate as a function of added sulfate concentration in buffered systems designated by open and solid circles.

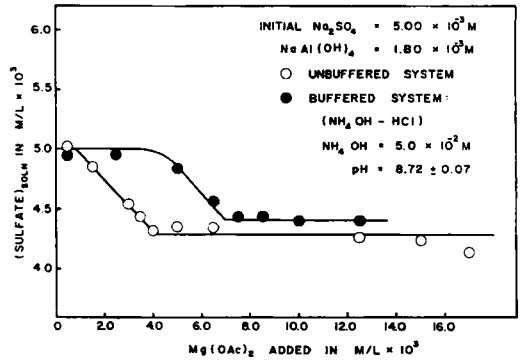

Fig. 23.—Changes in residual sulfate concentration in solution elicited by aluminate as a function of added magnesium acetate concentration in buffered and unbuffered systems.

CONCLUSION

The several solid species presumably formed in aqueous solutions by interactions of sodium, magnesium, aluminate, sulfate, and acetate ions in absence or presence of buffers are listed in Table IV. Their existence is proposed on the basis of experimental results presented in the preceding sections.

The evidence for the existence of species III and IV appears to be quite strong. The formation of species III which appears to be similar to the one reported by Hallmann (12) (who, however, indicated that sulfate was not part of the structure, but rather an impurity in the form of magnesium sulfate) is based on: (*a*) the phase solubility diagram obtained with the unbuffered systems (Fig. 7), (*b*) the potentiometric results given by magnesium acetate (Fig. 3), (*c*) the results from the sulfate study (Fig. 14), and (*d*) X-ray diffraction patterns (Fig. 25).

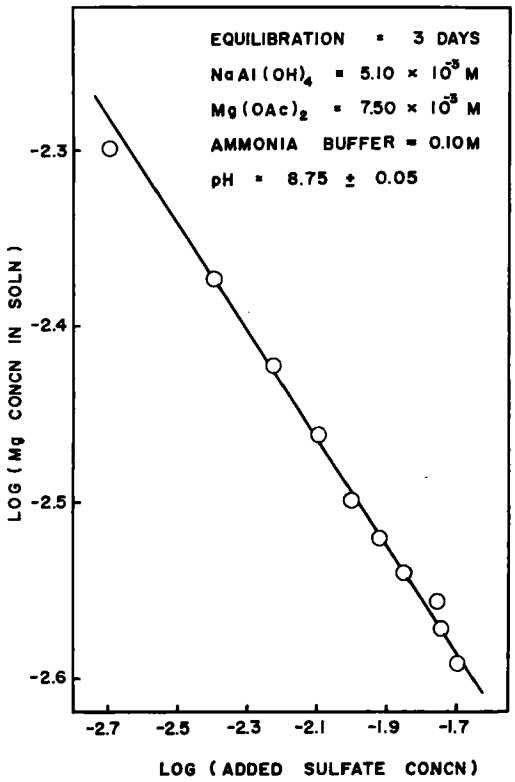

Fig. 24.—Logarithmic relation of the concentrations of residual magnesium ion in solution and added sodium sulfate in buffered systems containing aluminate with three days of equilibration.

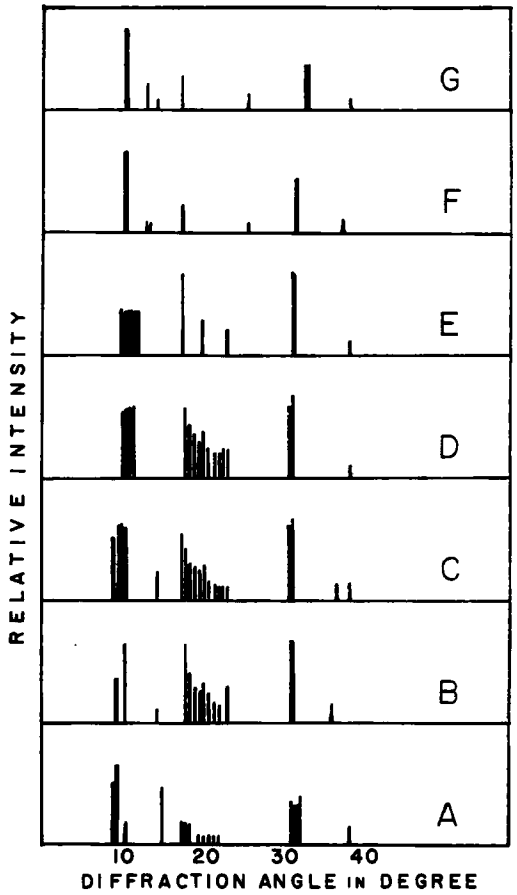

Fig. 25.—Relative intensity and diffraction angle relation of some stronger lines from Debye-Scherrer patterns of several powder samples with various Mg:Al ratios (for source and state see Table III) developed with filtered *CuKα* radiation, one hour exposure, 57.3-mm. diameter camera.

The phase solubility diagram shown in Fig. 7 gives extremely strong support to the existence of solid species III which apparently form in accordance with the phase rule (a solubility product-controlled process as evidenced by an invariant plateau). This certainly obviates the possibility of some of the earlier suggestions that solid solutions are possible over this range.

TABLE III.—INFORMATION RELATING TO THE SOURCE AND STATE OF THE X-RAY DIFFRACTION POWDER SAMPLES OBTAINED FROM PHASE SOLUBILITY STUDIES IN PRESENCE OF SULFATE

Sample	pH	$Mg(OAc)_2$ added in $M/L \times 10^3$	$NaAl(OH)_4$ added in $M/L \times 10^3$	Mg:Al ratio in ppt.
A	8.51	2.5	5.1	0.5
B	8.90	7.5	5.1	1.5
C	7.82	10.0	5.1	1.8
D	8.70	15.0	1.8	4.0
E[a]	8.72	12.5	1.8	1.7
F[b]	8.50	12.5	5.1	1.5

[a] Ammonia buffer = $1.0 \times 10^{-2} M$. [b] Ammonia buffer = $10.0 \times 10^{-2} M$.

TABLE IV.—SOLID SPECIES FORMED IN AQUEOUS SOLUTION BY INTERACTIONS OF SODIUM, MAGNESIUM, ALUMINATE, SULFATE, AND ACETATE IONS IN THE ABSENCE OR PRESENCE OF BUFFERS

Species	Composition	Conditions	Degree of Assurance
I	$MgO \cdot Al_2O_3 \cdot SO_3(?) \cdot nH_2O$	Low pH and high buffer concentration	Uncertain
II	$3MgO \cdot Al_2O_3 \cdot SO_3 \cdot xH_2O$	Low pH and moderate buffer concn.	Fair
III	$4MgO \cdot Al_2O_3 \cdot SO_3 \cdot yH_2O$	Unbuffered or at low buffer concn.	Definite
IV	$8MgO \cdot Al_2O_3 \cdot SO_3 \cdot zH_2O$	Unbuffered in an excess of Mg ion in solution	Definite

The 2 Mg:Al ratio of solid species III was obtained by the extrapolation of the rising portion of the curve to zero residual magnesium concentration in solution.

The composition of species III is also supported by the number of equivalents of hydrogen ion released when magnesium ion became bound through oxide to the aluminum system. Figure 3 shows that the amount of acetic acid required to obtain a pH value of approximately 8.5 in a system containing 1.80×10^{-3} *M* aluminate and excess sulfate is progressively decreased by addition of magnesium ions. The initial intensity of magnesium ionic binding appears to persist up to approximately two molar equivalents of aluminum present. The resulting composition corresponds to an atomic Mg:Al ratio of two to one, or that of solid species III.

Further evidence in support of the existence of species III is provided by the study of the effect of magnesium concentration on the extent of sulfate binding. The breaks in the plots shown in Fig. 14 indicate formation of a solid phase with an approximate 4 Mg:2 Al:1 SO_4 ratio which corresponds to that of species III.

Similar evidence is available in support of the existence of species IV. The phase solubility diagram as given in Fig. 8 provides the strongest indication for the formation of a solid species with the composition corresponding to that of species IV. This solid phase appears to form, however, without the characteristic invariant plateau. This behavior may be rationalized on the basis of a mass-controlled process rather than that of a solubility product. This is not an exception to the phase rule, but a modification with the addition of the mass law to account for the presumed dissociation phenomenon.

Figure 3 gives further support to the existence of solid species IV. The 4 Mg:1 Al ratio is obtained from the number of equivalents of hydrogen ion released when magnesium ions became bound through oxide to the aluminum system and by taking into account the effect of sulfate. The magnesium binding persists until approximately 12.6×10^{-3} mole per liter of hydrogen ions are released from 1.80×10^{-3} *M* aluminate. Since the sulfate effect is equivalent to 1.80×10^{-3} moles per liter of hydrogen ions, the atomic Mg:Al ratio is approximately equal to $(12.6 + 1.8) \div (1.8 \times 2) \doteq 4:1$.

Supplementary evidence in the support of the existence of solid species IV is afforded by the X-ray patterns shown in Fig. 25 for the sample D with a 4 Mg:1 Al ratio which corresponds to that of the composition of species IV. The diffraction lines show the solid sample to be crystalline.

It is to be noted that species IV may be similar to one of the double hydroxides of magnesium and aluminum reported by Feitknecht, *et. al* (13–15). These double hydroxides differ from the present reported species by having a characteristic varying formula in which the sum of the number of atoms of magnesium and aluminum is equal to five, and which may also contain an atom of chlorine.

The evidence in support of the existence of species II is based on: (*a*) phase solubility diagrams obtained with buffered systems (Figs. 17, 18, and 19), (*b*) the results of magnesium and sulfate relation study in the reference system (Fig. 24) and (*c*) X-ray diffraction patterns (Fig. 25). The formation of species II is suggested by the phase solubility diagrams with buffered systems shown in Figs. 17, 18, and 19. The formation of the 3 Mg:2 Al solid species apparently require a combination of low pH value and moderate buffer concentration. The behavior of the system suggests, however, that solid species II may be metastable relative to species III, since a longer period of equilibration, higher pH values, or lower buffer concentration led to the formation of the latter solid phase.

The solubility product relationship as shown in Fig. 24 also indicates the presence of a 3 Mg:1 SO_4 species in this system. Since the system shows 3 Mg:2 Al ratio, the formation of a solid species may be rationalized to have the overall 3Mg:2 Al:1 SO_4 ratio, which corresponds to that of species II.

The Debye-Scherrer pattern of sample F with the Mg:Al ratio of 1.5 corresponding to the composition of the species II indicates that the species in question is at least partially crystalline. The unbuffered sample B and the buffered sample F are similar in composition; the difference in their

X-ray patterns may be due to drying conditions and to the effect of buffer in sample F.

Here again, species II may be similar to one of the double hydroxides reported by Feitknecht, since the number of atoms of magnesium and aluminum in species II does add up to five. However, species II has a sulfate moiety in the formula which the double hydroxides apparently lack.

The evidence citable in support of the existence of species I is based on (*a*) the phase solubility diagram shown in Fig. 20 and (*b*) the X-ray diffraction pattern in Fig. 25. The results of the data shown in the reference diagram indicate that species I required a combination of high hydrogen ion, high buffer, and low residual magnesium ion concentrations. These prerequisites are met in the system as designated by half and open circles in Figs. 20 and 21. Figure 21 shows clearly the presence of an invariant plateau in each of the systems with pH values of 8.12 and 8.32. These two curves indicate approximate atomic Mg:Al ratios of 1:2, which correspond to that of the solid species I.

It should be explicitly pointed out that in these studies no serious attempt was made to determine the extent of participation of singly charged ions other than H^+ and OH^-. Acetate, chloride, sodium, and other ions present probably were coprecipitated to varying degrees. It appears likely, however, that their presence does not seriously alter the qualitative nature of these findings.

The results of the present investigation, nevertheless, appear to show that the hydrous-sulfated magnesium aluminate system could very well exist in a number of solid species with different stoichiometric ratios. They also serve to illustrate the value of phase solubility studies in delineating complex inorganic systems.

Triterpene Constituents of *Sarcostemma viminale* R.Br.

By JOHN D. TORRANCE and JOHANNES L. C. MARÁIS

The isolation of three triterpenes from a benzene extract of *Sarcostemma viminale* by alumina chromatography is described. Two of the triterpenes were identified as β-amyrin and friedelin, but the third, which occurred in the plant as an acetate, could not be identified with any known triterpene acetate. The monohydroxy-triterpene obtained by hydrolysis of the acetate has been designated viminalol.

SARCOSTEMMA VIMINALE is a leafless, glabrous, fleshy climbing plant belonging to the natural order *Asclepiadaceae*. The plant, which has numerous round-jointed stems and a slightly bitter milky latex, is found throughout Central and Southern Africa (1, 2) where it has been used medicinally by various tribes, both as an emetic and as a galactogogue (3). Steyn (4) found *Sarcostemma viminale* to be poisonous, and the plant is thought to be responsible for stock losses in southwest Africa (5).

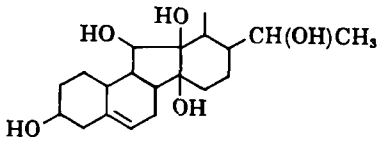
A similar plant, *Sarcostemma australe*, thought to be responsible for stock losses in Queensland (6), has been investigated by Earl and Doherty (7) who isolated *α*- and *β*-amyrin from it. A saponin also extracted from *Sarcostemma australe* was shown to be a glycoside of an aglycone containing benzoyl and cinnamoyl groups (8). Cornforth and Earl called the hydrolysis product of the saponin "sarcostin." Reichstein, *et al.*, who obtained sarcostin from *Asclepias giancophylla* (9) and from the roots of *Pachycarpus lineolatus* (10), proposed a C-nor-D-homo-skeleton for sarcostin which enabled Cornforth (11) to propose the following structure for this substance



RESULTS AND DISCUSSION

Sarcostemma viminale, collected in midwinter from the Loskop dam area, was minced and oven-dried before extracting with benzene. The extract was evaporated to dryness, and after redissolving the residue in the least possible volume of benzene it was chromatographed on a basic alumina column. A waxy substance *A*, an amorphous solid *B*, and two crystalline substances *C* and *D* were obtained.

Elementary analysis and micro-Rast molecular weight determinations gave the formula $C_{30}H_{50}O$, for both the crystalline substances *C* and *D*. From this formula it seemed probable that both substances belong to the triterpene group.

The infrared absorption curve of *D* has a broad band at 3333 cm.$^{-1}$ indicating the presence of an associated hydroxyl band (12); further bands at 1035 cm.$^{-1}$ and 996 cm.$^{-1}$ as well as an inflection at 1026 cm.$^{-1}$ indicated an equatorial -3-hydroxy group (13). A trisubstituted ethylenic linkage was indicated by bands at 825 cm.$^{-1}$ and 813 cm.$^{-1}$ (14). The presence of this center of unsaturation was also suggested by the pale yellow color which *D* gave with tetranitromethane. The acetate and

TABLE III.—ANALYSIS OF COMPOUNDS

	Rast MW.	Empirical formula	Analysis Calcd, % C	Calcd, % H	Found, % C	Found, % H
Viminalol	442	$C_{30}H_{50}O$	84.50	11.74	84.05	11.61
Substance *C*	432	$C_{30}H_{50}O$	84.50	11.74	84.20	11.67
Substance *D*	446	$C_{30}H_{50}O$	84.50	11.74	84.09	11.79
Clemmensen redn. of *C*		$C_{30}H_{52}$	87.37	12.62	86.90	12.45

benzoate of *D* were prepared and from the physical constants of *D* and its esters it was concluded that *D* was β-amyrin (see Table I).

The melting point of β-amyrin showed no depression on admixture with *D* and the infrared absorption curve of an authentic sample of β-amyrin was identical with that of *D*.

The infrared curve of *C* had a sharp intense peak at 1706 cm.$^{-1}$ indicating the presence of a six-membered-ring ketone (15); no bands indicating either hydroxyl groups or unsaturation were present. Substance *C* gave no color with tetranitromethane, suggesting a saturated structure for substance *C*.

Clemmensen reduction of *C* gave the corresponding hydrocarbon $C_{30}H_{52}$. The keto group was reduced with lithium aluminum hydride and also with sodium/propanol, to give two different alcohols. The acetates of both alcohols were prepared, and from the physical constants of these compounds it was concluded that *C* was friedelin (see Table II).

An authentic sample of friedelin gave an infrared absorption curve identical with that of substance *C* and its melting point showed no depression on admixture with *C*.

It is of interest to find both β-amyrin and friedelin in the same plant since the friedelin series of compounds can be derived from the β-amyrin series by a sequence of 1:2 shifts of methyl groups and hydrogen atoms away from ring *A* toward ring *E*.

Corey and Ursprung (16, 17) have shown this relationship to exist by converting friedelin-3β-ol into olean-13-(18)-ene using various acidic reagents to bring about the multigroup rearrangement.

The same authors suggest that a possible biosynthetic pathway to friedelin in the plant is as shown in Fig. 1. The intermediate (*a*) which is originally derived from squalene can undergo a Wagner Meerwein rearrangement to give, by way of the intermediate (*b*), either α- or β-amyrin. β-Amyrin, in turn, is converted into friedelin and theoretically α-amyrin should undergo a similar transformation to form an as yet unknown derivative of friedelin.

If this biosynthetic scheme is valid, lupeol should also be found in *Sarcostemma viminale*. We have not been able to isolate lupeol, but the amorphous acetate *B* appeared to belong to the lupeol series.

This amorphous solid, after being rechromatographed in hexane on a basic alumina column, had a melting point of 160–162° but could not be crystallized. The infrared absorption curve indicated the presence of an isopropenyl group (bands at 3069 cm.$^{-1}$, 1639 cm.$^{-1}$, and 878 cm.$^{-1}$) (18) and an acetoxy group (bands at 1730 cm.$^{-1}$ and 1247 cm.$^{-1}$) (19), as well as a trisubstituted double bond (bands at 826 cm.$^{-1}$ and 808 cm.$^{-1}$) (14).

The amorphous powder was hydrolyzed with alcoholic potash to give the corresponding alcohol, m.p. 176–178°. Elementary analysis indicated the empirical formula $C_{30}H_{50}O$ for this alcohol. Since the alcohol could not be identified with any of the known triterpene alcohols, the name viminalol has been assigned to it.

The infrared curve of viminalol has a broad band at 3322 cm.$^{-1}$ indicating an associated hydroxyl group (12), further bands due to the hydroxyl group at 1036 cm.$^{-1}$, 1024 cm.$^{-1}$, and 903 cm.$^{-1}$ indicated that the hydroxyl group was most probably situated at the C-3 position of the triterpene skeleton (13). The absorption curve also showed that the isopropenyl group and the trisubstituted double bond were still present in viminalol. The latter observation was also indicated by the pale yellow color which was obtained with tetranitromethane.

The amorphous compound *B*, which must be viminalol acetate, took up one mole of hydrogen on hydrogenation in glacial acetic acid with Adam's catalyst to yield a product melting point 172–178°, which could not be crystallized. The infrared curve of this reduction product showed that the isopropenyl group was no longer present.

It is possible that viminalol acetate may be similar in nature to scandol (20, 21), which was originally reported as a new triterpene, but which was later found, by Corey, *et al.* (22), to be a mixture of β-amyrin and lupeol.

Further work is in progress to identify viminalol and substance *B*.

Use of Dielectric Constants in the Classification of Surfactants

By WILLIAM G. GORMAN and GARY D. HALL

The polar balance of a surfactant, as reflected by its hydrophile-lipophile balance (HLB), was found to possess a linear relationship with the log dielectric constant (log DEC) of the surfactant. From this relationship, a rapid method of classifying surfactants was presented. A correlation between the polarity of an oil and that of the required emulsifying system was shown for oil-in-water emulsions. The use of direct DEC measurements for mixed surfactants and mixed oils was presented. Correlations between the DEC system and several phases of the HLB system were shown. Possible uses, advantages, and limitations of the DEC system were discussed.

IT HAS been reported (1) that the most formidable obstacle in the selection of surfactants for any particular application is the staggering number that are available. In order to efficiently and rationally select surfactants from among this number, a suitable method of surfactant classification is required. Such a method should provide a parameter that is easily measured with reliability and reproducibility. In recent years many methods (1–12) have been proposed for the classification of surfactants. Although some of these methods have been successful in limited areas of application, only the hydrophile-lipophile balance (HLB) system (1,2,8–12) appears to have found widespread usage. As its basis for classification, the HLB system successfully utilized the long recognized concept of the balance between the polar and nonpolar portions of the surfactant molecule.

Since a balance of polar and nonpolar groupings in a molecule is essentially an expression of molecular polarity, it follows that any method of measuring molecular polarity should provide a means of surfactant classification. According to Debye (13) the word polarity has been used in different ways to express molecular properties more or less connected with the actual arrangement, or the mobility, of the charges of which molecules are supposed to consist. All definitions of polarity are based on a fundamental picture which represents a molecule as a system of electric charges. Nonuniformity in the distribution of these electric charges results in polar groups which confer upon the molecules containing them a characteristic permanent electric moment, which reveals itself in dielectric phenomena. On this basis, it appeared that the polar balance of a surfactant should be quantitatively reflected in a measurement of its dielectric constant. The exploration of this hypothesis was the object of this investigation.

Received August 17, 1962, from Sterling-Winthrop Research Institute, Pharmacy Division, Rensselaer, N. Y.
Accepted for publication September 6, 1962.

EXPERIMENTAL

The dielectric constants (DEC's) of commercial grade surfactants were determined using a Sargent model V oscillometer. The instrument was calibrated using the standard procedures as outlined in the manual of instructions (14). All of the surfactants were dried prior to use in a vacuum desiccator containing calcium chloride in order to minimize experimental error due to the presence of moisture which may be significant, especially in the more hydrophilic samples. DEC values for the liquid surfactants were determined at room temperature (25 ± 1°), using the pure samples without further treatment. Because of the low melting points of the few solid surfactants examined in this study, their DEC's were determined at the lowest temperature consistent with the maintenance of the surfactant in a liquid state.

RESULTS AND DISCUSSION

Pure Surfactants.—A comparison of the reported HLB's of a number of surfactants and their experimentally determined DEC's is presented in Table I. An apparent linear relationship between these HLB values and DEC values is shown in Fig. 1, where reported HLB was plotted *vs.* log DEC. This linear relationship lends strong support to the hypothesis that surfactant polarity as inferred by its HLB value is quantitatively expressed by its DEC value.

Surfactant Mixtures.—Besides offering a system for classifying pure surfactants, DEC values also provide a means of directly measuring the polarity of mixed surfactants. The HLB system (2) claims that the HLB values of surfactants are additive in behavior on a weight-to-weight basis and that the HLB value of surfactant mixtures may be calculated accordingly. Linear relationships of an additive nature would be expected for surfactant mixtures only if the individual surfactants behaved independently of each other and exhibited no intermolecular reactions. Since it is seldom that these conditions would actually be met, a strictly additive relationship for the HLB of surfactant mixtures would not usually be expected.

Chun and Martin (6) found negative deviations from linearity in the interfacial tension measurements of Igepal[1] mixtures which suggest positive deviations from linearity of HLB values, thus indicat-

ing that HLB values may not be strictly additive in nature. Likewise, Maclay (17) found some positive deviations from linearity in the cloud points of Pluronic[2] mixtures and Igepal mixtures.

The nonlinearity of the DEC's of mixtures of pure binary organic systems is illustrated by the work of Miller and Maass (18). Although the same deviations are observed in the dielectric constants of mixed surfactant systems, it is possible to make direct measurements even on multicomponent surfactant mixtures. The deviations from linearity of several surfactant mixtures are shown in Fig. 2. It is interesting to note that these mixtures gave positive deviations from linearity which are in general agreement with the previously reported interfacial tension and cloud point findings for other surfactant mixtures. More importantly, however, is the fact that over a considerable portion of the range for mixtures of Tween 20/Span 20 and for Tween 80/Span 80, deviations from linearity of approximately 0.04 log DEC units (approximately 1.3 HLB units) were observed.

Surfactant Solvent Relationships.—Since dielectric constants give relative values in the same numerical system for surfactants as well as for solvents (including water and oils), it is proposed that dielectric constants, in addition to offering a means of classifying surfactants, could provide a means for relating solvents and surfactants. This feature is not offered by the presently employed systems of surfactant classification. The approximate required HLB's for oil-in-water (o/w) emulsions of various oils, empirically determined by trial and error (1,2,9,12,19) have been reported. A comparison of the required HLB for o/w emulsification of several oils with the log DEC of these oils is presented in Table II. In Fig. 3 the reported required HLB of surfactant for o/w emulsion is plotted against the log DEC of these oils. Using the relationship indicated in Fig. 1, the approxi-

[2] Trade name for ethylene oxide condensates of polypropylene glycols marketed by Wyandotte Chemicals Corp.

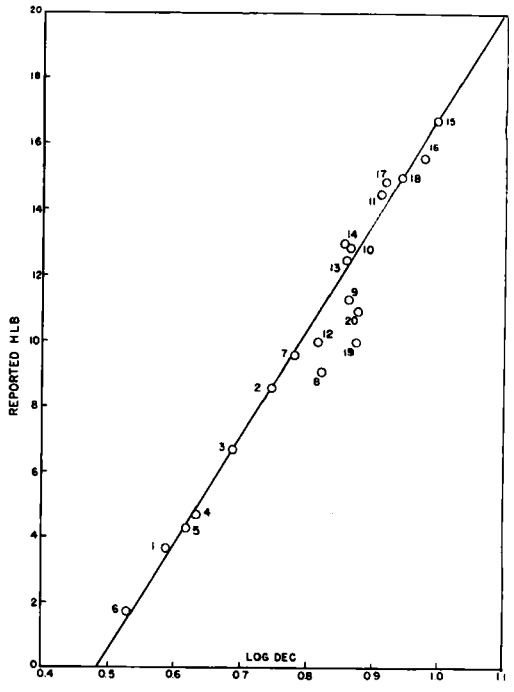

Fig. 1.—Reported HLB *versus* log DEC of pure surfactants.

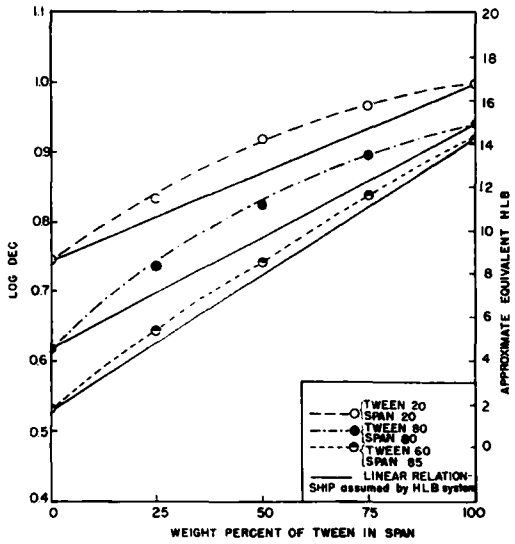

Fig. 2.—Log DEC of surfactant mixtures.

mate equivalent log DEC of surfactant is plotted as a second ordinate. Considering the fact that the required HLB values are reported as whole numbers with a range of approximately ±1 HLB unit, Fig. 3 illustrates the following interesting relationships:

1. A linear relationship exists between the log DEC of these oils and (*a*) the required HLB of surfactant for o/w emulsion and (*b*) the approximate equivalent log DEC of surfactant.

2. A proportional relationship is apparent between polarity of the oil (log DEC) and polarity (log DEC) of the surfactant required to effect o/w emulsion. The relationship suggests that for o/w emulsions, the higher the DEC of the oil, the higher would be the required DEC of the emulsifying surfactant.

3. The DEC of surfactant required for producing an o/w emulsion of any oil can be approximated from the graph by determining the DEC of the oil.

Solvent Mixtures.—The polarities of a series of oil mixtures, as indicated by their log DEC values, are reported in Fig. 4. Although these mixtures in general approximated additive or linear relationships more closely than the surfactant mixtures, there were still some deviations from linearity as shown by the kerosene-pine oil mixture, which exhibited a slight negative deviation.

The required DEC for producing o/w emulsions of oil mixtures can also be approximated, as described above, by determining the DEC of the oil mixture.

DISCUSSION

Although the data presented in this paper have been necessarily restricted to a limited number of surfactants with known HLB values, it appears that measurements of surfactant balance or polarity can be obtained for many surfactants from dielectric constant data. Such data offer distinct advantages over many of the presently employed systems since DEC's provide physical-chemical values (rather than empirical numbers) which can be duplicated experimentally with a minimum of effort and time.

In comparing DEC and HLB values, preference was given to the HLB values determined experimentally in Griffin's earlier work. It was felt that although the experimental method of determining HLB is tedious and has certain inherent weaknesses, the resulting HLB values are more significant than those calculated from the equations given in the literature (1,8,11). This seems reasonable when we consider that these equations are approximations which appear to have been empirically derived from data based on experimentally determined HLB values.

[a] Reported estimate of reliability ±1 HLB unit. [b] These oils have been omitted from Fig. 3 since there appears to be considerable variation in the reported required HLB values.

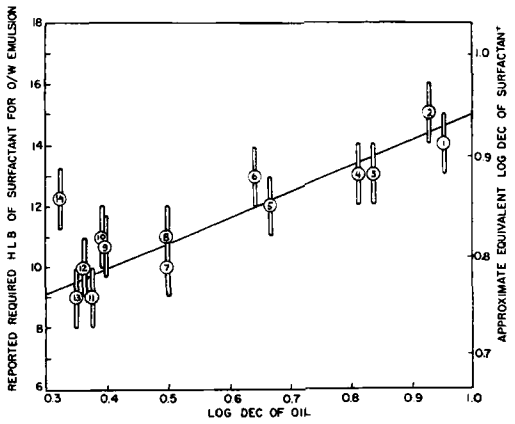

Fig. 3.—Reported required HLB of surfactant for o/w emulsion *versus* log DEC of oil.

The DEC values obtained for some solid surfactants containing large polyethylene oxide chains (usually >10 moles) were frequently lower than anticipated by their reported HLB values. This is probably due to the fact that DEC values of the pure surfactants are representative of the polar balance of the surfactant molecule alone without the influence of an aqueous or solvent environment. Since Maclay (17) reports that the high water solubility of the polyethylene oxide chain is due to hydrogen bonding between the solvent and the ether oxygen atoms in the chain, such interactions might not be apparent from DEC measurements in a solvent free environment. It is probable, however, that the extent of such solvent interactions could be determined from DEC measurements of the pure compounds and of solutions of these compounds in the solvents in question.

Since the "required HLB" of an emulsion is usually determined using a particular pair of surfactants before other groups of surfactants are considered, any deviation of the actual HLB from its theoretical value could be misleading. The positive deviations from linearity observed in the DEC values of surfactant mixtures suggest that the actual HLB's frequently deviate from the theoretical values assumed for such mixtures. These deviations were apparent whether DEC's or log DEC's were plotted *vs.* concentration, expressed in terms of % w/w, % v/v, or mole fractions. The use of DEC's could be extremely useful in the study of such mixed surfactant systems.

Expressed in terms of dielectric constants, most surfactants would have a value in the range of 3–13. However, it should be remembered that a surfactant must also have certain other properties. The molecule of a surfactant must contain one portion which is strongly attracted by the first phase or excluded by the second and another portion which should be excluded by the first phase or attracted by the second. For most systems this usually requires a lipophilic portion of substantial molecular size. Griffin (8) states that compounds should have molecular weights of at least 200 to be surfactants, while materials with molecular weights below 200 in the HLB (DEC) range of surfactants are often some of our best solvents.

Although this present investigation was intended mainly to introduce the concept and application of DEC measurements in the areas of surfactant classification and usage, there are many related applications which have not been covered in this study. Besides the general correlation of DEC values with HLB values, there also appear to be some correlations of DEC values with cloud point data, interfacial tension measurements, surface tension measurements, foaming properties, the solubilization of liquids and solids in other liquids, and critical micelle concentrations of some surfactants.

SUMMARY

1. The polar balance of a surfactant, as reflected by its hydrophile-lipophile balance (HLB), was found to possess a linear relationship with the log dielectric constant (log DEC) of the surfactant.

2. A rapid method of surfactant classification based on dielectric constants has been presented.

3. The use of this system for the direct measurement of surfactant mixtures was shown. Positive deviations from linearity were observed on the mixtures studied.

4. The use of the DEC system for the measurement of several oil mixtures and a range of polar and nonpolar solvents was described.

5. In the preparation of oil-in-water emulsions, a correlation between the DEC of the oil and that of a required surfactant system has been demonstrated. It was shown that the more polar the oil the more polar the emulsifying system required.

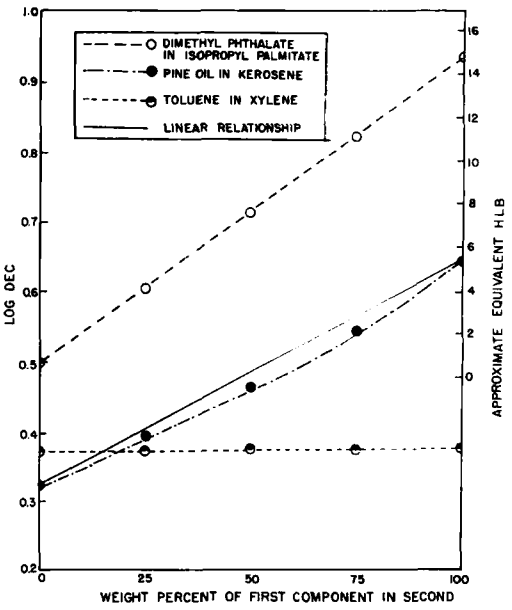

Fig. 4.—Log DEC of oil mixtures.

6. General agreement between phases of the DEC system and the HLB system was noted.

7. The DEC system was presented as offering values which can be measured directly and which can be reproduced in any laboratory by the use of established procedures.

Antitussive Activity of a Series of Dialkylaminodiphenylbutanol Esters

By JOSEPH A. MILLER, JR., E. BROWN ROBBINS, and DONALD B. MEYERS†

The effect of structural modifications upon the antitussive activity of a series of dialkylaminodiphenylbutanol esters was examined. In an attempt to investigate a possible correlation of pharmacological activities, the compounds were also evaluated for their spasmogenic effect upon the intestine and their analgesic activity. Antitussive activity was determined in guinea pigs by means of SO_2-induced cough. Spasmogenic activity was determined by inserting a balloon into the duodenum of anesthetized dogs. Analgesic activity was determined by the rat-tail heat method. The optimum antitussive structure tested within this series was *α-dl*-2-propionoxy-1,2-diphenyl-3-methyl-4-dimethylaminobutane hydrochloride. The optimum analgesic structure tested in this series was the 2-acetoxy analog of the same compound. Some degree of correlation was shown among the activities, although exceptions were noted.

THE PRIMARY purpose of this study was to investigate the influence of certain structural modifications upon the antitussive activity of dialkylaminodiphenylbutanol esters. Since it had been observed that these compounds exhibited analgesic and spasmogenic activities, the possibility of correlations among these activities also was investigated. The antitussive evaluation was made using a new method which will be described in detail.

The compounds chosen for this study were from a series of dialkylaminodiphenylbutanol esters prepared by Pohland and Sullivan (1) of The Lilly Research Laboratories. All of these compounds were racemic mixtures, and were synthesized by the same general procedure from their corresponding ketones. The compounds used in this study are listed in Table I with their respective melting points.

EXPERIMENTAL

Antitussive Testing Method.—Many problems are associated with the evaluation of antitussive agents and a variety of methods have been employed in an attempt to overcome these difficulties. The major problem is in evoking a reproducible cough. This reproducible cough must be responsive to known antitussive agents, and the method must be sensitive enough to discriminate among varying doses of these compounds. Often this discrimination is not good and results in a flat dosage-response relationship. The numerous disadvantages and problems of most methods led to the development of the following procedure which was used to determine the antitussive activity of the diphenylbutanol esters.

6. General agreement between phases of the DEC system and the HLB system was noted.

7. The DEC system was presented as offering values which can be measured directly and which can be reproduced in any laboratory by the use of established procedures.

Antitussive Activity of a Series of Dialkylaminodiphenylbutanol Esters

By JOSEPH A. MILLER, JR., E. BROWN ROBBINS, and DONALD B. MEYERS†

The effect of structural modifications upon the antitussive activity of a series of dialkylaminodiphenylbutanol esters was examined. In an attempt to investigate a possible correlation of pharmacological activities, the compounds were also evaluated for their spasmogenic effect upon the intestine and their analgesic activity. Antitussive activity was determined in guinea pigs by means of SO_2-induced cough. Spasmogenic activity was determined by inserting a balloon into the duodenum of anesthetized dogs. Analgesic activity was determined by the rat-tail heat method. The optimum antitussive structure tested within this series was *α-dl*-2-propionoxy-1,2-diphenyl-3-methyl-4-dimethylaminobutane hydrochloride. The optimum analgesic structure tested in this series was the 2-acetoxy analog of the same compound. Some degree of correlation was shown among the activities, although exceptions were noted.

THE PRIMARY purpose of this study was to investigate the influence of certain structural modifications upon the antitussive activity of dialkylaminodiphenylbutanol esters. Since it had been observed that these compounds exhibited analgesic and spasmogenic activities, the possibility of correlations among these activities also was investigated. The antitussive evaluation was made using a new method which will be described in detail.

The compounds chosen for this study were from a series of dialkylaminodiphenylbutanol esters prepared by Pohland and Sullivan (1) of The Lilly Research Laboratories. All of these compounds were racemic mixtures, and were synthesized by the same general procedure from their corresponding ketones. The compounds used in this study are listed in Table I with their respective melting points.

EXPERIMENTAL

Antitussive Testing Method.—Many problems are associated with the evaluation of antitussive agents and a variety of methods have been employed in an attempt to overcome these difficulties. The major problem is in evoking a reproducible cough. This reproducible cough must be responsive to known antitussive agents, and the method must be sensitive enough to discriminate among varying doses of these compounds. Often this discrimination is not good and results in a flat dosage-response relationship. The numerous disadvantages and problems of most methods led to the development of the following procedure which was used to determine the antitussive activity of the diphenylbutanol esters.

TABLE I.—4-DIMETHYLAMINO-1,2-DIPHENYL-2-BUTANOL ESTERS

Compound	M.p.,°C.
dl-2-Acetoxy-1,2-diphenyl-4-dimethylaminobutane HCl	227–228
α-*dl*-2-Acetoxy-1,2-diphenyl-3-methyl-4-dimethylaminobutane HCl	187–188
α-*dl*-2-Acetoxy-1,2-diphenyl-4-dimethylaminopentane HCl	210–211
α-*dl*-2-Acetoxy-1,2-diphenyl-3-methyl-4-pyrrolidinobutane HCl	202–203
α-*dl*-2-Acetoxy-1,2-diphenyl-3-methyl-4-piperidinobutane HCl	215–216
α-*dl*-2-Acetoxy-1,2-diphenyl-3-methyl-4-morpholinobutane HCl	195–196
dl-2-Propionoxy-1,2-diphenyl-4-dimethylaminobutane HCl	188–189
α-*dl*-2-Propionoxy-1,2-diphenyl-3-methyl-4-dimethylaminobutane HCl	170–171
α-*dl*-2-Propionoxy-1,2-diphenyl-4-dimethylaminopentane HCl	210–211
α-*dl*-2-Propionoxy-1,2-diphenyl-3-methyl-4-pyrrolidinobutane HCl	196–197
α-*dl*-2-Propionoxy-1,2-diphenyl-3-methyl-4-piperidinobutane HCl	191–192
α-*dl*-2-Propionoxy-1,2-diphenyl-3-methyl-4-morpholinobutane HCl	190–191

Spotted male guinea pigs weighing 250–400 Gm. were used as test animals. The guinea pigs were restrained in a plastic stock that permitted a face mask to fit flush against the front. The face mask was made by cutting off the bottom of a 6 cm. diam. plastic bottle. The neck of the bottle was fitted with a rubber stopper that had a hole bored in it to accommodate a syringe tip. The cough-producing stimulus was sulfur dioxide obtained from a cylinder. No pressure gauge was necessary, but an estimate of the gas flow was made by allowing the gas to bubble in a beaker of water in an exhaust hood. The gas was passed from the cylinder through a suction flask which served as a water trap for any water which might be siphoned into the tubing when the cylinder valve was closed. This was necessary because the sulfur dioxide within the tubing dissolved in water, resulting in a decreased pressure within the tubing. The apparatus is illustrated in Fig. 1.

Five milliliters of the gas was diluted to 10 ml. with air by means of a 30-ml. syringe, and the 10 ml. of diluted sulfur dioxide was expelled into the plastic mask held over the guinea pig's head. After the gas was administered to the guinea pigs, they were released and observed for cough frequency within the next two minutes.

A responsive colony of guinea pigs was first established by beginning with 3 ml. of gas diluted to 10, then 4 ml. diluted to 10 the next time, and finally 5 ml. diluted to 10 ml. By the third control run, nonresponders were discarded as well as those pigs on subsequent tests that did not respond after having received no treatment.

All assays were of a cross-over design in which each pig received every treatment in a randomized order. All drugs were administered subcutaneously and there were approximately ten pigs used at each dose level. There was at least one day's rest between treatments. The mean number of coughs per pig on a treatment was compared with the mean control response, and the per cent cough depression was calculated by dividing the control value into the difference between treatment and control.

Drugs were evaluated on the basis of their ED_{50}'s. This may be defined as that dose necessary to produce a 50% depression of cough. The ED_{50}'s and their standard errors were estimated by the method of Bliss (2) and are shown in Table II. Although the ED_{50} values were estimated on the basis of individual slopes, when a comparison within the series was to be made it was more appropriate to use a common slope to arrive at an estimate of relative potency. The adjusted ED_{50} of a drug was related to the adjusted ED_{50} of the reference standard.

In all methods of cough stimulation in which the recording is done by measuring the force of expired air, the possibility of false responses must be kept in mind. True cough responses may be confused with gasps, sneezes, and various contractions of the abdominal musculature without the total integrated

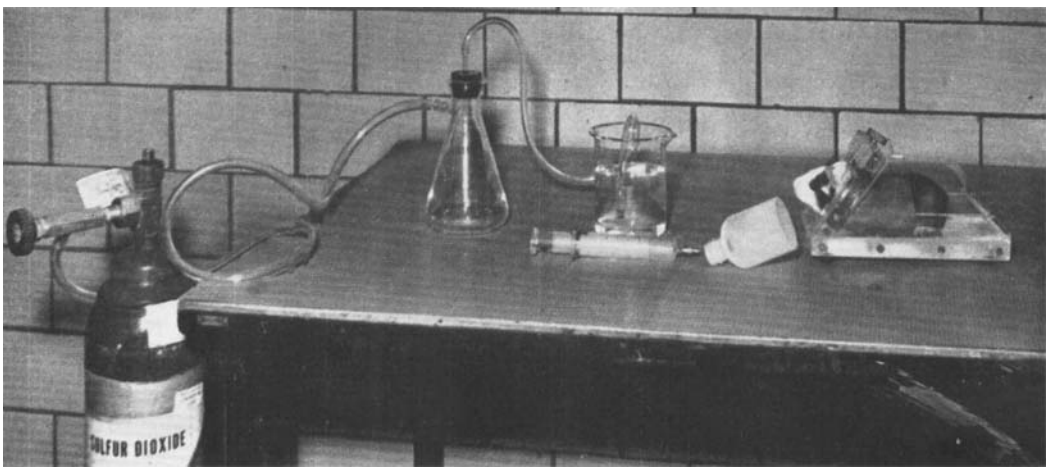

Fig. 1.—The antitussive screening apparatus. The apparatus has since been moved to a closed hood as a precaution against the sulfur dioxide fumes.

cough reflex occurring. This confusion was avoided by recording a response that was seen and heard.

Many electrical methods, due to the necessary surgery, involve acute experiments and the use of anesthetics. Due to their depressant effect on neural conduction, there is the possibility that these anesthetics as well as nonantitussive compounds with anesthetic properties will influence the results.

To avoid inconsistencies in cough response, mechanical methods of cough stimulation must be well controlled so that the stimulus is always applied equally and to the same area. This would be difficult enough to reproduce within the same laboratory using the same animal, but much more so in different laboratories.

None of these problems are encountered with the method described; the simplicity of the method eliminates many variables, and the equipment required is at a minimum. The variance in response due to animals was quite high, but error was greatly reduced by designing cross-over studies in which each animal served as his own control.

In an attempt to criticize and establish confidence in this method, those compounds which would be suspected to yield false positive results were administered, as well as known antitussive agents. Subtoxic doses of phenaglycodol,[1] a central synaptic depressant, secobarbital,[2] a barbiturate, and procaine hydrochloride, a local anesthetic, produced no depression of cough. No significant difference was shown between control (no treatment) and placebo (0.9% saline) when tested on a blind basis. This indicated that the effect of a saline injection was negligible and also showed the reproducibility of the control values in the same animals. On the other hand, morphine sulfate, codeine phosphate, and dextromethorphan hydrobromide[3] produced results (Table II) consistent with clinical findings.

Spasmogenic Testing Method.—Mongrel dogs, 6–12 Kg., anesthetized with an intravenous dose of 140 mg./Kg. phenobarbital, were used as test animals. A tracheal cannula was attached through a two-way valve to a volume-flow gas meter which measured inspired air. The carotid artery was cannulated and connected to a mercury manometer for blood pressure recording. An incision was made in the abdomen to expose the stomach. A cannula of No. PE 350 polyethylene tubing with a small balloon approximately $2^1/_2$ in. long tied around the end was inserted through an incision in the fundus of the stomach. This was passed through the pylorus and down 6 to 8 in. into the duodenum. A purse-string suture was made around the stomach incision to retard bleeding, and the abdominal incision was closed with wound clips. The balloon was inflated with approximately 6 ml. of air and attached to a tambour to record intestinal motility. All injections were made into the exposed femoral vein. A kymograph tracing of duodenal activity, blood pressure, and respiration is shown in Fig. 2.

Analgesic Testing Method.—Female, albino, Harlan strain rats weighing 70–80 Gm. were used as test animals. The method was a modification (3) of that used by Davies and co-workers (4). Mean reaction times of treated rats were compared with mean control values obtained at the same time to arrive at a mean increase in reaction time for each treatment group. A mean increase in reaction time of 1.5 seconds per rat ($ED_{1.5}$) was arbitrarily established as a basis for comparing different drugs. This represented a significant rise in threshold response. Dosage-response curves were calculated for each drug, and using individual slopes, the dose necessary to obtain an increase in reaction time of 1.5 seconds was computed. These figures are to be found in Table II.

The error was estimated by the method used for determining regression coefficients found in most standard statistical texts (5). The error of log dose x was estimated for the special case where y equals 1.5 seconds.

As was done in the case of antitussive evaluations, relative potency figures were estimated on the basis of a common slope and the adjusted $ED_{1.5}$ values were compared with the adjusted $ED_{1.5}$ of the reference standard.

RESULTS

The results of the antitussive, analgesic, and spasmogenic evaluations are summarized in Table II. The minimal toxic dose refers to the dose that produced the first observable signs of toxicity. These consisted of either sedation or tremors. The spasmogenic dose refers to the lowest dose that produced any increase in activity of the duodenum. Explanations of the remaining columns have been given under the appropriate testing methods.

Dotted spaces indicate that no significant effect was seen at subtoxic doses. A dotted space will also be noted after the figure 54.2 ± 26.7 on line 9, under "Analgesic Activity." Although this compound was of a low-order analgesic potency, an estimate of the $ED_{1.5}$ was not impossible. However, due to its poor dosage-response relationship and flat slope, it was not included in the calculation of relative potency. It was felt that inclusion would flatten the common slope of the remaining active compounds, resulting in distorted estimates of relative potency.

DISCUSSION

In the following discussion of structure-activity relationships all remarks will be limited to those twelve compounds that were reported in this paper. It must also be emphasized that these were racemic mixtures and that observations and conclusions apply only to these mixtures and not to their optical isomers. From previous reports, it might be expected that there would be a division of activity in the isomers upon resolving the racemate. In the case of the α-*dl*-2-propionoxy-1,2-diphenyl-3-methyl-4-dimethylaminobutane analog (*dl*-propoxyphene), it was demonstrated (6) that all of the analgesic activity resided in the dextrorotatory isomer. Also, this compound was shown to be unique in that the nonanalgesic isomer (*l*) possessed greater antitussive activity than the *d* isomer or the racemic mixture.

No structure-activity study should be considered complete without a study of the optical isomers within that series, and further work in this area should provide additional valuable data.

Antitussive Activity.—In the acetoxy derivatives,

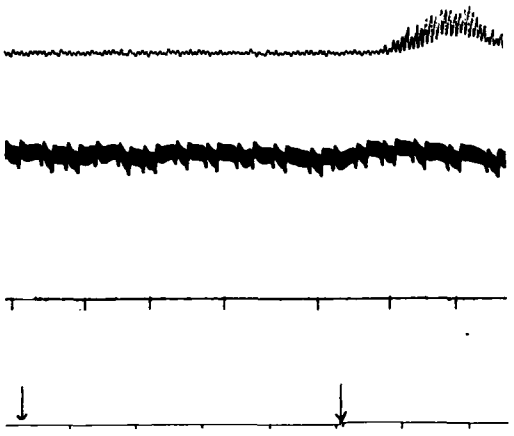

Fig. 2.—The effect of .025 mg./Kg. followed by .05 mg./Kg., i.v. of α-*dl*-2-acetoxy-1,2-diphenyl-3-methyl-4-pyrrolidinobutane hydrochloride on the duodenum of an 8.8 Kg. female dog, anesthetized with 140 mg./Kg. sodium phenobarbital i.v. Top line, duodenal activity; second line, blood pressure; third line, respiratory volume in liters; fourth line, time in minutes.

the compound unsubstituted at R^1 and R^2 possessed weak antitussive activity. Substitution at R^2 with a methyl group enhanced activity, but substitution at R^1 was more effective. The activity of the R^1 methyl-substituted compound was further enhanced by the substitution of a pyrrolidine group for the dimethylamine group. A piperidine substitution at *x* resulted in decreased activity and the morpholine-substituted analog was void of antitussive activity.

In the propionoxy derivatives, results obtained by substituting a methyl group at R^1 and R^2 were inconsistent with the acetoxy analogs. Although both R^1 methyl-substituted analogs were more potent than their corresponding unsubstituted or R^2 methyl-substituted analogs, the R^2 methyl-substituted propionoxy analog was less potent than its unsubstituted (R^1 and R^2 = H) analogs. This was not true in the acetoxy derivative. A pyrrolidine substituent at *x* did not enhance potency as was the case in its acetoxy analog. The piperidine analog was less potent than the acetoxy analog, and in both cases the morpholine analogs were inactive.

From the data it was concluded that the most effective antitussive structure among these compounds was represented by the R^1 methyl-substituted, propionoxy, dimethylamine analog. Pharmacological studies of this compound have been reported previously in the literature (3).

Spasmogenic Activity.—The spasmogenic data on the dog intestine were quite difficult to correlate. The active compounds in the series fell within the range of 0.04 to 0.4 mg./Kg. i.v., which is consistent with other antitussives and analgesics except morphine. The acetoxy derivatives were more active than their corresponding propionoxy analogs, and those compounds which showed weak or no antitussive and analgesic activity were consistently less active in their intestinal effect. If a compound had shown either antitussive or analgesic activity, it was also active upon the intestine. In this respect, it would be concluded that spasmogenic activity paralleled antitussive or analgesic potency, but not in any direct relationship.

Analgesic Activity.—In the compounds tested, it was observed that the acetoxy derivatives were consistently more potent than their propionoxy analogs. This relationship also held true with respect to toxicity resulting in no therapeutic advantage.

The unsubstituted (R^1 and R^2 = H) dimethylaminobutane acetoxy analog produced no analgesia. Substitution with a methyl group at R^2 produced an analgesically active compound and this activity was enhanced by shifting the methyl group to the R^1 position. The substitution of a pyrrolidine group for the dimethylamine moiety resulted in a slight loss of analgesic activity. Activity was further reduced by the substitution of a piperidine group at *x*. The morpholine analog was void of analgesic activity.

In the slightly less active propionoxy analogs, the R^1 methyl-substituted compound was also the most active of the dimethylamine analogs. A progressive loss in activity resulted from shifting the R^1-methyl group to the R^2 position and finally removing it. The effects of the pyrrolidine substitution at *x* were consistent with the acetoxy analog, but the piperidine substitution resulted in a total loss of activity. The morpholine analogs of the acetoxy and propionoxy derivatives were consistently inactive. The ratio of the $ED_{1.5}$ to the minimal toxic dose (therapeutic index) was roughly the same throughout the series.

It was concluded that among these compounds, the acetoxy derivative with a methyl group in the R^1 position and a dimethylamine moiety at *x* represented the optimum analgesic structure.

Correlation.—Only one compound (α-*dl*-2-propionoxy-1,2-diphenyl-4-dimethylaminobutane hydrochloride) exhibited good antitussive activity without analgesic activity. The remaining compounds in which antitussive activity was demonstrated also exhibited analgesic activity. There was only one compound of good analgesic potency which exhibited low antitussive potency (α-*dl*-2-acetoxy-1,2-diphenyl-3-methyl-4-piperidinobutane hydrochloride). All compounds which were active upon the intestine were also active as analgesics and/or antitussives. These observations are suggestive of some degree of correlation between analgesic and antitussive potency, while a strong correlation was shown between antitussive activity and spasmogenic activity although not quantitatively so.

SUMMARY

1. A series of dialkylaminodiphenylbutanol esters was tested for antitussive activity, and this activity was compared with their analgesic potencies and effect upon the intestine.

2. A new method for evaluating antitussive activity was described.

3. The optimum antitussive structure within this series tested was represented by α-*dl*-2-propionoxy - 1,2 - diphenyl - 3 - methyl - 4-dimethylaminobutane hydrochloride.

4. The optimum analgesic structure within this series tested was represented by α-*dl*-2-acetoxy - 1,2 - diphenyl - 3 - methyl - 4 - dimethylaminobutane hydrochloride.

5. Some degree of correlation was shown among the three activities, although exceptions were noted.

Chlorpromazine and Dextro-amphetamine as Antidotes in Acute Antihistaminic Toxicity in Rats

By I. H. MAEL† and J. F. BESTER

Acutely toxic oral doses of a number of antihistaminics were determined in adult white rats of both sexes. Toxic symptoms included convulsive seizures which lasted some minutes and were periodically repeated, followed by generalized central depression, terminating in unconsciousness and death. Chlorpromazine and dextro-amphetamine were administered in that order, intraperitoneally, in varying quantities and at varying time intervals. It was found that, if chlorpromazine was administered at the onset of convulsions and dextro-amphetamine at the first signs of depression, the recovery rate of animals was quite high.

THERAPEUTICALLY useful antihistaminics were developed well over 20 years ago, and for most of that time their acutely toxic capabilities have been recognized. Just as the various antihistaminics vary in their potencies, so they vary in the frequency and severity of their toxic manifestations. Such variations are largely quantitative, however; and when they occur, the symptoms of acute toxicity are quite similar regardless of the drug used. Typically, drowsiness followed by nervousness, tremors, muscle twitching, delirium, and convulsions are observed along with respiratory depression and cyanosis and followed by unconsciousness and death (1).

Despite the fact that repeated efforts have been made to find satisfactory methods of treatment of acute poisoning with the antihistaminic drugs, methods of treatment continue to be difficult and not overly successful. The need for uniformly adequate antidoting has not lessened with the years; acute antihistaminic poisoning is not uncommon. Each month, for example, several such intoxications are reported in Arizona, totaling 27 for the year 1961 (2). The Poison Information Center in Los Angeles in the first 6 months of 1961 reported 42 acute poisonings from antihistaminics as such, plus an additional 65 due to antihistaminic-containing nonbarbiturate sedatives (3).

The difficulty in preventing poisoning with these drugs and in coping with them when they arise is complicated by the fact that dose effect relationships are inconsistent. For example, the oral LD_{50} of diphenhydramine in rats has been reported as 500 mg./Kg. (4), and of pyrilamine hydrochloride, subcutaneously in rats, as 150 mg./Kg. (5). Yet 400 mg. of diphenhydramine and 1.3 Gm. of pyrilamine, respectively, caused the deaths of two 2-year-old children (1). Connolloy reported serious intoxication of a $5^1/_2$-year-old child following ingestion of 12 mg. of chlorpheniramine (6).

Because antihistaminics typically cause toxic symptoms of mixed characteristics, single antidotes offer little hope of success. Various drugs and drug combinations have been tried and reported. These include histamine, atropine plus epinephrine, phenobarbital, caffeine, dextro-amphetamine (7), ether (8), phenobarbital plus caffeine and ephedrine (9). Results were generally unsatisfactory.

Chlorpromazine reportedly has shown the ability to cause a definite decrease in motor activity without evidence of hypnosis (10). Dextro-amphetamine has long been recognized as an

Chlorpromazine and Dextro-amphetamine as Antidotes in Acute Antihistaminic Toxicity in Rats

By I. H. MAEL† and J. F. BESTER

Acutely toxic oral doses of a number of antihistaminics were determined in adult white rats of both sexes. Toxic symptoms included convulsive seizures which lasted some minutes and were periodically repeated, followed by generalized central depression, terminating in unconsciousness and death. Chlorpromazine and dextro-amphetamine were administered in that order, intraperitoneally, in varying quantities and at varying time intervals. It was found that, if chlorpromazine was administered at the onset of convulsions and dextro-amphetamine at the first signs of depression, the recovery rate of animals was quite high.

THERAPEUTICALLY useful antihistaminics were developed well over 20 years ago, and for most of that time their acutely toxic capabilities have been recognized. Just as the various antihistaminics vary in their potencies, so they vary in the frequency and severity of their toxic manifestations. Such variations are largely quantitative, however; and when they occur, the symptoms of acute toxicity are quite similar regardless of the drug used. Typically, drowsiness followed by nervousness, tremors, muscle twitching, delirium, and convulsions are observed along with respiratory depression and cyanosis and followed by unconsciousness and death (1).

Despite the fact that repeated efforts have been made to find satisfactory methods of treatment of acute poisoning with the antihistaminic drugs, methods of treatment continue to be difficult and not overly successful. The need for uniformly adequate antidoting has not lessened with the years; acute antihistaminic poisoning is not uncommon. Each month, for example, several such intoxications are reported in Arizona, totaling 27 for the year 1961 (2). The Poison Information Center in Los Angeles in the first 6 months of 1961 reported 42 acute poisonings from antihistaminics as such, plus an additional 65 due to antihistaminic-containing nonbarbiturate sedatives (3).

The difficulty in preventing poisoning with these drugs and in coping with them when they arise is complicated by the fact that dose effect relationships are inconsistent. For example, the oral LD_{50} of diphenhydramine in rats has been reported as 500 mg./Kg. (4), and of pyrilamine hydrochloride, subcutaneously in rats, as 150 mg./Kg. (5). Yet 400 mg. of diphenhydramine and 1.3 Gm. of pyrilamine, respectively, caused the deaths of two 2-year-old children (1). Connolloy reported serious intoxication of a $5^1/_2$-year-old child following ingestion of 12 mg. of chlorpheniramine (6).

Because antihistaminics typically cause toxic symptoms of mixed characteristics, single antidotes offer little hope of success. Various drugs and drug combinations have been tried and reported. These include histamine, atropine plus epinephrine, phenobarbital, caffeine, dextro-amphetamine (7), ether (8), phenobarbital plus caffeine and ephedrine (9). Results were generally unsatisfactory.

Chlorpromazine reportedly has shown the ability to cause a definite decrease in motor activity without evidence of hypnosis (10). Dextro-amphetamine has long been recognized as an

TABLE I.– ESTABLISHMENT OF DOSAGE AND ANTIDOTAL SCHEDULES

No. of Rats	Drugs Given	Dosage, mg./Kg.	When Given	Results
5	Diphenhydramine	250	...	Recurring epileptiform convulsions. All dead within 2 hours.
5	Chlorpromazine	50	...	Depression; three deaths.
5	Diphenhydramine Chlorpromazine	250 50	Simultaneously	Severe depression; four deaths.
5	Diphenhydramine	100	...	Excitation only; no convulsions.
5	Diphenhydramine Chlorpromazine	100 25	Simultaneously	Marked depression only.
5	Diphenhydramine Chlorpromazine	250 25	Simultaneously	Depression and death of all.
5	Diphenhydramine Chlorpromazine	250 15	Simultaneously	Depression and death of all.
5	Diphenhydramine Chlorpromazine	250 10	Simultaneously	Depression and death of all.
5	Diphenhydramine Dextro-amphetamine	250 0.15	Simultaneously	Convulsions; all dead in 2 hours.
5	Diphenhydramine Chlorpromazine	250 10	Simultaneously	Depression; all dead in 24 hours.
...	Dextro-amphetamine	0.75	Upon onset of depression	...
5	Diphenhydramine Chlorpromazine Dextro-amphetamine	250 10 1.25	... Simultaneously upon onset of symptoms	No convulsions, but excitation. Later depression with three deaths.
10	Diphenhydramine	250	...	All symptoms well controlled.
...	Chlorpromazine	10	Upon onset of convulsion	...
...	Dextro-amphetamine	0.625	Upon onset of depression	...
...	Dextro-amphetamine	0.3	As needed	...

analeptic. It therefore appeared logical to test their combined abilities in controlling the acute toxic manifestations of antihistaminic agents.

EXPERIMENTAL

White adult Wistar strain rats of both sexes were employed in the study. They were deprived of food and water for 24 hours prior to use. Antihistaminic drug doses were administered in aqueous solution by stomach tube. Concentration of solutions was adjusted so that all doses were of the same volume. Antidotal drugs were administered intraperitoneally, and again volumes were kept constant.

Diphenhydramine was used initially because its action and side effects seemed most typically representative of the group (11).

After antidoting, the animals were kept under observation for 72 hours.

Initial experimental procedures were designed to establish appropriate doses, dosage schedules, and sequence of drug administration. The results of this testing are shown in Table I.

Symptoms exhibited by those animals receiving only diphenhydramine followed closely the pattern described for humans. The time between drug administration and first symptoms varied from 8 minutes to 65 minutes. Excitation increased, particularly to such stimuli as noise and touch. Respiratory depression developed. Spontaneous movements increased, but gait became unsteady. A Straub reaction occurred in some animals. Muscle twitching steadily increased in intensity until full epileptiform convulsions ensued. Cyanosis was quite evident. Short periods of collapse separated convulsive episodes. Unconsciousness, accompanied by decreasing convulsions and increasing cyanosis, led ultimately to death.

Those animals receiving diphenhydramine plus chlorpromazine showed only the signs of depression; those receiving diphenhydramine plus dextro-amphetamine developed the signs of excitation more rapidly and more severely.

Because the last procedure shown in Table I appeared to be most effective, a total of 32 additional animals were treated by this routine. Diphenhydramine (250 mg./Kg.), was administered orally. As soon as convulsions became evident, chlorpromazine (10 mg./Kg.), was given intraperitoneally and as depression developed, dextro-amphetamine (0.625 mg./Kg.), was given intraperitoneally. If depression continued or returned, further doses of dextro-amphetamine (0.3 mg./Kg.), were given. In no instance was it necessary to administer more than three such additional doses.

DISCUSSION

All 32 animals showed the initial symptoms of toxicity, but only 22 developed convulsive seizures and only these were treated. The remaining ten animals recovered without treatment. Of the 22 treated, three failed to respond to chlorpromazine

and died during convulsions. Of the 19 whose convulsions ceased following chlorpromazine administration only one died during the ensuing depression while 18 recovered. Thus, of a total of 42 animals receiving 250 mg./Kg. of diphenhydramine, 32 developed symptoms requiring treatment and 28 of these recovered.

Limited studies of the effectiveness of this regimen in combating acutely toxic doses of several other antihistaminics were conducted. The protocol was unchanged, except that challenging doses of antihistaminics were altered to parallel potency. The results are reported below.

Tripelennamine.—Doses of 100, 150, 200, and 250 mg./Kg., respectively, were administered to eight rats. Chlorpromazine (4 mg./Kg. for each 100 mg./Kg. of tripelennamine), and dextro-amphetamine (0.25 mg./Kg. for each 100 mg./Kg. tripelennamine), served as antidotes. Only at the largest challenging dosage level was it necessary to give more than one dose of dextro-amphetamine. At this level one animal died. All others recovered.

Thenylpyramine.—Dosage and antidotal procedures were identical with those for tripelennamine. However, in all cases three doses of dextro-amphetamine were given. At each of the 200 and 250 mg./Kg. levels of thenylpyramine one animal died. All others recovered.

Chlorphenamine.—Challenging doses were 10, 15, 20, and 25 mg./Kg., respectively. Antidoting doses were 4 mg./Kg. of chlorpromazine and 0.25 mg./Kg. of dextro-amphetamine for each 10 mg./Kg. of chlorphenamine. A single administration of dextro-amphetamine sufficed in all cases and all animals recovered.

At the present time, these studies are continuing. Because current antidotal procedures against antihistaminic acute toxicity leave much to be desired, any improvement in method warrants further study. It is hoped that the combination of drugs herein described, or closely related drugs to be tested in our laboratory, will continue to show promise.

Solubility of Carbon Dioxide, Krypton, and Xenon in Lipids

By SHU-YUAN YEH and RICHARD E. PETERSON

The solubility of carbon dioxide, krypton, and xenon has been measured at one atmospheric pressure and at temperatures of 25, 30, 37, and 45° in olive oil, dog fat, human fats, and rat-pooled fat. The solubility of the gases studied in the oil and fats was found to decrease as the temperatures increased. Heats and entropies of solution have been calculated from linear dependencies of logarithm of the solubility with reciprocal absolute temperature. There seems to be a linear relationship between solubility, surface tension, and viscosity of the lipids.

THE PRIMARY objective of this study is to obtain some precise data on the solubility of krypton and xenon in lipids for calculation of body fat in a living body. Carbon dioxide was also included in this study because of the paucity of such data in lipids.

The solubilities of carbon dioxide, air, oxygen, nitrogen, and hydrogen in corn oil, in both unhydrogenated and hydrogenated lard, and in cottonseed oil have been measured at various temperatures by several investigators (1–3). They found that all the gases, with the exception of carbon dioxide, are increasingly soluble in the fat as the temperature rises. The solubility of carbon dioxide in human fat, dog fat, and rat fat at 38° was reported by Nichols (4). The solubility of xenon in olive oil and other aromatic oils, and of radioactive krypton and xenon in olive oil has been measured at 20, 22, and 37° by Steinberg and Manowitz (5), and Lawrence, *et al.* (6), respectively. Steinberg and Manowitz claimed their data, which are identical with Lawrence, *et al.*'s, to be accurate within 10%. It is obvious that these data are not sufficiently precise for calculating body fat in a living body.

EXPERIMENTAL

Materials Employed.—Research grade carbon dioxide, krypton, and xenon were purchased from Matheson Co. According to their specifications,

carbon dioxide contained maximum possible impurities of 0.3% mole of nitrogen, or carbon monoxide and oxygen; krypton contained maximum possible impurities of 0.04% nitrogen and xenon; and xenon contained maximum possible impurities of 0.02% nitrogen and 0.05% krypton.

Olive oil U.S.P. was purchased from Magnus, Mabee and Raynard Co., Inc.

Dog Fat.—Dog perineal, mesenteric, omental, and other adipose fats were extracted with petroleum ether C.P. (b.p. 36–65°). The fat was stored in a screw-capped jar under refrigeration after the ether was evaporated from the fat under vacuum at about 80° for several hours.

Human Fat.—Human omental fats, obtained from two different deceased patients, were marked as human fat No. 1 and No. 2, respectively, and treated as described under "Dog Fat." The human fats No. 1 and No. 2 seemed no different, except that the human fat No. 2 appeared to have more precipitate (stearine) than No. 1 at the temperature of about 23°.

Rat Fat.—Rat retroperitoneal, mesenteric, omental fats, and hair clipped skin, which was cut in about one square inch sections, were dried at about 80° under vacuum, crushed coarsely, and finally extracted with petroleum ether in a Soxhlet extractor. The procedure, as described under "Dog Fat," was then followed.

Measurement of the Solubility of Gases in Lipids.—The apparatus used is shown in Fig. 1. *A* is a modified Geffken's gas buret (7). Burets *B* and *C* include three 20-ml. bulbs and four 5-ml. bulbs, respectively. The volume of *D* is 5 ml. and is graduated to 0.01 ml. within a 45 cm. length. The volume of the ungraduated part of the modified buret, up to stopcock *3* and the volume of the graduated parts between the marks, were calibrated with mercury at 25° and 30°. The capacity of the connecting tube, from stopcocks *3* to *7*, and above the oil surface of the differential oil manometer, was determined by measuring the gas volume to fill the evacuated tube. The whole buret was enclosed in a water jacket and kept constant in temperature within ±0.05° by circulating water from a thermostat bath, which was equipped with a heating and refrigerating unit.

L is an absorption flask, of about 50 ml. capacity, with a standard taper male joint and a mercury sealing cup on the top. The volume of the absorption flask, containing the glass sealed stirring bar, *K*, up to stopcock *6*, was determined by measuring the gas volume to fill the evacuated flask at several experimental temperatures.

R is a differential oil manometer, which was charged with Octoil-S (2-ethyl-hexyl-sebacate) pump oil (saturated with the experimental gas), and was kept with the pure experimental gas above the oil surfaces through stopcocks *4* and *5* after it was charged.

The connection between the pressure reducing valve, gas tank, and copper tube was screw-tightened and sealed with wax. All joints and stopcocks in the whole system were tested from point to point to make sure there was no leakage before an experiment was conducted. The pressure from any part could be evacuated down to 50–100 μ, as measured with the McLeod gauge.

Manipulation.—Part of the prepared fat was

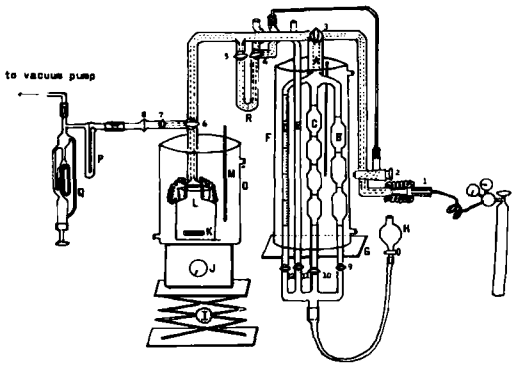

Fig. 1.—Apparatus for the determination of solubility of gases.

dried under stirring and vacuum at about 80° for about 12 hours (overnight) before it was charged to the absorption flask. All moisture or volatile materials should be evacuated under this treatment (8). The dried sample was charged to the cleaned and dried absorption flask and stirring bar by semimicro differential weighing. After the flask was assembled to the apparatus, the mercury in the gas buret was raised up to stopcock *3* and the air of the connecting system was evacuated. The gas was passed from the tank into the connecting tube and the gas buret and equilibrated with the temperature at least one hour before it was passed into the absorption flask. Water was circulated into the bath, *O*, and the oil was stirred and evacuated from the flask until no bubbles appeared. The apparatus was then disconnected from the vacuum pump. The gas pressure in the gas buret was adjusted to the ambient pressure and the initial reading was taken. Stopcocks *4* and *5* were turned off immediately after the reading was taken. Gas was passed into the absorption flask by turning stopcock *6* on and off occasionally until equilibrium was reached as indicated by the differential oil manometer for at least one-half hour. The temperature of the absorption flask was lowered as the thermoregulator was reset at a lower temperature. A series of solubilities at lower temperatures was obtained by this stepwise method.

This apparatus and technique have been tested with carbon dioxide in water. The solubility of carbon dioxide in water at 25, 30, 37, and 45° gave α = 0.7438, 0.7457; 0.6589, 0.6551; 0.5568, 0.5542; 0.4716, 0.4683, compared with the literature value (30) of 0.759, 0.665, 0.562, 0.479. The reproducibility of the data, obtained from this apparatus and technique, is within ±0.5%. It is believed that the apparatus and method described afford several advantages over other apparatus previously used. The liquid was constantly stirred in the absorption flask with a glass sealed magnet stirring rod, thus facilitating degassing as well as the saturation process and avoiding supersaturation. A considerable series of solubility data can be obtained with a single sample charged in the absorption flask. The solvent does not come in contact with mercury surfaces, thus eliminating contamination, or reaction, of the liquid with mercury. A water bath, whose temperature is easily controlled at a constant value, was used and the need for an elaborate air

thermostat was eliminated. The gas buret can be recharged for larger solubilities. It is easy to clean and dry the absorption flask and to charge the sample accurately, especially with the more viscous oil, fat, and tissue homogenates. In addition, an oil differential manometer was added to the system, thus increasing the sensitivity of the change of gas pressure within the gas buret and allowing one to easily determine whether the liquid was equilibrated with the gas or not.

The absorption coefficient, α, as defined by Bunsen (9), is given by the formula

$$\alpha = \frac{V_{o(a)}}{v}\frac{P_o}{P} = \left[\frac{V_{o(1)} + V_{o(C_1)} - V_{o(2)} - V_{o(C_2)} - V_{o(g)}}{v}\right]\frac{P_o}{(P_B - P_S)}$$

where $V_{o(a)}$, $V_{o(1)}$, $V_{o(C_1)}$, $V_{o(2)}$, $V_{o(C_2)}$, and $V_{o(g)}$ are the volumes of the gas absorbed, originally introduced in the gas buret and connecting tube, remaining in the gas buret, the connecting tube, and over the liquid surface in the absorption flask after equilibrium at standard temperature and pressure.

v is the volume of liquid at the saturation temperature, equal to the weight of liquid charged, divided by the density of the liquid at the saturation temperature. P is the partial pressure of the gas in mm. Hg. P_B is the corrected barometric pressure at the end of saturation. P_S is the vapor pressure of liquid at the experimental temperature and P_o is 760 mm. Hg.

Measurement of the Density of Lipids.—The densities of olive oil and fats were determined at 25 and 30° according to the standard procedure (10). The densities of olive oil and fats at the other temperatures studied were calculated according to the well established equation (11)

$$D_2 = D_1 - K(t_2 - t_1)$$

where D_2 and D_1 are densities of oil or fats at temperatures t_2 and t_1, respectively. K is equal to 0.00066, a universal constant for all the oil and fats, except the rat-pooled fat, where K, equal to 0.0007 was used to fit the data obtained at 25 and 30°.

Measurement of the Viscosity and Surface Tension of Lipids.—The viscosities of olive oil and fats were determined using a Hoeppler precision viscometer. The surface tensions of the oil and fats were measured with a Cenco du Nouy Surface and Interfacial Tensiometer, model 70545, using a platinum-iridium ring of 5.996 cm. mean circumference. The ratio of the radius of the ring to that of the wire of the ring (R/r) is 53.9. Measurements were made in 100-ml. beakers, having an inside diameter of approximately 5 cm. All experimental values obtained were corrected by applying the Zuidema and Waters correction equation (12). The surface tensions of the oil and fats were also measured with a Traube stalagmometer and calculated using the surface tension of benzene and toluene at 20 and 30° as reference. Five to eight determinations of the viscosity and surface tension were made for each sample. The temperature was maintained by circulation of water from a thermostat water bath.

RESULTS AND DISCUSSION

The solubility of carbon dioxide, krypton, and xenon in olive oil, dog fat, rat-pooled fat, human fats No. 1 and No. 2 was measured at temperatures of 25, 30, 37, and 45°. Each sample was measured three times. The error of those measurements will be predominantly due to the barometric pressure reading, which is assumed to have ± 0.5 mm. error and the temperature setup, which is assumed to have ±0.05° flexibility. Therefore, for the large solubility of xenon in lipids, it will cause an approximate 0.2% deviation, and for the smaller solubility of carbon dioxide and krypton, it will cause an approximate 0.15 and 0.1% deviation, respectively.

The results obtained from these measurements, in terms of Bunsen's absorption coefficient, α, and of Ostwald's solubility coefficient, L, are presented in Tables I, II, and III. The relationship between L and α is $L = \alpha T/T_o$. The literature values taken were reduced in terms of Bunsen's absorption coefficient for uniform comparison. The data obtained from the present study agree well with the data of Lawrence, *et al.* (6), who measured the solubility of radioactive krypton and xenon in olive oil at 22 and 37°.

It is very interesting to note that although the fatty acid compositions of the oil and fats differ, the respective solubilities of carbon dioxide, krypton, and xenon are essentially the same in the oil as in the fats. Using olive oil as a standard, the deviation of the solubility ratio of the fat to olive oil is ±0.15%. These findings agree with the data of Nussbaum (13), who reported that the solubilities of the highly fat-soluble inert gas, radon, in fatty acid and synthetic triglycerides, increases with an increase in the number of carbon atoms per mole of fatty acid. This holds up to 7 carbon atoms per molecule. There then "appears to be a slight, and possibly insignificant, decline in solubility as the number of carbon atoms per molecule increase above eight."

Effect of Temperature on Solubility.—For an isothermal process, the effect of temperature on solubility of gas in liquid can be obtained as follows (14)

$$\text{Log } L = \frac{-\Delta H^\circ}{2.303RT} + \frac{\Delta S^\circ}{2.303R}$$

Graphically, log L is a linear function of $1/T$. Heat of solution, ΔH°, and entropy of solution, ΔS°, can be calculated from the slope and intercept of the straight line. The solubility of carbon dioxide, krypton, and xenon in the oil and fats in present studies was found to decrease as temperature increased. In this respect, our data agree with the data of Clever, *et al.* (15), covering the solubility of krypton and xenon in nonpolar hydrocarbon solvents and perfluoromethylcyclohexane. Interestingly, Clever, *et al.* (15*a*), and Lanning (16) reported

that the solubility values of helium, neon, and argon in both nonpolar hydrocarbon solvents and polar organic solvents increased as the temperature rose. In plotting logarithms of the solubility of carbon dioxide, krypton, and xenon in the oil and fats against the reciprocal absolute temperature, straight lines were obtained. The heats and entropies of solution, calculated according to the least square method, are essentially the same in the oil as in the fats. The heat and entropy of solution for krypton is -1185 ± 46 cal./mole, -5.6 ± 0.10 cal./mole; for carbon dioxide -2713 ± 30 cal./mole, -8.5 ± 0.10 cal./mole; and for xenon -2273 ± 80 cal./mole, -6.4 ± 0.2 cal./mole, respectively.

Solubilities and Surface Tension of Solvent.—Assuming the energy change on transferring a gas molecule from the gas phase to the solution is the sum of two energy changes: (*a*) the energy expanded to create a cavity of gas molecule radius, γ, in the solvent and (*b*), an interaction energy that arises when the gas molecule is placed in the cavity; Uhlig (17) derived the following equation

$$\ln L = 4\pi r^2\sigma/kT + E/kT$$

which predicts that a linear relation should be formed between the logarithm of the Ostwald coefficient, L, and the solvent's surface tension, σ, assuming the interaction energy, E, is a constant for the various solvents, and K is Boltzmann's constant. Both Uhlig and Clever, *et al.* (15), found this relationship to be justified. However, Gjaldbaek (18) found this relationship does not hold for water to which surfactant has been added. Our data indicate that gas solubility increases with increasing surface tension of lipids. Plotting logarithm of Bunsen's absorption coefficient against the surface tension of the oil and fats at different temperatures, straight lines were obtained. This result is in contrast to the inverse relationship between surface tension and gas solubility in a variety of hydrocarbon solvents at one temperature deduced by Uhlig (17).

Solubility and Viscosity of Solvent.—Winkler (19) proposed an equation relating solubility to viscosity. The equation is

$$\frac{\alpha_1 - \alpha_2}{\alpha_1} = \frac{Z_1 - Z_2}{Z_1}\frac{\sqrt[3]{M_g}}{K}$$

in which Z_1 and Z_2 are the viscosities at temperatures t_1 and t_2. M_g is the molecular weight of the gas. For five diatomic gases in water, K was found to be nearly equal to the cube root of 54, three times the molecular weight of water. Steinberg and Manowitz (5) reported that the less viscous silicone oil (1 centistoke) had a 63% higher xenon solubility than the more viscous silicone oil (10 centistoke). Using our data and applying the Winkler equation, the calculated (average of 30 data) K values are 8.13, 21.7, and 13.8 for carbon dioxide, krypton, and xenon, respectively. Our data suggest that gas solubility decreases with a decrease in the viscosity of the lipids. Plotting logarithm of Bunsen's absorption coefficient against logarithm of viscosity of the oil and fats at different temperatures, straight lines were obtained. Our data are in agreement with the statement of Thorpe and Rodger (20). They stated that, "Winkler's conclusion must be changed to: for same gas, the decrease in solubility (not percentage decrease) is proportional to the corresponding decrease in viscosity, and further, for any gas, the factor of proportionality is greater for a greater molecular weight, but no simple relation exists."

The linear relationship obtained from a plot of the logarithm of the solubility, against the surface tension, or logarithm of the viscosity of the lipid, appears to be a cross-relation plot. These relations can also be considered as a relation between solubility and temperature, since the surface tension and viscosity change as temperature varies.

Past efforts to elucidate the forces and factors which determine solubility have provided information on surface tension (17), viscosity (5,19), and the empty volume (15*b*) of the solvent as being related to gas solubility. Since our studies involved lipid mixtures, it was impossible to calculate Bondi's empty volume (15*b*). Our data of surface tension and viscosity measurements of solvents as well as those reported in the literature (15,17) were ob-

tained with the solvents saturated with air. No data are available for measurements with degassed solvents or solvents saturated with the experimental gas.

The vapor pressures of the oil and fats, which are involved in the calculation of the solubilities, are negligible. The vapor pressures of olive oil and hydrogenated cottonseed oil have been reported as 0.001, 0.37, 0.01, and 0.04 mm. at 250°, respectively (21–23). Likewise, the natural fats have very low pressures.

The uncorrected surface tensions (maximum pull P) of the olive oil in the present study agree well with the data of Halpern (24), of Kaufmann and Kirsch (25), and of Canals, *et al.* (26). After applying the Zuidema and Waters correction (12), the surface tensions of the oil and fats of our present study were 10% lower than the data of Halpern, of Kaufmann and Kirsch, and of Canals, *et al.*, which we assumed are uncorrected. To further check this point, the drop weight method has been used to measure the surface tension of oils and fats over the same range of temperatures. For the purposes of comparison, uncorrected and corrected surface tensions of the lipids are presented in Table IV.

SUMMARY

1. The solubility of carbon dioxide, krypton, and xenon in olive oil, dog fat, rat-pooled fat, and human fats, has been measured at one atmosphere and at temperatures of 25, 30, 37, and 45°. The solubility of these gases in the above mentioned oil and fats is essentially the same, except for the rat-pooled fat, which is slightly less.

2. The heats and entropies of solution, calculated according to the least square method, are essentially the same in the oil as in the fats.

3. The viscosity and surface tensions of the oil and fats have also been measured at the temperatures of 25, 30, 37, and 45°. The density of olive oil and fats has been measured at the temperatures of 25 and 30°.

Pithecolobium dulce I

Isolation and Characterization of Legume Constituents

By S. K. NIGAM, R. K. GUPTA†, and C. R. MITRA

The seed and the mesocarp of the *P. dulce* legumes were worked up separately. The alcoholic extract of the seed powder yielded (I) a saponin, m.p. 175–181°; sapogenin provisionally named pithogenin, $C_{28}H_{44}O_4$, m.p. 207–208°; $[\alpha]_D^{17°}$ + 81°; elemental analyses and the spectrophotometric data suggest it to be a steroid genin; (II) a sterol-glucoside-B, m.p. 276–278°; the aglycone, m.p. 159–160°; and (III) a flavone, m.p. 298–306°. The seed fat (20%) similar to the leguminous fats in general, was purified and refined and the characteristics noted. The seed also yielded pure lecithin (0.7%). The sweet pulpy mesocarp yielded hexacosanol and a sterol-glucoside-A, m.p. 282–286°; aglycone, m.p. 136–138°. The sugar (66.5%; mostly glucose) and the amino acids, L-proline, L-leucine, L-valine, and asparagine were present.

PITHECOLOBIUM DULCE, Benth., N. O. *Leguminosae* (habitat: Mexico and Deccan peninsula of India), is extensively cultivated as a hedge plant. The shrub is hardy and stands frequent pollarding. It is reported in folk medicine to be useful in the treatment of leprosy (1). A few species of this genus are toxic. Alkaloidal principles have been isolated from *P. saman* (2). The bark and beans of another species, *P. lobatum* (3), are reported to cause dysuria and colic. As no work appears to have been carried out with the *P. dulce* legume, systematic chemical examination of the legumes was undertaken.

The ripe legumes consist of six to eight hard, black, flattened seeds embedded in a sweet pulpy mesocarp. The mesocarp appears to be edible, but it is reported to cause colic and gives a tickling sensation to mouth mucosa.

Constituents of Mesocarp

The residue from the alcohol-miscible free-flowing syrup, obtained from the mesocarp on extraction with nonpolar solvents, yielded a waxy fraction and a sterol-glucoside-A, m.p. 282–286° in yields of 0.8% and 0.02%, respectively. The fatty alcohol constituting the major portion of the waxy fraction was identified as hexacosanol. The sterol-glucoside-A yielded on hydrolysis an apparently new sterol-aglycone-A, m.p. 136–138°; the sugar moiety of the glucoside has been identified as glucose through paper co-chromatography in two solvent systems (*n*-butanol 4, acetic acid 1, water 5; and pyridine 1, ethyl acetate 2, water 2; aniline phthalate spray). The dextrorotation and other characteristics of the sterol-aglycone-A (Table I) differ from those of the sito-sterols and so also of the parent sterol glucoside-A from the β-D-glucoside of β-sitosterol (4).

The alcohol-soluble fraction of the mesocarp, when examined in aliquot portions, showed the presence of 66.5% of total sugar of which reducing sugar [estimated as glucose; iodometric (5)] was found to be 62.9% of the alcohol-soluble total solid. The paper chromatograms in two solvent systems (same as above) showed the presence of two spots of glucose and fructose but no sucrose was indicated. The alcoholic extract of the mesocarp yielded an osazone identical with authentic glucosazone. The amino acids, L-proline, L-leucine, L-valine, and asparagine were identified by paper chromatography (*n*-butanol 4, acetic acid 1, water 5; ninhydrin spray) while an additional spot in the chromatogram remained unidentified (6). The more soluble (aqueous) fraction of the alcoholic extractive showed the presence of traces of a saponin and a flavone.

Constituents of the Seed

In addition to 20% fixed oil, an appreciable quantity of a saponin (*ca.* 2.4%) as well as lecithin (*ca.* 0.7%) and a flavone (*ca.* 0.0001%) have been isolated from the seed for the first time. Generally, leguminous plants do not bear saponins, the subfamily, *Papilionoideae* (7) and the genera, *Albizzia* (8) and *Acacia* (9) being a few exceptions. An unidentified saponin has so far been indicated to be present in only one species of this genus, *P. cauliflorum* (10).

In order to isolate the different constituents of the seed under mild conditions and to avoid interference of the fat towards the isolation of the lipid-associates, such as phosphatides, powdered seed material was at first exhaustively percolated with alcohol and the fat in the residual meal was subsequently extracted with hydrocarbon solvent. The extractives from both the solvents were worked up separately. Concentration of the alcoholic extract deposited microcrystalline needles of sterol-glucoside-B, m.p. 276–278° (*ca.* 0.007%) which had glucose as the sugar component (confirmed through paper chromatography). The sterol-aglycone-B melted at 159–160°.

The mother liquor, freed of alcohol under reduced pressure, was macerated successively with excess of

TABLE I.—CHARACTERISTICS OF THE STEROLS OF *P. dulce* LEGUME

	Sterol-aglycone-A	Sterol-aglycone-B	Sterol from Phosphatidic Fraction
Melting point	136–138°	159–160°	159–160°
Optical rotation	+37°	−44°	...
I.R. (Nujol; cm.$^{-1}$)	3279, 2817, 2532, 1695, 1450, 1366, 1163, 1129, 1082, 1048, 966,	3380, 1713, 1641, 1600, 1323, 1254, 1216, 1197, 1155, 1141, 1103, 1067, 1047, 1040, 1018, 971, 939, 892, 869, 846, 832.	...
Acetate: m.p.	119°	176°	176°
$[\alpha]_D$	−16°	−16.4°	−16.0°
Benzoate: m.p.	192°	185°	185°

petrol-ether (b.p. 40–60°), ether, and ethyl acetate. Four well-defined fractions were obtained: (*a*) petrol-ether soluble, (*b*) petrol-ether insoluble and ether soluble, (*c*) ethyl acetate soluble but petrol-ether and ether insoluble and (*d*) alcohol-water soluble but insoluble in petrol-ether and ether. The dark green semisolid petrol-ether soluble fraction (*a*) on digestion with acetone yielded acetone-insoluble phosphatidic material, and the acetone solution yielded the glycerides. The phosphatidic fraction on usual purification and fractionation with alcohol yielded lecithin, $[\alpha]_D^{28°}$ + 14° (c, 1.0; $CHCl_3$); nitrogen, 1.0% (11), as the major component. The sterol, isolated from the unsaponifiable fraction of the phospholipids of the seed, was identical with the sterol-aglycone-B (Table I; the mixed melting points of both the sterols as well as of their acetates and the benzoates were undepressed). Obviously, the phytosterol present in the seed is different from that of the mesocarp. Further studies in the sterols are being continued.

The ether- and ethyl acetate-soluble fractions (*b*) and (*c*) yielded a very small quantity of a flavone melting at 298–306°; $\lambda_{max.}^{EtOH}$ 270, 349 mμ, $\lambda_{min.}^{EtOH}$ 248 mμ; color tests: magnesium hydrochloric acid, orange-red; ferric chloride, dark olive-green; and lead acetate, bright lemon-yellow; its acetate melted at 208–209°. The paper chromatogram (*n*-butanol 5, acetic acid 1, water 4) of the flavone confirmed it to be a single substance.

The dilute alcohol-soluble fraction (*d*) of the seed extractive manifested considerable frothing on removal of most of the solvent under reduced pressure and on usual working. This fraction yielded a saponin as a white foam, m.p. 175–181°; $[\alpha]_D^{25°}$ + 48.5° (c, 1.0; 60% alcohol). Graded hydrolysis with 2–6% hydrochloric acid of the saponin gave the genin which, after purification through and regeneration from its acetate, melted at 207–208°; $[\alpha]_D^{17°}$ + 81° (c, 1.0; $CHCl_3$). Persistent difficulty was encountered in isolating the genin in workable yield by conventional hydrolysis of the saponin. Mild hydrolysis even at stages did not give satisfactory results. The crude genin was mostly resinous and repeated attempts for purification through chromatography using different eluents met with little success. Crude genin acetate was, therefore, prepared under mild conditions and purified through chromatography. In either case, the ultimate yield of the genin was very poor. However, the purity of

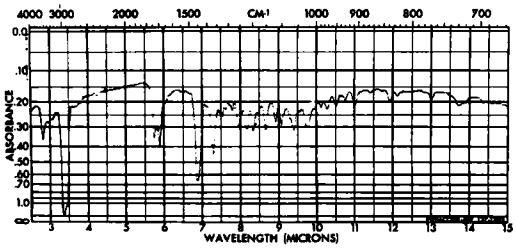

Fig. 1.—Spectrophotometric data of pithogenin.

the genin obtained through the acetate was ensured by repeated chromatography. A tentative molecular formula, $C_{28}H_{44}O_4$, was arrived at through elemental analyses of the genin and its acetate. The genin, provisionally named pithogenin, is LB-positive (pink to violet); with thionyl chloride-ferric chloride it develops orange to red; with thionyl chloride and antimony trichloride, a yellow to orange color (12). Spectrophotometric data of pithogenin [infrared bands at 3569, 2959, 2882, 1742, 1701, 1453, 1370, 1009, 988, 973, 951, 928, 907, 854, 839, cm^{-1} (Fig. 1); ultraviolet absorption (Fig. 2), $\lambda_{inflex.}^{EtOH}$ 260 mμ (ε, 772.4)] indicate the presence of hydroxyl and an isolated carbonyl group which suggest a similarity with steroid sapogenins (13, 14); further correlating data are being collected. The sugar moiety of the saponin was found to be gluclose identified through paper co-chromatography and confirmed through the mixed melting point of its osazone with glucosazone.

The seed fat obtained as a greenish oil was processed free from alcohol-soluble material, refined and bleached (15), and showed the following characteristics: color (Lovibonds, 1-cm. cell), 1.1 Y; sp. gr. (26°), 0.9064; $n_D^{26°}$, 1.4635; acid No., 0.2; sap. No., 183; iodine value (Wij's), 68; and unsaponifiable, 1.07%.

EXPERIMENTAL[1]

Examination of Mesocarp

Mature legumes used in this investigation were collected during May and June. Average weight of a legume was 25 Gm. and that of a seed, 110 mg.

[1] Melting points are uncorrected.

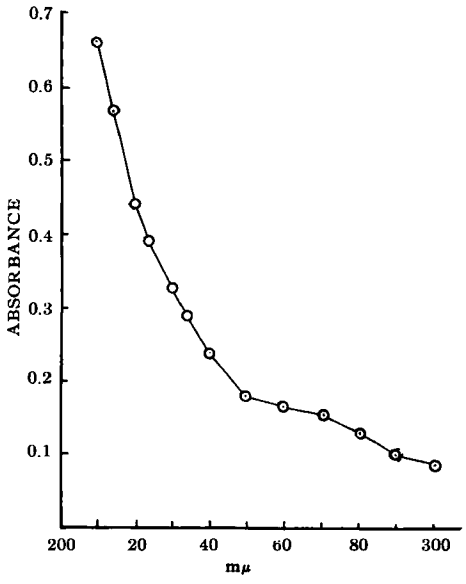

Fig. 2.—Ultraviolet absorption of pithogenin: $\lambda_{\text{inflex.}}^{\text{EtOH}}$ 260 mμ (ε, 772.4).

The seeds were separated from the pulpy mesocarp freed of brown brittle legume coat.

Sterol-glucoside-A.—Seventeen kilograms of air-dried sticky mesocarp was macerated and percolated with 21 L. alcohol five times until the alcohol insoluble material (*ca.* 10% of the air-dried mesocarp) was left behind mostly as fibrous residue. On removal of major bulk of alcohol by distillation under reduced pressure, a dark brown, syrupy, free-flowing mass was obtained which was successively extracted with 4 L. petrol-ether (b.p. 40–60°) three times, 4 L. ether three times, and 5 L. ethyl acetate twice. During this processing 3.1 Gm. sterol-glucoside-A separated out as microcrystalline shiny needles. It was further purified by crystallization from 2 L. of 90% alcohol and the final product melted at 282–286°, $[\alpha]_D^{25°}$ −20° (c, 1.0; pyridine).

Anal.—Calcd. for $C_{35}H_{60}O_6$: C, 72.9; H, 10.42. Found: C, 71.7; H, 10.7.

Sterol-aglycone-A.—Hydrolysis of 230 mg. of sterol-glucoside-A was effected by refluxing it with 75 ml. alcoholic hydrochloric acid (5% v/v) for 5 hours. After cooling the reaction mixture, the precipitated aglycone was taken up in ether and worked up. Its ether-petrol-ether mixture (90:10) was passed through a column of 5 Gm. alumina, and the resultant product on crystallization from alcohol-ether (90:10) yielded the sterol, m.p. 136–138°; $[\alpha]_D^{17°}$ + 37° (c, 1.0; $CHCl_3$).

Anal.—Calcd. for $C_{29}H_{50}O$: C, 84.07; H, 12.1. Found: C, 83.8; H, 12.2.

Sterol-aglycone-A-acetate.—The sterol aglycone-A (100 mg.) was dissolved in 1 ml. pyridine and refluxed with 2 ml. acetic anhydride for 8 hours at 110° and the reaction mixture worked up in the usual manner. The acetate was purified by passing its ether-petrol-ether (80:20) solution through a column of 5 Gm. alumina. When finally crystallized from alcohol it melted at 118–119°; $[\alpha]_D^{17°}$ − 16° (c, 1.0; $CHCl_3$).

Anal.—Calcd. for $C_{31}H_{52}O_2$: C, 81.53; H, 11.4. Found: C, 81.45; H, 11.2.

Sterol-aglycone-A-benzoate.—Fifty milligrams of the aglycone was taken up in 1 ml. pyridine and 2 ml. benzoyl chloride added dropwise. The reaction mixture was left at room temperature (20–35°) for 24 hours. The benzoate, on usual working and purification by passing its ethereal solution through a column of 4 Gm. alumina and on subsequent crystallization from alcohol, melted at 192°.

Anal.—Calcd. for $C_{36}H_{54}O_2$: C, 83.4; H, 10.4. Found: C, 83.1; H, 10.4.

Hexacosanol.—The ether, petrol-ether, and ethyl acetate soluble fractions, separately worked up, yielded 13.2 Gm. of waxy compound having a melting range of 65–75°. On repeated crystallizations from petrol-ether, hot alcohol, and alumina column chromatography using petrol-ether as eluent, the waxy compound yielded hexacosanol as a white microcrystalline product, m.p. 79°, mixed melting point with authentic sample 78–79°.

Anal.—Calcd. for $C_{26}H_{54}O$: C, 81.7; H, 14.1. Found: C, 81.5; H, 14.2.

Hexacosanol Acetate.—This was prepared with acetic anhydride and sodium acetate and after usual working and crystallization from alcohol it melted at 64°.

Anal.—Calcd. for $C_{28}H_{56}O_2$: C, 79.2; H, 13.2. Found: C, 79.3; H, 13.4.

Examination of the Seed

Powdered seeds weighing 8.8 Kg. were percolated at room temperature (15–30°) successively with 7 L. 95% alcohol four times and 7 L. petrol-ether (b.p. 60–80°) three times.

Sterol-glucoside-B.—The alcoholic percolate on concentration under reduced pressure below 50° deposited 0.8 Gm. microcrystalline sterol-glucoside-B which when recrystallized, as in the case of sterol-glucoside-A, melted at 276–278°; $[\alpha]_D^{25°}$ −25° (c, 1.0; pyridine).

Anal.—Calcd. for $C_{34}H_{58}O_6$: C, 72.6; H, 10.3. Found: C, 71.9; H, 10.2.

Sterol-aglycone-B.—Hydrolysis of 200 mg. of sterol-glucoside-B was carried out as in the case of sterol-glucoside-A to yield the sterol-aglycone-B which on usual purification and crystallization from alcohol melted at 159–160°; $[\alpha]_D^{36°}$ −44° (c, 1.0; $CHCl_3$).

Anal.—Calcd. for $C_{28}H_{48}O$: C, 84.0; H, 12.0. Found: C, 82.8; H, 12.0.

Sterol-aglycone-B-acetate.—Prepared in the usual way, the acetate on crystallization from alcohol melted at 176°; $[\alpha]_D^{34°}$ −16.4° (c, 1.0; $CHCl_3$).

Anal.—Calcd. for $C_{30}H_{50}O_2$: C, 81.4; H, 11.3. Found: C, 80.3; H, 10.6.

Sterol-aglycone-B-benzoate.—This was also prepared by heating the substance with benzoyl chloride in pyridine at 110° for 3 hours. The benzoate after repeated crystallizations from alcohol melted at 185°.

Anal.—Calcd. for $C_{35}H_{52}O_2$: C, 83.3; H, 10.3. Found: C, 82.7; H, 10.0.

The mother liquor after removal of the sterol-glucoside-B was further concentrated under reduced pressure when the resultant aqueous solution manifested copious frothing. It was ice cooled and extracted successively with 4 L. petrol-ether (b.p. 40–60°) three times, 4 L. ether three times, and 3 L.

ethyl acetate three times when finally a gelatinous mass was left in the aqueous phase. The petrol-ether soluble fraction obtained on removal of solvent finally *in vacuo* yielded 200 Gm. greenish residue which when repeatedly agitated with acetone, finally gave 54 Gm. acetone-insoluble phosphatidic material. The phospholipoid fraction was further extracted with cold alcohol and the residue, after removal of alcohol under reduced pressure, was purified by acetone and ether to yield 27.5 Gm. cream-white lecithin. The alcohol-insoluble phosphatidic material was then extracted with hot alcohol to yield a further quantity of 21.6 Gm. of alcohol soluble lecithin and 4.9 Gm. of alcohol-insoluble cephalin. Twenty-one grams of lecithin fraction on acid hydrolysis and subsequent saponification gave 0.8 Gm. of sterol, m.p. 160°. The acetate and the benzoate of the sterol were prepared as in the foregoing cases for comparison (Table I).

The ether and ethyl acetate soluble fractions yielded only the flavone.

Saponin and Pithogenin.—The gelatinous precipitate from the aqueous fraction of the seed extractive was dissolved in 300 ml. alcohol and 3 L. ether slowly added; the saponin precipitated out. On repeating the process with aliquot portions several times, 211 Gm. of the saponin was finally obtained as white foam, m.p. 175–181°, on removal of last traces of solvent *in vacuo*.

Saponin Acetate.—To a solution of 600 mg. of the saponin in 5 ml. pyridine, 25 ml. of acetic anhydride was added and the mixture left for 48 hours at room temperature (20–25°). The reaction mixture was next macerated with crushed ice and the precipitated saponin acetate was washed with water until free from acid. It was crystallized from alcohol and melted at 138°.

Pithogenin.—Ninety-four grams of saponin was hydrolyzed in 300 ml. of 90% alcohol with 2% hydrochloric acid at 20–35° for 24 hours. The cooled reaction mixture was extracted with 400 ml. of benzene. After separation of the benzene extract, the aqueous fraction was heated to 90° for 24 hours, cooled and extracted with benzene. The process was repeated five times with successive 1% increments in the acid percentage up to 6%. The combined benzene extract on usual working yielded 4.8 Gm. of crude genin as a dark brown product. Alumina column chromatography of 2.4 Gm. of genin using benzene-chloroform mixture (80:20) as the eluent yielded only 6 mg. of crystalline genin, melting at 195°, softening earlier.

Pithogenin Acetate.—This was prepared by heating 2.4 Gm. of the crude genin with 30 ml. of acetic anhydride and 8 Gm. of freshly fused sodium acetate on a steam bath for 72 hours. The reaction product was worked up in the usual manner. The genin acetate was eluted in a column of 20 Gm. alumina with ether-petrol-ether mixture (75:25) and six fractions were collected. The fourth and fifth fractions gave 120 mg. crystalline acetate which was further crystallized from ether-petrol-ether mixture (50:50) to yield a colorless acetate, m.p. 176–180°.

Anal.—Calcd. for $C_{28}H_{43}O_3 \cdot OCOCH_3$: C, 74.1; H, 9.5. Found: C, 73.8; H, 9.8.

Regeneration of Pithogenin.—Pithogenin was regenerated from 100 mg. of acetate with 10 ml. of 5% sodium carbonate solution at ordinary temperature. After usual working, 70 mg. of genin was obtained and purified by chromatography using ether-petrol-ether (85:15) as the eluent. Fifty milligrams of the product thus obtained were crystallized from ether-alcohol (90:10) to yield silky-white needles of pithogenin, m.p. 207–208°, $[\alpha]_D^{17°}$ +81° (c, 1.0; $CHCl_3$).

Anal.—Calcd. for $C_{28}H_{43}O_3OH$: C, 75.6; H, 9.6. Found: C, 75.3; H, 10.1.

Effect of Chlorination on the Anticonvulsant Activity of Phenobarbital

By EWART A. SWINYARD, JAMES T. MIYAHARA†, and LOUIS S. GOODMAN

The lethal doses, neurotoxic doses, anticonvulsant potencies, and protective indices for two chlorinated barbiturates, 5-(4-chlorophenyl)-5-ethylbarbituric acid (monochloro) and 5-(3,4-dichlorophenyl)-5-ethylbarbituric acid (dichloro), were determined in mice and the results compared with similar values concomitantly determined for phenobarbital. Chlorination was found to delay markedly the time for peak anticonvulsant effect and to prolong duration of action. The lethal dose for monochloro was somewhat larger and that for dichloro significantly smaller than that for phenobarbital. The minimal neurotoxic dose for monochloro was significantly larger than that for either dichloro or phenobarbital. All three compounds exhibited anticonvulsant activity in nontoxic doses. Although chlorination of phenobarbital had no significant effect on protective indices, the protective indices for dichloro tended to be somewhat higher than those for the other two compounds.

NUMEROUS compounds have been halogenated in an effort to improve their pharmacological properties and/or margins of safety. To cite a few examples, some anti-inflammatory steroids (1), thiazide diuretics (2), antihistaminics (3), and phenothiazine ataractics (4) have been subjected to such chemical manipulation. Therefore, the availability of two chlorinated analogs of phenobarbital provided an opportunity to study the effects of chlorination on the anticonvulsant activity of an agent with well-established clinical usefulness.

METHODS

Male albino mice (Carworth Farms, CF No. 1 strain) were used as experimental animals. They were maintained on Rockland mouse diet and allowed free access to food and water except for the short time they were removed from their cages for testing. The following anticonvulsant agents were studied: 5-(4-chlorophenyl)-5-ethylbarbituric acid (monochloro), 5-(3,4-dichlorophenyl)-5-ethylbarbituric acid (dichloro), and 5,5-phenylethylbarbituric acid (phenobarbital). All three agents were administered orally in 0.9% sodium chloride solution; but, in order to increase the solubility of the two chlorinated compounds, two drops of a 10% solution of sodium hydroxide were added to each 50 ml. of solvent.

Two tests were utilized to determine anticonvulsant potencies (ED_{50}'s): one electrical and one chemical. The test based on electrically induced convulsions measured the ability of the drug to prevent the hindleg tonic-extensor component of maximal electroshock seizures evoked by supramaximal current (MES test; 50 ma. alternating current, 0.2-sec. stimulus duration, corneal electrodes). The test based on chemically induced convulsions measured the ability of a drug to afford complete protection against seizures induced by the subcutaneous injection of pentylenetetrazol (Metrazol; 85 mg./Kg.; s.c. Met. test). The details of the techniques, the end points employed in mice, and the characteristics of the electroshock apparatus have been published elsewhere (5, 6). The dose lethal to 50% of animals within 24 hours after drug administration (LD_{50}) and the mean neurotoxic dose (TD_{50}) were also determined for each drug. The end point used to estimate minimal neurotoxicity was muscular incoordination, based on the inability of the animal to remain for one minute on a horizontal rod rotating at 6 r.p.m. Each drug was tested at the time of peak activity as measured by the maximal electroschock seizure (MES) test. For the determination of the ED_{50}, TD_{50}, or LD_{50}, groups of 8 to 12 mice were given various doses of drug until at least three points were established in the range between 0 and 100% seizure protection, minimal neurotoxicity, or lethality, respectively. The results obtained were plotted on logarithmic probability paper and a regression line was fitted to the plotted points by eye. From this plot of the data the respective ED_{50}, TD_{50}, LD_{50}, 95% fiducial limits, and protective index (P.I. = TD_{50}/ED_{50}) were calculated by the method of Litchfield and Wilcoxon (7).

RESULTS

The time courses of anticonvulsant activity, as measured by the MES test, are shown in Fig. 1.

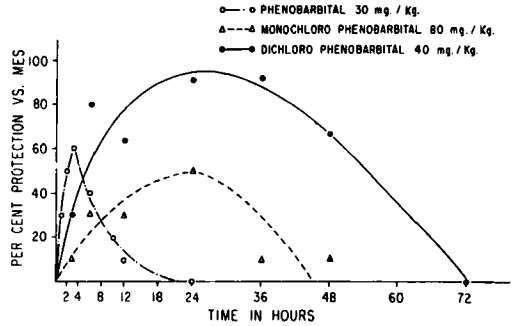

Fig. 1.—The anticonvulsant activity for phenobarbital and its monochloro and dichloro analogs.

Received July 16, 1962, from the Departments of Pharmacology, College of Pharmacy and College of Medicine, University of Utah, Salt Lake City.
Accepted for publication August 13, 1962.
This investigation was supported by research grants from the National Institute of Neurological Diseases and Blindness (B-381), National Institutes of Health, U. S. Public Health Service, and Eli Lilly and Co.
Presented to the Scientific Section, A.PH.A., Las Vegas meeting, April 1962.
† University of Utah Research Fellow, 1960–62.

TABLE I.—EFFECT OF CHLORINATION ON THE NEUROTOXICITY AND ANTICONVULSANT PROPERTIES OF PHENOBARBITAL

Drug	Toxicity		Anticonvulsant Activity			
			MES Test		s.c. Met. Test	
	LD_{50}[a] mg./Kg.	TD_{50}[b] mg./Kg.	ED_{50} mg./Kg.	P.I.	ED_{50} mg./Kg.	P.I.
Phenobarbital	250 (219–285)	70 (59–83)	27.5 (22.2–34.1)	2.55 (1.92–3.35)	24.5 (19.3–31.1)	2.86 (2.12–3.86)
Monochloro	290 (259–325)	215 (169–273)	125 (106–148)	1.72 (1.27–2.32)	60 (48–75)	3.58 (2.59–4.94)
Dichloro	190 (158–220)	84 (74–96)	26.5 (17.4–40.2)	3.16 (2.06–4.88)	18.4 (12.5–27.1)	4.57 (3.04–6.84)

[a] Twenty-four-hour observation period. [b] Minimal neurological toxicity. Values in parentheses are 95% fiducial limits.

As indicated in this figure, chlorination markedly altered the time of peak anticonvulsant activity and the duration of action. Phenobarbital exerted its peak anticonvulsant effect 3 hours after oral administration, whereas the two chlorinated analogs exhibited maximum activity 24 hours after such treatment. Thus, chlorination extended the time of peak response approximately eightfold. Chlorination of phenobarbital also prolonged the duration of anticonvulsant activity. As may be calculated from the figure, it required 5 hours for the peak anticonvulsant activity of phenobarbital to fall 50%, whereas it required 14 and 30 hours for the activity of monochloro and dichloro, respectively, to decline to a similar degree.

The LD_{50}'s, TD_{50}'s, anticonvulsant ED_{50}'s, and protective indices for the chlorinated compounds, in comparison with those for phenobarbital, are shown in Table I. Except for the LD_{50}'s, which were determined 24 hours after drug administration, all tests were conducted at the time of peak drug activity as derived from the figure (3 hours for phenobarbital and 24 hours for the two chlorinated compounds). Chlorination had no dramatic effect on the LD_{50} for phenobarbital. The LD_{50} for monochloro was somewhat higher than that for phenobarbital, whereas the LD_{50} for dichloro was on the borderline of being significantly lower. Dichloro and phenobarbital induced overt symptoms of neurotoxicity in 50% of the animals after doses of 84 and 70 mg./Kg., respectively, whereas the TD_{50} for monochloro was significantly larger (215 mg./Kg.) than that for phenobarbital.

With regard to anticonvulsant potencies, the data in Table I indicate that monochloro was considerably less potent than either phenobarbital or dichloro by the two tests utilized. For example, the ED_{50} and 95% fiducial limits by the MES test were 27.5 (22.2–34.1) mg./Kg. for phenobarbital and 125 (106–148) mg./Kg. for monochloro. However, there was no significant difference between the ED_{50} for phenobarbital and that for dichloro by either the MES test or the s.c. Met. test.

When compared on the basis of protective indices (P.I.'s), it may be seen that the two chlorinated compounds do not differ significantly from phenobarbital. The P.I.'s by the MES test were 1.72 and 3.16 for monochloro and dichloro, respectively, as compared to 2.55 for phenobarbital. On the other hand, the P.I.'s as determined from data obtained by the s.c. Met. test were 2.86, 3.58, and 4.57 for phenobarbital, monochloro, and dichloro, respectively. The P.I.'s of all three compounds were higher by the s.c. Met. test than by the MES test, but the difference was significant only for monochloro.

DISCUSSION

The data presented indicate that chlorination of phenobarbital extends the time required for the drug to exert peak anticonvulsant effect, prolongs the duration of anticonvulsant action, alters the ratio of the LD_{50} to the TD_{50}, and may modify anticonvulsant activity. These observations are in agreement with the findings of Gibson and coworkers (8) in rats. The time required to reach peak anticonvulsant activity was approximately 8 times longer for monochloro and dichloro than for phenobarbital. The time required for peak anticonvulsant activity to fall 50% was found to be 3 and 7 times longer for monochloro and dichloro, respectively, than for phenobarbital.

It is interesting to note that the dose fatal to 50% of mice within a 24-hour time period is not inextricably related to the dose which causes minimal neurological deficit in a similar percentage of animals. For example, the TD_{50} for monochloro was significantly higher than that for phenobarbital, whereas the LD_{50}'s for the two compounds were not significantly different. On the other hand, the LD_{50} for dichloro was significantly lower than that for phenobarbital, whereas the TD_{50}'s for the two compounds were not significantly different. Thus, the ratio of the LD_{50} to the TD_{50} is 3.6, 1.3, and 2.3 for phenobarbital, monochloro, and dichloro, respectively. This indicates that chlorination modifies the lethal dose and the minimal neurotoxic dose independently.

With respect to anticonvulsant activity, monochloro is significantly less potent than either phenobarbital or dichloro. There is no significant difference in the anticonvulsant activity of phenobarbital and dichloro as estimated by the two tests employed.

An evaluation of the P.I.'s derived from the experimental data indicates that all the drugs have a higher margin of safety by the s.c. Met. test than by the MES test, but this difference is significant only in the case of monochloro. The P.I. for monochloro is less than that for phenobarbital by the MES test and more than that for phenobarbital by the s.c. Met. test. On the other hand, the P.I.'s for dichloro tend to be higher by both tests than those for phenobarbital, but the differences are not statistically significant.

A study of structure-activity relations suggests that 4-phenyl chlorination of phenobarbital decreases minimal neurotoxicity and anticonvulsant potency, whereas 3,4-dichlorophenyl substitution has no significant effect on either minimal neurotoxicity or anticonvulsant potency. The chlorination of phenobarbital markedly prolongs the dura-

tion of anticonvulsant activity. The more favorable anticonvulsant effects were observed when the phenyl ring of phenobarbital was chlorinated in the 3,4 positions.

Preliminary clinical trial (9) suggested that dichloro in a dose of 300 mg. per day has no significant anticonvulsant activity in man. This was unexpected since the results presented herein for mice and those reported by Gibson, *et al.* (8), for rats indicate that, except for its temporal properties, dichloro has a profile of anticonvulsant action remarkably similar to that of phenobarbital. In view of this dichotomy and because of the well-known usefulness of phenobarbital in epilepsy, the clinical value of dichloro should be unequivocally determined in order to test the validity of current laboratory procedures for screening potentially useful antiepileptic drugs.

SUMMARY

The anticonvulsant potencies (ED_{50}'s) of two experimental chlorinated barbiturates, 5-(4-chlorophenyl)-5-ethylbarbituric acid (monochloro) and 5-(3,4-dichlorophenyl)-5-ethylbarbituric acid (dichloro), and for phenobarbital were determined in mice by the following two tests: maximal electroshock seizure pattern (MES) test and pentylenetetrazol (Metrazol) seizure threshold (s.c. Met.) test. In addition, the dose of each drug fatal to 50% of animals (LD_{50}) and the dose which induced minimal evidence of neurotoxicity in 50% of animals (TD_{50}) were determined. Protective indices (P.I. = TD_{50}/ED_{50}) were calculated. On the basis of the results obtained the following conclusions appear to be justified.

1. Chlorination of phenobarbital modifies the lethal dose independently of the minimal neurotoxic dose.

2. Chlorination extends approximately eightfold the time required for the drug to exhibit peak anticonvulsant activity and prolongs three- to sevenfold the time for anticonvulsant activity to fall 50%.

3. The chlorinated barbiturates exhibit anticonvulsant activity by both tests; *monochloro* is less potent than phenobarbital, whereas the anticonvulsant potency of dichloro is not significantly different from that of phenobarbital.

4. On the basis of P.I.'s, dichloro exhibits the most favorable indices, but the P.I.'s for dichloro are not significantly different from those for phenobarbital. The P.I.'s for all three compounds are higher by the s.c. Met. test than by the MES test, but this difference is significant only in the case of monochloro.

Structural Studies on the Triterpene Obliquol

By LEMONT B. KIER and WALLACE S. BREY, JR.

Oxidation studies have indicated that the two hydroxyl groups of obliquol are secondary, one of which exhibits some hindrance as in the Oppenauer oxidation. Nuclear magnetic resonance studies have supported the chemical evidence that the second hydroxyl group is in the 12 position in obliquol. The C-18 methyl peak of obliquol diacetate has shifted downfield from the corresponding peak in lanosterol acetate due to perturbation by the 12-acetyl group. Therefore, it was concluded that obliquol has the structure I. The complete NMR spectra of obliquol, lanosterol, and their acetates are interpreted.

IN A PREVIOUS communication (1) there was reported the isolation of a new triterpene, obliquol (I), from the fungus, *Poria obliqua* (Bres.). At that time, obliquol (I) was shown to be a tetracyclic triterpene with two hydroxyl groups. It was shown to possess two double bonds, one of which was shown to be unreactive and assigned to the 8,9 position. The possibility, based on infrared data, was proposed that one of the hydroxyl groups was primary. This has since been found to be a secondary hydroxyl group. Additional studies on the structure of obliquol comprise the contents of this communication.

tion of anticonvulsant activity. The more favorable anticonvulsant effects were observed when the phenyl ring of phenobarbital was chlorinated in the 3,4 positions.

Preliminary clinical trial (9) suggested that dichloro in a dose of 300 mg. per day has no significant anticonvulsant activity in man. This was unexpected since the results presented herein for mice and those reported by Gibson, *et al.* (8), for rats indicate that, except for its temporal properties, dichloro has a profile of anticonvulsant action remarkably similar to that of phenobarbital. In view of this dichotomy and because of the well-known usefulness of phenobarbital in epilepsy, the clinical value of dichloro should be unequivocally determined in order to test the validity of current laboratory procedures for screening potentially useful antiepileptic drugs.

SUMMARY

The anticonvulsant potencies (ED_{50}'s) of two experimental chlorinated barbiturates, 5-(4-chlorophenyl)-5-ethylbarbituric acid (monochloro) and 5-(3,4-dichlorophenyl)-5-ethylbarbituric acid (dichloro), and for phenobarbital were determined in mice by the following two tests: maximal electroshock seizure pattern (MES) test and pentylenetetrazol (Metrazol) seizure threshold (s.c. Structural Studies on the Triterpene Obliquol

By LEMONT B. KIER and WALLACE S. BREY, JR.

Oxidation studies have indicated that the two hydroxyl groups of obliquol are secondary, one of which exhibits some hindrance as in the Oppenauer oxidation. Nuclear magnetic resonance studies have supported the chemical evidence that the second hydroxyl group is in the 12 position in obliquol. The C-18 methyl peak of obliquol diacetate has shifted downfield from the corresponding peak in lanosterol acetate due to perturbation by the 12-acetyl group. Therefore, it was concluded that obliquol has the structure I. The complete NMR spectra of obliquol, lanosterol, and their acetates are interpreted.

IN A PREVIOUS communication (1) there was reported the isolation of a new triterpene, obliquol (I), from the fungus, *Poria obliqua* (Bres.). At that time, obliquol (I) was shown to be a tetracyclic triterpene with two hydroxyl groups. It was shown to possess two double bonds, one of which was shown to be unreactive and assigned to the 8,9 position. The possibility, based on infrared data, was proposed that one of the hydroxyl groups was primary. This has since been found to be a secondary hydroxyl group. Additional studies on the structure of obliquol comprise the contents of this communication.

Received June 28, 1962, from the University of Florida College of Pharmacy, Gainesville.
Accepted for publication September 11, 1962.
This investigation was supported by grant number CY-5453 from the National Institutes of Health, United States Public Health Service.

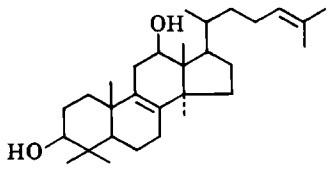
In an effort to elucidate the character of the double bond assumed to be in the side chain, obliquol was subjected to ozonolysis. The isolation of acetone from this treatment proved the presence of the isopropylidene group in the side chain.

Several oxidative procedures were attempted *in order* to locate the hydroxyl groups of obliquol. The Oppenauer oxidation, using various conditions, gave the same compound which, however, could not be thoroughly purified. The infrared spectrum indicated that this compound was an hydroxy ketone. The compound gave a positive Zimmermann test indicating a 3-keto group. The resistance of the second hydroxyl group to Oppenauer oxidation gave the first indication that obliquol contained two secondary hydroxyl groups, one of which was partially hindered.

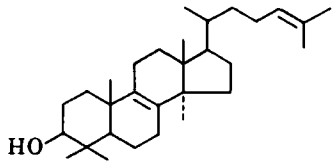
Subsequent titration of obliquol with a standard acidic chromium trioxide solution confirmed that both hydroxyl groups were secondary since almost exactly two equivalents of oxidant were consumed, indicating the formation of two keto groups by this method.

Oxidation with chromium trioxide in acetic acid gave an impure product which showed no hydroxyl group absorption in the infrared but possessed a strong single band at 1715 cm.$^{-1}$, indicative of one or more keto groups in six-membered rings. This finding eliminated the five-membered D ring as the sight for the second oxygen function (2). Therefore, the positions that this second hydroxyl group could occupy were the 6, 7, 11, or 12. Position 1 could be eliminated since Oppenauer oxidation of a 1,3 dihydroxy system results in the loss of the 1-hydroxyl group (3). A 2-hydroxyl group was eliminated as a possibility since oxidation to an α-diketo system would be detected in the infrared spectrum.

The 7 or 11 hydroxyl group possibilities were eliminated since they would be allylic to the 8,9 double bond, hence quite susceptible to oxidation (4). The 6 α or 6 β hydroxyl groups have also been shown to be susceptible to Oppenauer oxidation (5). This narrowed the possibilities to the two epimeric 12 positions. In the case of the triterpene, polyporenic acid A, the 12 α hydroxyl group is sufficiently hindered to resist benzoylation (6). Obliquol formed a dibenzoate readily, which narrowed the possibilities to the 12 β position for the second hydroxyl group. This position is consistent with the findings but more conclusive evidence was derived from nuclear magnetic resonance data.



I



II

The resonances of obliquol (I), lanosterol (II), and their acylated products are discussed in turn, the numbers cited being tau values (see Fig. 1). Starting at low field there appears first the resonances of the olefinic hydrogens on the side chain as a broad triplet between 4.79 and 4.95. The exact value of the shift in obliquol diacetate, where another peak is superimposed on this one (the peak for the H on the same C as the acetoxy group) is in doubt. The H's on the same C as an OH group in the two triterpenes appear next. The C-3 H is at 6.69 and 6.80, while the other H on a C—OH in obliquol falls at 6.29. Acetylation shifts these peaks downfield by about 1.2 p.p.m. In obliquol diacetate they appear at 4.95 (nearly coincident with the olefinic hydrogen peak), and 5.43, and in lanosterol acetate at 5.52. The acetyl methyls appear at 7.85, 7.88, and 8.00. The two terminal methyls appear as a broadened pair of peaks between 8.3 and 8.5 in all compounds except obliquol diacetate. In this derivative there appears at this point in the spectrum a single broad hump with an area which corresponds to three methyl groups. We interpret this as the superposition on the pair of peaks of the isopropylidene methyls with a methyl group of which the chemical shift is reduced by the presence of the second hydroxyl group in obliquol. If this hydroxyl group is at the 12 position, then the nearest methyl group is the 18 methyl group. In corroboration of this, the C-18 peak appears in lanosterol at 9.32 and in lanosterol acetate at 9.35, but in obliquol and obliquol diacetate there are no methyl groups with chemical shifts this high.

The remaining methyl peaks cannot be definitely assigned. One of the peaks, that corresponding to the side chain methyl, should be a doublet. In lanosterol, half of the doublet can be seen at 9.10 and the other half is presumed to

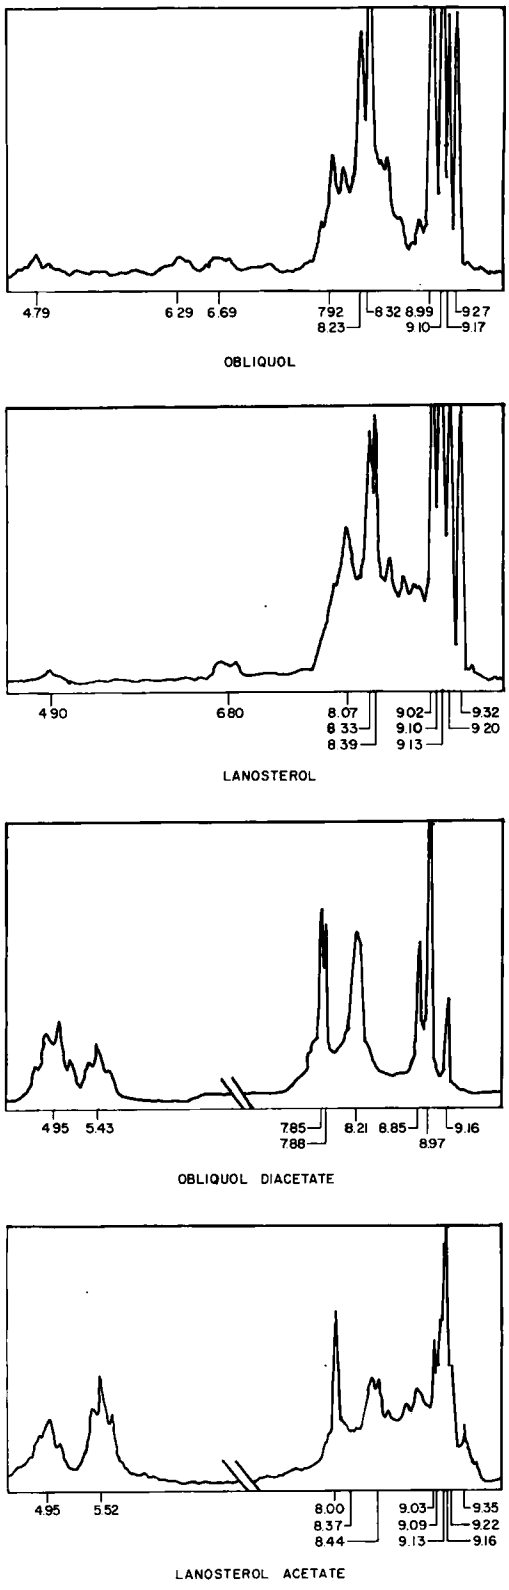


Fig. 1.—Nuclear magnetic resonance spectra of obliquol, lanosterol, and their acetylated products. Numbers are expressed as tau values.

be part of the peak at 9.02, the remainder of this peak corresponding to two other methyls, one of which is probably C-19. The remaining three ring methyl groups, at positions 4 and 14 are at 9.02 and 9.13.

In lanosterol acetate, the C-18 methyl group appears at 9.35, while one other methyl group is clearly defined at 9.03 and the remaining peaks are overlapping in the region surrounding 9.16. The principal effect of acetylation would be expected for the two methyls at position 4, and they seem to have been shifted upfield.

In obliquol, individual methyl peaks appear clearly defined at 9.10, 9.17, and 9.27. Two methyls appear in the resonance at 8.99, one of which is probably C-19. The doublet for the side chain methyl is apparently half in the peak at 8.99 and half in the peak at 9.10. In obliquol diacetate, that which is probably C-19 appears at 8.85, and what is probably the C-18 methyl group appears at 9.16. The remaining methyl groups appear in an unresolvable band at 8.97.

In consideration of the finding of the interference with the C-18 methyl hydrogens by one of the acetyl groups of obliquol diacetate, we conclude that this acetyl group is on the proximate C-12 position. Furthermore, from a study of a model this acetyl group in the 12 position must be β oriented in order to be in a position to interact with the β oriented C-18 methyl hydrogens. This finding was completely consistent with all of the chemical evidence and therefore led us to provisionally assign structure I to obliquol.

EXPERIMENTAL

Nuclear magnetic resonance spectra were determined with a Varian 4300-C spectrometer operating at 56.4 megacycles. The samples were examined as saturated solutions in deuterated chloroform. Chemical shifts were calculated from audio side bands applied by an oscillator with frequency continuously monitored by a Hewlett-Packard 523B counter. The shifts are expressed in tau values computed by using the H of the chloroform in the solvent as an internal reference and adding 2.72 p.p.m. to the shift observed from this reference. Several spectra were also referenced with external benzene, which falls 0.86 p.p.m. to high field of the chloroform peak. In the spectra of the acetates, the regions at low field were run at higher gain than the regions at high field.

Ozonolysis of Obliquol Diacetate.—One hundred milligrams of obliquol diacetate in 20 ml. of carbon tetrachloride was subjected to a stream of 3% ozonized oxygen at −5° for 30 minutes. The solution was then treated with water and powdered zinc and finally steam distilled into an acidic solution of 2,4-dinitrophenylhydrazine. The phenylhydrazone that formed was crystallized, m.p. 122–124°. A mixed melting point with authentic

acetone 2,4-dinitrophenylhydrazone gave no depression.

Oppenauer Oxidation of Obliquol.—A solution of 0.4 Gm. of obliquol in 5 ml. of cyclohexanone and 10 ml. of toluene was treated with 0.8 Gm. of aluminum isopropoxide and refluxed for 2 hours. This solution was cooled and 5 ml. of 10% sulfuric acid added. The solution was then extracted with ether and the residue recrystallized repeatedly from methanol, m.p. 160–165°. Further attempts to purify this compound were unsuccessful. The above procedure was repeated using aluminum tertiary butoxide. It was refluxed for 9 hours. A substance was obtained that was identical to the one obtained by the previous method. It also resisted further purification. Both compounds gave identical infrared spectra. In both cases the compounds gave positive Zimmermann tests but no absorption in the ultraviolet. The infrared spectra showed bands at 3450 cm.$^{-1}$ (O—H), 1715 cm.$^{-1}$ (keto carbonyl), and 1040 cm.$^{-1}$ (C—O).

Chromic Acid Titration of Obliquol.—Obliquol (221 mg., 0.0005 mole) was titrated with a chromium trioxide solution in sulfuric acid that was prepared according to the procedure described by Curtis (7) and Bowers (8). The volume of solution consumed was equivalent to the conversion of 1.95 hydroxyl groups to carbonyl groups.

Chromic Acid–Acetic Acid Oxidation of Obliquol.—A solution of 100 mg. of obliquol in 10 ml. of benzene was treated with 130 mg. of chromium trioxide in 1.5 ml. of water and 3 ml. of glacial acetic acid and allowed to stand for 18 hours. The benzene solution was separated, concentrated, and placed on an alumina column. A small fraction that was eluted with benzene-methanol remained as a viscous oil. The infrared spectrum showed no hydroxyl group absorption but showed a strong carbonyl peak at 1715 cm.$^{-1}$. The substance gave a positive Zimmermann test.

New Method for Location of Organic Acids on Paper Chromatograms

By GILBERT C. SCHMIDT, CARL FISCHER†, and JOHN M. McOWEN

A modification of Riegler's nitrite test, employing betanaphthol, sodium nitrite, and naphthylamine or sulfanilamide, has been adapted for location of organic acids on paper chromatograms. Most of the twelve acids tested are detectable at a level of 5 mcg. or less although 50–75 mcg. are required in isolated cases. The reagent may be used with all four of the common solvent systems employed, with no notable differences in sensitivity. The sensitivities of this reagent and four previously described detection reagents have been compared. The new reagent is more sensitive than the best of the previously described procedures.

The introduction of paper chromatography as a method for identifying organic acids (1) has been followed by the use of numerous detection reagents. The acid-base indicators have been most frequently used, but colors are transient, complete solvent removal is essential, and it is difficult to distinguish true spots from artefacts. Better results have been reported if the indicator is added to the solvent system (2, 3), but this modification has not been generally accepted. Potassium permanganate, usually used to locate unsaturated and hydroxy compounds (4), has been combined with indicators to produce a general location reagent. The reported sensitivity is poor, but final colors and development times vary for different acids. The combined reagent has therefore been recommended to distinguish acids having similar R_f values (5).

The acid catalyzed condensation of aniline and reducing sugars to form colored compounds has been used to locate both sugars (6) and acids (7). Sugars are detected with an aniline-phosphoric acid mixture, while acids are detected with an aniline-xylose mixture. The aniline-xylose reagent and acridine appear to be the most useful of the remaining detection reagents (7), but both are carcinogenic and little has been written about them.

Nessler's reagent and starch-iodine-iodate reagent have been used to locate the ammonium salts of acids, but neither is a satisfactory general location reagent (7, 8). Aqueous ferric chloride

New Method for Location of Organic Acids on Paper Chromatograms

By GILBERT C. SCHMIDT, CARL FISCHER†, and JOHN M. McOWEN

A modification of Riegler's nitrite test, employing betanaphthol, sodium nitrite, and naphthylamine or sulfanilamide, has been adapted for location of organic acids on paper chromatograms. Most of the twelve acids tested are detectable at a level of 5 mcg. or less although 50–75 mcg. are required in isolated cases. The reagent may be used with all four of the common solvent systems employed, with no notable differences in sensitivity. The sensitivities of this reagent and four previously described detection reagents have been compared. The new reagent is more sensitive than the best of the previously described procedures.

The introduction of paper chromatography as a method for identifying organic acids (1) has been followed by the use of numerous detection reagents. The acid-base indicators have been most frequently used, but colors are transient, complete solvent removal is essential, and it is difficult to distinguish true spots from artefacts. Better results have been reported if the indicator is added to the solvent system (2, 3), but this modification has not been generally accepted. Potassium permanganate, usually used to locate unsaturated and hydroxy compounds (4), has been combined with indicators to produce a general location reagent. The reported sensitivity is poor, but final colors and development times vary for different acids. The combined reagent has therefore been recommended to distinguish acids having similar R_f values (5).

The acid catalyzed condensation of aniline and reducing sugars to form colored compounds has been used to locate both sugars (6) and acids (7). Sugars are detected with an aniline-phosphoric acid mixture, while acids are detected with an aniline-xylose mixture. The aniline-xylose reagent and acridine appear to be the most useful of the remaining detection reagents (7), but both are carcinogenic and little has been written about them.

Nessler's reagent and starch-iodine-iodate reagent have been used to locate the ammonium salts of acids, but neither is a satisfactory general location reagent (7, 8). Aqueous ferric chloride

Received March 26, 1962, from the University of Cincinnati College of Pharmacy, Cincinnati, Ohio.

† Present address: University of Rochester School of Medicine, Rochester, N. Y.

may be used to locate hydroxy acids (4), but it is highly insensitive and is not generally applicable. A variety of diazonium salts are useful in selected instances, particularly for the detection of phenolic acids (8–10), but many metabolically important acids do not give colors. The same difficulty arises with ammonium vanadate, dinitrophenylhydrazine, *p*-dimethylaminobenzaldehyde, phosphomolybdic acid, potassium ferrocyanide-ferric ammonium sulfate, and dichlorophenolindophenol.

Chloranilic acid, previously used to detect inorganic ions and certain nitrogenous compounds, has been introduced as a highly sensitive reagent for locating sodium salts of organic acids (11). Volatile acids are stabilized and tailing is reduced, but buffered papers or chelating agents cannot be used. A neutral or basic solvent is required and the paper must be thoroughly dried to prevent interference by "ghost" spots.

Riegler's nitrite test (12) has been modified by the authors and introduced as a location reagent for acids (13). In Riegler's test, nitrites give a color with alphanaphthol and sodium naphthionate in acid solution. Acids give a positive test in the presence of alphanaphthol, sodium naphthionate, and sodium nitrite. Both tests result in a deep red color and apparently depend on the formation of an azo dye. We reasoned that paper chromatograms sprayed with a mixture of alphanaphthylamine and betanaphthol, followed by a sodium nitrite spray or dip, should form nitrous acid only in those spots occupied by migrated free acids. Consequently, only the acid spots should undergo diazotization, coupling, and color development.

The original method is highly sensitive and has been successfully used for more than a year, but replacement of the highly carcinogenic alphanaphthylamine is desirable. This report describes our original procedure and a recent modification in which sulfanilamide replaces the carcinogen. Sensitivities of these two procedures and some other available methods are compared.

EXPERIMENTAL

Standard Solutions.—Choice of reference acids was based on our own interests and on general biochemical importance. Commercial acids of the best available grade were used without further purification. Stock aqueous 1% solutions were prepared as needed. The quantity of acid applied to each spot was controlled by dilution of the stock solutions and by varying the sizes of micropipets throughout the range 1–25 μl.

Chromatogram Development.—Acids were chromatographed on Whatman No. 1 paper. Areas of applied spots were controlled by rate of sample delivery and by drying with unheated air from a hair dryer during application of the samples. Heat was avoided because some of the acids are unstable. Air dried chromatograms were then developed for the prescribed period by the ascending method.

Solvent Systems.—Several common solvent systems were chosen to determine if solvent composition would severely limit use of the alpha naphthylamine or sulfanilamide location reagents. Butanol-acetic acid-water (7), propanol-eucalyptol-formic acid-water (14), ethanol-ammonia-water (15), and an 8:1:1 propanol formic acid-water system were used for this purpose. The propanol-formic acid-water system was used for comparing sensitivities of the proposed reagents and several previously described reagents. Solvents were freshly prepared each day and were equilibrated for 1 hour before transferring to the chromatographic tanks. An additional 1 hour equilibration preceded introduction of the chromatograms. Chromatograms were routinely dried at room temperature for at least 4 hours, but in most instances location reagents could be applied after drying for 1 hour.

Alphanaphthylamine Reagent.—Chromatograms were sprayed with a solution of alphanaphthylamine (1%) and betanaphthol (0.5%) in 95% ethanol. They were then air dried at room temperature until the ethanol had evaporated, but for no longer than 1 hour. Dried chromatograms were then sprayed with 1% aqueous sodium nitrite. Acids immediately appear as dark orange spots on a pale pink background. Intensity of the background color increases on standing but is less pronounced if the naphthylamine-naphthol solution is allowed to age for a day or two before use. This solution is stable for at least two weeks at room temperature, but the sodium nitrite solution is preferably prepared just before use since it is stable for only 12 hours at room temperature.

Sulfanilamide Reagent.—Chromatograms were treated as described for alphanaphthylamine reagent, except that the initial spray contained 2% sulfanilamide and 0.5% betanaphthol in 95% ethanol. Following the sodium nitrite spray, acids immediately appear as orange spots on an almost colorless background. Background color does not appreciably increase when chromatograms are stored for several weeks. The use of aged reagent has no advantage.

Other Location Reagents.—Four previously described location reagents were chosen for sensitivity comparisons. Aniline-xylose (7), acridine (7), and combined indicator-permanganate reagent (5) were prepared and used as previously described. Bromcresol green reagent (16) was purchased in spray cans.[1]

RESULTS AND DISCUSSION

Preliminary Experiments.—Filter paper circles were spotted with 10 μl. quantities of tropic acid solutions, representing different amounts of acid. These test plates were then developed under a variety of experimental conditions to establish the feasibility, potential sensitivity, and certain requirements for color development.

[1] "Spraytec" reagents, available from Aloe Scientific Co., St. Louis, Mo.

In support of the assumption that diazotization and coupling are responsible for color development, a variety of diazotizable amines and a variety of coupling phenols or amines produced colors. Of the combinations tested, the naphthylamine-naphthol and sulfanilamide-naphthol reagents gave the best results. Only these combinations were further studied.

These experiments also disclosed that the diazotizable amine and the coupling agent must be applied as a single solution, that the sodium nitrite must be freshly prepared to prevent intense coloration of the entire chromatogram, that the use of ice cold reagents decreases sensitivity, and that application of reagents by spraying is preferable to dipping.

Sensitivity of the Proposed Method.—Preliminary estimates of sensitivity were obtained from the previously described spot plates, but these tests were confined to tropic and mandelic acids and did not involve migration. Accurate sensitivity comparisons were therefore conducted under more probable experimental conditions.

Twelve commonly encountered aliphatic acids, and the propanol-formic acid-water system were arbitrarily chosen. Graded amounts of each acid were applied to a series of chromatograms. The chromatograms were then developed and were sprayed with naphthylamine or sulfanilamide reagent as previously described. Sensitivities shown in Table I represent the lowest levels at which color could be visually detected when chromatograms were held against a window and viewed by daylight. At levels somewhat higher than those recorded, spots were immediately visible after spraying with sodium nitrite.

TABLE I.—SENSITIVITIES OF NAPHTHYLAMINE AND SULFANILAMIDE REAGENTS

Acids Tested[a]	Mcg. of Acid Detected per 10 μl. Spot: Sulfanilamide	Mcg. of Acid Detected per 10 μl. Spot: Naphthylamine
Citric	2	7
Lactic	2	4
Succinic	2	3
Malic	2	5

Glyoxylic	2	1
Tartaric	5	9
α-Ketoglutaric	2	4

[a] All chromatograms were developed in propanol-formic-water.

The reported sensitivities were further checked by chromatographing mixtures of acids in propanol-water-formic acid. Mixtures were prepared as stock solutions containing 50 mcg. of each component in 10 μl. of solution. Each mixture, and dilutions of it, were spotted on a single chromatogram which was then developed and sprayed as previously described. Figure 1 shows a representative chromatogram. It is apparent that the individual components of a mixture are visible in a photograph when the concentrations are approximately twice the minimal detectable levels shown in Table I. The same situation occurs with chromatograms of single acids, consequently sensitivities are not appreciably altered when a mixture is separated.

Fig. 1.—Representative separation of acid mixture at different concentration levels: solvent, propanol-formic acid-water (8:1:1); acids in order of increasing R_f value, tartaric, malic, succinic, and mandelic; acid concentrations, from left to right, 50, 25, and 10 mcg. of each component.

Although this report is not primarily concerned with separation techniques, it may be noted that the propanol-formic acid-water system produces excellent separation of many acids. Spots are compact and there is no tailing.

Comparative Sensitivities.—Sensitivities of the naphthylamine and sulfanilamide reagents were compared with four previously described general acid location reagents. For the sake of simplicity, all comparisons were made after migration in the propanol-formic acid-water system. Sensitivities of the previously described reagents for the twelve acids used in this study are shown in Table II. The data in Table II provide a controlled comparison of these four methods and, in conjunction with data in Table I, illustrate the excellent sensitivity of the new reagents.

In obtaining these data, it was noted that the degree of increased sensitivity obtained by reading acridine stained chromatograms by ultraviolet light is extremely time dependent. The more quickly chromatograms are read, the greater is the increase in sensitivity. Tabulated values were obtained by reading immediately after dipping. The sensitivity of the combined indicator-permanganate reagent of Paskova and Munk was confirmed, but we were unable to obtain the color variations reported by these authors.

Effect of Solvent Composition on Sensitivity.—Since the requisite use of a single solvent system would severely limit usefulness of the proposed reagents, the effects of four common solvent systems were investigated. The sensitivity of both alpha-

α-Ketoglutaric	2	9	12	2

naphthylamine reagent and sulfanilamide reagent was determined for each of the twelve reference acids in each solvent system, in the manner described above. The results, shown in Table III and Table IV, demonstrate that none of the four solvents would prohibit use of the proposed reagents. Both reagents could be used with any of these systems, and both may be directly applied to chromatograms that have been developed with ammoniacal solvents. The effect of buffered papers is unknown, since no attempt was made to evaluate this variable.

The failure to obtain a spot with sulfanilamide reagent in the presence of 100 mcg. of *cis*-aconitic acid, using butanol-acetic acid-water as the developing solvent, is unexplained. The same is true for naphthylamine reagent and oxalacetic acid in the ethanol-ammonia system. It should also be noted that some spots may develop slowly with the sulfanilamide reagent. Chromatograms sprayed with this reagent should therefore be re-examined for latent spots after standing overnight.

SUMMARY AND CONCLUSIONS

Two new reagents have been developed for the location of organic acids on paper chromatograms. Color development apparently depends on an acid catalyzed diazotization and coupling to form a highly colored compound, since colors are produced in the presence of a wide variety of diazotizable amines and coupling amines or phenols. The proposed reagents differ in the nature of the diazotizable amine, one employing naphthylamine and the

other sulfanilamide. The sulfanilamide reagent is generally, but not universally, the more sensitive. It usually produces less background color than naphthylamine and the spots are more stable because the background darkens much less rapidly. The sulfanilamide reagent does not have the disagreeable odor of naphthylamine and does not have the carcinogenic action of the latter compound.

Both reagents have been tested against twelve reference acids in four commonly used solvent systems. Sensitivities vary somewhat from one solvent to the next, but the variations are minor and do not prevent use of any solvent tested. Both reagents are much more sensitive than the indicator-permanganate or acridine procedures. The sulfanilamide reagent is notably more sensitive than aniline-xylose or bromcresol green and does not possess the carcinogenicity of aniline-xylose. Both reagents give more reproducible sensitivities than any reagent tested, and neither produces "ghost" spots.

Intense background colors may develop with either sulfanilamide or alphanaphthylamine if chromatograms are exposed to high concentrations of laboratory fumes, but minimal care will prevent this occurrence.

An 8:1:1 propanol-formic acid-water system has been used to develop most of these chromatograms. It has not been extensively studied as a solvent for separating organic acids, but may certainly be used to advantage. It produces excellent separations of many compounds tested, causes little or no tailing, and gives compact spots.

Protective Coatings XVI

Disintegration of Protective-Coated Tablets as Determined by Urinary Excretion in Humans

By TADAO IDA, SHOJI TAKAHASHI, KAZUO NODA, SHUZO KISHI, SETSUO NAKAGAMI, and ISAMU UTSUMI

A disintegration test of protective coated preparations in human bodies was carried out by determining the riboflavin amount excreted in urine after administration of the riboflavin tablets coated with the previously reported protective-coating agents. Though the rate of the riboflavin excretion was somewhat slow, there was no indication of unusual disintegration of the coated tablets in human bodies.

IN PRECEDING PAPERS, studies on the protective-coating agents were reported in which the amino derivatives and the amino acid derivatives of cellulose, saccharides and polyhydric alcohols, polyvinylamines, polyvinylaminoacetals, polyvinylpyridines, and others were synthesized and examined (1–12). Polyampholites of the vinylpyridine-methacrylic acid system were also studied for the protective-coating agents which solubilize in both gastric and intestinal juice (13). All preparations coated with these agents showed excellent results in the tests—water-resistance, *in vitro* disintegration, and others.

In this report, the *in vivo* test was examined in human bodies for the disintegration of the preparations. Since riboflavin absorbed in excess is rapidly excreted in urine, disintegration rate was determined by the riboflavin amount in urine excretion after the administration of the coated riboflavin tablets.

EXPERIMENTAL

Tablets.—The compressed tablets (9.0 mg. of riboflavin each) were used in the experiments. Mean thickness, weight, and diameter of the tablets were 3.5 mm., 120 mg., and 7 mm., respectively. The disintegration time of the tablets in distilled water, artificial gastric juice, and artificial intestinal juice was 2–3 minutes as determined by the method specified in U.S.P. XVI (14).

Protective-Coated Tablets.—By the dipping method, the compressed riboflavin tablets were coated with two different coating solutions: 10% methanol solution of the copolymer, 2-vinyl-5-ethylpyridine-styrene (VEP-St), and 10% ethanol-trichloroethane (1:1) solution of the copolymer, 2-vinyl-5-ethylpyridine-methacrylic acid-methylacrylate (VEP-MAA-MA).

TABLE I.—*In Vitro* DISINTEGRATION TEST OF THE COATED TABLETS

Tablets	Film Thickness, μ	Disintegration Time: Distilled Water, hrs.	Disintegration Time: Artificial Gastric Juice, min.	Disintegration Time: Artificial Intestinal Juice
VEP-St-coated	150	4	5–10	4 hrs.
VEP-MAA-MA-coated	145	4	5–10	10–15 min.

Mean thicknesses of the coating films and disintegration times of the coated tablets are shown in Table I. The mean thicknesses were calculated from the mean weights of coating agents applied to each tablet. The disintegration time of the coated tablets in distilled water, artificial gastric juice, and artificial intestinal juice was determined by the method specified in U.S.P. XVI (14).

Administration test.—Seventy-nine men and 52 women ranging from 18–55 years were divided into three groups, A, B, and C (as shown in Table II), and each person was administered one tablet—uncoated tablets for the A group, VEP-St-coated tablets for the B group and VEP-MAA-MA-coated tablets for the C group. The amounts of riboflavin in total urine excreted in 3 hours prior, 3 hours, and 6 hours after administration were determined individually by the U.S.P. fluorometric procedure (14).

TABLE II.—GROUPS IN ADMINISTRATION

Group	Administered Tablet	Men	Women	Total
A	Uncoated	20	10	30
B	VEP-St-coated	29	21	50
C	VEP-MAA-MA-coated	30	21	51

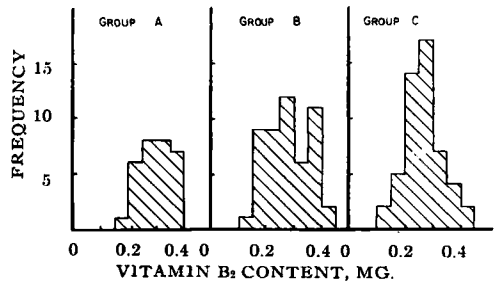

Fig. 1.—Vitamin B_2 content of urine before administration.

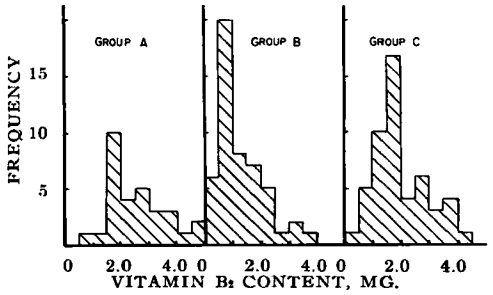

Fig. 2.—Vitamin B_2 content of urine 0–3 hours after administration.

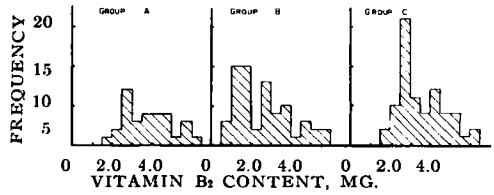

Fig. 3.—Vitamin B_2 content of urine 0–6 hours after administration.

RESULTS AND DISCUSSION

Riboflavin Contents of Urine Before Administration.—Figure 1 shows the riboflavin content of urine before administration. All individuals showed almost similar values, and no particular difference was observed between men and women.

Amounts of Riboflavin Excreted in Urine After Administration.—Figures 2 and 3 show the total amounts of riboflavin excreted in urine during 3- and 6-hour periods after administration, and Table III shows the mean values of riboflavin in the three groups after 6 hours.

As shown in Table III, the B group excreted less riboflavin than the other two groups, and women excreted less than men. Analysis of the variances by Snedecor's method (15) shows that these differences are statistically significant at the 5% level, but

TABLE III.—MEAN AMOUNT OF RIBOFLAVIN EXCRETED IN URINE IN 0–6 HOURS

Tablets	Men: Administered Number	Men: Mean Value of Excreted Riboflavin, mg.	Women: Administered Number	Women: Mean Value of Excreted Riboflavin, mg.	Mean: Administered Number	Mean: Mean Value of Excreted Riboflavin, mg.
A	20	3.95	10	3.49	30	3.797
B	29	2.87	21	2.26	50	2.614
C	30	3.60	21	3.24	51	3.447
Total	79	3.40	52	2.89	131	3.211

the lower excretion of women might result from some errors in urine collection.

Variation of Riboflavin Amounts Excreted in Urine With the Lapse of Time.—Table IV shows the mean values of riboflavin excreted in both 3-hour periods. X_1 and X_2 indicate milligrams of riboflavin excreted in 3 hours and the next 3 hours, respectively.

TABLE IV.—MEAN VALUES OF RIBOFLAVIN EXCRETED IN 0–3 (X_1) AND 3–6 (X_2) HOURS

Tablet Group	X_1, mg.	X_2, mg.
A	2.512	1.285
B	1.251	1.363
C	1.951	1.496

The B and C groups showed lower values of X_1 as compared with the A group. But the C group showed the highest X_2 value of the three, and the total for 6 hours was nearly the same as the A group.

The B group (as described above) showed the lowest total value of the three, but the X_2 value was greater than the X_1. It can be seen that the excretion gradually increased with the lapse of time, and further increase of the value might be expected in the following period.

These differences of riboflavin excretion between the groups were statistically significant at the 5% level in the result of analysis of dispersion.

The results show that the excretion of riboflavin with the coated tablets was slightly slower than the uncoated tablets. This was expected as the disintegration rate of the coated tablets was somewhat retarded.

Disintegration of Coating Films in Humans.—Variances of the amounts of excreted riboflavin in each group were calculated in order to see whether an unusual disintegration of the coated tablets occurred.

TABLE V.—VARIANCES OF RIBOFLAVIN EXCRETED IN 0–3 AND 0–6 HOURS

Tablet Group	0–3 Hours	0–6 Hours
A	1.0220	1.3257
B	0.7204	1.9221
C	0.8080	1.6065

As can be seen in Table V, amounts of the excretions showed no significant difference between three groups and, it can be considered that there were no unusual disintegrations in humans with both coated tablets.

It may be concluded from these results that the coated tablets must disintegrate to release medicaments in humans.

SUMMARY

1. Riboflavin tablets were coated with the copolymers 2-vinyl-5-ethylpyridine-styrene (VEP-St), and 2-vinyl-5-ethylpyridine-methacrylic acid-methyl acrylate (VEP-MAA-MA). The disintegration of the coated tablets was tested by determining the riboflavin amount excreted in human urine after administration of the tablets.

2. The group administered VEP-St-coated tablets showed lower excretion of riboflavin in 6 hours after administration than the group administered uncoated tablets. The group administered VEP-MAA-MA coated tablets showed nearly the same as the control in the excretion.

3. Both groups administered the coated tablets showed lower excretions of riboflavin in 3 hours after administration, and higher excretions in the following 3 hours than the control.

4. The coated tablets disintegrated in humans to release medicaments. Any unusual disintegration did not occur.

Relationship of Prostatic Serum Acid Phosphatase to Age and Size of the Prostate in Rats

By R. H. WOJNAS† and J. F. BESTER

Serum of freshly killed rats of various ages was treated with *p*-nitrophenyl phosphate in citric acid buffer solution pH 4.8. Total serum acid phosphatase was determined colorimetrically on the basis of *p*-nitrophenol formation. Residual serum acid phosphatase was determined on duplicate serum specimens similarly, but with the addition of L (+) tartrate. Prostatic serum acid phosphatase activity was computed by subtraction. This activity was found to increase markedly until prostate weight reached approximately 200 mg. after which there was little change in activity. Increases in prostatic weight continued as body weight and age increased. Hence, in young animals prostatic serum acid phosphatase activity is indicative of normal prostatic growth and not necessarily indicative of abnormality.

PROSTATIC enlargement is one of the more common afflictions of the elderly male, occurring in from 30–40 per cent of men over 60 years of age. In general, such enlargement is due to benign hypertrophy, carcinoma, or fibrosis. Despite the fact that the resulting symptomology, if any, will show many similarities regardless of cause, it is obviously important that early differential diagnosis be made so that appropriate corrective measures may be undertaken.

As early as 1935 Kutscher and Wolbergs (1) reported that normal prostatic tissue is extraordinarily rich in a phosphatase having an optimum activity at about pH 5.0. It is present principally in the Golgi region of prostatic epithelium, while a second prostatic phosphatase with an optimum activity at about pH 10.5 is found in the basement membrane of the acini of the gland (2). The former, with optimum activity at pH 4.9, has been designated "acid" phosphatase; the latter has been designated "alkaline" phosphatase.

Significant amounts of acid phosphatase appear in blood plasma as a result of malignant growth of the prostate and metastases of prostatic cancer in the bones (3). It has been shown that prostatic acid phosphatase can enter the circulation very readily (4). Gutman, Sproul, and Gutman (5) noted the presence of acid phosphatase at the site of skeletal metastases secondary to carcinoma of the prostate. Huggins and Hodges (6) observed marked increases in serum concentration of acid phosphatase in prostatic carcinoma. They reported that the concentration could be decreased by reducing the activity of androgens by castration or by estrogen administration and increased by the injection of androgens. Gutman and Gutman (7) reported that serum acid phosphatase activity exceeded maximal normal values in 12 of 15 cases of disseminated prostatic carcinoma, but that there was no significant increase in such prostatic diseases as benign hypertrophy and acute prostatitis, nor in uremia or lymphosarcoma.

Because of observations such as these, the determination of serum levels of prostatic acid phosphatase has become a routine step in the diagnosis of prostatic cancer. Indeed, Bonner, *et al.* (8), discovered the presence of unsuspected prostatic carcinomas in five patients by this technique. They also reported that in three cases diagnoses of prostatic cancer based upon detection of nodules by finger palpation were

TABLE I.—BODY WEIGHT, PROSTATE WEIGHT, AND PROSTATIC SERUM ACID PHOSPHATASE ACTIVITY

[a] Activity expressed as optical density of solution.

Received April 16, 1962, from the School of Pharmacy, University of Southern California, Los Angeles.
Accepted for publication October 23, 1962.
Abstracted from a thesis presented by R. H. Wojnas to the Graduate School, University of Southern California, Los Angeles, in partial fulfillment of Master of Science degree requirements.
The authors express their gratitude to Dr. Frederick G. Moore for his statistical evaluations of results published in THIS JOURNAL.
† Present address: School of Medicine, University of California, San Francisco.

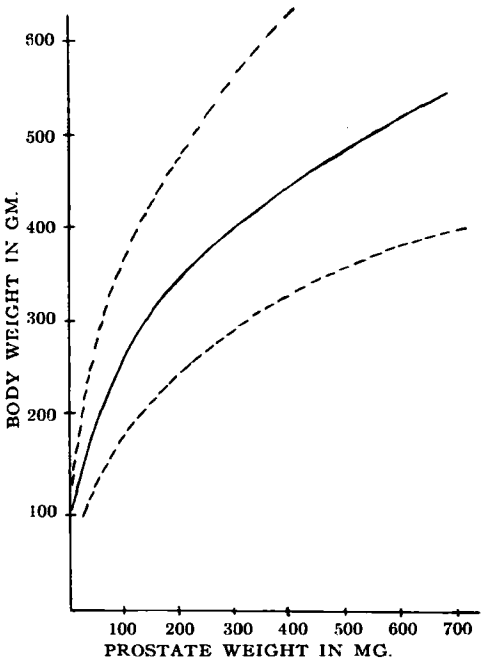

Fig. 1.—Relationship of body weight and prostate weight, showing mean values and 90% confidence limits.

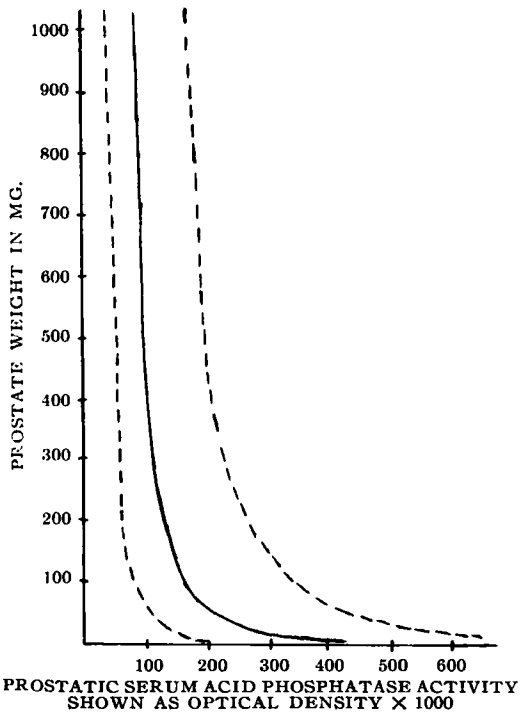

Fig. 2.—Relationship of prostate weight and prostatic serum acid phosphatase activity, showing mean values and 90% confidence limits.

shown to be incorrect by this test; the error was further shown by subsequent biopsy indicating benign hypertrophy.

Earlier work in our laboratory indicated that in some respects the prostate was markedly influenced by age (9). It therefore seemed important to determine whether prostatic serum acid phosphatase level and activity change appreciably at various age levels.

Various investigators have used *p*-nitrophenyl phosphate as a reagent for measuring phosphatase activity (10, 11). It is colorless, but the *p*-nitrophenol liberated by phosphatase hydrolysis is yellow and has a maximum absorbance between 400–420 mμ. The substrate is thus the indicator in the test. However, it is not specific for prostatic acid phosphatase in serum. As reported by Fishman and Lerner (12), erythrocytes increase serum phosphatase levels upon hemolysis. The same investigators showed that L-tartrate will inhibit prostatic serum acid phosphatase but will not inhibit other serum phosphatases. Thus, it is possible to determine total serum phosphatase activity of a specimen and then, by L-tartrate inhibition, to determine "residual" phosphatase activity. The difference between these will be prostatic serum acid phosphatase activity. This procedure formed the basis of the method used in the study being reported.

EXPERIMENTAL

Equipment and Reagents.—Wistar strain rats were used in the study. No restrictions in diet were observed. The rats were of two general age groups—about 6 weeks and about 18 months. The *p*-nitrophenyl phosphate reagent and the buffer solutions were obtained commercially as a prepared kit for phosphatase determination.[1] All other reagents used were Baker and Adamson reagent grade chemicals. Colorimetric determinations were made in a Beckman DU spectrophotometer.

Procedure.—After recording the age and weight of the rat, it was sacrificed in a closed jar of ether. An incision was made along the ventral midline of the body and 5–10 ml. of blood were removed from the aorta with a syringe. The blood was centrifuged in a refrigerated clinical centrifuge for approximately 10 minutes or until complete separation of serum had been obtained. The serum was then removed by pipet and frozen until used in the determination of its enzyme content.

The viscera of the rat were then pushed to one side and the prostate gland was teased from its surrounding organs and fat deposits. The lobes of the prostate were excised with a minimum of connective tissue. The gland was placed in a refrigerated calcium chloride desiccator overnight. The following day the gland was weighed and assayed for its total iodine content by the method of Menschenfreund (13). This procedure was dictated by the concurrent study (in this laboratory) of the

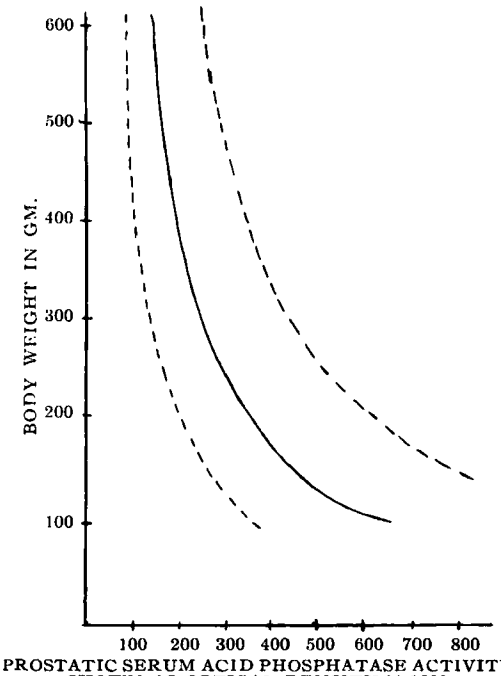

Fig. 3.—Relationship of body weight and prostatic serum acid phosphatase activity, showing mean values and 90% confidence limits.

possible role of iodine in prostatic function. However, this study is not part of the present report.

Total serum acid phosphatase and residual serum acid phosphatase activities were determined by standard procedures (14). The activity of prostatic serum acid phosphatase was obtained by subtraction.

It was unnecessary to prepare a standard curve for the Beckman DU spectrophotometer since relative rather than absolute values for phosphatase activity were being studied.

RESULTS AND DISCUSSION

Data obtained in the study appear in Table I. Logarithmic transformation of the data was necessary to reduce skewness. In all cases the data were multiplied by 1000 before determining their respective logarithms in order to avoid the use of negative computations.

Ages of the rats are not shown. Obviously, animals of approximately 18 months of age were much heavier than those of approximately 6 weeks of age. From examination of Table I, it is apparent that age is paralleled by body weight with an evident separation between the groups.

The data in Table I were then transformed to their respective arithmetic values; these were then used to show the relationships of interest in Figs. 1, 2, and 3.

The relationship between body weight and prostate weight shown in Fig. 1 has a t value of 15.9 with $p < 0.001$. As expected the greatest rate of increase in prostatic weight occurred in animals whose body weights were less than 200 Gm.

Figure 2 indicates the relationship between prostatic serum acid phosphatase activity and prostate weight. Here the t value was 6.64 with $p < 0.001$. This is rather remarkable correlation, and as Fig. 2 clearly shows, enzyme activity is greatest in those rats whose prostates weigh less than 200 mg., *i.e.*, in young rats. This is also indicated by Fig. 3; enzyme activity is markedly greater in young rats with body weights of less than 200 Gm. In this latter relationship, a t value of 8.59 with $p < 0.001$ was obtained.

Elevation of prostatic serum acid phosphatase activity has been accepted as an indication of prostatic cancer. Results of this study indicate that care must be exercised to prevent incorrect interpretation of the test in the young because activity of that enzyme is considerably higher in young animals.

Preparation of Certain Biologically Active Anthraquinone Derivatives Containing Nitrogen

By ALFRED C. CORE† and ERNST R. KIRCH

A new approach to the synthesis of benzo[g]quinoline-5,10-diones is presented and discussed. Five benzo[g]quinoline-5,10-diones and two amino-hydroxyanthraquinones were prepared and screened for antibacterial activity. Some inhibition of growth of one or more common organisms was demonstrated by most of the compounds tested.

SINCE SOME naturally occurring hydroxyanthraquinones as well as other compounds of similar structure have been shown to possess antibacterial activity (1–3), it was felt that a series of such compounds might be tested for like activity. In addition, since many of the known antibiotics contain nitrogen, either in the form of an amine or within one of the rings of the compound (as in the actinomycins), it was desired to investigate a series of benzo[g]quinoline-5,10-diones for similar activity.

For this purpose the compounds (hitherto not synthesized) prepared and screened for antibacterial activity were 6,9-dihydroxybenzo[g]-quinoline-5,10-dione(I), 6-hydroxy-9-chlorobenzo[g]quinoline-5,10-dione(II), 6,9-dichlorobenzo[g]quinoline-5,10-dione(III), 1-hydroxy-4-dimethylaminoanthraquinone(IV), bis-(4-chlorophenyl) quinolinate(V).

It was desired to have a compound which had been prepared previously and which could serve as a reference compound for comparison of physical and chemical properties of the new compounds. The particular reference compound chosen was 2-hydroxybenzo[g]quinoline-5,10-dione-4-carboxylic acid, which was prepared from 3-amino-2-naphthoic acid according to the method of Etienne and Staehelin (4, 5). As reported by these authors, the compound when heated decarboxylated to form 2-hydroxybenzo[g]quinoline-5,10-dione, which in turn sublimed.

Since such treatment led to appreciable decomposition of the compound with resulting loss of material, it was decided to carry out the decarboxylation under reduced pressure.

However, when the material was heated *in vacuo*, the product collected was not the expected decarboxylated compound. Instead it was found that at low pressure the carboxylic acid could be sublimed unchanged.

No attempt was made to synthesize compounds bearing substituents on the benzenoid ring by this method, since the yields for all steps after formation of 1-acetylbenzindoxyl were good only if the quantities of starting material were kept within a range of from 100–500 mg.

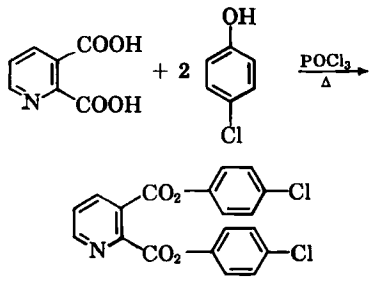
As an alternative it was hoped that a method might be found for condensation of quinolinic acid, its acid chloride or anhydride with a suitably substituted aromatic nucleus.

Attempts to condense the acid or its derivatives with activated aromatic ring systems using aluminum chloride (6), polyphosphoric acid (7), or sulfuric acid (8), were unsuccessful. No tractable products other than starting material were obtained.

Phosphoryl chloride acts as a Lewis acid which might serve to promote the formation of the desired benzo[g]quinolinediones. Further support for its use lay in the finding that aged phosphoryl chloride usually contains polyphosphoric acid (9) which might be expected to further the cyclization.

Treatment of *p*-chlorophenol and quinolinic acid with phosphoryl chloride resulted in the formation of a product which proved to be bis-(4-chlorophenyl) quinolinate.

Formation of the ester may be represented by



The use of a combination of phosphoryl chloride and polyphosphoric acid has been reported (10, 11). Assuming polyphosphoric acid could arise only from hydrolysis of the

Received August 7, 1962, from the Department of Chemistry, College of Pharmacy, University of Illinois at the Medical Center, Chicago.

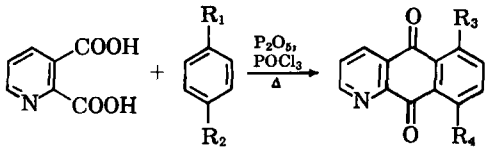
† Present address: School of Pharmacy, West Virginia University, Morgantown.

phosphoryl chloride in aged samples of the latter, phosphorus pentoxide should react with any phosphoric acid—arising either from hydrolysis or as the result of reaction with the quinolinic acid—to produce polyphosphoric acid.

Treatment of a 2.5:1 molar ratio mixture of quinolinic acid and hydroquinone monomethyl ether with the mixture of phosphoryl chloride and phosphorus pentoxide under reflux conditions led to the formation of 6,9-dihydroxybenzo[g]-quinoline-5,10-dione (I). This same method (with but slight modifications) was used in the preparation of the other benzo[g]quinoline-5,10-diones.

A general equation for these syntheses is



I. R_1 = —OCH_3; R_2 = —OH, —OCH_3; R_3 = R_4 = —OH
II. R_1 = R_3 = —OH; R_2 = R_4 = —Cl
III. R_1 = R_2 = R_3 = R_4 = —Cl

When the same reaction was run using the dimethyl ether of hydroquinone in place of the monomethyl ether an identical product was formed, as confirmed by physical constants and mixed melting point determination. Product identity was confirmed because the ether underwent cleavage to the phenolic compound when treated with phosphoryl chloride under reflux conditions. That cleavage occurred after ring closure was suggested by the somewhat better product yield when the dimethyl ether was used. Such an increase in yield could be attributed to the greater stability toward oxidation of the ether, hydroquinone itself tending to undergo oxidation to the quinone, which would be expected to be less amenable to attack by the electrophilic agent.

Treatment of *p*-chlorophenol and quinolinic acid under the same conditions led to the formation of a mixture of products. Since more than 94% of the total yield consisted of one isomer, it was felt that this compound was 6-hydroxy-9-chlorobenzo[g]quinoline-5,10-dione. Such an assumption was made on the basis that such reactions as have been reported which involve a Friedel-Crafts reaction between quinolinic acid and a benzenoid nucleus have led only to the formation of substituted picolinic acids rather than nicotinic acids (6); and further, that reactions involving phthalic acid condensations with substituted phenols to form substituted benzoylbenzoic acids have produced reactions *ortho* to the hydroxyl group when *p*-chlorophenol, *o*-cresol, or *p*-cresol were used (12).

It was possible to synthesize the 6,9-dichloro compound by the use of *p*-dichlorobenzene. In this case the yield was somewhat lower than when phenolic compounds were used. This is not surprising when one considers that the latter are in general much more amenable to nucleophilic attack.

BIOLOGICAL TESTING[1]

Due to the similarity in structure to some of the antibiotics currently in use, it was hoped that the compounds which were prepared might show some bacteriostatic activity. With this in mind, it was decided to screen the compounds for activity against several common organisms.

Since a rapid screening was desired, it was felt that a method similar to the original disk method (13) might well be used. Although the procedure was not quantitative, some quantitation could be achieved by comparison of the effects produced by the test compound with those of a known antibiotic.

A technique was employed whereby small filter paper disks were impregnated with alcoholic solutions of the compounds, and after streaking the agar plates with the test organism, the disks were imbedded in the surface of the agar. In this way it was possible to demonstrate activity of a limited nature by most of the compounds tested.

While nearly all of the compounds displayed at least slight activity, only two could be considered significant. These were 1-hydroxy-4-dimethyl*aminoanthraquinone* and 6,9-dihydroxybenzo[g]-quinoline-5,10-dione. Neither, however, was as effective as tetracycline under the conditions employed.

EXPERIMENTAL

Syntheses

2-Hydroxybenzo[g]-quinoline-5,10-dione-4-carboxylic Acid.—This compound was synthesized according to the method of Etienne and Staehelin (4, 5), starting with 3-amino-2-naphthoic acid. As reported by these authors, decarboxylation occurred upon heating, and the 2-hydroxybenzo[g]-quinoline-5,10-dione sublimed, observed m.p. 341–343° (uncorrected). Reported m.p. 349–351° (5). If heated to 230–240° at 0.3 mm. Hg pressure, the acid sublimed without decomposition.

1-Hydroxy-4-dimethylaminoanthraquinone.—The acid sulfate of *p*-aminophenol was prepared by dissolving the phenol in an excess of 10% sulfuric acid and precipitating the salt by the addition of ethanol. After recrystallization from absolute ethanol, the melting point was found to be 308–310° (uncorrected).

A mixture of 7.0 Gm. (0.034 mole) of the salt, 11.3 Gm. (0.076 mole) phthalic anhydride, and 1.5

[1] The authors are indebted to Dr. Leon LeBeau, Department of Microbiology, College of Medicine, University of Illinois, and to Dr. Carmen Mascoli, Department of Microbiology, West Virginia University, for their assistance and advice in the testing procedures.

Gm. boric acid with 30.0 ml. concentrated sulfuric acid was heated slowly in an oil bath to a temperature of 160°, and maintained at this temperature for 8 hours. At the end of this time, the melt was cooled and poured on about 200 Gm. chipped ice with constant stirring. The reaction mixture was then carefully neutralized to approximately pH 7 by the addition of sodium bicarbonate. The mixture was evaporated to dryness, the residue powdered and extracted with chloroform using a Soxhlet extractor. The chloroform extract was evaporated to dryness and the crude product (7.5 Gm. = 93%) purified by recrystallization from 95% ethanol, followed by sublimation at 3 mm. Hg, and a bath temperature of 140°. The bright red needles darkened slightly at 168–170° and melted at 212–213° (uncorrected). Reported m.p., 215° (14).

A solution of 200 mg. (0.0084 mole) of 1-hydroxy-4-aminoanthraquinone in 10 ml. absolute methanol was treated with 5 Gm. (0.035 mole) methyl iodide and 0.1 Gm. anhydrous potassium carbonate. After refluxing on a steam bath for 6 hours, the solvent and excess methyl iodide were allowed to evaporate.

The dry residue was purified by sublimation under reduced pressure at 160–180°. Overall yield 155 mg. (69.7%) of orange needles, m.p. 204–205° (uncorrected).

Anal.—Calcd. for $C_{16}H_{13}NO_3$: C, 71.90; H, 4.90; N, 5.24. Found: C, 71.82; H, 4.93; N, 5.19.

Bis-(4-chlorophenyl) Quinolinate.—A mixture of 2.1 Gm. (0.013 mole) quinolinic acid and 6.4 Gm. (0.050 mole) *p*-chlorophenol was treated with 13.4 Gm. phosphoryl chloride, and the mixture refluxed 6 hours. After cooling, the reaction mixture was poured into ice water and the excess phosphoryl chloride allowed to decompose. The reddish-brown oily product was separated from the aqueous layer and treated with solid sodium carbonate. The resulting oily green material was dissolved in chloroform, the solution dried over anhydrous sodium sulfate, and the chloroform evaporated. The still-oily residue was dissolved in a small amount of boiling methanol and filtered. Water was added dropwise until the solution began to cloud. The mixture was agan heated to boiling, filtered, and the filtrate cooled in an ice bath. The resulting dark green crystals were removed by suction filtration and dried. Repeated recrystallization from methanol and water gave 2.1 Gm. dark green needles, m.p. 121–122° dec. (uncorrected).

Anal.—Calcd. for $C_{19}H_{11}NO_4Cl_2$: C, 58.78; H, 2.86; N, 3.61; Cl, 18.27. Found: C, 58.65; H, 2.91; N, 3.58; Cl, 18.20; sapon. equiv., 192.

6,9-Dihydroxybenzo[g]-quinoline-5,10-dione.—A mixture of 5.0 Gm. (0.030 mole) quinolinic acid and 33.5 Gm. phosphoryl chloride was heated under reflux for 45 minutes. At the end of this time, 1.5 Gm. (0.012 mole) hydroquinone monomethyl ether and 3.0 Gm. phosphorus pentoxide were added, and the mixture again refluxed for 3 hours. The cooled reaction mixture was poured on crushed ice to decompose the phosphorus pentoxide and phosphoryl chloride. The dark brown precipitate was removed by suction filtration and recrystallized from absolute methanol, yielding 1.7 Gm. (58.4%) dark purple leaflets, m.p. 308–310° (uncorrected).

Anal.—Calcd. for $C_{13}H_7NO_4$: C, 64.73; H, 2.92; N, 5.81. Found: C, 64.65; H, 2.95; N, 5.85.

Alternate Method.—A mixture of 8.0 Gm. (0.048 mole) quinolinic acid, 6.0 Gm. (0.043 mole) hydroquinone dimethyl ether, 10 Gm. phosphorus pentoxide and 42.0 Gm. phosphoryl chloride was refluxed for 5 hours. After the isolation and purification reported above, the yield was 7.4 Gm. (70.6%) of 6,9-dihydroxybenzo[g]-quinoline-5,10-dione, identical with that obtained above as established by analysis and mixed melting point.

6 - Hydroxy - 9 - chlorobenzo[g]quinoline - 5,10 - dione.—To a mixture of 42.0 Gm. phosphoryl chloride and 10 Gm. phosphorus pentoxide were added 5.0 Gm. (0.030 mole) quinolinic acid and 3.5 Gm. (0.027 mole) *p*-chlorophenol. After refluxing for 6 hours, the mixture was cooled and poured onto chipped ice. The dark orange precipitate was removed by filtration. Recrystallized from absolute methanol, the orange crystals melted at 318–320° (uncorrected). The yield was 6.8 Gm. (70.9%).

Anal.—Calcd. for $C_{13}H_6NO_3Cl$: C, 60.13; H, 2.33; N, 5.40; Cl, 13.66. Found: C, 60.02; H, 2.38; N, 5.45; Cl, 13.75.

6,9 - Dichlorobenzo[g]quinoline - 5,10 - dione.—A mixture of 8.0 Gm. (0.048 mole) quinolinic acid, 5.0 Gm. (0.034 mole) *p*-dichlorobenzene, 10.0 Gm. phosphorus pentoxide and 50.0 Gm. phosphoryl chloride was refluxed for 6 hours, cooled, then poured on chipped ice.

The reddish-brown tar-like mass was dissolved in acetone and reprecipitated by the addition of water. The resulting brown powder was recrystallized twice from 95% ethanol to give fine dark yellow crystals (4.6 Gm. = 48.4%), m.p. 316–317° (uncorrected).

Anal.—Calcd. for $C_{13}H_5NO_2Cl_2$: C, 56.14; H, 1.81; N, 5.04; Cl, 25.50. Found: C, 55.80; H, 1.85; N, 4.95; Cl, 25.12.

Bacteriological Screening

A weighed sample of each of the compounds was dissolved in absolute methanol, and the volume adjusted so that the final solution contained 0.300 mg./ml. Filter paper disks were impregnated by placing them on a glass plate and allowing 0.2 ml. of a solution of one of the compounds to flow slowly onto the surface of the disk. The solvent was then allowed to evaporate, leaving each of the disks impregnated with 60 mcg. of one of the compounds under test. For comparison of activity, disks containing 40 mcg. of tetracycline were used.

The impregnated disks were placed on tryptose-glucose-agar plates inoculated with one of the following organisms: β-hemolytic *Strep. pyogenes*, *Proteus vulgaris*, *Escherichia coli*, *Staph. aureus*, *Salmonella enteritidis*, *Bacillus cereus* var. *terminalis*. The disks were gently pressed directly into the surface of the agar with the aid of a sterile glass rod. After covering, the cultures were incubated at 37° for 24 hours, then examined for inhibition of growth of the organisms.

The results obtained are shown in Table I.

SUMMARY

The following hitherto unreported compounds were synthesized and screened for bacteriostatic

TABLE I.—INHIBITION OF GROWTH OF TEST ORGANISMS[a]

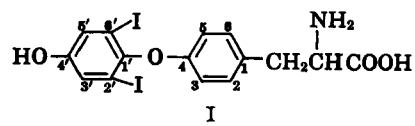
Thyroxine Analogs IX

4′-Deoxy-4′-β-L-alanyl-3,5-diiodo-L-thyronine and Related Stereoisomers as Thyroxine Antagonists

By EUGENE C. JORGENSEN and RICHARD CAVESTRI

On the basis of structural considerations and the activity of 2′,6′-diiodothyronine (I), 4′-deoxy-4′-β-L-alanyl-3,5-diiodo-L-thyronine (VIIb)[1] and a mixture of related stereoisomers have been prepared and tested for activity as thyroxine antagonists in the rat antigoiter assay. The L,L-isomer (VIIb) proved moderately effective as an antagonist at a molar ratio to L-thyroxine of 100:1. The mixed DL,DL-isomers (VIIa) as well as the L,L-isomer (VIIb) were ineffective when tested at a molar ratio to L-thyroxine of 200:1.

STUDIES directed at the preparation of peripheral antagonists to the thyroid hormones have had two principal objectives: (*a*) the development of an agent capable of rapidly reducing the undesirable effects due to high levels of circulating hormone in the various forms of hyperthyroidism, and (*b*) the gaining of a better understanding of the nature of interactions between the thyroid hormones and their biological receptor sites (1). 2′,6′-Diiodo-DL-thyronine (I) was the first compound containing the intact thyronine nucleus characteristic of thyroxine which was shown to possess thyroxine antagonistic properties. Among a number of halogenated thyronines prepared by Niemann and McCasland (2) and tested by Cortell (3),



I

only the 2′,6′-diiodo analog (I) showed thyroxine

Thyroxine Analogs IX

4′-Deoxy-4′-β-L-alanyl-3,5-diiodo-L-thyronine and Related Stereoisomers as Thyroxine Antagonists

By EUGENE C. JORGENSEN and RICHARD CAVESTRI

On the basis of structural considerations and the activity of 2′,6′-diiodothyronine (I), 4′-deoxy-4′-β-L-alanyl-3,5-diiodo-L-thyronine (VIIb)[1] and a mixture of related stereoisomers have been prepared and tested for activity as thyroxine antagonists in the rat antigoiter assay. The L,L-isomer (VIIb) proved moderately effective as an antagonist at a molar ratio to L-thyroxine of 100:1. The mixed DL,DL-isomers (VIIa) as well as the L,L-isomer (VIIb) were ineffective when tested at a molar ratio to L-thyroxine of 200:1.

STUDIES directed at the preparation of peripheral antagonists to the thyroid hormones have had two principal objectives: (*a*) the development of an agent capable of rapidly reducing the undesirable effects due to high levels of circulating hormone in the various forms of hyperthyroidism, and (*b*) the gaining of a better understanding of the nature of interactions between the thyroid hormones and their biological receptor sites (1). 2′,6′-Diiodo-DL-thyronine (I) was the first compound containing the intact thyronine nucleus characteristic of thyroxine which was shown to possess thyroxine antagonistic properties. Among a number of halogenated thyronines prepared by Niemann and McCasland (2) and tested by Cortell (3),

[1] An alternate chemical name, 3,5-diiodo-4-(4′-L-phenylalanyloxy)-L-phenylalanine, is used in the *Experimental* section.

antagonistic activity when tested together with thyroxine at a molar ratio of 150:1 in the rat antigoiter assay. This compound has been extensively studied since. Antagonistic activity in the rat antigoiter assay has been confirmed (4) as well as the absence of detectable thyroxine-like activity in the rat and in man (5). Weak activity has been shown by the DL-isomer in antagonizing the thyroxine-induced elevation of oxygen consumption in the mouse (6).

With the exception of 2′,6′-diiodothyronine, all thyronine derivatives thus far studied have required at least one substituent in the 3 or 5 positions of the alanine-bearing ring for the presence of either thyroxine-like or antagonistic activity. For example, thyronine and its 3′-iodo- and 3′,5′-diiodo-derivatives have been shown to possess neither thyroxine-like (7–10) nor thyroxine-antagonistic (11, 12) properties. Thyronine derivatives with a single iodine atom in the alanine-bearing ring, *e.g.*, 3-iodo-, 3,3′-diiodo-, and 3,3′,5′-triiodo-DL-thyronines, have been shown to act as thyroxine antagonists by a variety of biological tests (12). 3,3′-Diiodothyronine (L-isomer (10), DL-isomer (13)), and 3,3′,5′-triiodo-DL-thyronine (14) have also been reported to show weak thyroxine-like activity. Maximal thyroxine-like activity in mammals has been invariably associated with the 3,5-diiodotyrosinyl grouping present in the natural hormones, L-thyroxine and 3,3′,5-triiodo-L-thyronine (7, 15). These consistent structural requirements for 3 or 3,5 substitution in the thyronine nucleus have led to the hypothesis (16) that the ring bearing these substituents may be responsible for primary binding to the biological receptor. Appropriate activating groups in the 3 or 5 positions (such as halogen or methyl (17)) may then function by contributing to the binding forces between the ring bearing these groups and the biological receptor. Bulky 3,5 substituents may also serve by steric effects to orient the two aromatic rings of the thyroid hormones and their analogs, so that the planes of the rings are perpendicular to each other. The suitably oriented phenolic ring with its hydroxyl group conjugated 1,4 to the ether oxygen may then comprise the functional unit of the thyromimetic molecule (16).

A peripheral antagonist may be visualized as one capable of binding to the hormonal receptor site but considerably less effective than the natural hormone in its functional role. Since in all other compounds tested 3 substitution is a requirement for minimal thyroxine-like activity, it seems possible that the iodine-bearing ring of 2′,6′-diiodothyronine may be the portion of the molecule fulfilling the binding role of the 3,5-diiodophenyl ring of thyroxine. Interaction of the 2′,6′-diiodo analog (I) with a hypothetical receptor structure (16) may be pictured as in Fig. 1. If so bound, the alanyl side chain of 2′,6′-diiodothyronine would occupy a position in space normally filled by the 4′-hydroxyl group of thyroxine. Phenyl ethers of 3,5-diiodotyrosine with a methyl group blocking the 4′ position against potential metabolic hydroxylation have shown thyroxine antagonistic properties in the rat antigoiter assay (16, 18). If the normal binding and functional roles of the alanine-bearing and phenolic rings are reversed with 2′,6′-diiodothyronine, the functional requirement for a 4′-hydroxyl group is not met and the alanyl residue acts as a 4′ blocking group. The molecule contains features which would be expected to facilitate transport to the biological receptor site—the alanyl group and a weakly dissociated phenolic group. It also possesses the diiodophenoxy structure for binding to the receptor, but if so bound, it lacks the structural characteristics at the "functional receptor" (Fig. 1) necessary for the functional role of a thyroxine-like compound—a hydroxyl group in 1,4 conjugation to the ether oxygen.

Because of the potential ability for an amino acid side chain to form ionic and hydrogen bonds with functional groups which might occupy positions peripheral to the receptor area, it was considered that the alanyl group could serve both as a blocking group and one providing a more firmly bound drug-receptor complex. To test this concept, a thyroxine analog possessing the 3,5-diiodotyrosinyl inner ring and a 4′-alanyl blocking group in the outer ring was prepared. The L-alanyl side chain in the inner ring was considered the most desirable for transport and binding since L-thyroxine and related

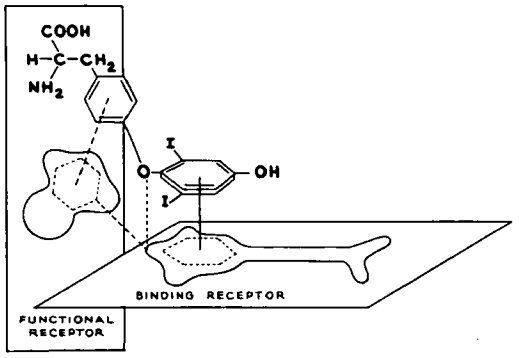

Fig. 1.—Schematic representation of 2′,6′-diiodothyronine interacting with a hypothetical thyroid hormone receptor.

L analogs display strong hormonal activity, while the corresponding D isomers possess relatively little (7). However, the more desirable configuration for the 4′-alanyl group (if such exists) could not be deduced, since activity has been reported only for the DL isomer of 2′,6′-diiodothyronine (3, 4, 6). Therefore, both the DL,DL compound (VIIa), comprising a mixture of all optical forms, and one of its enantiomers, the L,L compound (VIIb), were prepared.

The analogs were synthesized by the Meltzer (19) modification of the method of Chalmers, *et al.* (20). The appropriate DL or L isomer of N-acetyl 3,5-dinitrotyrosine ethyl ester was allowed to react with methanesulfonyl chloride and pyridine to form the N-acetyl 3,5-dinitro-4-pyridinium phenylalanine ethyl ester methanesulfonate (IIa,b). This was not isolated but was allowed to react with either the DL or L isomer of N-acetyl tyrosine ethyl ester (IIIa,b) to form the substituted dinitrodiphenyl ethers (IVa,b). These were converted to the diamines by hydrogenation and were bis-diazotized under anhydrous conditions without isolation and converted to the diiodo compounds (Va,b). Mild alkaline hydrolysis afforded the di-N-acetyl derivative (VI), while acidic conditions yielded the desired bis-amino acids (VIIa,b).

EXPERIMENTAL

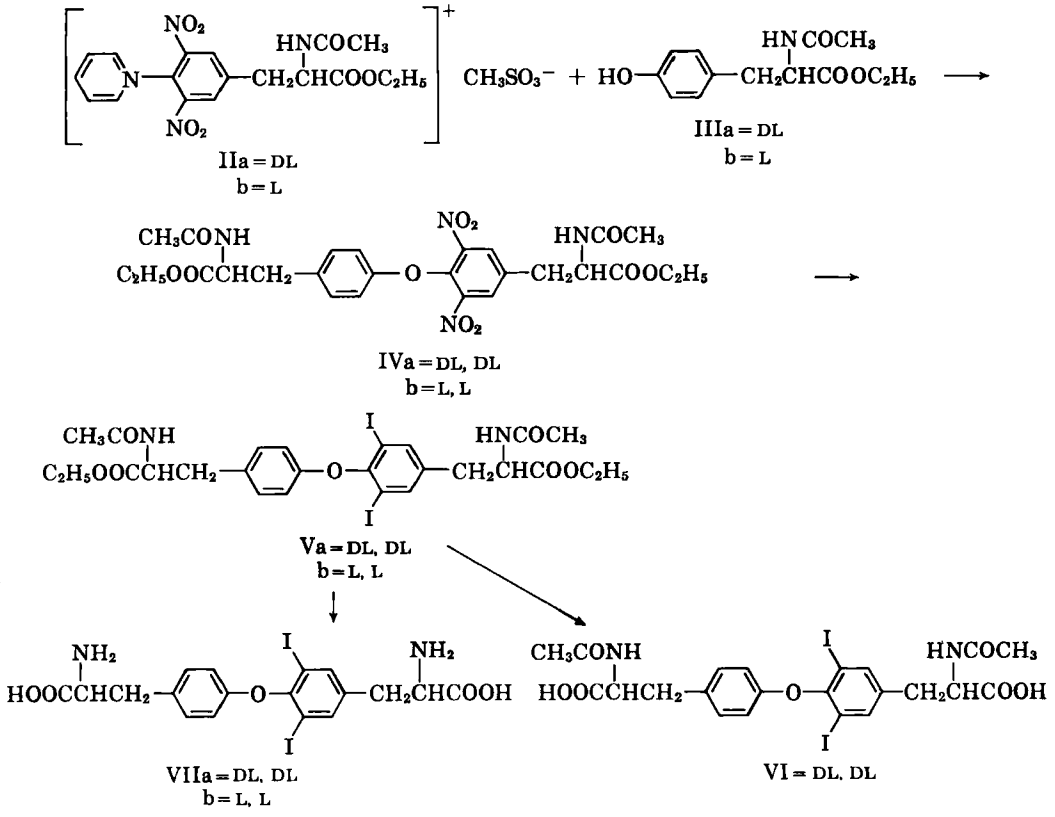
Synthetic

All melting points were taken on a Fisher-Johns melting point apparatus and are uncorrected. Optical rotations were measured with a Rudolph polarimeter. Microanalyses were carried out by the Microanalytical Laboratory, Department of Chemistry, University of California, Berkeley.

N-Acetyl 3,5-Dinitro-4-(N-acetyl 4′-DL-phenylalanyloxy ethyl ester)-DL-phenylalanine Ethyl Ester (IVa).—To a solution of N-acetyl 3,5-dinitro-DL-tyrosine ethyl ester (21) (17.0 Gm., 0.05 mole) in dry pyridine (100 ml.), methanesulfonyl chloride (6.3 Gm., 0.055 mole) was added, and the mixture heated under reflux for 2 minutes. N-Acetyl DL-tyrosine ethyl ester (2) (IIIa, 15.9 Gm., 0.063 mole) was added and the solution heated under reflux for 15 minutes. The reaction mixture was poured into cold water (200 ml.) and extracted with benzene and chloroform. The combined extracts were washed successively with 2 *N* hydrochloric acid, water, 0.3 *N* sodium hydroxide, and water. The residue obtained following removal of the solvents under reduced pressure was crystallized from aqueous ethanol yielding 13.7 Gm. (46%), m.p. 171–172°.

Anal.—Calcd. for $C_{26}H_{30}N_4O_{11}$; C, 54.35; H, 5.25. Found: C, 54.30; H, 5.41.

N-Acetyl 3,5-Dinitro-4-(N-acetyl 4′-L-phenylalanyloxy ethyl ester)-L-phenylalanine Ethyl Ester (IVb).—The condensation of N-acetyl 3,5-dinitro-L-tyrosine ethyl ester (20) and N-acetyl L-tyrosine ethyl ester (6) (IIIb) was carried out as described above, except that reflux time was increased from 15



to 30 minutes. Crystallization from 50% ethanol yielded 16.5 Gm. (58%), m.p. 163–164°. $[\alpha]_D^{23}$ −8.0° (*c* 2.00, $CHCl_3$).

Anal.—Calcd. for $C_{26}H_{30}N_4O_{11}$; C, 54.35; H, 5.25. Found: C, 54.52; H, 5.33.

N-Acetyl 3,5-Diiodo-4-(N-acetyl 4′-DL-phenylalanyloxy ethyl ester)-DL-phenylalanine Ethyl Ester (Va).—The dinitro compound (IVa, 10.7 Gm., 0.019 mole) dissolved in acetic acid (200 ml.) was shaken for 45 minutes in the presence of palladium-on-charcoal (10%, 2.0 Gm.) and hydrogen (45 p.s.i. initial pressure). Concentrated sulfuric acid (40 ml.) was added with cooling. The catalyst was removed by filtration through Celite, and the solution of the diamine was added from a pressure-equalized dropping funnel under nitrogen during 1 hour to a well-stirred mixture of nitrosylsulfuric acid maintained at −5°. The nitrosylsulfuric acid was prepared from sodium nitrite (5.52 Gm., 0.08 mole), added in small portions to concentrated sulfuric acid (60 ml.) at 60–70°, then diluted when cool with acetic acid (60 ml.). After the addition was complete, the dark solution of the bis-diazonium compound was stirred for an additional hour at −5°, then poured rapidly into a well-stirred mixture at 5° of iodine (21.4 Gm., 0.084 mole), sodium iodide (30.0 Gm., 0.2 mole), urea (3.12 Gm., 0.052 mole), water (300 ml.), and chloroform (300 ml.). After stirring for 1 hour below 15°, the reaction mixture was allowed to reach room temperature and stirring was continued for an additional hour. The chloroform phase was removed, the aqueous layer was extracted with chloroform, and the combined chloroform extracts were washed successively with water, 10% aqueous sodium bisulfite, water, 1 *M* sodium bicarbonate, and water. The chloroform extract was dried over anhydrous sodium sulfate, and the chloroform removed at reduced pressure. The residue was taken up in acetone, and the oil which precipitated upon addition of an equal volume of ligroin (b.p. 35–60°) crystallized after standing for about 1 month at 0° yielding 4.2 Gm. (35%), m.p. 140–143°.

Anal.—Calcd. for $C_{26}H_{30}I_2N_2O_7$; C, 42.41; H, 4.11. Found: C, 42.89; H, 4.35.

N-Acetyl 3,5-Diiodo-4-(N-acetyl 4′-L-phenylalanyloxy ethyl ester)-L-phenylalanine Ethyl Ester (Vb).—The L,L-dinitro compound (IVb, 3.3 Gm., 0.0058 mole) was treated in the same way as above. The oily residue obtained crystallized readily on scratching and was recrystallized from ethanol yielding 2.4 Gm. (57%), m.p. 197–198°. $[\alpha]_D^{23}$ −6.3° (c 2.00, $CHCl_3$).

Anal.—Calcd. for $C_{26}H_{30}I_2N_2O_7$; C, 42.41; H, 4.11. Found: C, 42.67; H, 4.09.

N-Acetyl 3,5-Diiodo-4-(N-acetyl 4′-DL-phenylalanyloxy)-DL-phenylalanine (VI).—The bis-N-acetyl amino acid ethyl ester (Va, 1.11 Gm., 1.5 mmoles) was dissolved in absolute ethanol (30 ml.), sodium hydroxide (1.12 Gm., 30 mmoles) was added, and the mixture was stirred at room temperature for 2 hours. The solution was diluted with an equal volume of hot water, acidified to pH 3 with 2 *N* hydrochloric acid and allowed to crystallize overnight at 0°. Recrystallization from aqueous acetone yielded 0.27 Gm. (38%), m.p. 143–145°.

Anal.—Calcd. for $C_{22}H_{22}I_2N_2O_7$; C, 38.85; H, 3.26. Found: C, 38.6; H, 3.4.

3,5-Diiodo-4-(4′-DL-phenylalanyloxy)-DL-phenylalanine (VIIa).—The bis-N-acetyl amino acid ethyl ester (Va, 1.0 Gm.) was heated under reflux for 12 hours in glacial acetic acid (10 ml.) and concentrated hydrochloric acid (10 ml.). The mixture was treated with decolorizing carbon and taken to dryness under reduced pressure. The cream-colored residue was dissolved in 15 ml. of hot water with the aid of a few drops of concentrated hydrochloric acid. The hot solution was adjusted to pH 5 with a saturated solution of sodium acetate. After three such isoelectric precipitations, the white amino acid weighed 0.337 Gm. (37%), m.p. approximately 350° dec.

Anal.—Calcd. for $C_{18}H_{18}I_2N_2O_5 \cdot H_2O$; C, 35.21; H, 3.48. Found: C, 35.41; H, 3.57. On a separate sample dried at 65° (2 mm.)—Calcd. for $C_{18}H_{18}I_2N_2O_5$; I, 42.53. Found: I, 42.48.

3,5-Diiodo-4-(4′-L-phenylalanyloxy)-L-phenylalanine Dihydrochloride (VIIb).—The bis-N-acetyl amino acid ethyl ester (Vb, 1.0 Gm.) was heated under reflux for 12 hours in glacial acetic acid (10 ml.) and concentrated hydrochloric acid (10 ml.). The clear solution was taken to dryness at reduced pressure. The solid residue was dissolved by heating in boiling water (15 ml.) and concentrated hydrochloric acid (1 ml.). Cooling yielded the crystalline dihydrochloride, 0.832 Gm. (93%), m.p. 293–295° dec. $[\alpha]_D^{23}$ −1.6° (c 2.00, 1 *N* sodium hydroxide-ethanol (1:2)).

Anal.—Calcd. for $C_{18}H_{18}I_2N_2O_5 \cdot 2HCl$; C, 32.34; H, 2.99; I, 37.81. Found: C, 32.5; H, 2.9; I, 37.7.

Biological

The rat antigoiter assay was based on that of Dempsey and Astwood (22) and Cortell (3), in which thyromimetic activity was estimated by determining the amount of the test compound required to prevent the increase in thyroid weight brought about by the goitrogen, thiouracil. Thyroxine-antagonistic activity was tested by the ability of the test compound to reverse the antigoiter effect of thyroxine when administered concomitantly in thiouracil-fed rats. The assay was carried out as previously described (16). Specific assay conditions and results are collected in Table I.

DISCUSSION

At a molar ratio to L-thyroxine of 100:1, the L,L-isomer (VIIb) produced a 46.5% reversal[2] of the goiter preventing effect of thyroxine (Table I, assay 1). When the data was examined by the student's "t" test, the probability that the thyroid weight produced by thiouracil, thyroxine, and VIIb (14.9 ± 3.0 mg./100 Gm.) was the same as that produced by thiouracil and thyroxine alone (10.3 ± 4.0 mg./100 Gm.) was $P < 0.10$. Thus a moderate degree of antagonism of the antigoitrogenic effect of thyroxine was indicated. This is the same order of effectiveness reported[3] for 2′,6′-DL-diiodothyronine, where a 63% reversal of the effect of DL-thyroxine was observed at a molar ratio of 82:1; a constant reversal of between 43–48% was observed in a duplicate assay at molar ratios of 82:1,

[2] For the method of calculation see Reference 18.

[3] Values for per cent reversal and molar ratios were calculated from the data presented in Reference 4.

TABLE I.—RAT ANTIGOITER ASSAY OF 4′-DEOXY-4′-ALANYL-3,5-DIIODOTHYRONINES

Assay No.	Food	Compound Injected[a]	Daily Dose per 100 Gm., mcg.	Molar Ratio	Thyroid Wt. per 100 Gm. mg.	± s.d.
1[b]	Untreated				6.6	0.8
	TU[c]				20.2	3.9
	TU	Thyroxine	2.0	0.67	14.4	3.5
	TU	Thyroxine	3.0	1.0	10.3	4.0
	TU	Thyroxine	4.5	1.5	6.1	3.0
	TU	Thyroxine plus L,L-isomer (VIIb)	3.0 225	1.0 100	14.9[d]	3.0
2[b]	Untreated				8.2	1.6
	TU[c]				29.5	4.5
	TU	Thyroxine	2.0	0.67	18.2	5.2
	TU	Thyroxine	3.0	1.0	10.7	3.6
	TU	Thyroxine	4.5	1.5	9.1	3.9
	TU	Thyroxine plus L,L-isomer (VIIb)	3.0 450	1.0 200	12.7[e]	3.6
	TU	Thyroxine plus DL,DL-isomers (VIIa)	3.0 400	1.0 200	10.6[f]	2.6

[a] Thyroxine was used as sodium L-thyroxine pentahydrate, kindly provided by Dr. James Kerwin, Smith Kline and French Laboratories. [b] Six rats at each control and dose level. [c] Thiouracil 0.3%. [d] Reversal of thyroxine effect, 46.5% ($P < 0.10$). [e] Reversal of thyroxine effect, 11%; not significant. [f] No reversal of thyroxine effect.

164:1, and 328:1. This difficulty in producing a greater response with increased dose or duplicating the level of significance found earlier was observed in the second assay shown in Table I. At a molar ratio to L-thyroxine of 200:1, the L,L-isomer (VIIb) produced an 11% reversal of thyroxine's antigoitrogenic effect, a value which was not significantly different from the thyroxine-control value. The mixture of DL,DL-isomers (VIIa) had no effect at a molar ratio to L-thyroxine of 200:1 in the same assay.

The results with the L,L-isomer (VIIb) are indicative of a low order of thyroxine antagonistic activity. However, the inability to obtain reproducible and significant results in the rat antigoiter assay makes it undesirable to use this data in support of the proposals put forth regarding the nature of the antagonistic activity demonstrated by 2′,6′-diiodothyronine without further evaluation in other test systems. Since such evaluation will not be possible in the near future, the rationale for the preparation of these compounds and the results obtained to date are presented now.

Prolongation of Chlorzoxazone Plasma Levels by Zoxazolamine

By JOHN W. POOLE and JOSEPH F. GARDOCKI

The plasma levels of chlorzoxazone were determined in humans, dogs, and mice. It was shown that the co-administration of zoxazolamine and chlorzoxazone prolonged the plasma concentrations of the latter substance in mice and dogs. An interaction between the compounds under consideration, which resulted in the formation of an insoluble complex, was demonstrated by means of a solubility study. Evidence was presented to show that the prolongation of chlorzoxazone plasma levels was probably a result of a change in metabolism of this compound in the presence of the additive, zoxazolamine. It is suggested that the molecular complex formed between chlorzoxazone and zoxazolamine is directly responsible for the proposed alteration in metabolism of chlorzoxazone and the prolonged plasma levels of this compound which results when the combination of drugs is administered.

CHLORZOXAZONE (5-chlorobenzoxazolinone) is a centrally acting muscle relaxant which has been found useful in the treatment of a number of spastic diseases. The physiological disposition and metabolic fate of this compound have been reported previously by Conney and Burns (1). The present investigation is concerned with the absorption and biological life of this substance in several animal species after the administration of the drug alone and in combination with a potentiating agent.

Specifically, the animal species employed in this investigation were mice, dogs, and humans, and the potentiating agent utilized was zoxazolamine (2-amino-5-chlorobenzoxazole). The potentiating effect of the additive was demonstrated by a prolongation of chlorzoxazone plasma levels when the combination of drugs was administered.

The basis for investigating the chlorzoxazone-zoxazolamine combination was the hypothesis developed by Brodie, Hogben, Schanker, and associates (2–4) to explain the rate and extent of absorption of acidic and basic drugs from the gastrointestinal tract. It was thought that administration of chlorzoxazone (the acidic drug) and zoxazolamine (the basic compound) would demonstrate a more prolonged muscle relaxant activity than either of the compounds administered singly since the weakly acidic drug would be absorbed more readily in the acidic portion of the gastrointestinal tract, and the weakly basic drug in the more basic segments of the tract. However, it was noted that the chlorzoxazone plasma levels were appreciably prolonged when the combination of drugs was administered when compared to the levels observed after administration of chlorzoxazone alone.

The purpose of this study was to characterize the absorption pattern of chlorzoxazone in various animal species with the possibility of utilizing this information in the development of more efficient dosage forms, and to investigate the mechanism responsible for the prolongation of chlorzoxazone plasma levels noted when this compound is administered in conjunction with zoxazolamine.

EXPERIMENTAL

The estimation of chlorzoxazone levels in the biological samples was made by the method described by Conney, *et al.* (5). This procedure involved extraction of acidified biological material with an organic solvent consisting of 1.5% isoamyl alcohol in petroleum ether. The drug was then extracted from the organic phase into a 0.5 *N* sodium hydroxide solution and measured spectrophotometrically at 287 mμ where the compound exhibits an absorption maximum.

The method employed for the determination of zoxazolamine was similar to that described for chlorzoxazone. However, the drug was extracted from alkalinized biological material into the organic solvent and re-extracted into a 3 *N* hydrochloric acid solution. Measurements were made spectrophotometrically at 278 mμ.

The experimental procedure utilized to demonstrate the interaction between chlorzoxazone and zoxazolamine in distilled water and mouse plasma was similar to that reported by Higuchi and Lach (6). The analytical procedures employed were similar to those described for the biological samples.

The spectrophotometric measurements were made on a Cary model 14 recording spectrophotometer.

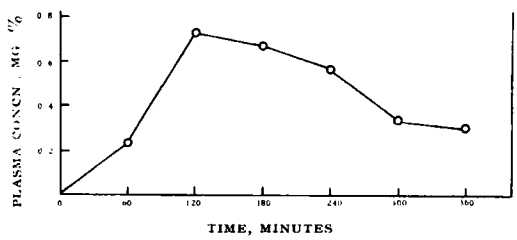

Fig. 1.—Mean plasma levels of chlorzoxazone in humans after oral administration of 0.50 Gm. of drug.

RESULTS AND DISCUSSION

Ten humans received 0.50 Gm. of chlorzoxazone orally in tablet form, and the plasma levels were measured at various time intervals. Blood samples were obtained from five of the subjects at 0, 60, 180, and 300 minutes and from the remaining five subjects at 0, 120, 240, and 360 minutes. Figure 1 presents the mean plasma levels observed in this study. Peak plasma levels were attained 120–180 minutes after administration and the biological half-life was determined to be about 170 minutes. These data are consistent with the duration of action noted with this compound in clinical studies. In addition, the results noted in this investigation are in general agreement with the observations previously reported by Conney and Burns (1).

The mean plasma levels observed in dogs after oral administration of 30 mg./Kg. and 60 mg./Kg. chlorzoxazone are shown in Fig. 2. Six dogs were used at each dose level, and the drug was administered in capsule form. The biological half-life in this species was determined to be about 120 minutes with a peak level observed between 90–180 minutes. Figure 2 also shows the mean plasma levels of chlorzoxazone observed after administration of 60 mg./Kg. chlorzoxazone in conjunction with 60 mg./Kg. zoxazolamine. Four dogs were employed on this dosage schedule. Although the peak concentration of chlorzoxazone did not differ significantly from that obtained after administration of chlorzoxazone alone, there was a definite prolongation of the plasma concentration. From the limited data presented, it appears that the half-life of chlorzoxazone is prolonged to about 300 minutes when this compound is administered with an equivalent dose of zoxazolamine.

The plasma levels of chlorzoxazone determined after administration of a suspension of the drug to mice at levels of 100 mg./Kg. and 200 mg./Kg. are shown in Fig. 3. The chlorzoxazone determinations were made on a pooled blood sample from about 20 mice. The peak chlorzoxazone levels in this species were noted at 5 minutes with a half-life of only 20 minutes. The short half-life observed in this species is consistent with the data reported by Conney and Burns (1) which showed that liver homogenates prepared from mouse or guinea pig tissue metabolized chlorzoxazone three to four times as fast as a corresponding preparation using rat or rabbit tissue. The chlorzoxazone plasma levels attained in mice after oral administration of 100 mg./Kg. each of chlorzoxazone and zoxazolamine are also shown in Fig. 3. The plasma concentrations reported for the combination are the means of three separate sets of pooled blood samples. The results were similar to those observed with dogs since there was a significant prolongation of the chlorzoxazone plasma concentrations when the combination of drugs was given. The biological half-life of chlorzoxazone in this instance was about 80 minutes or four times longer than that noted when chlorzoxazone was administered singly.

Several of the possible mechanisms which could account for the prolonged chlorzoxazone plasma concentrations demonstrated after administration of the combination of drugs are (*a*) conversion of zoxazolamine to chlorzoxazone in the biological system, (*b*) prolonged dissolution, and therefore prolonged absorption due to the formation of a poorly soluble interaction product of chlorzoxazone and zoxazolamine, (*c*) an increase in absorption from the gastrointestinal tract of chlorzoxazone in the presence of zoxazolamine, (*d*) lower chlorzoxazone tissue levels (or more rapid removal of this drug from the tissues when zoxazolamine is also in the system), and (*e*) an alteration in the metabolism of chlorzoxazone when both compounds are present.

It is known that 2-aminobenzoxazoles are converted *in vitro* to 2-benzoxazolinones in dilute mineral acid. However, the *in vivo* conversion of zoxazolamine to chlorzoxazone as the mechanism responsible for the prolongation of chlorzoxazone plasma levels was readily eliminated when no detectable levels of chlorzoxazone were found after administration of 60 mg./Kg. of zoxazolamine to dogs and 100 mg./Kg. of this agent to mice.

Although it is possible that prolonged dissolution and absorption occur when chlorzoxazone and

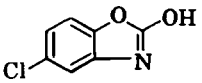
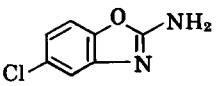
zoxazolamine are administered simultaneously (due to their interaction at the absorption site), this mechanism alone would not seem to explain adequately the large areas under the time-concentration curves observed for the drug combination.

The remaining possible mechanisms listed above also may be rationalized on the basis of an interaction between these muscle relaxant compounds. An examination of the chemical structure of the compounds under consideration shows that the structural requirements necessary for the formation of a molecular complex in aqueous solution similar to those described in previous communications (6–8) are present in these substances. The expected interaction was illustrated by means of a solubility study. The phase diagrams describing this interaction are



Chlorzoxazone



Zoxazolamine

shown in Figs. 4 and 5. Analysis of the phase diagrams and chemical analysis of the relatively insoluble complex formed showed the addition product to be composed of one molecule of chlorzoxazone to one of zoxazolamine.

It is unlikely that the complex demonstrated in aqueous solution would be stable in the acidic medium of the stomach. However, if the formation of a complex between these compounds was responsible for an increase in absorption of chlorzoxazone from the gastrointestinal tract, a corresponding increase in zoxazolamine plasma levels would also be observed. That this does not occur is demonstrated in Fig. 6 which shows the mean plasma levels of zoxazolamine after oral administration to dogs of 60 mg./Kg. zoxazolamine and 60 mg./Kg. zoxazolamine in combination with a like amount of chlorzoxazone. Similar results were noted with the plasma levels attained in mice after oral administration of 100 mg./Kg. zoxazolamine alone and in combination with 100 mg./Kg. chlorzoxazone. The early levels noted in both species were lower when the combination of drugs was administered than those observed when zoxazolamine was given alone. This may be a result of a lowering of the solubility or a slower dissolution rate of the zoxazolamine in the presence of chlorzoxazone in the gastrointestinal tract.

If an increase in gastrointestinal absorption is not

responsible for the prolongation of the chlorzoxazone levels noted, then administration of the combination by other than the oral route should also result in a prolongation of chlorzoxazone plasma levels. Table I shows the chlorzoxazone plasma levels determined after intraperitoneal administration of 100 mg./Kg. chlorzoxazone alone and in combination with 100 mg./Kg. zoxazolamine. It is apparent from these results that this route of administration affects the chlorzoxazone levels in a manner similar to that observed after oral administration of the drug combination.

A comparison of Table I with Fig. 3 shows that at times greater than 5 minutes post administration the plasma levels resulting from the intraperitoneal route are similar to those observed when the same drug combination was administered orally to mice.

In order to obtain evidence for the *in vivo* formation of a complex between the compounds under consideration, a solubility study was conducted utilizing mouse plasma as the solvent and maintaining the temperature at 37.5°. Because of the limited number of experimental points available, it was not possible to analyze the phase diagram as was the case for the aqueous study described previously. However, evidence of complex formation in this system was obtained since (in each instance) the presence of one of the molecules in the system significantly decreased the solubility of the other in the biological fluid.

The effect of administration of the combination of drugs on the chlorzoxazone tissue levels was made by determining chlorzoxazone levels in the brains of mice. The dosage regimen utilized for this part of the study was 200 mg./Kg. chlorzoxazone alone and 200 mg./Kg. chlorzoxazone in combination with 50 mg./Kg. zoxazolamine. The brains of ten mice were pooled and homogenized with distilled water and an aliquot of the final preparation was used for the drug determination.

The results of this experiment, along with the chlorzoxazone plasma levels attained employing the same dosing schedule, are presented in Table II.

The data indicate that the brain levels of chlorzoxazone are proportional to the plasma levels of this drug, and that the prolongation of plasma concentrations is reflected in prolonged tissue concentrations. Therefore, the prolonged chlorzoxazone plasma levels noted in this study are probably not the result of a lowering or more rapid depletion of tissue chlorzoxazone in the presence of zoxazolamine.

The brain levels of zoxazolamine observed after oral administration of 50 mg./Kg. of this compound alone and in combination with 200 mg./Kg. chlorzoxazone are shown in Table III along with the plasma concentrations of zoxazolamine determined at these same dosage levels.

It is interesting to note that the brain levels of zoxazolamine are considerably lower after administration of the drug combination than those observed after administration of the zoxazolamine alone. However, there was no significant difference in the plasma levels noted after either dosage regimen was used. These results may be rationalized on the basis of complex formation between the muscle relaxant compounds. Since a large excess of chlorzoxazone molecules (in relation to zoxazolamine) is available in the system, the tissue distribution of this material would not be expected to be influenced significantly by the formation of the proposed complex. However, because of the relatively low concentration of zoxazolamine present, the distribution of this compound in the various biological compartments could be considerably altered by an interaction of the type suggested.

The data indicate that the prolongation of chlorzoxazone plasma levels demonstrated when this agent is administered in combination with zoxazolamine is probably due mainly to an alteration in the metabolism of chlorzoxazone. In addition, evidence has been presented to support the theory that this modification in the metabolism of chlorzoxazone may be mediated through the formation of a molecular complex between the muscle relaxant compounds.

Prolongation of drug activity by mechanisms similar to that described in this study would be especially useful for those drugs which are absorbed in a limited portion of the gastrointestinal tract and therefore cannot be prolonged by a delayed release mechanism. Furthermore, many of the problems encountered in controlling the release of drugs and assuring their complete availability from the various sustained action forms would be greatly simplified in a system of this type.

SUMMARY AND CONCLUSIONS

Chlorzoxazone plasma levels were determined in humans, mice, and dogs after the oral administration of this compound alone, and in mice and dogs after administration of this agent in conjunction with zoxazolamine. In addition, the chlorzoxazone plasma levels in mice after intraperitoneal administration of the drug alone and in combination were determined.

The zoxazolamine plasma levels in mice and dogs were observed after oral administration of this compound alone and in combination with chlorzoxazone.

The brain levels of these compounds attained in mice after the oral administration of the drugs alone and in combination were also determined.

Formation of a molecular complex between the agents under study was demonstrated by means of solubility studies.

A prolongation of chlorzoxazone plasma levels was noted when this compound was administered simultaneously with zoxazolamine to mice or dogs. Evidence was presented to show that this prolongation probably results mainly from an alteration in the metabolism of chlorzoxazone. Furthermore, it is suggested that the proposed change in metabolism is mediated through the formation of a molecular complex *in vivo* between these muscle relaxant compounds.

A Programmed Automated Film-Coating Process

By LEON LACHMAN and JACK COOPER

The design and operation of a programmed automated tablet coating process[1] is described. The electronics of the programmer, the baffle design for the coating pan, and the spray equipment used are illustrated and discussed. The advantages and superiority of this process as compared with the customary manual coating techniques are presented.

DURING THE PAST several years there has been a continuous and rapid movement away from the time-honored sugar coating to film coating of tablets. Considerable research time has been devoted to the development and testing of water- and gastric-soluble (1–11) and enteric (12–19) film-coating formulations. However, during this same period of time, little has been done to improve the process of applying the film coating onto tablets to insure reproducibility of the physical appearance and disintegrating characteristics of coating from batch to batch of tablets. The few attempts in this direction consisted of using a pneumatic gun to spray the tablets manually with coating solution (20) or the use of fluidized bed–coating techniques (21–23). Both methods, while being improvements over the customary manual technique of coating, still left something to be desired.

Most of the film coats presently on the market are of the water-soluble type which, in part, is the cause of the lack of progress in improving the coating process. Uniformity of water-soluble coating from batch to batch of tablets is of less importance than for enteric film coats. Satisfactory physical appearance and sufficient coverage to mask an unpleasant odor or taste are the major criteria for water- or gastric-soluble film coats. However, it is essential that the enteric film coating be uniform from batch to batch of tablets since the coated tablets must meet certain required disintegrating properties (U.S.P. XVI, p. 935) which are critically affected by film uniformity.

It is generally recognized that the human element is responsible for the variations that take place in batches of film-coated tablets. The thinness of the film coats, generally 1–10% of the uncoated tablet weight, cannot tolerate human variations or errors from batch to batch of tablets, which are known to occur in the customary sugar-coating technique. However, since sugar coats are usually equal to the weight of the uncoated tablet, the variations and errors due to the human factor become less meaningful.

In film coating, and more particularly in enteric film coating, it is imperative to remove the "art" from the coating process and place it on a more exact basis. This could most readily be accomplished by eliminating or minimizing the human factor in the coating process.

This report presents a detailed description of a programmed automated process for film coating of tablets recently developed in our laboratories which completely removes the human factor from the coating operation. In addition, data will be presented illustrating the superiority of this process over the customary manual method of tablet coating.

DESIGN AND EQUIPMENT

The schematic diagram in Fig. 1 illustrates the overall design and equipment involved in automating and programming the film-coating operation. Before detailing the various components of this process, a brief description of the operation and function of the programmer will be presented.

The coating process is controlled by a perforated

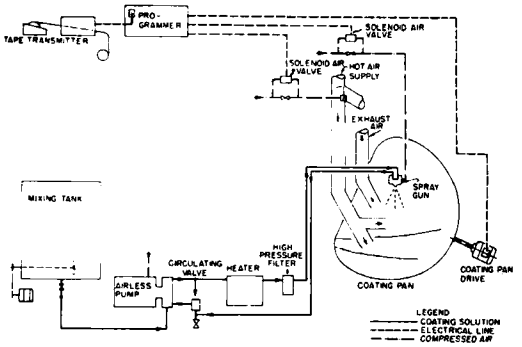

Fig. 1.—A schematic diagram of the design and equipment for the programmed automated coating operation.

tape traveling at a certain distance per unit time and transmitting its signals through a tape transmitter to the necessary relays in the programmer to activate the several components of the coating cycle, which include: (*a*) switching on coating-pan motor to start pan rotation; (*b*) regulating the pneumatic solenoid which opens and closes the automatic spray gun; (*c*) controlling a pneumatic solenoid which activates a single acting air cylinder that opens and closes the damper on the forced hot air duct; and (*d*) activating a latching relay terminating the coating operation.

In order to present a clear description of the design and equipment for this process, it has been divided into three segments which will now be discussed in detail.

Coating Pan, Forced Air, and Exhaust Ducts.—As mentioned earlier, the purpose of automating and programming the coating operation was to eliminate or reduce to a minimum any manual operations during the film-coating process. A phase of the coating operation where manual handling of the tablets is generally essential is subsequent to the addition of the coating solution. At this point the wet tablets tend to slide instead of tumbling. The coater usually places his hand into the pan and manually moves the tablets to aid the distribution of the coating solution until the tablets have partially dried and begin to tumble. In an effort to eliminate this manual handling phase of the coating operation, the influence of (*a*) pan rotational speed, (*b*) pan design, and (*c*) baffles placed into the pan on the tumbling action of tablets in the wet and dry state were investigated. Results from these tests indicated that the use of baffles of a particular design would provide the most suitable means for attaining this objective.

After considerable testing of different shapes, sizes, and numbers of baffles for use in a 42-in. pear-shaped stainless steel pan, the baffle system illustrated in Fig. 2 was found to be optimal. As is shown, the pan was divided into quadrants and a baffle was placed in each quadrant equidistant from one another. Figure 3 shows a schematic representation of the baffle designs and their placement in the coating pan. It is evident from this figure that the baffles have a gradual rise from the bottom to the top of the pan as well as slope in the direction of the pan's rotation.

The rise in baffle height from the inside to the outside of the coating pan was necessary to effect an even tumbling action throughout the pan, since the pan shape would cause the tablets to tumble at different speeds from the bottom to the top of the pan.

The slope of the baffles in the direction of the pan's rotation varies from 1 in. at the bottom to 2.5 in. at the top. This slope of the baffles is essential to prevent a too high carry over of tablets with a subsequent high fall causing irregular tumbling action and a possible focal point for tablet sticking and collection of coating solution and duster.

The baffles are 33 in. long, made of stainless steel, and fit the curvature of the pan. The baffles begin about 5 in. from the bottom center of the pan to about 10 in. from the top. Placing the baffles 5 in. from the center point of the pan gives a 10-in. diam. bottom area that is not baffled. This free area is necessary for correct tumbling action. The 10 in. at the top of the pan remain unbaffled for the same reason. If the baffles were extended at either end, the tablets no longer exhibit a smooth tumbling action, but rather a jumping action. It is also desirable to taper off both ends of the baffle gradually to enhance further smooth tumbling of the tablets.

Studies of the coating operation showed that sticking of tablets on the pan wall (when present) would radiate from the bottom center of the pan. Entering air is not sufficient to assist in drying this section of the pan wall because it is almost continuously covered with tablets. To eliminate this focal point for sticking, a Y attachment was developed for the forced hot air duct so that one part of the Y directed air to this focal point and the other part of the Y directed air onto the tablets. This is illustrated in Fig. 4 (the other duct shown in the pan is the exhaust duct which removes solvent vapors and dust).

Spray Equipment for Application of Coating Liquid and Duster.—With one of the human factors now eliminated, the other major variable was the

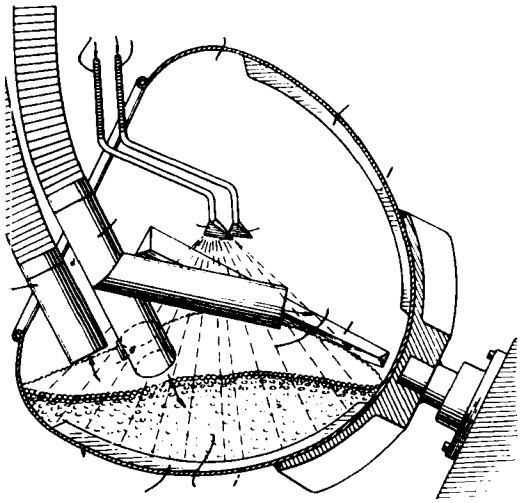

Fig. 4.—A schematic illustration of the Y attachment on the forced hot air duct.

application of the coating liquid and duster. In order to insure the addition of exact quantities of coating liquid and duster to the tablets at definite time intervals, this phase of the coating operation had to be placed on an automated basis and removed from the control of the tablet coater. To automate this operation, it was essential to develop an electronically controlled method of adding the coating liquid and duster. Spray guns for applying the coating liquid and duster seemed most feasible.

Existing methods for applying the coating liquid and duster to tablets consist of pouring a portion of coating liquid from a measuring container and a quantity of duster from a scoop. This method relies essentially on the tumbling action of the tablets for the distribution of coating liquid and duster. However, if the liquid and duster are added as a fine spray, the distribution of these coating materials on the tablets should be significantly improved compared to the hand method of addition. The reproducibility and uniformity of repeated coats can be accurately controlled through the use of a sprayed quantity of liquid and duster by regulating the duration of spray. This would in turn produce tablets exhibiting a more uniform and elegant film.

A spray process could be further improved by including the duster (*e.g.*, talc) in the coating liquid and applying the suspension as a spray, thereby eliminating the dusting step from the operation. This could produce four advantages: (*a*) talc in liquid suspension lends itself to easier fluidization than talc powder so that a reproducible quantity of material is sprayed per unit time; (*b*) using talc in liquid suspension permits a more uniform distribution of talc on the tablets being coated and consequently a thinner enteric film; (*c*) a reduction or elimination of the inherent dust problem of a fluidized talc spray resulting when talc in the form of a liquid suspension is used; and (*d*) the elimination of one operation from the coating cycle.

For film coating it seemed that a spray gun which gives an *airless spray* would be most desirable. The term *airless spray* is used to refer to a spray coating method in which a coating material is atomized by ejecting it from a spray nozzle by a hydraulic pressure imposed on the coating material itself.

The conventional *air spray method* atomizes the coating material by striking it with a high speed jet of compressed air at the end of the atomizing gun chamber. Because air is so light, it takes a tremendous amount of air moving at a high speed to atomize properly a viscous material. The stream emerging from an air atomizing gun is actually a high speed air current in which a small fraction of liquid is dispersed, generally about 1% or less. The liquid droplets are blown forward at high speeds and the atomizing air expands and rebounds causing much of the coating liquid to be blown away from the material to be coated. In addition, as the atomizing air expands, it also cools. This effect, coupled with the cooling effect of solvent evaporation, can lower the temperature of the atomized droplets far below the temperature of the surrounding air. If the temperature were to drop below the dew point, atmospheric water could condense on the particles and could cause the particles to deposit irregularly on the tablets, exhibit poor flow-out properties, cause the film to take on a blush appearance, and possibly rub off from the tablets.

However, the airless spray gun gives a completely different type of spray. Here, since no atomizing air is used, the coating material itself is discharged from the spray nozzle with possibly a minimum amount of air. The droplets move forward by their own momentum. The atmosphere between the spray gun and material to be coated resists the movement of droplets which are appreciably slowed down by this air resistance. Further, the energy released at the nozzle of an airless gun is only a fraction of that required in the air atomizing gun with a consequent drastic reduction in rebound or overspray from the material being coated. In addition, by the use of the airless spray gun, the amount of solvent vapors escaping from the coating pan is kept at a minimum and substantially below explosive and health limits. The airless spray gun would be particularly necessary if a duster were to be sprayed onto the tablets. One could just imagine the dust problem that would result if an air atomizing gun was used.

Figures 5 and 6 depict the relative spray characteristics for an air and airless spray gun using a coating liquid of the same viscosity. It is readily evident that a significantly greater overspray and rebound takes place for the air spray system as well as requiring a higher energy for atomization. Figure 6 shows that when the liquid is heated before spraying, a reduction of atomization energy takes place with the airless system requiring about one-third and the air system about two-thirds that of the cold spray.

Since it would be advantageous for the spraying system to be used for automating the coating process to have maximum versatility, a thorough investigation was made of the various spray equipment available. A unit of particular suitability and versatility was found in a Nordson airless spray-coating unit. This spray system atomizes the coating liquid, heated or unheated, by ejecting it from the spray nozzle through a hydraulic pressure imposed on the coating material itself.

The design and components of the spray system are schematically presented in Fig. 7. In this system the coating liquid in the supply tank is drawn up the siphon tube to the pump and pressurized, pushed

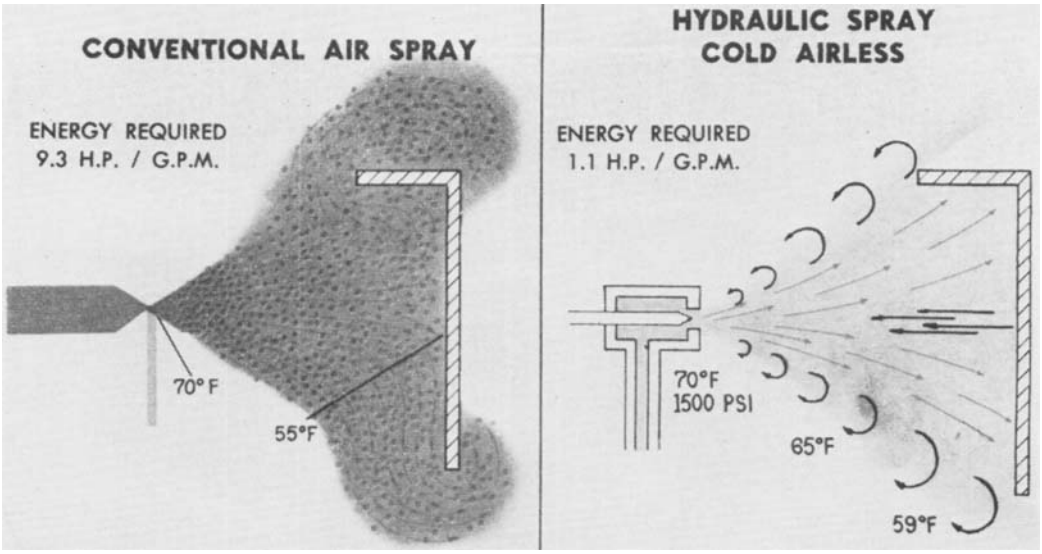

Fig. 5.—The relative spray characteristics of a liquid at room temperature for an air and airless spray system.

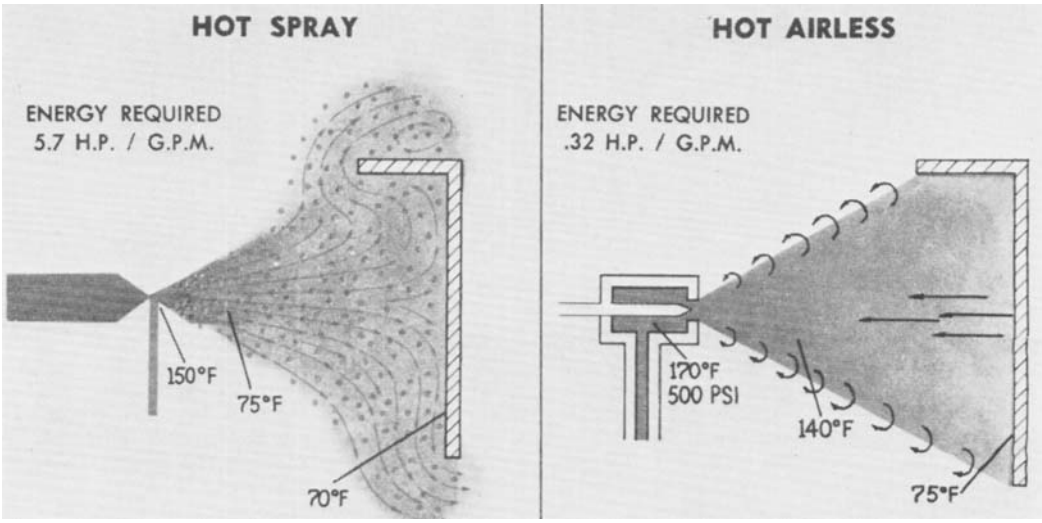

Fig. 6.—The influence of heated liquid on the spray characteristics of an air and airless system.

through the heater (which is specially designed to withstand the high hydraulic pressures needed for atomization), the high pressure filter (which removes particles in liquid suspension that are greater than the nozzle orifice), and then flows to the spray guns available for atomization. The Nordson automatic guns are of a special design making it possible to open and close the gun in less than *one-hundredth* of a second.

This spray system is designed to keep the liquid in the unit circulating to and from the gun when the gun is and is not spraying. When the system is not spraying, the coating liquid travels from the gun through a return line and then through a recirculating valve permitting a controlled amount of liquid to pass into the suction part of the pump. From here the liquid is repressurized for circulating through the system. This assures a continual flow of material through the system; the coating material

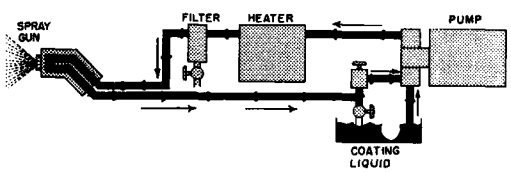

Fig. 7.—Design and components of the airless spray system.

at the nozzle is always at the correct temperature and ready to be sprayed whenever the gun is triggered. In addition, it prevents material in suspension from settling out as well as eliminating possible clogging of the orifice tip due to particle accumulation resulting from the loss of volatile solvents. When the gun is triggered and coating liquid forced out of the nozzle, a similar amount of

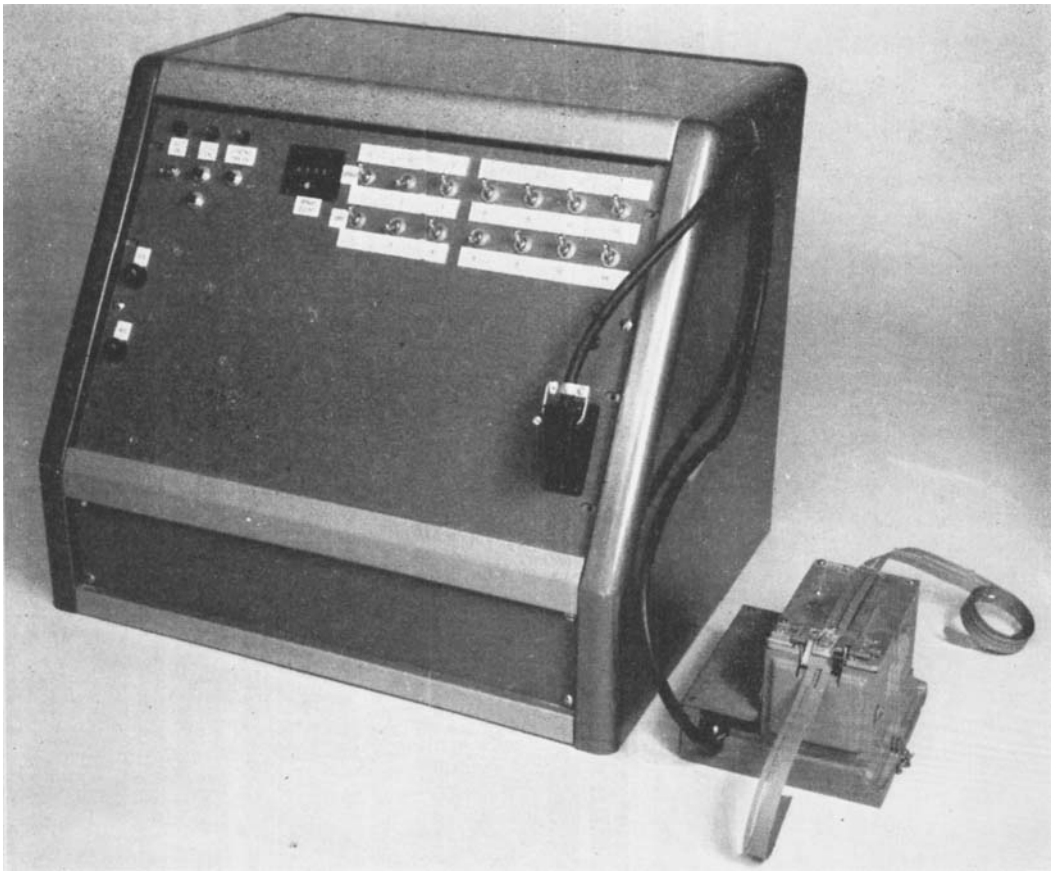

Fig. 8.—Photo of programmer used to automate coating operation.

liquid is withdrawn from the supply container and added to the recirculating pump. Therefore, recirculation is maintained even when the system is spraying. In this system coating liquid does not flow back into the supply container. If it did, then the entire supply of coating material would eventually become heated causing evaporation of the low boiling solvents in the coating material.

In our studies, carbide tip nozzles giving a flat spray pattern were used. The flow rate of the liquid through the nozzle is dependent upon the viscosity and temperature of the liquid, hydraulic pressure, and orifice measurements. However, the major controlling factor for flow rate and spray angle is the nozzle geometry and dimensions.

Automation and Programming of Film-Coating Operation.—With the spray equipment chosen and the coating pan modified to permit tablets to tumble when wet or dry, the final step was to design a programmer to automate the coating operation and remove the human element completely from the coating process. After studying various ways to program the film-coating operation, a punched tape traveling at a certain distance per unit time and transmitting its signals through a tape transmitter to the necessary relays to activate the several elements of the coating cycle appeared to be the simplest to design, install, and operate. In addition, such a system could be built with binary circuitry giving maximum flexibility relative to making changes in the time allotted to each sequence of the cycle. When the changes in cycle time involve only the repetitive spray-dry cycles of the coating operation, the same tape can be employed and the changes made on the programmer by adjusting the toggle switches controlling the binary circuitry. Only when the irregular parts of the coating cycle require changing is it necessary to use a new tape. Therefore, such a programming system can readily be used for various tablet formulations requiring different coating cycles. Any programming arrangement can be obtained with this system by modifying the tape or modifying the binary circuitry on the programmer. Paper tapes can generally be used between 50 to 100 times before replacement. If greater permanency is desired, mylar tapes can be used.

Figure 8 shows the programmer which consists of a Western Union tape transmitter designed for 5-unit code transmission using perforated tape with in line feed holes. The perforated tape travels at a certain distance per unit time transmitting its signals through the tape transmitter to the necessary relays in the control box which activates the several elements of the coating cycle. The timer in the control box regulates the residence time in the transmitter for each hole in the tape.

As the tape is pulled over the code pins of the tape transmitter by the feed wheel traveling at a certain rate, signals are transmitted to the relays in the

control box activating the various functions of the coating cycle and (*a*) starts coating pan rotation by switching on motor through a relay and step down transformer; (*b*) regulates the three-way pneumatic solenoid which opens and closes the automatic spray gun used to spray doses of coating suspension; (*c*) controls a pneumatic solenoid which activates a single acting air cylinder which opens and closes the damper to the forced hot air duct, supplying the hot air for drying the tablets; and (*d*) activates a latching relay which terminates the coating cycle and shuts off the programmer.

By employing this programmed automated process of tablet coating, the volume of coating suspension and, if needed, the weight of talc can be controlled by the length of time of spray at constant hydraulic pressure and nozzle size. Consequently, it should be possible to obtain readily reproducible coatings from batch to batch of tablets.

EXPERIMENTAL

The influence of the human factor on the disintegration properties, uniformity, and physical appearance of enteric films will be illustrated with data obtained from coating $^{15}/_{32}$-in. modified ball tablets weighing 1.06 Gm. by both the customary coating techniques and by the programmed automated process. In both instances the coating operation was performed on 85 Kg. batches of tablets in the stainless steel 42-in. pear-shaped baffled coating pans. For the automated process the tablets were coated with a suspension of 10% talc in a 10% solution of cellulose acetate phthalate containing diethyl phthalate as plasticizer and a solvent system of anhydrous ethanol-acetone, while for the customary technique the same coating solution was used except that the talc was added as a duster between coats instead of in suspension.

In the automated process the suspension was sprayed at a temperature of 50° and at a flow rate of about 1000 ml./minute. The hot air flowing into the pan to dry each coat was at 47°. The coating cycle employed was (*a*) an initial 90-second spray and 120-second dry period; (*b*) then repetitive cycles of 15 seconds consisting of 3-second spray and 12-second drying periods; (*c*) at the end of the repetitive cycles, a 5-minute drying period is permitted in the pan as the tablets tumble; (*d*) then the tablets are placed in an oven at 40° for thermosetting of the film coating and removal of residual solvents.

The normal coating procedure is the term applied to the procedure that was used in our Production Division and consisted of (*a*) manually spraying a quantity of coating solution onto the tablets, (*b*) permitting the tablets to tumble for a prescribed period of time, (*c*) manually dusting on a quantity of talc, (*d*) allowing the tablets to tumble to permit distribution of the talc, and (*e*) directing forced heated air onto the tablets for drying the coatings. These steps are repeated until the desired coating is obtained. At the completion of the coating operation the tablets are removed from the coating pan and placed into a circulating-air oven maintained at 40° to thermoset the film.

By removing samples of tablets during the programmed automated coating operation it was found that the tablets develop enteric properties between 150–200 repetitive cycles. Additional coatings within definite limits provide a safety margin for disintegration properties and improved appearance. Table I shows comparative data of film weight and film uniformity from batch to batch of tablets prepared by the automated process after 200 and 350 repetitive cycles (called end coating) and tablets prepared by customary coating techniques. It is readily evident from this table that it is possible to obtain enteric film coated tablets by the automated spray process with film coatings of about one-third the weight of those prepared by customary coating techniques. In addition, the range of mean coating weights for the 200 and 350 repetitive cycle (called end coating) coated tablets are approximately one-fourteenth and one-sixth that of tablets coated by customary manual coating techniques.

TABLE I.—MEAN WEIGHTS OF COATING OBTAINED BY AUTOMATED AND NORMAL COATING TECHNIQUES

Batches	Mean Coating Weights— 200 Coats	End Coating
Normal A	...	0.1007
Normal B	...	0.0914
Normal C	...	0.0736
Normal D	...	0.1269
Overall Mean	...	(0.0981)
Range of Means	...	0.0533
Automated A	0.0358	0.0594
Automated B	0.0341	0.0639
Automated C	0.0365	0.0580
Automated D	0.0378	0.0671
Automated E	0.0370	0.0639
Overall Mean	(0.0362)	(0.0623)
Range of Means	0.0037	0.0091

Table II summarizes the standard deviations for the uncoated and coated tablets used for the normal and automated processes. Comparing the overall mean standard deviation of uncoated tablets used for the normal and automated process of coating, it was found that they do not differ significantly from one another. However, in comparing the overall mean standard deviation for the tablets coated by the normal techniques with those coated by the automated process it is found that the overall standard deviation for the tablets coated by the automated process is significantly less than that for the tablets coated by the normal process.

TABLE II.—STANDARD DEVIATIONS OF MEAN WEIGHTS OF UNCOATED AND COATED TABLETS

Batches	Uncoated Std. Dev.	End Coating Std. Dev.
Normal A	0.0050	0.0203
Normal B	0.0064	0.0222
Normal C	0.0091	0.0288
Normal D	0.1110	0.0315
Overall Mean	(0.0079)	(0.0257)
Automated A	0.0106	0.0098
Automated B	0.0106	0.0130
Automated C	0.0106	0.0100
Automated D	0.0102	0.0095
Automated E	0.0059	0.0100
Overall Mean	(0.0089)	(0.0105)

The time required for the automated process to give tablets coated by 200 repetitive cycles is about 60 minutes and by 350 repetitive cycles, about 90 minutes.

From our experiences with this programmed automated process of coating it became readily apparent that it offered a number of advantages over the manual method of coating, the most significant ones being:

Tablets from a particular pan batch show uniform coatings relative to physical appearance and disintegrating properties.

Reproducibility of coating from batch to batch of tablets is insured.

The more even film coating deposited by this process produces enteric coated tablets with one-third or less the film weight necessary for manual coating procedures.

Using this process with the repetitive short spray-dry cycles of coating, no coating build-up on the pan wall takes place. This permits the continuous coating of batches of tablets without the need of washing the pans between batches.

The possibility of pimples forming on the coating is eliminated because no coating build-up on the pan wall results.

The time required to obtain enteric film coated tablets by the automated process is at least half that required for the manual process.

A manifold increase in production capacity is possible through this process of film coating.

One operator will be able to supervise the coating of many batches of tablets per day.

It is unnecessary to use an experienced tablet coater with this system of film coating.

This method of coating is adaptable for use with water-soluble films as well as sugar coating.

SUMMARY

A programmed automated process for film coating has been developed which is capable of concurrently coating multiple pan batches of tablets containing 85–100 Kg. of tablets per pan.

As a result of eliminating the human element from the coating operation and consequently the so-called "art" of tablet coating, film-coated tablets prepared by the automated process show close reproducibility of coating from batch to batch of tablets as well as greater uniformity of coating within batches of tablets.

Concentric Double Electrolytic Junction Calomel Reference Electrode

By NORMAN ADLER

Aqueous calomel reference electrodes are frequently unsuitable for use in titrations in acetic acid or acetic anhydride as they often lead to erratic potentials and drifting, irreproducible end points (1–4). These difficulties have been attributed to contamination of the electrode (3), to insufficient electrode-solution interfacial contact (1), and to changes in the liquid junction potential as the electrolyte flows from the electrode to the solution (4). Asbestos fiber-type electrodes, notoriously troublesome in nonaqueous titrations (4, 5), may be particularly prone to contamination. As the titration solution (often containing perchlorate ion) diffuses into the fiber, it mixes with saturated aqueous potassium chloride. Less soluble potassium perchlorate may then be precipitated, thereby disturbing or breaking the electrolytic contact. Depending on the titration medium, the electrolyte may also be precipitated. A crust of precipitate has been observed to form at the tip of the fiber in contact with the titration medium (6). Fiber electrodes that become shorted or erratic during nonaqueous titrations may often be rejuvenated by soaking overnight in water.

The difficulties with aqueous electrodes may also be attributed to the nature of the electrolyte and the solvent used. The addition of water to the titration medium changes the nature of the system, often deleteriously (3). Water and the occasionally used methanol (7, 8) are not suitable for acetic anhydride systems as they undergo acid-catalyzed

Concentric Double Electrolytic Junction Calomel Reference Electrode

By NORMAN ADLER

Aqueous calomel reference electrodes are frequently unsuitable for use in titrations in acetic acid or acetic anhydride as they often lead to erratic potentials and drifting, irreproducible end points (1–4). These difficulties have been attributed to contamination of the electrode (3), to insufficient electrode-solution interfacial contact (1), and to changes in the liquid junction potential as the electrolyte flows from the electrode to the solution (4). Asbestos fiber-type electrodes, notoriously troublesome in nonaqueous titrations (4, 5), may be particularly prone to contamination. As the titration solution (often containing perchlorate ion) diffuses into the fiber, it mixes with saturated aqueous potassium chloride. Less soluble potassium perchlorate may then be precipitated, thereby disturbing or breaking the electrolytic contact. Depending on the titration medium, the electrolyte may also be precipitated. A crust of precipitate has been observed to form at the tip of the fiber in contact with the titration medium (6). Fiber electrodes that become shorted or erratic during nonaqueous titrations may often be rejuvenated by soaking overnight in water.

The difficulties with aqueous electrodes may also be attributed to the nature of the electrolyte and the solvent used. The addition of water to the titration medium changes the nature of the system, often deleteriously (3). Water and the occasionally used methanol (7, 8) are not suitable for acetic anhydride systems as they undergo acid-catalyzed

Received September 7, 1962, from the Chemical Division, Merck and Co., Inc., Rahway, N. J.
Accepted for publication October 3, 1962.

acetylation reactions. Chloride salt electrolytes are also potentially troublesome.

When the titration medium contains mercuric acetate, the alkali chloride electrolyte flowing into the solution is quantitatively converted to a strong base (3). In the absence of mercuric acetate, titrable base is formed less rapidly by the volatilization of hydrochloric acid (9, 10). In both cases the effect is manifested by a slow drift of the E.M.F. back to the alkaline side of the end point and leads to erroneously high results. Since the rate of base production is not appreciable, the effect may be noticed only in the end point region of the titration where the rate of change of potential with acid concentration is at a maximum.

In view of these effects many workers (6, 11) have recommended either modified calomel electrodes or alternate electrode systems for use as the reference electrode in nonaqueous titrimetry. The modifications of the calomel electrode usually consist either of using various alternate electrolyte-solvent combinations (2, 7, 8, 12) in the built-in salt bridge of commercial calomel electrodes (single junction type), or of immersing the aqueous calomel electrode in an external nonaqueous electrolytic bridge (double junction type). Various geometries for the external bridge chamber have been proposed (1, 4, 5, 11–13). The double junction type, although more complex, permits simpler trouble shooting in the event of electrode difficulties. Their higher resistance is ordinarily not a drawback if used with the high impedance pH meters currently available. In fact, Warner and Haskell (4) have successfully used acetic acid without added electrolyte as the solvent in the second bridge.

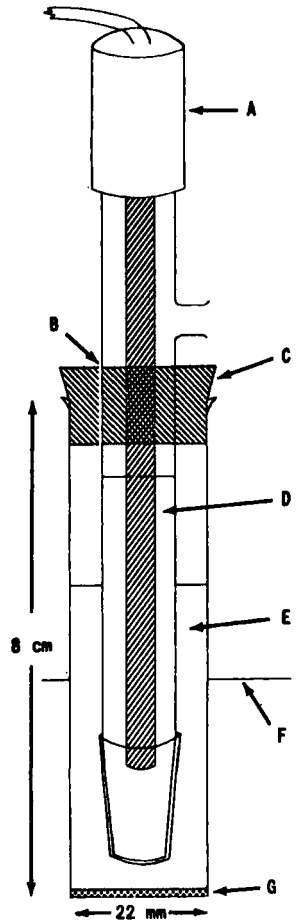

Fig. 1.—Concentric double electrolytic junction calomel reference electrode: *A*, Beckman sleeve-type calomel electrode, No. 1170–71; *B*, vent; *C*, stopper; *D*, saturated aqueous potassium chloride; *E*, saturated solution of potassium perchlorate in acetic acid; *F*, maximum insertion of electrode into solution; and *G*, porous disk.

A convenient version of the double junction type is shown in Fig. 1. It consists essentially of a simplification of the Warner and Haskell design (4) to avoid the necessity of a special titration cell. The compactness of the concentric tube design permits this electrode to be used as easily as an ordinary calomel electrode in the conventional two electrode holders supplied with commercial pH meters. For titrations in poorly conducting solutions where the distance between electrodes may be important (14), the outer bridge may be further modified by placing the porous frit on the side of the tube facing the glass electrode. When not needed for nonaqueous work, the aqueous calomel electrode may be easily removed, and, after rinsing, immediately used for aqueous titrations.

The porosity of the fritted disk (Corning Glass No. 37730, Allihn tube with fritted disk, 30F, 20 mm. diam., 100 mm. height, is cut flush with the disk and to a height of 8 cm.) is adjusted by flame treatment to give a flow rate of less than one drop/hour for a 2 inch head of electrolyte. Acetic acid saturated with potassium perchlorate is used as the electrolyte in the outer bridge. Introduction of reasonable amounts of this electrolyte into the titration system is without effect. As indicated in Fig. 1, the relative levels of the electrolytes in relation to the solution are arranged to give a positive outward flow, thus minimizing the possibility of electrode contamination by inward diffusion of the titration medium. Monthly changes of inner and outer electrolytes are usually sufficient to keep the electrode working properly. In use, the electrode equilibrates rapidly to give stable potentials of the same magnitude as obtained for other calomel reference electrodes. (A fresh aqueous fiber type, a sleeve type filled with lithium chloride in acetic acid, and the above type, gave the same potential within 10 mv. when measured against the same glass electrode in the same solution.) The concentric tube electrode has been in satisfactory use for many years in this laboratory.

Low Molecular Weight Carbohydrates in *Sargassum natans* from Puerto Rico

By NOEMÍ G. MARTÍNEZ NADAL, LUZ V. RODRÍGUEZ, and CARMEN CASILLAS

***d*-Mannitol, *d*-mannitol monoacetate, and an unidentified carbohydrate were isolated from *Sargassum natans*.**

PRELIMINARY tests carried out in this laboratory indicated that an ether extract of *Sargassum natans* exhibited antibiotic properties (1). To obtain further data, aqueous and alcoholic extracts of this alga were prepared and tested for antibiosis. Negative results were obtained.

Since no work is reported on the polysaccharides found in *Sargassum natans*, we separated and identified some of the carbohydrates present in the alcoholic extract of this alga. The presence of *d*-mannitol, *d*-mannitol monoacetate, and unknown carbohydrate were evidenced.

EXPERIMENTAL

A chemical analysis of dried *Sargassum natans* from Puerto Rico gave the following results: 1.23 Gm. ether extract, 74.21 Gm. carbohydrates, 14.21 Gm. fiber, 0.77 Gm. nitrogen, 4.81 Gm. protein, 33 mg. tryptophan, 44 mg. methionine, 174 mg. lysine, 19.75 Gm. ash, 289 mg. calcium, 57.2 mg. phosphorous, 57.4 mg. iron, 0.01 mg. carotene, 0.31 mg. riboflavin, 1.46 mg. niacin, 3.70 mg. ascorbic acid, 326 calories.

An extract prepared by continuous extraction of 100 Gm. of dried alga, with 95% ethanol for 24 hours, on cooling, deposited about 3% of a white crystalline precipitate (ppt. No. 1).

The alcohol was removed from the rest of the sample under reduced pressure. The residue consisted of a crystalline, brownish mass, with an oily layer, which was removed by washing with ether. Several recrystallizations of this mass from alcohol gave ppt. No. 2. A small amount of ppt. No. 3 was obtained by the evaporation of cold alcoholic extracts.

Osazones, hydrazones, and semicarbazones were prepared of precipitate No. 1 and 2.

A second batch of 800 Gm. of dried alga was extracted for 67 hours with ether, followed by 71 hours of alcoholic extraction. A 19.8 Gm. quantity of ppt. No. 1 was obtained by decantation of the alcoholic extract. After concentration to dryness, the residue was dissolved in water and filtered. Lead acetate was added to the filtrate, the precipitate formed was removed, and the excess of lead was precipitated with hydrogen sulfide. After evaporation of the solution to dryness, the residue was dissolved in 1% ethanol and absorbed on a carbon Celite column (35 × 4.5 cm.) which was eluted with aqueous ethanol (1–15%). From 30–40 μl. of each fraction was investigated by paper chromatography prior and after hydrolysis with 0.1 *N* hydrochloric acid. Ethyl acetate:acetic acid:water (3:1:3 v/v) was used as solvent. The indicator spray used on monosaccharides was ammoniacal silver, Hough's method (2) and modified method of Trevelyn, *et al.* (3). The sugar alcohols were spotted by bromcresol purple reagent and appeared as yellow spots on a blue background owing to the pH change of the sugar-borate complex of Bradfield (4) and Hackmann (5).

Received July 5, 1962, from the University of Puerto Rico, Mayaguez.
Accepted for publication September 28, 1962.
The work was carried out at the Research Center, College of Agriculture and Engineering, University of Puerto Rico, Mayaguez.

RESULTS

Sargassum natans is a brown alga, whose chemical composition revealed it to be rich in carbohydrates and low in nitrogen. It grows abundantly on the coasts of Puerto Rico.

Three pure compounds were obtained from the alcoholic extraction of this alga. Ppt. No. 1, m.p. of over 300°, contained carbon, hydrogen, and oxygen, reduced the silver nitrate sodium ethoxide reagent, gave a positive carbazol reaction for carbohydrates, did not reduce Fehling's solution and reacted with semicarbazide hydrochloride to form a compound, m.p. 119–120°. Its chromatographic strip resembles in R_f and appearance a cyclitol.

Ppt. No. 2, identified, as *d*-mannitol, by paper chromatography, and by derivatives of phenylhydrazine and semicarbazide hydrochloride, was confirmed by microanalysis.[1]

Ppt. No. 2 (pure) Found: C = 39.47; H = 7.79. Calculated as *d*-mannitol: C = 39.53; H = 7.74. Phenylhydrazine derivative of ppt. No. 2. Found: C = 64.51; H = 6.17; N = 18.80. Phenylhydrazine derivative of pure *d*-mannitol. Found: C = 64.55; H = 6.19; N = 19.00. Semicarbazide derivative of ppt. No. 2. Found: C = 20.49; H = 5.6; N = 46.55. Semicarbazide derivative of pure *d*-mannitol. Found: C = 20.46; H = 5.08; N = 46.47.

Ppt. No. 3, m.p. 124–126°, which was identified by paper chromatography as *d*-mannitol monoacetate was confirmed by microanalysis as $C_8H_{16}O_7$. Found: C = 42.8; H = 7.19. Calcd.: C = 42.9; H = 7.05. The hexacetate formed from the hydrolyzed sample of this monoacetate was also confirmed by microanalysis. Found: C = 50.84; H = 5.92. Calcd.: C = 50.21; H = 5.76.

SUMMARY

1. Chemical analysis of *Sargassum natans* indicated it to be rich in carbohydrates and low in nitrogen.

2. Three natural products were separated by solubility ratios and column chromatography from *Sargassum natans* from Puerto Rico.

3. *d*-Mannitol and *d*-mannitol monoacetate were identified among the three products obtained.

Investigation of Pantothenyl Alcohol in Experimentally Induced Intestinal Atony

By THOMAS A. LYNCH, WILBUR L. HIGHLEY, and ALBERT G. WORTON

Pantothenyl alcohol (10 mg./Kg.) given subcutaneously significantly increased gastrointestinal motility at 15 and 18 hours in mice and at 20 and 24 hours in rats following cecectomy, but exerted no effect in normal animals. Optimal conditions for evaluating pantothenyl alcohol consisted of measuring the 30- and 45-minute progression of an orally administered charcoal meal through the gastrointestinal tract, 14 to 24 hours following cecectomy.

BLY, *et al.* (1), in 1943 and Jurgens and Pfaltz (2) in 1944 were the first to report the occurrence of intestinal atony in pantothenic acid deficient animals. These observations lead to clinical investigations by Kareha, *et al.* (3), Haycock, *et al.* (4), Stone, *et al.*, (5), Frazer, *et al.* (6), and Nardi and Zuidema (7), who reported pantothenyl alcohol to be effective in preventing and treating intestinal atony and gaseous abdominal distention in postsurgical patients. In 1950 Lipmann, *et al.* (8), established pantothenic acid as an integral part of coenzyme A. The *in vivo* formation of acetyl coenzyme A and the acetate transfer to choline, elaborate the transmitter substance, acetylcholine, required for intestinal motility. Unna and Greslin (9) reported pantothenic acid to be pharmacologically inert and relatively nontoxic. Polacek, *et al.* (10), using a double blind technique, were able to significantly reduce the duration of experimental post-surgical ileus in mongrel dogs. In this study a method of evaluating pantothenyl alcohol or similarly acting agents in small laboratory animals is presented.

EXPERIMENTAL

Mice (15–36 Gm.) and rats (60–250 Gm.) were anesthetized with ether, the abdominal cavity opened, and the cecum tied off and removed. Following the closure of the abdomen by suturing, the drug was administered subcutaneously. At various intervals following cecectomy, a 12.5% powdered charcoal suspension in 1% methyl cellulose solution was given orally using a dosage equivalent to 2.5% of the body weight. At a specific time following charcoal administration, the animals were decapitated, the entire gastrointestinal tract was removed, and the distance that the charcoal meal had progressed was expressed as per cent of the total length of the gastrointestinal tract.

RESULTS AND DISCUSSION

Pantothenyl alcohol (10 mg./Kg.) given subcutaneously just after cecectomy did not alter the 12 to 18 hours passage of charcoal meal, which progressed only 60 to 100% the length of the gastrointestinal tract as determined in 106 black (C-57)[1] male mice (15–36 Gm).

Using a 30-minute charcoal passage period, pantothenyl alcohol (1000 mg./Kg.) did not affect gastrointestinal motility in normal Swiss female mice (15–30 Gm.) at 1 to 14 hours, but increased motility at 14 hours in cecectomized mice ($P < 0.10$).

Gastrointestinal charcoal passage rates at 45 minutes in mice, as shown in Table I, indicate that the optimal effect of pantothenyl alcohol occurs between 11 and 18 hours following cecectomy. Pantothenyl alcohol significantly enhanced gastrointestinal activity at 15 hours ($P < 0.05$) and at 18 hours ($P < 0.001$).

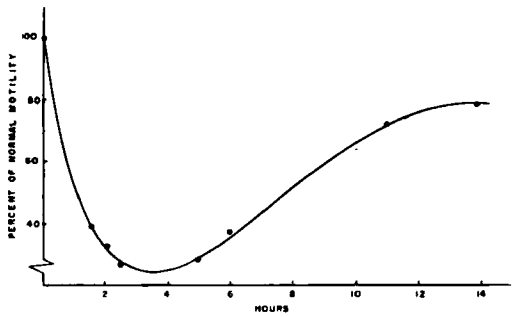

Fig. 1.—Pattern of surgically induced gastrointestinal atony and restoration in cecectomized mice as determined by the 30-minute passage of orally administered charcoal. Normal motility = 100%.

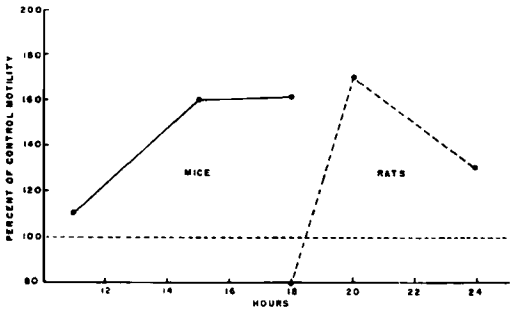

Fig. 2.—Pantothenyl alcohol (10 mg./Kg.) effect in the response phase of surgically induced atony as determined by the 45-minute passage of charcoal. Control motility in cecectomized animals = 100%.

upper gastrointestinal motility in regard to surgical cecectomy and pantothenyl alcohol effect appears to be: (*a*) an atony phase, (*b*) a restoration phase, and (*c*) a pantothenyl alcohol-effect phase.

The results suggest that upper gastrointestinal motility as measured by 30 or 45 minutes charcoal passage rates at 14 to 24 hours postoperatively in mice and rats is optimal for evaluating pantothenyl alcohol or similarly acting compounds.

The data presented tend to confirm in part the work of Unna and Greslin (9) in that pantothenic acid does not exert a direct pharmacologic effect in normal animals, and substantiates the report of Polacek, *et al.* (10), in which pantothenyl alcohol hastened the return of normal gastrointestinal motility. The difference in response of normal and post-surgical animals suggests that surgically induced atony may be related to a depression in function of the pantothenate-coenzyme A-acetylcholine biochemical pathway. Pantothenyl alcohol may act by accelerating this function in the post-surgical animal.

Quantitative Evaluation of Surface Anesthetics in Albino Mice

By W. R. JONES and L. C. WEAVER

The corneal reflex of the albino mouse is satisfactory for the quantitative determination of relative potency of local anesthetics. It was found that dyclonine was more active, benzonatate equally active, and procaine less active than cocaine.

THE CORNEAL reflex of cats (1), dogs (2), rabbits, and guinea pigs (3) has been used for the detection of local anesthetic activity. Pittenger (1) suggested the use of the cornea of cats for the qualitative detection of local anesthetic action. However, Munch (2) concluded that cats are not as suitable as rabbits because of greater individual differences in activity and because of greater reluctance on the part of the test animal to permit the touching of the cornea at frequent intervals. He also concluded that qualitative tests made upon the cornea of dogs offer no particular advantage. The corneal reflex in the rabbit has not been successfully standardized and has not withstood statistical examination (3). Although Chance and Lobstein (3) report that guinea pigs show a more regular reflex response, both normally and when anesthetized, than do rabbits, Bulbring and Wajda (4) found that guinea pigs frequently fail to blink even if the cornea is not anesthetized. Regardless of the relative advantages of guinea pigs *vs.* rabbits, however, Chance and Lobstein (3) introduced a method which made possible a quantitative comparison of local anesthetics.

When preliminary tests indicated that the albino mouse might be a satisfactory animal for the bioassay of local anesthetics, an experiment was carried out to determine a dose-response curve for cocaine, procaine, dyclonine, and benzonatate. The ac-

tivity of these compounds relative to cocaine was then calculated.

EXPERIMENTAL

Male Swiss-Webster albino mice were used. After trimming the eyelashes, one drop of the solution to be tested was placed on the surface of each eye. (Grasping the skin near the back of the head caused the eyes to protrude so that the drop readily adhered to the surface.) Approximately 25–30 seconds later, the remaining solution was removed by touching the eyes with a piece of absorbent tissue (Kleenex). One minute from the time the solution was applied, the surface of the cornea was touched with a small glass probe[1] and the presence or absence of the corneal reflex was recorded. Corneal stimulation was repeated at one-minute intervals until the animal failed to show anesthesia on three successive occasions. In testing for the corneal reflex, the animal was placed on a piece of wire mesh and held by the tail with one hand while the other hand was braced on the table top and used to manipulate the glass probe so that the surface of the eye could be gently touched without touching the eyelids. For purposes of calculation, only the first 10-minute interval was used. Thus, each animal contributed 20 responses to the total. The number of times the animal failed to blink was divided by the number of times the eyes were stimulated and the percentage response for each group was plotted against the dose (in mg./ml.). Six to nine mice were used to locate each point on the dose response curve, which was calculated by the method of Litchfield and Wilcoxon (5).

Relative potency was determined by comparing the dose-response curves of each drug to that of cocaine (Table I) and the following results obtained: (*a*) Dyclonine was significantly more active than cocaine. The potency ratio and 19/20 confidence limits were 9.07 and 3.73–21.94. (*b*) Benzonatate did not differ significantly from cocaine. The potency ratio and 19/20 confidence limits were 1.00 and 0.45–2.24. (*c*) Procaine was significantly less active than cocaine. The potency ratio and 19/20 confidence limits were 0.07 and 0.03–0.16.

[1] A piece of glass tubing (0.5 cm. i.d.) was heated and drawn out so that the tip, when sealed, was approximately 1 mm. in diameter. To facilitate the application of this tip to the cornea, the final 2 mm. were bent at a 60° angle and a 30° angle was made 2 cm. above this point. The overall length was about 13 cm.

DISCUSSION AND CONCLUSIONS

These data suggest that the procedure presented may be used for quantitative evaluation of surface anesthetics in mice. Accurate dose-response curves were economically and easily obtained. A further advantage was the fact that stimulation of the unanesthetized cornea of the albino mouse never failed to elicit a blink in our studies to date.

This test, as most tests, is not entirely objective. At the time the drug effect begins to wane, some difficulty may arise in scoring corneal responses. The response which occurs when the unanesthetized eye is touched is clean, clear-cut, and distinct. The total lack of response of the fully anesthetized eye likewise presents no difficulty to the observer. However, at some point between these extremes, the animal squints or blinks in response to corneal stimulation in a manner very different from the normal rapid response. Any movement of the eyelid was taken as lack of anesthetic effect. This was actually a minor problem in the experiment and should not be unduly emphasized.

Since it is common practice to modify procedures, the following variables might well be investigated to improve on the procedure presented. These include: (*a*) Choice of different time intervals. (*b*) Alterations of the time of drug contact with the eye. (*c*) Examination to determine whether there is less variability between the right eye and the left eye than there is between different animals. If so, a more valid comparison of relative potency could be obtained by treating one eye with a standard drug and the other eye with the drug whose relative potency is to be determined. In this manner, both drugs could be compared in the same animal at the same time.

Isolation of Podophyllotoxin from *Callitrus drummondii*

By LEMONT B. KIER, DOROTHEA B. FITZGERALD†, and SHIRLEY BURGETT

Aqueous suspensions and extracts of the dried needles of *Callitrus drummondii* have been shown to be tumor inhibiting against Sarcoma 37 in mice. Hydrolysis of the water extract has given a good yield of podophyllotoxin which is a known tumor-inhibiting substance.

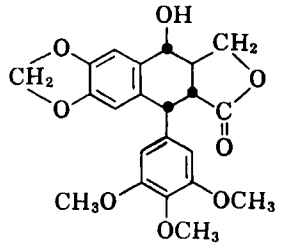
CALLITRUS DRUMMONDII (Parlat) F. Muell is an evergreen tree native to Australia where it is commonly known as Drummond's cypress pine. In a recent survey of conifers for tumor-damaging substances (1), the needles of *C. drummondii* were found to cause necrosis and hemmorrhage in Sarcoma 37 in mice. This study was initiated in an effort to isolate and characterize the principle responsible for this activity.

An initial test indicated that an aqueous suspension of the needles ground to a 100 mesh fineness was active at a level of 100 mg./Kg. against Sarcoma 37 in mice. Extracts of the needles made with ethyl acetate and ethanol were inactive in the same test at levels of 400 mg./Kg. and 750 mg./Kg., respectively. These results indicated that the active principle was highly water soluble, exhibiting a low solubility in nonpolar solvents. A preliminary extraction with water followed by lyophylization produced a residue with an activity of 50 mg./Kg., confirming the belief that the active principle was highly water soluble. Furthermore, the finding of some activity in a xylene defatting solution and the extent depending upon the time of exposure indicated that the active principle could be a glycoside. Partial hydrolysis during processing might well produce a xylene soluble aglycone.

Large-scale defatting and extraction with water followed by lyophylization produced an amorphous hygroscopic material.

Column chromatography of this material was attempted on several adsorbents, silica gel (2) proving to be the most satisfactory. Water eluents became increasingly more active as they became lighter in color. A maximum activity of 2 mg./Kg. was obtained for the light-colored lyophylized residue of the final eluents.

The ultraviolet adsorption of the active fraction showed a high intensity maximum at 290 mμ and a minimum at 260 mμ. The infrared spectrum indicated a very close resemblance to that of podophyllotoxin (I) from an authentic specimen.



(I)

Received September 17, 1962, from the College of Pharmacy, University of Florida, Gainesville.

† Present address: Cancer Chemotherapy Section, National Institutes of Health, Bethesda, Md.

Hydrolysis of the combined active eluents with emulsin produced glucose, identified as the phenylhydrazone. The aglycone portion was recrystallized from benzene, m.p. 110–113°. This is close to the melting point reported for the hydrated form of podophyllotoxin (I) (3). Drying this hydrate gave a material (m.p. 180–182°) which gave no depression with authentic podophyllotoxin (I). The infrared and ultraviolet spectra were identical.

The finding of podophyllotoxin (I) in a conifer is not unusual. It has been reported in several *Juniperus* species (4, 5). The minimum effective dose for podophyllotoxin (I) against Sarcoma 37 in mice has been reported to be 2 mg./Kg. (4). This activity is consistent with the finding of the activity of the chromatographed fractions of *C. drummondii*. Although this fact does not preclude the possibility that activity may also be due to some other constituent present, it cannot be doubted that podophyllotoxin (I) is certainly largely responsible for the antitumor activity of *C. drummondii*.

EXPERIMENTAL

Plant Material.—The needles were collected in the fall of 1960 near Ravensthorpe, Western Australia, and dried prior to shipment. They were identified as *C. drummondii* (Parlat) F. Muell by T. C. Dunne, Director of Agriculture, Western Australia.

Preliminary Studies.—A quantity of needles were ground to 100 mesh fineness and subjected to antitumor screening.[1] The minimum effective dose of an aqueous suspension was found to be 100 mg./Kg. against Sarcoma 37 in mice. A second portion of ground needles was extracted with water, lyophylized, and the residue subjected to the same test. The M.E.D. was found to be 50 mg./Kg. Extracts of the ground needles with ethanol and ethyl acetate gave no activity at levels of 750 and 400 mg./Kg., respectively.

Extraction.—One-hundred grams of the ground needles were stirred for 5 minutes in 500 ml. of xylene then filtered and dried. The dried marc was vigorously stirred successively in four 1-L. portions of water. The combined aqueous filtrates were lyophylized to a light brown hygroscopic residue weighing 20 Gm.

Isolation of Podophyllotoxin (I) Glycoside.—The lyophylized residue, about 20 Gm., was placed on 1500 Gm. of hydrated silica gel. The column was eluted with water. Fractions were taken according to the intensity of color. The first fractions were dark in color and showed little tumor-damaging activity. As the eluents became lighter in color, the activity rose. The lyophylized residue from the final cuts yielded a light, fluffy, slightly yellow material having a M.E.D. of about 2 mg./Kg.

[1] All antitumor testing was conducted under the auspices of the Cancer Chemotherapy Section, National Institutes of Health, Bethesda, Md.

The ultraviolet absorption of the more active fractions showed a high intensity maximum at 290 mμ and a minimum at 260 mμ. The infrared absorption showed a broad hydroxyl band (3450 cm.$^{-1}$), a lactone (1740 cm.$^{-1}$), and an overall resemblance to a spectrum of podophyllotoxin (I).

Isolation of Podophyllotoxin(I).—The active lyophylized fractions were dissolved in water at pH 5, treated with half their weight of emulsin and allowed to stand 24 hours at 37°. The solutions were then extracted with chloroform in a continuous extractor. The chloroform was concentrated to dryness and the residue recrystallized from benzene, m.p. 110–113°. This melting point is in fair agreement with the value reported for podophyllotoxin (I) benzene hydrate (6, 7). The material was dried for 24 hours *in vacuo* at 100°, m.p. 180–182°. A mixed melting point with authentic podophyllotoxin (I) gave no depression and the infrared and ultraviolet spectra were identical.

Anal.—Calcd. for $C_{22}H_{22}O_8$: C, 63.75; H, 5.35; OCH_3, 22.47. Found: C, 63.88; H, 5.62; OCH_3, 22.18.

The yield of podophyllotoxin (I) from the dried needles based on spectrophotometric analysis was about 1.4 per cent.

The water solution from the chloroform extraction was treated with phenylhydrazone hydrochloride and sodium acetate. The resulting crystals of the phenylhydrazone gave no depression with the corresponding glucose derivative.

Synthesis and Antifungal Activity of Anilides of Salicylic Acid and *o*-Coumaric Acid

By H. WAYNE SCHULTZ

A series of *o*-hydroxycinnamanilides and the corresponding series of salicylanilide derivatives were prepared and tested for antifungal activity. These compounds were investigated for the purpose of determining the effect of vinylogy and also the effect of substitution on the anilide rings. The results showed that all of the *o*-hydroxycinnamanilide derivatives had less antifungal activity than did their corresponding salicylanilide derivatives. Most of the compounds had some antifungal activity at the tested concentration of 0.5%; however, only two compounds had activity greater than salicylanilide. These compounds were the 3′-chloro- and the 4′-chloro-salicylanilides.

ALTHOUGH a large number of salicylanilide derivatives have been investigated for antifungal activity (1–10), the structural modifications have been generally limited to substitution on one or both of the aromatic rings. It was of interest to note that none of the reported investigations have been concerned with the vinylog derivatives, which are represented by the anilides of *o*-coumaric acid (*o*-hydroxycinnamanilides). Because of the principle of vinylogy (11), it appeared that such derivatives might possess activity similar to that of the related salicylanilide derivatives.

In this investigation a series of *o*-hydroxycinnamanilide derivatives and the corresponding series of salicylanilide derivatives were prepared and tested for antifungal activity. The compounds consisted of the free acids, the unsubstituted anilides, the 2′-, 3′-, and 4′-chloro-anilides, the 2′-, 3′-, and 4′-nitro-anilides and the 2′-, 3′-, and 4′-methyl-anilides. These derivatives not only provided the possibility of determining the effect of vinylogy but also the effect of substitution in varying positions on the anilide rings.

EXPERIMENTAL

Synthesis of *o*-Hydroxycinnamanilides

***o*-Coumaric Acid.**—From 32.1 Gm. (0.22 mole) of coumarin treated with 400 ml. of 8% sodium hydroxide and 4 Gm. of yellow mercuric oxide according to the procedure of Seshadri and Rao (12), there was obtained 27.5 Gm. (76%) of coumaric acid having a m.p. of 208°. This material was used in the following reaction.

***o*-Acetoxycinnamic Acid (13).**—A mixture of 27.5 Gm. (0.17 mole) of *o*-coumaric acid, 7.0 Gm. (0.85 mole) of sodium acetate and 90 ml. (0.95 mole) of acetic anhydride was heated on a steam bath for 7 hours. After cooling to room temperature, the reaction mixture was poured into 1 liter of ice and water and allowed to stand overnight. The white crystalline material was separated and washed with cold water and dried in air to give 33.0 Gm. of product (94% yield). A sample after recrystallization from benzene gave m.p. 153–154°.

***o*-Acetoxycinnamoyl Chloride (14).**—A mixture of 10.3 Gm. (0.05 mole) of *o*-acetoxycinnamic acid, 11.8 Gm. (0.1 mole) of thionyl chloride and 15 ml. benzene was heated under reflux for $^1/_2$ hour and cooled to room temperature. The solvent and excess thionyl chloride was removed *in vacuo* with gentle heating. Upon standing, a white crystalline material resulted.

4′-Methyl-2-Hydroxycinnamanilide.—In a typical example, the above *o*-acetoxycinnamoyl chloride

The ultraviolet absorption of the more active fractions showed a high intensity maximum at 290 mμ and a minimum at 260 mμ. The infrared absorption showed a broad hydroxyl band (3450 cm.$^{-1}$), a lactone (1740 cm.$^{-1}$), and an overall resemblance to a spectrum of podophyllotoxin (I).

Isolation of Podophyllotoxin(I).—The active lyophylized fractions were dissolved in water at pH 5, treated with half their weight of emulsin and allowed to stand 24 hours at 37°. The solutions were then extracted with chloroform in a continuous extractor. The chloroform was concentrated to dryness and the residue recrystallized from benzene, m.p. 110–113°. This melting point is in fair agreement with the value reported for podophyllotoxin (I) benzene hydrate (6, 7). The material was dried for 24 hours *in vacuo* at 100°, m.p. 180–182°. A mixed melting point with authentic podophyllotoxin (I) gave no depression and the infrared and ultraviolet spectra were identical.

Anal.—Calcd. for $C_{22}H_{22}O_8$: C, 63.75; H, 5.35; OCH_3, 22.47. Found: C, 63.88; H, 5.62; OCH_3, 22.18.

The yield of podophyllotoxin (I) from the dried needles based on spectrophotometric analysis was about 1.4 per cent.

The water solution from the chloroform extraction was treated with phenylhydrazone hydrochloride and sodium acetate. The resulting crystals of the phenylhydrazone gave no depression with the corresponding glucose derivative.

Synthesis and Antifungal Activity of Anilides of Salicylic Acid and *o*-Coumaric Acid

By H. WAYNE SCHULTZ

A series of *o*-hydroxycinnamanilides and the corresponding series of salicylanilide derivatives were prepared and tested for antifungal activity. These compounds were investigated for the purpose of determining the effect of vinylogy and also the effect of substitution on the anilide rings. The results showed that all of the *o*-hydroxycinnamanilide derivatives had less antifungal activity than did their corresponding salicylanilide derivatives. Most of the compounds had some antifungal activity at the tested concentration of 0.5%; however, only two compounds had activity greater than salicylanilide. These compounds were the 3′-chloro- and the 4′-chloro-salicylanilides.

ALTHOUGH a large number of salicylanilide derivatives have been investigated for antifungal activity (1–10), the structural modifications have been generally limited to substitution on one or both of the aromatic rings. It was of interest to note that none of the reported investigations have been concerned with the vinylog derivatives, which are represented by the anilides of *o*-coumaric acid (*o*-hydroxycinnamanilides). Because of the principle of vinylogy (11), it appeared that such derivatives might possess activity similar to that of the related salicylanilide derivatives.

In this investigation a series of *o*-hydroxycinnamanilide derivatives and the corresponding series of salicylanilide derivatives were prepared and tested for antifungal activity. The compounds consisted of the free acids, the unsubstituted anilides, the 2′-, 3′-, and 4′-chloro-anilides, the 2′-, 3′-, and 4′-nitro-anilides and the 2′-, 3′-, and 4′-methyl-anilides. These derivatives not only provided the possibility of determining the effect of vinylogy but also the effect of substitution in varying positions on the anilide rings.

(11.2 Gm., 0.05 mole) was dissolved in 25 ml. benzene and a solution of 10.7 Gm. (0.1 mole) of *p*-toluidine in 25 ml. benzene was added slowly with stirring. The resultant mixture was refluxed for 15 minutes on a steam bath and then placed in an evaporating dish and allowed to evaporate to dryness. The solid residue was finely powdered, mixed with 300 ml. of 3% hydrochloric acid, and allowed to stand overnight. The solid material was separated with filtration and washed well with water. This material was dissolved in 150 ml. of 0.1 *N* sodium hydroxide solution and refluxed for 2 hours. After cooling to room temperature, the solution was acidified with hydrochloric acid and diluted with 200 ml. of water. The solid was collected, washed with water, and recrystallized from aqueous ethanol to give 8.1 Gm. of light tan crystals, m.p. 223–234°.

Synthesis of Salicylanilides

2′-Chlorosalicylanilide.—In a typical example a mixture of 10.4 Gm. (0.075 mole) of salicylic acid, 17.7 Gm. (0.15 mole) thionyl chloride, and 15 ml. benzene was refluxed for ½ hour and then cooled to room temperature. The solvent and excess thionyl chloride were removed *in vacuo* with gentle heating. The product was dissolved in 25 ml. benzene and a solution of 19.1 Gm. (0.15 mole) of *o*-chloroaniline in 25 ml. benzene was added slowly with stirring. The resultant mixture was refluxed for 15 minutes on a steam bath and then placed in an evaporating dish and allowed to evaporate to dryness. The solid residue was finely powdered, mixed with 300 ml. of 3% hydrochloric acid, and allowed to stand overnight. The solid material was separated with filtration and washed well with water. Upon recrystallization from aqueous ethanol there was obtained 13.2 Gm. (71%) of white crystals, m.p. 165–166°.

Antifungal Activity

The compounds were tested for their ability to inhibit the growth of three pathogenic species of fungi using a procedure similar to that described by Kligman and Rosenweig (15). Petri dishes containing sterile Sabouraud's agar were innoculated with the test organisms and a sterile filter paper disk was placed in the center of each dish. Test

[a] Average of two measurements.

solutions of the compounds at 0.5% concentration were prepared using alcohol or acetone as the solvent. Alcohol (95% w/v) was used for all of the compounds except the 2′-, 3′-, and 4′-nitro-2-hydroxycinnamanilide derivatives and the 3′- and 4′-nitrosalicylanilide derivatives. For these compounds, which were insoluble in alcohol at the desired concentration, acetone was used as the solvent. To each filter paper disk, 0.8 ml. of a test solution was applied by means of a pipet. Two plates of an organism were treated with each test solution. The pure solvents, alcohol and acetone, were also tested. The plates were incubated at 28° for 72 hours. At the end of this time the diameter of the zone of inhibition was measured.

DISCUSSION

As shown in Table III, all of the *o*-hydroxycinnamanilide derivatives had less antifungal activity than did their corresponding salicylanilide derivatives. Most of the compounds had some antifungal activity at the tested concentration of 0.5%; however, only two compounds had activity greater than salicylanilide. These compounds were the 3′-chloro- and the 4′-chloro-salicylanilides. Of these two, the 4′-chlorosalicylanilide derivative had greater activity against *T. rubrum* and *E. floccosum* than salicylanilide and had an activity against *T. mentagrophytes* which was almost equal to that of salicylanilide.

Among the substituted chloro- and nitro- salicylanilide derivatives it was found that the 4′- position gave the greatest antifungal activity, while the 3′-position was the most effective of the methyl derivatives. The anilide derivatives of *o*-hydroxycinnamic acid did not show this overall consistency in relationship between position and activity. The results further showed that the activity of salicylanilide was enhanced only by the substitution of a 4′-chloro group on the anilide ring, while with its vinylog, *o*-hydroxycinnamanilide, substitution of either 2′-chloro, 3′-chloro, 2′-methyl, or 3′-methyl enhanced its activity.

Synthesis of a Vinylog of *p*-Aminobenzoylglutamic Acid

By C. DEWITT BLANTON, JR., and W. LEWIS NOBLES

In an attempt to prepare a folic acid vinylog, a vinylog of *p*-nitrobenzoylglutamic acid has been prepared using an alkyl carbonic-carboxylic acid-mixed anhydride. This intermediate nitro vinylog was reduced in the presence of Raney nickel to give a vinylog of *p*-aminobenzoylglutamic acid.

IN PURSUING a program dealing with the preparation of a vinylog of folic acid (pteroylglutamic acid), a relatively large quantity of *p*-nitrocinnamoylglutamic acid and *p*-aminocinnamoylglutamic acid was desired. Since the method (1) reported in the literature for preparing *p*-nitrobenzoylglutamic acid involved the condensation of *p*-nitrobenzoyl chloride and glutamic acid, it was believed that the condensation of *p*-nitrocinnamoyl chloride and glutamic acid would give the vinylog corresponding to *p*-nitrobenzoylglutamic acid. The preparation of *p*-nitrocinnamoylglutamic acid by this technique has been reported (2) to give a 37% yield of a pale yellow material melting at 206–208°. The modified Schotten-Baumann described by Siegart and Day (3) for the preparation of *p*-nitrobenzoylglutamic acid when applied to this study failed to improve the yields. In both procedures, *p*-nitrocinnamic acid and glutamic acid can be recovered in considerable quantity. This might have been anticipated due to the much higher degree of reactivity of *p*-nitrocinnamoyl chloride than that of *p*-nitrobenzoylchloride.

At this point, our attention was turned to the use of alkyl carbonic-carboxylic acid-mixed anhydrides for the preparation of amides (4). The use of this method of synthesis has become of increasing importance, especially in the synthesis of peptides (5). This reaction was readily adapted to the synthesis of *p*-nitrocinnamoylglutamic acid.

The reaction of the anhydride of *p*-nitrocinnamic acid and ethyl chloroformate with the diethyl ester of glutamic acid proceeded smoothly in diethylene glycol dimethyl ether (diglyme) or tetrahydrofuran (THF) at 0–5°. The diethyl ester of glutamic acid was employed to avoid possible interaction with the carboxylic groups. Hydrolysis of the diethyl *p*-nitrocinnamoylglutamate obtained in 50 to 73% yield gave a pale yellow product identical to that reported by Carrol (2).

The use of a solution of ammonium sulfide (6) for the selective reduction of the nitro group of cinnamic acids appears to be inadequate here since its basic character and the high reaction temperature (85–90°) is sufficient to split the amide linkage. For the conversion of the diethyl *p*-nitrocinnamoylglutamate to diethyl *p*-aminocinnamoylglutamate, the procedure of Blout (7) was found to be effective. In Blout's work, it was demonstrated that Raney nickel does effectively catalyze the hydrogenation of aromatic nitro groups in preference to aliphatic double bonds conjugated with a benzoid ring, and that it was possible to prepare in good yields amino cinnamic acids and esters from the corresponding nitro compound. However, if 2 to 3 Gm. (wet wt.) of Raney nickel were used, as in Blout's original work, an oil was the only product isolated. If, on the other hand, 1 to $1^1/_2$ Gm. (wet wt.) of Raney nickel were employed, a yellow solid substance was obtained; this proved to be diethyl *p*-aminocinnamoylglutamate. In the latter case, the rate of hydrogen absorption was very slow. Adkins (8) has reported that the use of sufficient quantities of Raney nickel can be employed to reduce esters of certain amino acids to amino alcohols. This may, in part, account for the undesirable oil which was isolated when 2 or 3 Gm. (wet wt.) of Raney nickel was employed.

As the similarity in physical and chemical properties of a compound and its vinylog is well known (9), it has become of interest to learn whether or not vinylogs of folic acid will demonstrate similar biological activity. At this time, the only significant observation occurring among these vinylogous substances has to do with one of their physical properties, *viz.*, melting points (Table I).

EXPERIMENTAL

Diethyl *p*-Nitrocinnamoyl-DL-glutamate.—The general method of Sam (10) was utilized with some modification. The procedure of Pandya (11, 12) was employed for preparing *p*-nitrocinnamic acid. Diethyl glutamate was prepared by the method of Chiles and Noyes (13). To a stirred and cooled

TABLE I.—COMPARISON OF MELTING POINTS

Parent Compound	M.p., ° C.	Vinyl Compound	M.p., ° C.[a]
p-Nitrobenzoylglutamic acid	112.5 to 113.5	*p*-Nitrocinnamoylglutamic acid	205–207
Diethyl *p*-nitrobenzoylglutamate	96	Diethyl *p*-nitrocinnamoylglutamate	97–99
p-Aminobenzoylglutamic acid	172–173	*p*-Aminocinnamoylglutamic acid	193.8 to 196.6
Diethyl *p*-aminobenzoylglutamate	143–144	Diethyl *p*-aminocinnamoylglutamate	115.5 to 117

[a] Melting points are corrected.

mixture of 20 Gm. (0.103 mole) of *p*-nitrocinnamic acid in 1 L. of diglyme there was gradually added 10.4 Gm. (0.103 mole) of triethylamine. The resulting solution was maintained at 0–5° during the addition of 13 Gm. (0.128 mole) of ethyl chloroformate. After the mixture had been maintained at 0° for 30 minutes there was added 20.0 Gm. (0.146 mole) of diethyl DL-glutamate dissolved in 100 ml. of diglyme; the temperature was maintained at 0 to 5°. The contents of the reaction vessel were allowed to warm to room temperature (32°) and stirred at that temperature for 6 hours. A white crystalline material (triethylamine hydrochloride) was collected by filtration. The yellow solution was allowed to stand overnight at room temperature. Five-hundred milliliters of distilled water was then added to this yellow solution, followed by the addition of chipped ice until precipitation was complete. There was obtained 25.7 Gm. (66.0%) of diethyl *p*-nitrocinnamoyl-DL-glutamate. After recrystallization to analytical purity from an ethanol-water solution, a m.p. of 97–99° was observed.

Anal.—Calcd. for $C_{18}H_{22}N_2O_7$: C, 57.14; H, 5.82; N, 7.14. Found: C, 57.32; H, 5.60; N, 7.46.

Diethyl *p*-Aminocinnamoyl-DL-glutamate.—Ten grams (0.026 mole) of diethyl *p*-nitrocinnamoyl-DL-glutamate was suspended in 50 ml. of absolute ethanol in a pressure bottle and approximately 1 to 1.5 Gm. (wet wt.) of Sponge Nickel Catalyst[1] was added. The bottle was flushed with hydrogen and then shaken mechanically until the rate of hydrogen uptake had decreased tenfold (approx. 24 hours). The catalyst was filtered off and ice-water added to the filtrate. Upon chilling, a pale yellow solid formed. The product obtained in yields of 64–77% melted in the range of 115.5 to 117°.

Anal.—Calcd. for $C_{18}H_{24}N_2O_5$: C, 62.06; H, 6.90; N, 8.05. Found: 62.16; H, 7.12; N, 8.05.

p-Aminocinnamoyl-DL-glutamic Acid.—One gram (0.003 mole) of diethyl *p*-aminocinnamoyl-DL-glutamate was suspended in 25 ml. of 1 *N* NaOH and stirred overnight at room temperature. The resulting solution was chilled and acidified to pH 3–4 with concentrated hydrochloric acid. A cloudy solution resulted but no precipitation occurred. To this solution was added about 1 Gm. of sodium chloride. Upon stirring, a yellow-brown solid appeared. This material was collected on a sintered-glass filter-funnel. Recrystallization from hot water to which a few milliliters of ethanol were added gave a yellow product. This material was observed to melt in the range of 193.8 to 196.6°.

Anal.—Calcd. for $C_{14}H_{16}N_2O_5$: C, 57.53; H, 5.53; N, 9.58. Found: C, 57.54; H, 5.57; N, 9.38.

The presence of a dicarboxylic acid was also confirmed by the determination of its neutralization equivalent.

Lack of Anticonvulsant Properties of Orally Administered Creatinine in Mice

Sir:

Cade (1) reported that pentylenetetrazol-induced convulsions in guinea pigs were controlled successfully by intraperitoneal injections of creatinine. Further, creatinine injections to control seizures of epileptic patients were encouraging. Pfeifer and co-workers (2) found creatinine administered subcutaneously in rats to show some protection against pentylenetetrazol-induced convulsions in summer but not winter, to abolish convulsions produced by hydration, and to be ineffective against electrically induced convulsions.

We have evaluated creatinine in male albino Swiss-Webster mice, using standard anticonvulsant procedures (3). Mice (groups of ten each) received daily oral administration of creatinine 100, 200, 400, and 800 mg./Kg./day for 4 days. On the third day, the animals were challenged by electroshock (M.E.S. test) 1 hour after the third dose and on the fourth day they were challenged with pentylenetetrazol (Met. test) 1 hour after the fourth dose. No protection was observed. However, deaths following electroshock became progressively less as the dose of creatinine became larger (60, 20, 30, and 0%, respectively). In a second experiment, creatinine was mixed in the diets (0, 0.5, 1.0, and 5.0%) and fed for 7 days to groups of 30 mice per diet. The mice were challenged with electroshock on the third and sixth day, and with pentylenetetrazol on the seventh day. No protection was observed. The number dying was almost identical for the four groups. Weight changes were not appreciably different for the four groups.

We were unable to show anticonvulsant properties for creatinine in mice using two standard anticonvulsant laboratory procedures.

Use of Sulfur Tetrafluoride in Syntheses of Potential Anticancer Agents

Sir:

The recent communication (1) dealing with the synthesis of the trifluoromethyl analog of thymine as a potential anticancer agent has prompted us to report an alternate method of synthesis utilizing sulfur tetrafluoride. Fluoro analogs of many of the naturally occurring pyrimidines have been prepared and tested as potential anticancer agents. Specifically, the trifluoromethyl group has been substituted on the 2, 4, and 6 positions of pyrimidines (2) by classical procedures utilizing a convenient two or four carbon starting material derived from trifluoroacetic acid. For several years we have tried unsuccessfully to prepare 5-trifluoromethyluracil by condensation of ethyl 3,3,3-trifluoropropionate, urea, and ethylorthoformate,[1] a modification of the procedure developed by Whitehead (3).

Since sulfur tetrafluoride was introduced as a reagent for the conversion of the carboxyl group to the trifluoromethyl group (4), many reports have appeared on the selective nature of this reagent (5). Raasch (6) noted the protective effect of excess hydrogen fluoride on the fluorination of aliphatic amino acids. The synthesis of 5-trifluoromethyluracil was successfully completed by a convenient one-step synthesis starting with uracil-5-carboxylic acid. Introduction of fluorine at the 5-carboxyl group in preference to attack of the other reactive sites was observed. The selective nature of the reagent under controlled temperature and with excess hydrofluoric acid (generated *in situ* from water and SF_4) demonstrates the versatility and the many applications possible in the synthesis of trifluoro-

[1] Appreciation is expressed to Donald A. Thompson for exhausting methods of synthesis of 5-trifluoromethyluracil by this approach.

methyl substituted heterocycles containing oxygen.

Uracil-5-carboxylic acid[2] (1.00 Gm., 0.0064 mole) and 0.5 ml. of water (0.028 mole) were placed in a steel bomb which was sealed. After cooling the bomb in dry ice-acetone, approximately 45 Gm. of sulfur tetrafluoride[3] (0.41 mole) was introduced. This was heated to 100°, agitated for 16 hours and subsequently allowed to cool to room temperature. The volatile material was vented and decomposed in 10% potassium hydroxide solution and the residue was recrystallized several times from water and sublimed giving 0.883 Gm. (77%, m.p. 247–249° dec., reported (1) m.p. 239–241°).

Anal.[4]—Calcd. for $C_5H_3F_3N_2O_2$: C, 33.35; H, 1.68; F, 31.65; N, 15.55. Found: C, 33.49; H, 1.61; F, 31.87; N, 15.69.

The following ultraviolet absorption spectra were recorded: 0.1 *N* HCl, λmax. 257 mμ, ε molar 8150; pH 7, λmax. 257 mμ ε molar 7210; pH 12.2, λmax. 279 mμ, ε molar 6500.

The pharmacological results and the synthesis of this and other analogs will be published in full detail in the future.

Synthesis of Dehydrocycloheximide

Sir:

In addition to our interest in the stereochemistry of cycloheximide (1, 2), we have been concerned with the development of a method for the synthesis of cycloheximide and certain of its degradation products. Recently, Lawes has described the synthesis of anhydrocycloheximide (3); the present communication describes the total synthesis of dehydrocycloheximide.

The method which we selected for the synthesis of dehydrocycloheximide employs the combination of the two fragments, 2,4-dimethylcyclohexanone and glutarimide-β-acetyl chloride. The preparation of (+)-*trans*-2,4-dimethylcyclohexanone (I) was accomplished by thermal degradation of cycloheximide (4). When I was allowed to react with piperidine in benzene solution according to the general procedure of Stork (5), a 47% yield of the enamine (II) was obtained; b.p. 79–82°/2.0 mm., $[\alpha]_D^{26} = +44.5°$ (c = 5.66% in ethanol).

Anal.—Calcd. for $C_{13}H_{23}N$: C, 80.76; H, 11.99; N, 7.24. Found: C, 80.58; H, 12.02; N, 7.16.

Condensation of the enamine (II) with glutarimide-β-acetyl chloride (III) (6) in dioxane solution gave, after hydrolysis, a 19% yield of dehydrocycloheximide (IV), m.p. 177–179°, $[\alpha]_D^{20} = -30.9°$ (c = 1.00% in $CHCl_3$).

Anal.—Calcd. for $C_{15}H_{21}NO_4$: C, 64.49; H, 7.58; N, 5.02. Found: C, 64.30; H, 7.37; N, 5.22.

Synthesis of Dehydrocycloheximide

Sir:

In addition to our interest in the stereochemistry of cycloheximide (1, 2), we have been concerned with the development of a method for the synthesis of cycloheximide and certain of its degradation products. Recently, Lawes has described the synthesis of anhydrocycloheximide (3); the present communication describes the total synthesis of dehydrocycloheximide.

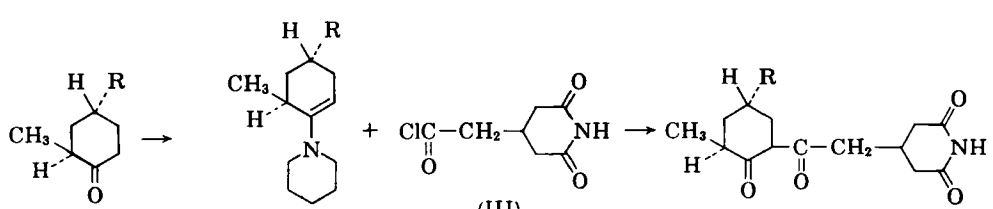
The method which we selected for the synthesis of dehydrocycloheximide employs the combination of the two fragments, 2,4-dimethylcyclohexanone and glutarimide-β-acetyl chloride. The preparation of (+)-*trans*-2,4-dimethylcyclohexanone (I) was accomplished by thermal degradation of cycloheximide (4). When I was allowed to react with piperidine in benzene solution according to the general procedure of Stork (5), a 47% yield of the enamine (II) was obtained; b.p. 79–82°/2.0 mm., $[\alpha]_D^{26} = +44.5°$ (c = 5.66% in ethanol).

Anal.—Calcd. for $C_{13}H_{23}N$: C, 80.76; H, 11.99; N, 7.24. Found: C, 80.58; H, 12.02; N, 7.16.

Condensation of the enamine (II) with glutarimide-β-acetyl chloride (III) (6) in dioxane solution gave, after hydrolysis, a 19% yield of dehydrocycloheximide (IV), m.p. 177–179°, $[\alpha]_D^{20} = -30.9°$ (c = 1.00% in $CHCl_3$).

Anal.—Calcd. for $C_{15}H_{21}NO_4$: C, 64.49; H, 7.58; N, 5.02. Found: C, 64.30; H, 7.37; N, 5.22.

Comparison of the optical rotation, the ultraviolet and infrared spectra, the R_f on thin-layer



(I) R = CH_3
(V) R = H

(II) R = CH_3
(VI) R = H

(III)

(IV) R = CH_3
(VII) R = H

chromatography, and the melting and mixture melting points of the synthetic product (IV) with an authentic sample of dehydrocycloheximide (7) revealed that the two products were, in fact, identical.

Our research on the synthesis of IV was initiated on the model enamine (VI) prepared from piperidine and 2-methylcyclohexanone (V) since it has been suggested that enamines which are substituted in the 2-position might not undergo reaction (5). However, we have found that enamines of this type are reactive; thus, condensation of the model enamine (VI) with glutarimide-β-acetyl chloride (III) resulted in the formation of a 25% yield of (±)-nordehydrocycloheximide (VII), thereby establishing that acylation at the 6-position is feasible. The reason that the yield of VII and of IV was not over 50% is most probably caused by the fact that the distilled enamine is actually a mixture of double bond isomers in which the double bond is either at C_1-C_6 or C_1-C_2. Since only that isomer in which the double bond is at C_1-C_6 (II or VI) can give IV or VII, the reduction in yield can readily be understood. Evidence that the enamine is a mixture of double bond isomers is available from its infrared spectrum. Thus, in the C=C region, II exhibits two peaks, one at 1680 cm.$^{-1}$ and one at 1645 cm.$^{-1}$ The enamine VI also exhibits peaks at 1670 cm.$^{-1}$ and 1640 cm.$^{-1}$ However, the enamine prepared from cyclohexanone and piperidine exhibits only one peak in the C=C region at 1645 cm.$^{-1}$ This result would be predicted for this enamine since it cannot exist in an isomeric form as can II or VI.

One final point which requires comment is the stereochemical assignment of the methyl groups of dehydrocycloheximide (IV). It has been established that in cycloheximide the methyl groups are *trans* (1, 4), but no proof of the stereochemistry of dehydrocycloheximide has been reported. However, the present synthesis of dehydrocycloheximide (IV) establishes that the methyl groups are *trans* since IV was synthesized from (+)-*trans*-2,4-dimethylcyclohexanone (I). It might be argued that the α-methyl group of I could be isomerized during the preparation of the enamine, but this hypothesis was shown to be rather unimportant when it was found that the acid catalyzed hydrolysis of the enamine (II) regenerated a 75% yield of (+)-*trans*-2,4-dimethylcyclohexanone (I). This result therefore offers strong support to the assignment of the *trans* methyl groups in dehydrocycloheximide (IV).

Book Notices

Year Book of Drug Therapy. 1962–1963 Series. Edited by HARRY BECKMAN. Year Book Medical Publishers, Inc., 35 E. Wacker Drive, Chicago 1, Ill., 1962. 648 pp. 13 × 20 cm. Price $8.50.

A new section has been added to this revised volume entitled "Precautions," replacing the section entitled "Critical Evaluation of the Year's New Drugs." As with prior editions, the major presentation is through abstracts covering reports of new therapeutic or prophylatic uses and applications of drugs during the "series year." The abstracts are well written in the concise and meaty form which has become characteristic of this series. In the newly added section, sketches of accumulated experience regarding the toxic actualities and potentialities of drugs in current use will be of invaluable assistance to pharmaceutical and medical personnel.

Protein Metabolism. Edited by F. GROSS. Springer Verlag, Berlin-Wilmersdorf, Heidelberger Platz 3/, West Berlin, Germany, 1962. xi + 521 pp. 14 × 20.5 cm.

The proceedings of an international symposium are reported—the fourth in a series of such symposia sponsored by Ciba, Ltd., Basle. Major topics covered by the participants include: Action of hormones at the cellular level; Factors influencing protein metabolism in the organism; Evaluation and mode of action of anabolic steroids; Protein metabolism in human pathological states; and

chromatography, and the melting and mixture melting points of the synthetic product (IV) with an authentic sample of dehydrocycloheximide (7) revealed that the two products were, in fact, identical.

Our research on the synthesis of IV was initiated on the model enamine (VI) prepared from piperidine and 2-methylcyclohexanone (V) since it has been suggested that enamines which are substituted in the 2-position might not undergo reaction (5). Protein Metabolism. Edited by F. GROSS. Springer Verlag, Berlin-Wilmersdorf, Heidelberger Platz 3/, West Berlin, Germany, 1962. xi + 521 pp. 14 × 20.5 cm.

The proceedings of an international symposium are reported—the fourth in a series of such symposia sponsored by Ciba, Ltd., Basle. Major topics covered by the participants include: Action of hormones at the cellular level; Factors influencing protein metabolism in the organism; Evaluation and mode of action of anabolic steroids; Protein metabolism in human pathological states; and

Effects of anabolic agents in man. Papers presented and the discussions which followed are reported under the pertinent topic heading. Subject and author indexes are included for ready access to items of particular interest to the reader.

Chemistry of Carbon Compounds. Vol. 5. Edited by E. H. RODD. American Elsevier Publishing Co., Inc., 52 Vanderbilt Ave., New York 17, N. Y., 1962. xv + 912 pp. 15 × 22 cm. Price $29 single; $26 series.

This concluding volume in this series furnishes a general index to the entire five volumes and supplements, in part, selected topics in which there have been conspicuous advance during the decade which has elapsed since the work was started. The general index covers 676 pages. Topics included in this volume are The preparation and use of isotopically labelled organic compounds, Natural acetylenic compounds, Developments in carbohydrate chemistry, and The structure of proteins.

Tables of Random Permutations. By LINCOLN E. MOSES and ROBERT V. OAKFORD. Stanford University Press, Stanford, Calif., 1963. 233 pp. 15.5 × 23.5 cm. Price $7.

Tables of random permutations of 9, 16, 20, 30, 50, 100, 200, 500, and 1000 integers are provided. The source was the RAND deck of a million random digits; the method utilized to generate permutations from the random integers is described in detail in an appendix. The authors point out that for many common uses in the biological, physical, and social sciences and in engineering, tables of random numbers are less useful than tables of random permutations.

Practical Pharmaceutical Chemistry. By. A. H. BECKETT and J. B. STENLAKE. The Athlone Press, University of London, 2 Gower Street, London, S.C. 1, 1962. viii + 378 pp. 15.5 × 25 cm. Price $10.10.

As a student text in quantitative pharmaceutical chemistry, this book covers a wide variety of methods for the control of chemical purity in medicinal substances. The classical methods of volumetric and gravimetric analysis and limit tests for trace impurities are included but in addition, the authors have included complexiometric, electrometric, and conductometric titration techniques, titration in nonaqueous media, aquametry, and the use of ion-exchange resins in analysis. Instrumental methods based on absorptiometry, spectrophotometry, fluorimetry, and polarography are also included. The first three chapters cover chemical purity and its control and the technique and theoretical basis of quantitative analysis. Along with chapters on specific techniques, the book also includes a chapter on the theory of absorption spectra.

Infrared, Ultraviolet, and Visible Absorption Spectra of Some USP and NF Reference Standards and Their Derivatives. By ALMA L. HAYDEN, OSCAR R. SAMMUL, GEORGE B. SELZER, and JONAS CAROL. Association of Official Agricultural Chemists, Box 540, Benjamin Franklin Station, Washington 4, D. C., 1962. 104 pp. 17.5 × 25.5 cm. Price $2.

Infrared, ultraviolet, and visible absorption spectra of 175 USP and NF Reference Standards are illustrated, together with structural formulas and recording data. Infrared absorbance spectra of 32 organic nitrogenous bases derived from some of these standards are also presented. Text and tables describe, in considerable detail, sample handling and recording techniques.

Recent Developments in the Sterilization of Surgical Materials. A Symposium. The Pharmaceutical Press, 17 Bloomsbury Square, London, W.C. 1, 1961. xi + 232 pp. 15 × 23 cm. Paperbound. Price $7.

This paperbound volume reports a symposium on recent developments in the sterilization of surgical materials held at the University of London in April of 1961 and consists of papers presented and discussions during the symposium. The report covers sterilization by ionizing radiation, gaseous methods of sterilization, and sterility tests. It is indexed by subject.

The Chemistry and Manufacture of Cosmetics. Vol. 2. By MAISON G. DENAVARRE. D. Van Nostrand Co., Inc., 120 Alexander St., Princeton, N. J., 1962. xiv + 413 pp. 15.5 × 23.5 cm. Price $12.50.

Included in this second volume of a four volume set is extensive coverage of the materials used or of potential use in cosmetics manufacture. Each class of material is arranged alphabetically and fully described to include its chemistry, toxicity, commercial materials, cosmetic uses, germicidal properties, methods of manufacture, emulsifying properties, hazards, and sources. Essential formulations are also included. When the four volumes of this second edition are completed, the cosmetic chemist will have a ready reference to assist him in his work.

Staining, Practical and Theoretical. By EDWARD GURR. The Williams and Wilkins Co., 428 East Preston St., Baltimore 2, Md., 1962. xii + 631 pp. 15 × 22 cm. Price $16.

The author's stated objectives in writing this book are to present new ideas regarding the mechanism and theory of staining reactions and to bring together, in concise form, a large number of staining procedures previously scattered throughout the literature. He has succeeded in providing an encyclopedic reference volume. Some 700 stain formulas and 300 procedures are included. The first section of the book deals with theoretical considerations and the second section provides procedures in monograph form, frequently with a boldfaced description of the use of the particular stain. A third section contains the formulas for the stains, fixatives, and tables needed in this work. An index for rapid reference completes the book.

Readings in Pharmacology. Edited by LOUIS SHUSTER. Little, Brown and Co., 34 Beacon St., Boston 6, Mass., 1962. xii + 548 pp. 15.5 × 23.5 cm. Paperbound. Price $5.50.

Effects of anabolic agents in man. Papers presented and the discussions which followed are reported under the pertinent topic heading. Subject and author indexes are included for ready access to items of particular interest to the reader.

Chemistry of Carbon Compounds. Vol. 5. Edited by E. H. RODD. American Elsevier Publishing Co., Inc., 52 Vanderbilt Ave., New York 17, N. Y., 1962. xv + 912 pp. 15 × 22 cm. Price $29 single; $26 series.

This concluding volume in this series furnishes a general index to the entire five volumes and supplements, in part, selected topics in which there have been conspicuous advance during the decade which has elapsed since the work was started. The Chemistry and Manufacture of Cosmetics. Vol. 2. By MAISON G. DENAVARRE. D. Van Nostrand Co., Inc., 120 Alexander St., Princeton, N. J., 1962. xiv + 413 pp. 15.5 × 23.5 cm. Price $12.50.

Included in this second volume of a four volume set is extensive coverage of the materials used or of potential use in cosmetics manufacture. Each class of material is arranged alphabetically and fully described to include its chemistry, toxicity, commercial materials, cosmetic uses, germicidal properties, methods of manufacture, emulsifying properties, hazards, and sources. Essential formulations are also included. When the four volumes of this second edition are completed, the cosmetic chemist will have a ready reference to assist him in his work.

Staining, Practical and Theoretical. By EDWARD GURR. The Williams and Wilkins Co., 428 East Preston St., Baltimore 2, Md., 1962. xii + 631 pp. 15 × 22 cm. Price $16.

The author's stated objectives in writing this book are to present new ideas regarding the mechanism and theory of staining reactions and to bring together, in concise form, a large number of staining procedures previously scattered throughout the literature. He has succeeded in providing an encyclopedic reference volume. Some 700 stain formulas and 300 procedures are included. The first section of the book deals with theoretical considerations and the second section provides procedures in monograph form, frequently with a boldfaced description of the use of the particular stain. A third section contains the formulas for the stains, fixatives, and tables needed in this work. An index for rapid reference completes the book.

Readings in Pharmacology. Edited by LOUIS SHUSTER. Little, Brown and Co., 34 Beacon St., Boston 6, Mass., 1962. xii + 548 pp. 15.5 × 23.5 cm. Paperbound. Price $5.50.

Effects of anabolic agents in man. Papers presented and the discussions which followed are reported under the pertinent topic heading. Subject and author indexes are included for ready access to items of particular interest to the reader.

Chemistry of Carbon Compounds. Vol. 5. Edited by E. H. RODD. American Elsevier Publishing Co., Inc., 52 Vanderbilt Ave., New York 17, N. Y., 1962. xv + 912 pp. 15 × 22 cm. Price $29 single; $26 series.

This concluding volume in this series furnishes a general index to the entire five volumes and supplements, in part, selected topics in which there have been conspicuous advance during the decade which has elapsed since the work was started. The general index covers 676 pages. Topics included in this volume are The preparation and use of isotopically labelled organic compounds, Natural acetylenic compounds, Developments in carbohydrate chemistry, and The structure of proteins.

Tables of Random Permutations. By LINCOLN E. MOSES and ROBERT V. OAKFORD. Stanford University Press, Stanford, Calif., 1963. 233 pp. 15.5 × 23.5 cm. Price $7.

Tables of random permutations of 9, 16, 20, 30, 50, 100, 200, 500, and 1000 integers are provided. The source was the RAND deck of a million random digits; the method utilized to generate permutations from the random integers is described in detail in an appendix. The authors point out that for many common uses in the biological, physical, and social sciences and in engineering, tables of random numbers are less useful than tables of random permutations.

Practical Pharmaceutical Chemistry. By. A. H. BECKETT and J. B. STENLAKE. The Athlone Press, University of London, 2 Gower Street, London, S.C. 1, 1962. viii + 378 pp. 15.5 × 25 cm. Price $10.10.

As a student text in quantitative pharmaceutical chemistry, this book covers a wide variety of methods for the control of chemical purity in medicinal substances. The classical methods of volumetric and gravimetric analysis and limit tests for trace impurities are included but in addition, the authors have included complexiometric, electrometric, and conductometric titration techniques, titration in nonaqueous media, aquametry, and the use of ion-exchange resins in analysis. Instrumental methods based on absorptiometry, spectrophotometry, fluorimetry, and polarography are also included. The first three chapters cover chemical purity and its control and the technique and theoretical basis of quantitative analysis. Along with chapters on specific techniques, the book also includes a chapter on the theory of absorption spectra.

Infrared, Ultraviolet, and Visible Absorption Spectra of Some USP and NF Reference Standards and Their Derivatives. By ALMA L. HAYDEN, OSCAR R. SAMMUL, GEORGE B. SELZER, and JONAS CAROL. Association of Official Agricultural Chemists, Box 540, Benjamin Franklin Station, Washington 4, D. C., 1962. 104 pp. 17.5 × 25.5 cm. Price $2.

Infrared, ultraviolet, and visible absorption spectra of 175 USP and NF Reference Standards are illustrated, together with structural formulas and recording data. Infrared absorbance spectra of 32 organic nitrogenous bases derived from some of these standards are also presented. Text and tables describe, in considerable detail, sample handling and recording techniques.

Recent Developments in the Sterilization of Surgical Materials. A Symposium. The Pharmaceutical Press, 17 Bloomsbury Square, London, W.C. 1, 1961. xi + 232 pp. 15 × 23 cm. Paperbound. Price $7.

This paperbound volume reports a symposium on recent developments in the sterilization of surgical materials held at the University of London in April of 1961 and consists of papers presented and discussions during the symposium. The report covers sterilization by ionizing radiation, gaseous methods of sterilization, and sterility tests. It is indexed by subject.

The Chemistry and Manufacture of Cosmetics. Vol. 2. By MAISON G. DENAVARRE. D. Van Nostrand Co., Inc., 120 Alexander St., Princeton, N. J., 1962. xiv + 413 pp. 15.5 × 23.5 cm. Price $12.50.

Chemistry of Carbon Compounds. Vol. 5. Edited by E. H. RODD. American Elsevier Publishing Co., Inc., 52 Vanderbilt Ave., New York 17, N. Y., 1962. xv + 912 pp. 15 × 22 cm. Price $29 single; $26 series.

This concluding volume in this series furnishes a general index to the entire five volumes and supplements, in part, selected topics in which there have been conspicuous advance during the decade which has elapsed since the work was started. The general index covers 676 pages. Topics included in this volume are The preparation and use of isotopically labelled organic compounds, Natural acetylenic compounds, Developments in carbohydrate chemistry, and The structure of proteins.

Tables of Random Permutations. By LINCOLN E. MOSES and ROBERT V. OAKFORD. Stanford University Press, Stanford, Calif., 1963. 233 pp. 15.5 × 23.5 cm. Price $7.

Tables of random permutations of 9, 16, 20, 30, 50, 100, 200, 500, and 1000 integers are provided. The source was the RAND deck of a million random digits; the method utilized to generate permutations from the random integers is described in detail in an appendix. The authors point out that for many common uses in the biological, physical, and social sciences and in engineering, tables of random numbers are less useful than tables of random permutations.

Practical Pharmaceutical Chemistry. By. A. H. BECKETT and J. B. STENLAKE. The Athlone Press, University of London, 2 Gower Street, London, S.C. 1, 1962. viii + 378 pp. 15.5 × 25 cm. Price $10.10.

As a student text in quantitative pharmaceutical chemistry, this book covers a wide variety of methods for the control of chemical purity in medicinal substances. The classical methods of volumetric and gravimetric analysis and limit tests for trace impurities are included but in addition, the authors have included complexiometric, electrometric, and conductometric titration techniques, titration in nonaqueous media, aquametry, and the use of ion-exchange resins in analysis. Instrumental methods based on absorptiometry, spectrophotometry, fluorimetry, and polarography are also included. The first three chapters cover chemical purity and its control and the technique and theoretical basis of quantitative analysis. Along with chapters on specific techniques, the book also includes a chapter on the theory of absorption spectra.

Infrared, Ultraviolet, and Visible Absorption Spectra of Some USP and NF Reference Standards and Their Derivatives. By ALMA L. HAYDEN, OSCAR R. SAMMUL, GEORGE B. SELZER, and JONAS CAROL. Association of Official Agricultural Chemists, Box 540, Benjamin Franklin Station, Washington 4, D. C., 1962. 104 pp. 17.5 × 25.5 cm. Price $2.

Infrared, ultraviolet, and visible absorption spectra of 175 USP and NF Reference Standards are illustrated, together with structural formulas and recording data. Infrared absorbance spectra of 32 organic nitrogenous bases derived from some of these standards are also presented. Text and tables describe, in considerable detail, sample handling and recording techniques.

Recent Developments in the Sterilization of Surgical Materials. A Symposium. The Pharmaceutical Press, 17 Bloomsbury Square, London, W.C. 1, 1961. xi + 232 pp. 15 × 23 cm. Paperbound. Price $7.

This paperbound volume reports a symposium on recent developments in the sterilization of surgical materials held at the University of London in April of 1961 and consists of papers presented and discussions during the symposium. The report covers sterilization by ionizing radiation, gaseous methods of sterilization, and sterility tests. It is indexed by subject.

The Chemistry and Manufacture of Cosmetics. Vol. 2. By MAISON G. DENAVARRE. D. Van Nostrand Co., Inc., 120 Alexander St., Princeton, N. J., 1962. xiv + 413 pp. 15.5 × 23.5 cm. Price $12.50.

Included in this second volume of a four volume set is extensive coverage of the materials used or of potential use in cosmetics manufacture. Each class of material is arranged alphabetically and fully described to include its chemistry, toxicity, commercial materials, cosmetic uses, germicidal properties, methods of manufacture, emulsifying properties, hazards, and sources. Essential formulations are also included. When the four volumes of this second edition are completed, the cosmetic chemist will have a ready reference to assist him in his work.

Staining, Practical and Theoretical. By EDWARD GURR. The Williams and Wilkins Co., 428 East Preston St., Baltimore 2, Md., 1962. xii + 631 pp. 15 × 22 cm. Price $16.

The author's stated objectives in writing this book are to present new ideas regarding the mechanism and theory of staining reactions and to bring together, in concise form, a large number of staining procedures previously scattered throughout the literature. He has succeeded in providing an encyclopedic reference volume. Some 700 stain formulas and 300 procedures are included. The first section of the book deals with theoretical considerations and the second section provides procedures in monograph form, frequently with a boldfaced description of the use of the particular stain. A third section contains the formulas for the stains, fixatives, and tables needed in this work. An index for rapid reference completes the book.

Readings in Pharmacology. Edited by LOUIS SHUSTER. Little, Brown and Co., 34 Beacon St., Boston 6, Mass., 1962. xii + 548 pp. 15.5 × 23.5 cm. Paperbound. Price $5.50.

Effects of anabolic agents in man. Papers presented and the discussions which followed are reported under the pertinent topic heading. Subject and author indexes are included for ready access to items of particular interest to the reader.

Chemistry of Carbon Compounds. Vol. 5. Edited by E. H. RODD. American Elsevier Publishing Co., Inc., 52 Vanderbilt Ave., New York 17, N. Y., 1962. xv + 912 pp. 15 × 22 cm. Price $29 single; $26 series.

This concluding volume in this series furnishes a general index to the entire five volumes and supplements, in part, selected topics in which there have been conspicuous advance during the decade which has elapsed since the work was started. The general index covers 676 pages. Topics included in this volume are The preparation and use of isotopically labelled organic compounds, Natural acetylenic compounds, Developments in carbohydrate chemistry, and The structure of proteins.

Tables of Random Permutations. By LINCOLN E. MOSES and ROBERT V. OAKFORD. Stanford University Press, Stanford, Calif., 1963. 233 pp. 15.5 × 23.5 cm. Price $7.

Tables of random permutations of 9, 16, 20, 30, 50, 100, 200, 500, and 1000 integers are provided. The source was the RAND deck of a million random digits; the method utilized to generate permutations from the random integers is described in detail in an appendix. The authors point out that for many common uses in the biological, physical, and social sciences and in engineering, tables of random numbers are less useful than tables of random permutations.

Practical Pharmaceutical Chemistry. By. A. H. BECKETT and J. B. STENLAKE. The Athlone Press, University of London, 2 Gower Street, London, S.C. 1, 1962. viii + 378 pp. 15.5 × 25 cm. Price $10.10.

As a student text in quantitative pharmaceutical chemistry, this book covers a wide variety of methods for the control of chemical purity in medicinal substances. The classical methods of volumetric and gravimetric analysis and limit tests for trace impurities are included but in addition, the authors have included complexiometric, electrometric, and conductometric titration techniques, titration in nonaqueous media, aquametry, and the use of ion-exchange resins in analysis. Instrumental methods based on absorptiometry, spectrophotometry, fluorimetry, and polarography are also included. The first three chapters cover chemical purity and its control and the technique and theoretical basis of quantitative analysis. Along with chapters on specific techniques, the book also includes a chapter on the theory of absorption spectra.

Infrared, Ultraviolet, and Visible Absorption Spectra of Some USP and NF Reference Standards and Their Derivatives. By ALMA L. HAYDEN, OSCAR R. SAMMUL, GEORGE B. SELZER, and JONAS CAROL. Association of Official Agricultural Chemists, Box 540, Benjamin Franklin Station, Washington 4, D. C., 1962. 104 pp. 17.5 × 25.5 cm. Price $2.

Infrared, ultraviolet, and visible absorption spectra of 175 USP and NF Reference Standards are illustrated, together with structural formulas and recording data. Infrared absorbance spectra of 32 organic nitrogenous bases derived from some of these standards are also presented. Text and tables describe, in considerable detail, sample handling and recording techniques.

Recent Developments in the Sterilization of Surgical Materials. A Symposium. The Pharmaceutical Press, 17 Bloomsbury Square, London, W.C. 1, 1961. xi + 232 pp. 15 × 23 cm. Paperbound. Price $7.

This paperbound volume reports a symposium on recent developments in the sterilization of surgical materials held at the University of London in April of 1961 and consists of papers presented and discussions during the symposium. The report covers sterilization by ionizing radiation, gaseous methods of sterilization, and sterility tests. It is indexed by subject.

The Chemistry and Manufacture of Cosmetics. Vol. 2. By MAISON G. DENAVARRE. D. Van Nostrand Co., Inc., 120 Alexander St., Princeton, N. J., 1962. xiv + 413 pp. 15.5 × 23.5 cm. Price $12.50.

Included in this second volume of a four volume set is extensive coverage of the materials used or of potential use in cosmetics manufacture. Each class of material is arranged alphabetically and fully described to include its chemistry, toxicity, commercial materials, cosmetic uses, germicidal properties, methods of manufacture, emulsifying properties, hazards, and sources. Essential formulations are also included. When the four volumes of this second edition are completed, the cosmetic chemist will have a ready reference to assist him in his work.

Staining, Practical and Theoretical. By EDWARD GURR. The Williams and Wilkins Co., 428 East Preston St., Baltimore 2, Md., 1962. xii + 631 pp. 15 × 22 cm. Price $16.

The author's stated objectives in writing this book are to present new ideas regarding the mechanism and theory of staining reactions and to bring together, in concise form, a large number of staining procedures previously scattered throughout the literature. He has succeeded in providing an encyclopedic reference volume. Some 700 stain formulas and 300 procedures are included. The first section of the book deals with theoretical considerations and the second section provides procedures in monograph form, frequently with a boldfaced description of the use of the particular stain. A third section contains the formulas for the stains, fixatives, and tables needed in this work. An index for rapid reference completes the book.

Readings in Pharmacology. Edited by LOUIS SHUSTER. Little, Brown and Co., 34 Beacon St., Boston 6, Mass., 1962. xii + 548 pp. 15.5 × 23.5 cm. Paperbound. Price $5.50.

This paperbound volume presents a representative sampling of approaches and techniques that have been applied to some of the basic problems in pharmacology and also gives the reader some insight into the setting of the work itself. As the foreword to the book notes, each stage of literary distillation away from the original article leaves something behind—the technical detail that may have been crucial, the personal bias, the loose ends which usually get covered up in the review, and the surprises and disappointments of experimentation. To implement the objective, the author has selected papers from 1785 to 1957, 19 in all. For the student, this book will make a good tool for orientation purposes and for practicing pharmacologists, a brief and refreshing interlude placing current work in perspective.

Accepted Dental Remedies 1963. 28th ed. Council on Dental Therapeutics of the American Dental Association. American Dental Association, 222 E. Superior St., Chicago 11, Ill., 1963. xiv + 212 pp. 15.5 × 22.5 cm. Paperbound. Price $3.

This current issue of ADR contains expanded sections on dental therapeutics and particular attention has been directed to recent reports of the occurrence of toxic reactions and other current scientific information in the revision of its monographs. A seven-page section is devoted to prescription writing in dental practice which explains the desirability of prescription writing in dental practice and includes basic information on proper prescribing.

Another chapter discusses the prevention and treatment of emergencies in the dental office and another discusses pharmaceutical aids such as sweetening agents, essential oils, and preservatives.

As in earlier editions, this ADR includes information concerning drugs of recognized value in dentistry, drugs of uncertain status more recently proposed for use by the dentist, and some drugs once employed extensively but now generally regarded as obsolete. The information, throughout, is presented in a clear and concise form. Prefactory remarks for each section provide a brief review of important factors to be considered in a particular class of therapeutic agents which it covers.

Practical Therapeutics. By H.-J. B. Galbraith, J. Q. Matthias, and R. C. King. Year Book Medical Publishers, Inc., 35 East Wacker Drive, Chicago, Ill., 1962. vii + 446 pp. 14 × 22 cm. Price $7.50.

Primarily aimed at medical students during their hospital training, this book is designed to assist in applying pharmacological theory in clinical practice. As the book is not designed as a comprehensive reference source, no reference to original sources in the medical literature are included. The chief value of this book to scientific pharmacy will probably be as a memory prodder in pharmacology and as a collateral reference for pharmacology students.

Enzymatic Synthesis of DNA. By Arthur Kornberg. John Wiley & Sons, Inc., 440 Park Ave. South, New York 16, N. Y., 1962. ix + 103 pp. 12.5 × 18.5 cm. Price $4.

This represents the fifth published work in the Ciba Lectures in Microbial Biochemistry. Chapter 1 concerns itself with the replication of DNA—structure, enzymatic approach to replication, properties of the enzyme, evidence for base-pairing mechanism of replication, and some of the unsolved questions. Chapter 2 is entitled "De Novo Synthesis of DNA-like Polymers" and concerns itself with the dAT copolymer and the dGdC polymer. Chapter 3 deals with synthesis of HMC deoxynucleoside monophosphate and HMC deoxynucleoside triphosphate. Dr. Kornberg, one of the recipients of the Nobel Prize in Medicine in 1959, has included figures, tables, structures, and literature references to produce a valuable source of information on the synthesis of DNA.

Encyclopedia of Plant Physiology. Vol. XVII Physiology of Movements, Part 2. Edited by W. Ruhland. Springer-Verlag, Berlin-Wilmersdorf, Heidelberger Platz 3/, West Berlin, Germany, 1962. 17 × 25 cm. xii + 1174 pp. Price DM272.

The volume is an extensive discussion and survey of the basic facts of protoplasmic streaming in plant cells and problems relevant to its mechanism. The biological meaning of this phenomenon is not discussed. The contributed sections are printed in the language of the contributor, mainly English or German. An English to German subject index is included as well as an author index. Extensive literature references are provided following each section.

Advances in Enzymology. Vol. 24. Edited by F. F. Nord. Interscience Publishers, 440 Park Ave. South, New York 16, N. Y., 1962. v + 572 pp. 15.5 × 23 cm.

Included in this volume are contributed sections on Aspects of the Biosynthesis of enzymes; Metabolism of spermatozoa; Chemical modifications of proteins and their significance in enzymology; immunochemistry, and related subjects; Structure and function of ribonuclease; Molecular properties and transformations of glycogen phosphorylase in animal tissues, Distribution of enzymes between subcellular fractions in animal tissues; The effects of ionizing radiation on enzymes; Identical and analogous peptide structures in proteins; and Mechanisms related to enzyme catalysis. Subject and author indexes as well as a cumulative index for volumes 1–24 are included.

Pyridine and its Derivatives. Vol. 14, Part III. Edited by Erwin Klingsberg. Interscience Publishers Division of John Wiley & Sons, 440 Park Ave. South, New York 16, N. Y., 1962. ix + 914 pp. 15.5 × 22.5 cm. Price $65.00.

Included in this third part of a four-part work, are Aminopyridines, Pyridinecarboxylic acids, Pyridine side-chain carboxylic acids, and Pyridinols and pyridones. As part of a larger series, "The Chemistry of Heterocyclic Compounds," the editors and authors have made a splendid contribution towards making a subject of such importance and intrinsic difficulty readily available. Extensive literature references carefully document each section to permit ready access to original reports.

This paperbound volume presents a representative sampling of approaches and techniques that have been applied to some of the basic problems in pharmacology and also gives the reader some insight into the setting of the work itself. As the foreword to the book notes, each stage of literary distillation away from the original article leaves something behind—the technical detail that may have been crucial, the personal bias, the loose ends which usually get covered up in the review, and the surprises and disappointments of experimentation. Primarily aimed at medical students during their hospital training, this book is designed to assist in applying pharmacological theory in clinical practice. As the book is not designed as a comprehensive reference source, no reference to original sources in the medical literature are included. The chief value of this book to scientific pharmacy will probably be as a memory prodder in pharmacology and as a collateral reference for pharmacology students.

Enzymatic Synthesis of DNA. By Arthur Kornberg. John Wiley & Sons, Inc., 440 Park Ave. South, New York 16, N. Y., 1962. ix + 103 pp. 12.5 × 18.5 cm. Price $4.

This represents the fifth published work in the Ciba Lectures in Microbial Biochemistry. Chapter 1 concerns itself with the replication of DNA—structure, enzymatic approach to replication, properties of the enzyme, evidence for base-pairing mechanism of replication, and some of the unsolved questions. Chapter 2 is entitled "De Novo Synthesis of DNA-like Polymers" and concerns itself with the dAT copolymer and the dGdC polymer. Chapter 3 deals with synthesis of HMC deoxynucleoside monophosphate and HMC deoxynucleoside triphosphate. Dr. Kornberg, one of the recipients of the Nobel Prize in Medicine in 1959, has included figures, tables, structures, and literature references to produce a valuable source of information on the synthesis of DNA.

Encyclopedia of Plant Physiology. Vol. XVII Physiology of Movements, Part 2. Edited by W. Ruhland. Springer-Verlag, Berlin-Wilmersdorf, Heidelberger Platz 3/, West Berlin, Germany, 1962. 17 × 25 cm. xii + 1174 pp. Price DM272.

The volume is an extensive discussion and survey of the basic facts of protoplasmic streaming in plant cells and problems relevant to its mechanism. The biological meaning of this phenomenon is not discussed. The contributed sections are printed in the language of the contributor, mainly English or German. An English to German subject index is included as well as an author index. Extensive literature references are provided following each section.

Advances in Enzymology. Vol. 24. Edited by F. F. Nord. Interscience Publishers, 440 Park Ave. South, New York 16, N. Y., 1962. v + 572 pp. 15.5 × 23 cm.

Included in this volume are contributed sections on Aspects of the Biosynthesis of enzymes; Metabolism of spermatozoa; Chemical modifications of proteins and their significance in enzymology; immunochemistry, and related subjects; Structure and function of ribonuclease; Molecular properties and transformations of glycogen phosphorylase in animal tissues, Distribution of enzymes between subcellular fractions in animal tissues; The effects of ionizing radiation on enzymes; Identical and analogous peptide structures in proteins; and Mechanisms related to enzyme catalysis. Subject and author indexes as well as a cumulative index for volumes 1–24 are included.

Pyridine and its Derivatives. Vol. 14, Part III. Edited by Erwin Klingsberg. Interscience Publishers Division of John Wiley & Sons, 440 Park Ave. South, New York 16, N. Y., 1962. ix + 914 pp. 15.5 × 22.5 cm. Price $65.00.

Included in this third part of a four-part work, are Aminopyridines, Pyridinecarboxylic acids, Pyridine side-chain carboxylic acids, and Pyridinols and pyridones. As part of a larger series, "The Chemistry of Heterocyclic Compounds," the editors and authors have made a splendid contribution towards making a subject of such importance and intrinsic difficulty readily available. Extensive literature references carefully document each section to permit ready access to original reports.

This paperbound volume presents a representative sampling of approaches and techniques that have been applied to some of the basic problems in pharmacology and also gives the reader some insight into the setting of the work itself. As the foreword to the book notes, each stage of literary distillation away from the original article leaves something behind—the technical detail that may have been crucial, the personal bias, the loose ends which usually get covered up in the review, and the surprises and disappointments of experimentation. To implement the objective, the author has selected papers from 1785 to 1957, 19 in all. For the student, this book will make a good tool for orientation purposes and for practicing pharmacologists, a brief and refreshing interlude placing current work in perspective.

Accepted Dental Remedies 1963. 28th ed. Council on Dental Therapeutics of the American Dental Association. American Dental Association, 222 E. Superior St., Chicago 11, Ill., 1963. xiv + 212 pp. 15.5 × 22.5 cm. Paperbound. Price $3.

This current issue of ADR contains expanded sections on dental therapeutics and particular attention has been directed to recent reports of the occurrence of toxic reactions and other current scientific information in the revision of its monographs. A seven-page section is devoted to prescription writing in dental practice which explains the desirability of prescription writing in dental practice and includes basic information on proper prescribing.

Another chapter discusses the prevention and treatment of emergencies in the dental office and another discusses pharmaceutical aids such as sweetening agents, essential oils, and preservatives.

As in earlier editions, this ADR includes information concerning drugs of recognized value in dentistry, drugs of uncertain status more recently proposed for use by the dentist, and some drugs once employed extensively but now generally regarded as obsolete. The information, throughout, is presented in a clear and concise form. Prefactory remarks for each section provide a brief review of important factors to be considered in a particular class of therapeutic agents which it covers.

Practical Therapeutics. By H.-J. B. Galbraith, J. Q. Matthias, and R. C. King. Year Book Medical Publishers, Inc., 35 East Wacker Drive, Chicago, Ill., 1962. vii + 446 pp. 14 × 22 cm. Price $7.50.

Primarily aimed at medical students during their hospital training, this book is designed to assist in applying pharmacological theory in clinical practice. As the book is not designed as a comprehensive reference source, no reference to original sources in the medical literature are included. The chief value of this book to scientific pharmacy will probably be as a memory prodder in pharmacology and as a collateral reference for pharmacology students.

The *Journal of Pharmaceutical Sciences* is published monthly by the American Pharmaceutical Association at 20th & Northampton Sts., Easton, Pa. Second-class postage paid at Easton, Pa., and at additional mailing office.

All expressions of opinion and statements of supposed fact appearing in articles or editorials carried in THIS JOURNAL are published on the authority of the writer over whose name they appear, and are not to be regarded as necessarily expressing the policies or views of the American Pharmaceutical Association.

Offices—Editorial, Advertising, and Subscription Offices: 2215 Constitution Ave., N. W., Washington 37, D. C. Publication Offices: 20th & Northampton Streets, Easton, Pa.

Annual Subscription—United States and foreign, $15.00; single copies, $1.50; combined rate with the *Journal of the American Pharmaceutical Association*, $20.00. Subscription rates are subject to change without notice. Members of the American Pharmaceutical Association may elect to receive the *Journal of Pharmaceutical Sciences* as a part of their annual $27.00 A.Ph.A. membership dues.

Claims—Missing numbers will not be supplied if claims are received more than 60 days after the date of the issue, or if loss was due to failure to give notice of change of address. The Association cannot accept responsibility for foreign delivery when its records indicate shipment has been made.

Change of Address—Members and subscribers should notify at once both the Post Office and the American Pharmaceutical Association, 2215 Constitution Ave., N. W., Washington 37, D. C., of any change of address.

The Editor comments

OPPORTUNITY FOR GROWTH

The A.PH.A. Scientific Section has had a long history of valuable service to the pharmaceutical scientist. While the record of the A.PH.A. Industrial Pharmacy Section is considerably shorter, nevertheless, even during its relatively brief history it has made a very significant contribution to the profession.

In an effort to consider how the needs and desires of their respective members might be served even better, the officers of these Sections have held discussions to explore the possibility of pooling their individual efforts toward the formation of a single, unified group. Much of the original impetus for such a reorganization came from a combined Section resolution which was passed during the 1962 Las Vegas annual meeting and referred to the A.PH.A. Council for study. Recognizing the great potential value of the suggested plan to this vital segment of the ASSOCIATION membership, both the Council and the A.PH.A. staff endorsed the principle of the general proposal and encouraged the officers of the Scientific and Industrial Sections to discuss the plan with their respective Section memberships. In order to meet the expanded services which the membership would require, the employment of a full-time staff person to serve as permanent Secretary of the proposed group was also considered.

After subsequent consideration and preliminary study on the part of the Section officers, a broadly defined organizational structure was drawn up, and the "*Academy of Pharmaceutical Sciences*" was suggested as a name for the group. The Section officers then referred the proposals to their respective memberships in order that the matter might be given further consideration at this year's annual meeting.

During the meeting this May, resolutions were adopted by each Section calling for the establishment of a formal Committee composed of representatives designated by each of the interested Sections. The Committee is to be charged with the responsibility of exploring the feasibility of creating such a unified body of pharmaceutical scientists, and with developing a more detailed proposal for consideration by the individual Section memberships. The action taken this May might well represent the initial step in what eventually could lead to unprecedented growth for the pharmaceutical sciences, for while enormous strides have already been made, the ultimate potential is even far greater. The ability of such an Academy to realize these goals will depend largely upon the continued efforts of the Section officers and memberships in patiently, but resolutely working out a more defined proposal for its establishment.

Review Article

Pharmaceutical Aerosols

By JOSEPH L. KANIG

In May of 1960 a ten-page survey questionnaire was mailed to approximately one-hundred pharmaceutical companies. The purpose of this survey, instituted by a manufacturer of aerosol containers, was to elicit information regarding the needs of the pharmaceutical industry in its projected thinking on the potential of the pharmaceutical aerosol. The results of this survey (227) indicated a greater need for dissemination of more information on the pressure package throughout the pharmaceutical industry than had been realized. This was apparent from the widely divergent views on aerosol components and disagreement on potential aerosol applications. The survey also concluded that only a small number of companies possessed sufficient experience to make considered statements.

The unreliability of questionnaire surveys is well known. Nevertheless, this survey revealed a large void in the scientific and technical knowledge of the principles of aerosols as they pertain to pharmaceuticals. Considering the extent and volume of prognostication in this area (9, 10, 29, 96, 101, 124, 155–157, 159, 163, 171, 173, 185–191, 196, 241), one may speculate as to the reasons why this void has not yet been filled. They may range from traditional conservatism among members of the pharmaceutical industry to the lack of specially trained and experienced research personnel to conduct the required experimental studien In all likelihood, one of the major reasons has bees. the time required for product development and research personnel to assimilate the new concepts and technologies involved in pressure packaging, and to bring these into play in the design of pressurized dosage forms. Important innovations in medical therapy and dosage forms do not generally spring full grown from idea to practice in short periods of time.

The advantages which are claimed for pharmaceutical aerosols are, for the most part, valid enough to command consideration. Evidence of the unique properties of some of these ideas has already been manifested by several of the products in current use (64, 69, 70, 80, 90).

Lists of pharmaceutical aerosols available in the United States (10, 189) and abroad (4) are beginning to indicate a trend away from products offering only push-button convenience toward those which are truly unique and presumably more effective therapeutically. Advantages of aerosol therapy are being brought to the attention of medical practitioners (136) and this increased familiarity with the properties of aerosol pharmaceuticals is contributing to the upsurge of interest.

Another barometer of the increase in aerosol development is the number of patents issued in this area. Most of these are concerned with valves, containers, and special adapters for use

Received from Columbia University, College of Pharmacy, New York 23, N. Y.

with pharmaceuticals. Methods of applying aerosols to the eye (234), for administering medication orally into the lungs (21, 22, 71, 158), pressurized douches (27), and special aerosol formulations for use in veterinary medicine (30, 60, 228) are a few of the many patents which have been issued in recent years.

Most of the advances which have been made in aerosol technologies have been concerned with the development of valves, containers, and propellants. These are the essential components of the pressure system and it is therefore understandable that emphasis should have been placed on their development. It is not the intent of this review to delve into the specifics of these components other than to indicate their role in the problems associated with the development of aerosol pharmaceuticals. The reader is directed to two books (96, 196) which adequately present the basic principles of aerosol technology together with discussions of the factors in formulating and filling aerosols.

PROPELLANTS

One of the most intriguing aspects of aerosol formulation is the dual role played by most of the currently available propellants. These supply the necessary energy required by the self-propelling features of the aerosol, and, in addition, become an integral component of the contents. In many instances the propellant used may be quite satisfactory in supplying pressure, but at the same time introduces serious problems which affect therapeutic efficiency and product stability. The extent to which these problems can be solved will ultimately dictate the range and type of pharmaceutical applications of aerosol systems.

Propellants in current use may be divided into two major categories: liquefied or compressed. The bulk of the liquefied gas propellants are fluorochloro derivatives of methane and ethane. These halogenated propellants are marketed throughout the world under a variety of names, but most of them are also designated by a numbering system which generically indicates the number and identity of atoms in each compound. The newest member of this family of propellants is octafluorocyclobutane (Propellant C-318). This nonchlorinated cyclic compound is considered the most stable of the halocarbon propellants and has been cleared for use with edible products. Its potential in pharmaceutical applications has not yet been fully explored (88). Reed (166) has secured a patent for a mixture of octafluorocyclobutane (Freon C-318) and isobutane which he claims is suitable for pressurized aqueous products which have either an acid or alkaline pH and are intended for cosmetic or pharmaceutical application.

Among the liquefied halocarbon propellants, trichloromonofluoromethane (Propellant 11) is somewhat more reactive than the others and undergoes hydrolysis in the presence of water and metal catalysts. Solutions containing alcohol and Propellant 11 also become acidic and develop unpleasant odors (233). It has been demonstrated by Sanders (178) that this reaction is not due to hydrolysis but rather to a free radical reaction between Propellant 11 and ethyl alcohol. Experiments with several types of free radical inhibitors showed that nitromethane, a colorless, odorless, nontoxic liquid, was suitable for stabilizing solutions against the reaction (26). Propellant 11 stabilized with nitromethane is now commercially available as "Freon 11" S and seems to offer advantages in the formulation of stable alcohol based solutions.

Hydrocarbon propellant gases, such as propane, isobutane, and *n*-butane have enjoyed limited use in nonpharmaceutical aerosols (2, 36). Their chief disadvantage is their flammability when used alone, but it is claimed that this hazard is minimized when these compounds are mixed with the halocarbon propellants. The possibility of leaks of these flammable propellants from stored containers, however, has become a matter of concern to city fire departments (3, 152).

The nonliquefied or compressed gas propellants such as carbon dioxide, nitrous oxide, or nitrogen (93, 104, 131, 164, 226), and chlorinated propellants such as vinyl chloride (193), methylene chloride, or chlorothene have been used in limited capacities (113).

AEROSOL DOSAGE FORMS

The wide range of pressures and properties offered by the available propellant gases together with the variety of valves (both metering and continuous action) and containers make it theoretically possible to design aerosols which possess advantages not normally encountered in conventional dosage forms. For example, anhydrous suspensions of mucolytic enzymes were developed in this laboratory and were found to retain their enzymatic activity when stored under ambient conditions for extended periods of time. This is not easily possible in any other ready-for-use form. The growth of the aerosol as a dosage form depends, to a large degree, on the ability of the pressurized units to offer similar advantages. Since the attainment of unique features is almost always attended with the necessity of solving

unique problems, a review of the basic types of aerosol dosage forms is in order before considering specific applications.

Solutions

Most of the liquefied propellants used in aerosol formulations exhibit solvent characteristics similar to the nonpolar organic solvents. They are very poor solvents for polar compounds and are immiscible with polar liquids. This rather severe limitation inherent in the properties of the propellants has prevented their use alone in those instances where solutions are desirable or required.

The solvent power of the various propellants for different materials has been investigated only to a limited extent (11, 18, 209). Several methods for describing or evaluating the solvent power of the propellants have been developed (100, 149, 151) and used in solubility studies. A qualitative method of estimating miscibility is the use of kauri-butanol values. These are obtained by titrating 20 Gm. of a standardized solution of kauri gum in butyl alcohol at 77° F. with the liquid under consideration. The end point is reached when turbidity produced due to precipitation of the gum prevents reading 10 point type through the solution in a 250-ml. Erlenmeyer flask. This method is used in the solvent and paint industries and seems to agree with results obtained in solubility studies (126). The kauri-butanol values for halocarbon propellants have been reported (210).

Considering the advantages to be gained, it is surprising to find that very little has been done to circumvent the problems imposed by the poor solvent properties of the propellants for polar compounds. The results of work done in this area may be divided into two types of aerosol systems.

Three-phase Systems.—One method (57) of obtaining sprays containing water-soluble compounds is the use of the three-phase system. This aerosol contains water or an aqueous solution plus the liquefied propellant which forms a separate layer, either below or above the aqueous layer, depending on relative liquid densities. The two immiscible liquid layers and the vapor in the headspace of the sealed container constitute the "three phases" of such systems. When the propellant layer is on the bottom of the container, a dip tube, or standpipe, must be attached to the valve and its length adjusted so that it does not extend into the liquid propellant phase (Fig. 1). In such systems, components which are soluble in, or miscible with, the aqueous layer are maintained as a solution until sprayed.

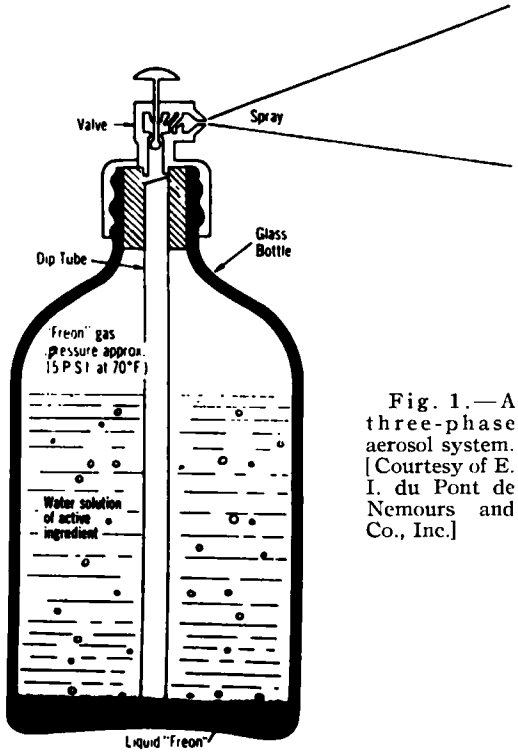

Fig. 1.—A three-phase aerosol system. [Courtesy of E. I. du Pont de Nemours and Co., Inc.]

Actually the propellant phase serves to supply the pressure required to force the aqueous solution up the dip tube and out of the container. It does not materially affect the character of the spray; this becomes the function of the valve components. None of the liquefied propellant is introduced into the aqueous solution while it is being ejected and the atomized spray which results is therefore similar to an aqueous spray produced by conventional squeeze-type atomizers.

Variations of the three-phase type consist of water-based products dispensed by means of the vapor pressure produced by floating small quantities of flammable hydrocarbon gases on top of the aqueous layer. These sprays offer no advantages over those which employ denser halocarbon propellants since the spray characteristics are still limited and pose the additional problem of the possibility of highly flammable liquids being dispensed when the container is nearly empty.

The three-phase system is very similar in operation to the use of compressed gas as the propellant force. A compressed gas (such as nitrogen) occupies the headspace above the liquid solution and simply exerts sufficient pressure on the liquid to force it up the dip tube when the valve is actuated. Here, too, the spray characteristics are limited to the mechanical break-up action of the valve components, and the entire system is sub-

ject to the disadvantages imposed by the use of compressed rather than liquefied gases. Notable among these disadvantages are: (*a*) a large gas space is required in the container to maintain sufficient pressure to empty the contents, (*b*) pressure decreases as the contents are discharged giving rise to changes in the nature of the spray, and (*c*) the possibility of misuse causing an accidental discharge of gas content which produces an inoperable product.

A patented multi-component three-phase system (36) claims to overcome the cited objections and limitations by employing a mixture of propellants, a hydro-alcoholic phase, and a specially designed valving device. The propellant phase is composed of a mixture of halocarbon and hydrocarbon propellants. Hydrocarbon propellants suggested include propane, isobutane, isopentane, or 2,2-dimethyl propane. The mixture of propellants is adjusted so as to possess a liquid density almost equal to but not exceeding the density of the hydro-alcoholic phase. In this manner the propellant phase floats on top of the other, in the static state, but the two are easily mixed by moderate agitation of the container prior to use. The alcohol (ethyl or isopropyl) content helps in dispersing the propellant liquid throughout the aqueous phase. The water content is said to inhibit flammability, reduce cost, and as a component of the hydro-alcoholic phase, makes possible the use of solutes which are soluble in water and alcohol mixtures.

The admixture of the propellants and hydro-alcoholic solution makes it possible to produce sprays with a variety of desirable characteristics as the dispersed propellants rapidly boil away from the spray. This feature is supposedly assisted by the valving arrangement which is comprised of a mixing chamber to premix the liquid and vapor phases before emission from the valve.

Two-phase Systems.—Aerosol terminology defines the two-phase system as having one vapor and one liquid phase. Any nonvolatile material dissolved in the liquid phase is left suspended in air as a fine dispersion immediately after spraying as the liquefied propellants boil rapidly away. Because of the poor solvent power of the halocarbon propellants for polar compounds, only nonpolar materials are directly dissolved by them. Efforts to increase the solvent power of the liquefied halocarbon propellants have centered mainly on the use of co-solvents. Primary objectives of such studies are the development of water-based aerosol formulations which would permit the incorporation of ingredients soluble in water, reduce the flammability hazard, and decrease formulation costs. A successfully formulated two-phase aerosol is also the simplest to manufacture. The added solvent becomes an important factor in such systems. It not only diversifies and enhances the solvent action of the propellant, but also exercises a considerable role in determining the characteristics of the spray produced and the applicability of the solution.

Early formulations which appeared employed alcohol as the co-solvent. A patent issued in 1959 (158) describes the use of ethyl alcohol in providing medicaments in aerosol form suitable for inhalation therapy of water-soluble drugs such as isoproterenol hydrochloride, epinephrine hydrochloride, and phenylephrine hydrochloride, or alcohol-soluble materials such as atropine, octyl nitrite, and ephedrine. The liquid phase of the aerosol, according to this patent, consists of the medicament dissolved in ethanol (20–40%) and water (1.5–2.0%), with the remainder of the composition consisting of liquefied halocarbon propellants designed to produce a total vapor pressure of between 20 and 40 pounds per square inch gauge (psig) at 70° F. Antioxidants such as sodium ascorbate, ascorbic acid, or sodium bisulfite are added as stabilizers where required.

A more recent patent (205) utilizes essentially the same procedure for producing aerosol compositions containing isoproterenol hydrochloride for oral inhalation. This patent, however, claims that the use of ascorbyl palmitate as an antioxidant for such solutions is superior to ascorbic acid since the latter agent comes out of alcohol solution in the presence of halocarbon propellants. Isoproterenol hydrochloride is stated to be more suitable than isoproterenol sulfate for the same reason. Apparently, the physical-chemical laws which govern stability of nonpressurized solutions must not be overlooked in formulating pressurized medicaments.

Additional attempts to produce aqueous two-phase systems successfully have utilized a variety of co-solvents. A rather extensive study of co-solvents has been conducted by Geary (72), who first determined the miscibility of the solvents with propellants and then conducted solubility studies of the ternary systems of water, halocarbon propellants, and co-solvents. The ternary plots of these systems are excellent guides in formulating water-based aerosol products with ketones, alcohols, glycols, and other solvents. A similar study (215) has been conducted with glycols, glycol ethers, and polyglycols as the co-solvents.

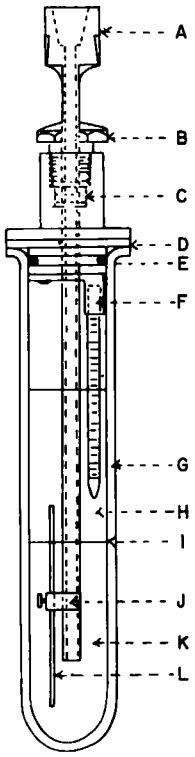

Fig. 2.—A pressure tensiometer for the measurement of surface and interfacial tensions in pressure systems. [From Reference 108 (patent pending).]

On the basis of published data, many of these systems appear to offer improved solvent power for two-phase aerosol formulations together with a wide range of spray characteristics. The major problem associated with their use, however, is the toxicity of many of the solvent materials. Solvents such as acetone, methanol, the "carbitols," and "cellosolves" are almost automatically excluded from pharmaceutical applications in the quantities required. Others, such as 1,3 butylene glycol, dipropylene glycol, and triethylene glycol would require additional toxicity and irritation data before they could be considered for even topical application.

Modification of Interfacial Barrier.—The use of surface-active agents in preparing two-phase aerosol solutions has only recently been considered (106, 108, 110). Surfactants had previously been suggested as a means of forming dispersions with propellants and water. These dispersions were described (32) as being "neither true solutions, nor emulsions, but . . . somewhere in between." These authors proposed the use of nonionic surfactants such as Tweens and Spans, but it was not made clear as to whether water was dispersed in propellants or *vice versa*.

Current concepts and knowledge of the functions of surfactants in solubilizing materials make it obvious that such activity can be successfully applied to problems in aerosol solutions. The relationships which have been established between the physical-chemical properties of surfactants and their specific activities in nonpressurized systems could conceivably be defined for aerosols as well. A study has been reported which was conducted to initiate the development of procedures to measure the effects of surfactants in aerosols (108). The first requirement in this study was an accurate method of measuring the surface tension of the aerosol propellants and the interfacial tension of the propellants with other immiscible liquids. Of the several methods available for the measurement of surface and interfacial tensions, only the capillary height method was found to be adaptable for use with pressure systems. The capillary height method is generally considered to be the most accurate of all, partly because the theory has been developed with considerable exactitude and partly because the experimental variables can be closely controlled (89).

Figure 2 illustrates the pressure tensiometer which was designed to embody the basic principles of the capillary height method in an instrument capable of controlling the unique variables encountered in working with liquefied gases. The capillary tube (*L*) was positioned at the surface or interface of the contents of the glass pressure tube (*G*) by adjusting the height of capillary tube mounting (*J*) or raising or lowering the inlet tube (*A*) after loosening the gland nut (*B*). Escape of pressurized contents was prevented by stainless steel gland washers and a neoprene gland (*C*) plus "O" ring and washers (*E*). Liquefied propellants were introduced into the pressure chamber by means of a needle valve inserted in the coupling on top of the Monel inlet tube (*A*). Water or any other fluid was admitted by means of the same tube but under a positive pressure just exceeding the internal pressure created by the particular propellant in the chamber. A calibrated thermometer inserted into a bracket (*F*) indicated internal temperature.

The capillary height was measured at constant temperature by means of a micrometer slide cathetometer with a 50-mm. range and an accuracy of 0.005 mm. Surface and interfacial tensions were calculated by

$$\gamma = {}^1/_2\, rhg\,(d - d') \qquad \text{(Eq. 1)}$$

where r = radius of the capillary tube, h = height of the meniscus, g = acceleration due to gravity, and $(d - d')$ = difference in density between liquid and vapor phases.

The pressure tensiometer was used to measure surface tensions of selected propellants. The

resulting values compared favorably with theoretical values (Table I). Interfacial tensions of propellant-water systems with and without surfactants present were also determined. Table II indicates the effect of one surfactant on these interfacial tensions.

Several interesting and potentially useful preliminary observations were made possible by use of the pressure tensiometer. One was the linear relationship (Fig. 3) between the solvent power of four different halocarbon propellants and the interfacial tension against water with 0.1% of a nonionic surfactant dissolved in the propellants. This introduces the possibility of another parameter in the ability to predict and control the interfacial barrier. Since the liquefied halocarbon propellants are rarely used alone, but in mixtures, the resulting broad range of solvent power for any given surfactant makes possible a corresponding range of interfacial tensions.

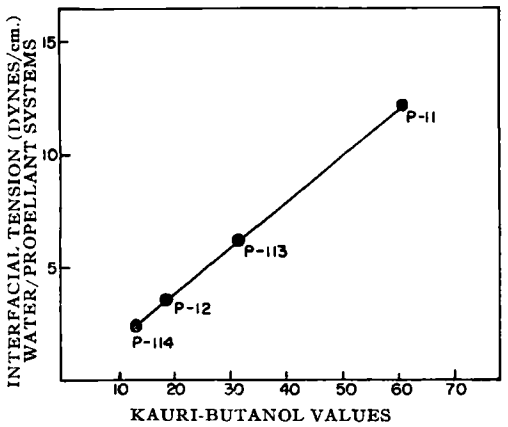

Fig. 3.—Relationship between solvent power of propellants and the interfacial tension against water with 0.1% Igepal CO-530 dissolved in the propellants. [From Reference 108.]

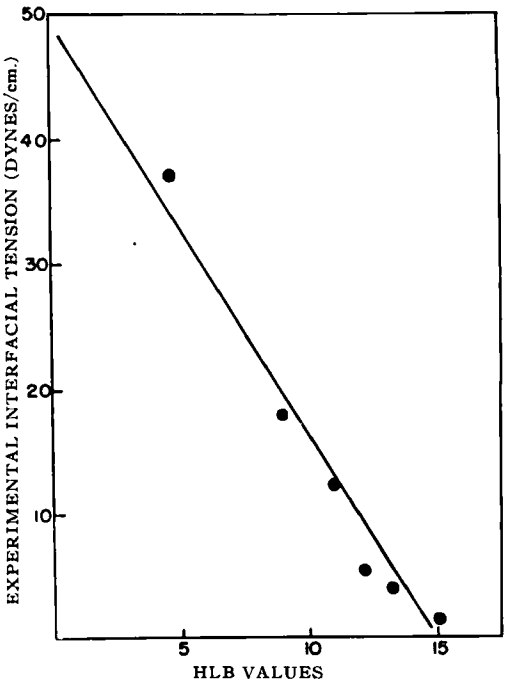

Fig. 4.—Interfacial tension *vs.* known HLB values. [From Reference 108.]

Chun and Martin (35) have demonstrated a linear relationship between interfacial tensions and HLB values of surfactants in toluene-water systems. The pressure tensiometer was employed to establish a similar relationship for surfactants in propellant-water systems. The Igepal CO surfactants were used in Propellant 11-water systems. Interfacial tensions obtained with 0.1% surfactant dissolved in the propellant plotted against HLB values resulted in a linear relationship as shown in Fig. 4. By means of the method of least squares, the equation of this line is given by

$$\gamma = 49.5 - 3.32\,(\text{HLB}) \qquad \text{(Eq. 2)}$$

Utilizing known HLB values for the Igepal CO surfactants, theoretical interfacial tensions in Propellant 11-water systems were calculated by means of Eq. 2. These values and their deviation from experimental values are shown in Table III.* Agreement between calculated and experimental values has encouraged additional studies in this laboratory which currently seek to expand these relationships in the use of surfactants to

* See p. 533 for Table III.

solubilize polar compounds directly in propellant mixtures.

Suspensions

Of all the aerosol dosage forms which have appeared since the time the pressure package became technically feasible, the one offering the greatest challenge in successful formulation is that which consists of a suspension of finely powdered insoluble materials in the liquefied propellants. The ability to dispense a self-propelled dry powder from an hermetically sealed container offers the opportunity for aerosol formulations which are uniquely different from their nonpressurized counterparts.

Attempts to suspend powders in liquefied propellants introduce several problems. Foremost among these is the agglomeration of the suspended particles. This most often occurs immediately after the suspension is prepared, or within a short period thereafter. The rate and extent of agglomeration are apparently modified by the composition of the suspended solids. Agglomeration results in a clogged valve, either initially or after it has been in use for a while. Where uniformity of dosage is imperative, agglomerated particles may cause variation in the amounts of powder delivered even if the valve remains operable. Another problem is the tendency of the suspended powders to become deposited in a cake form on the inner walls of the container, particularly in the area above the liquid level, the headspace. This results in a loss of active ingredients which are not dispensed from the container. Inaccurate dosage also results because the concentration of the ingredients left suspended in the liquid phase progressively decreases.

Early attempts to overcome these problems varied as to method and effectiveness. A patent issued to Beard in 1954 (17) claimed successful formulation of suspensions of powders of terramycin hydrochloride, viral agents used to inoculate chickens against different virus diseases, and sodium bicarbonate. Beard relied on simple suspension of the dry finely powdered materials in various combinations of halocarbon propellants which possessed "a specific gravity such as to inhibit agglomerative sedimentation of the powdered material." No mention was made of optimum particle size or use of additives to stabilize the suspensions.

Several methods have been reported which make use of additives, such as isopropyl myristate (51, 52) or light mineral oil (217), to provide "slippage" between particles, to lubricate the component parts of the aerosol valve, and to increase adherence of the sprayed particles to skin or other surfaces. Isopropyl myristate was found to be ineffective by Thiel and his coworkers (218) when the suspended powders were dispensed with a metering valve. Bird (23) discovered that he could prepare sprayable antibiotic compositions by converting the crystalline forms of tetracycline hydrochloride and chlortetracycline hydrochloride to their amorphous calcium salts. He further specifies that the salt be dry and finely subdivided so that at least 95% of it is less than 15 μ in diameter.

A satisfactory suspension of high solids content without particle agglomeration has been reported by Geary and West (73). This suspension contained bulking agents such as Santocel 54 to fill the void space between suspended particles.

The various factors which are responsible for particulate stability in aerosol suspensions and the relative importance of these factors have been thoroughly elucidated in a patent issued to Thiel, Porush, and Law, assigners to Riker Laboratories, Inc. (219). Their findings have been confirmed by Kanig and Cohn (107) in a parallel study.

Variables Affecting Particulate Stability.—There is general agreement in the literature that the state of subdivision of the solid is critical not only for proper utilitization of the aerosol but also as a factor in the stability of the suspension. It is obvious that the particle size of the suspensoids must be at least smaller than the smallest valve orifice and small enough to fulfill the operational objective of the product. However, the more finely subdivided the powder is made, the more free surface energy is generated. Molecules inside a powder particle are acted upon by balanced forces produced by molecules surrounding them. On the surface of each particle, however, the molecules are acted on by inward forces only, and this produces an imbalance of forces at the surface. Decrease in particle size with the attendant increase in surface area results in a surface energies to mass of particles ratio so great that when particles collide they adhere strongly. This is probably one of the primary causes of agglomerate formation in pharmaceutical aerosol suspensions where 95% of the particles are generally under 10 μ in diameter and none are larger than 50 μ.

Another variable is the moisture content of the system. The degree of sensitivity of different suspended materials has been shown to vary directly with the solubility of the solids in water. Observations made on the rate of agglomeration of different suspended materials indicated that

the more soluble the material is in water, the more rapidly it agglomerates in the presence of moisture (107). Since water is immiscible with the propellants, any moisture in the system would tend to be attracted to the more polar solids, and the more water-soluble compounds would undergo physical changes leading to agglomeration. In the presence of a sufficient amount of water, growth of crystalline materials could take place. Crystal growth in this instance is due primarily to the conversion of a less stable configuration to one which has a lower energy state. This has been demonstrated in nonpressurized liquid suspensions of finely divided crystalline materials (99). No significant differences in rate of agglomeration were observed when water was introduced into the system, either by being added to the dried powders before they were suspended in the propellants or to the completed suspension (107).

Relative polarity between suspensoid and suspending medium has an influence on particulate agglomeration. The greater the difference in polarity between the powder and the liquid, the more difficult it is for the liquid to wet the surface of the solids and the greater the tendency for moisture to cause agglomeration.

An additional variable is the relative density of suspended powders and propellants. Where possible, equalization of the densities of the suspension medium and the particulate solids tends to reduce the rate of settling. However, results obtained with suspensions in which the density ratios had been adjusted to unity were inconclusive as to the role of equalized densities in preventing particulate agglomeration (107).

A beneficial result of the adjustment of densities was observed in a decrease in the amount of caking which occurred on the inner walls of the container. Thiel, *et al.* (219), found that the addition of a sufficient quantity of an auxiliary finely divided solid of density greater than that of the liquid phase will prevent the surface spread of lighter powders, thus avoiding "caking out" and its associated drawbacks. The auxiliary powder may be of any chemical type, provided it is compatible with the other ingredients and insoluble in the propellant. It may also serve as a desiccant for the system as when anhydrous sodium sulfate or calcium chloride is used. A formula for the calculation of optimum concentration of the auxiliary powder is provided by these authors.

Control of the Variables.—The use of surface-active agents in overcoming the problems of suspension stability has been recognized in several fields. There is ample evidence in the literature to indicate that surfactants can be utilized as protectives and stabilizers in the preparation of suspensions (12, 13, 40, 99, 182, 201).

It was found that surface-active agents could be used as dispersing agents in aerosol systems and serve several purposes. By becoming oriented at the solid-liquid interface, a surfactant provides a physical barrier to agglomeration caused by free surface energy, differences in polarity, and the presence of moisture. The ultimate and desired effect is therefore the maintenance, in the suspension, of particles at approximately the original size. Liquid, nonionic, lipophilic surfactants which are readily soluble in the propellants were observed to be the most effective in a range of from 0.25 to 5% by weight of the total composition. Surfactants such as sorbitan trioleate, sorbitan sesquioleate, polyoxyethylene sorbitol tetraoleate, and polyoxyethylene sorbitol pentaoleate have been found satisfactory in providing stable suspensions, provided that no more than 300 p.p.m. of water are present in the total aerosol system. Maximum water content tolerated without particle agglomeration will vary with the solubility of the suspensoid in water, the surfactant employed, and its concentration in the solution.

Additional work is still required in this area since there are some factors inherent in the use of surface-active agents which offer disadvantages. It is conceivable that some surfactants may partially solubilize a suspensoid in the halocarbon propellants. This might lead to changes in crystal configuration and result in growth or agglomeration. Partial solubility and recrystallization may lead to a gradual deposition in the orifices and expansion chambers of the valve and cause a leaking or clogged valve (16). Maximum solids capacities of such systems are somewhat limited. An increase in total solids content requires correspondingly larger quantities of the surfactant. In suspensions containing 25% solids or higher, the films of sprayed powder are oily or greasy in nature. Depending on the intended use of the suspension, this effect may be a nuisance or an advantage.

Emulsions

More fundamental work has been done in the area of emulsions than in any other aerosol form because emulsions have offered the greatest opportunity for new and useful applications of pressurized systems and because the principles which control conventional emulsions are easily applicable to aerosols. In addition, the pressurized emulsion presents features not usually or easily obtained in ordinary emulsions since there

is greater versatility to be found in characteristics of the emulsion spray.

Emulsions which would otherwise be judged as being poorly formulated are vastly improved by the mechanical shearing action of the valve or the flashing off of dissolved propellants. In fact, the mechanical forces brought into play when an aerosol emulsion is propelled from the container may be considered to be the equivalent of *in situ* homogenization. Moreover, the propellant plays a more vital role in aerosol emulsions than in other aerosol forms. Not only does the propellant supply the energy for the self-propelling features of the aerosol, but it also has a decided effect on the spray character by modifying foam density, foam strength, drying time, and other important features (34, 174, 207, 212). These features have accounted for the phenomenal success of aerosol shaving lather which was invented and developed in 1949. The product as described in the original patent (168) consists of an aqueous soap solution and a liquefied propellant in a container with a valve-controlled opening. The propellant is only slightly soluble in the soap solution but is readily emulsified in it to produce what might ordinarily be evaluated as a poor emulsion. When the emulsion is dispensed, however, it develops a lather possessing desirable characteristics as the propellant rapidly expands and flashes off.

Aerosol emulsions do not produce lathers or foams only. Spray characteristics may be varied from a fine mist spray to a stream or a foam, depending on the type of emulsion formulated, the emulsifying agent, the propellant composition and proportion, the presence and nature of additives, and the type of valve and valve actuator used on the container (91, 174, 207, 224). Aerosol emulsions are classified as oil-in-water or water-in-oil types but take on the extra dimension imposed by the propellant. In o/w emulsions, the propellant becomes dispersed as fine droplets in the internal phase and has a great effect on the characteristics of the foam. Stiff, dry, resilient foams are obtained with a high vapor pressure propellant and a high concentration of propellant. Conversely, soft, wet, flat foams are produced with lower vapor pressures or lower concentration of propellant in the internal phase (216). These effects are demonstrated by use of either the liquefied halocarbon propellants or the hydrocarbon propellants such as propane, butane, and isobutane. Water-in-oil emulsions produce unstable wet foams since the propellant is in the outer phase and flashes away without creating the voluminous foam which it does when it is dispersed in the internal phase.

It is only when a compressed gas, such as nitrogen, is used that the emulsion characteristics remain substantially unchanged. Emulsions are merely expelled from the container by the piston-like action of the inert and undissolved gas. This offers no advantages over the conventionally contained emulsion but imposes many shortcomings which are characteristic of the compressed gases.

Nonaqueous emulsions and foams have been developed for use in aerosols. By replacing water with different polyhydric alcohols or with glycol derivatives, Sanders (208) has produced foams which may be varied widely to suit any particular application. Extremely stable foams may be produced because the glycols do not dry rapidly. In some instances, these foams may approach creams in their consistency, or they may be varied to achieve "quick-breaking," unstable foams. The range of foam characteristics together with the nonaqueous feature of these emulsions makes them suitable for pharmaceuticals where water is not desired for reasons of stability, or where it is contraindicated in the condition being treated.

Emulsifying Agents.—The selection of aerosol emulsifying agents is still being made on a rather haphazard and pragmatic basis. Considering the wealth of scientific information available regarding the selection, use, and evaluation of emulsifying agents for nonpressurized systems, it is surprising to observe how little of this has been applied to aerosol emulsions. While it is true that hundreds of surfactants have been evaluated for this purpose, most of the work has been concerned with effects rather than causes. As a result, only generalized rules-of-thumb are available as guides when a new pressurized emulsion is contemplated. Moreover, even these guide lines are inadequate in predicting the behavior of an emulsifying agent in a system other than that in which it was tested (211).

It has been advocated (106) that methods of research and evaluation which have proved reliable for nonpressurized emulsions should be adapted for use in pressurized systems. Proceeding along these lines, effective relationships have been observed between emulsion stability and HLB values of surfactants (Fig. 5) and kauri-butanol values of propellants (Fig. 6). Preliminary evidence exists to indicate that the relative polarity of propellant-surfactant solutions exerts an influence on pressure emulsification (108).

No reports have appeared to indicate that

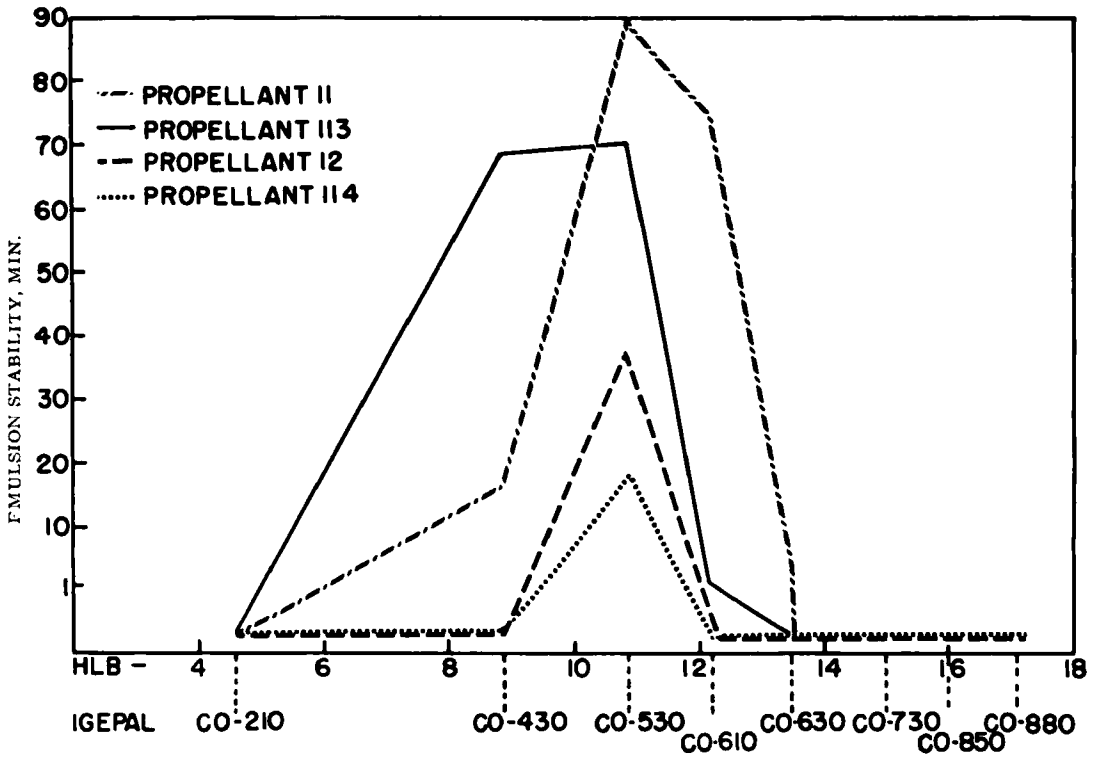

Fig. 5.—Relationship between HLB values of Igepal CO series of surfactants and emulsion stability of propellant-water systems. [From Reference 108.]

studies have been conducted on the use of emulsions in pressure systems as vehicles for insoluble suspended matter. Aerosol emulsion-suspensions offer interesting possibilities for application in topical and related therapeutics.

INHALATION AEROSOLS

Inhalation therapy, it has been said (122, 141, 163, 185), goes back at least as far as written medical history. Fumes of burning herbs or powders, steam inhalations, and nebulized or atomized solutions of a variety of compounds have been in use for the direct therapy of bronchial and pulmonary diseases for many decades (24). Therapeutic aerosols have been produced by various types of equipment (39, 109, 195), and improved devices such as inhalers, atomizers, nebulizers, and insufflators (141) have been a prime factor toward increasing the efficiency and acceptability of inhalation therapy over the years. Long before the introduction of the self-contained pressurized aerosols as pharmaceutical dosage forms, many studies had been conducted on the use of medicaments for local therapy of the respiratory tract or for rapid systemic effects through absorption from the inner surface of the lungs. As newer chemotherapeutic agents of interest in inhalation therapy became available, they were investigated for a variety of pulmonary conditions (1, 94, 111, 194). These substances include antibiotics (66, 162), antitubercular drugs, sympathomimetic amines (75, 109), antispasmodics (160, 161), mucolytics (61, 123, 203, 222, 223), surface-active agents (128–130), certain vitamins (notably Vitamin B_{12}) (137, 138), and corticosteroids (74, 167). This partial accounting of pulmonary therapeutics serves to indicate that the aerosol is not nearly so new an approach as one might assume by reading the recent papers describing the potential of the pressure pack in inhalation therapy. It is only when a comparison is made between the utility, dependability, and reproducibility of the devices employed that the advantages of the new type of unit become apparent.

It has been recognized that the physical state of the particles in therapeutic aerosols exercise a critical effect on the site of deposition and absorption from the respiratory tract (1, 109, 145, 150). Therefore it is claimed that the pressurized aerosol dosage form offers the advantages of accurate delivery of a measured dose of aerosolized drugs, particles of which are within a specified range of effective diameter sizes. Reproducibility of amounts delivered from this dosage form is said to be superior to oral liquid preparations

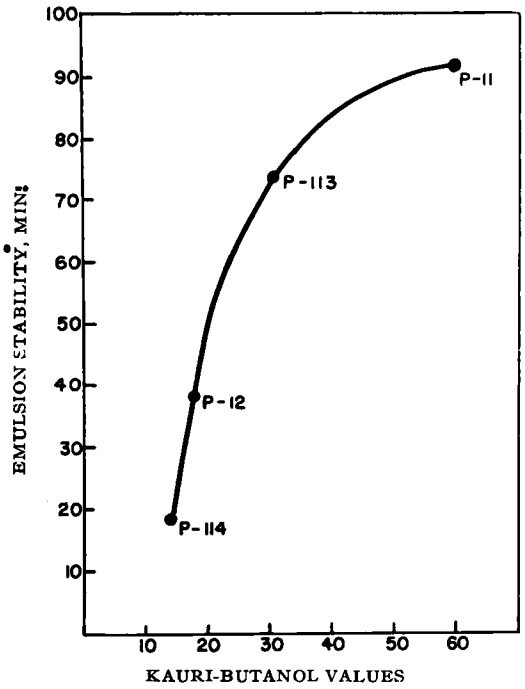

Fig. 6.—Propellant-water emulsion stability related to solvent power of propellants with 0.1% Igepal CO-530. [From Reference 108.]

dispensed by teaspoon or dropper and to compare favorably with weight variations permitted for hard gelatin capsules (159, 241).

Additional unique advantages over other types of vaporizers include: (*a*) a compact container capable of delivering hundreds of single doses, making it the least clumsy of all devices and perhaps the most economical; (*b*) application is rapid and convenient and does not require manipulative skill on the part of the patient; and (*c*) the container is hermetically sealed which makes it tamper-proof and its contents protected against bacterial contamination, moisture, and oxidation or evaporation during periods of disuse. Presumably these factors are sufficient reasons for the reappraisal of the oral inhalation route in therapeutics and for the increased interest in methods for evaluation and control. Enthusiasm for this dosage form has even caused some of its advocates to proclaim that inhaled aerosolized drugs may ultimately replace the parenteral or oral routes of administration in some instances.

This has already been clinically demonstrated in the use of orally inhaled ergotamine tartrate in the treatment of vascular headaches, including migraine and histaminic cephalalgia. The efficiency of this route of administration is said to parallel closely that of injection and to be superior in speed and effectiveness to suppositories, sublingual or oral therapy (64, 79, 90, 202).

To appreciate the potential of this route of administration, it is necessary to examine the critical aspects of the physiology of the lungs on the rentention and absorption of inhaled particles and to relate these to the ability of the aerosol dosage form to meet these requirements. It is conceivable that some of the negative clinical results obtained by oral inhalation methods were due to poor control over the critical variable of particle sizes.

Deposition in the Lungs.—One square meter of lung surface is required for each kilogram of body weight to sustain the life processes depending on the exchange of oxygen and carbon dioxide. In the normal adult this amounts to the area of a tennis court (37). Such an area is encompassed in the small volume of the thorax by subdivision of the inner lung surface into hundreds of millions of alveoli. Within the walls of the alveoli the blood is spread out in a thin sheet, separated from the air by a membrane about 1 μ in thickness. This large area, richly endowed with blood and separated from airborne substances by only a thin membrane, theoretically offers a highly absorptive area for rapid transfer of drugs into the blood stream. Davies has stated "Particles of solid material that deposit on the ciliated lining and the tubes have rapid access to the blood stream. Lung defenses are completely avoided, and immediate toxic action can be exerted, sometimes more effectively than in the case of oral administration. The importance of solubility is demonstrated by the behavior of lead compounds. The dust inhaled by miners of Galena has low solubility and is not dangerous, but the mining and smelting of lead carbonate ore have frequently caused acute lead poisoning by inhalation of the relatively soluble dust" (49).

The chance of an inhaled particle reaching the alveolar regions depends on its size, weight, and shape. The defense of the lungs against retention of any particle is provided by the tortuous nature and decreasing size of the channels through which it must pass, thus making impaction with the walls very probable. After impaction, a particle which is slowly soluble in the mucus on the walls is removed upward by ciliary action. This inertial impaction is an important mechanism in the nasal airways and in the upper lung where the air velocity is fairly high (134). Studies on deposition of particles in curved tubes have indicated that the large particles are likely to be removed from the air stream by this mechanism and that the inertial impaction of the particles is directly proportional to the density and to the square of the particle diameter (116, 125).

Large particles which may survive inertial influence in the upper respiratory tract will settle downward in the lungs and become deposited by sedimentation in the areas where air velocity is reduced. Here, too, the sedimentation rate is proportional to density and to the square of the diameter.

Particles small enough to penetrate into the alveolar spaces where air velocity is very low are made to collide with the walls by Brownian motion which increases in activity as the size becomes smaller.

Particle Size and Retention.—Interest in particle retention in the lungs has been sharpened by studies in chemical warfare, aerosol therapy, and the hazards associated with industrial dusts and radioactive fallout (5, 6). Papers published in this area fail to agree on the relationship between particle size and retention in the lungs. Mathematical models have been proposed for theoretic calculations of the extent of retention of particulate matter of various sizes in the lungs of man (7, 20, 48, 59, 65, 92, 221, 232). The classical theoretic treatment of retention was made by Findeisen (65). He computed the average dimensions of the adult tracheobronchial tree on a functional concept of structure rather than a strictly anatomic description. His calculations were later modified by Landahl (114), who used slightly different dimensions of the tracheobronchial tree and computed retention values for several different flow rates. The schematic representation of the pulmonary tree used by Landahl is shown in Fig. 7. This indicates that particles larger than 20 μ should fail to go beyond the terminal bronchioles; those 6 μ in diameter would be removed before they reach the lower alveolar ducts, and almost all particles 2 μ or larger are removed in the lower alveolar ducts.

Experimental studies in man with heterogeneous aerosols have been reported (5, 15, 31, 42, 43, 47, 48, 55, 115, 116, 120, 121, 127, 139, 180, 236), while others have designed special techniques for generating monodispersed aerosols in which all the particles are nearly the same size. These were used in respiratory retention experiments (8, 117, 118, 231).

Figure 8 indicates the results obtained by Brown (31), using clay dusts having median diameters from 0.24 μ to more than 5 μ. Employing nasal inhalation techniques, Brown

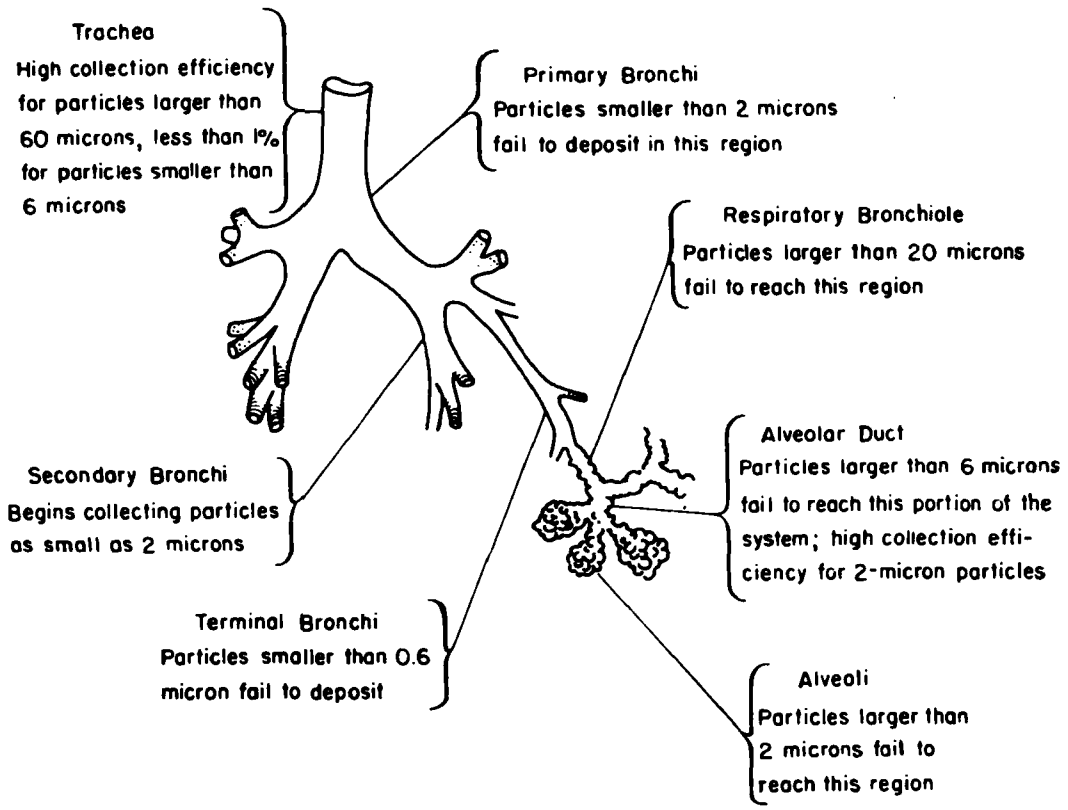

Fig. 7.—Schematic representation of the pulmonary tree showing theoretic retention computed by Landahl. [From Reference 134.]

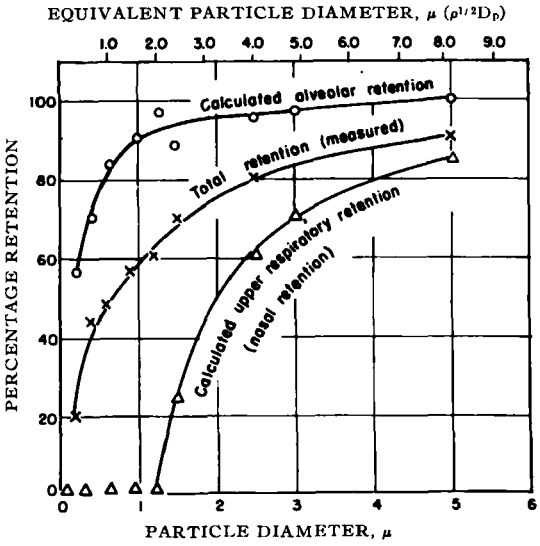

Fig. 8.—Lung retention of clay dusts as a function of particle size. [From Reference 134.]

showed that 85% of the particles of 5 μ in diameter were retained in the upper respiratory tract and that more than 90% of the particles between 1–5 μ in diameter which pass the upper respiratory tract are retained in the alveolar region.

Dautrebande disagrees with such findings and contends "that for ensuring deep penetration into the most efficient part of the lungs of the largest quantity of drugs, the micellary size of the aerosol should be below one micron" (41). He has authored many articles on his studies of methods of generating submicron particles and evaluating their effects and deposition in the lungs (44–46, 50).

The disagreement between these and other workers has not yet been completely resolved. Possible reasons for the conflicting theories and experimental results may be summarized by:

1. Experiments conducted in man or animals may alter normal respiratory mechanics by tracheal catheterization, anesthesia, or use of irritant particles.

2. Differences in the methods of generating aerosolized particles, length of exposure, and methods of detection of expired particles are critical.

3. Either homogeneous or heterogeneous particle size distributions have been used in different studies. Heterogeneous distributions have been criticized because much of the meaning of test results become obscured when an average diameter is used to represent a broad size distribution (134).

4. The possibility exists that materials detected in the lower regions of the pulmonary tree reach there by the indirect route of systemic absorption and circulation.

5. Depending on the efficiency of the aerosol generating system, agglomeration of the particles may occur after leaving the apparatus. Some particles may also increase in size as they encounter the moist air in the lungs while others generated from aqueous or other volatile solutions may decrease in size. If these dynamic changes are not taken into account, erroneous results may ensue.

6. Some investigators have failed to use uniform breathing rates in experiments with humans. In addition to particle size, the next important variable in the retention of particles is the length of time the particles remain in the lungs. The effect of breathing rate is more pronounced for large particles than for smaller ones (134).

7. Methods of measuring particles vary in accuracy and range. As a result, retention values may vary depending on the validity of the method used in measuring the particles.

The entire picture of inhalation therapy is made more complex by the discovery of the existence of a powerful surface-active agent which coats the alveolar spaces in the lungs (37). The substance is thought to be a phospholipid, particularly dipalmitoyl lecithin. It has been found in the lungs of all mammals tested (mouse, rat, guinea pig, rabbit, cat, dog, cow, and man), but not in amphibians (frog and toad), reptiles (snake and crocodile), or bird (pigeon and chicken). It now appears that the surfactant maintains the elasticity of lung tissue and keeps the lungs from collapsing. The surfactant has the further function of assisting osmotic forces acting across the surface of the lungs, and this keeps the film of moisture present there from drawing fluid into the alveolar spaces.

The presence of this powerful surface-active agent in lung tissue fluids may have a profound effect on particulate retention and absorption. This has not been considered in any of the cited studies.

The fact that a surface-active agent is critical to normal lung function must also be taken into account when oral inhalation dosage forms are designed. Substances which are included in the inhalations as active therapeutic agents or for product stability might have a neutralizing or adverse effect on the physiological surfactant. The ultimate results of continuous or prolonged oral inhalation of a variety of substances are open to investigation.

PARTICLE SIZE MEASUREMENT

Particle technology has become increasingly

important in so many diverse areas (204) that the development of particulate fractionation and measurement techniques have been accelerated by the demands of research into fine particle properties and behavior. Methods have been developed for a variety of industrial, meteorological, and biological purposes. Without such methods the study of the role of particulate matter in production, agriculture, and health and disease would be seriously hampered. For the most part, however, many of the particle size analysis methods are of limited value in measuring particles which originate from pressurized systems or which fall into the particle size ranges of interest in the therapeutic applications of aerosols.

Particle size measurement is rarely an absolute procedure. Inherent in almost every method are limitations which are imposed by the physical

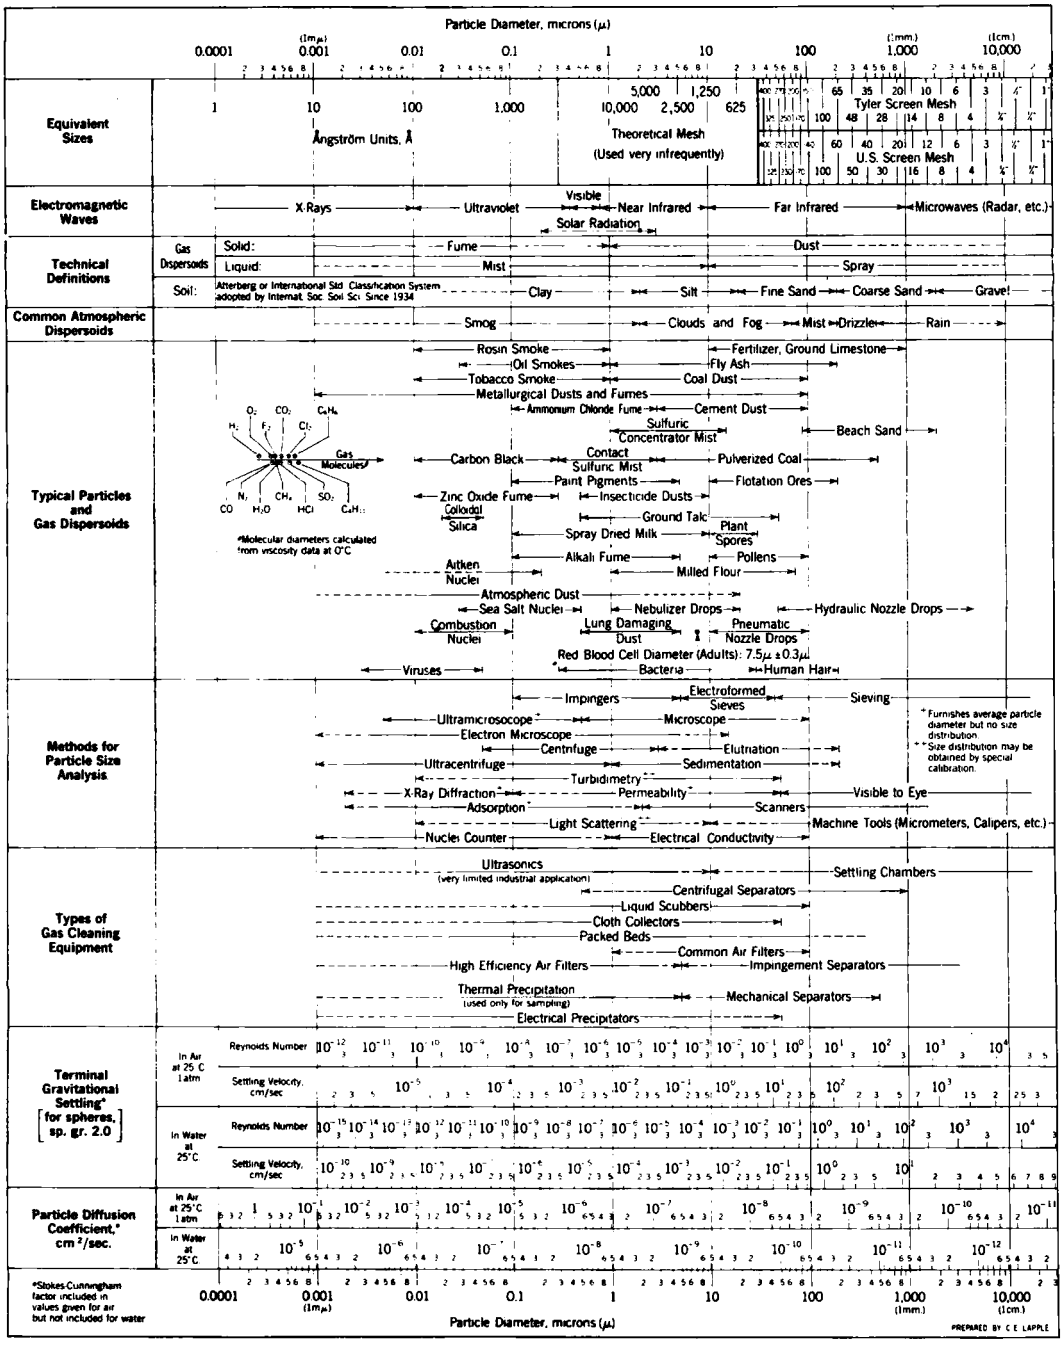

Fig. 9.—Characteristics of particles and particle dispersoids. [From Reference 204.]

principles which are employed. These limitations affect not only the accuracy of the method but also dictate the types of particles which may be measured and their sources. Many of them furnish only average particle diameters but no size distribution, while the size distribution obtained from others may be accomplished only by means of special calibration. The scope of characteristics of particles and an indication of the complexities which exist in the area of particle technology may be ascertained from Fig. 9.

It must also be remembered that almost every technique which has been employed in particle size measurement presupposes an accurate conveyance of a valid and representative sample to the instrument. Particles sampled from a pressurized container must be prevented from agglomerating before they are measured; this aspect of the procedure imposes serious limitations on the types of techniques which may be employed. When little attention is placed on the sampling of particles and the effect it can have on the accuracy of the method, the results obtained are only approximate answers (81).

As a consequence of these limitations, relatively few methods may be considered as being capable of accurately measuring the size range of particles within the framework of aerosol dosage forms and under the restrictions of the unique variables imposed by the generating mechanisms.

The nature of the particle delimits the size analysis method as well. Suspensions of particulate solids in aerosol propellants produce particles essentially unchanged if agglomeration can be avoided as the propellants boil away. Solution-type aerosols offer additional complications in that the droplets are constantly changing size after being sprayed. A reduction in size with time results when the propellants or co-solvents evaporate within seconds and precipitate or crystallize the dissolved solids. Particle size growth may occur when the particles suspended in air are hygroscopic and begin to absorb moisture (77), or when they are liquids under ambient conditions and coalesce upon impact.

Any measurement of aerosol particles must therefore take into account the changes which occur in these dynamic systems after spraying and the possible effects these may have on the accuracy of sampling and size analysis.

Methods of Particle Size Measurement

Microscopic Measurement.—Microscopic techniques have been classified as being among the most accurate of the *direct* methods (*i.e.*, methods in which the actual dimensions of particles are directly measured as contrasted with *indirect* methods which are based on measuring some other property of the particles which is related to their size) (67, 98).

The unique feature of microscopic measurement is that particles are sized directly and individually rather than being grouped statistically by some process of classification. Disadvantages to the method lie in the tediousness associated with the necessity of measuring a sufficiently large number of particles to provide adequate representation.

Limitations in the use of the optical microscope are due to the fundamental laws fixing maximum resolution which set the lower limits of particle size measurement using visible light. This limit of resolution has been reduced by use of ultraviolet light or monochromatic sodium light. Electron microscopy has further reduced the lower limit of resolution to 0.001 μ. However, the upper limit of size is not greater than 10 μ and problems associated with sample preparation reduce the utility of the electron microscope. Ultra-microscopy has been employed to count and measure particles suspended in a gaseous medium but has been supplanted, for the most part, by light-scattering techniques.

Sedimentation Techniques.—Speed of fall under controlled or predictable conditions has become one of the more widely used techniques among the indirect methods of measurement. Application of Stoke's law to free falling particles in liquid or air media is the basis for several instrumental methods of measuring. The physical methods involved in the actual determination of particle size generally conform to the same fundamental principle. If the particles are initially distributed uniformly in a column of fluid at rest, there will be, after a lapse of time, a density gradient in concentration of particles along the height of the column. Determination of this density gradient enables the proportion by weight of the various sizes of particles to be calculated. Any property of the suspension which is a function of the density or particle concentration may thus be used to determine the size distribution. A discussion of the methods of determining variation in particle concentration has been published by Work and his associates (184, 235). Additional theoretical concepts advanced by Heywood (97) and Egolf and McCabe (58) are useful in this area.

A sedimentation balance, described by Oden (142), provides a method of directly weighing particles at selected time intervals as they fall in a liquid system. For continuous observations, an automatic recording-type balance is available.

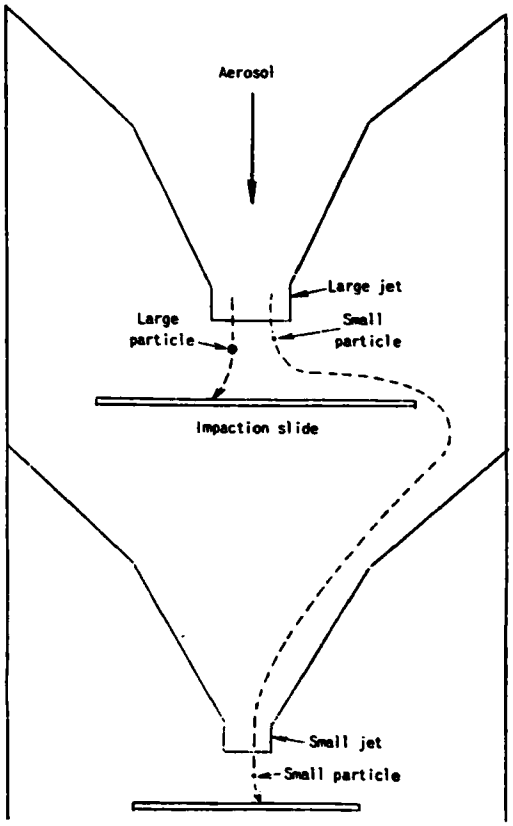

Fig. 10.—Schematic diagram showing principle of the cascade impactor. [From Reference 154.]

Additional refinements of the sedimentation method have been reported. The pipet method, advocated by Schweyer (183), involves the withdrawal of samples of the dispersion at predetermined depths. Evaporation of the solvent then yields concentration data from which particle size may be derived.

A hydrometer bulb method, advanced by Bauer (14), measures changes in density induced by variations in concentration. This is an advantage over the pipet method in that it does not permanently withdraw a portion of the suspension under study. A disadvantage of this method is that the introduction of the hydrometer bulb tends to disturb the settling particles. The Diver method (102) overcomes this disadvantage by utilizing small vessels of varying known density which assume equilibrium positions in the suspension system according to the density gradient that forms as the particles settle.

An innovation in the area of gravitational sedimentation is the Carey and Stairmand photosedimentometer (33) which photographs the tracks of particles as they fall in a dispersion system. The size determination is derived from the length of the photographic track, which is an indication of the distance traveled by the particles, and the time of exposure of the photograph.

The lower limit of size to which gravitational sedimentation methods can be applied is controlled by temperature variations causing circulatory currents in the suspension, by flocculation of particles during the progress of sedimentation, and by diffusion or Brownian movement of the very small particles. All these factors, plus the extreme length of time required by these methods, make it advisable to shorten the sedimentation process as much as possible. This may be accomplished by substituting centrifugal force for gravitational acceleration. The principles of sedimentation are unaffected, except that the factor g in Stoke's equation becomes a variable according to the speed and radius of rotation of the particle within the centrifuge. For example, using gravitational sedimentation, it would require 1057 minutes for a 1-μ diam. particle to fall 5 cm. but would only require 3.3 minutes to traverse the same distance when using a centrifugal speed of 2000 r.p.m. Instruments embodying the centrifugal principle have been described by Schachman (181) and Kamack (105).

Another process which considers the velocity of motion relative to a fluid for the determination of particle size is that of elutriation. Elutriation differs from sedimentation techniques in that the particles are held stationary in space through the attainment of balance between the gravitational

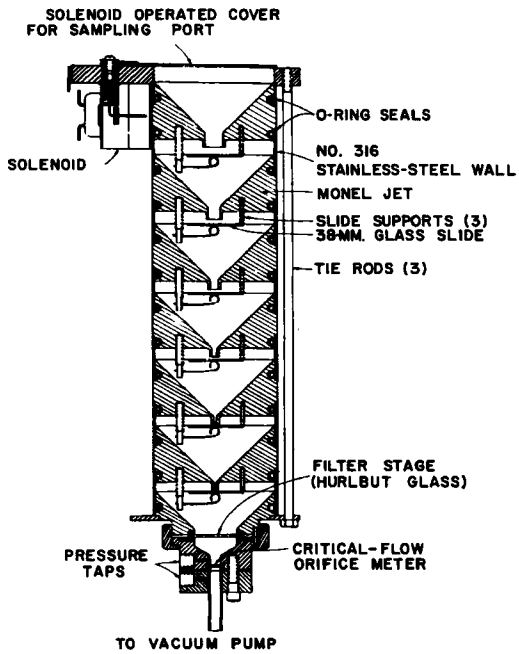

Fig. 11.—Multi-stage cascade impactor. [From Reference 154.]

forces acting on the particles and the viscous forces between the particles and an upward moving column of fluid or gas (78, 170).

Impaction and Inertial Techniques.—Methods in this category for the sampling and estimation of particles in the sub-sieve range are based on laws governing the trajectories of particles in fluid streams. These inertial principles, which are a function of size, have permitted the development of a wide variety of instruments. Included are techniques embodying cyclone deposition, impactor sampling, inertia separation, and electrostatic and thermal precipitation. In a number of these methods it is possible only to effect a separation of a sample into a series of size fractions. The exact particle size of each fraction must subsequently be determined by additional means. In other instances, a size analysis can be obtained directly by theoretical treatment or prior calibration of the instrument.

Impaction devices utilize the deposition characteristics of fine particles in a moving air stream when directed past obstacles of defined geometric form, or in being forced from a jet device onto a plane surface. The cascade impactor has received considerable attention for use with aerosol particles. This device, described by Pilcher and his co-workers (154), forces particle-laden air at very high speed and fixed rate through a series of jets (each smaller than the preceding one) onto glass slides; impaction takes place in a series of stages. The velocity of the air stream and particles suspended in it are increased as they advance through the impactor. As a result, the particles are classified by impaction on the different slides, with the larger particles on the top slides and the smaller particles on the downstream slides. Figure 10 illustrates the basic principles in operation. Modifications in the cascade impactor method have been made to increase the sharpness of classification and to extend the range of particle sizes (135) (Fig. 11). Additional impaction devices employing similar principles have been described by Owens (148), Gurney (84), and Sawyer and Walton (179). Extensive theoretical treatment has been reported by Ranz and Wong (165), Gillespie and Johnstone (76, 103), and Wilcox (229, 230). A small light compact portable cascade impactor for industrial use has been designed and studied by Brink (28). An instrument which operates on similar inertial principles to those of the cascade impactor has been described by Tillotson (220). This variation may be adapted for automatic readout of size distribution by means of light scattering techniques and electronic counters. The method is claimed to be able to produce a complete particle size distribution in a few minutes.

The most serious deficiency of the cascade impactor is the relatively large sample required for analysis. Porush, *et al.* (159), have indicated that this makes determinations of particles emanating from single doses of most aerosols impossible by ordinary analytical methods.

Thermal Precipitation.—The movement of fine particles in a thermal gradient has been described by Watson (225). The underlying principle depends on the introduction of the particles into a region between two bodies of differing temperatures. The particles will move toward the colder body and be deposited on it since the particles are affected by a force directly proportional to the temperature gradient and inversely proportional to the absolute temperature (197). Watson's instrument (225) was capable of measuring particles of 5 μ or smaller, but size distribution was possible only by resorting to microscopic methods of measurement.

Electrostatic Precipitation.—Determination of particle size by the estimation of the magnitude of charges on individual particles has been studied. The charges are either naturally present or are induced on the particles. The magnitude of the charge is directly related to the size of the particle (56, 112, 119). This method has been criticized by Orr and Dalla Valle (147) as being capable of producing erroneous size distribution due to the chance of precipitating more than one size particle at a given point. Instruments which have been developed in attempts to overcome this shortcoming are described by Yoshikawa (240) and Guyton (85). A more advanced and accurate method described by Berg (19) suspends the particles in a conductive liquid which flows through an aperture with a simultaneous flow of electrical pulses (each pulse being proportional in size to the volume of the particle originating it). The pulses are amplified, scaled, and counted to provide data for plotting cumulative particle frequency against particle size. The size range claimed for the instrument is 0.5 to 200 μ diameter at a counting rate of 6000 particles per second.

An excellent review of the theoretical consideration involved in the determination of aerosol particle size distribution by precipitation of charged particles is offered by Drozin and La Mer (56). These authors also describe a method utilizing this principle which takes about 20 minutes, including the necessary calculations, and is carried out with relatively inexpensive equip-

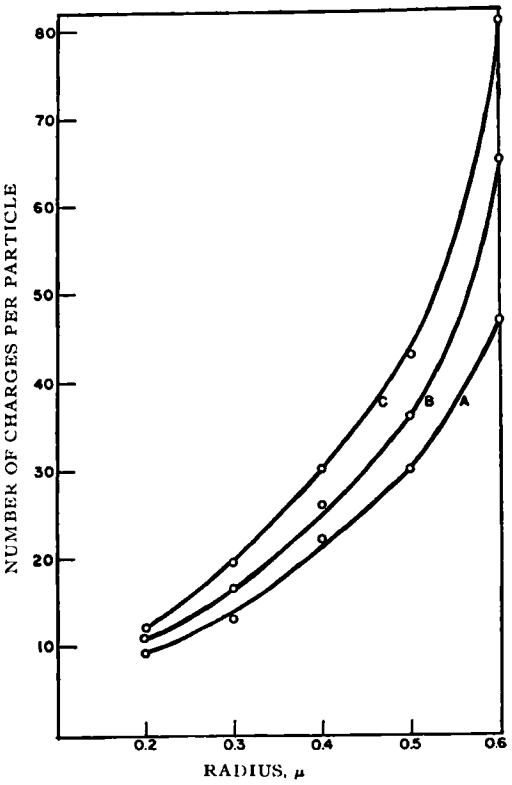

Fig. 12.—Number of charges per particle *vs.* particle radius. Stearic acid aerosol particles charged with current of 40 μa. (*A*); 80μa. (*B*); and 120μa. (*C*). [From Reference 56.]

ment on particles in the submicron range above 0.2-μ radius. Figure 12 illustrates some of the results of their study.

Optical Methods.—The characteristic optical behavior of small suspended particles forms the basis of several indirect methods for assessing particle size. Observations of suspended particles transversed by a beam of light disclose the ability of the particles to scatter, absorb, or reflect the incident radiation to a specific degree. These phenomena have been investigated, and it has been found that the degree is dependent upon the size of the particles, among other variables.

Theoretical treatment of these properties has led to the formulation of equations based upon light scattering and light transmission which permit the evaluation of particle size and cloud concentration (146, 198).

Light transmission or extinction methods are based on the Beer-Lambert law (25) and an instrument utilizing this principle is described by Sinclair (198). The instrument measures the extent to which a beam of light of known intensity is diminished as it emerges from a suspension of particles in gaseous media.

The principles of light scattering formulated by Mie and Rayleigh have been used more extensively in fine particle measurement by Sinclair and La Mer (200). Rayleigh's equations state that the intensity of light scattered from a particle varies as the sixth power of the particle radius for particles which are very much smaller than the wavelength of light, approximately 0.5 μ. The upper limit of size applicable to these equations is about 0.03 μ radius, therefore, these equations have a restricted value for the study of general particulate systems. In the case of larger particles equal to or greater than the wavelength of light, the equations of Mie apply. Here the angular distribution of scattering intensity varies as a function of the scattering angle, and the complexity of the mathematical calculation of size increases markedly with increasing particle size. Consequently, since the computations are massive and difficult and the equations for these larger particles are applicable to spherical monodisperse systems only, these theoretical methods do not lend themselves easily to universal application for particle size measurement. The value of light scattering, however, is apparent as a method of detection of changes in cloud concentration. For this application, light scattering techniques are more than sufficiently sensitive and have been found to be of great value (82, 83, 199).

Dimmick, *et al.* (53), have described an instrument employing light scattering techniques for measurement of small particles. The method is rapid, accurate, and reproducible and depends on an analysis of the change in intensity of a light beam projected through an aerosol cloud under turbulent conditions.

The settling rate of a monodisperse aerosol in a closed chamber under turbulent conditions (stirred sedimentation) is an exponential function of concentration defined as

$$\frac{N}{N_0} = e^{-Vt/H} \qquad \text{(Eq. 3)}$$

where N = concentration at time t in minutes, N_0 = concentration at time zero, V = Stoke's velocity of fall in cm./min. for a given particle and density expressed in Gm./cm.^{3}, and H = the effective height of the chamber.

Being exponential in nature, the log of the concentration plotted against time results in a straight line. The same slope is obtained whether the concentration is expressed in terms of number, geometric area, or volume (related to mass).

The slope is then defined in terms of the half-life ($L\ ^1/_2$) and the authors provide a nomograph which relates particle size and density to half-life for a chamber height of 100 cm. This instrument was employed in measuring particle size of iso-

proterenol and epinephrine aerosol suspensions and the distribution of particles was reported by giving the mass median diameter (159).

A similar approach has been developed by Mintzer (133) and has been used in a study on stability of aerosol suspensions (107). The instrument consisted of a separate sedimentation chamber in which the aerosol cloud was mechanically stirred. Air-tight connections continuously carried particles from the sedimentation chamber to the cell of an extremely sensitive light-scattering photometer. The cell was modified so that the particles could pass out of the instrument after being measured. Readout of phototube signals was accomplished by means of a wide-strip recorder (Fig. 13).

A portion of the recorder chart for a typical determination (Fig. 14) indicates the response to samples of particles withdrawn from the sedimentation chamber. Figure 15 is a plot of the slopes from which particle diameters were calculated using Dimmick's equations.

O'Konski and Doyle (144) have also measured aerosol particles by using light scattering coupled with an electronic particle counter in a single instrument. Fisher, *et al.* (67, 68), have described an instrument which they call an "aerosoloscope." The procedure involves the massive dilution of the airborne particles so that flow rate is controlled and each particle passes through an illuminated region where it produces a pulse of scattered light. The light scattered by each particle is received on a photomultiplier which gives rise to an electrical pulse, the amplitude of which is related to the size of the particle. The counts are sorted and registered separately on a bank of 12 electromechanical counters. Aerosol particles ranging from 1–64 μ in diameter can be measured at a maximum rate of 2000 per minute.

Patents have been issued to O'Konski (143) and Mumma (140) in which electrical impulses are used to measure particles illuminated by an incident light source.

Another aerosol particle analyzer employing right-angle light scattering was recently reported (242). This instrument is said not only to measure particle size distribution but also count them.

Size Analysis of Droplets.—Size analysis of water aerosols or droplets of completely volatile components is difficult because the droplets evaporate quickly in room air. "For this reason," state Reif and Mitchell (169), "most methods of size analysis are indirect, in the sense that water droplets are allowed to hit a suitably prepared surface where they leave a permanent imprint. However, evaporation may occur before the droplets reach the sam-

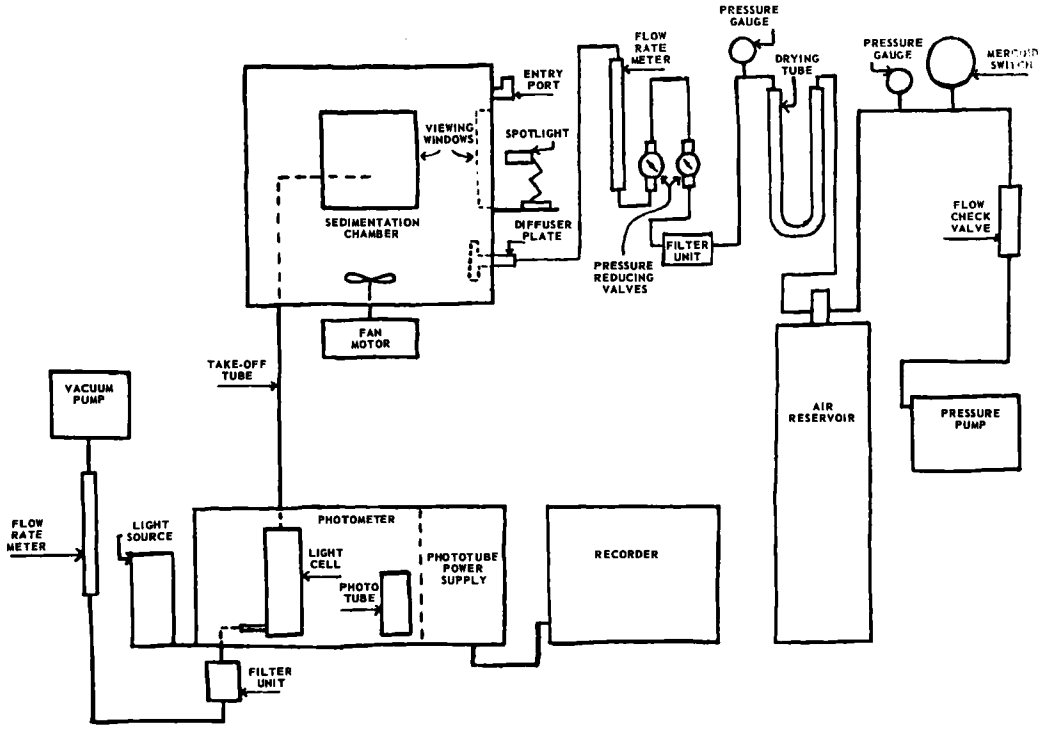

Fig. 13.—Schematic diagram of apparatus employing stirred sedimentation and light-scattering photometer for measurement of particle size. [From Reference 133.]

pling surface and only the largest droplets may carry sufficient momentum to penetrate it. Moreover, a round droplet is smaller than the flat imprint that it leaves on the sampling surface. Therefore, a calibration factor must be determined to convert the measured diameter of the flat imprint into the diameter of the round droplet that originally made the imprint." In recognition of this problem, these authors report an original study involving a vertical sedimentation chamber and the measurement of the effluent aerosol by means of a spectrophotometer. Unfortunately, their method is found to be applicable only to nonvolatile aerosol liquids. However, their report offers an excellent review and laboratory comparisons between six different methods which have been advocated for aerosol droplets. These methods are: (*a*) photographic film coated with polyvinyl alcohol which retains imprints of water droplets that hit it (62, 63); (*b*) a microscope slide covered with an even deposit of amorphous methylene blue powder which is dissolved by water droplets at point of impact and push it to the periphery of a circle (125); (*c*) a film of magnesium oxide which will leave pits proportional to the size of the droplets that hit it (125); (*d*) water droplets are "fixed" by allowing them to impinge on a viscous liquid such as oils or jellies (153, 199, 237); and (*e*) a lens method whereby aerosol droplets are permitted to impact on a scrupulously clean slide and form plano-convex "lens." The diameter of the equivalent spherical droplet can be calculated from three

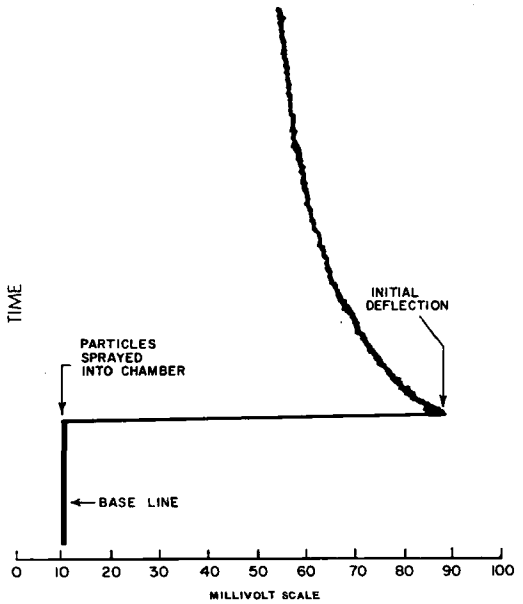

Fig. 14.—Section of strip recorder chart indicating phototube responses to initial stages of particle cloud settling. [From Reference 133.]

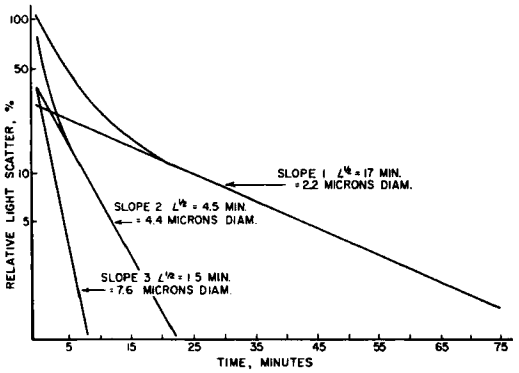

Fig. 15.—Light scattering curves for the determination of mean particle diameter. [From Reference 133.]

parameters. the diameter of the liquid lens, the focal length of the liquid lens, and the refractive index of the liquid (125). Owing to rapid evaporation, this latter method was also found to be suitable for nonvolatile liquids only. The authors conclude that the photographic film-polyvinyl alcohol method is satisfactory and presents factors required to convert the measured imprint to the original droplet diameter.

Standardized Particles.—Since many of the indirect methods of measurement require standardization of the instrument employed, the ready availability of a variety of fine particles of different chemical and physical properties is often welcomed. The Stanford Research Institute at Menlo Park, California, maintains a Particle Bank for both deposits of quantities of surplus particles and withdrawal of samples by research organizations.

EVALUATIVE PROCEDURES

Spray Patterns.—The thermodynamics of spray formation has been discussed by York (239), who analyzed the production of aerosol particulate matter and the energy relationships which exist under the influence of variables encountered in pressurized containers. In order to evaluate the effect of the variables on spray patterns, specialized techniques were developed. These techniques and the apparatus involved have been reviewed by Yeomans and Fulton (238), Dixon (54), Herzka (95), and Root (172). In general, the techniques utilize methods for visualizing and recording spray patterns under standardized conditions. Duplication of results is often poor and, if quantitative values are required, improved methods must be instituted.

Rheological Characterization.—Flow rates and rheological behavior of pressurized materials are important factors in the choice of valve, propellant, and specific formulation components. Consequently, a study of rheo-

logical behavior is of unusual importance when formulations possessing relatively high viscosities are pressurized. The rheological study of an aerosol product is a difficult problem because of different shear rates which are encountered in the various parts of the system. Cohen and his associates have divided the contents of a pressurized product into three rheological zones; within the container, in the narrow orifices within the valve, and at the point of delivery. This comprehensive report (38) analyzes the different shear rates within these zones and describes the use of an extrusion rheometer in measuring the types of flow of several pressure-packed formulations of high viscosities. The relationships between pressure and viscosity have been studied in the dispensing of liquid aerosols of high viscosities and their effect on delivery rates reported by Mina (132). This study also offers a suggested procedure for estimating delivery rates under various pressures.

Analysis of Volatile Constituents.—Gas chromatographic techniques have been shown to effectively circumvent the manifold problems associated with volatile constituents. Root and Maury (175–177) describe their methods of adapting gas chromatography for the analysis of a variety of volatile components under pressure.

Propellant Composition.—Since the vapor pressure exerted by the blend of propellants is critical to the performance of an aerosol, it becomes equally critical to determine accurately the exact composition of the blend. A simple and inexpensive pressure pycnometer has been developed which quickly relates halocarbon propellant composition to density of the blend (214). Tables of vapor pressures and densities as functions of composition at given temperatures are available (213). A similar approach has been reported for the determination of hydrocarbon gases in blends of these gases with liquefied halocarbon propellants (192)

Other Evaluative Procedures.—The Aerosol Division of Chemical Specialties Manufacturers Association publishes a loose-leaf Aerosol Guide which contains descriptions of procedures for a large number of tests developed by the Scientific Committee of the division. Many of these are still classified as "tentative methods" but this compilation is valuable as a reference source to the most reliable methods currently available. The Aerosol Guide also contains a premarketing product check list and information on federal and local acts pertaining to pressure packs.

STERILIZATION OF AEROSOLS

The temperature-pressure gradients of most propellants and the nature of the contents often preclude the use of terminal heat sterilization of the sealed units. The use of ethylene oxide together with liquefied halocarbon propellants has been shown to sterilize effectively the contents of aerosol systems (86, 87). One method (206) consists of presterilizing the containers in hot air ovens, the product and valves with ethylene oxide and ultraviolet light, and the propellant mixture through Seitz bacterial filters. Filling and assembling the antibiotic aerosol is then conducted under aseptic conditions in specially designed filling lines. Sterilization of aerosol products apparently does not pose any serious problems.

SUMMARY

While the development of pharmaceutical aerosols has not been as rapid or widespread as predicted, there is evidence in support of the contention that the aerosol may be counted among useful innovations in dosage forms.

Advances which have been made in evaluating the physical and therapeutic performances of drugs dispensed from pressurized units have made it possible to compare favorably the aerosolized drugs with other methods of administration. The possibility that orally inhaled medicinals may one day become a routine dosage route has been explored but it is clear that a large number of unknown factors must be investigated to insure predictable and controllable results. Other applications of aerosols in treatment of disease must meet the challenge of being compared with currently available medicinals. Unless they offer advantages not now possible with existing dosage forms, pressurized drugs will not be sustained on the basis of consumer convenience alone.

TABLE III.—INTERFACIAL TENSIONS *vs.* HLB VALUES[a]

Surfactant	HLB Values	Interfacial Tension, Dynes/cm. @ 25°C. Exptl.	Calcd.	Deviation (dynes/cm.)

Colorimetric Assay of Nystatin

By J. C. CHANG,† A. B. HONIG, A. T. WARREN, and S. LEVINE

A colorimetric method to assay nystatin both as powder and in pharmaceutical preparations is described. Nystatin is hydrolyzed with sodium hydroxide; the yellow color produced is extracted from a buffered solution into chloroform and measured colorimetrically. Comparison with microbiological assay is shown in a degradation experiment.

NYSTATIN is usually assayed by microbiological methods (1–4). A spectrophotometric method has been reported (5), but it has been known in our laboratories to be subject to ultraviolet absorbing interferences and is not suitable for stability studies.

A yellow color is produced by heating nystatin with sodium hydroxide and this may lead to a colorimetric assay method (6). Direct measurement of the color was tried in this laboratory, but the results did not agree too well with the microbiological assays. Unterman (7) reported a similar method recently.

It was thought that extraneous color was present in the solution after hydrolysis, and color produced by nystatin alone could be extracted into another solvent. Chloroform was found to be the best solvent. It was demonstrated that by measuring the color extracted into chloroform, the results were reproducible and agreed well with microbiological assays, and that degradation of nystatin could be followed by this method.

Preliminary experiments showed that the color produced by the basic hydrolysis of nystatin was unstable in both basic and acidic solution. However, the color was stable for at least 16 hours if the pH was kept at about 6.5. In order to maintain this pH, a citrate buffer was used and found to be satisfactory. Acid neutralization using bromthymol blue as indicator also was tried, but this was abandoned because the indicator was extracted into chloroform.

The time of color development was studied. The intensity of color reached a maximum in 2 minutes at boiling-water temperature and decreased rapidly upon longer heating (see Fig. 1); therefore it was necessary to quench the reaction in an ice bath after maximum color was obtained.

One 10-ml. portion of chloroform extracted about 95% of the color produced by nystatin, and the color was virtually completely extracted with two 10-ml. chloroform extractions. The chloroform extract was turbid due to the presence of water, but the turbidity was removed by adding alcohol. Drying agents were tried but were not as satisfactory.

Different solvents for nystatin were tried, among them methanol and isopropyl alcohol. Although hydrolysis occurred in all the solvents tried, dimethylformamide was chosen because nystatin dissolved in it readily.

EXPERIMENTAL

Reagents

Ethanol, U.S.P. (or SD3A, if colorless); dimethylformamide, reagent grade; chloroform, reagent grade; 1 *N* sodium hydroxide.

Citrate buffer: prepared by dissolving 210.15 Gm. citric acid and 29.4 Gm. sodium citrate, both reagent grade, in water to make 1 L. of solution

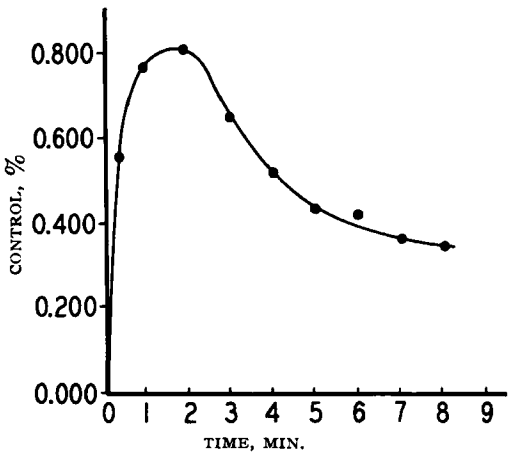

Fig. 1.—Color development of basic hydrolysis of nystatin (5080 units in 5 ml. aliquot).

Received August 9, 1962, from E. R. Squibb & Sons, Georges Road, New Brunswick, N. J.
Accepted for publication October 9, 1962.
The authors thank Mr. E. Wodarski for performing the microbiological assays of the degradation study and Mr. H. Prager for performing some of the colorimetric assays.
† Present address: Department of Chemistry, University of California, Los Angeles.

The pH of this solution should be 2.3 ± 0.2. If not, 10 *N* sodium hydroxide or 60% citric acid was added to adjust the pH.

Dilute buffer: prepared by diluting 20 ml. of the citrate buffer to 100 ml. with water.

Procedure

A solution of nystatin in dimethylformamide, representing about 700 u./ml., was prepared as directed in *Preparation of Samples*. To a test tube was added 3 ml. 1 *N* sodium hydroxide. Then a 5-ml. aliquot of nystatin solution was added along the side of the test tube in such manner that the nystatin solution formed a layer floating on top of the sodium hydroxide solution. The solutions were quickly mixed by a slight shaking motion, and immediately the test tube was placed in a boiling water bath for exactly 2 minutes. Then the test tube was cooled in an ice bath for 2 minutes, and the contents immediately transferred to a 60-ml. separator containing 6 ml. of dilute buffer. The test tube was rinsed with water, combining the rinsings in the separator. The yellow color was extracted twice with 10 ml. of chloroform, shaking 1/2 minute each time, and the chloroform extracts were withdrawn into a 50-ml. volumetric flask. Ten milliliters of ethanol was added to the flask, and chloroform was added to the mark. After mixing, the absorbance at 385 mμ was measured on a Beckman-DU spectrophotometer in 1-cm. cells, using chloroform to adjust to zero absorbance.

Duplicate aliquots of each sample solution were assayed simultaneously with duplicate aliquots of a standard, and the potency of the sample was calculated from that of the standard by a simple proportion. Although the procedure was standardized, the samples were always assayed with a standard in order to obtain best results.

Preparation of Samples

Powder.—A weighed amount of powder, representing about 70,000 u. was shaken with 50 ml. of dimethylformamide in a 100-ml. volumetric flask for 20 minutes, and dimethylformamide was added to volume.

Cream.—An amount containing about 70,000 u. of nystatin was weighed into a 50-ml. centrifuge tube and was shaken twice with 10 ml. of dimethylformamide for 1 minute. After each shaking the tube was centrifuged for 15 minutes, and the super-

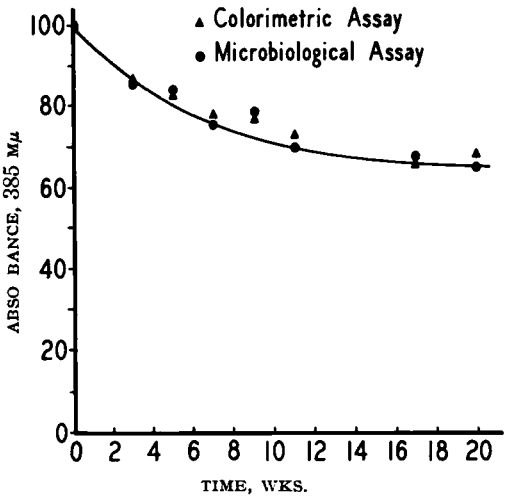

Fig. 2.—Degradation of nystatin at 50° C.

natant solution transferred into a 100-ml. volumetric flask. The volume was made up with dimethylformamide.

Ointment.—Same as *Cream*, but without centrifuging.

Capsule (containing tetracycline phosphate complex).—An amount of solids containing about 70,000 u. of nystatin from a mixture of the contents of five capsules was weighed into a 50-ml. centrifuge tube containing about 200 mg. of magnesium chloride hexahydrate. Twenty-five milliliters of water was added, and the tube shaken for 1 minute. After centrifuging, the water solution was discarded. The tube was washed with 25 ml. of water, centrifuged, and the water again discarded. The residue was then dissolved in small portions of dimethylformamide and transferred into a 100-ml. volumetric flask. The volume was made up with dimethylformamide.

All the nystatin solutions were prepared in low actinic glass volumetric flasks.

Degradation Study

One sample of powder (Powder 1) was chosen for a degradation study. Samples of 500 mg. each were placed in 2 × 9-cm. open vials spread out to a thickness of 0.5 cm. and stored in an oven at 50 ± 2°. The samples were withdrawn periodically over 20 weeks and assayed by both the colorimetric and microbiological methods.

RESULTS AND DISCUSSION

Results of assays of nystatin as the powder and in pharmaceutical preparations are shown in Table I along with comparisons to the microbiological assays and to the spectrophotometric assays (8) for four samples of powder. It can be seen that the agreement is good. The colorimetric assays show good reproducibility with a standard deviation of about 2%. The standard deviation for the microbiological assay is about 3.3% for the powders, and about 3.7% for the creams, ointments, and capsule.

Results of the degradation study are shown in Table II. A plot of the stability assays expressed as percentage of the control assay *vs.* time is shown in Fig. 2. Since the microbiological control assays varied quite widely due to differences in sensitivity of the organism, the percentages of the microbiological stability assays are calculated from the corresponding control assays. The percentages of the colorimetric stability assays, on the other hand, are calculated from the average of the control assays because deviation in the colorimetric control assays was small, the largest difference being only 1.5%. From the plot in Fig. 2, it can be seen that all the points lie closely on the same curve, demonstrating the colorimetric assay to be a stability assay.

Pyridazines I

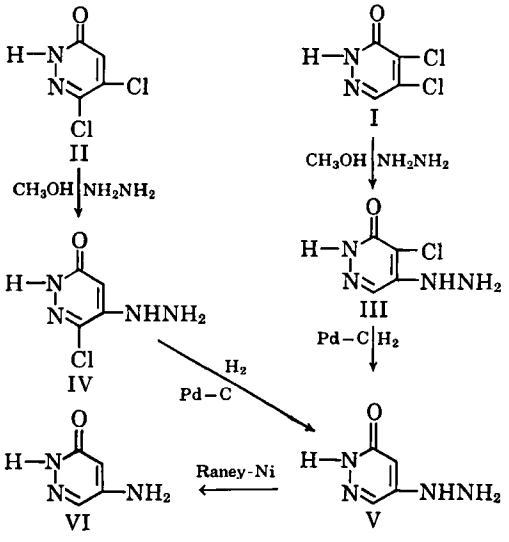
4-Halo-5-hydrazino-3-pyridazone and Its Derivatives

By WINNIFRED M. OSNER, RAYMOND N. CASTLE, and DUANE L. ALDOUS

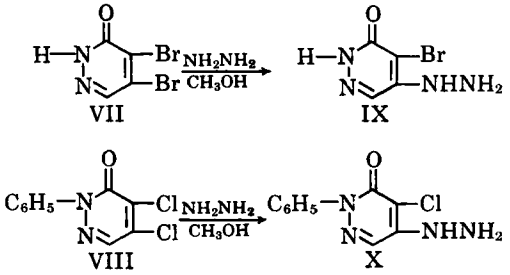
When 4,5-dichloro-3-pyridazone, 4,5-dibromo-3-pyridazone, or 4,5-dichloro-2-phenyl-3-pyridazone in methanol was allowed to react with 95% hydrazine, a mono-halo mono-hydrazino-3-pyridazone was obtained. An unequivocal proof of structure for 4-chloro-5-hydrazino-3-pyridazone is reported. Twenty-five hydrazones of 4-bromo-5-hydrazine-3-pyridazone and twenty-seven hydrazones of 4-chloro-5-hydrazino-3-pyridazone were prepared. One cyclized derivative of 4-chloro-5-hydrazino-2-phenyl-3-pyridazone is also reported.

During investigations in this laboratory of the relative reactivity of the chlorine atoms of 4,5-dichloro-3-pyridazone (I), the very facile reaction of this compound with hydrazine to yield a mono-halo mono-hydrazino-3-pyridazone was noted. The structure of 4-chloro-5-hydrazino-3-pyridazone (III) was determined by catalytic dechlorination followed by Raney-Ni cleavage of the hydrazino group to give the known 5-amino-3-pyridazone (VI) first prepared by Kuraishi (1).

Further confirmation was obtained by allowing 5,6-dichloro-3-pyridazone (II) to react with hydrazine. The product, compound IV, was catalytically dechlorinated to produce a compound (V) identical in all respects to that obtained from 4,5-dichloro-3-pyridazone under the same conditions.



4,5-Dibromo-3-pyridazone (VII) was also treated with hydrazine as was 4,5-dichloro-2-phenyl-3-pyridazone (VIII) and structures for the products—compounds IX and X, respectively—were assigned by analogy. The properties of compounds III through VI, IX, and X are listed in Table I.



The pyridazines have long been the subject of pharmacological studies, and the activities attributed to compounds of this ring system vary greatly (2–5). Similarly, the hydrazino group has frequently been found to confer activity upon a given structure. A complete review of hydrazine derivatives used as medicinals was published by Jucker in 1959 (6). With these facts in mind, it was deemed appropriate to prepare several carbonyl derivatives of both the bromo and chloro hydrazino compounds.

The properties of the derivatives are listed in Table II. Where a 1,3- or 1,4-dicarbonyl compound was employed, a cyclized derivative was obtained. Structures and properties for these products are given in Table III.

Infrared and ultraviolet absorption spectra of all the compounds prepared were recorded and contribute confirmatory evidence for the structure assigned.[1]

Data have been received concerning 23 of the compounds submitted to Cancer Chemotherapy National Service Center, National Cancer Insti-

tute, for tissue culture screening. Though it is in no way complete or conclusive, this information as indicated in the tables is included here for consideration.

EXPERIMENTAL

All melting points were determined with a Vanderkamp Melt-Pointer and are uncorrected.

4 - Chloro - 5 - hydrazino - 3 - pyridazone (III).—Thirty-three Gm. (0.2 mole) of 4,5-dichloro-3-pyridazone (I) prepared by the method of Mowry (7) were dissolved in 560 ml. of boiling methanol. To this solution 19 Gm. (0.6 mole) of 95% hydrazine was added portionwise, and a yellow precipitate appeared after 10 minutes. The mixture was allowed to reflux a total of 1.5 hours; then it was cooled and filtered. Recrystallization from water afforded 20 Gm. (62%) of pale yellow needles, m.p. 195° dec.

4 - Bromo - 5 - hydrazino - 3 - pyridazone (IX).—4,5-Dibromo-3-pyridazone prepared by the method

of Bistrzycki (9) was treated with hydrazine as described above for compound III. Recrystallization from water produced dark yellow needles, m.p. 180° dec.

4-Chloro-5-hydrazino-2-phenyl-3-pyridazone (X)—4,5-Dichloro-2-phenyl-3-pyridazone (VIII) prepared by the method of Mowry (7), when allowed to react with hydrazine as described above, gave a 75% yield of fine yellow needles, m.p. 164° dec.

6-Chloro-5-hydrazino-3-pyridazone (IV).—5,6-Dichloro-3-pyridazone (II), prepared by the method of Kuraishi (8), was similarly treated with hydrazine. The product (94%) was recrystallized from water to yield white crystals, m.p. 268° dec.

5-Hydrazino-3-pyridazone (V).—4-Chloro-5-hydrazino-3-pyridazone (III) (4.8 Gm., 0.05 mole) dissolved in 200 ml. of 1% sodium hydroxide was treated with hydrogen in the presence of 1.2 Gm. of 5% Pd-C catalyst at atmospheric pressure and room temperature. Following absorption of the theoretical amount of hydrogen, the catalyst was separated and washed with 50 ml. of 1% sodium hydroxide followed by methanol until washings were no longer basic. The filtrate and washings were neutralized with glacial acetic acid and the solution concentrated on a steam bath under reduced pressure. After cooling 48 hours, 2.8 Gm. (74%) of a dark orange solid was collected. Recrystallization from 95% ethanol (norite) afforded pale yellow needles, m.p. 267° dec.

5-Amino-3-pyridazone (VI).—A mixture of 1.75 Gm. (0.014 mole) of 5-hydrazino-3-pyridazone (V) dissolved in 85% ethanol and Raney-Ni W-2 (prepared from 15 Gm. of Raney-Ni alloy) was allowed to reflux 2 hours. The catalyst was removed and the filtrate evaporated on a steam bath under reduced pressure to approximately one-half volume. After cooling overnight, 0.9 Gm. (60%) of gray plates was collected and recrystallized from water (Norite) to yield white crystals, m.p. 288° dec.

General Procedure A.—One-tenth mole of the appropriate halo-hydrazino-pyridazone was treated with 8 ml. concentrated sulfuric acid followed by 70 ml. water and the mixture heated gently just until the solid dissolved, at which time the hot solution was poured into a second flask containing 1 ml. of carbonyl compound dissolved in 40–80 ml. 95% ethanol. After standing 12 to 48 hours, the solid was filtered and recrystallized usually from 95% ethanol.

General Procedure B.—To one-tenth mole of the halo-hydrazino-pyridazone were added 10 ml. concentrated hydrochloric acid in 10 ml. water and 15 ml. 95% ethanol. The mixture was heated then added to 1 Gm. of the carbonyl compound dissolved in 10 ml. of ethanol. After cooling 24 hours, the precipitate was filtered and recrystallized from an appropriate solvent.

Substituted Salicylanilides III

New Salicylanilides and Related Compounds with Antimicrobial Activity

By ROBERT G. TABORSKY† and ROLAND J. STARKEY

Eighteen substituted salicylanilides and related compounds have been synthesized and screened for antimicrobial activity. Most of these compounds have been prepared for the first time. The relationship of structure and activity for the series is discussed.

INTEREST IN SUBSTITUTED salicylanilides was a result of the observation of a high degree of antimicrobial activity of halonitrosalicylanilides (1) and other substituted salicylanilides (2). The first objective of the present investigation was to attempt to define further the structural requirements necessary for antimicrobial activity for this series. Some of the previously prepared salicylanilides possessed limitations to their usefulness because of toxicity, solubility, color, and inactivation by blood serum. Thus the second objective was to see whether new and more favorable members of the series could be developed.

All of the compounds under discussion are summarized and described in Table I. A considerable group (I–VIII) of those salicylanilides were synthesized by the reaction of a suitably substituted salicoyl chloride with an amine in an appropriate organic solvent, usually benzene.

Salicylanilides substituted in the "three" or "five" positions by an amino or acetylamino group were prepared by reduction of the respective nitro analogs. The reducing agent used for the former was sodium dithionate (3), and for the latter it was zinc and glacial acetic acid. The amino compound was converted to the diazo derivative by a normal diazotization (3).

The phthalyl-mono-chloroanilides were prepared by the reaction of a substituted or unsubstituted phthalic anhydride with *para*-chloroaniline (4). The imine, N-(5-nitrosalicylidene) *meta*-chloroaniline was prepared by the condensation of 5-nitrosalicylaldehyde and *para*-chloroaniline in ethanol.

4′ - Chloro - 5 - (N - *para* - chlorophenyl - sulfamido)salicylanilide was prepared by refluxing together 5-sulfosalicylic acid and *para*-chloroaniline with phosphorus trichloride in chloroform. 4′-Chloro-5-sulfamidosalicylanilide was prepared in a similar manner from 5-sulfamidosalicylic acid and *para*-chloroaniline.

All of the compounds have been synthesized for the first time with the exception of III, XI, XII, and XIII. The compounds were screened against two significant organisms by the cup-plate method. The results of that primary screening are summarized in Table II.

In the ensuing discussion, it must be remembered that all of the antimicrobial screening data are qualitative. The philosophy of the investigation has been to prepare compounds where certain parts of the previously prepared active halonitrosalicylanilides have been replaced by other groups, holding the remaining portions of the molecule unchanged. Therefore, in the following discussion, the halonitrosalicylanilides are viewed somewhat as parent compounds.

Several generalizations can be made from the results in Table II. In halonitrosalicylanilides where the *para*-chloroaniline moiety has been replaced by morpholine, picoline, or *meta*-carboxyaniline (*meta*-aminobenzoic acid), all activity was lost. Since 3′-chloro-5-nitrosalicylanilide has previously been shown to be active (1), it is apparent that a carboxyl group cannot replace a chlorine atom. On the other hand, the activity of III does show that a trifluoromethyl group can replace a chlorine atom with retention of activity. Furthermore, activity was retained when an aminothiazole entity replaced the *para*-chloroaniline portion of the molecule.

A degree of lipid solubility has at times been postulated as requisite for antimicrobial or drug activity (5, 6) in order to enable the molecule to cross or else combine with the lipid portion of the cell membrane. The halogen or nitro groups needed as substituents on salicylanilide to make it generally microbicidal probably increases its lipid solubility.

Since 4′-bromo-5-bromosalicylanilide is a known antimicrobial (7), 4′-dimethylamino-5-bromosalicylanilide (VII) was prepared with the idea that the dimethylamino group would confer

[a] Melted with decomposition.

equivalent or greater lipid solubility as the bromine atom to the molecule. However, the results were disappointing because the compound and its hydrochloride were both completely inactive. The hydrochloride was water insoluble which indicated that probably the dimethylamino group did increase lipid solubility. However, solubility versatility in both lipid and water may possibly be more important than either extreme as was shown to be the case for 8-hydroxyquinoline (oxine) (5).

Attempts to replace the nitro group of the active halonitrosalicylanilides by a sulfamido (XVII) or N-*para*-chlorophenylsulfamido group (XVI) produced compounds lacking antimicrobial activity. When an imine linkage replaced the amide linkage of 3′-chloro-5-nitrosalicylanilide, the resultant anil retained activity.

Recently, there has appeared in the literature an attempted correlation of pKa and activity for several salicylanilides with the idea that greater pKa represents greater chelating potential, which is possibly important to activity (8). For this reason and because of their ready synthesis, two phthalyl-mono-*para*-chloroanilides were prepared (XIII and XIV). In essence, compound XIV is equivalent to 4′-chloro-5-nitrosalicylanilide where, however, a carboxyl group has replaced the *ortho*-hydroxyl radical. However, such compounds were completely without antimicrobial activity. Although the acidity of the *ortho* group has been increased, the hydroxyl portion is farther in space and its connections to the ring lack the rigidity of the hydroxyl. Further, it would have to form a seven-membered ring with a chelating metal (hydroxyl-metal-carbonyl oxygen). Therefore, the hydroxyl group on the carboxyl would have a higher spatial entropy content (less ordered) and would require greater energies to enter into a chelate bond which probably would not be sufficiently offset by the stronger chelate bond of the ionic portion of the chelate ring due to a higher pKa. The inactivity of these latter compounds, therefore, does not necessarily rule out chelation as a factor for the active members.

A nitrosalicylanilide (V) was prepared having the amide nitrogen methylated with the resulting compound being inactive. A similar observation was made by

other investigators with the halogenated salicylanilides (2). In that article some of the requirements for activity among these compounds were discussed.

As a result of the present study, it has been possible to broaden some of the past known requisites for activity in the series. Of the compounds prepared that were active but did not possess a nitro group were those that yet retained a nitrogen on the "five" or "three" positions, in an amino (XI), acetylamino (IX, X), or diazo (XII) group. These latter compounds seem worthy of further investigation since they may possess physical and biological characteristics superior to other salicylanilides previously prepared.

EXPERIMENTAL[1]

Reactions of 5-Nitrosalicoyl Chloride and Amines.—Compounds I through VI were prepared by adding a benzene solution of 5-nitrosalicoyl chloride (1) to organic solutions of 2.5 molar excesses of morpholine, piperidine, *meta*-trifluoromethylaniline, *meta*-aminobenzoic acid, N-methylaniline, and 2-aminothiazole, respectively. VII was prepared from 5-bromosalicoyl chloride and N,N-dimethylphenylene diamine.

The amines were dissolved into benzene with the exception of *meta*-aminobenzoic acid, where diglyme and dimethylformamide were used as solvents. In each case the reaction mixture was vigorously stirred during the admixture and then allowed to stand at room temperature overnight. In each case a precipitate formed (usually very thick) consisting of the amine hydrochloride or a mixture of it with the respective product. The solids were filtered and varying amounts of further product could then be recovered by evaporating the filtrate to dryness. A preliminary purification was carried out by washing the product with 10% aqueous hydrochloric acid which removed the amine hydrochloride and amine. The treated solid was then dried and crystallized from boiling ethanol, sometimes adding either water or dimethylformamide to modify its solvency as necessary. The yields ranged from 67 to 100%.

Preparation of 4'-Chloro-3-acetylamino- and 5-Acetylaminosalicylanilide.—Both of these compounds were prepared in identical fashion which can be exemplified by the method for 4'-chloro-3-acetylaminosalicylanilide.

A solution of 5 Gm. (0.02 mole) of 4'-chloro-3-nitrosalicylanilide in 50 ml. of glacial acetic acid was heated to 85° and 20 Gm. of zinc dust was slowly added; vigorous action resulted. The mixture was then refluxed for 16 hours and vacuum filtered while hot to remove the zinc. The zinc was washed on the Büchner with small portions of boiling glacial acetic acid, the washings were added to the filtrate. Upon cooling the filtrate 4 hours at 5°, 5.3 Gm. (86.3% yield) of 4'-chloro-3-acetylaminosalicylanilide was obtained from the cooled solution upon filtration, m.p. 216–220°. Crystallization from chloroform gave a white product, m.p. 220–220.5°.

In a similar fashion, 5.0 Gm. of 4'-chloro-5-nitrosalicylanilide yielded 3.1 Gm. of 4'-chloro-5-acetylaminosalicylanilide which crystallized from alcohol as a white solid, m.p. 280–284°.

Preparation of 4'-Chloro-5-aminosalicylanilide and the Respective 5-Diazo Derivative.—This compound was prepared according to a recently reported procedure of reducing 4'-chloro-5-nitrosalicylanilide with sodium dithionate (3). It was then treated with nitrous acid according to the same reference to yield 4'-chloro-5-diazosalicylanilide.

Preparation of N-(5-Nitrosalicylidene) *meta*-Chloroaniline.—Two grams (0.012 mole) of 5-nitrosalicylaldehyde in 35.0 ml. of ethanol was added to 2.0 ml. (2.4 Gm.) (0.02 mole) of *meta*-chloroaniline in 10 ml. of ethanol. An immediate precipitate formed that filled the flask. The mixture was filtered after 2 hours to obtain a quantitative yield (3.3 Gm.) of the product. Crystallization from ethanol-dimethylformamide yielded yellow crystals, m.p. 205–206°.

Preparation of Monoanilides of Phthalic Acid.—Phthalyl-mono-*para*-chloroanilide was prepared from phthalic anhydride and *para*-chloroaniline according to a method described in the literature (4). In a similar manner the 3-nitrophthalic acid analog was prepared.

Twenty-one grams (0.1 mole) of 3-nitrophthalic anhydride was suspended in 100 ml. of chloroform and 12.7 Gm. (0.1 mole) of *para*-chloroaniline was added. An immediate warming and deepening of color and very heavy precipitation occurred which solidified the mixture. More chloroform was added to bring the total volume to about 300 ml. The mixture was allowed to stand overnight at room temperature, vacuum filtered, washed with chloroform, and dried to give a quantitative yield (32.0 Gm.) of 3-nitrophthalyl-mono-*para*-chloroanilide, m.p. 183.5°.

[1] Antimicrobial screening was carried out by the Wisconsin Alumni Association.

Preparation of 5-Sulfamidosalicylic Acid and N-Substituted Derivatives.—5-Chlorosulfonylsalicylic acid was prepared by adding dried salicylic acid to chlorosulfonic acid (9). A purified product was obtained upon crystallization from benzene, m.p. 171–174° (reported m.p. 171–172° (9)).

5-Sulfamidosalicylic acid was prepared by reacting the above chloride with aqueous ammonium hydroxide. Isolation and crystallization yielded a product, m.p. 256–259°, (reported m.p. 253–255° (10)).

Preparation of 4′-Chloro-5-sulfamidosalicylanilide.—Six-hundred milligrams (0.003 mole) of 5-sulfamidosalicylic acid was ground in a pestle to an intimate mixture with 300 mg. (0.004 mole) of *para*-chloroaniline. The mixture was placed into 8.0 ml. of chloroform along with 0.4 ml. of phosphorus trichloride and refluxed 72 hours. Upon cooling and filtering, 880 mg. of mixed products were obtained. These were washed with a small amount of water and crystallized from 1:2 water-ethanol to obtain the product, m.p. 234–237°.

Preparation of 5-(N-*para*-Chlorophenylsulfamido)-salicylic Acid.—Anhydrous 5-sulfosalicylic acid was prepared by taking the monohydrate and drying at 100° under a vacuum of 3 mm. for 18 hours. Ten grams (0.08 mole) of *para*-chloroaniline, 10.0 Gm. (0.05 mole) of the above anhydrous 5-sulfosalicylic acid, 75.0 ml. of chloroform, and 5.0 ml. of phosphorus trichloride were refluxed for 3 days. The mixture was then cooled in ice for several hours and filtered to obtain 14.6 Gm. of dried product. A portion was suspended in water, filtered, and crystallized from ethanol. A bright yellow insoluble material was removed by filtration during this operation. The filtrate produced white crystals of the title compound (as a monohydrate) m.p. 250–251°.

Preparation of 4′-N,N-Dimethylamino-5-bromosalicylanilide.—Twenty grams (0.09 mole) of 5-bromosalicylic acid were refluxed overnight with 15 ml. of thionyl chloride, 0.1 Gm. of anhydrous aluminum chloride, and 80 ml. of benzene. The mixture was filtered and all of the solvents removed under vacuum. The residual 5-bromosalicoyl chloride was brought into solution with pure benzene. One-third of this benzene solution (0.03 mole) was added to 13.0 Gm. (0.1 mole) of *para*-N,N-dimethylphenylenediamine in 60 ml. of benzene. The mixture was shaken and allowed to stand overnight to yield 18.7 Gm. of a dark green product obtained by filtering and drying the reaction mixture.

A 5-Gm. portion of material was crystallized from 80 ml. of ethanol to yield 4.3 Gm. of a dark green product. A considerable amount of residue had been removed by filtration. The material was crystallized a second time from 45.0 ml. of 3:1 ethanol-dimethylformamide to yield a dark green crystalline 4′-dimethylamino-5-bromosalicylanilide, m.p. 226°.

A second 5-Gm. quantity of the original product was shaken with 50 ml. of water and 15.0 ml. of concentrated hydrochloric acid. This treatment considerably lightened the product from a dark green to white with a greenish cast. The 4.3 Gm. of product from this treatment was crystallized from 36 ml. of 1:1 ethanol-water to yield 3.8 Gm. of the hydrochloride of 4′-N,N-dimethylamino-5-bromosalicylanilide as light green granules, m.p. 223° (eff.).

Effects of Ionizing Radiation on Two Gelatin Fractions II

Studies on Viscosity, Sedimentation Velocity, and Molecular Weight Effects

By LEONARD P. PRUSAK† and BARTLEY J. SCIARRONE

The effects of subdenaturant levels of irradiation on two fractions, F-I and F-II, isolated from commercial pigskin gelatin, were investigated through viscosity and sedimentation studies in 2*M* potassium thiocyanate solutions. The source of irradiation was a 3 Mev Van de Graaff accelerator. When used as controls, F-I and F-II were found to have intrinsic viscosity values of 0.675 and 0.550, respectively, while their respective average molecular weights were determined to be 173,000 and 86,000. After subjection to variable irradiation dose, the log of intrinsic viscosity values for F-I were directly proportional to the log of absorbed dose while an inverse proportionality occurred with F-II. Determination of Svedberg constants showed a similar pattern prevailed in the respective fractions when observed under sedimentation velocity conditions. Data obtained indicate random coil configuration was substantially undisturbed as radiation was applied, but bond rupture and linkage processes did occur.

IN OUR PREVIOUS PAPER (1) we described the isolation of the two fractions F-I and F-II from commercial pigskin gelatin by alcohol precipitation. We also discussed their acid/base titration behavior and the technique applied in irradiating these fractions in the form of 1% solutions, 5% gels, and dry films under the electron beam of a 3 Mev Van de Graaff Accelerator. We now report the results obtained in viscosity studies on both fractions before and after irradiation, their behavior under sedimentation velocity conditions, and the molecular weight determinations based on these data.

Viscosity measurements constitute a critical parameter in the evaluation of higher molecular weight polymers because of relationships to molecular weight, sedimentation rate, diffusion constant, and osmotic pressure.

The viscosity of a polymer solution (of which gelatin is a species) is a concentration-dependent factor. Huggins (2) established that the variation of viscosity with concentration of high polymer solutions can be expressed by

$$\frac{\eta_{sp}}{c} = [\eta] + k'[\eta]^2 c \qquad \text{(Eq. 1)}$$

where η_{sp}/c is the reduced viscosity, $[\eta]$ is referred to as the intrinsic viscosity and is defined as

$$\lim \left(\frac{\eta_{sp}}{c}\right) \text{ as } c \to 0$$

and k' is a polymer-solvent factor (also known as the Huggins constant or the hydrodynamic interaction constant).

The shape of the gelatin molecule in solution is generally accepted as being random coil. Boedtker and Doty (3) have so asserted on the basis of light scattering experiments. Williams, Saunders, and Cicirelli (4) established that the sedimentation rate constant for proteins in solution is proportional to the square root of the molecular weight; they concluded that gelatin molecules in solution exist in the form of a random coil. The equation of Staudinger in logarithm form appears to express best the relationship between intrinsic viscosity and molecular weight

$$\log [\eta] = \log K + \alpha \log M \qquad \text{(Eq. 2)}$$

where K is a solvent constant independent of molecular weight and α has a value dependent upon the size and shape of the molecule in question. For random coil gelatin Williams found the $\pm$ α value to be 0.62.

Pouradier and Venet (5), working with homogeneous fractions of Eastman Kodak F-74 gelatin (isoelectric point 4.75 and an average molecular weight 65,000), calculated α and K values through Eq. 2. Their values of 9.885 and 1.66×10^{-5} were for α and K, respectively.

The variable response of proteins to irradiation can be shown by their behavior under sedimentation velocity conditions. When considered together with intrinsic viscosity data, this information is useful in determining changes in molecular

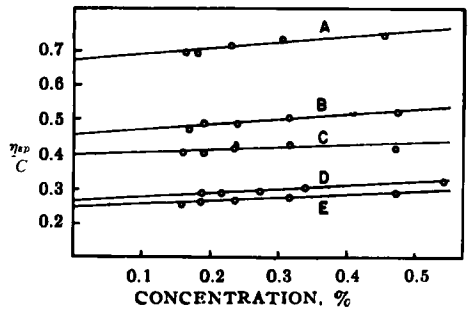

Fig. 1.—Plot of reduced viscosity *vs.* concentration to obtain intrinsic viscosity values for F-I before and after aqueous solutons were irradiated. One per cent solutions were irradiated (B = 0.17 Mrads.; C = 0.44 Mrads.; D = 1.27 Mrads., E = 2.80 Mrads.) and used as control (A). Viscosities were determined in 2 M KCNS solvent.

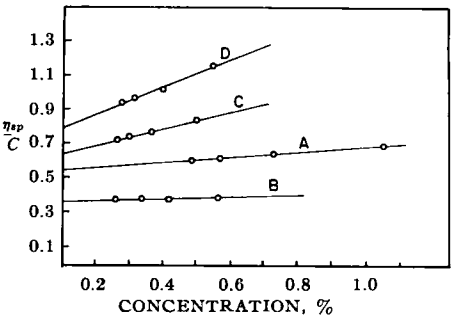

Fig. 2.—Plot of reduced viscosity *vs.* concentration to obtain intrinsic viscosity values for F-II before and after aqueous solutions were irradiated. One per cent solutions were irradiated (B = 0.16 Mrads.; C = 0.47 Mrads.; D = 1.19 Mrads.) and used as control (A). Viscosities were determined in 2M KCNS solvent.

weights. That such changes do occur has been shown by Alexander, *et al.* (6), who found that irradiation damage on solid crystalline bovine serum albumin (2 Mev electron beam) containing 4 to 6 per cent water (in the absence of oxygen) occurs in three stages. Primary ionization changes the shape of the molecule (as reflected in changes in sedimentation behavior) at doses insufficient to cause appreciable shifts in weight average molecular weights. This is the result of a breakdown of many secondary valency bonds, brought about by a single event which occurs on the average every 45 ev. A second ionization event opens the molecule still further so that half the disulfide bonds are accessible. Further irradiation causes extensive aggregation by intermolecular hydrogen bonds.

EXPERIMENTAL

Viscosity Studies.—Although considerable work has been reported on viscosity measurements of gelatin solutions, diverse opinion exists as to optimal solvent systems, pH, and temperature conditions. For this reason, preliminary runs were made under variable conditions to determine those most suitable for characterizing properly the particular fractions described here.

Water at 25° and 50° and sodium acetate-acetic acid buffer pH 4.8 at 25° and 50° gave unsatisfactory curve responses with respect to linearity and reproducibility. Sodium chloride 0.15 M at 25° and 50° gave positive straight-line plots with F-I and F-II but was not adopted as the experimental solvent because of its inability to inhibit aggregation (3) and to bring about reproducibility.

Straight-line plots of η_{sp}/c as a function of concentration were obtained with F-I and F-II in 2 M KCNS adjusted to pH 10.4. Viscosity determinations on irradiated 5% gels and dry films of F-I and F-II, after subsequent dilution to flowable 1% solutions, were conducted by pipetting a 5-ml. volume of the gelatin solution slowly into an Ubbelohde viscometer immersed in a water bath maintained at 25° ± 0.02°. An equal volume of 4 M KCNS was then added to the viscometer and (after gentle mixing) was allowed to come to temperature equilibrium. Subsequent dilutions were made with 5-ml. volumes of 2 M KCNS to maintain ionic strength constancy. Solvent flow time was 89.3 seconds. A sufficient number of readings were taken at each dilution level to assure reproducibility within ±0.05 second. A minimum of four dilutions followed the initial reading at 0.5% concentration. Solutions used in viscosity experiments were passed through a Seitz filter before irradiation.

TABLE I.—INTRINSIC VISCOSITY VALUES FOR CONTROL AND IRRADIATED FRACTIONS I AND II

F-I		F-II	
Dose, Mrads.	$[\eta]$	Dose, Mrads.	$[\eta]$
Control	0.675	Control	0.550
0.17	0.460	0.16	0.370
0.44	0.400	0.47	0.650
1.27	0.275	1.19	0.800
2.80	0.250	....	....

Reduced viscosity values plotted as a function of concentration for F-I and F-II are shown in Figs. 1 and 2. Intrinsic viscosity data are given in Table I. Log dose *vs.* log $[\eta]$ relationships were linear for both fractions; proportionality was inverse in the case of F-I and direct in the case of F-II.

The extrapolated $[\eta]$ value 0.675 obtained for F-I control corresponds closely to the 0.690 reported by Gouinlock, *et al.* (7), for their F-3 fraction, despite a 5° difference in temperature (30°) and half the molar concentration (1 M) of aqueous KCNS solvent. Pouradier's (5) value of 0.520 for his fraction Z1 (characterized as heterogeneous) is in reasonable agreement with our F-II, 0.550. The 0.640 value for his 5111 fraction is proximate to our F-I, 0.675.

Sedimentation Velocity Studies.—Rates of sedimentation of F-I and F-II in the form of 1% solutions as controls and irradiated in an aqueous environment were observed in the Spinco model E ultracentrifuge. Single and double sector cells were used on controls. Double sector cells were used exclusively on all irradiated samples. Sedimentation temperature was maintained at 25°, then corrected to 20°. In the case of controls run singly, instrument speed was set at 59,780 r.p.m. Double sector runs in all cases (except F-II irradiated at approximately

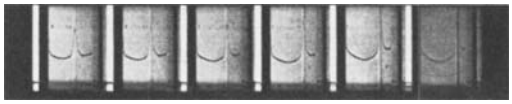

Fig. 3.—Sedimentation velocity run of 1% F-I in 2 *M* KCNS at 25°. Sedimentation boundary in a single sector cell was observed from right to left at 16-minute intervals using rotor speed of 59,780 r.p.m.

0.4 and 1.0 Megarad levels) were made at 39,460 r.p.m. Speeds in the excepted runs were reduced to 31,410 r.p.m. and 14,290–12,590 r.p.m., respectively, because of rapid boundary movement.

Figure 3 illustrates a sedimentation velocity run on F-I at 1% concentration in a single sector cell conducted at 59,780 r.p.m. at 25° in 2 *M* KCNS solvent. The sedimentation boundary was observed from right to left at 16-minute intervals. A similar peak was obtained at 0.7% concentration.

Single peaks were observed with F-I in double sector cells at 0.5% and 0.25% concentrations, at 39,460 r.p.m. observed at 32-minute intervals; single peaks with F-II at 0.9% and 0.45% concentrations, at 39,460 r.p.m. were observed at 16-minute intervals. Single peak characteristics prevailed in both fractions under all levels of irradiation employed.

Since irradiation was conducted on an aqueous system, sufficient quantities of potassium thiocyanate were subsequently added to each sample to bring the salt concentration to 2 *M* for sedimentation studies.

Sedimenting boundaries were analyzed with the aid of the Gaertner microcomparator. Plots of log x (where x is in cm. from axis of rotation) *vs.* t (in minutes) were constructed and extrapolated to zero time from which the uncorrected sedimentation coefficient was obtained through

$$S = \frac{dx/dt}{\omega^2 x} \qquad \text{(Eq. 3)}$$

Corrections of S to 20° were made through the relationship

$$S_{20w} = S_{obs}\left(\frac{\eta_t}{\eta_{20}}\right)\left(\frac{\eta}{\eta_0}\right)\left(\frac{1 - \bar{V}\rho_{20w}}{1 - \bar{V}\rho_t}\right) \qquad \text{(Eq. 4)}$$

where η_t is the viscosity of H_2O at 25° (8.949×10^{-3} poise); η_{20} is the viscosity of H_2O at 20° ($10\,087 \times 10^{-3}$ poise); η/η_0 is the factor for relative viscosity of 2 *M* KCNS to that of H_2O (0.915×10^{-2}); $\bar{V}$ is the partial specific volume of gelatin (0.695); ρ_{20w} is the density of the solvent (2 *M* KCNS) at 25° (1.090 Gm./ml.).

The ρ_t value was determined by experiment. Viscosity and density data for water are given by Svedberg (8). The specific volume factor and the η/η_0 relationship are those of Boedtker and Doty (9).

Plots of $1/S_{20w}$ *vs.* concentration were extrapolated to zero concentration and the reciprocal of the intercept taken as the coefficient value S^0 (Svedberg units). Results are shown in Table II and Figs. 4 and 5.

Molecular Weight Determinations.—Since the energy levels of irradiation imparted to F-I and F-II were designedly of low order, the extent of denaturation occurring in the irradiated solutions was small, and it was assumed that the random coil configura-

0.47	1,065,000	0.55
1.19	2,254,000	0.54

[a] From Eq. 2.

tion remained essentially intact. Intrinsic average molecular weights were calculated through the Scheraga-Mandelkern equation derived from the hydrodynamic elliposoidal model (10)

$$M = [\eta]^{1/2} \left(\frac{S^0 \eta_0 N}{\beta - (1 - \bar{V}\rho)} \right)^{3/2} \quad \text{(Eq. 5)}$$

A value of 0.915 for the viscosity of 2 *M* KCNS is in agreement with Boedtker and Doty (3). Taking 2.16×10^6 as the average beta value (11), molecular weights for F-I and F-II as well as their irradiated counterparts were obtained. The values are given in Table III along with α values determined from Eq. 2. A plot of the log of intrinsic viscosity *vs.* the log of molecular weight was linear for both fractions, as was the relationship of sedimentation constant to the square root of molecular weight, thus establishing maintenance of random coil configuration (4).

DISCUSSION

Viscosity Studies.—Since low order irradiation of F-I at 1% concentration produces successively lower intrinsic viscosity values in logarithmic relationship to dose, the question is posed whether scission plays a dominant role in reducing the viscosity of dilute gelatin solutions irradiated at these energy levels. According to Pasynsky (12) the rupture of peptide linkages, even if it does occur under the influence of biological radiation doses (0.3–2.5 R.), could not sufficiently change the configuration of the protein (serum albumin; gelatin) molecule. This, allegedly because the coiled state of the protein with numerous intramolecular bonds between chain links, is insensitive to radiation of this magnitude. As the dose is increased, internal structural changes take place, *i.e.*, aggregation, as reflected in an increase of absorption in the ultraviolet spectrum.

It is conceivable that these phenomena may occur in F-II, which shows progressive increase in viscosity after an initial decrease (with respect to the control). If the principle of proportionality between intrinsic viscosity and molecular weight is applied, one may assign responsibility for weight increases to (*a*) covalent linkage, or (*b*) excitation or activation of the molecules followed by regrouping the structural changes, *i.e.*, aggregation.

Bello, *et al.* (13), contend it is not likely that high intrinsic viscosities in unsolubilized gelatin are due to aggregation, but to crosslinking. Their experimental evidence, corroborated by the generally accepted capability of potassium thiocyanate to maintain gelatin solutions in a state of disaggregation, tends to negate the argument that aggregation is accountable for increased viscosity rather than crosslinking.

That large solvent:solute ratios are responsible for producing experimentally detectable intrinsic viscosity changes at low order irradiation levels is borne out by negligible and erratic viscosity changes in irradiated 5% solutions and films. Results obtained with films particularly give impetus to the proposition that secondary solvent-solute interactions during the ionization event are factors in producing shifts in intrinsic viscosity values. Impact of ionizing radiation on solid gelatin causes absorption of energy by the protein, but the absence of water during impingement deprives the molecules of freedom of movement and, consequently, interaction with solvent.

Wiederhorn, *et al.* (14), observed that thermally contracted (denatured) collagen obeys the kinetic theory of rubber elasticity. Assuming collagen to be a network polymer consisting of long chains tied together at intervals along their length, the average molecular weight of the chain between points of primary valence crosslinking was shown to be in the order of 55,000. This was based on the premise that the molecular weight between points of crosslinking can be determined from stress-strain behavior of a thermally contracted sample. From this quantity Wiederhorn deduced a method for calculating the number of crosslinks per unit volume of mass. The following mathematical relationship correlates the retractive force with elongation

$$f = \frac{v_2^{1/3}}{Mc} RT\rho \left(\alpha - \frac{1}{\alpha^2} \right) \quad \text{(Eq. 6)}$$

where f is the retractive force per unit cross section; α is the relative elongation of the sample, *i.e.*, the ratio of the stretch length to the initial length; ρ is the density of the unswollen sample; T is the absolute temperature; R is the gas constant 8.478×10^4 if the force is given in Gm./sq. cm. and the density in Gm./ml.; Mc is the average molecular weight of the chains between points of crosslinks; and v_2 is the volume fraction of the elastic constituent in the sample.

Employing a modified Wiederhorn device, stress-strain measurements were made on a series of commercial pigskin gelatin films irradiated as follows: control, 2.5, 5.0, 10.1, and 25.0 Megarads. It was found that the average molecular weight between crosslinks in the control varied from about 40,000–82,000; at the 2.5 Megarad level, it varied from 198,000–304,000, at the 5.0 Megarad level from 251,000–345,000, and at the 10 Megarad level from 499,000–1.2×10^6. Because of the brittleness of the sample and experimental difficulties, the stress-strain measurements on a 25.0 Megarad sample could not be obtained.

Determinations of molecular weight between crosslinks in irradiated F-I and F-II were unsuccessful. Films of both fractions irradiated at high (2.5 and greater Megarad) levels, succumbed to water at 60°, 65°, 75°, and 80°, indicating that thermostable crosslinking did not occur or, if it did, such crosslinking was of sufficiently low order to es-

cape Wiederhorn detection. Dry films (retained over calcium sulfate) and moist films (retained 12 hours over a water-saturated atmosphere), the latter theoretically providing the necessary electrons through an aqueous environment to enhance crosslinking, met with identical lack of success.

Sedimentation and Molecular Weight Studies.—It has been shown (4) that the relationship establishes random coil configuration of gelatin molecules in solution and entrapment of solvent within the coil where the sedimentation constant is a linear function of the square root of the molecular weight. On this basis, the proposition that irradiation at subdenaturant levels may have at least a partially scissive effect on the protein structure seems plausible. The decrease in molecular weight values (F-I) may be explained as due to a combination of moderate deaggregation and scission. The reverse effect (increase in molecular weight) would indicate a tendency toward crosslinking and weak bond formation. Further support for this suggestion is provided through linearly related sedimentation velocity *vs.* intrinsic viscosity and Svedberg constants (S^0) *vs.* the square root of molecular weight for both fractions.

One can now examine more closely the relationship between intrinsic viscosity and molecular weight as defined in the modified Staudinger equation (Eq. 2). The value of the semiempirical proportionality constant α is two for rigid rods, one for free-draining random coils and 0 for impenetrable spheres. Although independent of molecular weight, it is dependent on the flexibility of the polymer chain and solvent:solute characteristics. Assuming that the K factor of 2.9×10^{-4} is valid (4) for randomly coiled gelatin molecules, and that the exponential value α lies between 0.6–0.9 for a combination of the free-draining linear molecule and the swollen molecule with immobilized solvent, values of 0.64 for F-I and 0.66 for F-II are in reasonable agreement (Table III) with the established 0.62 value for randomly coiled gelatin. It appears justifiable to conclude that prior to irradiation both fractions had random coil convoluted configuration with solvent entrapment. In addition, it is evident from Table III that departure from the minimal 0.60 α value occurred on irradiation of both fractions.

It is interesting to note that Flory (15) sets an upper limit for α of 0.80 on the basis of randomly coiled linear polymer theory and a lower limit of 0.50. Since the constant is a function of solvent:solute interaction, the latter value would indicate the limit of a solvent capable of dissolving the polymer. The α values in all irradiated samples meet this requirement. It can be stated, therefore, that 2 M KCNS was capable of maintaining the gelatin fractions studied in a molecularly dispersed state and that random coil configuration was preserved.

A surprising result with respect to both fractions was the gross change in molecular weights imparted by small doses of energy on 1% solutions. This would seem contrary to prevailing opinion that low quanta of ionizing electrons produce relatively minor changes in protein (amino acid) structure. Although conceivably applicable in the case of solid states, it is not necessarily true of irradiated solutions. Considering that the higher molecular weight fraction (F-I) of the two studied nearly tripled in value on exposure to extremely low level irradiation and that (as the energy levels were increased) the molecular weight values became progressively lower, it is conceivable that the random coil configuration enters into a linking reaction, the extent of which diminishes in proportion to the intensity of irradiation. The lower molecular weight fraction (F-II) behaves conversely, *i.e.*, small quanta of radiation force linking of the protein. As the intensity of energy increases, so does the molecular weight, indicating direct proportionality between radiation and molecular weight. This behavior suggests that when gelatin molecules are subjected to excitation at high dilution they are oriented toward each other by forces induced through the mechanism of low order irradiation, causing a partial unfolding of the random coil, lengthening of the chain (as indicated in the initially high intrinsic viscosity value), and crosslinking. Provided that the energy imparted to the protein remains quantitatively below that required to rupture critical linkages, the attraction will induce an increase in molecular weight.

It seems reasonable to assume that the two fractions examined had random coil configuration with solvent entrapment and that an assignment of 0.6+ for the α value in the modified Staudinger equation is justified. Immobilization of the solvent within the swollen random coil can be inferred from the linear relationship between sedimentation constant and the square root of the molecular weight. Although F-I and F-II molecular weight values were related in 2:1 ratio, no experimental evidence was elicited which would establish substantial differences in the nature of the links holding the coiled entities together; the evidence suggested merely that a larger number prevailed. One can postulate as the most probable linkages van der Waals forces, weak hydrogen bonds (16), salt links, and covalent bonds joining the coils in a network structure. The lack of substantial coil bond strength is indicated by the lability toward denaturation by heat and, particularly in F-I and F-II, susceptibility to denaturation in aqueous solution on exposure to low order irradiation energy.

It is interesting to note that α decreases on irradiation of both gelatin fractions but does not in any case fall below 0.54. Evidently, application of stress to the freedraining random coil configuration effects increased coiling with consequent displacement of entrapped solvent as well as immobilization of solvent not displaced. This tendency follows the $[\eta]$ *vs.* $\sqrt{M_w}$ relationship already established.

Although (as noted previously) 2 M KCNS is acceptable as a solvent for maintaining gelatin in a molecularly dispersed state, some significance must be attached to the values obtained for k' in the modified Huggins equation (Eq. 1). This factor has been found to be a parameter of solute:solvent interaction. According to Thomas, *et al.* (17), for linear polymers in good solvents k' has values between 0.3–0.4. For F-I and F-II controls, F-I irradiated up to about 1.0 Megarad, and F-II irradiated to about 0.2 Megarad, the k' values lie between 0.3–0.6, in good agreement with the requirements of Thomas. In excess of these

energy levels, however, k' for both F-I and F-II rises above 1.0. Since intrinsic viscosity is dependent on the shape of the molecule in solution and the shape in turn depends on solute:solvent interaction, k' values vary with solvent power and are inversely proportional to intrinsic viscosity. This would implicate 2 *M* KCNS as an inadequate solvent for measuring viscosity of gelatin irradiated at levels greater than 0.5 Megarad.

Nevertheless, on the basis of favorable experiments with 2 *M* KCNS by others (3) and data obtained by us, this solvent was elected and found to be quite suitable for viscosity as well as sedimentation studies. In 1% concentration, F-I and F-II gave reproducible straight-line plots of η_{sp}/c *vs.* c at 50° and at 25°. Constant values could not be obtained with either F-I or F-II when 5% solutions and films were diluted to 1% concentrations. This would appear to confirm the admonition that comparisons cannot be made on gelatins whose thermal, solution, and aging histories are not identical. Deviations invariably give misleading results because configurations of the protein molecule are not the same in sol and in gel states. For example, gelatin films prepared by hot evaporation are in a fold where hydrogen bonds are intramolecular, whereas cold-evaporated gelatin contains intermolecular hydrogen bonds and forms more stable films (18). Similar reasoning would apply to comparison of 1% and 5% gelatin solutions. In the former, solution can be effected more readily, and the molecular state is characterized by relative freedom of motion, whereas the latter requires a somewhat longer period for final dissolution of the protein, which is more compact and has less movement capability.

Therefore viscosity studies on dilute solutions, gels, and films are not susceptible to comparison even though the same protein is involved because the preparation of more concentrated forms followed by dilution, but interrupted by a short aging period, disorients the molecule. The configuration of the converted form is not the same as that in the 1% solution prepared initially. Hence, the behavior of the final solutions in viscosity studies differ appreciably. This reasoning is supported by differences in viscosity behavior of the dilute solutions, and gels and films converted to sols, following exposure to low order irradiation. The 1% solutions of F-I and F-II gave sharply definable plots of η_{sp}/c *vs.* c, readily extrapolatable to zero concentration to yield $[\eta]$. Irradiated gels and films converted to 1% solutions gave erratic results—overlapping straight-line plots and low $[\eta]$ values which could not be reproduced. It appears that irradiation doses of the order 0.4–2.5 Megarads are capable of inducing discrete physical changes in the molecular make-up of gelatin in 1% solutions. The order of change in gels and solid states is comparatively small. Because of their compactness in 5% solution and their total immobility in the solid state, impingement of small quanta of ionizing radiation on gelatin molecules in these forms fails to disrupt their makeup to a degree sufficient for useful application of viscometric measurements.

The characteristically progressive reduction in $[\eta]$ values for F-I and the shifting viscosity behavior of F-II may be attributed to changes in the size and shape of the molecules and alterations in net charge with increased application of irradiation dosage. If scission or crosslinking (or both) occur, the increase or decrease in molecular weight is a function of scission and crosslinking rates which, in turn, are proportional to radiation intensity (19). The probability of crosslinking is proportional to the integrated dose R (in Megarads) of the radiation

$$q = \alpha R$$

where α is a proportionality constant having units of mass/energy. With respect to scission

$$p = P_0 + \beta R$$

where β, the proportionality constant for scission, has the dimensions of α, and p is the overall scission probability. Shultz (20) has evaluated the ratio β/α in terms of the effect of radiation-induced branching on intrinsic viscosity in the pregelation region. By plotting $[\eta]_{\text{branched}}/[\eta]_{\text{unbranched}}$ as a function of R/R^* where R^* is the critical radiation dose, it was shown that when $\beta/\alpha = 0$ no scission occurs, $[\eta]$ increases until R approaches R^*, then drops. The drop occurs sooner as the scission gains dominance. When $\beta/\alpha > 1$, $[\eta]$ decreases at the start, although molecular weight is increasing. The latter behavior is precisely that of F-II.

It is apparent that one cannot rely exclusively on intrinsic viscosity data to interpret changes in molecular weights of irradiated proteins. A more conservative approach would be to assume that several events occur during irradiation and that the final effects on the protein represent the total of the transformations on the entire molecule which would include scission, crosslinking, endlinking, charge transfer, polymerization, and deaggregation.

The drop in intrinsic viscosity of F-II with concurrent increase in molecular weight tends to support the proposition that if the β/α ratio (20) is greater than unity, $[\eta]$ decreases initially though the molecular weight is increasing, and that full reliance cannot be placed on $[\eta]$ values to interpret changes in molecular weights of irradiated polymers. Here again one must look to the three principal reactions which may occur following free radical formation. In the lower molecular weight F-II, the lowest radiation level causes an immediate twofold increase in molecular weight. At the next level, the molecular weight becomes substantially greater and continues in the same direction. This would indicate recombination and coupling reactions between free radicals resulting in copolymerization by crosslinking and/or endlinking.

The interdependence of intrinsic viscosity, sedimentation constant, and molecular weight values for irradiated F-I and F-II has been established. Gouinlock's F-2 and F-3 fractions (7) showed the same relationship as did irradiated F-I—namely, a decrease in $[\eta]$ reflected a decrease with respect to both S^0 and M_w. The reverse pattern, nevertheless interdependent, was manifested in irradiated F-II. If it is accepted that 2 *M* KCNS is capable of maintaining gelatin in solution in a molecularly dispersed state, it will necessarily follow that changes in intrinsic viscosity can be relied upon to reflect sedimentation and molecular weight changes. Since intrinsic viscosity is related to the size of the molecule, an increase in this value in the presence

of KCNS would indicate the presence of forces other than those responsible for aggregation to account for increases in molecular weight.

In our next and final paper in this series we will show experimental data which indicate that molecular weight changes in the two fractions studied occur through a free radical mechanism.

Antacid Properties of Calcium, Magnesium, and Aluminum Salts of Water-Insoluble Aliphatic Acids

By STUART P. ERIKSEN†, GEORGE M. IRWIN, and JOSEPH V. SWINTOSKY

The antacid properties of several calcium, magnesium, and aluminum salts of aliphatic acids were studied. A number of the salts showed potential antacid properties *in vitro*. Of this group calcium laurate also showed promising results by *in vivo* tests in dogs and humans. Along with their acid-neutralizing capacity, higher molecular weight metal salts have several interesting physical properties, for example, their insolubility in aqueous fluids above approximately pH 5, and their neutralizing properties below this pH. They tend to float on the surface of solutions and cling to the walls of a container before they react with acidic solutions. Following reaction with hydrochloric acid, salts of higher molecular weight aliphatic acids form insoluble aliphatic acids which are reputed to retard emptying of stomach fluids. A possible drawback to the higher molecular weight salts is a lower weight-to-weight antacid capacity when compared to antacids such as calcium carbonate and aluminum hydroxide.

ALKALI AND ALKALINE earth metal salts such as carbonates, bicarbonates, and glycinates have been of considerable use over the years as antacids. They possess the ability to neutralize the acid of the stomach efficiently but in some cases replace it with a considerable concentration of hydroxide ion. Recently, the authors have investigated the antacid properties of a series of metal-organic acid salts. It appeared from consideration of their physical properties that these substances might be useful antacids with interesting "secondary" properties. The *in vitro* and *in vivo* studies of these metal salts are reported in this paper.

The calcium, magnesium, and aluminum salts of long chain aliphatic acids possess several interesting properties which might counterbalance their high equivalent weight (low acid-combining power). Since they are essentially non-wetted, they tend to float on aqueous solutions, coat wet surfaces, and offer the possibility of good protective action. They react with acid only below a characteristic pH, depending on the compound. Because the acid product of the neutralization reaction is poorly dissociated and is often relatively water-insoluble, we may consider these metal salts as hydrogen ion-exchange compounds—hydrogen and metal ions being in equilibrium with the two solid forms according to the equation

† Present address: School of Pharmacy, University of Wisconsin, Madison.

of KCNS would indicate the presence of forces other than those responsible for aggregation to account for increases in molecular weight.

In our next and final paper in this series we will show experimental data which indicate that molecular weight changes in the two fractions studied occur through a free radical mechanism.

Antacid Properties of Calcium, Magnesium, and Aluminum Salts of Water-Insoluble Aliphatic Acids

By STUART P. ERIKSEN†, GEORGE M. IRWIN, and JOSEPH V. SWINTOSKY

The antacid properties of several calcium, magnesium, and aluminum salts of aliphatic acids were studied. A number of the salts showed potential antacid properties *in vitro*. Of this group calcium laurate also showed promising results by *in vivo* tests in dogs and humans. Along with their acid-neutralizing capacity, higher molecular weight metal salts have several interesting physical properties, for example, their insolubility in aqueous fluids above approximately pH 5, and their neutralizing properties below this pH. They tend to float on the surface of solutions and cling to the walls of a container before they react with acidic solutions. Following reaction with hydrochloric acid, salts of higher molecular weight aliphatic acids form insoluble aliphatic acids which are reputed to retard emptying of stomach fluids. A possible drawback to the higher molecular weight salts is a lower weight-to-weight antacid capacity when compared to antacids such as calcium carbonate and aluminum hydroxide.

ALKALI AND ALKALINE earth metal salts such as carbonates, bicarbonates, and glycinates have been of considerable use over the years as antacids. They possess the ability to neutralize the acid of the stomach efficiently but in some cases replace it with a considerable concentration of hydroxide ion. Recently, the authors have investigated the antacid properties of a series of metal-organic acid salts. It appeared from consideration of their physical properties that these substances might be useful antacids with interesting "secondary" properties. The *in vitro* and *in vivo* studies of these metal salts are reported in this paper.

The calcium, magnesium, and aluminum salts of long chain aliphatic acids possess several interesting properties which might counterbalance their high equivalent weight (low acid-combining power). Since they are essentially non-wetted, they tend to float on aqueous solutions, coat wet surfaces, and offer the possibility of good protective action. They react with acid only below a characteristic pH, depending on the compound. Because the acid product of the neutralization reaction is poorly dissociated and is often relatively water-insoluble, we may consider these metal salts as hydrogen ion-exchange compounds—hydrogen and metal ions being in equilibrium with the two solid forms according to the equation

Received August 29, 1962, from the Research and Development Division, Smith Kline and French Laboratories, Philadelphia, Pa.
Accepted for publication October 5, 1962.
The authors express their gratitude to Dr. E. Downs Longaker for his assistance in carrying out the *in vivo* studies in humans.
Presented to the Scientific Section, A.PH.A., Las Vegas meeting, March 1962.

TABLE I.—ANALYSIS AND SOURCES OF ANTACID MATERIALS STUDIED

Compound[a]	Manufacturer	Analysis[b] Metal, %	Acid, %	Solvent, %
A. Commercial Compounds				
1. Calcium stearate	Matheson Coleman and Bell	100.5	95.5	2.8
2. Calcium 12-hydroxy stearate	Baker Castor Oil Co.	102.5	93.5	0.8
3. Aluminum mono-12-hydroxy-stearate	" " " "	[c]	74.2	3.7
4. Aluminum di-12-hydroxystearate	" " " "	[c]	89.6	2.6
5. Aluminum tri-12-hydroxystearate	" " " "	90.8	98.2	1.7
6. Magnesium 12-hydroxystearate	" " " "	66.6	92.8	2.7
B. Synthesized Compounds				
7. Calcium pelargonate		96.0	81.8	4.5
8. Calcium caprate		94.8	89.8	3.9
9. Calcium laurate		90.5	90.6	3.7
10. Calcium myristate		85.7	86.0	2.6
11. Calcium palmitate		92.3	91.1	3.3
12. Magnesium laurate		99.3	78.6	[d]
13. Magnesium myristate		84.6	86.3	[d]
14. Aluminum laurate		92.4	88.3	[d]
15. Calcium azelate		86.5	92.0	2.0
16. Calcium sebacate		88.4	92.9	3.0

[a] Compounds 1–6 were purchased from the manufacturers and used without purification. Compounds 7–16 were synthesized by mixing aqueous solutions of the metal chlorides and the sodium aliphatic acid soaps. The precipitated products were then washed with water and air-dried. The free acids were obtained from the following manufacturers: pelargonic, Emery Ind., Inc.; myristic, Foremost Food and Chemical; all others from Matheson Coleman and Bell. Seven other compounds were studied—aluminum hydroxide, calcium hydroxide, calcium carbonate, calcium citrate, magnesium oxide, magnesium trisilicate, and magnesium stearate. These were obtained as U.S.P. grade materials and used without further purification or analysis. [b] Solvent was calculated as per cent weight loss on drying 5 hours at 110° C. Metal determinations were done by standard EDTA titration. Acid determinations were made by titration of acid-ether extraction residue. [c] Other metals than aluminum also present. [d] Solvent not determined.

$$H^+ + \text{metal salt (solid)} \rightleftarrows \text{metal ion} + \text{organic acid (solid)}$$

The pH at which some of these salts exert their buffering effect is in the optimum range (below pH 4 to 5) for effective antacid action (1). They are essentially odorless, tasteless, and innocuous; many of the aliphatic acids are natural constituents of foodstuffs (2). Finally, the low density and poor wettability of some of these salts might decrease the efficiency with which they are emptied from the stomach (through floating and adhering to the moist stomach lining), which would result in a prolongation of antacid action.

It was our intention to study the relative reaction rates of various of these metal-aliphatic acid salts in dilute hydrochloric acid as a function of the metal ion and the chain length of the aliphatic acid used in an effort to find a candidate of sufficient potential to warrant an *in vivo* test of the ideas suggested above.

EXPERIMENTAL

Materials Used.—Pertinent data concerning the analysis and source of the compounds studied are tabulated in Table I.

pH Recording Systems.—All pH measurements were made with a Photovolt line operated pH meter, model 110, altered to permit recording on a 10 mv. Brown potentiometric recorder. The span of the recorder was adjusted to match the meter scale.

Studies in Vitro.—Studies were carried out in a 100-ml. beaker stirred at about 150 r.p.m. with a magnetic stirrer. Acid was added with a screw-driven 5-ml. hypodermic syringe at a rate of 0.23 ml. of 1.75 *N* HCl per minute (equivalent to 4 ml. 0.1 *N* HCl per minute[1]). The steps in the *in vitro* testing procedure were

1. Fifty ml. of 0.1 *N* HCl were put in the beaker and pH recording begun.
2. Five Gm. of antacid was added to the stirring acid[2] as either a powder or a glycerin-wetted suspension.
3. The pH was allowed to rise to equilibrium.
4. Acid addition was begun and continued (never longer than 30 minutes) until a trend was established.
5. The curve was evaluated using the following performance factors: (*a*) delay time, (*b*) static equilibrium pH, (*c*) dynamic equilibrium pH. The definitions of these performance factors and the methods for obtaining them are illustrated in Fig. 1.

Studies in Vivo.—Beckman glass stomach electrodes (type x800-22) were modified and used to record gastric pH and the changes caused by ingested antacid in humans and dogs. A polyethylene shield (as suggested by Harrisson, *et al.* (3),) was added to protect the tip of the glass electrode. The calomel half-cell made contact with the stomach contents through a saturated KCl-soaked thread held alongside the glass electrode lead. A fine polyethylene tube[3] (containing the KCl-soaked thread together with glass-electrode lead) was pulled through a larger polyethylene tube,[3] and the end of the thread allowed to hang out of this outer tube just above where the latter was seated on the glass electrode tip. The end of the thread and tube external to the patient was held in the side arm of a standard saturated-calomel half-cell with a small

[1] It was observed that 0.1 *N* HCl and U.S.P. simulated gastric fluid (1) gave the same results, so that for simplicity we chose to use 0.1 *N* HCl.

[2] The exact amount added is not important, provided an excess is present; however, it must be in an immediately dispersable form. (See *in vivo Studies* for powder information.)

[3] Adams Intramedic tubing, PE No. 160 and No. 340.

cork stopper. Figure 3 is a drawing of the complete electrode system.

In vivo studies were carried out on human volunteers and anesthetized dogs. The measurement procedure used was essentially that described by Harrisson, *et al.* (3), where each subject served as his own control. Stomach pH was measured after 8 hours of fasting. (Water was given if needed.) Then the pH effects of a swallowed or intubated dose of antacid were recorded. The following suspension formula was used for all studies of powdered antacids: metal salt (5.0 Gm.), glycerin (7.0 ml.),[4] and water (30.0 ml.).

RESULTS AND DISCUSSION

The speed of response to added acid is essentially a measure of the rate of reaction with acid. If potentially longer-acting antacids are to be tested it is important that such rate of reaction studies not be done with concurrent removal of sample (simulated stomach emptying), *i.e.*, any antacid intended for prolonged action must be maintained in the stomach for the duration of its effect, either by some physical property of its own, or through special formulation.

The *in vitro* test used in this study is limited to the determination of reaction rates under two pH stresses, *i.e.*, "maximum stress" (pH 1) and "maximum rate of acid flow" (4 ml. of 0.1 *N* HCl per minue (4)). If reasonable stresses were used, it was expected that limits of response for each antacid could be observed *in vitro*, which would then correlate well with *in vivo* pH's as measured with the swallowed gastric glass electrode and would be true indications of the antacid utility of the compounds studied.

Figures 1 and 2 are tracings of pH *vs.* time records for aluminum hydroxide, calcium pelargonate, and magnesium stearate, showing the general shapes of the tracings and how the performance factors were determined. Using the performance factors shown in Fig. 1, 24 compounds were evaluated—six "simple" metal salts and hydroxides, and 18 aluminum, calcium, and magnesium salts of mono- and dicarboxylic acids of various chain lengths. The results of these *in vitro* studies are tabulated in Table II. The compounds studied show widely varying rates of reaction in acid of pH 1, the delay time for attaining static equilibrium ranging from several seconds to periods in excess of 30 minutes. The aluminum salts showed much slower rates of reaction than those of magnesium and calcium. The appearance of some rapid neutralizing effect by aluminum mono-12-hydroxystearate must be considered in the light of the presence of some other metal than aluminum (see Table I). Calcium and magnesium salts show much higher and more useful rates of reaction in acid, although the stearates in both cases seem to react slowly. All the so-called "simple" substances (hydroxide, carbonate, citrate, and trisilicate) show rapid rates of reaction. As one might expect, increase in the acid chain length slows reaction rates, though not always markedly. Dicarboxylic salts up to ten carbons show essentially the same reaction rate as the mono-basic acids.

Delay times are affected to some degree by factors such as rate of stirring, particle size, water solubility of the antacid, and degree of wetting. Although particle size may have been somewhat variable among these compounds, an effort was made to keep the rate of stirring constant and to wet the

[a] Calculated on the basis of 50 ml. 0.1 *N* HCl residual acid plus 1 or 4 ml. of 0.1 *N* HCl secretion per minute for 100 minutes.

powders uniformly before determining the pH *vs.* time records.

The static equilibrium pH's reflect the pKa of the acid and the properties of the metal ion produced by neutralization. For aluminum salts the static pH's are about 3, for calcium 4.8, and for magnesium 5.5. The dynamic equilibrium pH's follow the delay times as expected; *i.e.*, where there are long delay times dynamic pH values are also low, which indicates slow response of the compound to added acid. The static pH values indicate the maximum pH's that the antacid is able to create in the stomach, while the dynamic values give an indication of the ability of an antacid to respond to stomach secretions—essentially its ability to maintain pH under high rates of acid secretion. While varying with stirring, wetting, and particle size, the dynamic equilibrium pH's are also functions of the rate of acid addition chosen. The maximum rate currently suggested (4) was selected to set a lower limit on antacid capability. The dynamic equilibrium value desired in these studies was that pH at which the rate of acid neutralization equals the rate of acid addition under a standard set of conditions. For practical reasons (sticking, clumping, etc.) this point is difficult to observe, and the pH after 6 minutes of acid addition was selected as the dynamic equilibrium value. This is recorded in Table II to permit ranking of compounds.

The final two columns of Table II are included to give an idea of the relative dose sizes of these compounds required to maintain pH at a value greater than 2 for 100 minutes under two extremes of acid production or addition (1 and 4 ml./min.).

Current opinion (1) suggests that an effective antacid should be capable of maintaining the stomach pH between 2–5. One might then conclude that compounds yielding static equilibrium and dynamic equilibrium pH's outside this range would be inferior antacids; calcium hydroxide and carbonate, magnesium oxide, tri-silicate, laurate, and 12-hydroxystearate have static pH's that fall outside this range by our test procedure.

From the table one would select calcium pelargonate, azelate, or sebacate as having optimum characteristics, *i.e.*, relatively low dose, fast onset, rapid response, and low static pH (to prevent the possibility of "acid rebound").[5] In selecting the acid moiety to be used in conjunction with the metal, an acid of low toxicity and volatility and of moderately short chain length is desirable.[6] Minimal volatility is desirable to avoid taste and odor from the free acid formed during the *in vivo* neutralization reaction. Aliphatic acids of less than 12 carbon atoms are liquid at body temperature and have disagreeable odors. The 12-carbon lauric acid is solid at body temperature and is virtually free of odor, and its calcium salt is an antacid with properties making it a potentially useful antacid. Thus, calcium laurate was selected for *in vivo* studies with calcium carbonate as the control.

In order to circumvent any membrane potential error, which the authors and others (6, 7) have observed to amount to about 30 mv. or $^1/_2$ pH unit, *in vivo* studies were not done with the calomel cell on the arm (3) or in the mouth. Direct calomel contact with the gastric contents, even by such elementary means as we have described, permits true pH values to be obtained inside or outside the body.

A summary of the data obtained from *in vivo* studies on three dogs and three humans is shown in Table III. Two conclusions may be drawn from these *in vivo* tests: (*a*) calcium laurate is an effective antacid, and (*b*), though its duration appears to be

[5] We could not demonstrate "rebound" in any of our studies on dogs and humans.

[6] Though the toxicity of azelaic and sebacic acids is not well understood, they have been reported to be *nephrotoxic* in animals (5) and therefore were not considered for the *in vivo* test.

TABLE III.—SUMMARY OF ANTACID DATA OBTAINED FROM SEVERAL ANTACIDS BY THE *in Vivo* ELECTRODE RECORDING TECHNIQUE, USING DOGS AND HUMANS

	Calcium Laurate			Control

longer in a human than an equivalent amount of calcium carbonate control, the difference is probably not significant. One might extrapolate this to mean that the principle of "floating" or adhering through poor wetting does not enhance stomach retention time markedly, although considerable more controlled *in vivo* work would be required to prove this conclusively.

SUMMARY

1. The following compounds were evaluated *in vitro* for antacid activity: aluminum hydroxide, aluminum laurate, aluminum myristate, aluminum mono-12-hydroxystearate, aluminum di-12-hydroxystearate, calcium hydroxide, calcium pelargonate, calcium citrate, calcium carbonate, calcium caprate, calcium laurate, calcium myristate, calcium palmitate, calcium stearate, calcium 12-hydroxystearate, calcium azelate, calcium sebacate, magnesium oxide, magnesium trisilicate, magnesium laurate, magnesium myristate, magnesium stearate, and magnesium 12-hydroxystearate.

2. In the *in vitro* studies, pH *vs.* time recordings were made under conditions which allowed evaluation of performance. Performance factors were designated (a) *delay time*, (b) *static equilibrium pH*, and (c) *dynamic equilibrium pH*. These factors indicated under the experimental conditions employed (*a*) the time required for an excess of the antacid to raise the pH of a 0.1 *N* HCl solution to an equilibrium value, (*b*) the equilibrium pH value when no further HCl was added to the system, and (*c*) the approximate equilibrium pH resulting (under conditions of excess antacid) when acid was added continuously at a rate equivalent to 4 ml. 0.1 *N* HCl per minute.

3. Most of the salts of carboxylic acids used in these studies have not been reported previously to be antacid substances, yet they all appear to possess this property. Their antacid properties result from their ability to react with HCl and form the free carboxylic acids. These free acids are poorly dissociated and many are insoluble in aqueous fluids. Thus their formation results in removal of hydrogen ions from solution.

4. The pH's below which these salts exert antacid action are influenced in part by the pKa of the carboxylic acid and the nature of the metal cation. For the aluminum, calcium, and magnesium salts studied, effective antacid actions were exerted at pH's near 4, 4.8, and 5.5, respectively.

5. Rate of acid neutralization *in vitro* appears to be influenced by factors such as rate of stirring, particle size of the antacid, its water solubility, and its wettability. Rates of acid neutralization cannot be predicted beforehand; however, in general, for salts derived from a given metal, the lower equivalent weight salts reacted more rapidly than those of higher equivalent weight. For example, calcium pelargonate or calcium azelate neutralized HCl much more rapidly than did calcium stearate.

6. Limited studies were performed in anesthetized dogs and in humans using a stomach electrode. Calcium laurate (a typical salt of a carboxylic acid) was shown to possess antacid properties *in vivo*.

7. One can infer from these studies that many salts of carboxylic acids possess antacid properties; however, none of the salts studied appeared to offer general advantage over some commonly used antacids. The principal drawback of the salts derived from the higher molecular weight carboxylic acids is the relatively high doses that would be required in practical therapy.

Effect of Various Compounds on the Rate of Thiamine Hydrolysis

By JOHN J. WINDHEUSER and TAKERU HIGUCHI

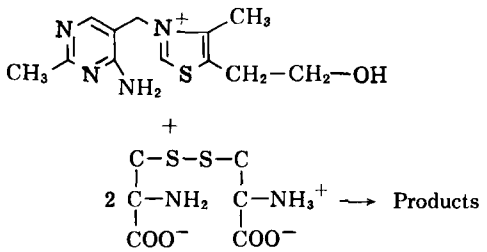
The catalytic effects of a variety of compounds on the rate of thiamine hydrolysis have been investigated. Although some catalysis was observed, thiamine degradation does not appear to be particularly sensitive to the presence of a number of nucleophilic agents other than sulfite and thiosulfate.

In our previous publication (1) dealing with the kinetics of thiamine hydrolysis, reference was made to the reports by others (2) indicating that certain compounds exhibited remarkable positive or negative catalytic effects on the rate of hydrolysis of this vitamin. Although investigation of some of these compounds under our experimental conditions failed to substantiate the reported dramatic effects, the possible theoretical and technical importance of finding catalytic agents has motivated further investigation in this area. The present communication is concerned with the effects of several amino acids and other compounds on the rate of thiamine cleavage at 96.4°.

RESULTS AND DISCUSSION

Amino Acids.—It has been reported in the literature (3) that the destruction of thiamine by shrimp thiaminase was retarded by the addition of cystine at pH 6.9. In order to determine whether the reported effect might be due to an interaction of cystine with thiamine resulting in stabilization or due to the amino acid lowering the catalyst activity, thiamine was subjected to hydrolytic conditions in the presence of various concentrations of cystine. Experiments were conducted at 96.4° under anaerobic conditions, at constant pH, ionic strength, and buffer concentration.

The results of studies at pH 6.3 are shown in Fig. 1. The increase of the reaction rate as a function of the cystine concentration indicates that rather than stabilizing thiamine, cystine actually acts to catalyze the degradation. The nonlinearity of the increase in reaction rate at rising amino acid titer suggests a higher order dependency of the reaction on cystine. Based on the observed pH dependence, the solid line on the graph was calculated on the assumption that the reaction could be represented as



From such a formulation it can be readily shown that

$$k_{obs} = k_o + k_{cy}\left[cy_t\left(\frac{K_a}{H^+ + K_a}\right)\right]^2$$

where k_{obs} is the observed pseudo first order rate constant, k_o is the first order rate constant at the experimental pH and buffer concentration, k_{cy} is the specific catalytic constant for cystine, cy_t represents the total cystine added to the system, and K_a denotes the acidic dissociation constant of the first amino group. The good agreement of the experimental points with the theoretical curve tends to support the proposed reaction dependency.

Figure 2 depicts the results obtained from the same reaction run at pH 6.69. The solid line again represents a theoretical curve calculated with the above equation utilizing the catalytic constant estimated from the reaction at pH 6.3.

TABLE I.—THE EFFECT OF VARIOUS AMINO ACIDS ON THE RATE OF THIAMINE HYDROLYSIS AT 96.4° IN THE PRESENCE OF 0.1 *M* PHOSPHATE BUFFER AT 0.5 IONIC STRENGTH

Compound	pH	Apparent Catalytic Constant, LM^{-1} $Hr.^{-1}$
Cystine	6.30	2.08×10^{6a}
Cystine	6.69	2.08×10^{6a}
Cysteine	6.30	-8.5×10^{-1b}
Tyrosine	6.30	...

[a] Calculated on the basis of Eq. 1 and using $pK_3 = 8.0$ for cystine. [b] Based on total cysteine concentration.

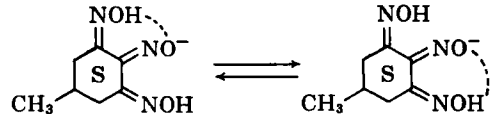
From the results of these experiments, which indicate that cystine *per se* catalyzes the decomposition of thiamine, it would appear probable that the retardation of the degradation of thiamine by thiaminase in the presence of cystine does not involve interaction of thiamine and cystine but rather an interaction of the amino acid with thiaminase.

The possible interconversion of cystine to cysteine under redox conditions led to the investigation of the behavior of cysteine. The results, as shown in Fig. 3, indicate that cysteine exhibits a definite inhibitory effect on the rate of cleavage. The apparent first-order dependence on cysteine and retardation of the rate of degradation, as compared to the results with cystine, would tend to suggest that the free sulfhydryl group is vital to the stabilizing mechanism. This is further substantiated when cysteine is compared to alanine which in our previous work (1) has been found to increase the rate of degradation. These findings would be in agreement with those of Watanabe (4) who reported that a number of sulfhydryl-containing compounds were found to prevent the formation of turbidity in thiamine solutions heated at 100° for three hours.

Although the structure of thiaminase has as yet not been elucidated, it has been shown that tyrosine is one of the amino acid components (5). Therefore experiments were carried out to determine if tyrosine might be one of the components of the active sites of this enzyme. The studies were conducted under the same conditions noted previously, and it was found that this compound exhibited no catalytic activity.

The results observed with the amino acids tested are summarized in Table I.

Carbonyl Derivatives.—Since it has been shown that thiamine hydrolysis is subject to general base catalysis, a number of ketones, ketoximes, and a triketo triazine were tested as each of these compounds is capable of acting as a nucleophilic catalyst, as has been shown by Russo (6) in his study of the hydrolysis of phosphate esters. Table II lists the compounds of this group that were tested and the catalytic constants observed. Figure 4 represents the kinetic dependency of the thiamine cleavage on the concentrations of cyclohexane oxime and 5-methyl-1,2,3-cyclohexanetrione-1,3-dioxime. In each case the reaction appears to be first order with respect to the catalytic agents. The higher catalytic constant of the dioxime may be due to a bifunctional attack of the weak nucleophilic and electrophilic centers in the molecule. The lack of activity of trioximes might be rationalized by the formation of intramolecularly bonded salts at this pH as follows



This supposition appears to be supported by the fact that the salicylate ion as well as the 2-hydroxy-1-naphthoate ion, both of which can form similar internal associations, exhibited no catalytic action.

TABLE II.—EFFECT OF VARIOUS COMPOUNDS ON THE RATE OF THIAMINE HYDROLYSIS AT PH 6.30 AND 96.4° IN THE PRESENCE OF 0.1 *M* PHOSPHATE BUFFER AND 0.5 IONIC STRENGTH

Compound	Apparent Catalytic Constant, LM^{-1} $Hr.^{-1}$	Max. Concn. *M*/L.
Cyclohexanone	No activity	1×10^{-2}
Cyclohexanone oxime	1.18	5×10^{-2}
1,2,3-Cyclohexanetrione trioxime	No activity	1×10^{-2}
5-Methyl-1,2,3-cyclohexanetrione 1,3 dioxime	2.46	3.5×10^{-2}
5-Methyl-1,2,3-cyclohexanetrione trioxime	No activity	1×10^{-2}
Trimethyl isocyanuric ester	No activity	1×10^{-2}

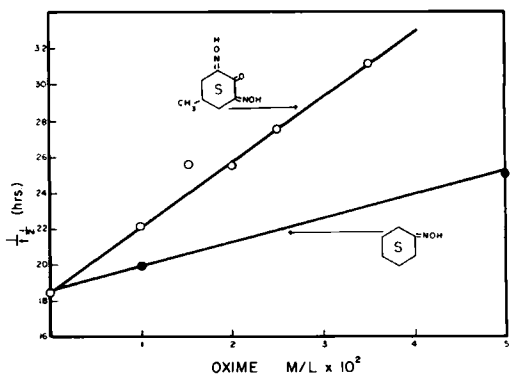


Fig. 4.—The effect of cyclohexanoxime and 5-methyl-1,2,3-cyclohexanetrione 1,3-dioxime on the rate of thiamine hydrolysis at pH 6.3 using 0.1 *M* phosphate buffer at an ionic strength of 0.5.

Other Compounds.—In addition to the amino acids and the agents tabulated in Table II, catechol, aniline, and 2-hydroxy-1-naphthoic acid were evaluated. None of these compounds altered the rate of the reaction.

EXPERIMENTAL

Reagents.—All chemicals used in the preparation of the buffers and the kinetic solutions were analytical reagent grade with the exception of the catalytic agents tested. These compounds were all purified by recrystallization from suitable solvents prior to use.

Analytical Procedure.—Residual thiamine was determined by the U.S.P. XVI (7) thiochrome method. All substances added to the system were checked for interference with the assay method.

Kinetic Procedure.—The procedure for the kinetic runs was identical with that previously described (1).

Kinetics of Air Oxidation of Sulfurous Acid Salts

By LOUIS C. SCHROETER

Sulfurous acid salts in common with many pharmaceutical antioxidants and oxygen-sensitive drugs undergo oxidation by a radical process. This has important implications in the testing and evaluation of oxidative tendencies of formulations since radical processes are inordinately sensitive to slight amounts (10^{-6} *M*) of compounds acting as radical inhibitors or initiators. Measurable inhibition of the rate of sulfite oxidation occurred in the presence of 10^{-6} *M* DMA or DMF; the inhibition is described by an empirical equation. Effect of hydrogen ion concentration on the oxidation of sulfurous acid salts was studied in detail and the results described in terms of a theoretically derived equation. Experimental data are presented in corroboration of the Abel theoretical equations and radical mechanism for sulfite oxidation.

SULFUROUS ACID salts in aqueous solution undergo oxidation in the presence of molecular oxygen by a radical process (1). Radical initiation very likely occurs through interaction of oxygen with an anion to produce free radicals

$$(I)\ O_2 + OH^- \rightleftharpoons OH + O_2^-(O_3H^-)$$

which in turn react with hydrogen sulfite species to produce a highly reactive radical.

$$(II)\ HSO_3^- + OH \rightarrow HSO_3 + OH^-$$

The product of the oxidation, sulfate ion (SO_4^{2-}), may be formed by the interaction of HSO_3 and OH radicals

$$(III)\ OH + HSO_3 \rightarrow SO_4^{2-} + 2H^+$$

Other mechanistic interpretations consistent with the concept of a radical process and conforming to the energetics of the system may adequately explain the experimental data. Consideration of plausible radical mechanism is aided by reviewing treatment accorded to other radical systems (2) and especially to free radical reactions occurring in solution (3).

Abel (4, 5) has proposed the following scheme for generalized anionic auto-oxidation

$$O_2 + A^- \rightarrow AOO^-$$
$$AOO^- + X \rightarrow 2O^- + X^+ + A$$
$$A + X \rightarrow X^+ + A^-$$

in which the hydroxyl ion appears to be the preferred electron donor, A^-. In this scheme X would represent hydrogen sulfite species, HSO_3^-.

Radical processes are extraordinarily sensitive to small amounts of compounds which may act to inhibit or to catalyze the reaction. Addition of sulfurous acid salts to pharmaceutical formulations generally results in rather complex systems from the standpoint of free radical chemistry. Drug molecules or other additives in the formulation may act as initiators, inhibitors, or catalysts of the oxidative process. Systems which decrease the efficiency of the antioxidant ultimately result in poor stability of the drug since failure of the antioxidant is generally followed by oxidative attack on the drug.

Accepted for publication October 3, 1962.

Antioxidants are added to pharmaceutical formulations as redox systems possessing higher oxidative potentials than the drug which they are designed to protect or as chain inhibitors of radical induced decomposition (6). Selection of the antioxidant is often based on sound theoretical grounds, such as the difference in redox potential between the drug and the compound; however, electrometric measurements only rarely serve to predict actual efficiency of antioxidants in complex pharmaceutical systems. Kinetics of the oxidation process and radical inhibitory or initiating action of the drug and/or the antioxidant cannot be deduced from redox potentials. Obviously, the most reliable information is obtained under field conditions (7). Laboratory evaluation of antioxidants in pharmaceutical formulations by exposing the system to oxygen under controlled conditions is a more realistic and dependable method. Manometric techniques have found considerable favor among investigators studying oxidations and auto-oxidations. Jorissen (8) describes typical manometric procedures in his interesting text on induced oxidation. Manometric techniques suffer from three main disadvantages: (*a*) in complex systems containing several oxidizable molecules or species it is not possible to assign oxygen uptake to a specific compound; (*b*) it is operationally difficult to assay the solution by an independent method while the experiment is underway; and (*c*) it is difficult to provide adequate stirring of the solution in contact with oxygen.

Many of the reported studies which have used manometric techniques are of questionable value inasmuch as critical evaluation of experimental techniques indicates that the diffusion rate of oxygen was the rate-determining step. If oxidation is sufficiently rapid, and if the stirring of the solution is slow, the rate at which oxygen is dissolved into the solvent determines how rapidly the system is oxidized.

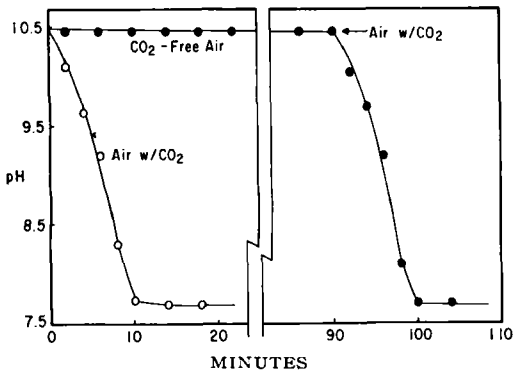

Fig. 1.—Effectiveness of gas scrubbers in removing CO_2 from air supply. Standard reactor containing 300 ml. water with 0.1 meq. NaOH stirred at 1000 r.p.m. at 25° with air flow rate of 50 cm.^{3} sec.$^{-1}$.

The comparative value of various antioxidants in protecting drug formulations is best accomplished by subjecting the system to standard oxidative conditions and periodically assaying the formulation for both drug and antioxidant. This procedure requires a maximum of effort but yields the most useful information for rational formulating. Complexity of radical oxidative processes and their sensitivity to small amounts of material place stringent limitations on the validity of comparisons among different pharmaceutical systems.

This study was designed to evaluate the operation of a standard air oxidation reactor with aqueous sulfurous acid salts and to make critical comparisons with theoretically derived kinetic data (9).

EXPERIMENTAL

Apparatus and Material.—Air oxidation of sodium sulfite solutions was carried out in a Pyrex vessel with a volume of approximately 600 ml. The vessel was provided with a gas dispersion tube, sampling port, short condenser, and a glass stirrer in a ground-glass bearing. Stirring speeds could be varied up to 1000 r.p.m. The reaction vessel was immersed in a thermostat maintained at 25 ± 0.01°.

Air supplied to the reactor was passed through a filter and molecular sieve to remove suspended solid and liquid particles. The air stream was then conducted through three gas scrubbing towers in series maintained in a thermostat at the same tem-

			Av.	2.86×10^{-3} sec.$^{-1}$

[a] Standard 500-ml. Pyrex reactor stirred at 1000 r.p.m. containing 300 ml. solution. Air (CO_2-free) saturated with water at 25° bubbled through solution at rate of 50 cm.^{3} sec.$^{-1}$. [b] Sample *A*—Fisher certified reagent sodium sulfite; *B* sample prepared by 2 × recrystallization of *A*; *C* sample—sodium sulfite N.F., Matheson Coleman and Bell; *D* sample prepared by 1 × recrystallization of *C*; *E* sample prepared by 1 × recrystallization of *D*.

perature as the reactor. Air flow rate was measured with a calibrated wet gas flow meter[1] and maintained within 5 cm.^{3} sec.$^{-1}$ of the desired flow rate. Tubing was Pyrex glass with short pieces of Tygon used for connections.

Water was distilled twice from a Pyrex apparatus and stored not longer than 12 hours under nitrogen atmosphere. Prior to use, this water was once again distilled and used within 4 hours for making solutions, filling gas scrubbers, and rinsing equipment. Sodium sulfite was recrystallized from distilled water and dried at 100° under vacuum. N,N-dimethylformamide and N,N-dimethylacetamide were spectroquality reagents (Matheson Coleman, and Bell).

Carbon Dioxide Removal from Air Supply.—Air was passed through three thermostated scrubbing towers containing water; flow rate was maintained at 50 ± 5 cm.^{3} sec.$^{-1}$ This air was conducted through the standard reactor which contained 0.1 meq. sodium hydroxide in 300 ml. triple distilled water. The reactor was maintained at 25 ± 0.01° and stirred at 1000 r.p.m. Samples were periodically removed for pH measurement. The procedure was repeated with another 300-ml. volume of solution containing 0.1 meq. hydroxide ion through which air scrubbed free from carbon dioxide by passage through (*a*) sodium hydroxide solution, (*b*) sulfuric acid solution, and (*c*) triple distilled water was conducted. After 90 minutes with no significant change in pH of the basic solution, air supply to the reactor was conducted through water scrubbers.

Effect of Air Flow Rate.—Three-hundred ml. of 0.02 *M* sodium sulfite contained in the standard reactor was stirred at 1000 r.p.m. at 25 ± 0.01°. Air (CO_2 free) was introduced through a medium glass frit beneath the surface of the stirred fluid at varying flow rates. Samples were removed periodically through the sample port with a syringe. Total sulfite concentration was determined iodometrically. The pH was determined using a Beckman GS pH meter.

Sulfite as a Function of Time.—The standard reactor was used for all studies. Three-hundred ml. of sulfite solution was stirred at 1000 r.p.m. at 25 ± 0.01° while water-saturated, carbon dioxide-free air was introduced at 50 ± 5 cm.^{3} sec.$^{-1}$ beneath the surface of the fluid. Total sulfite concentration of samples was determined iodometrically. The pH

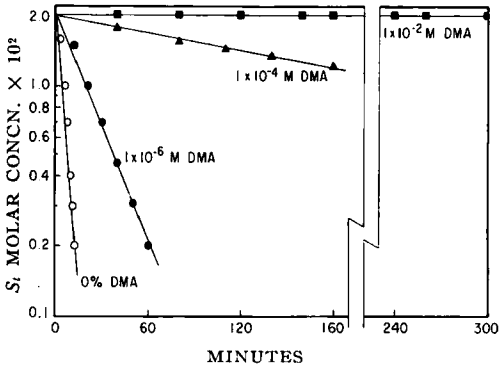

Fig. 4.—Inhibitory action of N,N-dimethylacetamide (DMA) on sulfite oxidation (0.02 *M*) in standard reactor stirred at 1000 r.p.m. at 25°. Air (CO_2-free) flow rate: 50 cm.^{3} sec.$^{-1}$

of samples removed from the reactor was determined with a Beckman GS pH meter.

RESULTS AND DISCUSSION

Removal of carbon dioxide as well as acidic or basic contaminants from air supplied to the reactor was especially important inasmuch as the aqueous sulfurous acid system is known to be sensitive to a wide variety of inhibitors and catalysts. Air contains about 0.03% by volume of carbon dioxide; thus, air flow rates around 3 L./min. result in the introduction of about 1 ml. of carbon dioxide per minute into the reactor. Effectiveness of the gas

[c] m = molar concentration of inhibitor; A and B constants for each inhibitor: (DMF): $A = 0.5 \times 10^{-6}$, $B = 1 \times 10^{-6}$; (DMA): $A = 0.25 \times 10^{-6}$, $B = 1 \times 10^{-6}$.

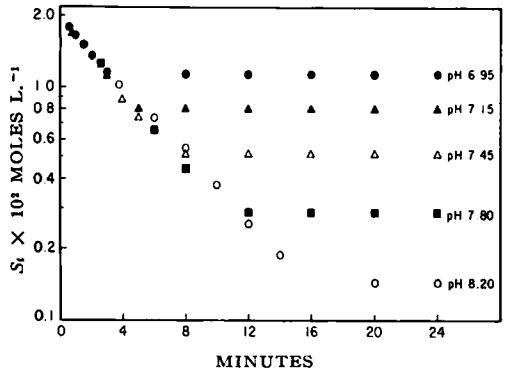

Fig. 5.—Effect of initial pH on oxidation rate of 0.02 *M* sodium sulfite at 25°. Standard reactor stirred at 1000 r.p.m. with CO_2-free air (50 cm.^{3} sec.$^{-1}$).

scrubbers in removing carbon dioxide from the air supply is shown in Fig. 1. Air introduced at a rate of 3 L./min. into a weakly basic solution contained in the reactor caused a rapid increase in hydrogen ion concentration of the solution; however, passing air through gas scrubbers effectively removed carbon dioxide: the pH of the solution changed little even after 270 L. of air had passed through it.

Preliminary tests showed that diffusion of oxygen was not a controlling factor with stirring rates greater than about 800 r.p.m. when the air flow rate was maintained at approximately 50 cm.^{3}/sec. Effect of air flow rate when the rate of stirring was held constant at 1000 r.p.m. is shown in Table I and Fig. 2. Flow rates greater than 38 cm.^{3} sec.$^{-1}$ appear to cause no significant variation in the rate of oxidation. It was therefore concluded that diffusion of oxygen was not a controlling factor in experiments in which the air flow rate was maintained at 50 ± 5 cm.^{3} sec.$^{-1}$ and the solution stirred at 1000 r.p.m.

Specific first-order rate constants for the oxidation of five different sodium sulfite solutions in the presence of air are shown in Table II. Recrystallization of the sodium sulfite effected a significant change in the rate of oxidation of but one sample. Order of the reaction with respect to oxygen was not experimentally determined. Nevertheless, a very favorable comparison can be made between these data obtained from air oxidation studies and Fuller and Crist's data (10) obtained in a pure oxygen system. Concentration of dissolved oxygen in water in equilibration with the pure gas at atmospheric pressure is approximately five times greater (11, 12) than the concentration of dissolved oxygen in equilibrium with air at atmospheric pressure. Assuming a first-order dependence with respect to dissolved molecular oxygen, the observed rate of reaction in the presence of air should be one-fifth that which is observed in the presence of oxygen. Thus, the specific reaction rate constant in pure oxygen is given by Fuller and Crist as 13×10^{-3} sec.$^{-1}$; one-fifth of this value is 2.6×10^{-3} sec.$^{-1}$, corresponding to the rate constant for the reaction in the presence of air. This latter theoretical value shows close agreement with the average experimental value 2.86×10^{-3} sec.$^{-1}$ reported in Table II.

Inhibitory effect of small amounts of N,N-dimethylformamide (DMF) and N,N-dimethylacetamide (DMA) on sulfite oxidation is shown in Figs. 3 and 4. Oxidation of sulfite is so inhibited in the presence of either 0.01 *M* DMF (0.73 mg. ml.$^{-1}$) or 0.01 *M* DMA (0.87 mg. ml.$^{-1}$) that no detectable reaction takes place within 380 minutes (ten half-lives of the noninhibited reaction). Comparison of inhibitory effects is shown in Table III in which the ratio of the first-order rate for the inhibited reaction, k_2, to the uninhibited reaction, k_1 is presented. The inhibitory effect of these amides on sulfite oxidation may be described with the following equation

$$\frac{-d(S_t)}{dt} = \frac{k_1(S_t)A}{B + m} \qquad \text{(Eq. 1)}$$

where S_t is the total sulfurous acid species, k_1 is the specific rate constant for the uncatalyzed reaction, 2.88×10^{-3} sec.$^{-1}$, m is the molar concentration of additive, and A and B are constants. The form of this equation describing sulfite inhibitors was first employed by Bäckström (13) and later modified by Fuller and Crist (10) in which they found $B = A$ for mannitol inhibition over a 10^5-fold concentration range. Their modification of the empirical inhibitory equation (Eq. 1) has found considerable application in describing sulfite inhibitors (1, 14).

Effect of initial hydrogen ion concentration on the rate and course of sulfite oxidation is shown in Fig. 5. Absolute initial rate of loss of sulfurous acid species, $-d(S_t)/dt$, is very nearly the same over a rather wide range of initial hydrogen ion concentrations as shown in Table IV. The course of the reaction, however, appears to be determined by the initial pH: higher hydrogen ion concentrations decreasing the total amount of sulfurous acid species oxidized during the time period of the experiment.

[a] $S_t = [HSO_3^-] + [SO_3^{2-}]$. [b] Calcd.: $[HSO_3^-] = S_t - SO_3^{2-} = S_t - \frac{S_t}{\left[\frac{[H^+]}{Ka'_2} + 1\right]}$. Apparent second ionization constant of sulfurous acid; $K_{HSO_3^-}$ 8.2 + 10^{-8}. [c] Experimentally determined $[H^+]$ except for calculated values shown in brackets.

The region at which the rate of oxidation *appears* to be invariant corresponds to conditions where the sulfurous acid species is present almost wholly as hydrogen sulfite, HSO_3^-, as shown in Table V.

At first glance one may intuitively infer that sulfite species are selectively oxidized. This is patently incorrect since it leads to the improbable conclusion that bisulfite species are not air oxidizable. It was pointed out by Abel (9) that the apparent course of the oxidation of mixed sulfurous acid species

$$\begin{array}{r} O_2 + 2HSO_3^- \rightarrow 2HSO_4^- \\ 2SO_3^{2-} + 2HSO_4^- \rightarrow 2HSO_3^- + 2SO_4^{2-} \\ \hline O_2 + 2SO_3^{2-} \rightarrow 2SO_4^{2-} \end{array}$$

is a consequence of the different strengths (12) of the two acids, HSO_3^- and HSO_4^-

$$\frac{K_{HSO_3^-}}{K_{HSO_4^-}} = \frac{[SO_3^{2-}]\,[HSO_4^-]}{[SO_4^{2-}]\,[HSO_3^-]} = \frac{6.24 \times 10^{-8}}{2 \times 10^{-2}} = 3.12 \times 10^{-6}$$

Thus, the oxidation of a solution containing both bisulfite and sulfite ions will always appear to change in total amount of sulfurous acid species, S_t, at the expense of the sulfite species.

The mechanism of sulfurous acid salt oxidation in aqueous systems has been discussed in rigorous detail by Abel (9), and the general aspects of kinetics and mechanism have been the subject of a recent review (1). Abel derived theoretically an expression describing the effect of hydrogen ion concentration on sulfite oxidation

$$-\frac{d(S_t)}{dt} = \frac{g[HSO_3^-]}{\sqrt{[H^+]}} \qquad \text{(Eq. 2)}$$

Validity of this equation was proved by demonstrating that it would describe Fuller and Crist's highly reliable experimental data on sulfite oxidation in presence of pure oxygen (9). Evaluation of g, the catalytic constant, for a pure oxygen system gave the value 8.7×10^{-6} (mole/L.)$^{1/2}$ sec.$^{-1}$ Since this value is proportional to the rate of loss of sulfurous acid species, S_t, and since we may assume a first-order dependency of the rate on dissolved oxygen concentration, air systems in which dissolved oxygen is one-fifth that of pure oxygen systems should yield a value of about 1.8×10^{-6} (mole/L.)$^{1/2}$ sec.$^{-1}$ Experimentally determined values of the constant, g, shown in Table IV appear to stand in reasonable agreement with this value.

The standard oxidation reactor employed in this study appears to provide reproducible and reliable data which are consistent with other carefully done independent studies on sulfite oxidation. Kinetics of the sulfite oxidation process are adequately described by Abel's theoretically derived equations which have received but little attention in pharmaceutical literature. This study corroborates much of Abel's mechanistic interpretations and kinetic expressions.

Potentiometric Determination of Sulfite Oxidation Rates

By LOUIS C. SCHROETER

Solutions containing hydrogen sulfite, HSO_3^-, and sulfite, SO_3^{2-}, species appear to undergo oxidation at the expense of the divalent anion; this is a consequence of the different strengths of the two acids, HSO_3^- and HSO_4^-. A theoretical equation has been derived which permits calculation of the rate of loss of total sulfurous acid species $[-d(S_t)/dt]$ from a pH-time plot of the oxidizing system. Rapid and reproducible rate studies of oxidizing sulfurous acid salt systems have been made possible through the development of an automated apparatus. Applications of the sensitive radical mediated oxidizing sulfite system for detecting presence of a wide variety of compounds in p.p.m. range are discussed. Empirical equations can be used to obtain semiquantitative analyses of compounds which inhibit the rate of sulfite oxidation in low (10^{-6} M) concentrations.

OXIDATION OF AQUEOUS solutions of sulfurous acid salts in the presence of air proceeds by a free radical chain mechanism; compounds capable of breaking the reaction chain serve as effective inhibitors of the oxidative process (1). Organic compounds in rather dilute solution (10^{-6} to 10^{-4} M) representing the following wide variety of classes are known to inhibit sulfite oxidation: acids (2), alcohols, glycols, mono- and polysaccharides (3–6), amines (7–10), amides (11), aldehydes (2), alkaloids (12), ketones (2), indoles (3), phenols and quinones (13, 14). Inorganic anions such as arsenite, antimonite, phosphite, and cyanide (3, 12) may function as chain terminators; the ammonium cation has been reported to be an effective inhibitor (12). Inhibitory action of these diverse compounds on sulfite oxidation which is now generally interpreted in terms of radical chain termination has been known for well over 60 years as shown by Young's observation (12): "... this inhibitive action is characteristic to a greater or less degree of all organic matter, and, in addition, of many nitrogen compounds not organic."

Most studies of sulfite oxidative behavior have been carried out in a qualitative manner which reflects the difficulty inherent in designing experiments to study free radical solution reactions in a rigorous manner. However, certain investigators, notably Bäckström (4, 6), have exercised greater care in experimental procedures and have treated data mathematically and offered evidence to support mechanisms. Various empirical equations have been used to describe bisulfite inhibition (15); most take the form

$$-\frac{d(S_t)}{dt} = \frac{A}{B + m}\, k_1 \cdot S_t \qquad \text{(Eq. 1)}$$

where S_t is the total sulfurous acid species, k_1 is the specific rate constant for the uncatalyzed reaction, and m is the molar concentration of additive. The constants A and B generally have values the order of 10^{-5} and are specific for each compound or class of compounds although the constants, A and B, are equal (10^{-5}) for the case of mannitol inhibition (5).

The relationship shown in Eq. 1 between the observed rate of reaction for sulfite oxidation and the molar concentration of inhibitor present in solution permits one to determine the concentration of inhibitor by comparing the rate constants for the standard k_1 and the inhibited k_2 reaction

$$\frac{k_2}{k_1} = \frac{A}{B + m} \qquad \text{(Eq. 2)}$$

Application of this equation to the determination of organic substances (m) in solution requires a knowledge of the values of the constants A and B. These constants can be evaluated from rate data obtained in systems containing known amounts of organic compound. However, good approximations may be made by assuming $A = B = 10^{-5}$. The oxidizing sulfite system can thus serve as a unique analytical method for the detection and approximate determination of organic compounds in dilute aqueous solution.

Heavy metal ions are known to function as catalysts of the bisulfite oxidative process. The mechanism proposed (1) for the catalytic effect of copper ions is typical

$$\begin{array}{r} 2(2Cu^{2+} + SO_3^{2-} + H_2O \rightarrow 2Cu^{+} + SO_4^{2-} + 2H^{+}) \\ 4Cu^{+} + O_2 + 4H^{+} \rightarrow 4Cu^{2+} + 2H_2O \\ \hline 2SO_3^{2-} + O_2 \rightarrow 2SO_4^{2-} \end{array}$$

Abel (16) has advanced a strong case for the second sequence as the rate-determining step. The mechanism assumes a steady state production of radicals and a time-dependent reaction with cuprous ion

$$Cu^{+} + OH \rightarrow Cu^{2+} + OH^{-}$$

Received May 7, 1962, from the Pharmacy Research Section, Product Research and Development, The Upjohn Co., Kalamazoo, Mich.
Accepted for publication October 3, 1962.

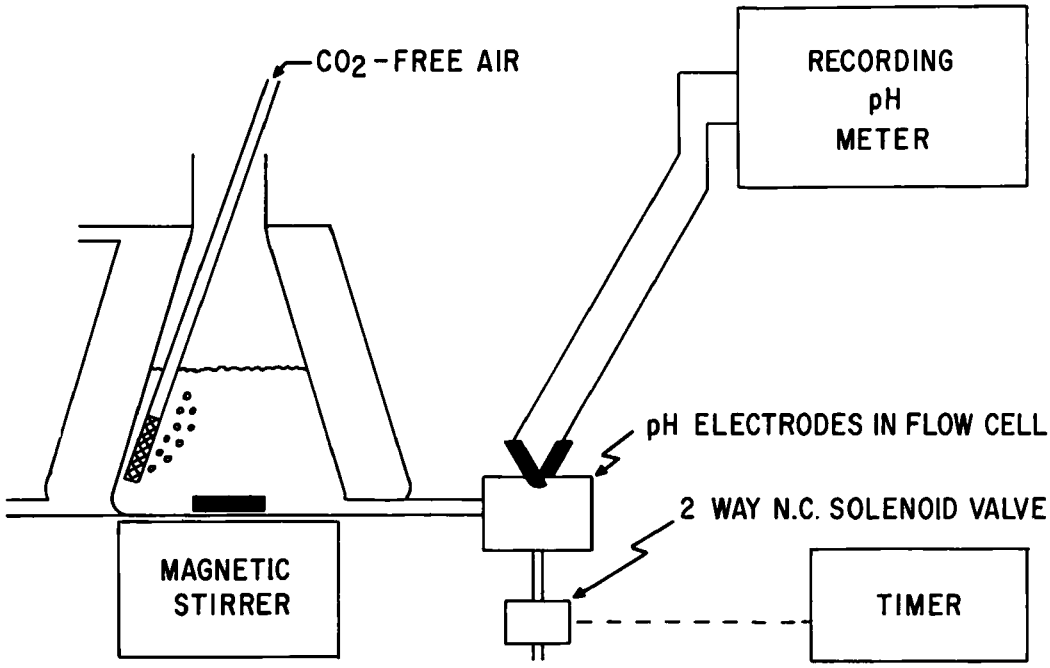

Fig. 1.—Arrangement of oxidation vessel for automatic pH monitoring of samples.

Abel's mechanism is lucid and well documented, but most important, it adequately describes Fuller and Crist's (5) experimental data.

Nonmetal ions may also function as catalysts of the oxidation of sulfurous acid salts. For example, thiosulfate, $S_2O_3^{2-}$, may participate in a chain process with bisulfite and sulfite ions (17). Mechanism of the reaction appears to involve trithionate ion, $S_3O_6^{2-}$, which arises from the interaction of thiosulfate with a OH, O_2^-, or HSO_3 radical

$$S_2O_3^{2-} + SO_3^{2-} + 2OH + 2H^+ \rightarrow S_3O_6^{2-} + 2H_2O$$

The trithionate ion is readily hydrolyzed to thiosulfate and sulfate

$$S_3O_6^{2-} + H_2O \rightarrow S_2O_3^{2-} + SO_4^{2-} + 2H^+$$

resulting in marked catalysis of the oxidative process.

Systematic investigations of the catalytic and inhibitory effect of various substances on the oxidative rate of sulfurous acid salts have been hampered in the past by the difficulty involved in providing reproducible and reliable systems. It is the purpose of this investigation to describe a reasonably simple yet highly reliable experimental technique and automated apparatus for studying the progress of air oxidation of sulfite systems and to demonstrate the analytical potential of these systems for detecting the presence of very low concentrations of organic compounds in aqueous systems.

TABLE I.—RELATIONSHIP BETWEEN INITIAL AND FINAL[a] BISULFITE CONCENTRATION IN OXIDIZED SULFUROUS ACID SALT SYSTEMS

	$[H^+] \times 10^8$	$[HSO_3^-] \times 10^{2b}$	$[SO_3^{2-}] \times 10^{2c}$
Initial	11.2	1.13	0.87
Final	3100	1.13	0.00
Initial	7.1	0.91	1.09
Final	2400	0.80	0.00
Initial	3.6	0.60	1.40
Final	2100	0.52	0.00
Initial	1.6	0.33	1.67
Final	1600	0.28	0.00
Initial	0.63	0.14	1.86
Final	1300	0.14	0.00

[a] "Final" means after 1200 seconds' exposure to standard reaction conditions with no further substantial reaction occurring. *c.f.*: Schroeter, L. C., THIS JOURNAL, 52, 559 (1963). [b] Calculated with the expression

$$[HSO_3^-] = S_t - SO_3^{2-} = S_t - \frac{S_t}{\left(\frac{[H^+]}{K_{a_2}} + 1\right)}$$

Experimentally determined apparent second ionization constant, $K'_{HSO_3^-}$, equals 8.4×10^{-8}. [c] Total sulfurous acid species $[HSO_3^-] + [SO_3^{2-}]$, determined iodometrically.

EXPERIMENTAL

Apparatus and Material.—Air oxidation of sodium sulfite solutions was carried out in a thermostatted vessel of the design shown in Fig. 1. The sampling port was placed tangentially to the vessel wall to take advantage of the centrifugal pumping action imparted to the liquid by the magnetic stirring bar. Samples were periodically removed from the reaction solution and passed through a flow cell containing micro electrodes (glass-calomel); this was done automatically through the use of a timer-controlled solenoid valve.

Air supplied to the reactor was passed through a filter and molecular sieve to remove suspended solid

and liquid particles. The air stream was then conducted through three gas scrubbing towers in series: *a*, sodium hydroxide solution, *b*, sulfuric acid solution; *c*, triple distilled water; gas scrubbers were maintained in a thermostat at the same temperature as the reactor. Flow rates were measured with a calibrated wet gas flow meter[1] and maintained within 5 cm.^{3} sec.$^{-1}$ of the desired flow rate. Tubing was Pyrex glass with short pieces of Tygon used for connections.

Triple distilled water produced from a Pyrex apparatus and stored not longer than 12 hours under nitrogen prior to use was employed for making all solutions and rinsing equipment. Sodium sulfite, reagent grade, was recrystallized twice from distilled water and dried at 90° under vacuum. All other materials were of reagent grade.

The standard reactor was used for all studies. Three-hundred and fifty ml. of sulfite solution was stirred at rates greater than 1000 r.p.m. at 25 ± 0.05° while water-saturated, carbon dioxide-free air was introduced at 50 ± 5 cm.^{3} sec.$^{-1}$ through a medium glass frit beneath the surface of the fluid. The pH of samples removed from the reactor by the automatic sampling system was determined manually with a Beckman GS pH meter, or automatically with a recording Beckman Zeromatic pH meter, or with a Sargent model D titrator. Total sulfurous acid salt concentration of samples was determined iodometrically.

RESULTS AND DISCUSSION

Free radical systems such as oxidizing bisulfite solutions are extraordinarily sensitive to the presence of extremely small amounts of compounds which may act either as inhibitors or catalysts. For example, it was found that certain glass-calomel combination electrodes placed directly in the oxidizing system would not alter or affect the rate of sulfite oxidation while other glass-calomel electrodes caused grossly erratic results. Erratic effects appeared to be related to different inherent diffusion rates of electrolyte solution from the calomel reference electrode. For this reason a pH flow cell was used to measure samples withdrawn from the solution. Measurement of pH was generally made with the more sensitive Beckman GS pH meter; however, the arrangement shown in Fig. 1 where a recording pH meter is employed yields reliable data for most studies.

The relationship between initial and final bisulfite concentration in air-oxidized mixed sulfurous acid species (HSO_3^- and SO_3^{2-}) is shown in Table I. Total sulfurous acid species present in solution, $S_t = HSO_3^- + SO_3^{2-}$, was determined by iodometric titration; concentration of bisulfite species was calculated with

$$[HSO_3^-] = S_t - SO_3^{2-} = S_t - \frac{S_t}{\left[\frac{[H^+]}{Ka'_2} + 1\right]} \quad \text{(Eq. 3)}$$

where Ka'_2, the apparent second ionization constant of sulfurous acid experimentally determined in 0.02 *M* solution at 25°, was 8.4×10^{-8}.

[1] Flowrator—Fischer-Porter Co., Hatboro, Pa.

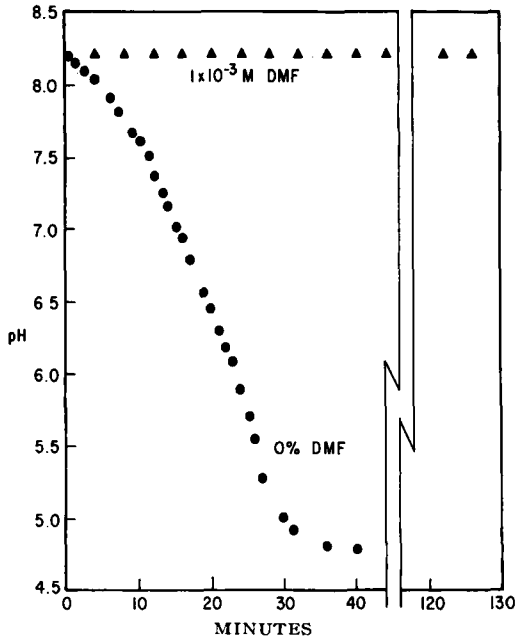

Fig. 2.—The pH of 0.02 *M* sodium sulfite solutions subjected to standard oxidizing conditions at 25°.

The remarkable constancy of the concentration of bisulfite in these systems, $C_{HSO_3^-}$ initial = $C_{HSO_3^-}$ final, is not a consequence of its inability to be oxidized. This reflects the different strengths of the two acids, $K_{HSO_3^-} = 6.24 \times 10^{-8}$, $K_{HSO_4^-} = 2 \times 10^{-2}$.

Solutions containing both bisulfite and sulfite species will always appear to undergo initial rapid oxidation at the expense of the sulfite species

$$\begin{array}{r} HSO_3^- + {}^1/_2O_2 \rightarrow HSO_4^- \\ HSO_4^- + SO_3^{2-} \rightarrow HSO_3^- + SO_4^{2-} \\ \hline SO_3^{2-} + {}^1/_2O_2 \rightarrow SO_4^{2-} \end{array}$$

Thus, total sulfurous acid species, S_t, present in the solution at any time, t, will be approximately described by

$$S_t \cong C_{SO_3^{2-}} + C_{HSO_3^-} \text{ initial} \quad \text{(Eq. 4)}$$

or its equivalent form

$$S_t \cong C_{HSO_3^-} \text{ initial} \left[\frac{Ka'_2}{[H^+]} + 1\right] \quad \text{(Eq. 5)}$$

Using Eq. 5, total sulfurous acid salt concentration may be described by potentiometric determination of hydrogen ion activity if the ionization constant is known; initial bisulfite concentration is determined by material balance and Eq. 3.

The assumption of constancy of bisulfite concentration in air-oxidized systems containing both mono- and di-valent sulfurous acid species is strongly supported by experimental evidence presented in Table I. However, it is important to qualify this assumption by indicating that the final bisulfite concentration refers to conditions such that no substantial change in total sulfurous acid salt concentration takes place within the time period of two half-lives of the initial rapid reaction. Otherwise, the assumption would lead to

the inference that a solution containing only bisulfite species is not subject to oxidation. This is not the case. The lowered rate of oxidation of sulfurous acid systems containing bisulfite, HSO_3^-, as the predominant species is a consequence of the hydrogen ion effect on the rate equation

$$-\frac{d(S_t)}{dt} = \frac{g[HSO_3^-]}{\sqrt{[H^+]}} \quad \text{.(Eq. 6)}$$

where g, the catalytic constant, has the value 2.0×10^{-6} (moles/L.)$^{1/2}$ sec.$^{-1}$ in air-oxidized systems (11). Thus, at pH 4 where bisulfite is the dominant species ($[SO_3^{2-}]/[HSO_3^-] = 6.24 \times 10^{-4}$), the rate of loss of sulfurous acid species, $-d(S_t)/dt$, is at least an order of magnitude less than at pH 8 ($[SO_3^{2-}]/[HSO_3^-] = 6.24$).

Change in pH accompanying oxidation of a solution containing initially 1.86×10^{-2} M sulfite and 0.14×10^{-2} M bisulfite is shown in Fig. 2. The solution containing 1×10^{-3} M N,N-dimethylformamide (DMF) did not change pH when subjected to the standardized oxidation conditions for a period of over 2 hours, nor did the total available sulfurous acid salt concentration (0.02 M) as determined by iodometric titration of samples change during this period. Inhibitory action of DMF has been reported in a prior communication (11).

The solution containing only sulfurous acid species underwent a change in pH from 8.2 to 4.8 as oxidation progressed. Total available sulfurous acid species, S_t, present in solution as a function of time was determined simultaneously by rapid iodometric titration of samples withdrawn from the reaction as shown in Fig. 3 in which solid circles represent experimentally determined values. Reaction profile shows an initial lag time of about 5 minutes due to stirring effects: the volume of solution contained in the reactor was increased

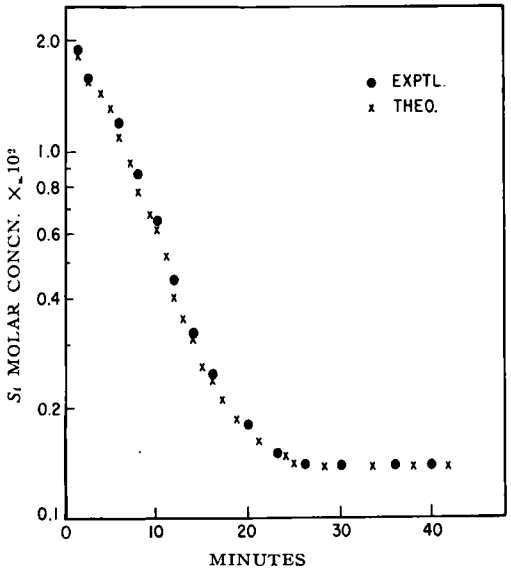

Fig. 3.—Total sulfurous acid salt concn. as a function of time in solution subjected to standard oxidizing conditions. Initial soln. composition: $[HSO_3^-] = 0.14 \times 10^{-2}$ M; $[SO_3^{2-}] = 1.86 \times 10^{-2}$ M

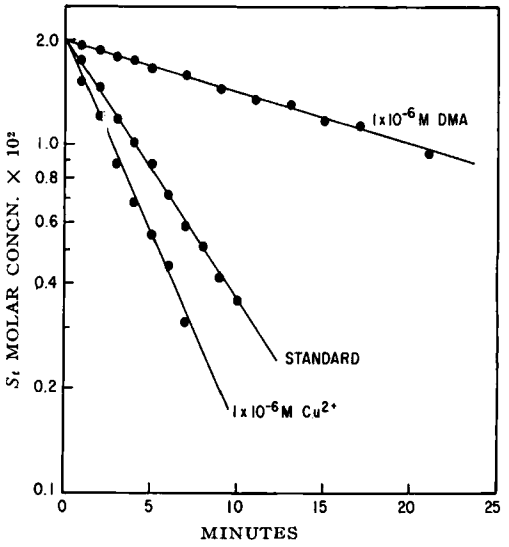

Fig. 4.—Effect of inhibitor (1×10^{-6} M DMA) and catalyst (1×10^{-6} M $CuSO_4$) on rate of sulfite oxidation. Initial solution composition: $[HSO_3^-] = 0.14 \times 10^{-2}$ M; $[SO_3^{2-}] = 1.86 \times 10^{-2}$ M.

from the standard 350 ml. to 450 ml. to illustrate the importance of controlling not only the stirrer speed but also all other factors (volume, vessel geometry, etc.) which may influence effective rates of stirring and dissolution of oxygen.

After the initial 5-minute lag period, the reaction appeared to follow a first-order dependency on total sulfite for about 75% of the reaction with a specific rate constant (2.67×10^{-3} sec.$^{-1}$) comparable to that found in earlier studies (11). As the solution became more acid, the rate of oxidation slowed rapidly and the total sulfurous acid concentration approached the value 0.14×10^{-2} M. Since the pH of the solution at this point was 4.8, this value corresponded almost entirely to bisulfite species. This stands in qualitative support of the assumption that bisulfite concentration appears to remain constant. Theoretical points shown as crosses in Fig. 3 were calculated from potentiometric data shown in Fig. 2 using Eq. 5. Good agreement between experimental and theoretical values attests to the validity of Eq. 5 and the soundness of explicit assumptions upon which it is based.

Analytical application of the automated procedure for detecting the presence of very low concentrations of organic compounds or heavy metal ions is shown in Fig. 4. Apparent first-order plots exhibiting no detectable initial lag periods were obtained under standard operating conditions. Ratio of the specific rate constant, k_2, for the reaction containing 1×10^{-6} M N,N-dimethylacetamide (DMA) to the specific rate constant, k_1, for the standard reaction was calculated

$$\frac{k_2}{k_1} = \frac{5.75 \times 10^{-4} \text{ sec.}^{-1}}{2.80 \times 10^{-3} \text{ sec.}^{-1}} = 0.205.$$

This ratio and reported values (11) for the constants ($A = 0.25 \times 10^{-5}$; $B = 1.0 \times 10^{-5}$) were used in Eq. 2 to calculate the concentration of DMA. The concentration of DMA found by rate data was

2.2×10^{-6} M which agrees within a factor of 2 with the theoretical amount (1×10^{-6} M) present; this appears to be the practical limit of sensitivity of this kinetic analytical system. While the method is semiquantitative, it will detect the presence of many organic compounds in very dilute (10^{-8} to 10^{-6} M) solutions and establish concentrations within an order of magnitude of the true value.

CONCLUSIONS

Radical processes such as oxidizing sulfurous acid salt systems are sensitive to many compounds which act to inhibit or accelerate the chain reaction. Characteristically these compounds are effective in significantly modifying the rate of the oxidation even in extremely high dilutions (10^{-6} M). Rate determinations of uncatalyzed reactions can be made in a matter of minutes with the automated apparatus; rates observed in air oxidized systems can be increased by a factor of 5 by using pure oxygen (Henry's law).

Establishment of a reproducible sulfite-bisulfite system in a standard automated reactor such as described in this report offers a unique detecting system. A wide variety of compounds including acids, alcohols, glycols, polysaccharides, amines, aldehydes, alkaloids, ketones, indoles, phenols and quinones, and *possibly many other classes of organic compounds will measurably inhibit the rate of oxidation in very low concentration.* Likewise, heavy metal ions in parts per million can be detected by observing their catalytic effect on the rate of oxidation. Presence of these various compounds in water or air samples (after bubbling through water) can be readily detected. Semiquantitative relationships between concentration of inhibitor and oxidation rate constant may be established with an empirical equation of the form (Eq. 2).

Role of Serotonin in the Thyroid Action of Reserpine

By B. B. WILLIAMS and S. T. COKER

The possible role of serotonin in the thyroid action of reserpine was studied in intact rats. Thyroid alteration by chronic reserpine medication and by chronic pharmacological treatment designed to alter serotonin levels and activity were compared with controls by three parameters. Direct effects of reserpine and serotonin were also investigated. Some evidence for reduced thyroid activity by chronic systemic reserpine administration was provided. It was found that reserpine directly *in vitro* slightly increased I^{131} uptake, and that serotonin in direct *in vitro* tests significantly reduced it.

REPORTS of alteration of thyroid function by reserpine have been numerous. Contradictory results, however, in different experimental subjects and in use of different parameters are unexplained, and much information on mechanism is yet to be provided.

Mayer, Kelly, and Morton (1) found that a concentration of 0.083 mg./ml. of reserpine reduced the uptake of I^{131} by calf thyroid slices. Their analysis of slices following incubation indicated that the inhibition of thyroid activity was predominantly one of interference with organic binding of iodine. Ershoff (2) reported that doses of desiccated thyroid and reserpine which were nonlethal when given separately to immature rats resulted in 100% mortality within 2 weeks when given concurrently. DeFelice, *et al.* (3), using oxygen consumption as a parameter of thyroid activity, showed that the administration of reserpine for 5 days to a hyperthyroid guinea pig would lower the oxygen consumption to normal. This group also found that the administration of reserpine to euthyroid animals would lower oxygen

Role of Serotonin in the Thyroid Action of Reserpine

By B. B. WILLIAMS and S. T. COKER

The possible role of serotonin in the thyroid action of reserpine was studied in intact rats. Thyroid alteration by chronic reserpine medication and by chronic pharmacological treatment designed to alter serotonin levels and activity were compared with controls by three parameters. Direct effects of reserpine and serotonin were also investigated. Some evidence for reduced thyroid activity by chronic systemic reserpine administration was provided. It was found that reserpine directly *in vitro* slightly increased I^{131} uptake, and that serotonin in direct *in vitro* tests significantly reduced it.

REPORTS of alteration of thyroid function by reserpine have been numerous. Contradictory results, however, in different experimental subjects and in use of different parameters are unexplained, and much information on mechanism is yet to be provided.

Mayer, Kelly, and Morton (1) found that a concentration of 0.083 mg./ml. of reserpine reduced the uptake of I^{131} by calf thyroid slices. Their analysis of slices following incubation indicated that the inhibition of thyroid activity was predominantly one of interference with organic binding of iodine. Ershoff (2) reported that doses of desiccated thyroid and reserpine which were nonlethal when given separately to immature rats resulted in 100% mortality within 2 weeks when given concurrently. DeFelice, *et al.* (3), using oxygen consumption as a parameter of thyroid activity, showed that the administration of reserpine for 5 days to a hyperthyroid guinea pig would lower the oxygen consumption to normal. This group also found that the administration of reserpine to euthyroid animals would lower oxygen

Grateful acknowledgment of generous supply of drugs is made to the following manufacturers: Ciba Pharmaceutical Co., for Serpasil (reserpine); Sandoz Pharmaceuticals, for LSD; and Hoffmann-LaRoche, Inc., for Marsilid (iproniazid).

consumption. Bierwagon (4) reported that a combination of reserpine and thyroxin lowered dehydrogenase activity in thyroid tissue, but that thyrotropin in combination with reserpine prevented this dehydrogenase inhibition. Taylor (5) found that the elevation of cooling rate by reserpine in rats exposed to low temperatures was lowered by prior administration of thyroxin but not by thyrotropin. They believe this confirms that the antithyroid effect is due in part to decreased response of the gland to thyrotropin. Pittman, *et al.* (6), in clinical studies using the thyroid secretion rate as a parameter, found that reserpine reduced thyroid activity in four of nine euthyroid patients. Since this inhibition could not be demonstrated in patients maintained on exogenous thyrotropin, they suggested that reserpine altered thyroid function by diminishing thyrotropin production.

Premachandra (7) reported that no level of reserpine dosage was found (5–100 mcg./100 Gm.) which depressed thyroid function in fowl without simultaneously reducing food intake and thus inferred that thyroid inhibition at high levels of reserpine administration was due to inanition. Uchida (8) concluded from growth studies in chick embryos that reserpine had practically no antithyroid action on the embryonic thyroid.

Elkes (9) found that reserpine counteracted the decrease in thyroid I^{131} uptake induced by LSD (*d*-lysergic acid diethylamide). Results with a similar implication were reported by Kar and Boscott (10) who found that LSD depressed I^{131} uptake in rats *in vivo* and that this depressed uptake was reversed by reserpine. Vogel and Tervooren (11) reported on the basis of oxygen consumption that reserpine reinforced the increased metabolic activity induced by thyroxin in rats. Johnson (12) found that reserpine in doses of 1–4 mg./Kg. increased oxygen consumption in rats.

It is generally recognized that the effects of reserpine are not due to the direct effect of the drug alone but also to release of certain physiological amines. The purpose of this study was to determine the possible role of serotonin in the thyroid action of reserpine by comparing thyroid function alteration induced by reserpine with that observed in animals with pharmacologically altered serotonin levels and activity.

EXPERIMENTAL

Systemic Administration.—Four groups of from 16 to 25 rats each were subjected to the following dosage regimens: (*a*), reserpine, 150 mcg./Kg. daily by intramuscular injection for 28 days; (*b*), LSD, 25 mcg./Kg. daily by subcutaneous injection for 14 days, followed by 50 mcg./Kg. daily by subcutaneous injection for 14 days (dose increased to compensate for tolerance); (*c*), iproniazid, initial single dose of 60 mg./Kg. by subcutaneous injection, followed by 5-hydroxytryptophan (5HTP) 50 mg./Kg. daily for 7 days, followed by 25 mg./Kg. daily for 21 days by intraperitoneal injection (toxicity of original dose level necessitated dosage reduction); (*d*), control (no drug). Rats were healthy Sprague-Dawley males ranging in weight from 350–500 Gm. at the beginning of the experiments.

The following parameters were used to estimate alteration in thyroid function in treated animals and controls: (*a*), basal metabolic rate; (*b*), oxygen uptake of slices of liver and kidney tissue; (*c*), 1 and 2-hour I^{131} uptake by thyroid glands.

Basal metabolic rates (BMR) were calculated from oxygen consumption rate determinations carried out in a modified vacuum desiccator in a temperature-controlled room. Soda lime in the desiccator base and in wire gauze wrapped packs in the upper chamber was used for CO_2 absorption. A 10-ml. pipet attached to the desiccator evacuation outlet was used in the measurement of oxygen consumption. The animals were fasted for 12 hours, placed in the desiccator, and left for a 7-minute temperature equilibration period. Oxygen consumption rates were then determined by a stop watch measurement of the time required for a soap bubble to traverse the 10-ml. interval of the pipet. Means of such determinations were used in calculation of BMR values.

Iodine^{131} uptakes were determined by the method of Williams and Doniach (13). Rats were given 10 μc. of I^{131} by intraperitoneal injection and sacrificed by exsanguination under ether anesthesia at 1 or 2 hours following injection. Thyroids were immediately removed, transferred to planchets, and counted by 1 in. NaI (Th.) crystal scintillation detector. Activities were recorded as percentages of those counts given by a standard sample.

Uptake of oxygen by kidney and liver slices was determined by the direct Warburg manometric method. Tissues taken from animals sacrificed by exsanguination were placed in cold Krebs-Ringer phosphate solution with 0.2% glucose buffered to pH 7.4. Slices were immediately prepared by Stadie-Riggs microtome, blotted with filter paper, and weighed. The gas phase was air. Equilibration period was 10 minutes and readings were made every 15 minutes. Rate of oxygen uptake was determined on wet weight basis and expressed as μl. O_2/100 mg. of tissue per 2 hours.

***In Vitro* Administration.**—Drugs were added directly to flasks containing slices of rat thyroid in determination of direct effects on the gland as measured by I^{131} uptake during incubation. Thyroid donors were healthy Sprague-Dawley males, ranging in weight from 350–450 Gm. and differing in age by no more than 3 weeks. The animals were sacrificed by exsanguination under ether anesthesia. Thyroids were removed, sliced in cold Krebs-Ringer phosphate solution, and placed in 25-ml. flasks containing Krebs-Ringer phosphate to which had been added 0.25 μc. of I^{131} and the drug. Each flask contained the sliced pair of thyroids from a single donor. Incubations were carried out for 2 hours at 38° in a Dubnoff incubator. Six such experiments were carried out, one for each of the following: (*a*),

TABLE I.—BASAL METABOLIC RATE, THYROID I^{131} UPTAKE, AND O_2 UPTAKE BY KIDNEY AND LIVER SLICES FOLLOWING CHRONIC, SYSTEMIC DRUG ADMINISTRATION

Treatment	Dose and Route	BMR ± S.E.[a]	Thyroid I^{131} Uptake ± S.E.[a] (% of Standard) 1 hr.	2 hr.	O_2 Uptake in μl./100 mg. Tissue/2 hr. ± S.E.[b] Kidney	Liver
Reserpine	150 mcg./Kg. daily for 28 days, i.m.	36.14[c] ± 2.04 (12)	2.36 ± 0.133 (11)	4.31[c] ± 0.431 (11)	31.89 ± 1.68 (11)	15.13 ± 0.76 (12)
LSD	25 mcg./Kg. daily for 14 days followed by 50 mcg./Kg. daily for 14 days s.c.	59.01 ± 2.33 (16)	2.21 ± 0.117 (11)	3.76[c] ± 0.367 (12)	25.90 ± 1.02 (10)	15.50 ± 0.36 (13)
Iproniazid and 5HTP	Iproniazid, single dose 60 mg./Kg. s.c., followed by 5HTP, 50 mg./Kg. daily for 7 days, followed by 5HTP 25 mg./Kg. daily for 21 days, i.p.	55.51 ± 3.41 (9)	...	3.60[c] ± 0.487 (7)	23.93 ± 3.31 (5)	8.84[c] ± 0.72 (6)
Control		50.20 ± 2.10 (17)	3.34 ± 0.524 (14)	7.86 ± 1.23 (8)	26.47 ± 1.38 (11)	16.66 ± 0.29 (13)

[a] Numbers in parentheses indicate number of animals. [b] Numbers in parentheses indicate number of flasks. [c] Differs significantly from control at 95% probability.

reserpine, 0.5 mcg./ml.; (*b*), LSD, 1 mcg./L.; (*c*), serotonin, 0.5 mcg./ml.; (*d*), methimazole, 5 mcg./ml.; (*e*), thyrotropin, 0.6 m u./ml.; and (*f*), control (no drug). Concentrations were chosen which would approximate those presented to tissues on systemic administration within usual therapeutic or experimental dosage range. Eleven flasks were incubated in each experiment, ten containing thyroid slices and a standard containing no tissue. Iodine^{131} uptake for each treatment was determined by comparing activities of 0.1-ml. samples from thyroid-containing flasks with the activity of a 0.1-ml. sample taken from the standard flask. These activity differences were expressed as percentages of standard sample counts. Activities were determined by use of a scintillation detector as previously described.

RESULTS

Behavioral effects and other observable changes were recorded during the 28-day periods of systemic drug administration. Reserpine-treated animals began to present signs of decreased activity after 2 or 3 days of drug administration. Ptosis was observed in all reserpinized animals beginning during the first week and continuing through the course of the experiment. Animals receiving LSD did not demonstrate signs of extreme behavior alteration; however, there were occasional signs of erratic activity such as backing movements and purposeless activity usually occurring within 20–30 minutes after injection. Animals receiving 5HTP following iproniazid presented evidence of drug toxicity in lethargy, anorexia, and weight loss. Four animals in this group died during the first week of treatment. this lethality necessitated a reduction in dose. Signs of toxicity persisted, however, and at sacrifice, kidneys of all animals in this group were found to be reduced in size and altered in color and consistency. Microscopic examination of stained sections showed tubular damage. Because of loss of animals during the dosing period, I^{131} uptakes were limited to 2-hour determinations for this group.

Table I presents data for BMR, I^{131} uptake, and tissue slice oxygen uptake for the four groups of systemically treated rats. Table II presents data from measurement of direct effect of the several treatments on thyroid tissue slices.

TABLE II.—I^{131} UPTAKE BY THYROID SLICES ON INCUBATION WITH CERTAIN DRUGS

Drug	Concentration	Flasks, No.	Uptake %, ± S.E.
Reserpine	0.5 mcg./ml.	10	47.4[a] ± 2.1
Serotonin	0.5 mcg./ml.	10	9.4[a] ± 1.7
LSD	1 mcg./L.	10	12.0[a] ± 2.0
Methimazole	5 mcg./ml.	10	0[a]
Thyrotropin	0.6 m u./ml.	10	35.0 ± 3.3
Control	...	10	30.4 ± 6.6

[a] Differs significantly from control at 95% probability.

Two of the parameters, BMR and 2-hour I^{131} uptake, gave evidence of a decreased thyroid activity in response to chronic reserpine administration. In the direct *in vitro* tests, however, reserpine increased I^{131} uptake by thyroid slices. This increased uptake was found to be significant at 95% probability when compared with uptakes of both the control and 0.6 m u./ml. of thyrotropin.

Increasing serotonin level by chronic administration of 5HTP following an initial iproniazid injection (14, 15) failed to alter BMR and oxygen consumption of isolated kidney slices but did reduce significantly the uptake of I^{131} at 2 hours and reduced the consumption of oxygen by liver slices. Serotonin added directly to incubating thyroid slices also significantly reduced I^{131} uptake.

Rats given LSD for 28 days showed a reduced 2-hour thyroid I^{131} uptake, but BMR values and oxygen uptakes by kidney and liver slices were not significantly different from controls. The direct effect of LSD on thyroid slices was a decrease in uptake of I^{131}.

DISCUSSION

Some evidence of a reduced rat thyroid activity in response to chronic reserpine administration was provided by reduction in both BMR and 2-hour I^{131} uptake. However, failure of reserpine to reduce I^{131} uptake of incubating thyroid slices when added directly to the medium suggested that the effects of reserpine on the thyroid were not direct. Since reserpine releases serotonin from binding sites and is believed to effect many of its actions through this medium, the direct effect of serotonin on thyroid slice I^{131} uptake was measured. Results of this

experiment indicated a significant capacity on the part of serotonin to reduce thyroid activity. This suggests that the thyroid effects of chronically administered reserpine are accomplished through the intermediation of serotonin. If this were true it might be expected that LSD through serotonin antagonism (16, 17) would increase thyroid activity, and that an increase in serotonin blood level induced by monoamine oxidase inhibition and 5HTP would reduce thyroid activity. However, the data obtained in testing these assumptions were not conclusive or consistent. There are possible explanations for failure of these attempts at confirmation. That both LSD and serotonin decreased I^{131} uptake by thyroid on *in vitro* administration may be only further evidence for the lack of specific antagonism between the two. In evaluating the role of free serotonin maintained in excess as presumably was accomplished by use of the drug combination, the possibility that toxicity may have altered parameters must be considered.

The evidence for a thyroid inhibiting effect for LSD is consistent with results obtained by others (9, 10). The significance of this in relation to the reserpine mechanism is not apparent. The finding that reserpine *in vitro* significantly increased I^{131} uptake by thyroid slices was not in agreement with Mayer, *et al.* (1), who used calf thyroid and a considerably higher concentration of reserpine. This phase of the work will receive further attention as also will the lethality of the combined effects of iproniazid and 5HTP.

Esters of Bicyclic Aminoalcohols IV

Local Anesthetic Esters Derived from 2-Hydroxyquinolizidine

By CHANDULAL N. PATEL and TAITO O. SOINE

Several pairs of substituted benzoate esters derived from 2-hydroxyquinolizidine and 3-(2-methylpiperidino)propanol were synthesized in order to enable comparison of each pair for relative duration of local anesthetic activity in the rabbit cornea. The tests indicate, in general, the 2-hydroxyquinolizidine esters provided a greater duration of activity than the corresponding esters of 3-(2-methylpiperidino)-propanol. Some of the implications of this increase in duration of action with respect to the structures are discussed.

RHODES AND SOINE (1), in 1956, reported the synthesis of a series of 2-hydroxyquinolizidine esters specifically designed as anticholinergics. The selection of 2-hydroxyquinolizidine as the aminoalcohol was based on its formal relationship to tropine with respect to the relative positions of the amine and alcohol functions. No mention was made of local anesthetic activity although the relationship of 2-hydroxyquinolizidine to ecgonine would be analogous. In 1960, Counsell and Soine (2) described the preparation of selected esters of 1-, 2-, and 3-hydroxyquinolizidines and (among the activities reported) noted local anesthetic activity associated with most of their esters. In connection with the comparative local anesthetic activities, two observations were of particular significance with respect to the present report: *a*, the activity of 2-hydroxyquinolizidine benzoate (I) was 3 and 5 times greater, respectively, than the activities of the isomeric 1- and 3-hydroxyquinolizidine benzoates, and *b*, the activity of I was 1.72 times greater than that of piperocaine (II) which was used as the standard for compari-

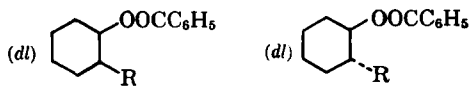
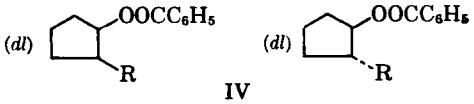
son. The latter observation was of interest because I could be looked upon as a closed ring analog of II. It was of further interest to note that the 2-methyl group in the piperidine moiety of II seems to have a direct influence upon activity inasmuch as its absence leads to inactivity (3). If one considers that the 2-methyl group of II imposes a degree of steric restriction to the esterified alkyl chain attached to the nitrogen of II it is immediately apparent that the closure of the esterified alkyl chain into a ring system as in I imposes still further steric restriction. That steric requirements for local anesthetic activity may be of importance is illustrated by several observations. Among these may be cited the findings of Mannich, *et al.* (4), with respect to the differing activities of the *cis* and *trans* isomers of III and IV wherein one form



III



IV

(R = —$CH_2N(CH_3)_2$)

(not specified) possesses strong activity and the other has either no activity or a greatly lessened activity. Likewise, the recent findings of Nachmansohn in connection with his demonstrations of the chemical basis of nerve activity (5) would seem to imply that structural specificity is important in interaction of the anesthetic base with receptor protein. Apparently, however, the structural specificity does not encompass optical isomers inasmuch as these have been shown in virtually all cases to be of essentially the same activity. Another factor in enhanced activity may be envisioned because esters of secondary alcohols, for steric reasons, are less rapidly hydrolyzed than corresponding esters of primary alcohols which would be expected *a priori* when comparing I and II.

These observations have led us to attempt to determine whether an enhanced duration of anesthetic activity of the 2-hydroxyquinolizidine-type esters over the 3-(2-methylpiperidino)-propanol esters was a general trend. To accomplish this purpose it was necessary to synthesize not only selected esters of the former but also the corresponding esters of the latter for direct comparison. The esters to be synthesized were selected on the basis of the previously reported activities by McElvain and Carney (6) of the 3-(2-methylpiperidino)propanol esters. The rabbit cornea as utilized by McElvain and Carney was the test object in the present study.

DISCUSSION

The synthetic method employed for 2-hydroxyquinolizidine was essentially that of Counsell and Soine (2) with incorporation of certain modifications in the synthesis of the intermediate ethyl 2-pyridyl acetate as described by Winterfeld and Flick (7). 3-(2-Methylpiperidino)propanol was synthesized by the method of McElvain and Carney (6). The necessary methyl esters were purchased where possible or synthesized by standard methods wherever necessary. The synthesis of esters of both aminoalcohols was carried out most conveniently by the ester-interchange method as described by Counsell and Soine (2). This method, for benzoate esters, has proved to be superior to the usual method of interacting an acid chloride with the aminoalcohol. All esters were prepared as hydrochlorides and crystallized to constant melting points. In general, it was found that the ester hydrochlorides derived from 2-hydroxyquinolizidine were less water soluble than the corresponding esters derived from 3-(2-methylpiperidino)propanol. Indeed, it was found impossible to carry out suitable anesthetic tests on several of the 2-hydroxyquinolizidine ester hydrochlorides for this reason.

Testing of the esters for their comparative anesthetic duration times was accomplished by a comparison of the corneal anesthetic duration time ratios on several rabbits. The methods employed are described in the experimental section. The results show conclusively that there is a significant enhancement of the duration of corneal anesthesia by using 2-hydroxyquinolizidine as the esterified aminoalcohol rather than 3-(2-methylpiperidino)-propanol. The average enhancement ratio appears to be approximately 1.40 with a variation from a low value of 1.09 (*o*-hydroxybenzoate) to a high value of 2.38 (*o*-*n*-butoxybenzoate). It should be pointed out that this high value was the only one of its magnitude with the exception of the *o*-benzoylbenzoate which was 2.12. Most of the values were clustered closely around a narrower range centering on 1.30.

The reasons for the enhancement of duration can be speculated upon only. The steric factor has already been mentioned, and it is entirely possible that a better fit at the receptor site is obtainable with molecules that are relatively more fixed sterically than with more flexible molecules. Also one can reasonably assume two major mechanisms whereby the activity of a local anesthetic ester can be terminated. The first of these would be by diffusion from the site of action and the second would be enzymatic inactivation through esterase hydrolysis. Both processes can be assumed to operate at any one site of activity but probably influence the disposal of the ester in varying proportions depending on the particular locus of action. In the present instance, if one assumes that enzymatic activity has at least some role in the disposal of the ester, then it becomes reasonable to assume that steric inhibition to hydrolysis should lead to greater duration of activity. Such steric

[a] New compounds.

inhibition combined with a possible better receptor fit may account for the observed longer duration of activity of the hydroxyquinolizidine esters in the present study.

EXPERIMENTAL

2 - Hydroxyquinolizidine.—*2 - Pyridylacetonitrile.*—This compound was prepared according to the method of Winterfeld and Flick (7) in 77.4% yield as a light yellow oil, b.p. 95–97° (3.7 mm.), n_D^{29} 1.5192 reported, b.p. 79–81° (0.4 mm.)(7); b.p. 80–85° (0.5 mm.), n_D^{29} 1.5193 (8); n_D^{25} 1.5224 (9). A picrate was formed in and recrystallized from absoute ethanol, m.p. 160–162° (reported, m.p. 155–157° (9)).

Ethyl 2-Pyridylacetate.—It was prepared according to the Winterfeld and Flick procedure (7) in a yield of 75.1% as a greenish-yellow liquid, b.p. 90–91° (0.3 mm.), n_D^{29} 1.4921. These properties, together with the picrate, m.p. 137–138°, corresponded in close detail to those previously reported in the literature (1, 10, 11).

2-Hydroxyquinolizidine.—Using ethyl 2-pyridyl acetate as the starting material, the synthesis of this aminoalcohol was carried out essentially as described by Rhodes and Soine (1) employing modifications suggested by Counsell and Soine (2). The yields of all intermediates and of the final product closely approximated those found by the above authors.

3-(2-Methylpiperidino)propanol.—This aminoalcohol was prepared from 2-methylpiperidine and trimethylene chlorohydrin according to the general procedure outlined by McElvain and Carney (6) in 60% yield, b.p. 110–115° (10 mm.) (reported, b.p. 112° (15 mm.) (6)).

Methyl Benzoates (see Table I).—Methyl benzoate, ethyl *o*-benzoylbenzoate, methyl *p*-(*n*-amyloxy)-benzoate and methyl *o*-hydroxybenzoate were purchased from commercial sources. The following examples describe the methods that were used for the synthesis of the other esters.

Alkoxybenzoates.—These were prepared by two methods: *1*, the methyl ester of the phenolic acid was alkylated with the appropriate alkyl halide in absolute methanol in the presence of sodium methoxide, and *2*, the appropriate benzoic acid was esterified with methanol and sulfuric acid. These are illustrated by the following examples.

Methyl p-(n-Butoxy)benzoate.—Sodium (4.6 Gm., 0.2 mole) was dissolved in 100 ml. of absolute methanol. Methyl *p*-hydroxybenzoate (30.4 Gm., 0.2 mole) and 36.8 Gm. (0.2 mole) of *n*-butyl iodide were added. The mixture was refluxed for 12 hours, cooled, and filtered free of inorganic salts. About half of the methanol was distilled off under reduced pressure, and the precipitated inorganic salts were removed by filtration. The solution was rendered alkaline with 5 ml. of 10% sodium hydroxide solution to dissolve unaltered methyl *p*-hydroxybenzoate, and the mixture was treated with 100 ml. of ether and 50 ml. of water. The ether layer and second ether extract were combined. The ether extracts were dried over anhydrous sodium sulfate and, after removal of solvent, the product was distilled to give 25.4 Gm. (61%) of product; b.p. 105–110° (0.2 mm.) (reported, b.p. 190–195° (20 mm.)(12)).

Methyl p-Cyclohexyloxybenzoate.—*p*-Cyclohexyloxybenzoic acid[1] (5 Gm.) absolute methanol (75 ml.), and 7.5 ml. of concentrated sulfuric acid were combined in a 100-ml. round-bottom flask and gently refluxed for 2 hours. The excess of methanol was removed under reduced pressure and the red-colored residue was treated with water. The insoluble ester was extracted from the aqueous mixture with ether and the ether washed with 5% aqueous sodium bicarbonate solution. The ether layer was dried over anhydrous sodium sulfate and after removal of the solvent, provided 3.5 Gm. of an orange-colored liquid. Attempts to distill this material resulted in decompositon and, therefore, it was used in the crude state for further synthesis for which it proved satisfactory.

Miscellaneous Benzoates.—*Methyl p-Phenoxybenzoate.*—A solution of 52.8 Gm. (0.335 mole) of potassium permanganate in 1500 ml. of water was added to a mixture of 20 Gm. (0.0704 mole) of 3-(*p*-phenoxybenzoyl)-propionic acid[2] and 20 Gm. (0.357 mole) of potassium hydroxide in 200 ml. of water. The mixture was heated on a steam bath for 5 hours. At the end of this time the mixture was cooled and carefully acidified with sulfuric acid. The mixture was heated for 30 minutes and cooled. The precipitated manganese dioxide was removed by the addition of a slight excess of 10% sodium bisulfite solution. The precipitated acid was removed by filtration and recrystallized from ethanol; yield, 14.0 Gm. (92.9%), m.p. 159–160° (reported, m.p. 160° (13)).

[1] The authors express their appreciation to Eli Lilly and Co., Indianapolis, Ind., for a generous gift of *p*-cyclohexyloxybenzoic acid.

[a] A, Ethanol, isopropyl ether; B, ethanol; C, absolute ethanol; D, methylene chloride, ethyl acetate; E, ethyl acetate, ether; F, isopropanol, ether.

The esterification of the phenoxybenzoic acid was carried out essentially as described above for *p*-cyclohexyloxybenzoic acid (*q.v.*) to yield 6.5 Gm. (81%) of colorless crystals after recrystallization from a methanol-water mixture, m.p. 60° (reported, m.p. 59.5 to 60° (14)).

Methyl p-(4-Methoxyphenyl)benzoate.—The first step in this synthesis was the preparation of *p*-(4-methoxyphenyl)acetophenone according to the procedure of Johnson, *et al.* (15). The product was prepared in a 53% yield, m.p. 145–147° and following recrystallization gave pure material, m.p. 153–154° (reported, m.p. 153–154° (15)).

The above product was then oxidized as described by Fieser and Bardher (16) with permanganate to provide a 56% yield of *p*-(4-methoxyphenyl)benzoic acid, m.p. 248–249° (m.p. reported 248–249° (16)).

The above acid was esterified with methanol and sulfuric acid in the manner described above for alkoxybenzoates to give a product, recrystallized from methanol, m.p. 172–174° (reported, m.p. 172–173° (16)). The yield was 86%.

2-Hydroxyquinolizidine Esters.—These esters were all synthesized by the ester-interchange method as described by Counsell and Soine as Method 2 (2). The analytical and physical constants are recorded in Table II.

3-(2-Methylpiperidino)propanol Esters.—These esters were also synthesized by the ester-interchange method according to the above method of Counsell and Soine (2). They all agreed within a few degrees with the reported melting points of McElvain and Carney (6) and from the constancy of their melting points were assumed to be identical with the products of the former workers and of a suitable purity for pharmacological testing.

Pharmacological Testing

Solutions.—All of the salts were dissolved in distilled water in identical concentrations for each pair of compounds tested. The solutions were made on the day of use in every case. These solutions represented essentially equimolar concentrations because of the negligible difference in molecular weights between each pair. The hydrochlorides of *p*-phenylbenzoic, *p*-(4-methoxyphenyl)benzoic, *p*-phenoxybenzoic, and *p*-benzyloxybenzoic acid esters were too insoluble to allow preparation of solutions at the concentration required and thus were not included in the comparison studies.

TABLE III.—LOCAL ANESTHETIC DURATION COMPARISONS

Ester Pair Corresponding to the Esters as Numbered in Table II.	Concentration, %	Duration,[a] min. A	Duration,[a] min. B	Duration Ratio[b] A/B
I	1.00	14	9	1.54 (±0.29)
III	1.00	34	32	1.09 (±0.11)
IV	0.30	38	16	2.38 (±0.36)
VII	0.25	43	35	1.25 (±0.06)
XIV	0.20	58	29	2.03 (±0.63)
X	0.10	24	18	1.29 (±0.09)
XI	0.10	26	21	1.24 (±0.08)
VI	0.10	29	23	1.25 (±0.10)
IX	0.10	31	24	1.32 (±0.33)
V	0.10	53	43	1.28 (±0.13)
VIII	0.10	58	40	1.44 (±0.17)

[a] A = 2-Hydroxyquinolizidine esters. B = 3-(2-methylpiperidino)propanol esters. [b] 95% confidence limits.

Animals.—Young adult white rabbits, equal numbers of each sex, were used for the corneal testing. The eyelids were carefully trimmed to remove the eyelashes. In most tests they were used only once each day but on occasion were tested in the morning and again in the afternoon.

Test Procedure.—The usual method of instillation for corneal testing was employed in which 0.5 ml. of solution was introduced into the conjunctival sac from a blunt-tipped syringe and allowed to act upon the cornea for 1 minute before beginning the duration count. All compounds induced anesthesia within the 1-minute period as evidenced by the absence of the wink reflex when the cornea was stimulated with a blunt glass rod. The time re-

quired for the animal to regain the wink reflex when the stimulus was applied was recorded in minutes. In most cases six rabbits were used for each comparison although in a few cases five were used and in one case 12 were employed. Each pair of esters was tested on the same rabbit's eyes with the right eye being used for one-half of the tests on the hydroxyquinolizidine esters and the left eye for the other half. Concomitantly, the alternate eye of the rabbits was used for the other ester. At no time were both eyes subjected to anesthesia at the same time.

The duration ratio between the pairs of compounds in each animal was obtained by dividing the duration of the 2-hydroxyquinolizidine ester by that of the 3-(2-methylpiperidino)propanol ester. The mean of these ratios was determined and the 95% confidence limits of the mean were calculated assuming a normal distribution for the mean and a chi-square distribution for the squares of the deviations (17). These results are given in Table III.

Observations.—No irritation of the cornea was observed with either series of esters in the concentrations employed. Both the *p*-isoamyloxybenzoate and the *o*-benzoylbenzoate were erratic in the 2-hydroxyquinolizidine series with respect to the comparative durations. The latter, in particular, exhibited an unpredictable behavior with the duration ratios varying widely (0.83 to 3.86). For this reason, the 95% confidence interval varies more widely than any of the other pairs tested. A further observation of interest was that the 2-hydroxyquinolizidine esters induced much less xerophthalmia than the corresponding 3-(2-methylpiperidino)-propanol esters.

SUMMARY

1. Fifteen new substituted benzoate esters of 2-hydroxyquinolizidine have been synthesized and described because of an interest in their comparative local anesthetic activity with the corresponding esters of 3-(2-methylpiperidino)propanol.

2. Four new methyl esters of substituted benzoic acids have been synthesized and described in the course of the investigation.

3. Several of the newly synthesized esters have been compared with their counterparts obtained from the esterification of 3-(2-methylpiperidino)-propanol for duration of corneal anesthesia in the rabbit. The observed results indicate that an enhanced duration of action can be expected as a general trend when comparing the two esters derived from the same acid. The duration ratios varied from 1.09 (± 0.11) for the *o*-hydroxybenzoates to 2.38 (± 0.36) for the *o*-(*n*-butoxy)benzoates.

Release of Drug from a Self-Coating Surface

Benzphetamine Pamoate Pellet

By W. I. HIGUCHI† and W. E. HAMLIN

The problem has been examined in which the rate of release in acid solution of an amine drug from a pellet of a weak acid salt of the amine is controlled by a coat which is formed by precipitation of a weak acid onto the pellet surface. A detailed mathematical analysis has been carried out and an expression for the rate of release is presented. The theory has been applied to data on the release of the drug from benzphetamine pamoate pellets.

RECENT STUDIES by Morozowich, *et al.* (1), on the release of benzphetamine from pellets of benzphetamine pamoate in 0.12 *N* hydrochloric acid medium led these investigators to propose that in this instance the rate was controlled by a layer of pamoic acid which was deposited on the pellet surface according to the reaction:

$$\text{benzphetamine pamoate (pellet)} \xrightarrow{H^+} \text{benzphetamine (solution)} + \text{pamoic acid (pellet surface)}.$$

Received July 5, 1962, from the Pharmacy Research Section, Product Research and Development, The Upjohn Co., Kalamazoo, Mich.

Release of Drug from a Self-Coating Surface

Benzphetamine Pamoate Pellet

By W. I. HIGUCHI† and W. E. HAMLIN

The problem has been examined in which the rate of release in acid solution of an amine drug from a pellet of a weak acid salt of the amine is controlled by a coat which is formed by precipitation of a weak acid onto the pellet surface. A detailed mathematical analysis has been carried out and an expression for the rate of release is presented. The theory has been applied to data on the release of the drug from benzphetamine pamoate pellets.

RECENT STUDIES by Morozowich, *et al.* (1), on the release of benzphetamine from pellets of benzphetamine pamoate in 0.12 *N* hydrochloric acid medium led these investigators to propose that in this instance the rate was controlled by a layer of pamoic acid which was deposited on the pellet surface according to the reaction:

$$\text{benzphetamine pamoate (pellet)} \xrightarrow{H^+} \text{benzphetamine (solution)} + \text{pamoic acid (pellet surface)}.$$

Received July 5, 1962, from the Pharmacy Research Section, Product Research and Development, The Upjohn Co., Kalamazoo, Mich.
Accepted for publication July 31, 1962.
† Present address: School of Pharmacy, University of Michigan, Ann Arbor.
Presented to the Scientific Section, A.PH.A., Miami meeting, May 1963.

This suggestion was based upon the reality of the pamoic acid layer determined by assay of the pellets exposed to the solution and the relative small effect of agitation on the rate of benzphetamine release.

It appeared worthwhile to examine this problem further, both experimentally and theoretically, particularly since the basic considerations may apply to other situations.[1] The results of a detailed analysis of this problem are presented in this report.

THEORY

The Model and Assumptions.—We will assume that the above picture is correct, *i.e.*, the rate of benzphetamine release is controlled by diffusional processes in the pamoic acid layer. Our concern will be only for the case in which the dissolving medium is acidic.

The model is illustrated in Fig. 1. At some time after the pellet is placed in the acid solution, a layer of pamoic acid of thickness s has formed on the surface. The H^+ must diffuse through this layer and react with the pamoate ion to precipitate more acid, releasing the benzphetamine cation

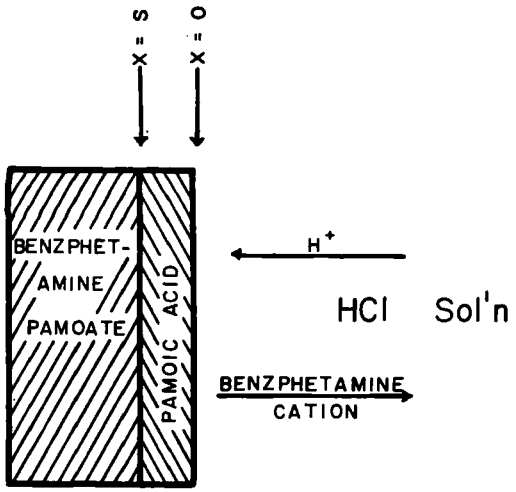

Fig. 1.—Model for the release of benzphetamine from benzphetamine pamoate in hydrochloric acid solution. See text for explanation.

which then diffuses out through the layer. Some of the benzphetamine cation will diffuse out without being released by the H^+ since benzphetamine pamoate has a finite solubility.

In order to make this problem mathematically tractable it is necessary to incorporate the following assumptions into the model: (*a*) quasi-steady-state in the pamoic acid layer; (*b*) Fick's law of diffusion is obeyed, constant effective diffusion coefficients in the layer, and diffusion takes place only in the aqueous phases of the layer; (*c*) effects of liquid diffusion layer negligible; (*d*) initial non-steady-state effects negligible. Some of these assumptions will be examined later.

Concentration-Equilibria-Diffusion Relations.—Let us now obtain an expression for the instantaneous release rate of benzphetamine at a given pamoic acid layer thickness s with the assumption that steady state concentration gradients are present. The appropriate boundary conditions for the problem are $C_{H^+} = C^\circ_{H^+}$, $C_{B^+} = C^\circ_{B^+}$, $C_{P=} = C^\circ_{P=}$, and $C_{H_2P} = K_l$ = constant at $x = 0$ where C_{H^+}, C_{B^+}, $C_{P=}$, and C_{H_2P} are the H^+, benzphetamine-H^+, pamoate anion, and the pamoic acid (in solution) concentrations, respectively. At $x = s$ we have $C_{H^+} = C^s_{H^+}$, $C_{B^+} = C^s_{B^+}$, $C_{P=} = C^s_{P=}$, and $C_{H_2P} = K_l$.

As before (4) we may write down the appropriate differential equations for diffusion and simultaneous chemical reaction in a one dimensional situation. Throughout the region $0 \leq x \leq s$ we have

$$D_{P=}\left(\frac{d^2C_{P=}}{dx^2}\right) + \Phi = 0 \qquad \text{(Eq. 1)}$$

$$D_{H^+}\left(\frac{d^2C_{H^+}}{dx^2}\right) + 2\Phi = 0 \qquad \text{(Eq. 2)}$$

$$D_{B^+}\left(\frac{d^2C_{B^+}}{dx^2}\right) = 0 \qquad \text{(Eq. 3)}$$

A forth equation involving H_2P is omitted because $C_{H_2P} = K_l$ is independent of x as long as solid pamoic acid is present. In Eqs. 1 to 3 the D's are the effective diffusion coefficients for the species indicated and Φ is the rate of reaction per unit volume for the reaction $P^= + 2H^+ = H_2P$ (aq.) = H_2P (s). Since there will be no formation or disappearance of benzphetamine in the pamoic acid layer, the second derivative of C_{B^+} is always zero.

If Eqs. 1 and 2 are combined and integrated over the limit $x = 0$ to $x = s$, we obtain

$$G = \frac{2D_{P=}(C^s_{P=} - C^\circ_{P=}) + D_{H^+}(C^\circ_{H^+} - C^s_{H^+})}{s} \qquad \text{(Eq. 4)}$$

Furthermore, integration of Eq. 3 over $x = 0$ to $x = s$ gives

$$G = \frac{D_{B^+}(C^s_{B^+} - C^\circ_{B^+})}{s} \qquad \text{(Eq. 5)}$$

In these equations, G is the rate of release of benzphetamine per unit area of pellet surface.

In order to eliminate the unknowns, $C^s_{P=}$, $C^s_{H^+}$, and $C^s_{B^+}$ from the expression for G, it is necessary to introduce the appropriate equilibrium relationships. These are the solubility product expressions for benzphetamine pamoate

$$K_{sp} = C^2_{B^+}C_{P=} \qquad \text{(Eq. 6)}$$

and the dissociation constant expression for pamoic acid

$$K_A = \frac{C^2_{H^+}C_{P=}}{C_{H_2P}} = \frac{C^2_{H^+}C_{P=}}{K_l} \qquad \text{(Eq. 7)}$$

If Eqs. 4–7 are combined, we may obtain the following relation upon eliminating G

[1] A similar but simpler situation is that of drug release from emulsion ointment bases (2). Another analogous situation has been reported by Levy and Procknal (3) for the release of acetylsalicylic acid from aluminum acetylsalicylic acid pellets in a basic aqueous medium which involves the formation of a water-insoluble aluminum compound on the surface of the pellets.

$$C^{s}_{B^+} = \frac{D_{B^+} C^{\circ}_{B^+} + 2D_{P=} [(K_{sp}/C^{s2}_{B^+}) - (K_A K_l / C^{\circ 2}_{H^+})] + D_{H^+} C^{\circ}_{H^+}}{D_{B^+} + D_{H^+} (K_A K_l / K_{sp})^{1/2}} \quad \text{(Eq. 8)}$$

Now the numerical values[2] for K_{sp}, K_A, and K_l are $K_{sp} = 3 \times 10^{-10}$, $K_A = 1 \times 10^{-6}$, and $K_l = 4 \times 10^{-6}$. Substitution of these into Eq. 8 gives

$$C^{s}_{B^+} = \frac{D_{B^+} C^{\circ}_{B^+} + 2D_{P=} \{[(3 \times 10^{-10})/(C^{s2}_{B^+})] - [(4 \times 10^{-12})/(C^{\circ 2}_{H^+})]\} + D_{H^+} C^{\circ}_{H^+}}{D_{D^+} + 0.12 D_{H^+}} \quad \text{(Eq. 9)}$$

In the experiments to be discussed later, $C^{\circ}_{H^+} \sim 0.01$ to 0.1 M. For this range of $C^{\circ}_{H^+}$ it can be shown by consideration of Eqs. 4 and 5 that to within a factor of ten, $C^{s}_{B^+} \sim C^{\circ}_{H^+}$. Therefore, the middle terms in the numerator of Eq. 9 are negligible compared to the first and last terms. Hence for our present purposes, Eq. 10 may be written

$$C^{s}_{B^+} = \frac{D_{B^+} C^{\circ}_{B^+} + D_{H^+} C^{\circ}_{H^+}}{D_{B^+} + 0.12\, D_{H^+}} \quad \text{(Eq. 10)}$$

Now if this expression is combined with Eq. 5 we get

$$G = \frac{D_{B^+}}{s} \left(\frac{D_{H^+} C^{\circ}_{H^+} - 0.12\, D_{H^+} C^{\circ}_{B^+}}{D_{B^+} + 0.12\, D_{H^+}} \right) \quad \text{(Eq. 11)}$$

Benzphetamine Release vs. Time Relation.— We may now relate G to the variation in thickness s with time t by means of the following equation

$$G = A \frac{ds}{dt} - {}^1/_2\, V C^{s}_{B^+} \frac{ds}{dt} \quad \text{(Eq. 12)}$$

where A is the concentration of benzphetamine in the solid benzphetamine pamoate and V is the volume fraction of the liquid (aqueous) phase in the pamoic acid layer. The first term on the right side of Eq. 12 is the amount of benzphetamine leaving[3] the solid benzphetamine pamoate per unit time and unit area, and the second term is the amount of benzphetamine needed to re-establish the steady-state concentration gradient in the region $0 \leq x \leq s$ after the change in s.

Letting

$$\Delta C = A - ({}^1/_2)\, V C^{s}_{B^+} \quad \text{(Eq. 13)}$$

combining Eqs. 11 and 12, and separating variables, we get

$$s\,ds = \frac{D_{B^+}}{\Delta C} \left[\frac{D_{H^+} C^{\circ}_{H^+} - 0.12\, D_{H^+} C^{\circ}_{B^+}}{D_{B^+} + 0.12\, D_{H^+}} \right] dt \quad \text{(Eq. 14)}$$

Integrating from $s = 0, t = 0$ to $s = s, t = t$ this becomes

$$s = \left[\frac{2D_{B^+}}{\Delta C} \left(\frac{D_{H^+} C^{\circ}_{H^+} - 0.12 D_{H^+} C^{\circ}_{B^+}}{D_{B^+} + 0.12\, D_{H^+}} \right) t \right]^{1/2} \quad \text{(Eq. 15)}$$

Then for the amount M released per cm.^{2} of surface we have

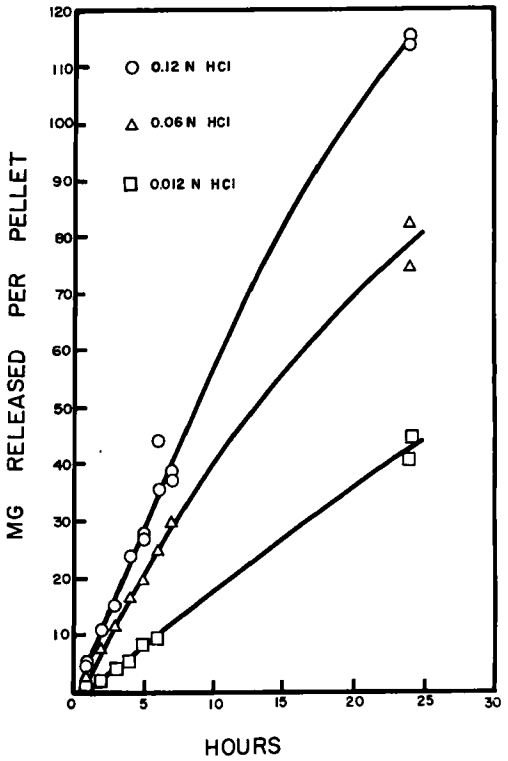

Fig. 2.—Data on the release of benzphetamine from pellet of benzphetamine pamoate in aqueous solutions of hydrochloric acid at 37°.

$$M = S\Delta C = \left[2D_{B^+} \Delta C \left(\frac{D_{H^+} C^{\circ}_{H^+} - 0.12\, D_{H^+} C^{\circ}_{B^+}}{D_{B^+} + 0.12\, D_{H^+}} \right) t \right]^{1/2} \quad \text{(Eq. 16)}$$

In order to make Eq. 16 workable, it is necessary to have estimates of D_{B^+}, D_{H^+}, and ΔC. For the diffusion coefficients we may write

$$D_{B^+} = f D'_{B^+}$$

and (Eq. 17)

$$D_{H^+} = f D'_{H^+}$$

where the D primes are the diffusion coefficients of the ions in pure aqueous phase. Therefore, f represents the effects of volume fraction, particle shapes, and other factors. The value of f may be estimated from approximate theories (6) based on data for other systems. We find that, if $V \sim 0.5$, $f \sim 0.25 \pm$ factor of 50%. The value for D'_{B^+} may be estimated from the Stokes-Einstein law to be about 5×10^{-6} cm.^{2} sec.$^{-1}$ and $D'_{H^+} \sim 3 \times$

[2] These are for 37°. The K_A value was determined at 25° by a potentiometric titration method in various concentrations of aqueous dimethylacetamide solutions and the results were extrapolated to 100% water. The temperature dependence of K_A values in water for carboxylic acids are usually small (5) near room temperatures. Since K_A for salicylic acid is about 1×10^{-3}, our value for pamoic acid is reasonable.

[3] It is assumed that the rate of change in thickness of the pamoic acid layer equals that of the pamoate layer. This is consistent with experimental observations.

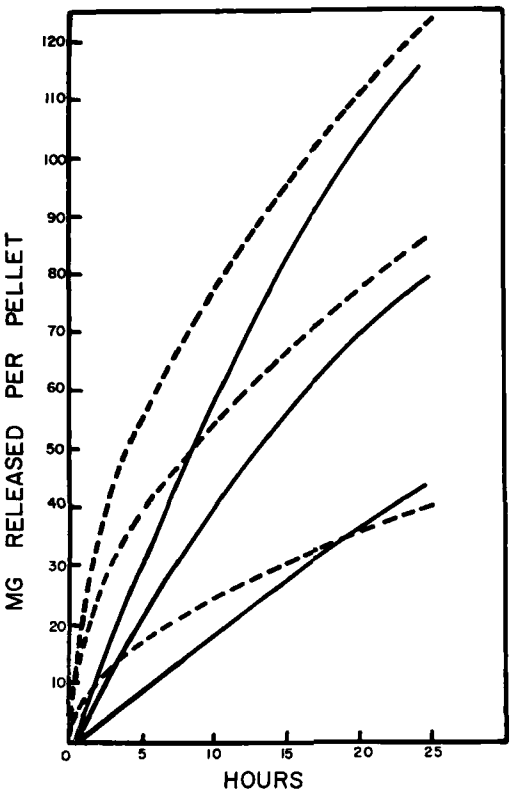

Fig. 3.—Comparison of experimental results (closed curves) with Eq. 19 of theory (dotted curves).

10^{-5} cm.^{2} sec^{-1} from the literature (7). Finally, since it can be easily shown from Eq. 10 and the above estimates of the diffusion coefficients that $C^{\circ}_{D^+} \ll A$ for our experimental conditions, we have $\Delta C \simeq A$. Therefore, $\Delta C \simeq 2.6 \times 10^{-3}$ moles ml.$^{-1}$ since the density of benzphetamine pamoate is 1.12 and the equivalent weight is 433. With these values for D_{B^+}, D_{H^+}, and ΔC, and noting that $C^{\circ}_{H^+} \gg 0.12\ C^{\circ}_{B^+}$ for our experiments, Eq. 16 becomes

$$M \simeq 1.5 \times 10^{-4} (C^{\circ}_{H^+} t)^{1/2} \text{ moles benzphetamine release per cm.}^2 \quad \text{(Eq. 18)}$$

if $C^{\circ}_{H^+}$ is in moles ml.$^{-1}$ and t is in seconds.

EXPERIMENTAL

Because of the large number of parameters in the theory, the values of which are known only approximately, it appeared that an evaluation of the problem on the basis of a single experiment would be difficult. Therefore, it was decided to vary an obviously important factor, the hydrogen ion concentration, to see whether the results of the experiments would fall self-consistently into the framework of the theory.

A series of experiments employing the hanging pellet method (8) at 0.12, 0.06, and 0.012 *N* hydrochloric acid were carried out. The pellets, which were one-half inch diameter and approximately two millimeters thick, were prepared by compressing benzphetamine pamoate in a potassium bromide die. The die was evacuated and a compressional force of 10 tons was applied. The pellets were mounted on aluminum plates by means of wax. Excess wax and any trace of magnesium stearate, which was used to coat the inner surfaces of the die, were removed from the one-half inch diameter surface by careful scrapping with a razor blade. Each pellet was then exposed to 100 ml. of the hydrochloric acid solutions. At a predetermined time a pellet was removed and the amount of drug released by it was determined by U.V. and colorimetric methods. All runs were carried out at 37°.

COMPARISON OF RESULTS WITH THEORY

The data on the release of benzphetamine with time are presented in Fig. 2 along with their best fit curves. Each experimental point represents a different pellet.

These data may be compared with theory in three ways. First, the coefficient, 1.5×10^{-4}, in Eq. 18 may be tested; secondly, the $C^{\circ}_{H^+}$ dependence may be examined; and finally, the time dependence may be tested.

In Fig. 3 the experimental results are compared with the adjusted equation

$$M = 1.25 \times 10^{-4} (C^{\circ}_{H^+} t)^{1/2} \text{ moles cm.}^{-2} \quad \text{(Eq. 19)}$$

which differs from Eq. 18 by only 20% in the coefficient. The surface area of 1.26 cm.^{2} was used with Eq. 19 for the calculation of the theoretical curves.

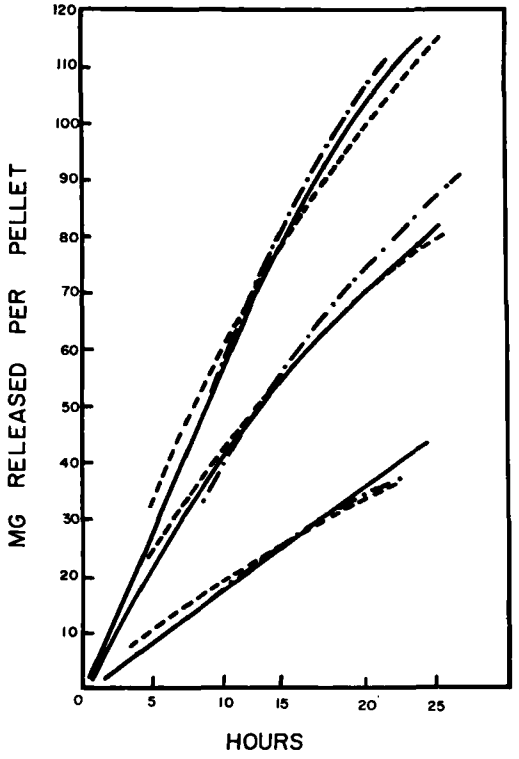

Fig. 4.—Comparison of experimental results (closed curves) with Eq. 20 (–·—·–) and with Eq. 21 (– – – –) of theory.

A close examination of Fig 3 shows that on two of the three tests of the theory with data the theoretical model appears to be in satisfactory agreement with the experiments. Firstly, the experimental $C^{\circ}{}_{H^+}$ dependence correctly fits the square root law[4] at essentially all times. Secondly, within the probable uncertainty of about a factor of two in theory, the coefficient, 1.5×10^{-4}, in Eq. 18, agrees[5] with data at large times for all $C^{\circ}{}_{H^+}$. Thus it appears that the disagreement between experiment and theory exists largely on the third point, the time dependence.

To amplify the idea that it is primarily the time dependence of the model which is at fault, let us consider two modifications of Eq. 18 which give better fit to the data. In Fig. 4 the data are compared with the following two equations

$$M = 1.4 \times 10^{-4} (C^{\circ}{}_{H^+})^{1/2} (t - \tau_1)^{1/2} \quad \text{(Eq. 20)}$$

and

$$M = 1.4 \times 10^{-4} (C^{\circ}{}_{H^+})^{1/2} (t^{1/2} - \tau_2^{1/2}) \quad \text{(Eq. 21)}$$

where we have taken τ_1 = six hours and τ_2 = one hour for the calculations. In these equations the coefficient and $C^{\circ}{}_{H^+}$ dependence have been retained from Eq. 18. Only changes in the time dependence, effective mainly at small t, have been incorporated. The meaning of τ_1, in Eq. 20, is that there is effectively a constant lag time, $\tau_1 \sim$ six hours, before the release process begins according to the theoretical model. The meaning of τ_2 in Eq. 21 is that there is not only a small lag time $\tau_2 \sim$ one hour, but there is effectively a small barrier in series with the pamoic acid barrier itself. This small effective barrier would, of course, be most important at small t values when the pamoic acid layer is thin. Actually, the data in Fig. 2 indicate a small lag time the order of one hour. It is more difficult to account for the barrier in series with the pamoic acid layer. It might be partially accounted for by the liquid diffusion layer and partially by a varying pamoic acid layer structure near the surface, *i.e.*, effectively smaller diffusion coefficients in the layer near the surface.

[4] If the coating phenomenon were absent, a linear law would be expected according to Eq. 11 with constant s.

[5] If the coating phenomenon were absent, rates ten to a hundred times greater would be expected.

Investigation of *in Vivo* Tracer Techniques in Drug Screening Studies

By BILLY D. RUPE, WILLIAM F. BOUSQUET, and JOHN E. CHRISTIAN

An *in vivo* tracer method for screening drugs which act by altering the normal body metabolism of certain elements is described. These studies involved the detection of natruretic or antinatruretic action of six compounds. Further extensions of the present work are also discussed.

THE RELATIVELY RECENT development of large volume liquid scintillation counters ("Whole Body Counters") (1, 2) has made possible research on the development of new methodology for the qualitative and quantitative evaluation of pharmacologically active substances. *In vivo* assay of gamma ray emitting radioisotopes, as made possible with large volume liquid scintillators, is particularly attractive to the research pharmacologist in drug screening studies. The obvious advantages of this technique are three: (*a*) observations may be made on the intact animal; (*b*) serial observations may be made on the same animal over extended periods of time; and (*c*) it should be possible to reduce the size of experimental groups of animals. This technique has not been exploited to date.

One such counter is the Purdue University Small Animal Counter (PUSAC). The specifications and operating characteristics of this counter are fully described in the literature (2). The PUSAC and similar counters now being commercially produced are of such size that mice, rats, or guinea pigs may be used as experimental animals.

Large volume scintillation counters should

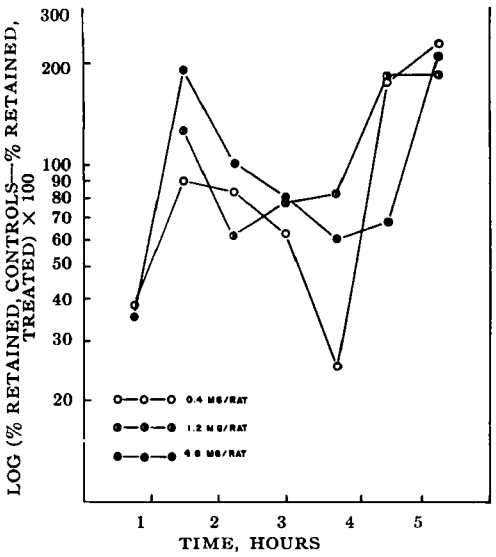

Fig. 1.—Effect of spironolactone on sodium retention in the rat.

provide a sensitive assay method for studying the effects of physiologically active substances on body pool, turnover time, and thus storage and excretion rates of several body ions of interest. However, the following criteria must be met: *A*, The ion must exist in the body in a measurable concentration. *B*, It must have been assigned a specific biochemical role, beneficial or otherwise. *C*, The concentration of the ion must be modified by drug administration or altered in disease conditions, so that a measurable change in concentration reflects the action of the drug or the development of a diseased state. *D*, The ion must have a suitable gamma emitting isotope.

Many ions existing in the body, such as sodium, potassium, calcium, and iodine meet all of the above criteria. Therefore, studies involving drugs or diseased states which alter the normal metabolism of these elements should be possible by the procedures discussed.

Classifications of the various possible studies concerning ions which meet the above criteria are: *A*, the role of the ion in normal physiology, with special reference to body pool, storage time, excretion patterns, and absorption studies; *B*, the effect of drugs in modifying normal body concentrations of the ion and interpretation of results in terms of drug-type and drug-dose, *i.e.*, screening methods; *C*, studies of normal ion concentrations as influenced by disease states. Relationship between body levels of specific metals and type and severity of disease, *i.e.*, diagnostic techniques; *D*, relating to items two and three above, studies of the effect of drug therapy on the diagnostic criteria and indications developed by whole body counting procedures, *i.e.*, evaluation of specific therapeutic procedures as opposed to screening techniques; and *E*, Industrial toxicology.

This study is an example of one of the many possible applications of large volume liquid scintillation counters to pharmacological studies.

The effects of various pharmacologic compounds, mainly diuretic agents, on sodium metabolism in the rat using sodium-22 were studied. This isotope emits a gamma ray of 1.30 Mev., thus making it possible to detect and quantitatively measure the amount of this isotope using external liquid scintillation detectors.

The most common method of studying the diuretic or natruretic activity of pharmacologically active compounds is to collect urine specimens and determine the volumes and/or electrolyte content. The electrolyte content is determined in most cases by flame photometry (3–5); however, this value is not always precise due to interference of trace ions present in the urine.

Since all diuretic agents affect sodium reabsorption in the kidney in some manner, a measure of the amount of sodium retained and by difference the amount excreted should give an indication of the pharmacological activity of the

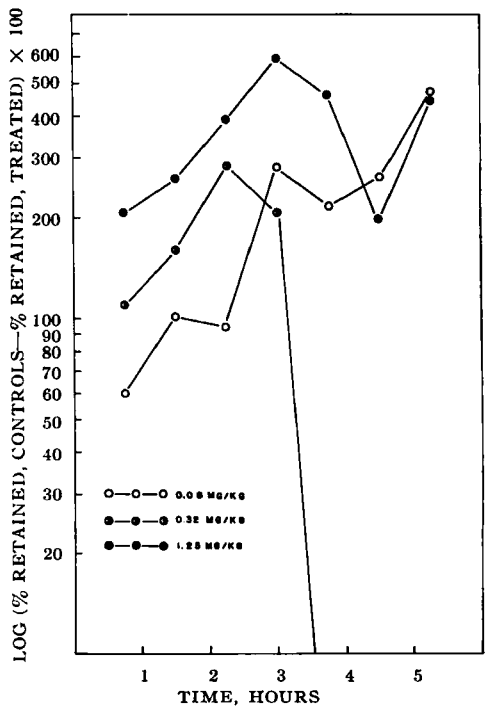

Fig. 2.—Effect of hydrochlorothiazide on sodium retention in the rat.

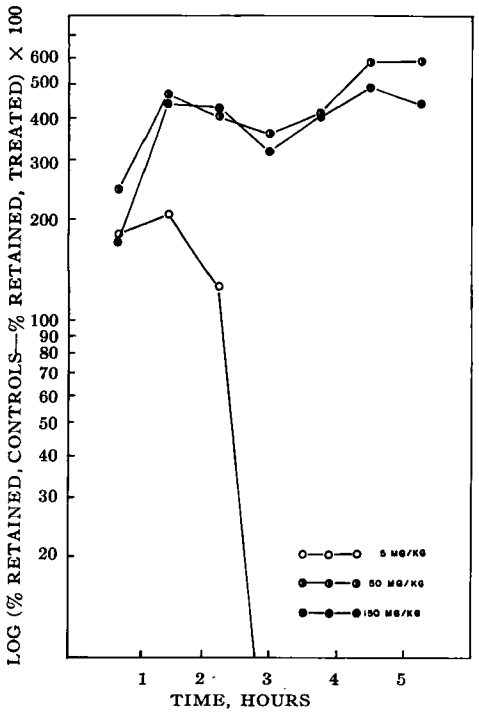

Fig. 3.—Effect of acetazolamide on sodium retention in the rat.

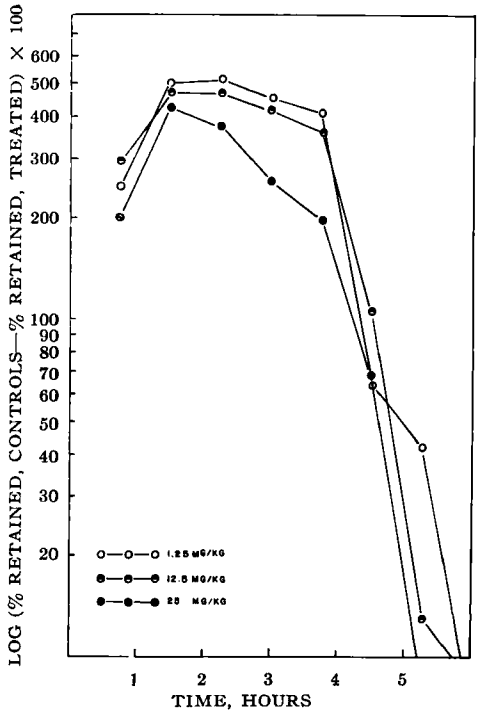

Fig. 4.—Effect of chlorothiazide on sodium retention in the rat.

drug. Wiebelhaus, *et al.* (6), found that if animals used in testing diuretics were first hydrated with 0.9% sodium chloride solution, the resulting values obtained for the natruretic activity of various diuretic compounds also were a good indication of their diuretic activity. This finding has also been reported elsewhere in the literature (7, 8).

In this study rats were hydrated with isotonic sodium chloride solution containing sodium-22. Known diuretic agents were administered and the whole body retention of sodium-22 measured, at several time intervals, as an indicator of natruretic efficacy. In other experiments urine was collected in addition to sodium-22 measurements on the whole animal to provide a correlation between natruretic and diuretic effect.

METHODS

Female Sprague-Dawley rats weighing between 180 and 220 Gm. were used throughout this study unless otherwise noted. The rats received treatment prior to test as indicated.

Desoxycorticosterone Blocking Effect of Spironolactone.[1]—This study dealt with the detection of the ability of spironolactone to relieve desoxycorticosterone acetate (DCA) induced sodium retention in the adrenalectomized rat. Four groups of six animals were adrenalectomized and maintained as described by Kagawa and Brown (3).

At the 24th hour after adrenalectomy, DCA in corn oil (12 mcg. in 0.05 ml.) was injected subcutaneously in the shoulder region of the animals. All animals were then hydrated by injecting subcutaneously 2.5 ml. of 0.9% sodium chloride solution, containing approx. 0.05 μc. of sodium-22, at divided sites in the shoulder region.

Three hours later, at the 27th hour after adrenalectomy, the rats were again injected with DCA as described above. At this time the control group received 0.5 ml. of corn oil subcutaneously, and group I received 0.4 mg.; group II, 1.2 mg.; and group III, 4.8 mg. of spironolactone in 0.5 ml. of corn oil.

The animals were then studied for a period of 5¼ hours by periodically determining the percentage of the original whole body sodium-22 activity remaining by *in vivo* radioassay.

Natruretic Activity of Four Diuretic Agents.—The natruretic activity of four diuretic compounds at three dose levels, chlorothiazide[2] (1.25, 12.5, and 25 mg./Kg.), hydrochlorothiazide[3] (0.08, 0.32, and 1.25 mg./Kg.), acetazolamide[4] (5, 50, and 150 mg./Kg.), and meralluride[5] (0.7, 3.5, and 7.0 mg. Hg/Kg.), was studied. Four groups of six

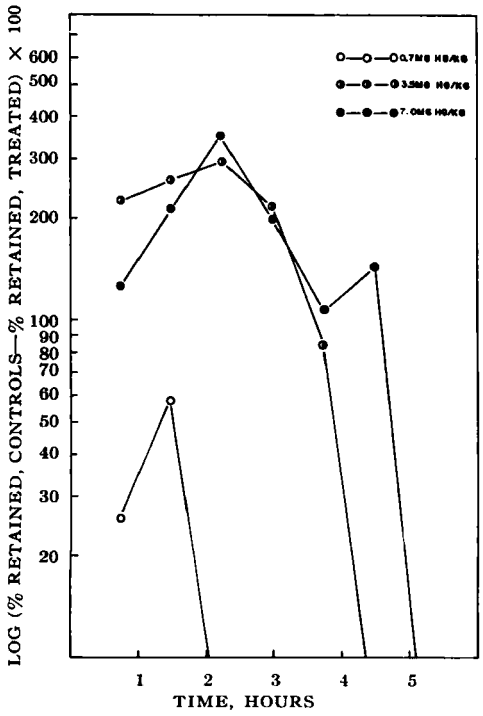

Fig. 5.—Effect of meralluride on sodium retention in the rat.

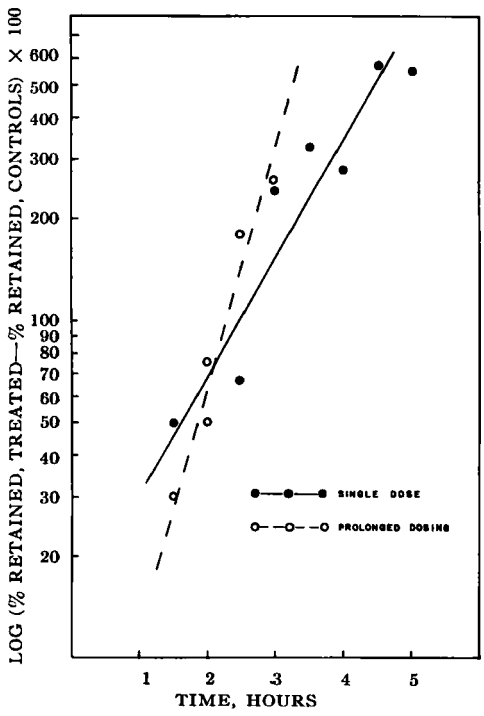

Fig. 6.—Effect of amphenone-B on sodium retention in the rat.

animals were used for each compound. One group was kept as a control in each case.

Hydration consisted of intraperitoneal injection of 25 ml./Kg. of 0.9% sodium chloride solution containing 0.05 μc. of sodium-22. The animals then received an intraperitoneal injection of each compound and control immediately after hydration. The amount of radioactivity retained was then determined by periodically determining the total body radioactivity at 45-minute intervals over 5¼ hours.

All meralluride injections were intramuscular.

Effect of Amphenone B[6] on Sodium Metabolism.—Vogt (9) noted that amphenone B would either increase or decrease sodium excretion in rats dependent upon whether the animal received a single dose of the compound or prolonged doses over a period of 2–17 days. Since the activity of this compound is evidenced by a change in sodium metabolism brought about by a change in aldosterone biosynthesis, it was subjected to examination by this technique.

In the single dose study, rats were injected intraperitoneally with 200 mg./Kg. of amphenone B in distilled water following hydration; the controls received an equal volume of distilled water. In the case of prolonged doses, the animals received 200 mg./Kg. of the compound in distilled water daily for 5 days. Controls again received an equal volume of distilled water at the same time. Hydration was undertaken just prior to the injection of the compound on the fifth day of dosing. Sodium retention was determined as previously described.

[6] 3,3-Bis(*p*-aminophenyl) butane; Ciba Pharmaceutical Products, Inc.

Ability of Diuretic Agents to Concentrate Sodium in the Urine.—Since there is reason to believe that diuretic activity and natruretic activity are related, all conditions in the previous experiments (with the exception of the amphenone B experiment) were duplicated; the animals were placed in metabolism cages and urine samples collected. The radioactivity contained in the samples was determined by placing the urine in a 20-ml. glass bottle and then placing in the PUSAC. The percentage of the original whole body radioactivity that was contained in the sample was determined.

RESULTS AND DISCUSSION

It was possible to detect effects on sodium metabolism elicited by each of the drugs used. Both natruretic responses and inhibition of sodium excretion were readily observed.

The results obtained in the experiments involving the DCA-blocking effect of spironolactone indicate a positive response at each dose administered (Fig. 1.)[7] These results suggest that the drug has a rapid onset and a duration of action of over 5 hours as well under the conditions of this experiment. The changes in slope are possibly explained by the mode of administration of DCA, since two oily subcutaneous injections were made 3 hours apart.

[7] In Fig. 1 and in all figures showing natruretic activity, a semilogarithmic plot was obtained by plotting the difference of the per cent of sodium retained by the controls, minus the per cent retained by the treated animals, multiplied by 100, along the *y*-axis and time along the *x*-axis. Where sodium retention was indicated, the difference of the per cent retained by the treated animals, minus the per cent retained by the controls, multiplied by 100, was logarithmically plotted on the *y*-axis.

TABLE I.—STUDIES OF SODIUM CONCENTRATION IN THE URINE[a]

[a] Five-hour samples unless otherwise stated. Doses: acetazolamide (50 mg./Kg. BW), chlorothiazide (12.5 mg./Kg. BW), hydrochlorothiazide (2.5 mg./Kg. BW), meralluride (3.5 mg. Hg/Kg. BW), spironolactone (1.2 mg./rat). [b] $\frac{\text{Activity in urine specimen}}{\text{Activity in whole animal at time } 0} \times 100$. [c] Urine volume × av. per cent of original activity. [d] Data from six animals, all others from three animals.

This could allow for a fluctuation in the blood level of DCA.

The results obtained from the studies involving the four known diuretic agents are shown in Figs. 2–5. In each case it was possible to detect the natruretic activity of the drug under study in the chosen test period. These compounds represent three physiologically different natruretic actions, suggesting the feasibility of this procedure for screening diuretic agents. The results also indicate a possibility that more elaborate experimental setups, primarily a more varied dose schedule, might give quantitative as well as qualitative indications regarding the efficacy of a particular drug. This was evidenced by the fact that the results obtained here closely correlate with the known action of the drugs in respect to onset and duration of action.

Amphenone B was shown to inhibit sodium excretion as a single dose or after prolonged doses. These results were reproducible under the conditions of these experiments, although they are not in complete agreement with earlier experiments reported in the literature (10).

Ability of Diuretic Agents to Concentrate Sodium in the Urine.—Results in Table I indicate that neither urine volume measurements alone nor sodium-22 excretion alone gave consistent indications of the activity of the known diuretic compounds in every case. The explanation for this may be that the experimental groups in this particular study were small and that the periods of observation were short. However, the DI (Diuretic Index) did give definite indications of drug action in all cases studied here. (See Table I.) (DI = Urine Volume × Average % of Original Whole Body Radioactivity in Urine.) The percentage of original activity was calculated by dividing the net amount of activity contained in the urine sample by the net amount of activity contained in the corresponding animal at time *0*, and then converting to per cent. This value was calculated for each animal, and the average of the values was determined for each test compound.

It appears from these results that an enhancing or inhibiting effect on sodium excretion by compounds known to affect sodium metabolism could be determined in a simple 5-hour experiment.

SUMMARY

Procedures have been described for detecting drug effects on sodium metabolism in rats over a period of 5 hours by whole body radioassay techniques in an effort to evaluate the feasibility of *in vivo* tracer techniques in drug screening studies. These procedures have the following advantages: short experiment times are possible; it is not necessary to collect urine samples; fewer test animals are required than in diuretic screening procedures presently in use; and it is not necessary to sacrifice the animal, thereby allowing for serial study of drug action on the same animal.

The procedures described here involve studies of sodium metabolism only; however, whole body liquid scintillation counting should be an effective tool in investigations of pharmacologically active substances, especially in cases where the drug in question exerts its major effect on a body constituent which is available in a labeled form. Compartmental analyses of the excretion curves of many metabolically active ions (Na, K, Ca, Fe, I) may be expected to serve qualitatively and quantitatively as sensitive indicators of drug action.

Reduction Studies on 3,4-Dihydroxyphenylglyoxylohydroxamyl Chlorides and Related Compounds

By JOSEPH P. LAROCCA and GEORGE R. McCLURE†

The preparation of four new phenylglyoxylohydroxamamides is described; however, only two of these products are fully characterized. The reduction of 3,4-dihydroxyphenylglyoxylohydroxamyl chloride and N-α-methylbenzylphenylglyoxylohydroxamamide with platinum-palladium catalyst under low pressure has been studied and conclusions drawn from chemical, physical, and analytical data.

In 1951, LaRocca, *et al.* (1), were able to reduce successfully phenylglyoxylohydroxamyl chloride to phenethanolamine by utilizing a mixed palladium-platinum catalyst. In addition, they prepared and reduced several arylglyoxylohydroxamamides. Efforts to prepare norepinephrine, either by reduction of the corresponding 3,4-dihydroxyphenylgloxylohydroxamyl chloride or by 3,4-dihydroxyphenylglyoxylohydroxamamide were unsuccessful, since the reduction products could not be identified. The purpose of this investigation is to study these reductions in an attempt to clarify the reaction.

EXPERIMENTAL

Low pressure (approx. 4 Atm.) and room temperature were used for all reductions. These were carried out in a Parr series 3910 hydrogenation apparatus. The platinum oxide used for the preparation of the mixed catalyst itself was prepared from platinum chloride by fusion with potassium nitrate as described in Reference 2. The mixed catalyst used in all reductions was composed of: 10.00 Gm. activated charcoal, 1.00 Gm. palladium chloride, 0.15 Gm. platinum oxide.

The catalyst was prepared by suspending these materials in 100 ml. of 1 *N* sodium acetate solution and shaking under 1 atmosphere of hydrogen until hydrogen uptake ceased. The catalyst was then filtered off and washed with several portions of distilled water, followed by ethyl alcohol. Attempts to dry the catalyst by suction usually resulted in spontaneous ignition of the catalyst so it was used while still damp.

Reduction of 3,4-Dihydroxyphenylglyoxylohydroxamyl Chloride.—The reduction of 4.27 Gm. (0.02 mole) of 3,4-dihydroxyphenylglyoxylohydroxamyl chloride was carried out by shaking (under 4 Atm. of hydrogen) an acidified hydroalcoholic solution (95 ml. of 95% ethanol and 5 ml. of concentrated hydrochloric acid) of the compound with the mixed catalyst described above.

The first mole of hydrogen was absorbed in 2 minutes, the second in 20 minutes, the third in 3 hours, and the fourth in 6 hours. From the reduction mixture, 2.9 Gm. (77.5% yield based on 3,4-dihydroxyphenethylamine hydrochloride) of a colorless solid was obtained. Repeated recrystallizations from hot absolute alcohol and benzene gave colorless plates which melted at 243°dec. The melting point of norephinephrine hydrochloride is 141°. This reduction was repeated 10 times with similar results. The reduction product was soluble in water, slightly soluble in alcohol, and insoluble in benzene and ether. It gave an emerald green color with ferric chloride solution, indicating an *o*-dihydroxyphenyl nucleus and (with aqueous silver nitrate) a precipitate of silver chloride which is quickly reduced to free silver. It is very susceptible to oxidation in alkaline solution, first giving a rose colored solution which darkens on standing.

Anal.—Found: C, 50.99 and 51.00; H, 6.45 and 6.45; Cl, 18.78 and 18.78; N, 7.15 and 7.24.[1] The best emprical formula obtained from this information is $C_8H_{12}ClNO_2$.

A quantitative determination of acetylatable groups by the method described by Siggia (3) indicated the presence of two such groups. However, the development of a rose color in alkaline solution indicated that at least one functional group had not been acetylated.

The infrared spectrum of the reduction product was determined on a 500-mg. potassium bromide disk containing 50 mg. of sample. This spectrum was determined on a Perkin Elmer model 112, double pass, single beam spectrophotometer. The interpretation of the spectrum was made from an energy transmission record. The presence of a NH_3^+ group was indicated by bands at 3.29, 6.18, and 6.78 μ; a hydroxy (or secondary amine) group gave a strong band at 3.02 μ. Bands at 6.24, 6.32, 6.56, 7.90, 9.05, 9.26, 10.38, 11.43, and 12.27 μ confirm the presence of a 1, 2, 4-trisubstituted benzene ring. Strong bands at 7.78 and either 7.46 or 7.58 μ show the presence of one or more phenolic hydroxyl groups.[2] The above data coupled with the ease of reducibility of hydroxyl groups on carbon atoms adjacent to the benzene ring seem to establish fairly conclusively that the reduction product is 3,4-dihydroxyphenethylamine hydrochloride. This is an agreement with the best empirical formula as determined from the analytical data. The injection of 1.0 ml. of a 1/200 *N* solution of the reduction product into a dog under pentobarbital anesthesia

Received October 9, 1962, from the Pharmaceutical Research Laboratories, University of Georgia, School of Pharmacy, Athens.

Accepted for publication November 13, 1962.

TABLE I.—SUMMARY OF ARYLGLYOXYLOHYDROXAMAMIDES

$C_6H_5 \cdot CO \cdot C(NOH) \cdot NR'R''$ R′	R″	M. p.[a]	Description	Yield, %	Nitrogen—Calcd.	Nitrogen—Found
Cyclohexyl	H	...	Brown oil	98.3	...	...
Ethyl	Ethyl	...	Yellow oil	119.0	...	...
						10.78
p-Methylphenyl	H	154°	Tan needles	74.0	11.01	11.03
						9.59
α-Methylbenzyl	H	128°	Yellow plates	88.0	10.44	9.67

[a] All melting points are uncorrected.

produced a pressor response similar to that obtained by Barger and Dale (4) with an equal dose of 3,4-dihydroxyphenethylamine hydrochloride. The melting points of the reduction product and 3,4-dihydroxyphenethylamine hydrochloride are in close agreement: literature value for 3,4-dihydroxyphenethylamine hydrochloride 240–241° dec. (5), reduction product 243° dec. The picrate of 3,4-dihydroxyphenethylamine is reported to melt at 189° (5); the picrate of the reduction product melts at 190–193°. In all instances reduction of 3,4-dihydroxyphenylglyoxylohydroxamyl chloride gave a small amount of a yellow oil in addition to the colorless crystalline 3,4-dihydroxyphenethylamine hydrochloride. This oil was found to be extremely hygroscopic, and it underwent color change in alkaline solution. Upon addition of a base, the solution became cherry red in color and changed to yellow when an acid was added. These properties were not possessed by either 3,4-dihydroxyphenylglyoxylohydroxamyl chloride or the 3,4-dihydroxyphenethylamine hydrochloride produced in the reduction reaction.

Preparation of Arylglyoxylohydroxamamides.—The arylglyoxylohydroxamamides were prepared by essentially the same method reported by LaRocca, *et al.* (1). As was expected, the aromatic amides were found to be crystalline solids, and the aliphatic amides to be resinous solids or oils. Attempts to prepare the hydrochlorides of the aliphatic amides failed to give crystalline solids. (See Table I.)

Reduction of N-α-methylbenzylphenylglyoxylohydroxamamide.—In a reduction solution identical with that previously described, 5.26 Gm. (0.02 mole) of N-α-methylbenzylphenylglyoxylohydroxamamide was shaken under 4 Atm. of hydrogen for 40 hours. During this time 3.5 moles of hydrogen were taken up. Removal of the catalyst and evaporation of the solvent under reduced pressure gave 4.5 Gm. of a yellowish white solid which melted at 154°. Repeated recrystallizations gave colorless plates which melted at 169–171.°

Anal.—Found: Cl, 11.73 and 11.56; N, 9.18 and 9.17. The best empirical formula which can be assigned from the analytical data is $C_{16}H_{19}Cl\ N_2O_2$ which indicates the reduction of the ketone group.

An infrared spectrum was determined on a Nujol mul of the compound. This spectrum showed a band at 3.02 μ (which is characteristic of a hydroxyl or secondary amino group), a strong band at 6 μ (indicative of a C=O or C=N), and bands at 6.29, 6.32, and 6.56 μ (indicative of a phenyl group).[3] These data indicate that the oximino alcohol is the product of the reduction. Attempts to reduce this compound further by the above procedure were unsuccessful.

[3] The infrared spectrum of this compound was determined and interpreted by the Department of Research in Chemical Physics, Mellon Institute of Industrial Research, Pittsburgh, Pa.

DISCUSSION AND CONCLUSIONS

The successful reduction of phenyl-, *p*-xynyl-, *p*-methylphenyl-, and probably 3,4-dihydroxyphenyl, glyoxylohydroxamyl chlorides to the corresponding arylethanolamines by the use of hydrogen under high pressure with a platinum-palladium catalyst has been reported (1). Attempts to reduce 3,4-dihydroxyphenylglyoxylohydroxamyl chloride with the same type catalyst under low pressure failed to give the corresponding phenethanolamine. The pharmacological, chemical, analytical, and physical data indicate that the reduction product is 3,4-dihydroxyphenethylamine. The same type data for the reduction product of N-α-methylbenzylphenylglyoxylohydroxamamide strongly indicates the formation of the corresponding oximino alcohol. These data indicate that, in the reduction of 3,4-dihydroxyphenylglyoxylohydroxamyl chloride, the oxygen atom on the carbon adjacent to the aromatic nucleus is removed by the reduction. In the case of phenyl-, *p*-xenyl-, *p*-methyl- phenylglyoxylohyoroxamyl chlorides and N-α-methylbenzylphenylglyoxylohydroxamamide it appears that this oxygen undergoes normal reduction to the corresponding alcoholic group. The most obvious explanation of this phenomena is that certain types of substituents in the aromatic nucleus (at least 3,4-dihydroxy substitution) tend to increase the susceptibility of the oxygen on the α carbon to over-reduction.

Hartung, *et al.* (6), report the reduction of α-isonitrosopropiophenone with palladium-charcoal catalyst proceeds to the amino-ketone first and then to the amino alcohol. All data acquired in this study indicate that, with a platinum-palladium-charcoal catalyst, reduction of the ketone group precedes the reduction of the oximino group. This conclusion is strengthened by the typical oxime color changes in acid and alkaline solution exhibited by the yellow oil by-product obtained from reduction of 3,4-dihydroxyphenylglyoxylohydroxamyl chloride.

Plate Assays for Griseofulvin in Pharmaceutical Preparations and Body Fluids

By EVERETT W. KNOLL, FRANCES W. BOWMAN, and AMIEL KIRSHBAUM

A microbiological assay for griseofulvin in pharmaceutical preparations using either cylinders or paper disks is described. A modification to assay griseofulvin concentrations in body fluids is also presented. Both assays offer more precision in assaying griseofulvin than existing microbiological methods.

GRISEOFULVIN, an orally effective antifungal agent, produced by *Penicillium griseofulvin* and other species of *Penicillium*, was first isolated in pure form in 1946 (1). Since that time it has been assayed by spectrophotometric (2), polarimetric (3), isotope dilution (3), and microbiological methods (1). In the latter method, solutions containing griseofulvin are serially diluted in nutrient broth which is later seeded with *Botrytis alli*. The greatest dilution causing distortion or curling of the hyphae of *Bortrytis alli* is recorded and used to estimate the potency of the solution. However, this procedure lacks precision and reproducibility, as do most methods employing observation of morphogenetic responses in microorganisms.

A microbiological assay was developed for griseofulvin in pharmaceutical preparations and in serum. The method is a modification of the cylinder-plate agar diffusion assay for penicillin (4). The response is a well-defined zone of mold inhibition which can be accurately measured by its diameter.

MATERIALS AND METHODS

Medium I.—Dextrose 40.0 Gm., peptone 10.0 Gm., and distilled water sufficient to make 1000 ml. The pH should be 5.65 ±0.05 after sterilization.

Medium II.—Dextrose 40.0 Gm., peptone 10.0 Gm., agar 15.0 Gm., chloramphenicol U.S.P. 0.05 Gm. (activity), and distilled water sufficient to make 1000 ml. The pH should be 5.65 ±0.05 after sterilization.

Medium III.—Dextrose 40.0 Gm., peptone 10.0 Gm., agar 15.0 Gm., chloramphenicol U.S.P. 0.05 Gm. (activity), and distilled water sufficient to make 1000 ml. The pH should be 5.65 ±0.05 after sterilization. To each 100 ml. of this agar at approximately 50° aseptically add 2 ml. of a sterile solution of cycloheximide. The solution contains 10 mg./ml. and is prepared by dissolving cycloheximide in distilled water. The solution is sterilized by filtering through a membrane filter having a porosity of 0.22 μ.

Preparation of Spore Suspension.—Grow *Microsporum gypseum* (ATCC 14683) for 3 weeks at 25° in four 3-L. Erlenmeyer flasks, each containing 200 ml. of *Medium I*. Remove the floating mat from the flask with a sterile wire loop and place in a sterile blending jar. Aseptically add 200 ml. of sterile distilled water and blend for approximately 30 seconds, allow to settle, then decant about 150 ml. of the supernatant into 100-ml. sterile, capped centrifuge tubes. Add the amount of distilled water equal to the amount removed each time and repeat this process four to five times to assure maximum recovery of spores from the mycelial mat. Centrifuge the tubes containing the spores at 4000 r.p.m. for 15 minutes and discard the supernatant. Wash the residual spores from all tubes, using a minimum of sterile distilled water (2–3 ml. per tube) and pool the washings into a sterile flask containing a few sterile glass beads. (This procedure usually yields about 25–35 ml. of spore suspension.) The spore suspension is stable for at least 2 months at 5°. Prepare test plates using a 6-ml. base layer of *Medium II* covered with a 4-ml. seed layer of *Medium III* inoculated with varying volumes of spore suspension, *e.g.*, 1 or 2%. Determine the proper per cent of inoculum to be used by observation of the largest and clearest zones of inhibition given by 5 mcg./ml. of griseofulvin on the test plate.

Add 6 ml. of *Medium II* to a 20 × 100-mm. Petri dish and allow to harden for use as a base layer. Cover the Petri dishes with sterile porcelain lids glazed on the outside. Add the proper amount (as previously determined) of the spore suspension to each 100 ml. of *Medium III* which has been cooled to approximately 50°. Mix the culture and agar thoroughly and add 4 ml. to each plate containing the uninoculated base agar. Tilt each plate back and forth to spread the inoculated agar evenly over the surface. When the agar has hardened place six cylinders on the surface so that they are at approximately 60°-intervals on a 2.8 cm. radius. Use stainless steel cylinders that have an outside diameter of 8 ±0.1 mm., an inside diameter of 6 ±0.1 mm., and a 10 ±0.1-mm. length.

Assay of Pharmaceutical Preparations.—Store the griseofulvin working standard at room temperature under desiccation. Dissolve about 50 mg. in sufficient N,N-dimethylformamide (DMF) to give a concentration of 1000 mcg./ml. This solution may be kept for 3 months under refrigeration. Prepare the standard curve by diluting the 1000 mcg./ml. griseofulvin solution to 64, 80, 100, 125, and 156 mcg./ml. in DMF. Then further dilute one part of each of these solutions with 19 parts of 0.1 *M* phosphate buffer pH 8.0 to give final solutions of 3.2, 4.0, 5.0, 6.25, and 7.8 mcg./ml.

Received December 12, 1962, from the Food and Drug Administration, U. S. Department of Health, Education, and Welfare, Washington 25, D. C.
Accepted for publication December 19, 1962.

Use three plates for the determination of each point on the curve, except the 5.0 mcg./ml. solution, a total of 12 plates. On each of three plates fill three cylinders with the 5.0 mcg./ml. solution and the other three cylinders with the concentration of the standard curve under test. There will be thirty-six 5.0 mcg./ml. determinations and nine determinations for each of the other points on the curve. Incubate the plates for at least 48 hours at 30°, and measure the diameters of the circles of inhibition. (Plates may be incubated longer if zones are indistinct.) Average the 36 readings of the 5.0 mcg./ml. concentration and the readings of the other concentrations for each set of three plates. The average of the 36 readings of the 5.0 mcg./ml. concentration is the correction point for the curve. Correct the average value obtained for each point to the figure it would be if the 5.0 mcg./ml. reading for that set of three plates were the same as the correction point. Thus, if in correcting the 4.0 mcg./ml. concentration, the average of the 36 readings of the 5.0 mcg./ml. concentration is 16.6 mm., and the average of the 5.0 mcg./ml. concentration of this set of three plates is 16.4 mm., the correction is plus 0.2 mm. If the average reading of the 4.0 mcg./ml. concentration of these same three plates is 14.8, the corrected value is then 15.0 mm. Plot these corrected values, including the average of the 5.0 mcg./ml. concentration on semilogarithmic paper, placing the griseofulvin concentrations on the logarithmic scale and the diameters of the zones on the arithmetic scale. Draw the line of best fit by inspection or by calculation as described by Deutschberger and Kirshbaum (5).

Dissolve an appropriate aliquot of the griseofulvin powder or suspension in DMF to give a convenient stock solution. Further dilute with DMF to give a concentration of 100 mcg./ml. Then further dilute one part of this with 19 parts of 0.1 *M* phosphate buffer pH 8.0 to give a final estimated concentration of 5.0 mcg./ml. of griseofulvin. For the assay of tablets, pool a representative number of tablets (usually five), blend them in 250 ml. of DMF, and follow the dilution procedure described for powders or suspensions.

Use three plates for each unknown sample. Fill three cylinders on each plate with the standard 5.0 mcg./ml. solution and three cylinders with the sample solution to be tested, alternating standard and sample. Incubate the plates for at least 48 hours at 30° and measure the diameter of each circle of inhibition. To calculate the potency of the sample, average the zone readings of the standard and the zone readings of the sample on each set of plates. If the sample gives larger average zone size than the standard, add the difference between them to the 5.0 mcg./ml. zone on the standard curve. If the average sample value is lower than the standard value, subtract the difference between them from the 5.0 mcg./ml. value on the curve. Read from the standard curve the concentration corresponding to the corrected zone size.

Assay of Potency of Pharmaceutical Preparations Using Paper Disks in Lieu of Cylinders.—In the method described above, paper disks may be substituted for the cylinders if preferred by making the following changes. Use round, blank disks having a diameter of 1/4 in. made of clear-white filter paper. Schleicher and Scheull No. 740-E paper or comparable grade may be used. Place blank disks on aluminum or stainless steel wire mesh which is supported in a manner to allow circulation of air above and below the disks. Prepare the solutions for the standard disks by further diluting the standard stock solution of griseofulvin in DMF to obtain solutions containing the following concentrations: 50, 62.5, 75, 95, and 120 mcg./ml. Pipet 0.02 ml. of each stock solution to three replicate disks, and put in vacuum desiccator for 2–3 hours until perfectly dry. The final concentration of griseofulvin per disk is 1.0, 1.25, 1.5, 1.9, and 2.4 mcg. Disks may be used for assay purposes that have been stored for up to 2 weeks under refrigeration. However, griseofulvin disks stored in stoppered test tubes containing a desiccant showed no loss of potency after 6 months.

Using disks prepared from the five different concentrations of standard described above, proceed as directed for establishing the standard curve by the cylinder-plate method, but in lieu of filling the cylinders, place the disks on the plates with forceps and tap gently to ensure an even seal. Use three plates (prepared as described for cylinder-plate method) for the determination of each point on the curve. On each of three plates, place three 1.5 mcg. disks and three disks containing one of the antibiotic concentrations of the standard curve. There will be thirty-six 1.5 mcg. determinations and nine determinations for each of the other points on the curve.

Prepare the stock solution of the sample as described for the cylinder plate assay. Then further dilute with DMF to a concentration of 75 mcg./ml. Prepare disks from this solution to give a final estimated concentration of 1.5 mcg./disk as described for the standard curves. Incubate the plates for at least 48 hours at 30°. Accurately measure the zones of inhibition with calipers, by projection on a calibrated screen, or by any other suitable method. Plot the standard curve and calculate the potency of the sample as described for the cylinder plate assay.

Assay of Griseofulvin in Body Fluids.—Prepare the suspension, standard curve, and plates as described for assay of griseofulvin in pharmaceutical preparations by the cylinder-plate method except modify preparation of the plates, and make 1 +19 dilutions for the standard curve using the appropriate body fluid. For example, if the body fluid to be assayed for griseofulvin content is serum, use antibiotic-free normal human serum instead of buffer for the final dilutions of the standard. Add the griseofulvin in DMF directly to the serum and shake immediately to distribute the antibiotic evenly through the serum. Prepare stock griseofulvin solutions in DMF to contain 90, 60, 40, 26, and 18 mcg./ml., and add 0.5 ml. of each solution to 9.5 ml. of serum to obtain final concentration of 4.5, 3.0, 2.0, 1.3, and 0.9 mcg./ml.

To prepare the plates, use heavy flat-bottomed (20 × 100 mm.) glass Petri dishes covered with sterile porcelain lids glazed on the outside. Add 5 ml. of *Medium II* seeded with 1% of the spore suspension previously described and allow to harden. Use one plate for each unknown tested. Test serum samples undiluted unless a concentration of greater than 4.5 mcg./ml. is expected. If so, dilute with serum to an estimated concentration of 2.0

mcg./ml. Add the 2.0 mcg./ml. standard solution to alternate cylinders on each plate and the sample to the remaining cylinders. Incubate the plates for at least 48 hours at 30°, read the zones of inhibition, and calculate the concentration of griseofulvin as described for the cylinder plate assay. The lowest concentration of griseofulvin that this method can detect in body fluids is 0.9 mcg./ml.

EXPERIMENTAL

Griseofulvin bulk material, tablets, and suspensions assayed by this cylinder plate or disk method gave results comparable to those obtained using a spectrophotometric method (2) as shown in Table I. Using the described method, standard curves were run using a commercial bulk sample of griseofulvin as a house standard. Four replicate assays of a bulk sample from a different manufacturer were performed on each of three consecutive days. From the results obtained the 95% confidence limits of a single assay of the method described for pharmaceutical preparations were calculated and shown to be ±10.9%. This range can be reduced of course by performing replicate assays. Different commercial preparations were assayed by this procedure and the spectrophotometric method (2). The results summarized in Table I show good agreement.

TABLE I.—GRISEOFULVIN PHARMACEUTICAL PREPARATIONS ASSAYED BY TWO METHODS

Product	Label Potency	Spectrophotometric	Microbial
Bulk	1,000 mcg./mg.	1000	1000
		978	1008
Tablets	250 mg./tablet	250	255
Oral suspension	250 mg./5 ml.	250	250

Experimental studies on the assay in serum were limited because of lack of clinical facilities. However, one male receiving therapy of griseofulvin (250 mg. every 4 hours, total dose 1 Gm./day) for 1 week volunteered to have his serum assayed for griseofulvin. Blood sample was taken 2 hours after a 250 mg. dose of griseofulvin. His serum assayed 0.9 mcg./ml., whereas the serum from a male volunteer receiving no drug was negative.

Basic 1,3-Dioxolanes

By A. R. PATEL and J. F. ONETO

The preparation of a series of 2-aminomethyl and 4-aminomethyl-1,3-dioxolanes has been described. A selected number of the products were subjected to preliminary pharmacologic evaluation.

IN RECOGNITION of the various structural aspects assigned to muscarine prior to 1942, Fourneau and associates (1) initiated studies on quaternary ammonium compounds which led to the synthesis of 2-methyl-4-dimethylaminomethyl-1,2-dioxolane methiodide. The compound exhibited strong muscarinic activity which decreased with the substitution of bulkier groups for the C-2 methyl moiety.

Subsequently, extensive investigations on the autonomic pharmacodynamics of basic 1,3-dioxolanes and their quaternary derivatives have been reported (2–8). Recently, Hardie and co-workers (9) have reported on the local anesthetic and spasmolytic properties of a series of 4-(2-piperidyl)-1,3-dioxolanes.

The present work was undertaken to prepare basic dioxolanes with additional structural variations for pharmacologic evaluation. The products represent essentially an extension of the Blicke series (5) of 2-aminomethyl and 4-aminomethyl substituted 1,3-dioxolanes.

The intermediate halodioxolanes (Tables I and II) required for the synthesis of the aminodioxolanes were prepared by two general methods: (*a*) condensation of an α-haloketone with a 1,2-glycol or with glycerol-α-monochlorohydrin in the presence of *p*-toluenesulfonic acid according to the procedure of Salmi (10); (*b*) condensation of a ketone with epibromohydrin in the presence of stannic chloride according to the procedure of Bersin and Willfang (11, 12).

The infrared absorption spectra of a number of the halodioxolanes listed in Table I are shown in Table III. The four bands found in the 990–

[a] Measured in potassium bromide disks (concentration 0.4%; disk thickness 0.6 mm.) with a Perkin-Elmer model 21 infrared spectrophotometer.

mediate halodioxolane, the amine, and a solvent in a pressure bottle on a steam bath. The periods of heating varied from 2 to 7 days. The products were isolated as hydrochlorides, oxalates, or methiodides.

In contrast to the above procedure for the preparation of 4-aminomethyl-1,3-dioxolanes, the preparation of the 2-aminomethyl analogs (Table V) required higher temperatures. For example, when a mixture of 2-bromomethyl-2-phenyl-1,3-dioxolane, morpholine, and benzene was heated in a pressure bottle on the steam bath for 7 days, the starting intermediates were recovered unchanged. The reaction was successfully conducted in the absence of solvent in sealed glass tubes heated at 140–150° for 24 hours. The products were also isolated as hydrochlorides, oxalates, or methiodides.

The condensation of Mannich bases with 1,2-glycols as a direct potential route to 2-aryl-2-(β-aminoethyl)-1,3-dioxolanes was studied. The condensation of β-morpholinopropiophenone hydrochloride with ethylene glycol was carried out with moderate success. Under similar reaction conditions, β-dimethylamino and α-methyl-β-dimethylaminopropiophenone hydrochlorides failed to yield the corresponding dioxolanes.

In preliminary experiments on isolated guinea pig ileum, compounds 1, 3, 5, 6, 8, 19, 22, 26, and 27 (Table IV), compounds 1, 6, and 10 (Table V), and 2-phenyl-2-(β-morpholinoethyl)-1,3-dioxolane hydrochloride exhibited low anticholinergic activity. Significant activity was observed with compound 9 (Table V).

In exploratory experiments on anesthetized dogs, compounds 3, 5, 13, 19, 27, 28, and 30 (Table IV), compounds 6 and 11 (Table V), and 2-phenyl-2-(β-morpholinoethyl)-1,3-dioxolane hydrochloride exhibited weak autonomic activity. Compound 9 (Table V) produced a fall in diastolic pressure and cardiac stimulation at an intravenous dose of 1 mg./Kg. A prolonged duration of action resulted on increasing the dosage to 5 mg./Kg.

EXPERIMENTAL[1]

The procedures used for the synthesis of the intermediate halodioxolanes and the final products are illustrated by the following examples.

2-Phenyl-2-(β-morpholinoethyl)-1,3-dioxolane Hydrochloride.—The compound was prepared according to the procedure of Salmi (10). A mixture of 38.5 Gm. (0.15 mole) of the required Mannich base salt (β-morpholinopropiophenone hydrochloride), 31.0 Gm. (0.5 mole) of ethylene glycol, 0.95 Gm. of *p*-toluenesulfonic acid monohydrate, and 200 ml. of toluene was refluxed for 3 hours in an assembly equipped with a Dean-Stark trap. The reaction mixture was rendered alkaline with 10% aqueous sodium hydroxide. The combined toluene layer and ether extracts of the aqueous phase were washed with water, dried, and concentrated to an oily residue *in vacuo*. Unreacted Mannich base was removed by vacuum distillation (b_3 77–83°). The distillation residue was converted to the hydrochloride with ethereal hydrogen chloride. The yield, after two recrystallizations from absolute ethanol, was 5.5 Gm. (12%), m.p. 220–221°.

Anal.—Calcd. for $C_{15}H_{22}ClNO_3$: N, 4.67; Cl, 11.83. Found: N, 4.40; Cl, 11.66.

2-Bromomethyl-2-(*p*-phenylphenyl)-1,3-dioxolane.—(Table I, compound 11).—The compound was prepared according to the procedure of Salmi (10). A mixture of 27.5 Gm. (0.1 mole) of *p*-phenylphenacyl bromide, 62 Gm. (1 mole) of ethylene glycol, 0.95 Gm. of *p*-toluenesulfonic acid monohydrate, and 200 ml. of toluene was refluxed for 15 hours. The yield was 24 Gm. (76%), m.p. 79.5 to 80° after recrystallization from ethanol.

2-Benzyl-2-methyl-4-bromoethyl-1,3-dioxolane.—(Table II, compound 16.)—The compound was prepared according to the procedure of Bersin and Willfang (11, 12). A stirred solution of 20 Gm. (0.15 mole) of phenyl-2-propanone and 27.5 Gm. (0.2 mole) of epibromohydrin in 150 ml. of dry carbon tetrachloride was maintained at 0–5° for 2 hours during the dropwise addition of

[1] Melting points were determined on a Fisher-Johns or Nalge melting point apparatus and are uncorrected. Microanalyses are by the Microanalytical Laboratory, Department of Chemistry, University of California, Berkeley.

Wool Wax Emulsions

By H. I. SILVERMAN

Emulsions prepared with a wool wax isolate and its ethoxylated derivative have been formulated and studied. Rheological patterns were determined over a 12-month period and flow types characterized. Globular sizes were also determined and correlated with the observed stabilities (creaming rates) and emulgent concentrations. The inapplicability of Stokes' law in theoretical calculations of creaming rate has been shown. A stable emulsion may be produced by selecting as an emulsifying agent a material that will not form a true solution with either of the emulsion phases while exhibiting an affinity for or a greater solubility (colloidal sol) in the external phase.

WOOL WAX, its numerous fractions and synthetic derivatives, enjoy wide and varied applications in the cosmetic, pharmaceutical, chemical, and other fields. The chemical composition of this natural wax is varied and extremely complex. Briefly, it may be described as a mixture of a majority of straight chain and steroid waxy esters plus a minority of free fatty acids and alcohols. A comprehensive literature survey has been recently published (1, 2) which contains, in addition to references on chemistry, numerous sources of wool wax derivatives, both the purified fractions and chemically altered components of these fractions.

It is the purpose of this paper to report on the feasibility of using two of the aforementioned derivatives as emulgents. No single component of wool wax is seemingly responsible for its ability to act as an efficient w/o emulsifier. Rather, its value as an emulsifying agent is probably due to both the alcoholic and free fatty acid components (3,4).

Wool wax components may be chemically modified to increase their dipole moment by ethoxylation (5, 6). Polarity will increase in a linear proportion corresponding to the length of the coupled ethylene oxide polymer. This hydrophilic polymer, upon reaching a definite number of ethenoxy groups per molecule will allow the preparation of a water "soluble" colloidal sol from the originally water insoluble component. Due to the high molecular weight hydrocarbon components, true aqueous solutions are not possible although transparent dispersions can be produced. In addition, the increased hydrophilic property will tend to reverse the original emulsifying ability from w/o to o/w.

Received October 5, 1961, from the Research Institute of the Brooklyn College of Pharmacy, Long Island University, Brooklyn, N. Y.
Accepted for publication October 3, 1962.
Presented to the Scientific Section, A.PH.A., Las Vegas meeting, March 1962.

MATERIALS

For this study an isolation product of wool wax and its ethoxylated derivative were selected as emulsifying agents. The isolation product was Lanfrax,[1] a water insoluble fraction, appearing physically as a stiff semisolid plastic material when at room temperature. This fraction is composed of a mixture of the higher melting range (49–51°) hard wax esters which have been removed from the lower melting components by a fractional solvent crystallization process (7).

Lanfrax WS55,[1] the ethoxylated derivative of the above-mentioned wax, is a nonionic surface-active and hydrophilic hard waxy material. Clear transparent colloidal sols may be prepared in water.

The balance of the emulsion systems was composed of distilled water, liquid petrolatum (viscosity 60 cps., sp. gr. 0.86), and a phenolic salt—sodium *o*-phenyl phenol[2] which functioned as a preservative.

EXPERIMENTAL

Formulations and Physical Data.—Lanfrax was used as the w/o emulsifying agent. At room temperature in mineral oil, clear colloidal sols may be produced using up to a 1% concentration by weight with uniform but cloudy dispersions possible at greater concentrations.

Lanfrax WS55 was used as the o/w emulsifying agent. Transparent colloidal sols in water may be produced at room temperature. The Tyndall cone phenomenon was observed with aqueous solutions of this ethoxylated wax derivative.

Experimental emulsions were similarly prepared by heating the external phase of each formulation to 65–70° and dissolving the emulsifying agent in it. The internal phases were likewise heated to the same temperature. The preservative was dissolved in each of the respective aqueous phases prior to emulsification. Emulsification was then carried

out by placing the external phase, containing the emulsifying agent, in a Waring Blendor connected to a powerstat (set to a dial reading of 75) and slowly adding the internal phase. After mixing 2–3 minutes, the emulsion, (which formed immediately in each case) was removed from the blender, allowed to cool to approximately 60°, and then passed twice through a piston homogenizer. Several batches of the respective emulsions (500 Gm. each) were processed by this method and were used in studying both stability and rheological patterns.

Formulations are set forth in Table I, and as can be noted each of the emulsion types was prepared at emulgent concentration of 3, 5, and 8%, respectively, by weight.

Stability Studies.—A 100-ml. quantity of each formulation was poured into separate matched glass cylinders of 2.5 cm. i.d. Emulsion height in these tubes was 20.5 cm. Apparent viscosities of the external emulsion phases, each of which contained the listed content of emulsifying agent, was determined at minimum shear by a Brookfield Viscometer, model LVT, and recorded in Table II. Specific gravities of the above-described phases were determined by the pycnometer method at 25° and are likewise recorded in Table II. At predetermined intervals emulsions were microscopically examined in order to record the globular size of the dispersed

[a] In cm. of zone height of separated emulsion containing a *lesser* concentration of dispersed phase; column part-L is bottom, U is top; C is creaming. [b] In cm. of zone height; column part-L is bottom, U is top; P is phase. [c] 100 ml. of each emulsion placed into glass tubes of 2.5 cm. i.d., height of emulsion in tubes was 20.5 cm.

phase. Droplet size may be used as an aid both in stability prediction (8) and creaming rate calculations by the use of Stokes' law.

With the use of outlined techniques as a guide (9, 10), diameters of the dispersed particles were determined and then recorded in Table III. A Levy Hemacytometer with Fuchs-Rosenthal ruling and a calibrated ocular micrometer disk were employed for the counting procedure. Approximately 1000 globules in each emulsion were microscopically measured. Brownian movement was noted in each of the experimental emulsions and was especially significant in the w/o series.

Creaming and phase separation were noted by measuring and recording their respective zone heights at definite intervals. These measurements coincided with times of globular examination.

Observations on the former two phenomena were recorded over a period of 4 months (Table IV). Separation zone placement in the stability columns is also recorded.

Creaming Rate Calculation.—Certain of the aforementioned data (diameter of dispersed globule, viscosity, and specific gravity) may be used in theoretical calculations of the creaming rate by applying Stokes' law. The actual zone distance through which the dispersed globules moved during the stability observation has been compared to the theoretical distance of movement calculated by Stokes' law (Table IV). As an example of a theoretical calculation the rate of globule movement (creaming) is herewith calculated for emulsion 02161A for a 5-day period of standing.

1. Viscosity at minimum shear of external phase containing emulsifying agent..... 0.1 poise
2. Specific gravity of external phase containing emulsifying agent..... 1.01
3. Specific gravity of the dispersed phase (liquid petrolatum)..... 0.86

$$\text{Stokes' eq.: } V = \frac{d^2(P_1 - P_2)g}{18\,n}$$

where V = velocity of sedimentation; d = diameter of globules of the dispersed phase; P_1 = specific gravity of the dispersed phase; P_2 = specific gravity of the dispersion medium; g = gravitational constant; n = viscosity of the dispersion medium.

Solving for V

$$V = \frac{(6 \times 10^{-4})^2\,(0.86 \times 1.01)\,980}{18 \times 0.1}$$

$$= 2.94 \times 10^{-5} \text{ cm./sec.}$$

To determine the rate of globular rise in a 5-day period, then multiply by a factor of 4.32×10^5. Since there are 60 seconds in a minute $\times$ 60 minutes in an hour = 3600 seconds. In 24 hours there are 86,000 seconds and in 5 days there would be 432,000 seconds: $(2.94 \times 10^{-5}) \times (4.32 \times 10^5) = 12.70$ cm./5-day rate of globule rise since the density of the dispersed phase is less than that of the continuous phase.

With the exception of theoretical calculations at the 120-day period, both actual and calculated zones have been recorded (Table IV).

[a] Brookfield Viscometer, model LVT, room temperature 23–25°C.

Apparent Emulsion Viscosities.—Emulsions were stored in 500-ml. quantities in suitable containers which were inverted three times prior to instrumental analysis of viscosities. In addition, at 3-day intervals for a 2-month period only, containers were opened, closed, and shaken vigorously. As was expected, all of the emulsions behaved similarly when their flow properties were studied. All were non-Newtonian and exhibited plastic flow. Apparent viscosities at time intervals have been recorded in Tables V and VI. Corresponding to these tables and using a semilog scale, Fig. 1 plots viscosity characteristics of the emulsions when they are subjected to increasing shearing rates. Finally, Figs. 2 and 3 illustrate a pseudoplastic type of non-Newtonian flow for all of the emulsions as well as an apparent yield value. The latter may be easily extrapolated from the base of each of the flow curves. Shearing rate was recorded as r.p.m. and shearing stress (torque) as scale readings of the Brookfield Viscometer, model LVT. It is most important when studying rheological characteristics of a non-Newtonian system to record all variables. In this experiment, temperature, emulsion age, Brookfield spindle size, rate and shear, and shearing stress or torque (Brookfield scale readings) have been recorded in order to classify properly rheological behavior.

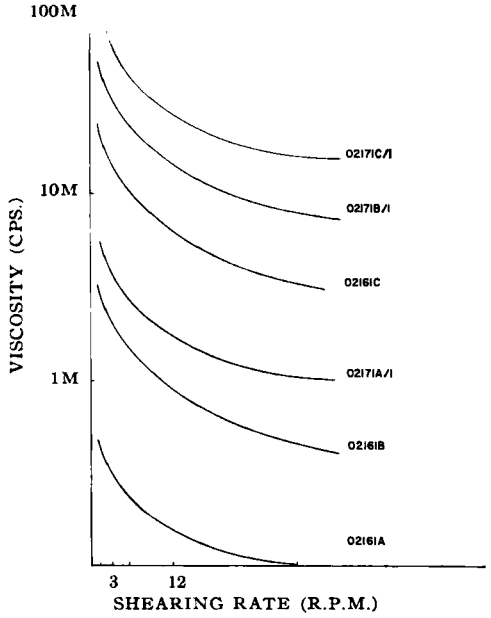

Fig. 1.—Rheogram characterizing type of flow. Sample age 5 days.

DISCUSSION AND CONCLUSIONS

In general, over the time period during which data were collected and recorded in this study (12 months), all emulsions of both types were stable in

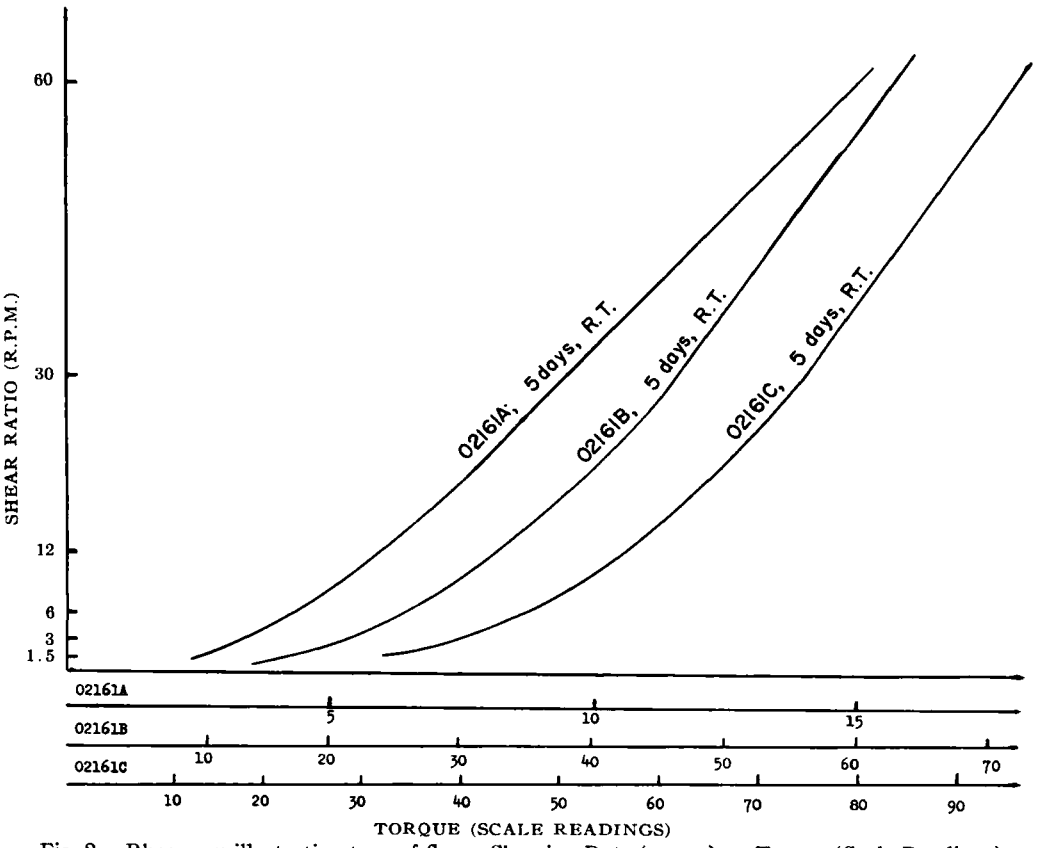

Fig. 2.—Rheogram illustrating type of flow. Shearing Rate (r.p.m.) *vs.* Torque (Scale Readings).

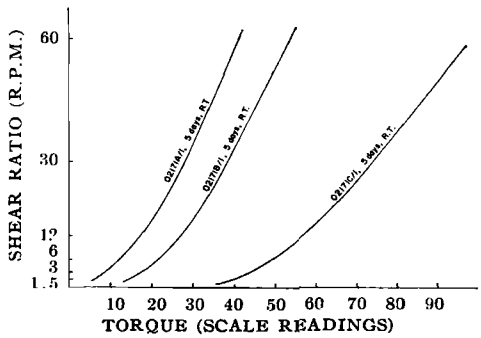

Fig. 3.—Rheogram illustrating type of flow. Shear Rate (r.p.m.) *vs.* Torque (Scale Readings).

regard to cracking. In the o/w series some creaming occurred when the concentration of emulsifying agent (Lanfrax WS55) was held at 3 and 5%, respectively.

As would be expected with the moderate creaming exhibited, simple container inversion was sufficient to reblend these formulas. At an 8% concentration a uniformly stable product resulted with good stability (both observed and when theoretically calculated by a commonly accepted procedure). The latter emulsions' optimum stability is interesting in light of common practice to use thickening agents and emulsifier blends to stabilize emulsion systems. Good stability was observed in all of the w/o emulsions, with again optimum stability at the higher emulgent concentrations. The greater viscosity of the external phase in this series assisted in stabilization. It is interesting to note that Lanfrax as a w/o emulsifying agent exhibits dual functions of thickener as well as emulsifier.

All of the rheograms show expected patterns. Flow may be characterized as pseudoplastic with yield values.

It is interesting to note that the o/w series exhibited a less changeable viscosity pattern than the w/o group. Viscosity drop was generally progressive for the first 2 months, and leveling off afterward. The repeated shaking during the initial 60 days may have contributed further to a weakening in gel pattern. Finally, the omission of an antioxidant from the w/o series and a possible interaction between the phenolic preservative and wax esters could also have played some part in the change of rheological characteristics.

Globular size was generally unchanged over the 2-month observation period. As the degree of creaming (when it occurred) was only moderate, this is not unexpected.

Contrary to Becher (8), Brownian movement was readily noted in all emulsions and this phenomenon was most apparent in the w/o series. That the w/o emulsions were, in general, somewhat less uniform in globular size may be a contributing factor. At the same time, however, the varied droplet size should also tend to increase stability by improved packing. Evidence of this assumption may be noted by examining data in Tables II and III. Observable instability proceeded at a lower rate in the w/o series than in the o/w emulsions.

While a higher viscosity of an emulsion external phase will improve shelf life through retardation of the creaming rate, such improvement in stability is necessarily coupled with globular packing.

The occasional application of Stokes' law to emulsion systems would appear to have several faults. To apply this law (which is suitable for highly dilute (under 0.5%) suspensions) to emulsion systems is seemingly in error. Few of the calculated rates of globular rise correspond to the observed rate. In addition, the following important considerations are neglected: globular size variation; dispersed phase charge (zeta potential); tendency of globules to coalesce; free globular movement hindered due to close packing; Brownian movement affecting globules of 1 μ and less diameter; temperature; concentration of emulsifying agent; and viscosity of dispersed phase may be non-Newtonian.

Stokes' law, in respect to emulsions, should be reserved simply to aid in determining the direction of creaming. It is obvious that a perfectly stable emulsion is one which does not exhibit creaming and/or phase separation. Of course the final stage of instability is where the system eventually reverts to completely separate phases (thermodynamically stable state). Since an emulsion is a potentially changeable system, its natural tendency is toward reversion. Reversion may be delayed through:

A Use of suitable equipment to produce dispersed globules with diameters of 1 $\pm$ 0.5 μ;

B Maintaining the specific gravity of the emulsified phases as close together as possible; and

C Use of an emulsifier to form a suitable interfacial film (which functions to prevent globular coalescence) as well as to cause an increase in the viscosity of the external phase.

This film may be produced by an agent having a greater solubility (colloidal sol) in one phase than another but yet will not form a true solution in either one.

Other factors such as temperature, viscosity, and phase volume ratio, play a part; however, the aforementioned points are those of greatest significance in emulsion stabilization.

Tumor Inhibitors II

Alkaloids of *Ervatamia dichotoma*. Isolation, Crystallization, and Pharmacological Properties of Coronaridine

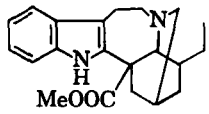
By S. MORRIS KUPCHAN, ALAN BRIGHT, and EDWARD MACKO†

Extraction of the fruit, root bark, and stem bark of *Ervatamia dichotoma* (Roxb.) Blatter from Mangalore, Mysore State, afforded substantial yields of alkaloids. Column chromatography of the petroleum ether-extractable alkaloids yielded coronaridine, which was obtained in crystalline form for the first time. Preliminary pharmacological testing in a variety of pharmacologic procedures revealed that the alkaloid mixtures and coronaridine possess interesting biologic activities.

ERVATAMIA DICHOTOMA (Roxb.) Blatter (syn. *Tabernaemontana dichotoma* Roxb.) is a small apocynaceous tree common in India and Ceylon. The seeds have been known to be poisonous and to possess narcotic and purgative properties; the leaves, bark, and milky sap have also been shown to be purgatives (1). The bark of *Ervatamia dichotoma* was studied by Subbaratnam, who reported the presence of alkaloids (0.01%) and sterols (0.2%) (2).

The work reported herein concerns the alkaloids of *Ervatamia dichotoma* from Mangalore, Mysore State. Initial petroleum ether extraction of the fruit yielded 0.7% of crude alkaloid; the root bark, 0.18%; and the stem bark, 0.09%. Subsequent methanol extraction of the fruit yielded 0.39% of crude alkaloids; the root bark, 0.49%; and the stem bark, 0.32%. The petroleum ether-extractable alkaloids of the fruit showed CNS depressant and hypotensive activities; the methanol-extractable fraction showed reproducible antitumor activity against 9KB cell culture.[1] Fractionation studies of the methanol-extractable alkaloids are in progress and will be described in a later communication.

Column chromatography on neutral alumina of the petroleum ether-extractable alkaloids of the fruits gave a crystalline material, m.p. 92–93°, $[\alpha]_D^{25}$ −34°, identified as coronaridine (I) (3).



I

Coronaridine does not appear to have been obtained in a crystalline form previously. The hydrochloride of the alkaloid showed m.p. 210–211° (decompn.) $[\alpha]_D^{25}$ −8°. The hydrochloride was found to be identical with coronaridine hydrochloride (3) by comparisons of infrared and ultraviolet spectra (4) and of X-ray diffraction patterns.

EXPERIMENTAL

Melting points, determined on a Hershberg apparatus, were corrected for stem exposure. Infrared spectra were determined on a Baird model B double beam infrared recording spectrophotometer. Ultraviolet absorption spectra were determined on a model 11 MS Cary recording spectrophotometer. All solutions were reduced in volume by heating at a temperature not exceeding 50–55° under reduced pressure. Chromatographic fractions were combined where indicated by paper chromatography and infrared spectroscopy. Petroleum ether of b.p. 40–60° was used throughout unless otherwise specified.

Extraction Procedure.—Dried powdered fruit of *Ervatamia dichotoma* (gathered in Mangalore, Mysore State, in April 1958)[2] (460 Gm.) was extracted with petroleum ether (2.5 L.) in a Soxhlet apparatus for 14 hours. The alkaloids were extracted with 4% hydrochloric acid and the acid solution was neutralized with ammonium carbonate and extracted with ether. Evaporation left an amorphous powder (3.0 Gm., fraction A). The dried marc remaining from the petroleum ether extraction was next extracted continuously with hot methanol (3 L.) with a fresh charge of solvent at the end of 2 days. The methanolic extract was evaporated to dryness under reduced pressure and the residue was triturated with 4% hydrochloric acid solution for 3 days. The process was repeated twice more with fresh charges of 4% hydrochloric acid. The suspension was filtered, and the acid solution was neutralized with ammonium carbonate and extracted with ether to yield a crude alkaloidal residue (1.78 Gm., fraction B).

Dried, powdered root bark (2.7 Kg.) was extracted as described above for the fruit. The petroleum

The investigation at the University of Wisconsin was supported in part by research grants from the National Institutes of Health (H-2952 and CY-4500).

Part I in the series: S. M. Kupchan and R. W. Doskotch, *J. Med. Pharm. Chem.*, **5**, 657(1962).

[1] The evaluation of the 9KB assay results by the Cancer Chemotherapy National Service Center in sequential testing is such that a material is considered active if the ED50 ≦ 20 mcg./ml. Assays were performed by CCNSC by the procedures described in Cancer Chemotherapy Reports, **25**, 1 (1962).

[2] We thank Dr. C. B. Sulochana, University Botany Laboratory, Madras, India, for confirming the identity of the plant, and Rajaranga and Co., Madras, India, for gathering and forwarding the dried plant material to us.

ether extract yielded 5.0 Gm. of crude alkaloidal residue (fraction C); the methanol extract yielded 13.30 Gm. (fraction D).

Dried, powdered stem bark (2.08 Kg.) yielded 1.9 Gm. of petroleum ether-extractable alkaloids (fraction E) and 6.67 Gm. of methanol-extractable alkaloids (fraction F).

Isolation of Coronaridine: Fraction A.—The crude mixture (3.0 Gm.) was dissolved in benzene and chromatographed on "neutral" alumina (Woelm. grade 1, 90 Gm.). The fractions eluted with benzene alone were combined. The chromatography on alumina was repeated as above, and the fractions eluted with benzene yielded crystalline residues upon evaporation. Repeated recrystallization from petroleum ether (b.p. 60–68°) gave colorless needles, 560 mg., m.p. 92–93°, $[\alpha]_D^{25} -34°$ (c 1.00, $CHCl_3$); $\lambda_{max.}^{alc.}$ 226 mμ (34,800), 286 mμ (8300), and 294 mμ (7800), $\lambda_{max.}^{CS_2}$ 2.82, 2.86, 3.33, 3.45, 5.82, 6.17, 7.04, 8.00, 8.51, 8.77, 9.26, and 9.80 μ.

Treatment of the crystalline alkaloid with a saturated ethereal solution of hydrogen chloride afforded an amorphous hydrochloride salt. Recrystallization from acetone yielded a microcrystalline solid, m.p. 210–211° (decompn.), $[\alpha]_D^{25} -8°$ (c 1.00, MeOH). The ultraviolet and infrared spectra were identical to those recorded for coronaridine hydrochloride (4). The X-ray diffraction pattern was found to be identical with an authentic sample of the hydrochloride of m.p. 235° (decompn.).[3]

PHARMACOLOGICAL RESULTS

Coronaridine was tested in a variety of pharmacologic procedures and found to possess biological activity. Thus, ptosis was produced in the mouse after doses as low as 5 mg./Kg. intraperitoneally. Higher doses, up to 100 mg./Kg., caused hypotonia, intermittent periods of increased and decreased activity, lacrimation, salivation, bradypnea, and finally tremors at the high dose level. Orally, coronaridine produced slight depression of spontaneous motor activity, lacrimation, bradypnea, and slight ptosis after doses as low as 20 mg./Kg. Lethal effects were apparent at 500 mg./Kg.

In the larger unanesthetized animal, coronaridine exhibited a variety of actions which were not consistent with different species. For instance, doses of 20 mg./Kg. intraperitoneally in the cat caused emesis, vocalization, ataxia, and death. A dose of 10 mg./Kg. intravenously in the dog produced excitation, ataxia, fear, ptosis, and restlessness, and yet in the monkey no overt effects were observed after doses of 10 mg./Kg. intravenously or 100 mg./Kg. orally. This phenomenon of species sensitivity to drugs is not uncommon. Many potentially interesting drugs have been very active in the lower animal but less active or inactive in the higher animal.

Coronaridine was found to possess analgetic activity in the rat using both the D'Amour Smith and Randall-Selitto test procedures over a range of doses from 15 to 100 mg./Kg. orally. In addition, this compound demonstrated weak but significant activity against foot shock induced rage in mice. This test can be used to uncover compounds which may possess mid-range tranquilizing activity.

Other tests were carried out in an effort to determine the possible central nervous system action of the compound. It was found that coronaridine did not potentiate hexobarbital anesthesia, that it failed to antagonize the lethal effect of amphetamine in aggregate mice, and did not produce an anticonvulsant action against maximal electroshock in mice.

The principal action of coronaridine on the blood pressure was depressor. In the anesthetized cat, this compound produced falls in pressure and a concomitant depression of respiration after intravenous doses as low as 0.5 mg./Kg. Lethality occurred at a dose of 10 mg./Kg.

In summary, coronaridine produced signs of autonomic as well as central nervous system activity when tested for biological action in animals. It produced analgesia and was effective in suppressing foot shock induced rage in mice. Toxicity appeared to be associated with respiratory depression in the anesthetized cat. Coronaridine was inactive against 9KB cell culture.

[3] We thank Dr. Norbert Neuss of the Lilly Research Laboratories, Indianapolis, Ind., for the X-ray pattern comparison of our material with authentic coronaridine hydrochloride.

Antimalarial Agents VIII. Synthesis of Amopyroquine

By W. LEWIS NOBLES, RAYMOND F. TIETZ, YUN SHIK KOH, and J. H. BURCKHALTER†

Synthesis of the new parenteral antimalarial amopyroquine and analogs is described.

A BRIEF chemical study was designed to provide analogs of the antimalarial agent amodiaquine (I) hydrochloride U.S.P. (1) in which the diethylamino group was replaced by pyrrolidino, hexamethylenimino, and 4-methylpiperazino (structures II, IV, and V, respectively). The piperidino

		—NR_2
I	(amodiaquine)	$-N(CH_2CH_3)_2$
II	(amopyroquine)	$-N$
III		$-N$
IV		$-N$
V		$-N\langle\rangle NCH_3$

analog III has been previously described (1). The ethyl groups of I are free to move, while the movements of the corresponding groups of II, III, IV, and V are restricted owing to the cyclic structures. Models readily show the three-dimensional nature of the cyclic amines piperidine, hexamethylenimino, and N-methylpiperazine, while all the carbon atoms of pyrrolidine occupy the same plane. Also, V contains an additional ionic center as seen in the second basic nitrogen. In view of these considerations, the compounds were desired for a study of relative antimalarial activity and usefulness.

In order to obtain amopyroquinone (II),[1] *p*-acetamidophenol, pyrrolidine, and aqueous formaldehyde were subjected to Mannich conditions (1). When the intermediate *p*-acetamido-α-pyrrolidino-*o*-cresol was not obtained in crystalline form, the oily substance was hydrolyzed by acid and the unisolated diamine condensed with 4,7-dichloroquinoline to give 4-(7-chloro-4-quinolylamino)-α-pyrrolidino-*o*-cresol (amopyroquine II) in 78% yield. Compounds IV and V were similarly prepared by substitution of hexamethylenimine and N-methylpiperazine for pyrrolidine. In the case of IV, intermediate *p*-acetamido-α-hexamethylenimino-*o*-cresol could be isolated as the crystalline monohydrochloride in 51% yield.

An acridine analog of amopyroquine was obtained by substitution of 6,9-dichloro-2-methoxyacridine for 4,7-dichloroquinoline in the preparative procedure of II.

Pharmacological Results.[2]—Compound II (amopyroquine) is 37 times as active as quinine (*Plasmodium lophurae* in chicks) or equiactive with amodiaquine (2). Toxicity studies reveal that amopyroquine is considerably less toxic than amodiaquine, suggesting the former as a potential antimalarial for parenteral use (2). It has been found to be effective in human malaria (3) and is especially recommended as an agent of choice for intramuscular administration (4).

Compound III is 10 times as active as quinine (*P. lophurae* in ducks) (6), while IV is 3.5 times as active as quinine, V is 1.5 and the 6-chloro-2-methoxy-9-acridyl analog of amopyroquine is 5 (*P. lophurae* in chicks).

Conclusions drawn from the limited biological data in animals are that a total of four carbon atoms in the NR_2 grouping of structures I to V affords optimum antimalarial effectiveness; and if the carbons are rigidly held in the same plane as in amopyroquine, systemic toxicity is low.

EXPERIMENTAL

4-(7-Chloro-4-quinolylamino)-α-pyrrolidino-*o*-cresol (II).—A mixture of 45.3 Gm. (0.3 mole) of *p*-acetamidophenol, 25 ml. (0.3 mole) of 37% formaldehyde solution, 21.3 Gm. (0.3 mole) of pyrrolidine, and 75 ml. of 95% ethyl alcohol was refluxed for 2½ hours. When a solid product was not isolated, the solvent was removed *in vacuo* to leave a thick, sirupy residue. One-third of the residue was refluxed for 1 hour with 50 ml. of 20% hydrochloric acid. The solution was cooled and treated with 6*N* sodium hydroxide until just acidic to Congo red. After the addition of 19.8 Gm. (0.1 mole) of 4,7-dichloroquinoline, the mixture was refluxed for 2 hours. The solution was cooled and made basic with 28% ammonium hydroxide to give 27.5 Gm. (78% yield) of light yellow product, m.p. 186–191° dec. A sample was prepared for analysis by repeated recrystallization from isopropyl alcohol-water, m.p. 196–198° dec.

Anal.—Calcd. for $C_{20}H_{20}ClN_3O$: C, 67.88; H, 5.69. Found: C, 67.60; H, 5.76.

Dihydrochloride of II.[3]—Crude II free base was dissolved in warm isopropyl alcohol, treated with charcoal and then with an excess of dry hydrogen chloride to precipitate a yellow crystalline dihydrochloride, m.p. 288–290° dec. Two recrystallizations from isopropyl alcohol elevated the melting point to 299–300° dec.

Received August 23, 1962, from the School of Pharmacy, The University of Kansas, Lawrence.

Accepted for publication October 12, 1962.

[2] Dr. P. E. Thompson, of Parke, Davis and Co., Research Department, Ann Arbor, Mich., has kindly furnished data on antimalarial studies in chicks.

[3] Data kindly furnished by Dr. Robert F. Meyer, Research Department, Parke, Davis and Co., Ann Arbor, Mich.

Anal.—Calcd. for $C_{20}H_{20}ClN_3O \cdot 2HCl$: C, 56.28; H, 5.20; Cl (ionic), 16.62. Found: C, 55.95; H, 5.36; Cl, 16.26.

4-(6-Chloro-2-methoxy-9-acridylamino)-α-pyrrolidino-o-cresol Dihydrochloride Sesquihydrate.—One-third of the residue from the preparation of II was treated as in that experiment except that 27.8 Gm. (0.1 mole) of 6,9-dichloro-2-methoxyacridine replaced 4,7-dichloroquinoline. The hot reaction mixture was filtered in order to remove insoluble 6-chloro-9-(4-hydroxyanilino)-2-methoxyacridine. Cooling the filtrate gave 30 Gm. (56% yield) of dihydrochloride, m.p. 245–249° dec. It was recrystallized from alcohol-acetone, m.p. 252–253° dec.

Anal.—Calcd. for $C_{25}H_{24}ClN_3O_2 \cdot 2HCl \cdot 1^1/_2H_2O$: C, 56.25; H, 5.47. Found: C, 56.54; H, 5.37.

p-Acetamido-α-hexamethylenimino-o-cresol Monohydrochloride.—A mixture of 15.1 Gm. (0.1 mole) of *p*-acetamidophenol, 9.9 Gm. (0.1 mole) of hexamethylenimine (5), 3 Gm. (0.1 mole) of paraformaldehyde, and 25 ml. of alcohol was heated to boiling for 4 hours. When cooling gave no precipitate, solvent was removed by distillation under reduced pressure. The residual dark oil was dissolved in ether, and excess alcoholic hydrogen chloride added to precipitate a yellow viscous oil. After decantation of the ether, solution in hot isopropyl alcohol and cooling gave 15.3 Gm. (51% yield) of product, m.p. 192–194°. Recrystallization from the same solvent elevated the melting point to 194.5 to 195°.

Anal.—Calcd. for $C_{15}H_{22}N_2O_2 \cdot HCl$: C, 60.29; H, 7.76. Found: C, 60.46; H, 7.96.

4-(7-Chloro-4-quinolylamino)-α-hexamethylenimino-o-cresol (IV).—A mixture of 14.3 Gm. (0.0478 mole) of *p*-acetamido-α-hexamethyleniminо-*o*-cresol monohydrochloride and 20 ml. of 20% hydrochloric acid was heated at reflux temperature for 1 hour. Sodium hydroxide solution was added to the cooled solution until it was barely acidic to Congo red. After the addition of 9.5 Gm. (0.048 mole) of 4,7-dichloroquinoline, the mixture was heated on a steam bath for 2 hours. Then, with cooling, it was made basic to litmus with 10% sodium hydroxide. The precipitated yellow solid was recrystallized twice from benzene to give 3.8 Gm. (21% yield) of IV, m.p. 212–214° dec.

Anal.—Calcd. for $C_{22}H_{24}ClN_3O$: C, 69.19; H, 6.33. Found: C, 69.31; H, 6.35.

It was found that following the procedure for II, which does not entail isolation of a purified acetamido Mannich phenolic base, actually led to a better yield of IV (45%).

4-(7-Chloro-4-quinolylamino)-α-(4-methyl-1-piperazinyl)-o-cresol (V) Trihydrochloride Dihydrate.—Procedure for II was followed; however, the free base was extracted with chloroform instead of being isolated. The extract was washed with water, dried over potassium carbonate, and treated with excess alcoholic hydrogen chloride. The addition of acetone completed precipitation of product. Recrystallization from alcohol gave 28 Gm. (53% yield) of bright yellow crystalline powder, m.p. 240–300° dec. It is very soluble in water.

Anal.—Calcd. for $C_{21}H_{23}ClN_4O \cdot 3HCl \cdot 2H_2O$: C, 47.73; H, 5.72. Found: C, 47.67; H, 5.93.

Antifungal Properties of Perfume Oils

By JASPER C. MARUZZELLA

The antifungal properties of 30 perfume oils were tested by allowing the organisms to grow in varying concentrations of the oils *in vitro*. Fifteen of the perfume oils inhibited the growth of all test organisms at concentrations ranging from 1:500 to 1:13,000. The remaining 15 oils inhibited some of the test organisms at concentrations up to 1:11,000. Oil of rose no. 81412 otto type, crab apple blossom, and rose briar were found to possess marked antifungal properties. The dermatophytes were extremely susceptible to many of the perfume oils at minute concentrations.

PERFUME OILS were demonstrated to possess remarkable fungicidal properties when studied by the filter paper disk method (1). However, the oils were tested in the undiluted form at which strength they are rarely used in cosmetics and medicaments. Small amounts of perfumery materials are added to toilet articles and dermatological products in an attempt to render the item more fragrant and to mask unpleasant odors. Whether such minute concentrations possess germicidal properties has been suggested (2) but not experimentally established. This investigation was undertaken in order to determine the mimimal concentration of perfume oil needed to inhibit the growth of fungi *in vitro*.

Rose odorata	1:1000	1:4000	1:1000	1:1000	1:3000	1:6000
Sweetgrass	1:1000	1:1000	1:1000	1:1000	1:3000	1:2000

[a] No inhibition at 1:500 concentration.

MATERIALS AND METHODS

The antifungal properties of 30 perfume oils were determined against growing cultures of *Aspergillus niger* ATCC 6277, *Sporotrichum schenkii* CDC 629, *Pityrosporum ovale* ATCC 12078, *Candida albicans* ATCC 10231, *Microsporum gypseum* CDC A-352, and *Trichophyton mentagrophytes* ATCC 9533. All of the test organisms were cultivated in Sabouraud maltose broth at 22 to 24° and subcultured every 7 days.

Stock solutions of each perfume oil were prepared in 95% ethyl alcohol. Aliquots of the stock solution were added to melted Sabouraud maltose agar, the contents were hand shaken and poured into Petri dishes. One-hundred milliliters of 7-day broth cultures was hand shaken thoroughly to mix spores and mycelial fragments. One-half milliliter of this fungal suspension was used as the inoculum for each dish and 5 ml. was used to inoculate 100-ml. broths used in subsequent experiments. Inhibitory levels were recorded at the end of 4 days at 22 to 24°. All perfume oils were tested in triplicate. Controls were included to demonstrate the lack of inhibition by the alcohol solvent employed. Replicate tests were conducted on different days in an attempt to minimize the day-to-day variation in the test procedure.

RESULTS AND DISCUSSION

The values listed in Table I are the minimal concentrations of oil found to inhibit growth of the test organisms. It may be observed that 15 of the 30 perfume oils produced inhibition of all test organisms at concentrations varying from 1:500 to 1:13,000. The remaining 15 oils prevented the growth of some of the test organisms at concentrations from 1:500 to 1:11,000. Perfume oil of lilas blanc L.S. and pine bouquet supreme showed slight antifungal properties while rose no. 81412 otto type, crab apple blossom, and rose briar were found to possess inhibitory action at high dilutions. Further inspection of the data in Table I seems to indicate that *T. mentagrophytes* and *M. gypseum* were extremely sensitive to all of the oils while *P. ovale* was resistant.

The data presented would tend to support the view that small amounts of certain perfume oils might be used effectively in the control of some dermatophytes. The concentrations used in this study fall well within the limits of their use in scenting toilet articles and medicaments.

Colorimetric Assay of Amphotericin B

By J. C. CHANG†, A. B. HONIG, A. T. WARREN, and S. LEVINE

AMPHOTERICIN B, like nystatin, is usually assayed by microbiological methods (1, 2). Following the development of the colorimetric assay of nystatin (3), the method was applied to amphotericin B and promising results were obtained.

The procedure of the assay was the same as for nystatin (3), except that the concentration of amphotericin B solution was about 80 mcg./ml. and absorbance measurements were made at 435 mμ. Results of assays of several samples of powder are shown in Table I.

The colorimetric assays show good reproducibility with a standard deviation of about 2%. The results agree well with the microbiological assays which have a standard deviation of about 2.7%.

It was observed that the absorbance of the color extracted into chloroform was lower if the amphotericin B solution was allowed to stand in the presence of sodium hydroxide, indicating that this method, as in the case of nystatin, may also be a stability assay for amphotericin B. Stability experiments and assays of pharmaceutical preparations are now in progress.

Saccharin Derivatives VII. Synthesis of 7-Nitrosaccharin and 7-Aminosaccharin

By GLENN H. HAMOR

RECENT work has shown that alkyl 4-amino-2-sulfamoylbenzoates possessing marked anticonvulsant activity may be prepared by alcoholysis of 6-nitrosaccharin, followed by reduction (1). Therefore, the preparation of 7-nitrosaccharin was undertaken as a starting material for synthesis of further compounds to be used in a structure-activity correlation study of anticonvulsants. In addition 7-aminosaccharin was synthesized in the hope that it, along with 7-nitrosaccharin, might give useful information concerning the relationship of chemical structure to taste (2).

The parent compound, 6-nitro-*o*-toluenesulfonamide (I), was prepared by the method of Szabo (3) according to the series of reactions shown below.

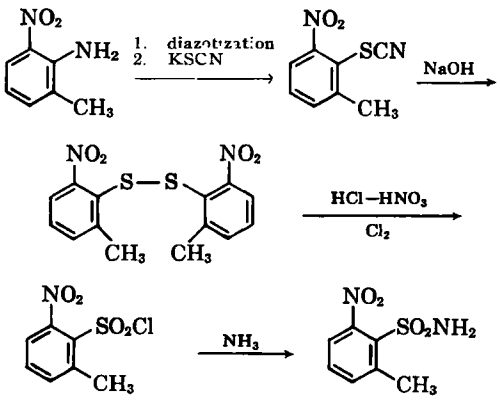
Saccharin Derivatives VII. Synthesis of 7-Nitrosaccharin and 7-Aminosaccharin

By GLENN H. HAMOR

RECENT work has shown that alkyl 4-amino-2-sulfamoylbenzoates possessing marked anticonvulsant activity may be prepared by alcoholysis of 6-nitrosaccharin, followed by reduction (1). Therefore, the preparation of 7-nitrosaccharin was undertaken as a starting material for synthesis of further compounds to be used in a structure-activity correlation study of anticonvulsants. In addition 7-aminosaccharin was synthesized in the hope that it, along with 7-nitrosaccharin, might give useful information concerning the relationship of chemical structure to taste (2).

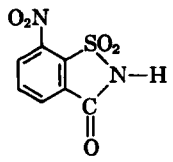
The parent compound, 6-nitro-*o*-toluenesulfonamide (I), was prepared by the method of Szabo (3) according to the series of reactions shown below.



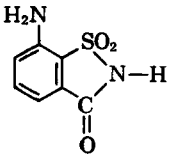
I

Received October 8, 1962, from the School of Pharmacy, University of Southern California, Los Angeles.
Accepted for publication October 23, 1962.
This investigation was supported by PHS research grant NB-03328-02 from the National Institute of Neurological Diseases and Blindness, U. S. Public Health Service, Washington, D. C.

Permanganate oxidation of 6-nitro-*o*-toluenesulfonamide gave 7-nitrosaccharin (II). Reduction of 7-nitrosaccharin by hydrogen with palladium-on-carbon catalyst yielded 7-aminosaccharin (III).



II



III

The 7-nitrosaccharin is essentially tasteless, while 7-aminosaccharin has a sweet taste.

EXPERIMENTAL[1]

7-Nitrosaccharin.[2]—This compound was prepared by alkaline potassium permanganate oxidation of 6-nitro-*o*-toluenesulfonamide by the method used by Noyes (4) to synthesize 6-nitrosaccharin. The 6-nitro-*o*-toluenesulfonamide, m.p. 201–202° [reported m.p. 197–199° (3)], was synthesized according to the series of reactions shown above. Recrystallization of the 7-nitrosaccharin from ethanol gave yields of approx. 25% of yellowish-white crystals, m.p. 262–264° dec. Approx. 30% of unreacted starting sulfonamide was recovered and used in succeeding oxidations.

Anal.[3]—Calcd. for $C_7H_4N_2O_5S$: C, 36.84; H, 1.77. Found: C, 37.02; H, 1.86.

7-Aminosaccharin.—Reduction of 7-nitrosaccharin using hydrogen with palladium-on-carbon catalyst according to standard procedures (5), followed by recrystallization of the product from ethanol gave crystalline 7-aminosaccharin (82%) m.p. 269–270°. Dilute solutions of the compound in ethanol displayed a bluish fluorescence.

Anal.—Calcd. for $C_7H_6N_2O_3S$: C, 42.42; H, 3.12. Found: 42.49; H, 3.09.

[1] Melting points were performed by the capillary tube method and are uncorrected.

[2] *Chem. Abstr.* nomenclature: 7-nitro-1,2-benzisothiazolin-3-one-1,1-dioxide.

Polytetrafluorethylene Tipped Tablet Punches

By SHELDON SIEGEL†, EDWARD J. HANUS, and JOHN W. CARR

Severe powder sticking to tablet punch surfaces during the production of an effervescent tablet has been overcome by the utilization of punches tipped with polytetrafluorethylene.[1]

The objective of this investigation was to develop an effervescent tablet containing a mixture of sodium isoascorbate and isoascorbic acid which would be rapidly soluble in water and form a solution completely free of turbidity. This tablet was to be used as a source of isoascorbate for meat curing processes to provide a convenient measure for the meat packer who wished to equate his antioxidant requirements to numbers of tablets in preference to units of weight or volume.

The manufacture of an effervescent tablet which yields a clear solution when dissolved in water is not possible when conventional tablet lubricants such as the metallic stearates, mineral oil, etc., are used. For this reason polyethylene glycol 4000 was chosen to act in the dual role of binder and water soluble lubricant. An effervescent tablet blend was prepared and compressed directly on a Stokes model DDS-2 tablet machine into 15-Gm. wafers having a diameter of $1^5/_{16}$ in. The blend had the following composition (1):

Sodium isoascorbate	9.92	Gm./tablet
Isoascorbic acid	2.02	"
Sodium bicarbonate U.S.P. powder	1.06	"
Citric acid anhydrous U.S.P. powder	0.50	"
Polyethylene glycol 4000 (100 mesh)	1.50	"
	15.00	"

When direct compression of this powdered formulation was attempted, severe picking and sticking occurred after compressing relatively few tablets; satisfactory production was impossible because of frequent breakdowns. As an outgrowth of this investigation the utilization of plastics, as components of tablet punches, was studied.

EXPERIMENTAL

Circles of polyethylene film were cut from a plastic bag and bonded to punch faces with a rubber cement. Satisfactory experimental facsimilies of the desired formulation were produced with these punches on a single punch Stokes model F tablet machine. It was noted that the sticking and picking observed in earlier experiments was significantly reduced. Polytetrafluorethylene (2–4) was subsequently investigated because of its inherent self-

lubricating property. Polytetrafluorethylene tablet punches were prepared from $^{5}/_{8}$-inch rods and used in conjunction with a $^{5}/_{8}$-inch metal die on the single punch machine. Sticking and picking were almost completely eliminated, but the operation was complicated by the tendency of this plastic to deform under pressure (a phenomenon known as "cold flow"). The punch area that entered the die retained its shape, but the shaft of the punch was deformed and buldged outwards. It was then reasoned that if faces of metal punches were tipped or coated with polytetrafluorethylene, the plastic would be confined within the die cavity during compression, thus preventing deformity. Coating the punch by spraying a thin layer of polytetrafluorethylene was somewhat effective; however, on extended tableting runs the material peeled off. Punches for the single punch machine were subsequently modified by bonding a small polytetrafluorethylene tip to the surface. The tableting operation using the latter punches was quite satisfactory and similar punches were modified and successfully used for the larger production equipment. The use of this device has eliminated much of the difficulty previously experienced with the manufacture of this product.

Several disadvantages were observed during the use of polytetrafluorethylene tipped punches. They are easily damaged and are subject to tip deformity and breakage. Because of the tendency of this plastic to deform under pressure, only flat faced or at most a slightly beveled tablet can be produced with these punches. Monogramming is obviously not practical. Nevertheless, for our specific problem polytetrafluorethylene tipped punches performed satisfactorily under production conditions.

Bonding Polytetrafluorethylene to Punch Surfaces.—Polytetrafluorethylene is not easily bonded to metal surfaces and requires a series of operations to produce a firm seal. An accepted procedure to facilitate bonding is to etch the surface of the plastic with molten sodium and cement it under high pressure to the metal surface by means of an epoxy resin cement. Tipped punches prepared in this manner were satisfactory but were subject to cleavage of the plastic component from the metal surface after a period of use. Modification of the bonding technique by first spraying the punch surface with a layer of pure molybdenum in order to produce a rough surface for greater plastic adherence significantly reduced this breakage (5).

SUMMARY

A method has been developed for preparing by direct compression a large effervescent tablet containing a mixture of sodium isoascorbate and isoascorbic acid which dissolves to form a solution free of turbidity or haze. The use of tablet punches tipped with polytetrafluorethylene has successfully circumvented the major problem of sticking and picking associated with the manufacture of this product.

The utilization of polytetrafluorethylene tipped punches may find application in other tablet formulations exhibiting similar difficulties. In addition, preliminary experimentation with this device has been successful in reducing lubricant levels in certain tablet blends and further investigation in this area is warranted.

Inactive Prednisone Tablets U.S.P. XVI

Sir:

We wish to report a case in which prednisone tablets meeting U.S.P. XVI specifications were found to be clinically inactive *in vivo* and some *in vitro* test results which suggest a possible reason for their inactivity.

A 25-year-old white married female of Mediterranean ancestry has been under the care of one of us (FAC) for approximately 5 years. Her clinical diagnosis was familial Mediterranean fever with repeated episodes of clinical peritonitis confirmed by laboratory studies and previous surgical exploration. The prompt use of oral prednisone in amounts of 20 mg. in a 24-hour period for the first 2 or 3 days would promptly abort the clinical symptoms, the laboratory findings of leukocytosis, etc., changing only slightly. The patient's prescriptions had been written with the generic name "prednisone." On one occasion, after 72 hours of 5 mg. four times a day, the patient had no clinical effects from the medication. It was discovered at that time that a different "brand" of prednisone had been dispensed than that previously used. The patient was immediately transferred to the brand of prednisone used previously and again within 24 hours there was almost complete resolution of the clinical syndrome.

The manufacturer's reassay of tablets, from the same lot as the tablets which were ineffective in treatment of the condition described, indicated that they contained essentially all of their labeled content. Also, the tablets passed the

Inactive Prednisone Tablets U.S.P. XVI

Sir:

We wish to report a case in which prednisone tablets meeting U.S.P. XVI specifications were found to be clinically inactive *in vivo* and some *in vitro* test results which suggest a possible reason for their inactivity.

A 25-year-old white married female of Mediterranean ancestry has been under the care of one of us (FAC) for approximately 5 years. Her clinical diagnosis was familial Mediterranean fever with repeated episodes of clinical peritonitis confirmed by laboratory studies and previous surgical exploration. The prompt use of oral prednisone in amounts of 20 mg. in a 24-hour period for the first 2 or 3 days would promptly abort the clinical symptoms, the laboratory findings of leukocytosis, etc., changing only slightly. The patient's prescriptions had been written with the generic name "prednisone." On one occasion, after 72 hours of 5 mg. four times a day, the patient had no clinical effects from the medication. It was discovered at that time that a different "brand" of prednisone had been dispensed than that previously used. The patient was immediately transferred to the brand of prednisone used previously and again within 24 hours there was almost complete resolution of the clinical syndrome.

The manufacturer's reassay of tablets, from the same lot as the tablets which were ineffective in treatment of the condition described, indicated that they contained essentially all of their labeled content. Also, the tablets passed the

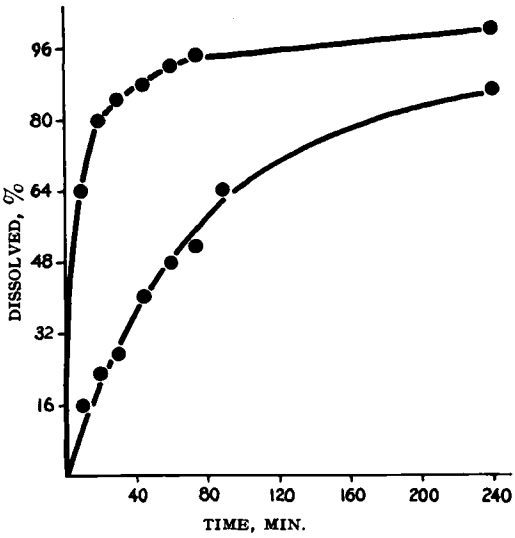

Fig. 1.—Cumulative per cent prednisone tablets dissolved *vs.* time from clinically active (upper curve) and inactive (lower curve) tablets of this substance.

U.S.P. XVI disintegration time test well within prescribed limits.

A small number of tablets were obtained from the manufacturer for a more detailed examination of their physical properties. The U.S.P. XVI disintegration time test was repeated in one of these laboratories and all the tablets had disintegrated within 6 minutes. It was observed, however, that large particles of the tablets remained on the bottom of the test beaker used in the procedure. In addition, during the conduction of the test it appeared that the disk used in the apparatus formed the large particles and subsequently forced them through the screen at the bottom of the testing tubes. One tablet was subjected to the disintegration time test without the disks and at 25°. The tablet had not disintegrated within 1 hour but had disintegrated within 2 hours.

In order to study the problem further, the remaining tablets were examined by means of a dissolution rate test. For comparison, tablets of the brand (which also disintegrated in less than 6 minutes in the U.S.P. XVI test) which gave a satisfactory clinical response were also subjected to the same test. The solution rate test conditions and apparatus used were those described by Levy and Hayes (1). The dissolution media were 500 ml. of water maintained at 37° and aliquots of it were assayed spectrophotometrically at 240 mμ for drug content at various times.

Figure 1 shows cumulative per cent of drug released from the two brands of tablets tested.

TABLE I.—SUMMARY OF DISINTEGRATION AND SOLUTION RATE DATA

Prednisone Tablets	U.S.P. XVI Disintegration Time (with disk)	Disintegration Time (without disks)	Av. time for 50% of Drug to Dissolve, ± S. D. Dev.
Active lot	<6 min.	<6 min.	4.3 ± 1.3 min.
Inactive lot	<6 min.	1–2 hr.	100 ± 53 min.

It is apparent from this figure that the tablets which were clinically ineffective dissolved much more slowly than the effective ones. The effective tablets released 50% of their content more than 20 times as rapidly as the ineffective ones.

Each point on the curve of Fig. 1 showing dissolution rate behavior of the clinically effective tablets is the average of six determinations. In the case of the ineffective brand, each point is the mean of three determinations. It was observed that the release of prednisone from the ineffective tablets was much more erratic in regard to tablet-to-tablet variation than from the effective brand of tablets. The various data obtained in this study are summarized in Table I.

This study provides additional evidence to previously published work (1–8) suggesting that the U.S.P. disintegration time test should be re-evaluated as a method to predict correctly physiological availability *in vivo*. The fact that a dissolution rate test gave results that appeared to be in qualitative agreement with clinical experience does not mean that the particular test used will necessarily be applicable to predict physiological availability from tablets of other drugs.

Rapid Detection of Excess Glucose in Coloring Syrups Used in Tablet Production

Sir:

When more than 2% glucose is present in the coloring syrup applied in tablet coating, the resulting tablets may be inelegant and exhibit a blotchy, wrinkled, or leathery surface. Such unmarketable tablets represent a substantial loss in material, labor, and time. This loss can be avoided if the offending batches of coloring syrup can be detected before they are used on the tablets.

We have found a simple procedure using a dip-and-read stick test, Clinistix,[1] to identify batches of coloring syrup that contain excess glucose. The stick test contains the enzyme glucose oxidase and so is specific for glucose. To use the test, the reactive area of the stick is dipped in a solution and removed. If glucose is present in the solution, the reactive area (originally red) turns purple. The purple can be compared with the color chart provided to determine if a little or a lot of glucose is present. The test was originally designed to detect glucose in urine.

To identify unsatisfactory batches of coloring syrup, we use a different procedure from that suggested by the manufacturer for the detection of glucose in urine. We prepare two dilutions of the coloring syrup, one of 2 drops in 10 ml. of water (1:110 dilution) and one of 5 drops in 10 ml. of water (1:44 dilution). (Under the conditions of this study there were 22 drops of coloring syrup in 1 ml.) One stick is dipped in each of these dilutions, removed, and the color allowed to develop for 30 seconds. The stick dipped in the 2-drop dilution is compared with the light color on the color chart and the stick dipped in the 5-drop dilution is compared with the medium color on the color chart. If either of the sticks is darker than the color it is compared with, the batch of syrup is discarded as containing too much glucose. Our experiments indicate that sticks dipped in the above dilutions of clear syrup (without dye) containing more than 2% glucose will give colors darker than the control colors on the chart. Sticks dipped in the same dilutions of clear syrup containing less than 2% glucose will give colors lighter than the control colors on the chart.

We have also carried out the stick procedure on some syrups containing dyes. We found the procedure as described satisfactory with syrups containing FD&C Yellow No. 5, FD&C Red No. 4, and an orange made by combining these two dyes. The procedure as described was not satisfactory with syrups containing FD&C Blue No. 1 and Hercules Mint Green. In both of these colored syrups, sticks dipped in dilutions of syrup which originally contained 1% glucose gave colors darker than the control colors on the chart. It is clear that the procedure would have to be modified to detect excess glucose in syrups of these colors. It is our opinion that for any particular operation the investigator should develop his own procedure with the stick test. The material presented here is only meant to illustrate that a practical system for detecting batches of coloring syrup containing excess glucose can be developed simply.

Our coating operation has been helped by the stick test control procedure. From the time we first encountered the excess glucose problem until we began testing all batches of coloring syrup, 21% of the tablets were rejected for discoloration resulting from excess glucose in the coloring syrup. Since we began testing all batches, no tablets have been rejected for discoloration related to the excess glucose.

When the cause of irregular coloring on tablets is obscure, the stick test can be used to determine if excess glucose in the coloring syrup used was a factor. To use the test for this purpose, three of the irregularly colored tablets are placed in 30 ml. of water in a small beaker. The tablets are left in the water until their color has been washed off, then are quickly removed. If the tablets are left in the water longer, sugar from subcoatings is washed off and the test results are not valid. A stick is dipped in the water in which the tablets were washed. At 30 seconds the color on the stick is compared with the color chart. If excess glucose is present in the tablet coloring, the stick will give a reaction darker than the medium color on the chart. This procedure is satisfactory for our coating operation; others who might want to use the test for this purpose would probably have to establish their own procedure empirically.

The undesirable glucose apparently is produced in the coloring syrup under normal production conditions. To determine how glucose might be produced, a simple experiment was carried out. One sample of freshly prepared coloring syrup was refrigerated for 3 days and a second sample of the same syrup was put in a small flask and heated in an oven at about 70° for 3 days.

[1] Marketed by the Ames Co. Inc., Elkhart, Ind.

The refrigerated sample showed no buildup of glucose; the heated sample developed about 2% glucose. In another experiment, one sample of freshly prepared coloring syrup was allowed to stand for 3 days at room temperature; a second sample of the same syrup was heated for 3 days at 70° in steam kettles used in preparing the syrup. The syrup allowed to stand at room temperature contained about 1% glucose after the 3 days. The heated sample contained about 8% glucose (higher than the sample heated in the oven, probably because the inner surface of the steam kettle has a higher temperature than the 70° of the oven). It appears that glucose can be produced by the hydrolysis of sucrose in coloring syrups that are heated for some time.

Excess glucose probably causes the unacceptable tablet surface by retarding the drying of the coating material. The moist tablets tend to be sticky and adhere to one another and to the pan. In this state the surface is subject to tiny "pulls," eruptions, and general surface disfigurement as a result of repeated sticky collisions. Coloring syrups with excess glucose are much more likely to result in disfigured tablets with inexperienced coaters than with experienced coaters who can recognize the trouble and modify their procedure to allow proper drying of the tablets.

The stick control procedure has been very useful in our coating operation. The stick test is simple enough that modifications in procedure are practical. We think the test might be useful to others for whom the determination of glucose in some phase of tablet manufacture is important.

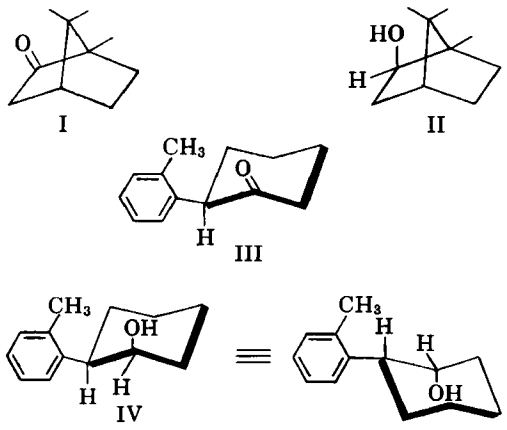
Asymmetric Synthesis in the Stereoselective Reduction of 2-*o*-Tolylcyclohexanone by Isobornyloxymagnesium Bromide

Sir:

Subsequent to the synthesis of optically active mandelic acid by the reduction of phenylglyoxylic acid with isobornyloxymagnesium bromide by Vavon and Antonini (1) other investigators (2–4) have used the same reducing agent for the asymmetric synthesis of optically active deuterated primary alcohols of known absolute configuration from symmetrical aldehydes and deuterio-isobornyloxymagnesium bromide or from isobornyloxymagnesium bromide and symmetrical 1-deuterio-aldehydes.

We wish to report the synthesis of optically active *cis*-2-*o*-tolylcyclohexanol by the reduction of racemic 2-*o*-tolylcyclohexanone with isobornyloxymagnesium bromide. The high degree of stereoselectivity of the reaction is indicated from the fact that the 2-*o*-tolylcyclohexanol obtained consist of about 92% *cis*-2-*o*-tolylcyclohexanol, $[\alpha]_D^{24} = -2.9$ (0.1 Gm./ml. in ethanol) (optical purity unknown), and only about 8% of the *trans* isomer. The *trans* isomer was not recovered in sufficient amount for optical rotation measurements. Nonspecific reduction of racemic 2-*o*-tolylcyclohexanone would of course yield the four optical isomers of 2-*o*-tolylcyclohexanol in equal quantities. Since *cis* alcohol is formed preferentially, the energy of activation for the transfer of the hydride ion to the carbonyl carbon of 2-*o*-tolylcyclohexanone is lower when the transfer leads to an equatorial C—H bond. Because the resulting *cis* alcohol has optical activity, the energy of activation is lower for the formation of the *cis* alcohol from one enantiomorph of 2-*o*-tolylcyclohexanone than from the other. Molecular models indicate that the least hindered of the four possible transition states is the one resulting from the interaction of II and that enantiomorph of 2-*o*-tolylcyclohexanone shown by structure III to give product IV.



Structure IV is suggested as the absolute con-

The refrigerated sample showed no buildup of glucose; the heated sample developed about 2% glucose. In another experiment, one sample of freshly prepared coloring syrup was allowed to stand for 3 days at room temperature; a second sample of the same syrup was heated for 3 days at 70° in steam kettles used in preparing the syrup. The syrup allowed to stand at room temperature contained about 1% glucose after the 3 days. The heated sample contained about 8% glucose (higher than the sample heated in the oven, probably because the inner surface of the steam kettle has a higher temperature than the 70° of the oven). It appears that glucose can be produced by the hydrolysis of sucrose in coloring syrups that are heated for some time.

Excess glucose probably causes the unacceptable tablet surface by retarding the drying of the coating material. The moist tablets tend to be sticky and adhere to one another and to the pan. In this state the surface is subject to tiny "pulls," eruptions, and general surface disfigurement as a result of repeated sticky collisions. Coloring syrups with excess glucose are much more likely to result in disfigured tablets with inexperienced coaters than with experienced coaters who can recognize the trouble and modify their procedure to allow proper drying of the tablets.

The stick control procedure has been very useful in our coating operation. The stick test is simple enough that modifications in procedure are practical. We think the test might be useful to others for whom the determination of glucose in some phase of tablet manufacture is important.

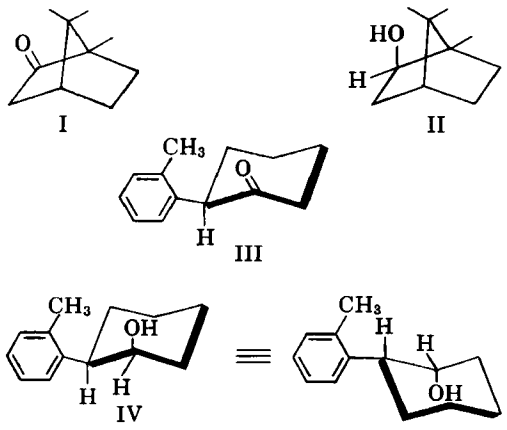
Asymmetric Synthesis in the Stereoselective Reduction of 2-*o*-Tolylcyclohexanone by Isobornyloxymagnesium Bromide

Sir:

Subsequent to the synthesis of optically active mandelic acid by the reduction of phenylglyoxylic acid with isobornyloxymagnesium bromide by Vavon and Antonini (1) other investigators (2–4) have used the same reducing agent for the asymmetric synthesis of optically active deuterated primary alcohols of known absolute configuration from symmetrical aldehydes and deuterio-isobornyloxymagnesium bromide or from isobornyloxymagnesium bromide and symmetrical 1-deuterio-aldehydes.

We wish to report the synthesis of optically active *cis*-2-*o*-tolylcyclohexanol by the reduction of racemic 2-*o*-tolylcyclohexanone with isobornyloxymagnesium bromide. The high degree of stereoselectivity of the reaction is indicated from the fact that the 2-*o*-tolylcyclohexanol obtained consist of about 92% *cis*-2-*o*-tolylcyclohexanol, $[\alpha]_D^{24} = -2.9$ (0.1 Gm./ml. in ethanol) (optical purity unknown), and only about 8% of the *trans* isomer. The *trans* isomer was not recovered in sufficient amount for optical rotation measurements. Nonspecific reduction of racemic 2-*o*-tolylcyclohexanone would of course yield the four optical isomers of 2-*o*-tolylcyclohexanol in equal quantities. Since *cis* alcohol is formed preferentially, the energy of activation for the transfer of the hydride ion to the carbonyl carbon of 2-*o*-tolylcyclohexanone is lower when the transfer leads to an equatorial C—H bond. Because the resulting *cis* alcohol has optical activity, the energy of activation is lower for the formation of the *cis* alcohol from one enantiomorph of 2-*o*-tolylcyclohexanone than from the other. Molecular models indicate that the least hindered of the four possible transition states is the one resulting from the interaction of II and that enantiomorph of 2-*o*-tolylcyclohexanone shown by structure III to give product IV.



Structure IV is suggested as the absolute con-

figuration of the optically active *cis*-2-*o*-tolylcyclohexanol obtained from the stereoselective reduction. This is consistent with the mechanism for stereoselective reduction by isobornyloxymagnesium bromide proposed by Streitwieser and co-workers (3) based on structure I being the absolute configuration of (+)camphor (3, 5) from which the isoborneol was prepared.

The isoborneol prepared by lithium aluminum hydride reduction of (+)camphor according to the method of Noyce and Denney (6) had $[\alpha]_D^{25} = -23.0°$ (*c* 5 in ethanol) compared to $-26.0°$ reported by these authors for a product which was reported contaminated with about 10% borneol (6). It has been shown (1, 3) that the presence of this amount of borneol does not affect the course of reduction by isobornyloxymagnesium bromide because borneol reacts so much slower under the same conditions. We have purified the isoborneol by elution chromatography on alumina to give $[\alpha]_D^{25} = -30.0°$ (*c* 5 in ethanol) (reported value (7) for pure isoborneol, 8% in ethanol, is $[\alpha]_D^{19} = -33.5°$) and have found no apparent difference in the stereospecificity of the reduction by the magnesium bromide salt of the purified isoborneol compared to that obtained from isoborneol contaminated with some borneol. A solution of racemic 2-*o*-tolylcyclohexanone in anhydrous benzene was added to a benzene solution of isobornyloxymagnesium bromide, prepared by the method of Streitwieser (3), and the mixture was heated to reflux. The progress of the reaction was followed by periodic work-up of small portions of the reaction mixture and analysis of the product by gas chromatography in comparison to the known *cis*- and *trans*-2-*o*-tolylcyclohexanols (8). Two conditions, referred to as *Methods A* and *B*, were used. In *Method A* slightly over two equivalents of the racemic ketone were used and the refluxing was carried on until practically all the isoborneol was depleted (about 45 hours of refluxing). In *Method B* two equivalents of isobornyloxymagnesium bromide were used and the reaction carried out until the ketone was practically depleted (about 60 hours of refluxing). The 2-*o*-tolylcyclohexanol obtained by *Method B* consisted of about 92% *cis* isomer and 8% *trans*. This ratio appeared to remain constant during the course of the reactions. The product of *Method A* consisted of about 91.5% *cis* after 23 hours of refluxing and about 89% *cis* and 11% *trans* at the end of 45 hours of refluxing. The *cis* isomer was recovered by preparative gas chromatography, using a 5-ft. column packed with 18% Carbowax 20M on acid-washed Chromosorb W. The *cis* product of reaction *A* had $[\alpha]_D^{24} = -2.88°$ and that from reaction *B* $-2.95°$. Resolution of *cis*-2-*o*-tolylcyclohexanol is in progress in order to establish the optical purity of the product of the asymmetric synthesis. The unreacted ketone recovered from reaction *A* was not optically active. This fact and the fact that complete reduction of the racemic ketone yielded optically active *cis* alcohol in reaction *B* indicates isomerization of the ketone through enolization. If isomerization did not occur, the remaining ketone in reaction *A* would be richer in the mirror image of structure III.

In a (Meerwein-Pondorff)-Oppenauer reaction of the type used, many species can be in equilibrium. The initial reaction between the isobornyloxymagnesium bromide and the 2-*o*-tolylcyclohexanone could be reversible, and the magnesium bromide salts of the 2-*o*-tolylcyclohexanols could possibly equilibrate with unreacted 2-*o*-tolylcyclohexanone. The apparent constant ratio of *cis* and *trans* products in reaction *B* and the apparent increase in *trans* isomer, with time, in reaction *A* suggest a tendency toward equilibrium between products and unreacted ketone. It is of interest that from molecular models and Streitwieser's mechanism (3) the reaction of the optically active product (salt of IV) with 2-*o*-tolylcyclohexanone is predicted to be faster with the enantiomorph shown by structure III, and that the most rapid reaction will yield IV as the product. This possibility is being investigated further.

Steric control of the reduction of certain cyclanones by diisopinocamphenylborane has been reported by Brown and Bigley (9).

Per Cent Absorbed Time Plots Derived from Blood Level and/or Urinary Excretion Data

Sir:

Dominguez and Pomerene (1) derived an equation, which had a form similar to Eq. 1, for calculating the rate of absorption as a function of time from blood level data

$$\frac{dA}{dt} = V\left(\frac{dC}{dt} + K.C\right) \qquad \text{(Eq. 1)}$$

Here, dA/dt is the rate of absorption or the rate of appearance of the substance in the blood, V is the apparent volume of distribution, C is the blood level in concentration units at time t, dC/dt is the slope of the blood level time curve at time t, and K is the first-order rate constant for loss of drug from the volume of distribution.

The assumptions behind Eq. 1 are: (*a*) equilibrium between drug in blood and other fluids of distribution is maintained; (*b*) V and K are constants, independent of time, over the time interval Eq. 1 is applied; and (*c*) the compound measured in the blood is the same compound as that absorbed (*i.e.*, A, in weight units, and C, in concentration units, refer to the same compound).

Nelson (2) derived Eq. 2 which may be used for calculating the rate of absorption as a function of time from urinary excretion data

$$\frac{dA}{dt} = \frac{1}{f}\left(\frac{1}{K}\cdot\frac{d^2A_e}{dt^2} + \frac{dA_e}{dt}\right) \qquad \text{(Eq. 2)}$$

Here, f is the fraction of drug reaching the circulation which is excreted unchanged in the urine, d^2A_e/dt^2 and dA_e/dt are the second and first derivatives, respectively, of a plot of cumulative amount of unchanged drug in the urine against time, and dA/dt and K have the same meaning as above. dA_e/dt is the rate of excretion at the time when the cumulative amount excreted is A_e. Theoretically, excretion rate is directly proportional to blood level (3); hence, substitution of $(1/V.K.f).(dA_e/dt)$ for C in Eq. 1 yields Eq. 2.

The assumptions behind Eq. 2 are: (*a*) equilibrium between drug in blood and other fluids of distribution is maintained; (*b*) f, K, and the renal clearance ($f.K.V_d$) are constants, independent of time, over the time interval Eq. 2 is applied; (*c*) $dA_e/dt = f.dA_e'/dt$ where dA_e'/dt is the rate of elimination of the drug from the volume of distribution by all processes; and (*d*) the compound measured in the urine is the same compound as that absorbed (*i.e.*, both A and A_e are weight units of the same compound).

The difficulties experienced in using Eqs. 1 and 2 are: (*a*) values of V and f are only determined, even with reasonable accuracy, by means of intravenous studies; (*b*) the second derivatives, d^2A_e/dt^2, are difficult to obtain with accuracy.

We wish to report that per cent absorbed–time plots may be derived directly from suitable blood level and/or urinary excretion data obtained following oral or parenteral administration of a drug without knowing the values of V, f, or d^2A_e/dt^2.

Integration of Eq. 1 between the limits $t = o$ and $t = T$ yields Eq. 3

$$A_T = V\left(C_T + K\int_{t=o}^{t=T} C.dt\right) \qquad \text{(Eq. 3)}$$

Here, A_T is the amount of drug absorbed from time of administration to time T, C_T is the blood level at time T, and the integral is the area under the blood level time curve between time zero and time T. Equation 3 has been previously published (4).

Integration of Eq. 2 between the limits $t = o$ and $t = T$ yields Eq. 4

$$A_T = \frac{1}{f}\left(\frac{1}{K}\cdot\frac{dA_e}{dt} + A_e\right) \qquad \text{(Eq. 4)}$$

Rearrangement of Eqs. 3 and 4 yields Eqs. 5 and 6

$$\frac{A_T}{V} = C_T + K.\int_{t=o}^{t=T} C.dt \qquad \text{(Eq. 5)}$$

$$f.A_T = \frac{1}{K}\cdot\frac{dA_e}{dt} + A_e \qquad \text{(Eq. 6)}$$

Equations 5 and 6 are those suitable to prepare per cent absorbed–time plots from blood level and urinary excretion data, respectively. The method using blood level data is as follows. Successive values of the righthand side of Eq. 5 are calculated from the time of administration ($t = o$) to some time after the peak in the blood level time plot (the areas may be estimated with the trapezoidal rule). The values progressively increase, then reach a maximum or asymptotic value. When the individual values are expressed as percentages of the maximum or asymptotic value, the results are per cent absorbed values to various times T. The method using a cumulative amount excreted–time curve is as follows. For the initial part of the plot, values of $\Delta A_e/\Delta t$ and the amount excreted at the midpoint of the interval, A_e, are calculated. The operations dictated by Eq. 6 are then performed to yield values of $f.A_T$. The values pro-

gressively increase, then reach a maximum or asymptotic value. When the individual values are expressed as percentages of the maximum or asymptotic value, the results are per cent absorbed values to various times. Theoretically, the maximum or asymptotic value of the right-hand side of Eq. 5 is $K.\int_{t=o}^{t=\infty} C.dt$ and of Eq. 6 is $(A_e)_\infty$, where $\int_{t=o}^{t=\infty} C.dt$ is the area under the blood level time plot from $t = o$ to $t = \infty$, and $(A_e)_\infty$ is the amount of unchanged drug excreted in the urine in infinite time. The methods are independent of the values of V and f since these values cancel out when the percentages are calculated. The per cent absorbed value so calculated is the cumulative amount absorbed to time T expressed as a percentage of the total amount of drug which is absorbed (not as a percentage of the dose).

When the cumulative percentages absorbed are plotted against time, the resulting plots may contain linear segments; the slope of such a linear segment is the absorption rate in per cent/hour. If the plot is curved, or contains curved and linear segments, it may often be resolved to yield the components of the rate $d\%A_T/dt$. In this way the model which applies to a particular set of blood level or urinary excretion data can be determined accurately. The method may also be applied to problems in chemical kinetics involving consecutive and/or simultaneous first-order and zero-order reactions.

The process of obtaining the per cent absorbed–time plots from blood level data has been automated in two ways. In the first method, the blood level data are plotted on suitable graph paper and the points joined with a smooth line using a special conducting ink. Using a curve-follower, an analog computer was programmed to perform the operations dictated by Eq. 5 and to plot the result on another piece of graph paper. The asymptotic value is estimated from the plot, the values of A_T/V are obtained from the plot, and then expressed as a percentage of the asymptotic value. In the second method, the blood level–time values are fed to a suitably programmed digital computer. The computer calculates the cumulative areas, using the trapezoidal rule, then performs the necessary operations shown in Eq. 5. The print-out contains the values T, C_T, $\int_{t=o}^{t=T} C.dt$, and $\left[C_T + K.\int_{t=o}^{t=T} C.dt\right]$. The latter are then expressed as percentages of the asymptotic or maximum value of the same function to yield the cumulative per cent absorbed values.

Per cent absorbed–time plots derived from *in vivo* data are the optimum data to correlate with per cent released time plots derived from *in vitro* testing.

Future publications will illustrate applications of these methods in detail.

Book Notices

Recent Advances In Pharmacology. 3rd ed. By J. M. ROBSON and R. S. STACEY. Little Brown and Co., 34 Beacon St., Boston 6, Mass., 1962. x + 406 pp. 15 × 23.5 cm.

The reader of this book will find several areas of recent progress in pharmacology discussed in some detail through the efforts of the authors and nine contributors. The chapter on pharmacologically active substances in the central nervous system requires 38 pages. One-third of the chapter is devoted to catechol amines and 5-hydroxytryptamine; 5-hydroxytryptamine is later treated in a separate chapter of 30 pages and the catechol amines in another of 25 pages. Other chapters deal with pyschotropic drugs, pharmacologically active polypeptides, hypoglycaemic agents and diabetes mellitus, diuretics and electrolyte balance, newer steroids, cholesterol, hypotensive drugs, bacterial chemotherapy, new drugs in the treatment of tropical diseases, and hypnotics, anticonvulsants, analgesics, and antitussives. References to pertinent literature follow each chapter.

The Exocrine Pancreas. Normal and Abnormal Functions. Edited by A. V. S. DE REUCK and MARGARET P. CAMERON. Little, Brown and Co., 34 Beacon St., Boston 6, Mass., 1961. xii + 390 pp. 13 × 20 cm. Price $11.50.

This new volume in the Ciba Foundation General Symposia series presents work and discussions on the exocrine pancreas by a broad range of international authorities. Content topics include Ultrastructure and histochemistry, Nature of pancreatic secretions, Physiological control of pancreatic secretion, assessment of pancreatic function, and Abnormal pancreas: genetic and metabolic aspects. Sixteen papers on various aspects of the topics listed above are included in the volume. A general discussion concludes the volume covering topics for future research: zymogen granules, the nervous control of pancreatic secretions, pancreatic regeneration, standardization of tests, the genetics of pancreatic disease, and pancreatic biopsy. Subject and author indexes complete the book.

Ionization Constants of Acids & Bases. By ADRIEN ALBERT and E. P. SERJEANT. John Wiley & Sons, Inc., 440 Park Avenue South, New York 16, N. Y., 1962. xii + 179 pp. 13 × 20 cm. Price $3.75.

The authors, in their prefatory remarks, point out that the volume is intended to be used by workers who, without previous experience, wish to determine an ionization constant. In addition, some more advanced materials are presented for those with more experience in this area. Practical application rather than theory is stressed. Following a general introduction to the subject, the chapter headings are: Determination of ionization constants by potentiometric titration using a glass electrode; Refinements of potentiometric titration: apparatus and calculations; Determination of ionization constants by spectrometry; Determination of ionization constants by conductimetry; Solubility—ionization relationships; Zwitterions (Dipolar ions); Ionization constants of 400 typical acids and bases; and Solubility constants of metal complexes. A subject index is appended and pertinent literature references appear as footnotes throughout the book.

Diffusion of Innovations. By EVERETT M. ROGERS. The Free Press of Glencoe Division of The Macmillan Co., 60 Fifth Avenue, New York 11, N. Y., 1962. xiii + 367 pp. 14 × 21 cm. Price $6.50.

As a study of the processes through which an individual adopts a new idea, the characteristics of the innovation itself which affect its rate of adoption, the underlying reasons why some innovations succeed and others fail, the predictability of innovation adoption, and numerous collateral questions, this book will be more useful to the marketing, advertising, sales staffs, and those dealing with consumer acceptance of products rather than those pharmaceutical scientists concerned with physiology, toxicology, etc., of products. However, as a study in *en masse* public psychology, many diverse disciplines will find this volume interesting and informative. The author reviews 506 diffusion studies covering a wide array of innovations to provide a basis to compare and point up some of the basic similarities the findings reveal about the spread and acceptance of new ideas. The reader is presented with an opportunity to appraise theoretical aspects of the diffusion process against a background of research case materials.

Tranquilizing and Antidepressive Drugs. By WILBUR M. BENSON and BURTRUM C. SCHIELE. CHARLES C THOMAS, 301–327 East Lawrence Ave., Springfield, Ill., 1962. xvii + 89 pp. 15 × 23 cm. Price $5.25.

In this monograph of the American Lectures in Pharmacology series edited by Chauncey D. Leake, the authors have made an excellent attempt to organize expeditious increase in the number of psychotherapeutic agents presently in use. The basic plan classifies the drugs into chemical types with descriptions of various actions and clinical indications. For example, part I deals with tranquilizers; part II, antidepressive drugs. Tranquilizers are then segregated into two groups: major and minor. Antidepressants are divided into stimulants (subdivided into direct and indirect) and suppressants. Further subgroupings contain the respective drugs. This is definitely a work on clinical indications and contraindications of psychotherapeutic drugs. It is clear that the authors intended and have created a guide to rational order in distinguishing one agent from another, aimed primarily at the practicing physician but of wide utility to others as well.

Clinical Trials. The Pharmaceutical Press, 17 Bloomsbury Square, London, W.C. 1, 1962. v + 83 pp. 14.5 × 23 cm. Price 15/-d.

This paperbound volume reports a symposium of wide interest to pharmaceutical scientists and others concerned with developing and evaluating drugs. Presentations reported discuss when clinical trials may be undertaken, clinical trials in hospitals and in general practice, and pharmaceutical collaboration in clinical trials. Other aspects discussed include what justifies the general distribution of a new drug after clinical trials and the adequacy of the clinical trial. Discussion sessions are also reported. The symposium was organized by the Department of Pharmaceutical Sciences of the Pharmaceutical Society of Great Britain and was held at the University of London School of Pharmacy in April 1962.

The Innervation of Blood Vessels. By T. A. GRIGOR'EVA. Pergammon Press, Inc., 122 East 55th St., New York 22, N. Y., 1962. xiii + 442 pp. 14.5 × 22.5 cm.

This book arose from an attempt to establish the functional micromorphology of the vascular system. It required the systematic collection of factual data on the structural relationships in vessels and their innervations, as well as the experimental checking of these data. Critical comparison of published data and the results of the experimental work revealed numerous conflicting interpretations of various aspects of the vascular system. A number of new hypotheses concerning the mechanism of specific local (visceral) circulation are presented. The book is a translation of the original volume, presumably in Russian.

The Exocrine Pancreas. Normal and Abnormal Functions. Edited by A. V. S. DE REUCK and MARGARET P. CAMERON. Little, Brown and Co., 34 Beacon St., Boston 6, Mass., 1961. xii + 390 pp. 13 × 20 cm. Price $11.50.

This new volume in the Ciba Foundation General Symposia series presents work and discussions on the exocrine pancreas by a broad range of international authorities. Content topics include Ultrastructure and histochemistry, Nature of pancreatic secretions, Physiological control of pancreatic secretion, assessment of pancreatic function, and Abnormal pancreas: genetic and metabolic aspects. The authors, in their prefatory remarks, point out that the volume is intended to be used by workers who, without previous experience, wish to determine an ionization constant. In addition, some more advanced materials are presented for those with more experience in this area. Practical application rather than theory is stressed. Following a general introduction to the subject, the chapter headings are: Determination of ionization constants by potentiometric titration using a glass electrode; Refinements of potentiometric titration: apparatus and calculations; Determination of ionization constants by spectrometry; Determination of ionization constants by conductimetry; Solubility—ionization relationships; Zwitterions (Dipolar ions); Ionization constants of 400 typical acids and bases; and Solubility constants of metal complexes. A subject index is appended and pertinent literature references appear as footnotes throughout the book.

Diffusion of Innovations. By EVERETT M. ROGERS. The Free Press of Glencoe Division of The Macmillan Co., 60 Fifth Avenue, New York 11, N. Y., 1962. xiii + 367 pp. 14 × 21 cm. Price $6.50.

As a study of the processes through which an individual adopts a new idea, the characteristics of the innovation itself which affect its rate of adoption, the underlying reasons why some innovations succeed and others fail, the predictability of innovation adoption, and numerous collateral questions, this book will be more useful to the marketing, advertising, sales staffs, and those dealing with consumer acceptance of products rather than those pharmaceutical scientists concerned with physiology, toxicology, etc., of products. However, as a study in *en masse* public psychology, many diverse disciplines will find this volume interesting and informative. The author reviews 506 diffusion studies covering a wide array of innovations to provide a basis to compare and point up some of the basic similarities the findings reveal about the spread and acceptance of new ideas. The reader is presented with an opportunity to appraise theoretical aspects of the diffusion process against a background of research case materials.

Tranquilizing and Antidepressive Drugs. By WILBUR M. BENSON and BURTRUM C. SCHIELE. CHARLES C THOMAS, 301–327 East Lawrence Ave., Springfield, Ill., 1962. xvii + 89 pp. 15 × 23 cm. Price $5.25.

In this monograph of the American Lectures in Pharmacology series edited by Chauncey D. Leake, the authors have made an excellent attempt to organize expeditious increase in the number of psychotherapeutic agents presently in use. The basic plan classifies the drugs into chemical types with descriptions of various actions and clinical indications. For example, part I deals with tranquilizers; part II, antidepressive drugs. Tranquilizers are then segregated into two groups: major and minor. Antidepressants are divided into stimulants (subdivided into direct and indirect) and suppressants. Further subgroupings contain the respective drugs. This is definitely a work on clinical indications and contraindications of psychotherapeutic drugs. It is clear that the authors intended and have created a guide to rational order in distinguishing one agent from another, aimed primarily at the practicing physician but of wide utility to others as well.

Clinical Trials. The Pharmaceutical Press, 17 Bloomsbury Square, London, W.C. 1, 1962. v + 83 pp. 14.5 × 23 cm. Price 15/-d.

This paperbound volume reports a symposium of wide interest to pharmaceutical scientists and others concerned with developing and evaluating drugs. Presentations reported discuss when clinical trials may be undertaken, clinical trials in hospitals and in general practice, and pharmaceutical collaboration in clinical trials. Other aspects discussed include what justifies the general distribution of a new drug after clinical trials and the adequacy of the clinical trial. Discussion sessions are also reported. The symposium was organized by the Department of Pharmaceutical Sciences of the Pharmaceutical Society of Great Britain and was held at the University of London School of Pharmacy in April 1962.

The Innervation of Blood Vessels. By T. A. GRIGOR'EVA. Pergammon Press, Inc., 122 East 55th St., New York 22, N. Y., 1962. xiii + 442 pp. 14.5 × 22.5 cm.

This book arose from an attempt to establish the functional micromorphology of the vascular system. It required the systematic collection of factual data on the structural relationships in vessels and their innervations, as well as the experimental checking of these data. Critical comparison of published data and the results of the experimental work revealed numerous conflicting interpretations of various aspects of the vascular system. A number of new hypotheses concerning the mechanism of specific local (visceral) circulation are presented. The book is a translation of the original volume, presumably in Russian.

The Exocrine Pancreas. Normal and Abnormal Functions. Edited by A. V. S. DE REUCK and MARGARET P. CAMERON. Little, Brown and Co., 34 Beacon St., Boston 6, Mass., 1961. xii + 390 pp. 13 × 20 cm. Price $11.50.

This new volume in the Ciba Foundation General Symposia series presents work and discussions on the exocrine pancreas by a broad range of international authorities. Content topics include Ultrastructure and histochemistry, Nature of pancreatic secretions, Physiological control of pancreatic secretion, assessment of pancreatic function, and Abnormal pancreas: genetic and metabolic aspects. Sixteen papers on various aspects of the topics listed above are included in the volume. A general discussion concludes the volume covering topics for future research: zymogen granules, the nervous control of pancreatic secretions, pancreatic regeneration, standardization of tests, the genetics of pancreatic disease, and pancreatic biopsy. Subject and author indexes complete the book.

Ionization Constants of Acids & Bases. By ADRIEN ALBERT and E. P. SERJEANT. John Wiley & Sons, Inc., 440 Park Avenue South, New York 16, N. Y., 1962. xii + 179 pp. 13 × 20 cm. Price $3.75.

The authors, in their prefatory remarks, point out that the volume is intended to be used by workers who, without previous experience, wish to determine an ionization constant. In addition, some more advanced materials are presented for those with more experience in this area. Practical application rather than theory is stressed. Following a general introduction to the subject, the chapter headings are: Determination of ionization constants by potentiometric titration using a glass electrode; Refinements of potentiometric titration: apparatus and calculations; Determination of ionization constants by spectrometry; Determination of ionization constants by conductimetry; Solubility—ionization relationships; Zwitterions (Dipolar ions); Ionization constants of 400 typical acids and bases; and Solubility constants of metal complexes. A subject index is appended and pertinent literature references appear as footnotes throughout the book.

The *Journal of Pharmaceutical Sciences* is published monthly by the American Pharmaceutical Association, at 20th & Northampton Sts., Easton, Pa. Second-class postage paid at Easton, Pa., and at additional mailing office.

All expressions of opinion and statements of supposed fact appearing in articles or editorials carried in THIS JOURNAL are published on the authority of the writer over whose name they appear, and are not to be regarded as necessarily expressing the policies or views of the American Pharmaceutical Association.

Offices—Editorial, Advertising, and Subscription Offices: 2215 Constitution Ave., N. W., Washington 37, D. C. Publication Offices: 20th & Northampton Streets, Easton, Pa.

Annual Subscription—United States and foreign, $15.00; single copies, $1.50; combined rate with the *Journal of the American Pharmaceutical Association*, $20.00. Subscription rates are subject to change without notice. Members of the American Pharmaceutical Association may elect to receive the *Journal of Pharmaceutical Sciences* as a part of their annual $27.00 A.Ph.A. membership dues.

Claims—Missing numbers will not be supplied if claims are received more than 60 days after the date of the issue, or if loss was due to failure to give notice of change of address. The Association cannot accept responsibility for foreign delivery when its records indicate shipment has been made.

Change of Address—Members and subscribers should notify at once both the Post Office and the American Pharmaceutical Association, 2215 Constitution Ave., N. W., Washington 37, D. C., of any change of address.

The Editor comments

FISCAL RESPONSIBILITY IS ESSENTIAL

In recent months a sister organization in the field of the biological sciences found itself in very serious difficulty because of certain fiscal irregularities which had occurred in its administration of sizeable grants awarded by the National Science Foundation. The organization involved has subsequently taken heroic measures to raise sufficient funds to reimburse the NSF for the entire sum of over a quarter of a million dollars which allegedly has been misused.

Almost simultaneously, Congressional investigators have brought to light several incidents in which funds provided under the National Institutes of Health grants program have been employed for the purchase of unauthorized equipment or in which budgets have been adjusted internally to allocate disproportionately for administrative or overhead costs.

Several features common to the cases involving both the NSF grants and the NIH grants appear to deserve some comment.

In the first place, in none of these disclosures was there any evidence of purely personal gain involved in the misdirection of funds; on the contrary, all evidence brought to light indicated that the irregularities were entirely motivated by unrestrained scientific zeal. Those entrusted with administering the grants made certain improper compromises in an effort to achieve more rapidly the desired goals of the specific study, or to expedite other phases of their general program of research activities.

Secondly, the overall effect of these disclosures has been to raise doubts in the minds of both Congress and the public as to the fiscal awareness and sense of responsibility which might be expected either from individual scientists or the scientific community. On this point Dr. James D. Ebert, director of the embryology department of the Carnegie Institution of Washington, has stated: *"Our lofty ideals, our high purpose in the laboratory and classroom, have not always been carried over in our day to day business practice; we have been more concerned with the advancement of our own fields than with safeguarding the public interest."*

Clearly, it is the individual responsibility of each grant recipient to exercise all diligence in the management of the funds entrusted to him by his fellow citizens through government agencies or private foundations. Scientists need to recognize that in financial matters attentiveness to details and accuracy must be exercised comparable to that employed in reporting on research experiments.

Edward G. Feldmann

The postal zone number for the JOURNAL OF PHARMACEUTICAL SCIENCES, as well as all other mail directed to the AMERICAN PHARMACEUTICAL ASSOCIATION, will be changed from "7" to "37," effective July 1, 1963.

Review Article

Pharmaceutical Sciences—1962. Part I

A Literature Review

By WAYNE McKEEHAN

CONTENTS

[Contents for Part II will accompany the concluding part of Dr. McKeehan's Review Article next month.]

THIS REVIEW covers the literature of pharmaceutical sciences reported in readily available journals or abstracted in the Pharmaceuticals or Pharmacodynamics sections of *Chemical Abstracts* in 1962. It is intended to be reasonably comprehensive; but the large volume of literature published last year prevented the inclusion of some papers, and others may have been inadvertently overlooked. The general aim is to aid the reader in becoming better acquainted with recent developments by presenting a representative sample of papers appearing in various areas of pharmaceutical science.

Some of the literature related to pharmaceutical sciences has been adequately reviewed elsewhere on an annual basis and is omitted. For such associated papers in analytical chemistry, antibiotics, bacteriology, biochemistry, biology, cancer, medicine, medicinal chemistry, microbiology, organic chemistry, pharmacology, physical chemistry, physiology, and plant physiology, the reader is referred to reviews in those areas. The *Advances in . . .* series, the *Annual Reviews of . . .* series, and the *Progress in . . .* series are particularly pertinent.

For the purpose of this review, the selected references have been divided into eight sections. These sections have been subdivided further, where necessary, in order to group related papers. The divisions were established arbitrarily and have no special significance other than to facilitate organization.

GENERAL PHARMACY

Included in this rather broad area are various portions of the literature which did not blend easily into the other divisions. Breunig and King discussed problems and effectiveness of modern statistical methods in acceptance sampling of finished pharmaceutical products (1). Investigations of the influence of seaweed products on the absorption of drugs were reported (2). Publications have appeared concerning the compatibility and manipulation of guar gum (3) and the incompatibilities of various compounds in pharmaceutical preparations (4, 5). Suspension sampling, studied by Anderson and Shaw, yielded the most consistent results when samples were obtained by weight (6). The influence of pH on surface charactertistics of silica gel in aqueous solutions was investigated (7). Brooks, *et al.*, cataloged solid pharmaceutical dosage forms for use in forensic toxicology (8), and Wagner suggested the use of a manually sorted punched-card system for pharmaceutical literature (9). Other writers discussed physical and physiological aspects of collyria (10) and the organization and economics of drug research (11).

Preservatives.—Bailey discussed and classified various antioxidants according to their mechanism of action (12). Physicochemical aspects of preservative selection for emulsions (13) and a manometric method for evaluation of preservatives (14) were reported. In the latter paper, Wailes suggested using the Warburg apparatus for screening potential preservative agents. Factors influencing the stability of antibacterial preservatives in parenteral solutions were explored by Lachman, *et al.* (15). The interaction of preservatives with certain macromolecules was also studied (16). Dimethoxane, a new preservative, retained its activity in the presence of nonionic emulsifiers (17).

Several papers concerning the use of hydroxybenzoate esters as preservatives were published in 1962. The role of alkyl *p*-hydroxybenzoate esters as pharmaceutical preservatives was reviewed (18). Matsumoto and Aoki studied the inactivation of *p*-hydroxybenzoic acid esters in the presence of surfactants (19, 20). Activity appeared to be dependent on the amount of material in the aqueous phase outside of the surfactant micelle. Another monograph reported research on the fungistatic activity of methyl and propyl hydroxybenzoates (21), and mixed parabens were used by Nuppenau for the preservation of hexachlorophene cream (22).

Humberstone found that chlorhexidine diacetate was not a suitable preservative for eyedrops in the presence of sulfate ions (23). Potassium metabisulfite had no inhibiting influence on the cleavage of Novocaine in solution (24). The antioxidant action of phenols was explored by McGowan and Powell (25). In a study of the preservation and degradation of adrenaline solutions, sodium pyrosulfite was added as a stabilizer to solutions of various adrenaline salts (26). A preliminary report was published on the effect of a quaternary ammonium compound on polyvinyl chloride (27).

Flavoring.—Pharmaceutical flavoring and its importance to the patient and the physician were reviewed by Moorish (28). The psychology, physiology, and physicochemical aspects of flavor and taste have been discussed (29, 30). A trained taste panel was used in studying the effectiveness of monosodium glutamate for masking bitter taste (31). Mauer continued his series on flavors and per-

Received from the Pharmaceutical Research Department of The Lilly Research Laboratories, Eli Lilly and Co., Indianapolis, Ind.

fumes from various flowers and leaves (32, 33); and many publications appeared on the isolation, identification, and pharmaceutical applications of essential oils (34–39). The utilization and evaluation of natural and synthetic sweetening agents were reported (40–42). Vasic has discussed the perfuming of various types of cosmetic formulations (43).

Adjuvants.—A study of the influence of solvent composition on the activity of various bacteriostats and bactericides was reported (44). The current status of certified colors has been summarized (45). Swartz and Cooper reviewed the chemistry, applications, and properties of various colorants (46), and Hamilton discussed the selection of colors and their effects (47). The properties and uses of linalyl esters as perfumes were investigated (48). Reviews were published on the utility of sorbitol in pharmaceutical liquids (49) and the use of sulfur in pharmacy and cosmetics (50). Pail and Todd discussed functions and formulations of three silicones (51), and Secard dislcosed some new pharmaceutical uses of Carbopol (52). Surfactant applications in pharmacy and cosmetics have been reviewed (53–55). Lower compiled a comprehensive listing of British surface-active agents (56–63). In studying the germicidal activity of hexachlorophene, Banks and Huyck investigated the effects of some wetting agents (64). Russell and Hoch described processes for the preparation of clear detergent solutions containing lanolin oil (65). A polyethylene oxide ether–fatty acid alkanolamide mixture was used to solubilize the lanolin oil.

Stability.—As indicated by the references which follow, the pharmaceutical scientist has shown considerable interest in the development of better methods for evaluating product stability. The influence of light on pharmaceutical formulations has been reported (66). In a short communication, Ramwell and Shaw suggested that aqueous solutions of picrotoxin are stable to light if stored in acid-washed glassware (67). Several investigators reported their work on the stability of tetracycline and its various derivatives (68–70), and the stability of nystatin in dry preparations was demonstrated (71). Physicochemical studies on the stability of various penicillin derivatives have been published (72–74). Citri and Garber concluded that the side chain of a penicillin may confer resistance to hydrolysis by penicillinase (75). A study of the stability of penicillin G sodium in the presence of nonionic surface-active substances was made (76). The stability of *p*-aminosalicylic acid in aqueous solution has been studied (77, 78). Various buffer salts were used by Tanaka and Takino to examine the stability of *p*-aminosalicylic acid and its salts (79). Research on stability and stabilization of acetylsalicylic acid in aqueous solutions was reported (80, 81). Hydrolysis of the undissociated acetylsalicylic acid molecule was suppressed by anionic, cationic, and nonionic surfactants. Decomposition of amethocaine hydrochloride solutions was accelerated by heat and high pH (82). Pantocaine solutions showed no detectable decomposition immediately after sterilization as measured by the diazo reaction, but solutions at several pH values gave a positive test after storage (83). Samuelsson investigated the stability of digitoxin in galenical preparations (84). The stabilities of solutions containing papaverine hydrochloride (85) and some reputedly unstable vegetable drugs (86) were examined.

The stabilization of arsenic solutions (87) and solutions of ferrous gluconate (88) has been studied. Bamann, *et al.*, considered the decomposition of phosphoric acid esters by metal ions at acid pH (89). An experimental method for studying the stability of cortisone and hydrocortisone was published by Takubo, *et al.* (90). Sodium metabisulfite was recommended as an antioxidant for solutions of isoprenaline (91). Most of the racemization of *l*-noradrenaline hydrochloride solutions was found to occur during the first 30 days (92). Nielsen found that poly(vinylpyrrolidinone) prolonged the effect of vasopressin and oxytocin but decreased the thermal stability of their solutions (93). Reports have appeared on the stabilization of solutions of thioproperazine (94) and chlorpromazine hydrochloride (95). Nicotinamide protected the latter from discoloration by light. The combined use of polyhydric alcohols and calcium acetate produced a stable bacterial alkaline proteinase solution (96). In another study, calcium was used to stabilize trypsin in a polyethylene glycol ointment base (97). Nogami and Awazu investigated the stabilization of methantheline bromide in aqueous solution by surface-active agents (98). Other investigations were made on the effect of surfactants on the stability of some pharmaceuticals (99) and the effect of ultrasonic waves on the stability of surfactants, sulfonamides, and *p*-aminobenzoic acid (100). Accelerated aging was used in the evaluation of pharmaceutical fat vehicles (101). Stability studies on buffer solutions (102) and pepsin elixir (103) have been reported. This elixir be-

gan to lose its pepsin activity after storage for 5 months. The influence of additives on the stability of glucose solutions was investigated by Parke (104).

Stability Kinetics.—Chemical kinetics has become a very useful tool in studying the stability of different formulations and in the prediction of shelf life. Sesaki, *et al.*, explored the application of chemical kinetics to the stability of chemicals (105). A method of plotting kinetic data to determine reaction order and specific rate constant has been suggested; evaluation of data up to 99% conversion was possible (106). Hochanadel described a simple device for determining slopes using the glass-rod method (107). In testing the stability of pharmaceutical preparations in a homogeneous liquid phase, the van't Hoff-Arrhenius relation was found useful (108). The kinetics of degradation of epinephrine in solution by molecular oxygen was studied by Sokoloski and Higuchi (109). An extensive study was conducted by Riegelman and Fischer on the stabilization of epinephrine—chelation of the catechol nucleus with boric acid gave marked stabilization (110, 111). Rates of degradation, half-life, and the effect of pH on the degradation of potassium phenethicillin in aqueous solution were discussed (112). The kinetics of degradation of glutethimide (113) and the stability of chloral hydrate solutions (114, 115) have been investigated. Studies on the aging of pharmaceutical preparations were reported by Inami, *et al.* (116, 117). The stability of pyridine-2-aldoxime methiodide in aqueous solutions was evaluated at different temperatures and pH values, and general equations for its half-life were derived (118). Chemical kinetics was used by Heimlich to study glucose degradation in acid solution (119) and by Zajta to develop a rapid method for investigating the stability of phenobarbital sodium solutions (120). Work carried out by Tishler, *et al.*, on phenobarbital degradation in solution was published (121). Nelson compared rate constants for sulfonamide acetylation *in vivo* with oil-in-water partition coefficient (122). Rates of oxidative destruction and alkaline saponification of some steroidal esters were determined—the sulfobenzoates, phosphates, and hexahydrobenzoates gave maximum stability (123). Schroeter stated that the reaction between bisulfite or sulfite ion and salicyl alcohol followed second-order kinetics over a wide pH range (124). Degradation of *l*-ascorbic acid solutions was found to be a pseudo-first-order reaction and dependent on pH and temperature (125). Kinetic studies were conducted by Rippie and Higuchi on the reaction between molecular oxygen and 2,3-dimercapto-1-propanol in aqueous solution (126).

Stability prediction, a very important part of pharmaceutical formulation, was reviewed in depth by Garrett (127). Scott and Lachman investigated the influence of nonequilibrium sample temperature on stability predictions extrapolated from elevated temperature studies (128). Stability prediction methods for liquid pharmaceuticals were reported (129). In a series of articles on pharmaceutical stability prediction, Garrett (130), Garrett and Royer (131), and Garrett and Umbreit (132) described detailed kinetic studies on steroids and antibiotics. The theory and practice of stability prediction in cosmetic formulation were treated by Lachman (133).

Degradation of a large number of therapeutically important compounds takes place by way of hydrolysis. Hence, knowledge of the kinetics of hydrolytic reactions is of importance in the formulation of stable pharmaceutical preparations. Windheuser and Higuchi (134) and Heathcote and Wills (135) have studied the kinetics of thiamine hydrolysis; the rate approximated a first-order reaction and was influenced by general base catalysis. In another paper, Finholt and Higuchi determined rates of hydrolysis of niacinamide (136). Kinetic studies on the hydrolysis of tropine esters were reported (137). Data published by Garrett and Weber showed that the stability of N-butylformamide to acid and enzymatic hydrolysis greatly exceeded any stomach retention time (138). Mitchell investigated the hydrolysis of ethyl benzoate, diethyl phthalate, and benzocaine in cetrimide solutions (139), and the hydrolysis of *p*-chlorobenzaldoxime has been related to its oral inefficacy (140). A kinetic study of the base-catalyzed hydrolysis of 3,5,5-trimethyl-2,4-oxazolidinedione was conducted (141). Suzuki employed chemical kinetics to evaluate the stability of aqueous succinylcholine chloride solutions (142, 143). Velocity constants were determined for hydrolysis of this choline derivative as a function of pH. A report on the hydrolytic kinetics of calcium acetylsalicylate carbamide in the presence of high concentrations of additives was published (144). Garrett has discussed the solvolysis of symmetrical and mixed aspirin anhydrides (145) and of 21-hydrocortisone esters and hemi-esters (146).

Vitamin Stability.—The general area of vitamin stability was reviewed by Parrak (147). Guillory and Higuchi investigated the solid state stability of some crystalline vi-

tamin A derivatives (148). Of the derivatives studied, vitamin A benzhydrazone and vitamin A succinate triphenylguanidine salt were the most stable. Other writers reported the effects of pH, antioxidants, metallic impurities, chelating agents (149), and thiamine hydrochloride (150) on the stability of liquid formulations containing vitamin A. The stability of cyanocobalamin in liver preparations used in the treatment of pernicious anemia was examined at different times and pH values (151). Spontaneous modifications of certain properties of vitamin B_{12}-Co^{60} during storage have been explored (152). Vitamin B_{12} stability in the presence of other vitamins has also been investigated (153, 154). Experimental work on the stability of some new thiamine derivatives was reported (155, 156), and various stabilizers for ascorbic acid in solution were compared (157).

Multivitamin preparations were the object of many stability investigations. Wai, *et al.*, studied the stability of vitamins A, B_1, and C in selected vehicles—formulation, method of combination, and manufacturing procedures were evaluated for their influence on stability (158). Also investigated were the stabilities of some polyvitamin products containing vitamins A_1, B_1, B_2, and C (159). The shelf life of different oral formulations containing vitamins B_1, B_2, B_6, and niacinamide was evaluated (160). In a preliminary report, Bonn, *et al.*, stated that some liquid multivitamin preparations were deficient in one or two ingredients before opening (161). Storage of vitamins B_1, B_2, B_6, and niacinamide was examined (162).

PHARMACEUTICAL TECHNOLOGY

This section of the review is primarily concerned with the technological aspects of pharmaceutical dosage forms. Cooper reviewed pharmaceutical technology in industrial pharmacy (163), while a similar review by Ullmann and Thoma dealt with pharmaceutical technology in research and education (164). Also reviewed were oral polio vaccine production (165), the technology of vitamin C (166), and micro-capsules—a new pharmaceutical dosage form (167). Progress in industrial mixing processes was reviewed by Baird (168). Barnett and James studied the particle-size distribution of marble after wet ball-milling and found that varying the solid-liquid ratio changed the mean particle size of the product (169). Some aspects of inhaler technology (170) and dermatological vehicle formulation (171) were reported. Faust has reviewed some of the newer materials used in cosmetics and dermatologic vehicles (172). Basic conditions for drying pharmaceutical residues have been investigated (173). Spray-drying of antibiotics and some other synthetic drugs (174) and the effectiveness of protective colloids in spray-drying of powdered flavoring materials (175) were evaluated. Selleri and Caldini studied some pharmaceutical compositions containing vitamin B_{12} and a new vitamin C derivative (176). They reported that gelatin capsules containing an anhydrous lipophilic substance provided better stability than syrups. The preparation and film-forming properties of synthetic glycerides were investigated by De Freitas (177).

Small amounts of belladonna tincture were made by a new extraction process for the preparation of tinctures (178). A study on the pH of pharmaceuticals dealt with various aspects of hydrogen-ion concentration and buffer capacity in tinctures (179). Kochhar and Lofgren studied the preparation of stable, sterile injections of physostigmine sulfate and salicylate (180). Sodium metabisulfite appeared to be the best stabilizer. Sciarrone explored some of the problems encountered in the preparation of isotonic solutions (181). Parenteral medication was the topic of two papers: one discussed parenteral solutions of vitamin B_{12} (182), while another described the use of wetting agents in the preparation of aqueous injectable solutions of oil-soluble vitamins (183). In another report, Gilroy and Mayne investigated the efficiency of a method for deaerating aqueous solutions (184).

Tablets.—The tablet is one of the most widely used forms of oral medication. Kovac reviewed its future with regard to automation and machinery (185, 186). Another discussion on automation suggested a punched-tape program for making tablets (187). Progress in coated and multilayered tablets was also reported (188). Research on tablet granulations was disclosed in the following three papers: in one, Perlman described the use of calcium sulfate granulations as a dry-blended tablet base (189); another proposed silicone oil as a good antiadherent in tablet granulations (190); and the third presented physicochemical studies on factors affecting granule strength and apparent granule density (191). Particle size of the powder was found to be an important element of both granule strength and apparent granule density. Some physical characteristics of compressed tablets were studied by Henderson (192).

Several articles on the disintegration of tablets were surveyed. One examined the influence of surfactants on the disintegration of tablets (193), and two others discussed the use of sodium bicarbonate–tartaric acid mixtures as disintegrating agents for tablets (194, 195). In still another, ten tablet disintegrants were evaluated in the formulation of tablets of two drugs of differing water solubility (196). Richter and Steiger-Trippi investigated tablet disintegration testing (197). The influence of the addition of mucilage to artificial gastric juice on tablet disintegration time has also been studied (198). In another study, the relationship between rate of dissolution and disintegration time was examined (199). Kaplan and Kish described a modification of the U.S.P. tablet disintegration apparatus (200). An apparatus was recommended by Krueger and Vliet for the *in vitro* testing of timed-release tablets and capsules (201).

A preliminary study of the temperature dependency of colorant loss in tablets was reported by Swartz, *et al.* (202), and Lachman, *et al.*, investigated the effect of ultraviolet absorbers on the photostability of colored tablets (203). Tablets of pyrilamine resin adsorbate with aspirin and vitamin C were more stable than control tablets containing the maleate salt of pyrilamine (204). Another paper discussed medicinal-Aerosil adsorbates in tablets (205). Castello and Mattocks studied the discoloration of tablets containing amines and lactose (206). No darkening occurred when amine salts were used with lactose. Of three emodin tablet formulas investigated, a lactose base provided the best stability (207).

Tablet coating with syrup (208) and the age stability of sugar coatings (209) were studied. Other researchers investigated the addition of moisture-resistant waterproof coatings to sugar-coated tablets (210, 211). In a series on protective coatings for tablets, Ida, *et al.*, studied amphoteric poly(vinylpyridine) derivatives (212). Another paper in this series reported research on the enteric coating properties of internally plasticized acrylic and methacrylic acid derivatives (213). Lappas and McKeehan described the use of synthetic polymers as enteric and sustained-release coatings (214). The use of cellulose acetate succinate (CAS) as an enteric coating for some compressed tablets was also reported (215). Using talc as a dusting powder, satisfactory tablets were obtained when CAS was applied from an acetone–ethyl acetate solution by a modified pan method. Fennell studied the development of an enteric coating (216), and enteric tablets prepared by coating or direct mixing have been described (217).

Emulsions.—In 1962 reviews were published on the theory (218) and on the structure and stability (219) of emulsions. Becher reviewed the theoretical aspects of emulsification with particular emphasis on factors affecting stability (220). Electrophoretic methods for evaluating various emulsions were studied (221), and dielectric constants of water-in-oil emulsions were employed in studying agglomeration (222). Higuchi, *et al.*, proposed a method for studying aggregation in oil-in-water emulsions (223). Other investigators explored the relationship between electrical resistance and dispersed-phase concentration of oil-in-water emulsions (224, 225). An equation was developed which would explain the results.

Many publications have appeared on the subject of emulsion stability. Riegelman discussed the theory of emulsions as applied to stability (226), and Riegelman and Pichon demonstrated that emulsion stability need not be related to the HLB values (227). A turbidimetric method for testing the stability of oil-in-water emulsions has been developed (228). In a quantitative theoretical study of the physical degradation of emulsions, Higuchi and Misra considered various factors governing the degradation rate of emulsions when the process is strictly molecular diffusion-controlled (229). An investigation of the dispersion and stability of several emulsions was published (230). Two investigations on the preparation of stable paraffin oil emulsions were also reported (231, 232).

Prediction of emulsion stability, including types of instability and test methods, has been discussed (233). The ultracentrifuge has been employed in studies relating to the stability of emulsions. In one study Garrett found the ultracentrifuge an excellent tool for evaluation and prediction of emulsion stability (234), and in another the ultracentrifuge was used for quantitative determination of emulsion stability (235). Still another, by Rehfeld, described a new rapid method for quantitatively studying the mechanical stability of emulsions using the ultracentrifuge (236). Coagulation of emulsions was separated into two distinct steps—namely, aggregation and coalescence.

Wachtel and La Mer have investigated the preparation and size distribution of some monodisperse emulsions (237). Phase inversion by homogenizer processing was explored by Shimamoto

(238). Factors affecting flavor loss after spray-drying of peppermint oil-acacia-water emulsions were also studied (239).

The use of various hydrocolloids in emulsions was reviewed by Schwarz (240). These materials have found their greatest use primarily as stabilizers. Ethoxylated higher fatty-alcohol emulsifiers for various types of emulsions have been investigated (241). Bogs and Naumann described an apparatus for measuring the strength of films around oil globules in emulsions (242). In another study by the same writers, viscosity determinations were employed in the evaluation of pharmaceutical emulsifying agents (243). Research on the development of fat emulsions for intravenous administration has also been published (244, 245).

Suppositories.—A penetrometer method for estimating the melting point of suppositories (246) and a method for measuring solution time of glycerin suppositories (247) were discussed. Another investigator explored deformation time and ability to liberate therapeutic substances as criteria for the evaluation of modern suppository bases (248). Setnikar and Fantelli developed an apparatus which reproduces conditions of the rectum for determining liquefaction time of rectal suppositories (249). The preparation and testing of "tropic proof" suppositories have been reported (250), and in a series on pharmaceutical preparations, Beral, *et al.*, have discussed the testing of suppositories (251). A rotational viscosimeter was employed in a study of the rheological properties of some suppository masses in the molten state (252). Measurements of *in vitro* activity were used to study the stability of chloramphenicol in several suppository bases (253).

Ointments.—The utility of methylcellulose (254), sodium carboxymethylcellulose (255), and water-soluble polyethylene glycol (256) as ointment bases has been reviewed. Mueller found that dextrans in combination with plasticizers produced good ointment bases (257). Belen, *et al.*, developed a modified vanishing cream base for chlorothymol ointments (258). The importance of the HLB system in ointments has been investigated (259). Also studied was the hydration of wool wax alcohols and their use as ointment bases (260). Determination of the water content of ointment bases (261) and rheological standardization of Hebra's lead ointment (262) have been reported. Steigleder and Raab discussed a new method for studying the protection by various ointments of the skin surface against contact with water (263). They found that ointments have prolonged influence on skin surface, even when protection from water is partially lost.

Suspensions.—Polderman has reviewed the use of suspensions as oral, topical, and injectable pharmaceutical vehicles—many references were cited (264). In another publication, Polderman discussed the physical chemistry of suspension systems with regard to stability, particle size, sedimentation, crystal growth, and zeta-potential (265). The grinding and evaluation of powders for suspension preparation were investigated (266), and a statistical investigation into the dispersibility of powdered drugs was conducted (267). Several advantages of using Cab-o-sil as a suspending agent were reported (268). Anderson and Plein published a pharmaceutical investigation on the geology, identification, and testing of selected Alberta bentonites (269, 270). Calamine lotion was the subject of two publications: one reviewed the application of bentonite as a suspending agent in calamine lotion (271); in the other, Swafford found that use of polyethylene oxide water-soluble resin as a suspending agent for calamine lotion produced a more elegant and more stable preparation (272).

Sterility.—Kirsch has reviewed new developments and problems in sterile pharmaceutical packaging (273). In a study of multiple-dose injectables, the effect of repeated withdrawals on sterility was investigated (274). The use of ethylene oxide gas in sterilization has been reviewed (275), and two more papers reported experimental work in chemical sterilization (276, 277). Gold studied sterilization of pharmaceutical preparations with ultrasonic energy (278). Steam sterilization of hollow containers has also been discussed (279). In another study, the sterilizing capacity of cationic exchangers in the preparation of demineralized water was investigated (280). Membrane filtration has been applied to testing the sterility of antibiotic materials (281).

Packaging.—Methods of testing pharmaceutical glassware have been reported (282, 283). Two papers discussed the utilization of plastics in pharmaceutical packaging (284, 285). In another, a comparison of different methods of washing, filling, and sterilization of ampuls was reported (286). Experimental data on rubber preparations and their effect on distilled water has been published (287). Strip packaging of pharmaceuticals was explored by Webb (288), and Frey considered packaging defects and methods of reducing them (289).

Aerosols.—A review with several references was published on the use of aerosols in the pharmaceutical field (290). An article by Sciarra and Eisen surveyed the formulation of various dermatological aerosols (291); while another, by Hart and Cook, reviewed emulsions as applied to various types of aerosols (292). Other papers discussed the advantages and problems of powder aerosols (293) and the improvement of aerosol packaging (294). The advantages of having a contract filler for aerosols were summarized by Peterson (295). Ruyssen reviewed the constitution and stability of foams (296). A report on the physical chemistry and stability of aerosols has also been published (297). As vehicles for bronchodilator drugs, Segal found aerosols to be of value for relief of bronchospasm (298).

PHYSICAL PHARMACY

Since its recognition in the late 1940's, physical pharmacy has grown to a place of prominence in pharmaceutical science. In this area, the principles of physics and physical chemistry are applied to the solution of pharmaceutical problems. Many papers were published on this theme in 1962.

Publications by Kamada on the applications of surfactants to pharmaceutical preparations described a temperature-scan method for studying solubilization (299, 300). Another investigator studied the interaction of pharmaceuticals with sucrose and hyprose esters (301). In a series of papers on the surface activation of medicinals, Utsumi and Harada (302–305), Harada (306), and Utsumi, *et al.* (307), explored the physical chemistry of several alkylsulfate derivatives. Salts of several basic drugs were prepared and examined for micelle formation, complexation, and solubility. Two film studies were presented: in one, some physical properties of interfacial films of potassium arabate were investigated (308); the other, by Kanig and Goodman, described evaluative procedures for pharmaceutical film-forming materials (309). Fuehrer (310) published a review on hydrogen bonds, and Huggins (311) discussed the physicochemical aspects of hydrogen bonds and their application to biology.

The validity and limitations of pH determinations (312) and the determination of activity coefficients with the glass electrode (313) were discussed. In another article, a nonlinear least-squares method was advocated for the calculation of activity coefficients from osmotic coefficient data (314). A discussion of the measurement and interpretation of dissociation constants of akaloids was published (315). Along this same line, Chatten studied the relationship between aqueous dissociation constants of organic bases and their half-neutralization potentials in organic solvents (316). A spectrophotometric method was employed for investigation of the acid dissociation constants of phenylalkanolamines (317). Chilton and Stenlake have investigated dissociation constants of some compounds related to lysergic acid (318), while Miyamoto and Brochmann-Hanssen investigated dissociation constants of certain γ-pyrone dicarboxylic acids (319).

A photoextinction-sedimentation method was recommended for the size analysis of barium sulfate powders (320). Gledhill has shown that particle-size distribution determination by turbidimetry is comparable with electron-microscopic analysis (321). Investigations of the particle-size distribution of monodispersed barium sulfate prepared by the EDTA method (322) and the physical properties of chloramphenicol particles (323) were reported.

As evidenced by the following reports, there is still considerable interest in the development of methods for studying medicament release from pharmaceuticals. Release of medication from various emulsified ointment bases was discussed by DeKay (324). An agar-plate test was used in studying the influence of different particle sizes of chloramphenicol on diffusion from a lipophilic hydrocarbon base (325). Wood, *et al.*, described a new diffusion cell for the measurement of salicylate diffusion within hydrophilic ointments (326). Ointment-base influence on the diffusion of other medicaments was also studied (327). In a study of various proflavine salts, Fenton and Warren found that the *n*-valerate exhibited the best diffusion from a cream base (328). Higuchi analyzed recently published data on medicament release from ointments and reported good agreement with theory (329). The diffusion of oxygen, nitrogen, and carbon dioxide through thin Teflon and silicone membranes has been investigated (330). In studying membrane permeability of various ions, Nakagaki, *et al.*, used a membrane electrode method (331). Membrane permeabilities, diffusion constants, and degree of association were determined for some phenoxazone compounds (332, 333).

Nogami and Nagai (334, 335) and Nogami, *et al.* (336), have studied the acid-neutralizing reaction of various antacid compounds, particularly dried aluminum hydroxide gel. They developed equations for acid-neutralizing velocity, one

for the calcium carbonate-type antacid and another for the dried aluminum hydroxide gel type. Experimental data demonstrated that the reaction between dried aluminum hydroxide gel and acid followed the proposed equation.

Solubility.—The solubility of solids in liquids is a very important aspect in the formulation of many types of pharmaceutical preparations. The literature of the physics and engineering of dissolution has been reviewed (337). Three monographs dealt with the relationship between agitation and dissolution. Larese, *et al.*, studied high-speed stirring techniques in solubility determination (338). At approximately 30,000 r.p.m. equilibrium is reached within 1 hour. Results were comparable with those obtained by conventional agitation. The second paper presented an investigation of the dissolution of particles in a stirred liquid (339). In the third, Hamlin, *et al.*, discussed loss of sensitivity in distinguishing real differences in dissolution rates due to increasing intensity of agitation (340). The relationship of chemical kinetics and dissolution was the subject of two investigations (341, 342). Reports of studies on the velocity of polymer dissolution were also found (343, 344). The relationship between *in vitro* dissolution rates, solubilities, and LT_{50}'s in mice for some salts of benzphetamine and etryptamine has been investigated—salt formation as a means of obtaining sustained release or prolonged action was also discussed (345).

An experimental method for studying growth rates of particles in aqueous media was developed by Higuchi and Lau (346). Electrical conductivity measurements were used to investigate the mode of action of solution adjuvants (347). Papers were published on the use of an approximate dielectric constant in solubility studies (348) and the correlation of solubility parameters and dielectric constants (349). The role of ionic strength, ion association, and solubility on the properties of electrolytes in solution has been reported (350). Another investigator studied the influence of inorganic salts on the solubility of organic pharmaceutical compounds (351). Levy and Procknal found that the dissolution rate of aluminum acetylsalicylate decreases with time because of the formation of a basic water-insoluble aluminum compound on the surface of the solid particles (352). Kato reported that glycols with hydroxyls on either terminal end or in 1,2 positions formed micelle-like structures in aqueous solution (353), and Mulley and Metcalf investigated the critical micelle concentration of some polyoxyethylene glycol monohexyl ethers in binary and ternary systems (354). In another solubility study, Higuchi and Misra examined the effect of solvent chain length on the solubilization of water by dioctyl sodium sulfosuccinate (355).

Investigations of the solubility of sucrose in aqueous mixtures of organic solvents (356) and the solubility of opium alkaloids in various organic solvents (357) were published. In another article, benzyl alcohol was suggested as a solvent for injectable solutions of quinine (358). Burnstine and Schmid found that the solubility of bilirubin in aqueous solutions was critically dependent on pH and ionic strength (359). Partition coefficients between water and butyl acetate were determined for various concentrations of benzylpenicillin (360). Debye and Coll used vapor-pressure measurements in studying the association of α-monoglycerides in nonaqueous solutions (361). Physicochemical investigations of aqueous sodium salicylate solutions were also reported (362, 363).

Two reviews on the solubilization of vitamins A and D were published (364, 365). Solubilization of benzoic acid derivatives in aqueous solutions with polyoxyethylene stearates was the subject of a monograph by Goodhart and Martin (366). Research on the solubilization of essential oils and oil constituents (367) and the use of amine salts of fatty acids for the solubilization of cholesterol (368) has also been published. Conductivity and surface tension measurements were used to study solubilizing properties of liquorice (369). Another report discussed the solubilizing ability of some polyethylene glycols and their esters (370).

Complexation.—The use of complexation in the stabilization of pharmaceuticals (371) and the application of chelating compounds in pharmacy and medicine (372) were reviewed. Walker has discussed the use of complexation in pharmaceutical systems (373). In another publication, Kennon and Chen presented a new approach to probability and complexation (374). They described and illustrated a method which considers the ability of the ionic atmosphere surrounding a drug in solution to form "probability complexes" with the drug.

Solubility experiments were used in studying the complexation of organic acids and bases with their salts in aqueous solution (375). A new molecular complex of tetracycline and urea was reported (376), and Guttman summarized results of a preliminary investigation of the effect of molecular interactions on velocities of reactions involving riboflavin (377). The stability of anionic complexes of some barbituric

acid derivatives and silver was studied by Leyda and Harris (378). Chelates of pyridine-2-aldoxime (379), metal chelates of mercapto-acid amides (380), and copper chelates of *l*-ephedrine (381) have been studied. Complex formation between boric acid and glycerin at elevated temperatures has been investigated (382). A method combining radioisotopes and ion exchange was used to study complexation of alkaline earth metals with citric acid and its derivatives (383). Metal complexes of nuclear-substituted salicylic acids and their biological effects were investigated by Foye and Turcotte (384). Two discussions on the preparation and properties of iron-carbohydrate complexes for injectable use were published (385, 386).

Surface Phenomena.—The importance of colloid and surface chemistry to biologically oriented and chemically oriented students has been reviewed—course content and methods of teaching were discussed (387–389). In a similar review, Wilson discussed the application of colloid and surface chemistry to problems in industrial research (390). Bailey, *et al.*, considered the meaning and function of average quantities in colloid science (391). They pointed out that the experimental method often determines the nature of the average obtained.

Barriers on the surfaces of dispersed particles (392) and the use of gelatin as a protective colloid (393) were the subjects of papers by two other investigators. In studies on the effect of deflocculating agents on suspensions of calamine and zinc oxide, Wood, *et al.*, measured particle size at various concentrations of sodium citrate (394). A new deflocculant and protective colloid for barium sulfate has also been reported (395).

Ikegami and Imai investigated the precipitation of polyelectrolytes by salts (396). Experiments on the flocculation of quartz and other suspensions with gelatin have been reported (397). Results indicated that gelatin must have a small positive charge for optimum flocculation of a negatively charged suspension. In his studies on the coagulation process, Packham investigated the effect of pH and turbidity (398). A new method was described which reduces pH variation. In a second paper Packham studied the effect of pH on the precipitation of aluminum hydroxide and measured the degree of precipitation by measuring the change in turbidity and the amount of residual soluble aluminum (399).

The sorption of water vapor by synthetic lecithin and cephalin has been studied (400). B-E-T plots showed that the synthetic compounds absorbed less than the corresponding natural compounds. An investigation of water vapor sorption and diffusion through hard gelatin capsules was also reported (401). A paper by Blank dealt with monolayer permeability and the properties of natural membranes; differences between bulk and monolayer processes were discussed (402). Methods for measuring gas adsorption on solids and their application to pharmaceutical products have been reviewed (403). Strickland studied water vapor sorption by pharmaceutical powders (404), and Gross examined the adsorption of some anticholinergic drugs by various antacids (405). Another investigator reported on the adsorption capacity of activated carbon (406).

Gillespie and Wiley considered the determination of London–van der Waals constants from suspension and emulsion viscosity and surface energy data (407), and other researchers employed solution adsorption in the measurement of specific surface areas of a wide variety of finely divided solids (408). In an experimental investigation of the behavior of a single droplet at an oil-water interface, Jeffreys and Hawksley found coalescence to be a stepwise phenomenon (409). Retention of liquids on solid surfaces was considered in two articles: a theory for spray retention based on the sliding of liquid drops on solid surfaces was developed in one (410); the other reported studies on the retention of aqueous suspensions on leaf surfaces (411). Surfactants were used for estimating the charges in gelatin at the isoelectric point (412). In a series on nonionic surface-active compounds, Becher studied the effect of electrolyte on micellar properties of some polyoxyethylene derivatives of lauryl and tridecyl alcohol and nonyl phenol in aqueous solutions (413). Another paper by Becher described a spectral dye method for the determination of critical micelle concentration (414). The effect of sucrose and cyclamate on the gel strength of gelatin, carrageenan, and algin has been studied (415). Another article reported the preparation of two-phase gels of iodinated poly(vinyl alcohol) (416).

Rheology.—In a series of papers on the subject of rheology in pharmacy, Lordi has discussed fundamental concepts (417), Newtonian flow (418), and non-Newtonian flow (419). Two papers on the swelling of polymer systems in solvents were published (420, 421): the first presented a method for obtaining complete swelling-time curves, while the second considered the mathematics of diffusion. Re-

view articles on the use of the Brookfield Synchro-Lectric viscometer for rheological investigation of pharmaceutical preparations (422) and theories of liquid viscosity (423) were also published. In the latter, Brush dealt with basic principles involved and some theories of current interest and cited almost 600 references. The role of viscosity and viscosity-enhancing materials in the compounding of pharmaceutical preparations has been discussed (424). Gold studied interfacial viscosity measurements and their relationship to selected emulsion systems (425).

A study of the coalescence of liquid drops in electric and shear fields was conducted (426). Umemura, in his studies on pharmaceutical dispersion, investigated the relationship between viscoelasticity and non-Newtonian flow (427, 428). In a third paper of this series, he extended the mathematical relationship of previous work to study temperature dependence of six dispersion systems (429). Haines has studied the caking of liquid dispersions (430). Theoretical calculations of sedimentation volume for the case of spherical particles attracted by cohesive force were presented (431), and Levine and Bell discussed an extension to the stability theory of lyophobic colloids (432). Effects of emulsification temperature and cooling rate on certain physical properties of a beeswax-mineral oil emulsion were studied by Boylan, *et al.* (433). Other researchers investigated the intrinsic viscosity of gelatin (434), and the influence of pH, concentration, time, dilute electrolyte, and functional groups on the gelation of gelatin and modified gelatins (435, 436).

Several papers were published on the rheological behavior of both aqueous (437) and organic (438–440) dispersions of Aerosil. Levy has investigated changes on aging of plain and polysorbate-80 containing dispersions (441). Another article by Levy dealt with the kinetics of structural recovery of thixotropic montmorillonite dispersions (442). In an investigation of unit layer interaction in hydrous montmorillonite systems, Van Olphen studied competition between double-layer repulsion forces and van der Waals attractive forces (443). The rheological behavior of clay-water systems was also discussed by Van Olphen (444). Application of the Verwey and Overbeek theory to the stability of kaolinite-water systems was described by Holtzman (445). A general method was presented for measuring adsorption of various anions on kaolinite.

Hydrodynamic studies on sodium carboxymethylcellulose in aqueous solutions have been conducted (446). An investigation was made of the rheological properties of corn oil emulsions with methylcellulose; a new equation was derived to explain flow properties (447). In another rheological study, consistency curves for procaine pencillin G aqueous suspensions were obtained at different concentrations (448). Non-Newtonian flow was observed in these suspensions at low shear rates, but Newtonian flow was found at high shear rates. The viscous behavior of a barium sulfate–water system has been studied (449). Rheological properties of aluminum stearate in benzene (450) and poly(ethylene oxide) in aqueous solutions (451) were investigated. Simonelli and Higuchi explored melting behavior, thermodynamic equilibrium, rate of crystal growth, and rate of melting of methyl stearate (452). Polymorphism in some pharmaceutically important lipid materials was examined by Eriksen, *et al.*, with the aid of heating and cooling curves (453).

PHARMACEUTICAL CHEMISTRY

For the purpose of this review, pharmaceutical chemistry is loosely defined as the area primarily concerned with the chemical aspects of pharmaceutical science. New drugs and drug products of 1961 (454, 455), principles and chemistry of central analgesics (456), crystallography (457, 458), and the use of quaternary ammonium compounds in medicinal chemistry (459, 460) were subjects of review articles published in 1962. A table of melting points of medicinals and index of synonyms has also been published (461). Melting points from 30 to 351° were listed. Several additional publications discussed properties and uses of enzymes in pharmacy and medicine (462–466). In another study on enzymes, the effect of sulfate content of anionic polymers on the *in vitro* activity of pepsin was investigated (467).

Surfactants were the subject of considerable research. Raphael reviewed detergents and surface-active agents (468). The surface activity of glycerol ethers (469) and some synthetic nonionic detergents (470) has been studied. Applications of polysorbate 60 in pharmaceutical compounding were described (471). Ullmann and Moser investigated the effect of polyoxyethylene-adducts on the antibacterial activity of antibiotics (472).

Many investigations have been published on phenothiazine derivatives. Borg and Cotzias examined structure-reactivity correlations, formation of free radicals, and the theory of the interaction of trace metals with phenothiazine deriva-

tives (473–475); and photodecomposition of thioproperazine was investigated by Yamamoto and Fujisawa (476). Other investigators have studied reduction products of santonin (477) and some difficultly hydrolyzable flavonosides (478). Ugai prepared codeine phosphate crystals with 0.5, 1, and 1.5 molecules of water of crystallization in stable form (479). Structural modifications in the search for new drugs (480) and the chemistry of thiamine and allied compounds (481) have been reviewed. Campbell (482) and Campbell and Slater (483) reported the alteration of physical properties of some therapeutic agents through the formation of N-cyclohexylsulfamate-drug salts. Several such drug-salts were prepared and evaluated; both taste and stability were good. Correlation of taste and structure of α-D-mannose and β-D-mannose was discussed (484). The chemistry and properties of a new plasma expander were also described (485).

Antibiotics.—Almost 400 references were cited in a review on the chemistry and pharmacology of antibiotics from 1956 to 1961 (486). The chemistry, pharmacy, and pharmacology of pencillin were also reviewed (487, 488). Synthesis of C^{14}-benzylpenicillin for tracer studies from C^{14}-phenylacetic acid and 6-aminopenicillanic acid was described by Nettleton, *et al.* (489). Several tasteless chloramphenicol derivatives have been prepared and evaluated—the best compound appeared to be the dodecylsuccinate (490). Research on properties and chemical purification of nystatin was reported (491).

The tetracycline antibiotics have been the subject of considerable experimental effort. Stempel has reviewed their development (492). Three different papers were concerned with tetracycline production and purification methods (493–495). The isolation and characterization of two new tetracycline antibiotics (496) and a new soluble tetracycline (497) have been reported. Remmers, *et al.*, described a new alkaline-stable species for selected members of the tetracycline family (498). Extensive use of half-life was made in measuring stability of the new derivatives. Demethylchlortetracycline was reviewed by Gill (499).

Ion Exchange.—The applications of ion-exchange resins in cosmetics, medicine, and pharmacy have been reviewed (500, 501). Hirscher and Miller discussed drug release from cation-exchange resins (502), and Schlichting described preparation, assay, and release rates of six new carbinoxamine cation-exchange resin salts (503). An experimental test of the theory of particle-diffusion controlled ion-exchange was reported (504). Bonner, *et al.*, employed measurements of ion-exchange equilibria as a rapid and convenient method for estimation of ionization constants of acids in the 10^{-3} to 10^{-1} range (505). The behavior of ion-exchange resins in aqueous ammonia solutions (506) and the behavior of ascorbic acid on redox ion-exchange resins (507) were studied. Adsorption of vitamin B_{12} by various cation exchangers was discussed by Morita and Tanaka (508). Carboxylic cation-exchange resins were used for the separation and purification of antibiotics (509). Ion-exchange resins have also been employed for the extraction of codeine (510) and the removal of inorganic salts from concentrated streptomycin solutions (511). In another study, ion-exchange resins and electrodialysis were combined for isolation and purification of mixtures of plant alkaloids (512).

Polymers.—In a study of the constitution of alginic acid, Drummond, *et al.*, confirmed the presence of 1,4′-linked L-guluronic acid units (513). Schweiger prepared some algin acetates and studied their viscosity (514) and reaction with calcium and other divalent ions (515). He concluded that gelation or precipitation of alginates with calcium ions occurs through a complex involving two carboxyl groups from neighboring units and two hydroxyl groups in a unit of probably another chain. Another investigator described conditions for the isolation of alginic acid from algae of the Adriatic Sea (516). Equilibrium dialysis studies were used in determining the extent of binding of alkaloids to carrageenan and other hydrocolloids (517).

Studies on the electrochemistry of azrechtic acid were published (518). Murty, *et al.*, studied the physical chemistry of water chestnut starch (519), while Greenwood and Thomson described the fractionation and characterization of starches from various plant origins (520). Complexes of pepsin with sulfates of oxidized starch and its reduced products have been reported (521). Cohen examined the interaction of pharmaceuticals with the Schardinger dextrins (522), and Blatz described the synthesis and preliminary characterization of new polyelectrolytes (523). Thermally stable salts of poly(vinylphthalic acid) were also investigated (524). The interactions between certain chemicals and some water-soluble macromolecules were studied (525, 526).

Methodology.—Paper chromatographic procedures were published for the characterization of antibiotics (527) and the separation of

codeine, morphine, and nalorphine (528). Brochmann-Hanssen and Svendsen described an extremely sensitive method for the separation and identification of barbiturates and some related compounds by means of gas-liquid chromatography (529). Thin-layer chromatography has been used to study the identity and purity of some fats and oils (530) and for separation of some pharmaceutically important corticosteroids (531). The preparation of microcrystalline progesterone using ultrasound was described by Principe and Skauen (532). Methods for the separation of sterols by countercurrent crystallization (533) and the purification of organic compounds by continuous zone freezing (534) have been reported. Automatic pH control of the preparation of medicinal compounds has been investigated (535).

Dosage Variation in Tablets

By E. BROCHMANN-HANSSEN and JORGE C. MEDINA†

Tablet granulations of phenobarbital and reserpine were prepared on a routine manufacturing basis and compressed on a single-punch tablet press. The tablets were collected in small groups in the order of compression, weighed, and analyzed individually. Statistical quality control charts were prepared for weight variation and per cent composition, the main variables affecting the dosage variation. Inspection of the control charts and results obtained by application of the *F*-test indicated that some disruption of uniformity occurred during the compression of the tablets.

THE TOLERANCE LIMITS in the "United States Pharmacopeia" and "National Formulary" are established in such a way as to make allowance for a number of unavoidable variables, including the assay error, the sampling error, and a certain amount of deterioration of the active ingredient (1, 2). In an effort to reduce the sampling error for tablets, the official compendia specify that not less than a stated number of tablets be taken as the sample. Although this number frequently may be as low as 10 or 20, it may run as high as 200 for tablets of certain potent drugs. The result of the assay expresses the average content of active ingredient per tablet in the sample but tells nothing about the uniformity of dosage. There are two obvious sources of variability affecting the drug dosage in tablets—namely, the variation in weight and the variation in per cent composition. The variation in weight has been extensively studied by many investigators (3–5) and can be determined and controlled by the official method or, better, by a method based on the standard deviation. The control chart is a useful tool for controlling the weight variation during production. Composition variation is not as easily determined. Studies carried out in several laboratories have indicated that this variation often is the largest of the two.

Variation in per cent composition is associated with the problems of mixing. Although there is now an appreciable literature on the mixing of solids in general, it is only in recent years that the pharmaceutical aspects of mixing have been studied and their effects on the uniformity of drug dosage and drug standardization have been recognized. In the production of tablets, a perfect mixture represented by a random distribution of the particles can never be attained. Proper equipment and sufficient time of mixing are certainly important considerations, but the mixing process is also affected by the size, shape, proportion, and density of the particles and by various surface-active forces (6, 7). Even if a fairly uniform particle distribution has been achieved, this condition is unstable and is easily disturbed by vibration or bumping (7). In the preparation of uniform tablet granulations, the solubility of the drug in the granulating solvent, and the conditions of drying also play important roles (8).

The various problems associated with the mixing of solids together with the minimum sample required for analysis of tablets have led Train (7) to predict that, although the official specifications may be met under the conditions of the assay, the dosage variation can be over twice the official limits in a few cases, over four times the official assay limits in most cases, and eight or more times the official limits with one or two formulations. This is especially true if the active ingredient is less than half the tablet weight and is added as a powder or a batch of concentrated granules which are mixed with other granular materials.

The effect of the particle size and the proportion of active ingredient on the uniformity of powder mixtures, granulations, and compressed tablets have been studied by Fryklöf (9) and Banker, Christian, and DeKay (8). Commercial samples of various tablet preparations analyzed by the Food and Drug Administration showed a wide range of dosage apparently not related to the weight variation (10). Moskalyk, *et al.* (11), reporting on the uniformity of drug dosage in commercial tablets, have also found

variations in potency which have been greater than those indicated by the weight variation.

Raff, *et al.* (12), have shown that internal flow and segregation of granulation take place during compression, causing a change in the weight and the hardness of the tablets. It is of interest to know to what extent such segregation affects the composition of the tablets. The present investigation was undertaken with this in mind and also for the purpose of studying the relationships between dosage variation and composition variation for tablets containing various concentrations of active ingredient.

EXPERIMENTAL

Tablet Preparations.—Phenobarbital tablets were prepared in three different strengths—16 mg., 65 mg., and 100 mg. per tablet—the drug constituting approx. 10, 33, and 44% of the tablet weight, respectively. A batch of 0.25 mg. reserpine tablets was also included in which reserpine amounted to about 0.175% of the tablet weight. The tablet granulations were prepared according to standard manufacturing procedures by wet granulation of mixtures of the drug and the diluents with aqueous granulating agents. The tablet press was a Colton model 2B single-punch machine operated at a speed of 90–100 tablets per minute. It had been in operation for many years and was worn to the extent of having a somewhat rough action. The batches which ranged in size from 60,000–300,000 tablets were produced on a routine basis in the Pharmaceutical Technology Laboratory for the University Hospital Pharmacy.

Sample Collection.—The hopper was filled, the machine adjusted for correct weight and pressure, and allowed to run for about 0.5 hour. From then on, samples of five tablets each were collected at 30-minute intervals; the tablets were weighed and assayed individually. This was done independently of the checking for weight variation and the normal adjustments made by the manufacturing personnel.

To study the uniformity of the tablet granulations, small samples were collected from the bulk granulation during the course of the tableting process. Amounts approximately equal to the tablet weight were weighed out and analyzed as described below.

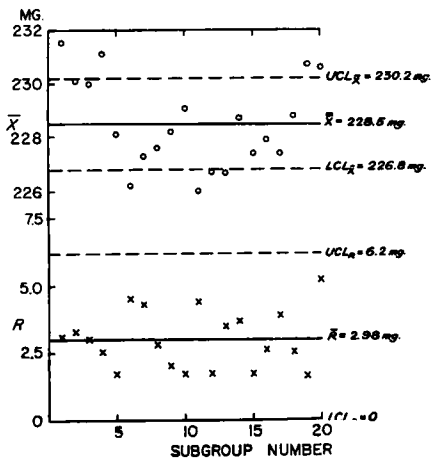

Fig. 1.—Control chart for weight variation of 100-mg. phenobarbital tablets.

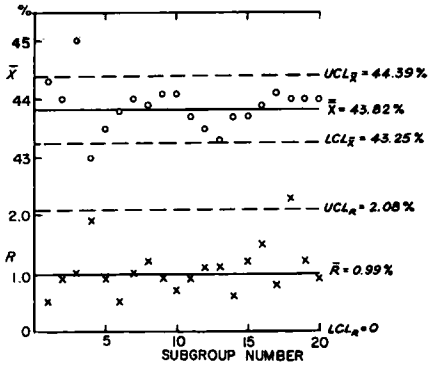

Fig. 2.—Control chart for the variation in per cent composition of 100-mg. phenobarbital tablets.

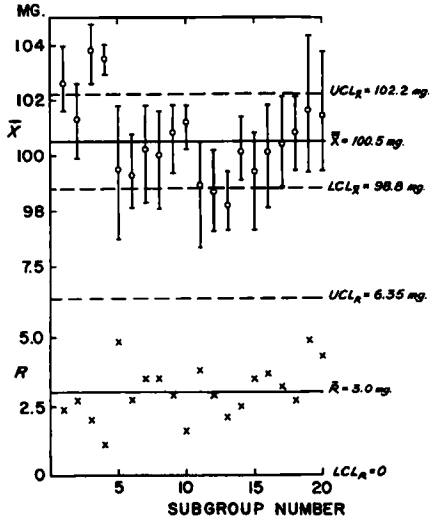

Fig. 3.—Control chart for dosage variation of 100-mg. phenobarbital tablets.

Assay Procedures.—Because of the large number of determinations to be made and the low dosage of some of the tablets, it was essential to have assay procedures which were rapid and sensitive and had a high degree of precision. Individual phenobarbital tablets were placed in 100-ml. volumetric flasks containing 25 ml. of water. After disintegration of the tablets, ethanol (95%) was added to volume. When the drug had dissolved, the solution was thoroughly mixed and filtered through a dry filter; the first 25 ml. of the filtrate was discarded. An aliquot portion of the filtrate was mixed with borate buffer of pH 10, diluted with water to an appropriate concentration, and the absorbance was read in a Beckman model DU spectrophotometer against a reagent blank at 240 mμ. Phenobarbital from the same production batch was used as the reference standard.

Reserpine tablets were also assayed by ultraviolet spectrophotometry. One tablet was placed in a 25-ml. volumetric flask, 2 ml. of water was added, and the tablet was allowed to disintegrate. After

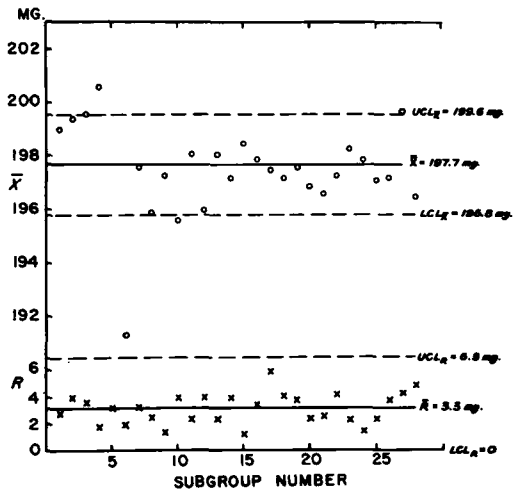

Fig. 4.—Control chart for weight variation of 65-mg. phenobarbital tablets.

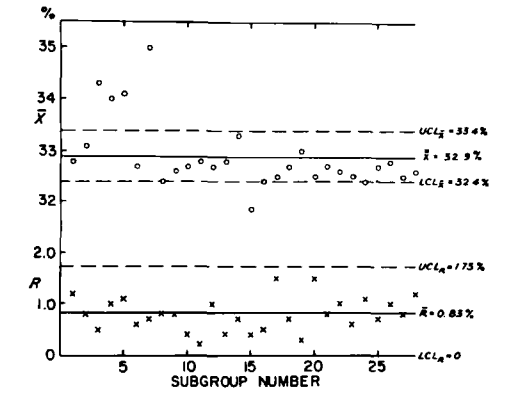

Fig. 5.—Control chart for the per cent composition variation of 65-mg. phenobarbital tablets.

addition of 20 ml. of reagent grade methanol, the mixture was heated gently on a steam bath for 5 minutes and then cooled to room temperature. Methanol was added to volume, the solution mixed well and filtered through a small dry filter; the first 10 ml. of the filtrate was discarded. The absorbance of the filtrate was determined at 268 mμ against a mixture of 2 ml. water and 23 ml. methanol.

Precision.—For the determination of precision, accurately weighed amounts of the reference standards were dissolved and treated in the same manner as the tablets. The standard deviation was calculated on the basis of 15 independent determinations. The coefficient of variation was 0.80% for the phenobarbital assay and 2.5% for the reserpine assay.

Control Charts.—The control chart designed by Shewhart, a commonly used tool for process control, is based on the two types of variables involved in the manufacturing process. One is the random variability associated with short-term variability in the raw material, handling, measurement, etc. The other is the variability due to real changes in the process level. The random variability is estimated on the basis of the variability within small subgroups collected in short periods of operation during which only random errors, but no real changes in process level, are likely to occur. Three-sigma limits are usually drawn about an established standard level. If there is no shift in the process level, 99.73% of the subgroup averages would be expected to fall within these control limits. The commonly used control charts for variables are the $\bar{X}$ and the R charts, showing shifts in the process average and the dispersion, respectively. The statistical methods for preparation and use of the control charts are given in standard texts (13, 14).

RESULTS AND DISCUSSION

Figure 1 illustrates the $\bar{X}$ and R charts for weight variation of 100-mg. phenobarbital tablets. The range shows evidence of control during the whole period of production, whereas the process average does not. This is partly due to the rough action of the tablet machine and segregation of the particles in the granulation. The variation in per cent composition for the same tablets is illustrated in Fig. 2. It is apparent that the system is not in control from a statistical point of view. Instead of being randomly distributed around the batch mean, the process average shows a cycling effect. The two sources of variation are combined in Fig. 3 which gives the actual dosage variation in terms of content of phenobarbital per tablet. The vertical lines in the $\bar{X}$ chart indicate the spread of individual tablets about the subgroup means. None of the 100 tablets analyzed during the compression of this batch deviated more than ±4% from the batch average or more than ±4.5% from the labeled amount.

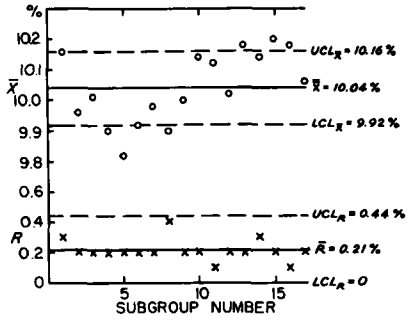

Fig. 6.—Control chart for the per cent composition variation of 16-mg. phenobarbital tablets.

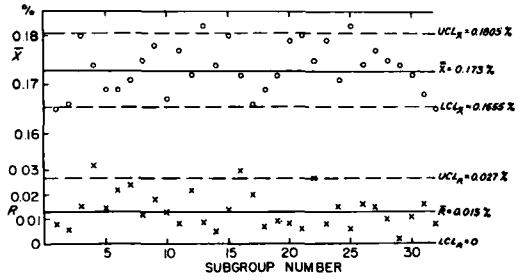

Fig. 7.—Control chart for the per cent composition variation of 0.25-mg. reserpine tablets.

TABLE I.—COEFFICIENTS OF VARIATION FOR TABLET WEIGHT, POTENCY, AND PER CENT COMPOSITION OF FOUR BATCHES OF TABLETS

Tablet Batch	Coefficient of Variation—Tablet Wt.	Dosage	Composition, %
Phenobarbital, 100 mg.	0.87	1.87	1.38 (1.12[a])
Phenobarbital, 65 mg.	1.21	2.84	2.32 (2.17[a])
Phenobarbital, 16 mg.	1.14	2.02	1.44 (1.20[a])
Reserpine, 0.25 mg.	2.01	4.86	4.43 (3.65[a])

[a] This value does not include the assay error.

The control charts for 65-mg. phenobarbital tablets are shown in Figs. 4 and 5.

After subgroup 12 had been collected, the hopper was refilled regularly every 30 minutes when it was about half full. This resulted in much better control of the weight variation (Fig. 4). The tablet composition showed considerable lack of uniformity during the early part of the operation. It improved later, but there was an apparent cycling tendency during the production schedule in the same way as shown in Fig. 2. Of the 140 tablets analyzed from this batch, only ten exceeded the limits of 100 ± 6% of the labeled amount, and all ten tablets came from the first 12 subgroups. Beginning with subgroup 13 no tablet deviated from the labeled amount by more than ±5%.

The per cent composition variation of 16-mg. phenobarbital tablets is illustrated in Fig. 6. Although the composition is not in control in a statistical sense, the variability is still relatively minor. A total of 85 tablets were analyzed from this batch, and no tablet deviated from the labeled amount by more than ±5%.

Figure 7 gives the control charts for the composition variation of 0.25-mg. reserpine tablets. A total of 160 tablets were analyzed individually and only six tablets fell slightly outside the limits of 100 ±10% of the batch average.

A comparison of the coefficients of variation for weight, potency, and per cent composition of the four tablet batches is given in Table I. The apparent variabilities calculated on the basis of the experimental results include the errors of measurement along with the actual variability in the tablets. Although the weighing error is very small and may be ignored in this connection, the assay error is appreciable, particularly for reserpine. In Table I the coefficients of variation in parentheses express the actual variability of the per cent composition (V'), calculated from

$$V'_{\text{compn.}} = \sqrt{V^2_{\text{compn.}} - V^2_{\text{assay}}}$$

The variation in composition was of approximately the same magnitude as the variation in weight in two of the tablet batches. The composition variation was the greatest in the other two batches. As would be expected, there was a tendency for the mixing error to increase as the percentage of the drug in the granulation decreased. This tendency is not always apparent when commercial tablets are studied because greater care is usually exercised in the mixing process when the drug is in low concentration. Generally speaking, the greatest variability in the tablet composition occurred early in the production schedule, after which the process appeared to settle down to a more or less regular cycle. This is not only due to a lack of homogeneity on the part of the granulation, but probably also due to a change in its composition during the compression of the tablets. Samples of granulation collected from the bulk container during the compression schedule gave a variance which by the F-test was significantly smaller than the variance of the tablets ($P = 0.05$). The vibration taking place in the hopper of the tablet press might cause many of the original granules to break up into smaller particles; they would pass through the spaces between the larger particles together with the finely powdered lubricant and disintegrating agents, thus changing the composition.

Banker, Christian, and DeKay (8) have shown that uniformity of a tablet granulation can be improved if a granulating solvent is used in which the drug is soluble. The aqueous granulating agents used for the tablets described in our work are poor solvents for phenobarbital and reserpine. In view of this handicap, the uniformity achieved in the tablet composition appears to be quite satisfactory.

Synthesis of DL-α-(Dihexanoyl-, Dioctanoyl-, and Didecanoyl)-Phosphatidyl DL-Serines

By JONAS MAURUKAS and STEPAS KAIRYS

Condensation of monophenylphosphoryl N-carbobenzyloxy DL-serine benzyl ester monosilver salt with the appropriate α-iodo diglyceride by the procedure of Bevan, Malkin, and Tiplady for the synthesis of racemic α-(distearoyl)-phosphatidyl serine, afforded dihexanoyl-, dioctanoyl-, and didecanoyl-DL-α-glycerylphenylphosphoryl N-carbobenzyloxy DL-serine benzyl esters. These esters, upon removal of the protective phenyl, benzyl, and carbobenzyloxy groups by catalytic hydrogenolysis, gave the short-chain fatty acid, DL-α-phosphatidyl DL-serines. In contrast to α-(distearoyl) phosphatidyl serine, these three phosphatidyl serines easily form an emulsion with water and should prove to be suitable substrates for biological and chemical studies.

SYNTHETIC PROCEDURES are available for the preparation of phosphatidyl serine containing a long-chain fatty acid (1, 2). However, investigation of the biological properties and effects of this compound is hampered by its insolubility in water and by the difficulty with which it forms aqueous emulsions (3). The work presented here describes the synthesis of phosphatidyl serines containing short-chain fatty acids. Such serines can be easily emulsified; therefore, they may be of value in biological investigations.

The synthesis reported in this paper utilizes the monophenylphosphoryl N-carbobenzyloxy DL-serine benzyl ester monosilver salt described by Bevan, Malkin, and Tiplady (2). The use of the monosilver salt eliminates the possibility of the formation of bis-phosphatidic acid which is obtained as a by-product in the method of Baer and Maurukas (1). The procedure shown in the reaction scheme is as follows: N-carbobenzyloxy DL-serine benzyl ester (I) was phosphorylated with phenylphosphoryl dichloride in the presence of anhydrous quinoline and anhydrous ethanol-free chloroform in a −10° bath. The product, consisting of phenylphosphoryl N-carbobenzyloxy DL-serine benzyl ester chloride (II) and bis-(N-carbobenzyloxy DL-serine benzyl ester)-phenyl phosphate (III), was caused to react further with potassium carbonate in water and pyridine to yield phenylphosphoryl N-carbobenzyloxy DL-serine benzyl ester monopotassium salt (IV). The potassium salt was converted into the monosilver salt V and purified by crystallization from boiling 95% ethanol. Condensation of DL-α-iodo diacylglycerol (VI) with phenylphosphoryl N-carbobenzyloxy DL-serine benzyl ester monosilver salt (V) in boiling xylene yielded diacyl-DL-α-glycerylphenylphosphoryl N-carbobenzyloxy DL-serine benzyl ester (VII). Hydrogenolysis in the presence of mixed platinum and palladium catalyst yielded phosphatidyl serines VIII in overall yields of 57–62%. This procedure should also prove suitable for the synthesis of both enantiomeric forms of the phosphatidyl serines.

EXPERIMENTAL

DL-α-(Dihexanoyl)-phosphatidyl DL-Serine

Condensation.—Five Gm. (8.46 mmoles) of phenylphosphoryl N-carbobenzyloxy DL-serine benzyl ester monosilver salt (2), 85 ml. of boiling anhydrous xylene, and 2.70 Gm. (6.78 mmoles) of DL-α-iodo dihexanoylglycerol[1] were placed in a 200-ml. two-necked round-bottom flask equipped with a reflux condenser and mechanical stirrer. The mixture was stirred and refluxed in the dark for 15 minutes with the exclusion of moisture. After a short cooling period under running tap water, the mixture was centrifuged to remove silver iodide, and the clear yellowish supernatant was evaporated under reduced pressure at a water bath temperature of 35–40°. The resulting oil (6.5 Gm.) was dissolved in 150 ml. of ether and washed successively with saturated sodium bicarbonate solution and water until the water was neutral to litmus. After drying over anhydrous sodium sulfate, the ethereal solution was evaporated to dryness under reduced pressure at a bath temperature not exceeding 40°. The residue was suspended in 40 ml. of warm petroleum ether, refrigerated for 1 hour at 0°, and separated from the supernatant petroleum ether by centrifugation. The residue was dried *in vacuo* (0.025 mm.) to constant weight. The dihexanoyl-DL-α-glycerylphenylphosphoryl N-carbobenzyloxy DL-serine benzyl ester, a viscous oil, weighed 4.0 Gm. (78.0% of theory). At room temperature this compound was highly soluble in ether, acetone, methanol, ethanol, ethyl acetate, and acetic acid, but insoluble in petroleum ether and water. For analysis, 0.5 Gm. of this product was further purified by dissolving in 5 ml. of chloroform

[1] The three required α-iodo diglycerides containing hexanoic, octanoic, and decanoic acids have not been described in the literature. They were prepared from racemic α-iodo glycerol (4) *via* acetone glycerol (5) and esterified with the appropriate fatty acid chloride as described for the preparation of α-benzyl ether didecanoyl glycerol (6).

and passing it through a chromatographic column (20 × 380 mm.) containing a mixture of 20 Gm. of silicic acid (Merck) and 10 Gm. of Celite (Johns-Manville).[2] The substance was eluted with 200 ml. of chloroform; the solvent evaporated to dryness at reduced pressure and at a water bath temperature not exceeding 40°. The recovery of dihexanoyl-DL-α-glycerylphenylphosphoryl N-carbobenzyloxy DL-serine benzyl ester was 0.46 Gm., N_D^{25} 1.5158.

Anal.—Calcd. for $C_{39}H_{50}NO_{12}P$ (755.78): C, 61.97; H, 6.67; N, 1.85; P, 4.10. Found: C, 61.20; H, 6.50; N, 1.76; P, 4.08.

Catalytic Hydrogenolysis.—A solution of 4.0 Gm. of dihexanoyl-DL-α-glycerylphenylphosphoryl N-carbobenzyloxy DL-serine benzyl ester in 75 ml. of glacial acetic acid with 3 Gm. of platinum oxide-palladium black catalyst (1 : 1) (7, 8) was placed in an all-glass hydrogenation vessel of 200-ml. capacity. The mixture was shaken vigorously in an atmosphere of pure hydrogen at an initial pressure of 40 cm. of water until the absorption of hydrogen ceased. One liter was consumed in approximately 2 hours. Hydrogen was replaced by nitrogen, an additional gram of mixed catalyst was added, and hydrogenation was continued until absorption ceased. Approximately 0.8 L. of hydrogen was consumed in 1 hour. Hydrogen was again replaced by nitrogen. The catalyst was removed by centrifugation and washed with a small amount of glacial acetic acid. The supernatant solutions were combined, and the acetic acid was removed by distillation under reduced pressure at a bath temperature of 35–40°. To complete the removal of traces of acetic acid, the substance was dissolved in 25 ml. of ether, the solution was diluted with 100 ml. of petroleum ether, and placed in a refrigerator at 0°. After 1 hour the crystalline material was centrifuged, washed with a small volume of ice-cold petroleum ether, and dried to constant weight *in vacuo* (0.025 mm.) over sodium hydroxide. The DL-α-(dihexanoyl)-phosphatidyl DL-serine weighed 1.93 Gm. (80% of theory); overall yield based on α-iodo diglyceride, 62.5%; m.p. 100°.[3] This waxy substance at room temperature is highly soluble in ether, chloroform, acetone, methanol, ethanol, ethyl acetate, and acetic acid, but insoluble in petroleum ether. It readily forms an emulsion in water.

Anal.—Calcd. for $C_{18}H_{34}NO_{10}P$ (455.44): C, 47.46; H, 7.53; N, 3.07; P, 6.80. $C_{18}H_{34}NO_{10}P$. Found: C, 47.29; H, 7.47; N, 3.02; P, 6.77.

DL-α-(Dioctanoyl)-phosphatidyl DL-Serine

DL-α-(dioctanoyl)-phosphatidyl DL-serine was prepared as described for the C_6 *homolog*. The condensation of 10.2 Gm. (17.3 mmoles) of phenylphosphoryl N-carbobenzyloxy DL-serine benzyl ester

[2] The mixture of silicic acid and Celite was washed successively with methanol and chloroform before placing it on the column.

[3] Melting points reported in this work were determined on the Fisher-Johns melting point apparatus.

monosilver salt with 6.2 Gm. (13.2 mmoles) of DL-α-iodo dioctanoylglycerol in 170 ml. of boiling dry xylene yielded 9.1 Gm. (82% of theory) of dioctanoyl-DL-α-glycerylphenylphosphoryl N-carbobenzyloxy DL-serine benzyl ester. This viscous oil at room temperature is highly soluble in acetone, methanol, ethanol, ethyl acetate, chloroform, ether, petroleum ether, and acetic acid, and is insoluble in water.

For analysis, 0.5 Gm. of substance was placed on a chromatographic column described for the C_6 *homolog* and was eluted with 210 ml. of chloroform. The recovery of analytically pure dioctanoyl-DL-α-glycerylphenylphosphoryl N-carbobenzyloxy DL-serine benzyl ester was 0.47 Gm.; N_D^{25} 1.5058.

Anal.—Calcd. for $C_{43}H_{58}NO_{12}P$ (811.88): C, 63.61; H, 7.20; N, 1.73; P, 3.82. Found: C, 63.51; H, 7.41; N, 1.71; P, 3.76.

The hydrogenolysis of 9.1 Gm. of dioctanoyl DL-α-glycerylphenylphosphoryl N-carbobenzyloxy benzyl DL-serine ester yielded 6.07 Gm. of crude phosphatidyl serine. This oil (containing traces of acetic acid) was dissolved in 116 ml. of warm ether and was precipitated with 350 ml. of petroleum ether. After 16 hours of refrigeration at −12°, the precipitate was centrifuged, washed with ice-cold petroleum ether, and dried *in vacuo* (0.025 mm.) over sodium hydroxide. The dioctanoyl-DL-glycerylphosphoryl DL-serine (weighing 4.0 Gm.) was obtained in a yield of 69.5% of theory (overall yield 57.0%), m.p. 160–161°. At room temperature this phosphatidyl serine was very soluble in chloroform, acetone, methanol, ethanol, ethyl acetate, acetic acid, and benzene, but insoluble in ether and petroleum ether. It readily formed an emulsion in water.

Anal.—Calcd. for $C_{22}H_{42}NO_{10}P$ (511.55); C, 51.85; H, 8.28; N, 2.74; P, 6.06. Found: C, 51.68; H, 8.36; N, 2.73; P, 6.02.

DL-α-(Didecanoyl)-phosphatidyl DL-Serine

DL-α-(didecanoyl)-phosphatidyl DL-serine was prepared as described for the C_6 *homolog*. The condensation of 10.0 Gm. (16.9 mmoles) of phenylphosphoryl N-carbobenzyloxy DL-serine benzyl ester monosilver salt with 7.0 Gm. (13.6 mmoles) of α-iodo didecanoylglycerol in 170 ml. of boiling dry xylene gave 9.5 Gm. (80% of theory) of didecanoyl-DL-α-glycerylphenylphosphoryl N-carbobenzyloxy DL-serine benzyl ester. At room temperature it was readily soluble in acetone, methanol, ethanol, ethyl acetate, chloroform, ether, petroleum ether, and acetic acid, but insoluble in water. For analysis, 0.5 Gm. was passed through a silicic acid chromatographic column as described for the C_6 *homolog*. The recovered substance weighed 0.44 Gm.; N_D^{25} 1.5030.

Anal.—Calcd. for $C_{47}H_{66}O_{12}NP$ (867.99): C, 65.03; H, 7.67; P, 3.57; N, 1.61. Found: C, 64.51; H, 7.57; P, 3.52; N, 1.56.

The catalytic hydrogenolysis of 9.5 Gm. of didecanoyl-DL-α-glycerylphenylphosphoryl N-carbobenzyloxy-DL-serine benzyl ester yielded 5.0 Gm. of a glass-like phosphatidyl serine. This product (containing trace amounts of acetic acid) was dissolved in 115 ml. of petroleum ether and was evaporated to dryness. The amorphous residue was recrystallized from 47 ml. of absolute ethanol by immersion in an acetone dry ice bath at −40°, centrifuged, washed several times with cold ethanol, and dried *in vacuo* over sodium hydroxide. The final product, DL-α-(didecanoyl)-phosphatidyl DL-serine, weighed 4.72 Gm. (85.5% of theory). The overall yield based on α-iodo diglyceride was 59%; m.p. 164–165°. At room temperature this waxy substance was highly soluble in chloroform, absolute ethanol, ethyl acetate, acetic acid, and benzene, moderately soluble in methanol, and insoluble in acetone, ether, and petroleum ether. It readily formed an emulsion in water.

Anal.—Calcd. for $C_{26}H_{50}NO_{10}P$ (576.65): C, 55.01; H, 8.88; N, 2.47; P, 5.46. Found: C, 55.19; H, 8.75; N, 2.46; P, 5.43.

Determination of the Oil/Water Distribution Coefficients of Glyceryl Trinitrate and Two Similar Nitrate Esters

By FREDERICK K. BELL, JOHN J. O'NEILL, and RAYMOND M. BURGISON

The oil/water distribution coefficients of glyceryl trinitrate, chloroglyceryl dinitrate (1-chloro-2,3-propanediol dinitrate), and ethylglyceryl trinitrate (1,2,3-pentanetriol trinitrate) are determined. The analytical method employed (described in detail) is based on the reduction of a portion of the nitrate of each ester to the nitrite upon alkaline hydrolysis. This was determined by diazotization of sulfanilic acid and subsequent coupling with N-(1-naphthyl)-ethylenediamine and measuring the color spectrophotometrically.

In connection with certain pharmacologic studies being conducted in this laboratory, information was desired concerning the oil/water distribution coefficient of glyceryl trinitrate and two closely related compounds of similar structure, *viz.*, chloroglyceryl dinitrate (1-chloro-2,3-propanediol dinitrate) and ethylglyceryl trinitrate (1,2,3-pentanetriol trinitrate). Since the water solubility of these substances is very low, the problem was to develop a method of estimation applicable to dilute aqueous solutions.

Under similar conditions, numerous workers have employed (in various modifications) the well known procedure of alkaline hydrolysis of glyceryl trinitrate resulting in the formation of nitrite which can be determined spectrophotometrically with a high degree of sensitivity through the customary diazotization and coupling procedure. We found this general method of analysis for glyceryl trinitrate, used successfully by Frauch and Burgin (1), applicable to the other two nitrate esters. This communication describes the method we have developed and its application to the determination of the desired oil/water distribution coefficients.

EXPERIMENTAL

Materials.—The three nitrate esters used for study were prepared in this laboratory.

1-Chloro-2,3-propanediol dinitrate was prepared according to the method of Henry (2). It assayed 99.2%.

Glyceryl trinitrate was prepared by nitration of C.P. glycerin with mixed sulfuric-nitric acids (3). It was purified by repeated washings with water and very dilute sodium bicarbonate solution to remove soluble impurities and traces of nitration acids, then dried over anhydrous sodium sulfate. It assayed 99.0%.

1,2,3-Pentanetriol trinitrate was obtained by the nitration of 1,2,3-pentanetriol ("ethyl glycerine") with a mixture of equal volumes of red fuming nitric (d. 1.60) and concentrated sulfuric acid at −10 to 0°. One-hundred and fifty milliliters of mixed acid was used to nitrate 20 ml. of the triol. The crude nitrate, obtained as a blue oil upon pouring the nitration mixture into 1 L. of finely crushed ice, was purified by repeated washings with 500-ml. portions of ice water until the oil was almost colorless and the washings nearly neutral. The purified oil was dried over anhydrous sodium sulfate. Yield: 8.6 Gm. d_{20}^{20} 1.4377, nD^{20} 1.4570. It is miscible with alcohol and acetone in all proportions and very slightly soluble in water. Analyses, adapting the U.S.P. XV–Devarda's alloy reduction procedure for glyceryl trinitrate, indicated a purity of 101.5%.

Reagents and Apparatus.—Wherever possible reagent grade chemicals were used. The following aqueous solutions are required: sodium hydroxide (2 *N*), hydrochloric acid (4 *N*), sulfanilic acid (2 mg./ml.), and N-(1-naphthyl)-ethylenediamine dihydrochloride (1 mg./ml.). This latter solution was found to be sufficiently stable over a period of some weeks when stored in an amber glass bottle. The oil used for the distribution experiments was Wesson corn oil.

The complete reaction, including hydrolysis and subsequent diazotization, was carried out conveniently in 15-ml. graduated glass-stoppered Pyrex centrifuge tubes. The colorimetric determinations were made with a Beckman model DU spectrophotometer using absorption cells having a light path of 1 cm. An efficient shaking device is required which can be regulated to avoid the formation of stubborn oil/water emulsions.

Procedure.—Standard solutions of each of the three esters, which are required for the establishment of standard curves, were prepared in the following manner: approximately 50 mg. of the nitrate ester was accurately weighed into a 50-ml. volumetric flask. One milliliter of absolute methanol was added and thoroughly mixed with the ester. Forty milliliters of warm water was added, immediately followed by vigorous shaking until the solution was complete. After cooling to room temperature, water was added to the mark followed by thorough mixing. These standard solutions were diluted quantitatively for use. A concentration of 5 mcg./ml. is satisfactory.

Triplicate aliquots of this diluted standard of 0.5, 1.0, 1.5, 2.0, and 2.5 ml. were transferred to the graduated centrifuge tubes; water was added to the

Accepted for publication December 6, 1962.

4-ml. mark. Three tubes containing 4 ml. of water served as controls. After the addition of 1 ml. of 2 *N* sodium hydroxide, mixing was accomplished by the inversion of the glass-stoppered tube. After the removal of the stoppers, the tubes were placed in a boiling water bath. It is important at this step to employ a rack of sufficient size to hold all the tubes of a given experiment so that they can be immersed in the boiling water and removed simultaneously. After a period of 10 minutes in the boiling water, the tubes are removed and (after cooling to room temperature) the contents of each tube were treated with the following reagents, respectively, (with mixing after each addition by inversion of the glass-stoppered tube): (*a*) 1 ml. 4 *N* hydrochloric acid, (*b*) 1 ml. sulfanilic acid solution, (*c*) 1 ml. N-(1-naphthyl)-ethylenediamine solution plus water to the 10-ml. mark. After standing 10 minutes, the absorbance of the solution in each tube was measured at 548 mμ with a slit width of approximately 0.03 mm. Distilled water was used as the reference standard. The corrected triplicate absorbance values were averaged and plotted against the concentration. Typical standard recovery curves for the three esters are shown in Fig. 1. A linear relation is apparent for each ester and the reproducibility was satisfactory.

For the determination of the oil/water distribution coefficients, the following procedure was carried out for each of the nitrate esters: approximately 25 ml. of corn oil was transferred to a tared 250-ml. glass-stoppered Erlenmeyer flask and accurately weighed. A second accurate weighing was made after the addition of a suitable amount of the ester (0.1 to 0.3 Gm.). After gentle rotation of the flask for some seconds, exactly 25 ml. of distilled water was added. A similar flask containing 25 ml. of corn oil and 25 ml. of distilled water served as a control. The flasks were stoppered and shaken for 1 hour at room temperature. A good separation of the two phases was obtained after standing 15 minutes. Then a portion of the aqueous layer was removed and passed through No. 2 Whatman filter paper. Aliquots of 0.1 or 0.2 ml. of these filtrates were then analyzed by the same procedure employed for the preparation of the standard curves. A summary of the analytical data is shown in Table I. The final values obtained for the oil/water distribution coefficients are: 109 ± 3 for glyceryl trinitrate, 146 ± 3 for chloroglyceryl dinitrate, and 97 ± 2 for ethylglyceryl trinitrate.

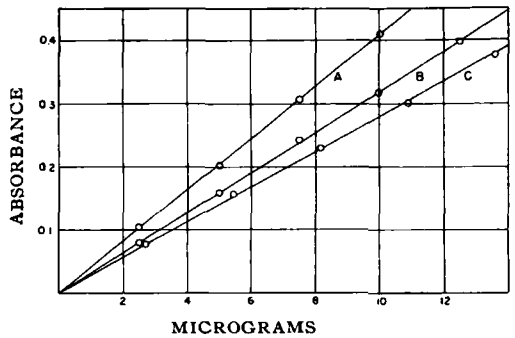

Fig. 1.—Typical standard recovery curves for the three esters: A, glyceryl trinitrate; B, chloroglyceryl dinitrate; C, ethylglyceryl trinitrate.

TABLE I.—SUMMARY OF EXPERIMENTAL DATA FOR THE DETERMINATION OF OIL/WATER DISTRIBUTION COEFFICIENTS

DISCUSSION

According to Hay (4), the saponification of glyceryl trinitrate is represented by

$$C_3H_5(ONO_2)_3 + 5\ KOH = KNO_3 + 2\ KNO_2 + HCOOK + CH_3COOK + 3\ H_2O$$

indicating a stoichiometry of reaction not supported by analytical data. According to Frauch and Burgin (1) the ratio of 2 moles of nitrite per mole of ester is usually lower and varies with the experimental conditions. The decomposition of nitrate esters is undoubtedly more complex, involving competition between hydrolytic reactions yielding nitrate, and internal oxidation-reduction (5) accounting for the formation of reduction products (nitrite and hydroxylamine) (6) and various oxidation products indicated in Hay's equation.

In this connection we have replotted the curves from Fig. 1 on a molar basis (as shown in Fig. 2) and have included for comparison a standard curve for sodium nitrite prepared from a standard solution of a reagent grade of this salt. It may be seen that the base catalyzed reaction of glyceryl trinitrate by

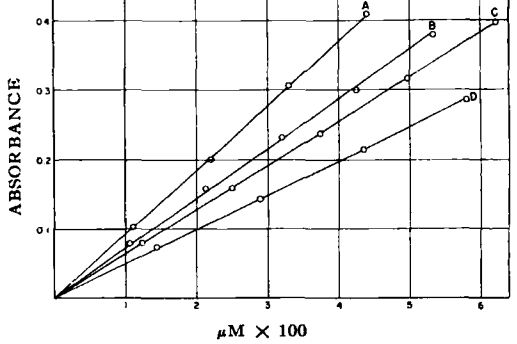

Fig. 2.—Typical standard recovery curves plotted on a molar basis: A, glyceryl trinitrate; B, ethylglyceryl trinitrate; C, chloroglyceryl dinitrate; D, sodium nitrite.

our procedure yields a nitrite:ester ratio appreciably lower than the value predicted by Hay.

If we apply the same general considerations to reactions involving the chloroglyceryl dinitrate and ethylglyceryl trinitrate and calculate ratios, we obtain an appreciably lower value in nitrite yield in the case of ethylglyceryl trinitrate. This suggests that the presence of an ethyl group has increased the stability of the molecule to oxidation-reduction or has favored reactions not resulting in nitrite formation. In the case of chloroglyceryl dinitrate having no nitrate group on carbon-1, an even higher degree of stability is indicated.

It appears that in each of the three nitrate esters one nitrate group is readily reduced and a second nitrate is reduced more slowly (or less completely). In spite of this apparent lack of stoichiometry, the highly consistent results obtained from repeated trials indicate that with reasonable care in the control of experimental conditions employing standard recovery curves, a satisfactory analytical procedure can be devised.

Investigation of the Stereochemistry of Cycloheximide and Its Degradation Products

By HOWARD J. SCHAEFFER and VIJAY K. JAIN

Cycloheximide tosylate has been shown to undergo elimination of *p*-toluenesulfonic acid to give a new anhydrocycloheximide. By a series of reactions this new anhydrocycloheximide has been converted into a dideoxycycloheximide which was shown to be optically inactive. This observation establishes the cis-orientation of the methyl groups in the new dideoxycycloheximide. The series of reactions employed and the stereochemistry of the products obtained are discussed.

THE DETERMINATION of the stereochemistry of the glutarimide antibiotics has been under investigation recently in a number of laboratories (1–4, 7). On the basis of these studies, it has been demonstrated both by chemical degradation (7) and by thermal degradation (1) that the two methyl groups in cycloheximide are oriented in a *trans* manner. We have now observed certain other degradative and isomerization reactions on cycloheximide which bear on its stereochemistry.

Treatment of cycloheximide (I) with *p*-toluenesulfonyl chloride in pyridine gave a good yield of the corresponding tosylate (II). When an attempt was made to displace the tosylate group in II with iodide ion using acetone as the solvent, only unchanged starting material was recovered. Therefore, II was treated with sodium iodide in dimethylformamide; the product isolated from this reaction was not the corresponding iodide, but rather an iodine-free compound which exhibited ultraviolet absorption at 235 mμ (ϵ, 9480). On the basis of its elemental analysis, infrared and ultraviolet spectra, and its further reactions, this compound has been shown to be *epi*-anhydrocycloheximide (III).[1] Subsequently, it was learned that this interesting elimination and rearrangement reaction occurred merely by heating II in dimethylformamide. However, if the reaction is carried out in the presence of one equivalent of sodium bicarbonate, elimination of *p*-toluenesulfonic acid occurs with the formation of anhydrocycloheximide (IV)—identical with anhydrocycloheximide prepared by known procedures (5).

Catalytic hydrogenation of *epi*-anhydrocycloheximide (III) with a palladium-on-charcoal catalyst gave *epi*-deoxycycloheximide (V) which upon further hydrogenation with a platinum catalyst gave *epi*-dihydrodeoxycycloheximide (VI). Compound VI could also be prepared by the direct hydrogenation of III with a platinum catalyst. When VI was allowed to react with phosphorus tribromide in dioxane solution, the corresponding bromo compound VII was obtained which after reaction with zinc and acetic acid

Investigation of the Stereochemistry of Cycloheximide and Its Degradation Products

By HOWARD J. SCHAEFFER and VIJAY K. JAIN

Cycloheximide tosylate has been shown to undergo elimination of *p*-toluenesulfonic acid to give a new anhydrocycloheximide. By a series of reactions this new anhydrocycloheximide has been converted into a dideoxycycloheximide which was shown to be optically inactive. This observation establishes the cis-orientation of the methyl groups in the new dideoxycycloheximide. The series of reactions employed and the stereochemistry of the products obtained are discussed.

THE DETERMINATION of the stereochemistry of the glutarimide antibiotics has been under investigation recently in a number of laboratories (1–4, 7). On the basis of these studies, it has been demonstrated both by chemical degradation (7) and by thermal degradation (1) that the two methyl groups in cycloheximide are oriented in a *trans* manner. We have now observed certain other degradative and isomerization reactions on cycloheximide which bear on its stereochemistry.

Treatment of cycloheximide (I) with *p*-toluenesulfonyl chloride in pyridine gave a good yield of the corresponding tosylate (II). When an attempt was made to displace the tosylate group in II with iodide ion using acetone as the solvent, only unchanged starting material was recovered. Therefore, II was treated with sodium iodide in dimethylformamide; the product isolated from this reaction was not the corresponding iodide, but rather an iodine-free compound which exhibited ultraviolet absorption at 235 mμ (ϵ, 9480). On the basis of its elemental analysis, infrared and ultraviolet spectra, and its further reactions, this compound has been shown to be *epi*-anhydrocycloheximide (III).[1] Subsequently, it was learned that this interesting elimination and rearrangement reaction occurred merely by heating II in dimethylformamide. However, if the reaction is carried out in the presence of one equivalent of sodium bicarbonate, elimination of *p*-toluenesulfonic acid occurs with the formation of anhydrocycloheximide (IV)—identical with anhydrocycloheximide prepared by known procedures (5).

Catalytic hydrogenation of *epi*-anhydrocycloheximide (III) with a palladium-on-charcoal catalyst gave *epi*-deoxycycloheximide (V) which upon further hydrogenation with a platinum catalyst gave *epi*-dihydrodeoxycycloheximide (VI). Compound VI could also be prepared by the direct hydrogenation of III with a platinum catalyst. When VI was allowed to react with phosphorus tribromide in dioxane solution, the corresponding bromo compound VII was obtained which after reaction with zinc and acetic acid

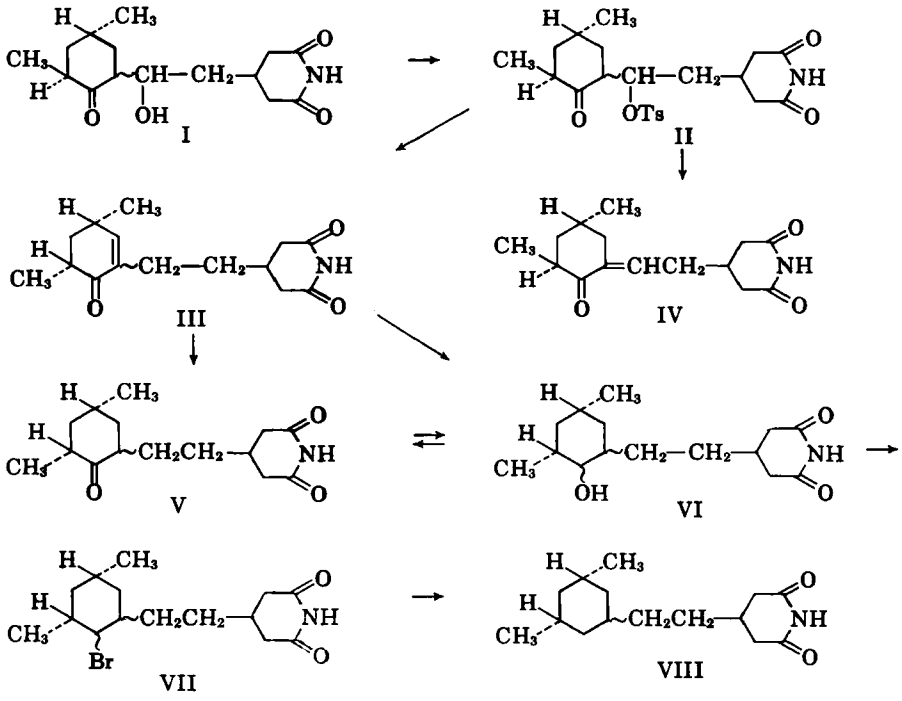
[1] In order to distinguish the degradation products which we have prepared in this research from the degradation products which have previously been prepared (5, 7), we have used the prefix *epi* for our new compounds. In each case, the *epi* compounds have been shown to be different from the previously prepared degradation products by comparing the infrared and ultraviolet spectra, melting points and mixture melting points, and by thin-layer chromatography.



gave *epi*-dideoxycycloheximide (VIII). An attempt to determine the optical activity of VIII revealed that it was optically inactive. This observation establishes that the methyl groups in VIII are *cis* since only the *cis*-compound possesses a plane of symmetry and therefore must be optically inactive.

Since it is known that the methyl groups in I (1, 7), and therefore in II, are *trans*, it is now apparent that during the preparation of III from II—in addition to the rearrangement of the double bond from *exo* to *endo*—an isomerization of the methyl group alpha to the ketone occurred to give the thermodynamically stable *cis* isomer. When III is hydrogenated with a palladium-on-charcoal catalyst, a new *epi*-deoxycycloheximide (V) is obtained. Hydrogenation of V with a platinum catalyst gave a new *epi*-dihydrodeoxycycloheximide (VI). Oxidation of VI with chromium trioxide in glacial acetic acid gave a good yield of V. An attempted isomerization of V with *p*-toluenesulfonic acid in dimethylformamide resulted in the recovery (in good yield) of unchanged starting material. Therefore, these results make it improbable that isomerization occurred during the hydrogenation of III. Since it is difficult to visualize an isomerization occurring in subsequent reactions, the assignment of the *cis*-methyl groups in III, V, VI, and VII is most probably justified.

By a series of reactions similar to those used in this work, anhydrocycloheximide (IV) was converted into a dideoxycycloheximide which was optically active (7). The observation that the dideoxycycloheximide was optically active established that the methyl groups were *trans;* therefore the methyl groups in cycloheximide (I) were also *trans*. Because the compounds obtained in this investigation are stereoisomeric with the compounds obtained in the previous series, we believe that our assignment of the *trans* configuration of methyl groups in the previous series is supported by the present work.

EXPERIMENTAL[2]

Cycloheximide Tosylate (II).—A solution of cycloheximide (3.96 Gm., 14.1 mmoles) in pyridine (15 ml.) was cooled in an ice bath for 30 minutes and *p*-toluenesulfonyl chloride (2.86 Gm., 15.4 mmoles) was added. The reaction mixture was allowed to stand overnight at room temperature and then was poured onto ice. After the ice had melted, the crystals were collected by filtration, washed with water, and then dried *in vacuo* at room temperature. Yield, 4.45 Gm. (71.7%) of cycloheximide tosylate, m.p. 115°. $\bar{\nu}$ in cm.$^{-1}$ (KBr): 3200 and 3100 (NH), 1710 and 1700 (C = 0), 1600 (phenyl). One recrystallization of the crude material from benzene gave the analytical sample, m.p. 114°. The compound decomposed on standing at room temperature. This compound has recently been prepared by Okuda, who reported a m.p. of 100.5 to 101.5° (6).

[2] The infrared spectra were determined on a Perkin-Elmer model 137 spectrophotometer; the ultraviolet spectra were determined on a Perkin-Elmer model 4000A spectrophotometer. The melting points were determined on a Kofler Heizbank and are corrected.

Anal.[3]—Calcd. for $C_{22}H_{29}NO_6S$: C, 60.66; H, 6.71; N, 3.21; S, 7.36. Found: C, 60.19; H, 6.34; N, 3.13; S, 6.90.

***epi*-Anhydrocycloheximide (III).**—A solution of cycloheximide tosylate (3.6 Gm., 8.4 mmoles) in 12 ml. dimethylformamide was heated under reflux for 40 minutes. The reaction mixture was allowed to cool to room temperature and then poured onto ice. After the ice had melted, the crystals were collected by filtration, and washed with water. Yield, 1.3 Gm. (59%) of *epi*-anhydrocycloheximide, m.p. 83–84°. On recrystallization from ethanol and water, the crude material gave the analytical sample, m.p. 85–86°. $\lambda_{max.}^{EtOH}$ ($\epsilon \times 10^{-3}$) 235 mμ (9.48), $\bar{\nu}$ in cm.$^{-1}$ (KBr): 3200 and 3100 (NH), 1740 and 1690 (C = 0).

Anal.—Calcd. for $C_{15}H_{21}NO_3$: C, 68.41; H, 8.04; N, 5.32; Found: C, 67.96; H, 7.91; N, 5.38.

Anhydrocycloheximide (IV).—A mixture of cycloheximide tosylate (1.0 Gm., 2.3 mmoles) and sodium bicarbonate (0.4 Gm., 4.6 mmoles) in dimethylformamide (15 ml.) was heated under reflux for 20 minutes. The reaction mixture was allowed to cool to room temperature and then poured onto ice. After the ice had melted, the crystals were collected by filtration and washed with water. Yield, 0.36 Gm. (60%) of anhydrocycloheximide, m.p. 125–127°. On recrystallization from benzene and hexane, the crude material gave the pure sample, m.p. 132–134°; mixed m.p. with authentic sample of anhydrocycloheximide 130 to 133.5° (5). $\lambda_{max.}^{EtOH}$ 240 mμ (ϵ = 8140); $\bar{\nu}$ in cm.$^{-1}$ (KBr): 3200 and 3100 (NH), 1710 and 1690 (C = 0), 1610 (C = C).

***epi*-Deoxycycloheximide (V).**—A solution of 0.20 Gm. (0.76 mmole) of *epi*-anhydrocycloheximide in 200 ml. of absolute alcohol was added to 150 mg. of 5% palladium-on-charcoal catalyst which had been wetted with a few drops of water. The mixture was hydrogenated at room temperature and at an initial pressure of 40.7 p.s.i. until no more hydrogen was absorbed. The solution was filtered, and the solvent was removed *in vacuo*. The residue was crystallized from ethanol and water and gave 0.13 Gm. (65%) of *epi*-deoxycycloheximide, m.p. 151–152°. Two recrystallizations of the crude product from ethanol and water gave the analytical sample, m.p. 151–152°. $\bar{\nu}$ in cm.$^{-1}$ (KBr): 3100 and 3200 (NH), 1690, 1700, and 1730 (C = 0). $[\alpha]_D^{24}$ = −4.1 (c = 4.8 $CHCl_3$).

Anal.—Calcd. for $C_{15}H_{23}NO_3$: C, 67.89; H, 8.74; N, 5.27. Found: C, 67.93; H, 8.63; N, 5.34.

***epi*-Dihydrodeoxycycloheximide (VI).**—A solution of 7.39 Gm. (28.0 mmoles) of *epi*-anhydrocycloheximide in 200 ml. of glacial acetic acid was added to a pre-reduced platinum dioxide catalyst (1.50 Gm.). The mixture was hydrogenated at room temperature at 59.8 p.s.i. Reduction was complete after 55.2 mmoles of hydrogen had been absorbed. After filtration, the solvent was removed *in vacuo*, and the semisolid residue on crystallization from benzene and hexane gave 2.22 Gm. (29.6%) of *epi*-dihydrodeoxycycloheximide, m.p. 137–138°. Two recrystallizations from methanol and water gave the analytical sample, m.p. 140–141°. $\bar{\nu}$ in cm.$^{-1}$ (KBr): 3500 (OH), 3240 and 3110 (NH), 1690 and 1710 (C = 0). $[\alpha]_D^{23}$ = −0.309 (c = 3.2 acetone).

Anal.—Calcd. for $C_{15}H_{25}NO_3$: C, 67.38; H, 9.42; N, 5.24. Found: C, 67.16; H, 9.54; N, 5.15.

Hydrogenation of *epi*-Deoxycycloheximide.—A solution of 0.21 Gm. (0.80 mmole) of *epi*-deoxycycloheximide in 200 ml. glacial acetic acid was added to 75 mg. of pre-reduced platinum dioxide catalyst. The mixture was hydrogenated at room temperature until the absorption of hydrogen stopped. After filtration, the solvent was removed *in vacuo*, and the semisolid residue on crystallization from methanol and water gave 0.15 Gm. (71.3%) of *epi*-dihydrodeoxycycloheximide, m.p. 140.5 to 142°, mixed m.p. with an authentic sample of *epi*-dihydrodeoxycycloheximide 140.5–141.5°. $\bar{\nu}$ in cm.$^{-1}$ (KBr): 3500 (OH); 3200 and 3100 (NH), 1690 and 1710 (C = 0).

Dihydrodeoxycycloheximide Bromide (VII).—A solution of *epi*-dihydrodeoxycycloheximide (0.28 Gm., 1.1 mmole) in *p*-dioxane (5 ml.) was cooled in an ice bath for 15 minutes; a solution of phosphorus tribromide in *p*-dioxane (5 ml.) was added. The reaction mixture was allowed to stand overnight at room temperature and then concentrated *in vacuo*. The colorless residue after crystallization from benzene and hexane gave 0.10 Gm. (27%) of *epi*-dihydrodeoxycycloheximide bromide, m.p. 142–144°. On recrystallization from benzene and hexane, the crude material gave the analytical sample, m.p. 151 to 151.5°. $\bar{\nu}$ in cm.$^{-1}$ (KBr): 3100 and 3200 (NH), 1690, and 1740 (C = 0).

Anal.—Calcd. for $C_{15}H_{24}NO_2Br$: C, 54.54; H, 7.32; N, 4.24; Br, 24.19. Found: C, 54.33: H, 7.15; N, 4.25; Br, 24.09.

***epi*-Dideoxycycloheximide (VIII).**—Zinc dust (0.85 Gm.) was added to a solution of *epi*-dihydrodeoxycycloheximide bromide (0.58 Gm., 1.75 mmoles) in 10.6 ml. of glacial acetic acid; the reaction mixture was stirred for 2 hours at 80°. After filtration, water was added to the filtrate which caused crystallization of the crude product. Yield, 0.34 Gm. (77.2%) of *epi*-dideoxycycloheximide, m.p. 120°. Two recrystallizations from methanol and water gave the analytical sample, m.p. 124–126°. $\bar{\nu}$ in cm.$^{-1}$ (KBr): 3290 and 3180 (NH); 1740 and 1690 (C = 0). $[\alpha]_D^{24}$ = 0.0 (c = 1.496 acetone).

Anal.—Calcd. for $C_{15}H_{25}NO_2$: C, 71.67; H, 10.02; N, 5.57. Found: C, 71.51; H, 9.85; N, 5.69.

Oxidation of *epi*-Dihydrodeoxycycloheximide.—To a solution of 0.21 Gm. (0.78 mmoles) of *epi*-dihydrodeoxycycloheximide in 5.1 ml. of glacial acetic acid was added a solution of chromic acid (0.69 Gm.) in 0.75 ml. of water. The reaction solution was heated on steam bath for 10 minutes, then was allowed to stand for 3 hours at room temperature. After dilution with 20 ml. of water, the solution was extracted with chloroform (four 20-ml. portions). The organic extract was washed with a saturated solution of sodium bicarbonate (three 25-ml. portions), water (30 ml.), dried with anhydrous magnesium sulfate, and then filtered. The volatile materials were removed *in vacuo*, and the semisolid residue on crystallization from ethanol and water gave 0.13 Gm. (66.7%) of *epi*-deoxy-

[3] The analyses in this paper were performed by Galbraith Microanalytical Laboratories, Knoxville, Tenn.

cycloheximide, m.p. 151–153°; mixed m.p. 150 to 151.5° with an authentic sample of *epi*-deoxycycloheximide. $\tilde{\nu}$ in cm.$^{-1}$ (KBr): 3200 and 3100 (NH), 1730, 1700, and 1680 (C = 0). The *epi*-deoxycycloheximide was further identified by thin-layer chromatography on silica gel when compared with the authentic sample of *epi*-deoxycycloheximide (R_f = 0.15, in chloroform containing 1% methanol).

Attempted Isomerization of *epi*-Deoxycycloheximide.—A solution of 0.10 Gm. (0.38 mmole) of *epi*-deoxycycloheximide and *p*-toluenesulfonic acid (0.08 Gm., 0.41 mmole) in 2.0 ml. of dimethylformamide was refluxed for 40 minutes. The reaction mixture was allowed to cool to room temperature and then poured onto ice. After the ice had melted, the crystals were collected by filtration and dried *in vacuo;* yield, 0.07 Gm. of *epi*-deoxycycloheximide, m.p. 140°. On recrystallization from ethanol and water, the crude material gave the pure sample, m.p. 149.5 to 152°; mixed m.p. 150–152° with the authentic sample of *epi*-deoxycycloheximide. $\tilde{\nu}$ in cm.$^{-1}$ (KBr): 3200 and 3100 (NH), 1730, 1700, and 1680 (C = 0). The *epi*-deoxycycloheximide was further identified by thin-layer chromatography on silica gel when compared with the authentic sample of *epi*-deoxycycloheximide (R_f = 0.15 chloroform containing 1% methanol).

Photometric Determination of Pentylenetetrazol in Pharmaceutical Preparations

By ROBERT A. DAOUST

Pentylenetetrazol is quantitatively precipitated from aqueous solution by cuprous chloride reagent. The pentylenetetrazol–cuprous chloride complex is dissolved in concentrated nitric acid; the solution is adjusted to pH 4 with acetate buffer and sodium hydroxide solution, and the deep blue color of the copper complex developed with tetraethylenepentamine is determined photometrically at 580 mμ. The method can be applied to samples containing from 2–10 mg. pentylenetetrazol and furnishes a rapid means of determining small amounts of the drug in the presence of other ingredients in pharmaceutical preparations.

PENTYLENETETRAZOL, a white, odorless, crystalline drug with a slightly pungent bitter taste is applied extensively as a central nervous system stimulant in the treatment of schizophrenia in shock therapy of psychoses and as an analeptic in narcotic poisoning.

This paper describes a method for the photometric determination of pentylenetetrazol in pharmaceutical liquids and tablets; the method can be performed rapidly and simply on small amounts of samples suitable for pharmaceutical control work. A gravimetric method which is determined by salting the drug from its aqueous solution with ammonium sulfate, followed by extraction with carbon tetrachloride has been officially adopted by "The National Formulary" (1, 2). Another gravimetric method involving precipitation with phosphotungstic acid is favored by some workers (3, 4). Numerous procedures have been reported for the assay of pentylenetetrazol: refractometric (5, 6), indirect polarographic (7), complexometric (8–10), colorimetric (11, 12), and volumetric and potentiometric methods (12).

The principle of the method proposed involves the precipitation of pentylenetetrazol from its aqueous solution with an excess of cuprous chloride reagent to give an insoluble, silver-white, crystalline, double salt complex which is then dissolved in concentrated nitric acid. The acid decomposes the pentylenetetrazol–cuprous chloride complex into its components and simultaneously oxidizes the cuprous salt to the cupric form. The acid solution is adjusted to pH 4 with acetate buffer and sodium hydroxide solution, and the absorbance of the deep blue color of the copper complex developed with tetraethylenepentamine

(13) is measured at 580 mμ with a suitable spectrophotometer.

EXPERIMENTAL

Reagents.—*Dister's Reagent* (14). A 1.250 Gm. quantity of cuprous chloride (reagent grade) is dissolved in distilled water to make 100 ml. of an aqueous solution containing 10 Gm. of ammonium chloride U.S.P. and 1 Gm. of sodium *meta*-bisulfite (reagent grade). This solution, if kept in a tightly stoppered amber bottle in a refrigerator immediately after use, is stable for several weeks.

Pentylenetetrazol Standard Solution. One-hundred milligrams of dried crystalline pentylenetetrazol N.F. is dissolved in about 50 ml. distilled water and the solution is diluted to the mark of a 100-ml. glass-stoppered volumetric flask. Each milliliter of this solution contains 1.0 mg. pentylenetetrazol.

Acetate Buffer Solution (15). A 16.6 Gm. quantity of anhydrous sodium acetate (reagent grade) is dissolved in about 100 ml. distilled water; 24 ml. glacial acetic acid is added and the mixture diluted to 200 ml.

Sodium Hydroxide Solution, 6% (w/v). Twelve grams of sodium hydroxide pellets (reagent grade) is dissolved in distilled water to make 200 ml. of solution.

Tetraethylenepentamine Solution, 2% (w/v). Four milliliters of tetraethylenepentamine (technical grade) is mixed with distilled water to make 200 ml. of solution.

TABLE I.—RELATION BETWEEN CONCENTRATION AND ABSORBANCE OF PENTYLENETETRAZOL

Concn., mg./50 ml.	Absorbance, S.D.
2	0.095 ± 0.008
4	0.177 ± 0.006
5	0.228 ± 0.004
6	0.267 ± 0.007
8	0.356 ± 0.011
10	0.444 ± 0.005

Dilute Acetic Acid Solution, 1% (v/v). One milliliter of glacial acetic acid is mixed with distilled water to make 100 ml. of solution.

Concentrated Nitric Acid (reagent grade).

Preparation of the Calibration Graph.—Aliquots of 2, 4, 6, 8, and 10 ml. of the standard solution of pentylenetetrazol are pipeted in order into each of five 50-ml. Erlenmeyer flasks. Each of the first four solutions is diluted to 10 ml. with distilled water, and 2 ml. of Dister's reagent is added to each of the five solutions. The flasks are stoppered and placed in an ice bath for 20 minutes with swirling a few times at 5-minute intervals to insure complete precipitation.

The precipitate is then filtered with suction through a 30-ml. sintered Pyrex glass filter funnel of medium porosity attached to a 500-ml. Pyrex glass suction flask; the filtrate, which is collected in a 18 x 150-mm. test tube placed inside of the flask, is rejected. The precipitate is washed twice with 5-ml. portions of cold dilute 1% acetic acid solution and the washings rejected.

The residue is dissolved by adding 1 ml. of concentrated nitric acid directly onto the sintered-glass funnel using a safety pipet or 50-ml. glass syringe. The filtrate is collected in the same manner in the test tube. The walls and plate of the glass funnel are washed with about 5 ml. of cold distilled water and aspirated through into the filtrate. The test tube (containing the filtrate) is carefully lifted out of the flask by a wire bent into a hook placed around the test tube. The filtrate is then poured into a 50-ml. glass-stoppered volumetric flask by means of a glass buret funnel. The washing is repeated with another 5 ml. portion and this is poured into the flask also. Ten milliliters each of the acetate buffer, 6% aqueous sodium hydroxide solution, and 2% aqueous tetraethylenepentamine solution is pipeted in succession into the acid solution; diluted to the mark with distilled water, stoppered, and mixed well. A blank solution is prepared by pipeting in succession into another 50-ml. glass-stoppered volumetric flask (containing a little distilled water) 1 ml. of concentrated nitric acid, 10

[a] Each 5 ml. contains 100 mg. Metrazol, 10 mg. niacinamide, 1 mg. pyridoxine hydrochloride, 1.4 mg. riboflavin sodium phosphate, and 2 mg. *d*-panthenol dissolved in 100 ml. of 15% ethanol. [b] Each 5 ml. contains 100 mg. Metrazol and 1 mg. thiamine hydrochloride in 15% ethanol. [c] Each 5 ml. contains 100 mg. Metrazol and 50 mg. nicotinic acid in 15% ethanol. [d] Based on an average tablet weight of 0.3353 Gm. [e] Absorbance of standard of 5 mg. concentration = 0.240. [f] Absorbance of standard of 5 mg. concentration = 0.235. [g] Absorbance of standard of 5 mg. concentration = 0.225. [h] Absorbance of standard of 5 mg. concentration = 0.230.

ml. each of acetate buffer, 6% sodium hydroxide solution, and 2% tetraethylenepentamine solution; the solution is diluted to the mark with distilled water, stoppered, and mixed well. The zero absorbance of the Beckman spectrophotometer, model DB, is set with this solution.

After allowing the solutions to stand for 10 minutes, the absorbance of the deep blue copper tetraethylenepentamine complex is measured at its maximum absorption, 580 mμ. The calibration graph of pentylenetetrazol, plotted on a linear scale at 2-mg. increments in the range from 2–10 mg., indicated that the method obeys Beer's law with good agreement. It is a straight line which passes through the origin.

Table I shows the relation between the absorbance and concentration of the standard solutions of pentylenetetrazol (which is directly proportional to the copper tetraethylenepentamine complex). Each value of the absorbance is the mean of ten determinations.

Procedure for Tablets.—The average tablet weight is ascertained from the weight of 20 tablets weighed accurately. Transfer a sample of the pulverized tablets, containing approximately 100 mg. pentylenetetrazol, into a 100-ml. glass-stoppered volumetric flask, dissolve in distilled water, fill up to the mark, stopper, mix well, and filter through paper, rejecting the first portion of the filtrate. Pipet 5 ml. of the filtrate, containing approx. 5 mg. pentylenetetrazol, into a 50-ml. Erlenmeyer flask and add 5 ml. of distilled water and 2 ml. of Dister's reagent. Stopper the flask, place in an ice bath, and follow the procedure described for the *Preparation of the Calibration Graph*. The amount of pentylenetetrazol present can be determined from the graph, or comparison with the absorbance of a solution obtained by similar treatment of 5 ml. of the *Standard Solution*.

Procedure for Liquids.—Pipet an aliquot of the liquid sample, containing approx. 100 mg. pentylenetetrazol, into a 100-ml. glass-stoppered volumetric flask, dilute to the mark with distilled water, stopper, and mix well. Proceed by the directions given for the *Procedure for Tablets* beginning with "Pipet 5 ml. . . ." then calculate

$$\frac{\text{A sample}}{\text{A standard}} \times \frac{5\text{ mg.}}{50\text{ ml.}} \times \frac{100\text{ ml.}}{\text{wt. sample (Gm.)}} \times \frac{\text{average tablet wt.}}{1\text{ tablet}} \times \frac{50\text{ ml.}}{5\text{ ml.}} = \text{mg./tablet}$$

$$\frac{\text{A sample}}{\text{A standard}} \times \frac{5\text{ mg.}}{50\text{ ml.}} \times \frac{100\text{ ml.}}{\text{vol. sample (5 ml.)}} \times \frac{50\text{ ml.}}{5\text{ ml.}} = \text{mg./5 ml.}$$

Table II shows the results of assays carried out on pentylenetetrazol pharmaceutical preparations manufactured by the Knoll Pharmaceutical Co., Orange, N. J. The absorbance of a solution obtained by similar treatment of 5 ml. of the *Standard Solution* was measured at the same time as that of the sample.

DISCUSSION

It was observed that small concentrations up to 4 mg. pentylenetetrazol were not precipitated immediately with Dister's reagent at room temperature, except on longer standing with frequent swirling. For this reason, the solutions were chilled in an ice bath for 20 minutes with occasional swirling of the stoppered flasks.

It is evident that other active ingredients and materials usually present with pentylenetetrazol do not interfere with the photometric method.

Ephedrine sulfate is not precipitated by Dister's reagent, so it should not interfere if present with pentylenetetrazol. On the other hand, quinine sulfate and quinidine sulfate form yellow flocculent precipitates with Dister's reagent, so the procedure cannot be applied directly if these alkaloids are present, unless they are separated by chromatographic adsorption or some other technique. However, the alkaloids can be determined satisfactorily by this method, although the sensitivity is about half that of pentylenetetrazol.

Eight solutions of pentylenetetrazol can be assayed in about 2 hours by the proposed method.

SUMMARY

Pentylenetetrazol can be determined quantitatively in the presence of active ingredients and materials usually present in pharmaceutical liquids and tablets by precipitation from aqueous solution with cuprous chloride reagent. The double salt complex formed is decomposed into the copper ion which is determined photometrically. The method proposed is sensitive and gives reproducible results on small samples. Since the method is not specific for pentylenetetrazol, it may be possible to apply it satisfactorily to other substances which react quantitatively with the cuprous chloride reagent.

Open-Chain Analogs of LSD II

Synthesis of Some 2-(3-Indolylethyl)- and 2-(3-Methyl-2-indolylethyl)piperidines

By CHARLES W. WHITTLE† and RAYMOND N. CASTLE

6-Methylpyridines substituted in the 3-position, which were quaternized with methyl or ethyl iodide, were condensed under Knoevenagel conditions with 3-indolealdehyde or with 3-methyl-2-indolealdehyde. The indolylethenylpyridinium iodides thus produced were hydrogenated to the corresponding indolylethylpiperidines. Conversion of the hydrogenation products into acid salts or into quaternary salts provided compounds for pharmacological testing. Some of these are open-chain analogs of LSD.

THE FIRST PAPER in this series (1) reported the synthesis of a number of 2-(3-indolylethenyl)-1-alkyl-5-substituted pyridinium iodides and some hydrogenation products. This series has now been extended and some of the compounds previously reported have been hydrogenated to the corresponding indolylethylpiperidines.

6-Methylnicotinoyl chloride was prepared by the action of oxalyl chloride on potassium 6-methylnicotinate according to the method of Wingfield (2). The acid chloride was not isolated but allowed to react directly with a secondary amine. In this manner 1-(6-methylnicotinoyl)-piperidine (I) and 4-(6-methylnicotinoyl)morpholine (II) were prepared. When I and II were allowed to react with methyl iodide, the quaternary salts were formed. When allowed to condense with 3-indolealdehyde, the quaternary salts of I and II gave 1-[6-(3-indolylethenyl)-nicotinoyl]piperidine methiodide (III) and 4-[6-(3-indolylethenyl)nicotinoyl]morpholine methiodide (IV).

Young (3) has shown that 3-indolealdehyde could be prepared in good yield by formylation of indole with a complex of N,N-dimethylformamide and phosphorus oxychloride. Using the same complex, Silverstein, Ryskiewiecz, and Willard (4) prepared 2-pyrrolealdehyde in 76% yield. Attempts to prepare 3-methyl-2-indolealdehyde (V) from skatole by the method of Young (3) gave 1-formyl-3-methylindole (VI) (55%) and V (20%). When the reaction temperature was changed from 5 to 60°, the yield of VI remained the same but the yield of V decreased. This is a contrast to the experience of Potokhin (5) who found that increased temperatures favored the formlyation of indole at position 3 over position 1.

Alessandri and Passerini (6) reported (without yields) that the 1-formyl-2-methylindole, when heated at 200° in the presence of zinc chloride, rearranged into 2-methyl-3-indolealdehyde. When VI was heated at 200° with zinc chloride no aldehyde was obtained. When it was heated at 250° a small amount of V was isolated. When V was allowed to react with 5-(N,N-diethylcarbamyl)-1,2-dimethylpyridinium iodide, 5 - (N,N - diethylcarbamyl) - 1 - methyl - 2-(3 - methyl - 2 - indolylethenyl)pyridinium iodide (XV) was obtained. When XV was hydrogenated, 5-(N,N-diethylcarbamyl)-1- methyl - 2 - (3 - methyl - 2 - indolylethyl)piperidine (XVI) was obtained as the hydriodide salt. This was readily converted into XVI by treatment with alkali.

Several indolylethenylpyridinium iodides were hydrogenated under high pressure to give the corresponding indolylethylpiperidines. These were converted into quaternary salts or into acid salts. The piperidine quaternary salts prepared were found to be less hygroscopic than the piperidine acid salts. Some of these transformations are shown.

3-Methylindole-1-carboxylic acid, which occurs in the beet, has been prepared from skatole in 86% yield *via* the Grignard reaction.

The pharmacological screening of this group of compounds was discontinued because of the lack of interesting activity[1] when screened for mouse behavior, oxytocic, and antimicrobial activity.

EXPERIMENTAL

The melting points are uncorrected. The micro melting points (m.m.p.) were determined on a Kofler hot stage. Carbon, hydrogen, and nitrogen analyses were performed by Tanabe Seiyaku Co., Ltd., Tokyo, Japan.[2] Basic nitrogen was determined by nonaqueous titration with perchloric acid in acetic acid (7).

1-(6-Methylnicotinoyl)piperidine.—6-Methylnicotinoyl chloride was prepared by allowing 26.0 Gm. (0.148 mole) of potassium 6-methylnicotinate to react with 18.0 Gm. (0.148 mole) of oxalyl chloride in a manner previously described (2). Eighteen milliliters of dry piperidine was added to the crude acid chloride solution. The product was extracted as the hydrochloride into water, decolorized with charcoal, then made basic with sodium hydroxide solution. The water was removed by vacuum evaporation; the solid residue was extracted into ether by Soxhlet extraction. After evaporation of the dried (calcium chloride) ether solution, the compound was distilled at 143–146° at 0.25 mm. Thirteen and one-half grams (45%) of product was obtained, m.p. 63 to 64.5°.

Anal.—Calcd. for $C_{12}H_{16}N_2O$: C, 70.56; H, 7.90; N, 13.71. Found: C, 70.22; H, 7.79; N, 13.52.

4-(6-Methylnicotinoyl)morpholine.—Twenty milliliters of dry morpholine was added dropwise to a solution of 6-methylnicotinoyl chloride (prepared as above); the reaction mixture was refluxed for 30 minutes. The cooled reaction product was extracted into water as the hydrochloride and decolorized twice with charcoal. After neutralization with sodium hydroxide solution, the water was removed by vacuum evaporation and the organic material was extracted into hot benzene. Removal of the benzene left a green oil which distilled at 135–136° at 0.08 mm. The liquid was dissolved in anhydrous ether, and a stream of dry hydrogen chloride was bubbled through the ethereal solution until precipitation was complete. The salt was collected, washed with dry ether, dried, and then recrystallized twice from ethanol-ethyl acetate to give the hydrochloride, m.p. 232–233°.

Anal.—Calcd. for $C_{11}H_{14}N_2O_2 \cdot HCl$: C, 54.44; H, 6.23; N, 11.54. Found: C, 54.70; H, 6.33; N, 11.71.

The salt was decomposed with ammonium hydroxide solution. After vacuum evaporation, the compound was extracted into ether. Removal of the dried ether gave 17.0 Gm. (58%) of the purified liquid compound.

Anal.—Calcd. for $C_{11}H_{14}N_2O_2$: C, 63.89; H, 6.84; N, 13.58. Found: C, 64.02; H, 6.62; N, 13.38.

1-(6-Methylnicotinoyl)piperidine Methiodide.—A precipitate separated from the reaction mixture when 10.0 Gm. (0.049 mole) of 1-(6-methylnicotinoyl)piperidine and excess methyl iodide dissolved in 300 ml. of benzene were allowed to reflux for 20 hours. The solid product was collected, washed with benzene, and dried. Upon crystallization from ethanol, 15.8 Gm. (93%) of a white solid was obtained m.p. 185–186°.

Anal.—Calcd. for $C_{13}H_{19}IN_2O$: C, 45.10; H, 5.53; N, 8.09. Found: C, 44.89; H, 5.47; N, 8.09.

4-(6-Methylnicotinoyl)morpholine Methiodide.—When 15.0 Gm. (0.074 mole) of 4-(6-methylnicotinoyl)morpholine and excess methyl iodide were allowed to react as above, a precipitate separated from the reaction mixture. After two recrystallizations from ethanol, 19.0 Gm. (76%) of white platelets was obtained, m.p. 238–239°.

Anal.—Calcd. for $C_{12}H_{17}IN_2O_2$: C, 41.39; H, 4.92; N, 8.05. Found: C, 41.04; H, 5.04; N, 8.08.

3-Methylindole-1-carboxylic Acid.—To an ethereal solution of methyl magnesium iodide, prepared from 2.68 Gm. (0.11 mole) of magnesium

[1] The authors are indebted to the Lilly Research Laboratories for screening these compounds.
[2] The authors thank Dr. S. Yamada for this service.

turnings and 15.6 Gm. (0.11 mole) of methyl iodide, was added dropwise 13.1 Gm. (0.10 mole) of skatole in 25 ml. of dry ether. A heavy ether-insoluble oil resulted from the reaction to which an excess of dry ice was added in portions while the two phases were stirred vigorously with gentle heating. The complex was decomposed with dilute hydrochloric acid; the organic portion dissolved in ether and separated. The solid remaining after the removal of the ether was recrystallized twice from benzene. There was obtained 15.0 Gm. (86%) of 3-methylindole-1-carboxylic acid as fine white needles. The decomposition point of the acid was dependent on the rate of heating. At 2° per minute decomposition occurred at 128°, and at 8° per minute decomposition occurred at 140–141°. In each instance, skatole (m.p. 92°) and carbon dioxide were the decomposition products.

Anal.—Calcd. for $C_{10}H_9NO_2$: C, 68.56; H, 5.17; N, 7.97. Found: C, 68.82; H, 5.08; N, 7.72.

1-Formyl-3-methylindole and 3-Methyl-2-indolealdehyde.—While cooling and stirring, 42.2 Gm. (0.253 mole) of phosphorus oxychloride was added to 20.0 Gm. (0.253 mole) of N,N-dimethylformamide over a period of 30 minutes. The resulting complex was dissolved in 65 ml. of ethylene chloride and cooled to 5° before 12.8 Gm. (0.25 mole) of skatole in 100 ml. of ethylene chloride was added dropwise over a period of 1 hour. A light yellow solid separated after heating at the reflux temperature for 15 minutes. After cooling the reaction mixture, 188 Gm. (1.375 moles) of sodium acetate in 250 ml. of water was added rapidly while the reaction mixture was stirred vigorously. The organic layer was separated, decolorized with charcoal, and the solvent was evaporated. The residue was distilled at 100–120° at 0.05 mm. A saturated solution of sodium bisulfite was added to the distillate and the oily layer was removed by extraction with ethylene chloride. The aqueous layer was acidified with dilute hydrochloric acid, then extracted with ethylene chloride. Both ethylene chloride solutions were evaporated until all the solvent was removed. The second solution gave 8 Gm. (20%) of 3-methyl-2-indolealdehyde, m.p. 139–140° (8). The oily residue from the first ethylene chloride solution was distilled *in vacuo* and gave 22 Gm. (55%) of 1-formyl-3-methylindole, b.p. 98–100° at 0.03 mm., $n_D^{18.5} = 1.6138$.

The structure of 1-formyl-3-methylindole was demonstrated by the facile hydrolysis into sodium formate and skatole, by the infrared spectrum, and by elemental analysis.

Anal.—Calcd. for $C_{10}H_9NO$: C, 75.45; H, 5.70; N, 8.88. Found: C, 75.66; H, 5.83; N, 9.00.

Rearrangement of 1-Formyl-3-methylindole.—A small amount of 3-methyl-2-indolealdehyde was obtained by heating 5 Gm. of 1-formyl-3-methylindole with a trace of zinc chloride in a nitrogen-filled Carius tube at 240–270° for 2 hours. The resulting black tar-like material was distilled under high vacuum leaving 2 Gm. of tar. The distillate was treated with sodium bisulfite solution to separate the aldehyde from the amide. A 2.8-Gm. quantity of starting material was recovered and about 0.1 Gm. of impure 3-methyl-2-indolealdehyde, m.p. 130–134° was obtained.

5-(N,N-Diethylcarbamyl)-1-methyl-2-(3-methyl-2-indolylethenyl)pyridinium Iodide.—A solution of 9.1 Gm. (0.057 mole) of 3-methyl-2-indolealdehyde and 18.0 Gm. (0.057 mole) of 5-(N,N-diethylcarbamyl)-1,2-dimethylpyridinium iodide in 300 ml. methanol which contained ten drops of piperidine was refluxed for 22 hours. After chilling overnight, fine orange crystals separated. After crystallization from ethanol, 21.5 Gm. (79%) of the product, m.p. 275° dec. was obtained.

Anal.—Calcd. for $C_{22}H_{26}IN_3O$: C, 55.59; H, 5.51; N, 8.84. Found: C, 55.68; H, 5.42; N, 8.38.

1-[6-(3-Indolylethenyl)nicotinoyl]piperidine Methiodide.—In a procedure similar to that given above, 10 Gm. (0.0303 mole) of 1-(6-methylnicotinoyl)piperidine methiodide and 5.5 Gm. of 3-indolealdehyde were allowed to react. After collection and purification of the product, 10.3 Gm. (72%) of a red compound was obtained m.p. 234–236° dec.

Anal.—Calcd. for $C_{22}H_{24}IN_3O$: C, 55.86; H, 5.11; N, 8.93. Found: C, 55.90; H, 5.34; N, 8.80.

5-Ethyl-2-(3-indolylethyl)-1-methylpiperidine.—A solution of 9.35 Gm. (0.0238 mole) of 5-ethyl-2-(3-indolylethenyl)-1-methylpyridinium iodide in 250 ml. of ethanol was hydrogenated at an initial pressure of 50 p.s.i. using 2 Gm. of 5% rhodium on alumina as the catalyst. The theoretical amount of hydrogen was absorbed during 9 hours at room temperature. Removal of the catalyst and evaporation of the solvent left the hydriodide salt as a syrup. This was not purified but converted directly to the free base by the addition of sodium hydroxide. The viscous, sticky compound was partially dried by azeotropic distillation with benzene. The balance of the moisture was removed by allowing the compound to stand over phosphorus pentoxide *in vacuo* for 3 weeks. Attempts to crystallize the compound from a variety of solvents were not successful. It was necessary to dry the compound *in vacuo* after each attempt. Attempts to purify the compound as the hydrochloride salt were also unsuccessful. The salt, although readily formed, was extremely hygroscopic. The micro melting point of the compound was 135–139°.

Anal.—Calcd. for $C_{18}H_{26}N_2$: Basic N, 5.18. Found: Basic N, 4.88.

1,5-Diethyl-2-(3-indolylethyl)piperidine.—1,5-Diethyl-2-(3-indolylethenyl)pyridinium iodide, 11.25 Gm. (0.0275 mole), was hydrogenated in the same manner as described above over a period of 30 hours. The product was isolated as above but remained as a semisolid after storage over phosphorus pentoxide *in vacuo* for 1 year.

Anal.—Calcd. for $C_{19}H_{28}N_2$: Basic N, 4.94; Found: Basic N, 4.55.

5-Carbamyl-1,1-dimethyl-2-(3-indolylethyl)-piperidinium Iodide.—The hydrogenation of 10.0 Gm. (0.0247 mole) of 5-carbamyl-2-(3-indolylethenyl)-1-methylpyridinium iodide in 200 ml. of ethanol was accomplished in 3 days at 100° and at 2,500 p.s.i. pressure over 0.5 Gm. of platinum oxide as the catalyst. The semisolid product obtained after removal of the catalyst and the solvent solidified upon drying *in vacuo* over phosphorus pentoxide. This salt was dissolved in methanol containing 0.0247 mole of sodium methoxide. After heating to the reflux temperature, the solvent was removed and the residue dried. Benzene was added to dissolve the or-

ganic compound and the solution was decanted from the insoluble portion. To the benzene solution was added 3.5 Gm. (0.0248 mole) of methyl iodide and this solution refluxed for 14 hours. The product separated when the solution was allowed to cool. After crystallization from ethyl acetate, 5.5 Gm. (52%) of quaternary salt was obtained. This compound does not possess a true melting point but decomposes over a wide range.

Anal.—Calcd. for $C_{18}H_{26}IN_3O$: C, 50.92; H, 6.13; N, 9.83. Found: C, 51.06; H, 6.06; N, 9.43.

5-(N,N-Diethylcarbamyl)-1-methyl-2-(3-indolylethyl)piperidine.—The low pressure hydrogenation of 5-(N,N-diethylcarbamyl)-2-(3-indolylethenyl)-1-methylpyridinium iodide has been described (1). At low pressure this reaction was very slow, but the uptake of hydrogen was steady. The reaction at 2,500 p.s.i. pressure over platinum oxide requires only 24 hours. The resulting hydriodide was converted to the free base as described in the preceding example. This compound was identical with that previously obtained by low pressure hydrogenation (mixed m.p., 213–214°).

Anal.—Calcd. for $C_{21}H_{31}N_3O$: Basic N, 4.11. Found: Basic N, 4.08.

5-(N,N-Diethylcarbamyl)-1,1-dimethyl-2-(3-indolylethyl)piperidinium Iodide.—A benzene solution of 5-(N,N-diethylcarbamyl)-2-(3-indolylethyl)-1-methylpiperidine was allowed to react with methyl iodide in the usual fashion. The product was recrystallized from ethyl acetate under anhydrous conditions. This quaternary salt decomposed over a wide range at about 200° with the evolution of gas.

Anal.—Calcd. for $C_{22}H_{34}IN_3O$: C, 54.66; H, 7.09. Found C, 54.41; H, 7.14.

5-(N,N-Diethylcarbamyl)-1-methyl-2-(3-methyl-2-indolylethyl)piperidine Hydriodide.—A solution containing 10.0 Gm. (0.0221 mole) of 5-(N,N-diethylcarbamyl)-1-methyl-2-(3-methyl-2-indolylethenyl)pyridinium iodide in 200 ml. of ethanol was hydrogenated at 2,500 p.s.i. over 0.5 Gm. of platinum oxide at 90° for 2 days. The solid remaining after removal of the catalyst and solvent was dried *in vacuo*. Platelets were obtained after crystallization from ethyl acetate, m.p. 113–115°.

Anal.—Calcd. for $C_{22}H_{34}N_3O \cdot HI$: C, 54.66; H, 7.09. Found: C, 54.59; H, 6.97.

5-(N,N-Diethylcarbamyl)-1-methyl-2-(3-methyl-2-indolylethyl)piperidine.—The hydriodide salt described above was dissolved in methanol. An excess of sodium methoxide was added to this solution and the mixture heated at the reflux temperature. The solvent was removed by flash evaporation; the resulting semisolid was dried. The residue was extracted with benzene, the solution decolorized, and the benzene evaporated. An analytical sample was prepared by crystallization from ligroin under anhydrous conditions, mmp 158–161°.

Anal.—Calcd. for $C_{22}H_{33}N_3O$: Basic N, 3.94. Found: Basic N, 3.58.

5-(N,N-Diethylcarbamyl)-1-methyl-2-(3-methyl-2-indolylethyl)piperidine Acid Tartrate.—The free base described above (about 0.02 mole) was dissolved in 20 ml. of methanol. A methanolic solution containing 3.0 Gm. (0.02 mole) of *d*-tartaric acid was added to this solution. The volume of the solution was reduced to about one-half before 50 ml. of anhydrous ether was added to precipitate the salt. After decantation, the residue was crystallized from methanol-ethyl acetate. There was obtained 6.8 Gm. (61%) (based on the amount of pyridinium iodide originally hydrogenated) of the salt, m.p. 67–69° (sealed tube).

Anal.—Calcd. for $C_{22}H_{33}N_3O \cdot C_4H_6O_6$: C, 61.76; H, 7.77. Found: C, 61.33; H, 7.95.

4-[6-(3-Indolylethyl)-1-methylnipecotoyl]-morpholine Hydriodide.—A solution containing 10.0 Gm. (0.0212 mole) of 4-[6-(3-indolylethenyl)-nicotinoyl]morpholine methiodide in 200 ml. of ethanol was hydrogenated at 3,000 p.s.i. pressure and at 90° over 0.5 Gm. of platinum oxide for 1.5 days. After removal of the catalyst and solvent, the residue was crystallized from absolute ethanol to give a white salt, m.p. 109–110°.

Anal.—Calcd. for $C_{21}H_{29}N_3O_2 \cdot HI$: C, 52.18; H, 6.26; N, 8.89. Found: C, 52.31; H, 6.20; N, 8.76.

4-[6-(3-Indolylethyl)-1-methylnipecotoyl]-morpholine.—The hydriodide salt described above was dissolved in hot water and the solution was made faintly alkaline with sodium hydroxide. Water was removed by flash evaporation and then by azeotropic distillation with benzene. The benzene mixture was decolorized with charcoal after which the insoluble salts and the charcoal were removed by filtration. After evaporation of the benzene, the solid was crystallized from ethyl acetate to give 7.1 Gm. (95%) of white plates, m.p. 65–67°.

Anal.—Calcd. for $C_{21}H_{29}N_3O_2$: Basic N, 3.94. Found: Basic N, 4.01.

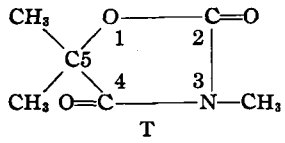
Kinetics of Base-Catalyzed Hydrolysis of Trimethadione

By JOSEPH F. GALLELLI† and H. B. KOSTENBAUDER

An infrared method is reported for determination of intact trimethadione (3,5,5-trimethyl-2,4-oxazolidinedione) in presence of products of hydrolysis. Kinetics have been determined for hydroxide ion–catalyzed hydrolysis of trimethadione and a mechanism is proposed in which there exists a rapid equilibrium between a cyclic and an acyclic structure. The rate of hydrolysis of trimethadione at pH 10 and 30° is 10^5 to 10^6 times that for acyclic compounds of similar structure.

TRIMETHADIONE (3,5,5-trimethyl-2,4-oxazolidinedione) is an anticonvulsant drug which is often administered in the form of an aqueous solution. Although it is recognized that trimethadione is rapidly decomposed in alkaline solution, the kinetics of this reaction have not been studied.

The trimethadione structure (T) can be considered as representing a lactone, a urethan (1,2,3 positions), and a cyclic amide (3,4,5 positions). Because of the multiplicity of labile



T

bonds in trimethadione, a complex mechanism of degradation is to be expected. Decomposition might occur through hydrolytic cleavage of the lactone, urethan, or amide moiety of the cyclic compound. Rekker and Nauta (1) identified products obtained on alkaline hydrolysis of trimethadione (T) as the salt of a carbamylo-α-hydroxy acid (A) and an N-methyl-α-hydroxy amide (B).

The present study was directed toward the development of an analytical procedure which would permit quantitative determination of residual quantities of intact trimethadione and toward elucidation of the kinetics and mechanism for the base-catalyzed hydrolysis of this drug.

EXPERIMENTAL

Reagents.—Trimethadione[1] U. S. P. was recrystallized twice from ethanol-water, m.p. 45–47°. The two decomposition products of trimethadione, N-methyl-α-hydroxyisobutyramide and N-methylcarbamylo-α-hydroxyisobutyric acid, were synthesized according to the method described by Rekker and Nauta (1, 2). Both compounds were recrystallized from toluene, m.p. 78–79° and m.p. 114–115°, respectively. All other chemicals were of reagent grade.

Apparatus.—A Perkin-Elmer model 137 B Infracord spectrophotometer, 0.099-mm. NaCl cell; Beckman pH meters, model H-2 and model 76; constant temperature bath ±0.01°; 1-ml. Gilmont micropipet-buret[2] with motorized syringe drive;[3] and a JKM "Stat"[4] were utilized in this study.

Kinetic Studies.—Two-gram portions of trimethadione were dissolved in distilled water in 100-ml. volumetric flasks. The solutions were brought to volume at the temperature of the bath. This solution was then transferred to a 250-ml. beaker

which was immersed to 90% of its length in the thermostatically controlled bath. Dipping beneath the surface of the liquid in the beaker were a glass-calomel electrode pair, a mechanical stirring device, and a 1-ml. micropipet-buret. The micropipet-buret contained a 12 *N* sodium hydroxide solution which was fed into the reaction vessel as required to maintain constant pH. Because of the high concentration of drug employed (2%) and the resulting consumption of large quantities of hydroxide ion, it was not practical to employ buffer systems to maintain constant pH. At no time did the volume of 12 *N* sodium hydroxide added exceed 0.5 ml. (0.5% of the total volume); therefore, no corrections were required to account for volume change during the reaction.

In most studies the pH in the reaction vessel was maintained by constant monitoring of pH and manual addition of sodium hydroxide solution from the micropipet-buret. For studies in the vicinity of pH 8, however, the reaction was followed for as long as 6 days and several modifications were necessitated. In these studies the reaction vessel was fitted with a rubber dam cover with a 22-gauge hypodermic needle providing an opening to avoid pressure changes. A pH stat, consisting of a Beckman model 76 expanded scale pH meter, a JKM "Stat" unit, and a motorized micropipet-buret, was employed to maintain constant pH. Maximum variation during a study was less than 0.02 pH.

At appropriate time intervals, 10-ml. portions of the aqueous alkaline reaction mixture were withdrawn and pipeted directly into 50-ml. separatory flasks. The reaction was quenched immediately by acidification to approximately pH 3 with concentrated hydrochloric acid. Trimethadione was shown to be stable at pH 3.

Determination of Intact Trimethadione.—At the end of the kinetic run each of the solutions in the separatory flasks was extracted with five 2-ml. portions of chloroform. After the addition of each portion of chloroform the separatory flask was shaken for approximately 1 minute. The chloroform extracts were filtered through a pledget of cotton into a 10-ml. volumetric flask. The cotton was rinsed with chloroform and the washings were collected in the same flask. The combined extracts were then brought to 10 ml. with chloroform and the trimethadione content of the solution was determined by measuring the absorbance at 5.49 μ, using the base-line technique (3).

An experiment was conducted in which 10-ml. portions of the aqueous alkaline solution of trimethadione were withdrawn at intervals and immediately extracted with chloroform without previous adjustment to pH 3. The chloroform extracts were then assayed as described above and the results were compared with data obtained from acid-quenching of the reaction. Both procedures gave the same result for concentration of intact trimethadione.

Determination of Decomposition Products.—The acid decomposition product, N-methyl-carbamylo-α-hydroxyisobutyric acid, was extracted from the reaction mixture with ether and was determined by titration with aqueous sodium hydroxide. A 7-Gm. quantity of anhydrous sodium sulfate was added to a 10-ml. sample of the reaction mixture from which trimethadione had been extracted. The resulting slurry was then extracted with four 10-ml. and two 5-ml. portions of ether. The combined ether extracts were evaporated and the residue was titrated with standard sodium hydroxide, approximately 0.01 *N* or 0.1 *N*.

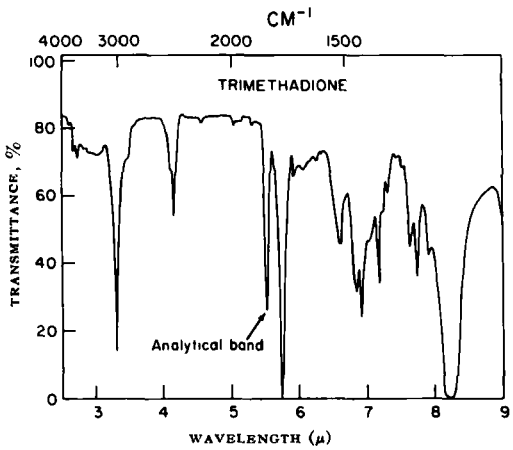

Fig. 1.—Infrared absorption spectrum for trimethadione in chloroform.

Direct determination of the amide decomposition product, N-methyl-α-hydroxyisobutyramide, in the reaction mixture was not practical; however, the reaction scheme indicates that formation of 1 mole of the amide must be accompanied by liberation of 1 mole of carbonate. Determination of carbonate in the reaction mixture, therefore, provided an indirect means of determining the quantity of amide formed.

The 10-ml. samples of reaction mixture to be used for carbonate determination were immediately acidified with 0.5 ml. of a sodium biphosphate solution (70 mg./ml.) to quench the reaction. The samples were then placed in a closed system and acidified with 1 ml. of concentrated sulfuric acid. The carbon dioxide evolved was flushed from the solution by bubbling nitrogen through the system for 1 hour and passing the effluent gases through two traps containing 30 ml. of standard barium hydroxide approximately 0.05 *N* in the first trap and 0.02 *N* in the second trap. The precipitate of barium carbonate was allowed to settle and a clear 10-ml. aliquot of the remaining barium hydroxide solution in each trap was titrated with 0.05 *N* hydrochloric acid to determine the equivalents of barium hydroxide precipitated by the carbon dioxide.

NMR Data.—A nuclear magnetic resonance spectrum[5] was obtained to confirm the structure of one of the products of decomposition, the N-methyl-α-hydroxyisobutyramide. The sample was run as a saturated solution in $CDCl_3$.

RESULTS AND DISCUSSION

Specificity of Assay for Intact Trimethadione.—Previously reported assay methods for trimethadione consist of determination of total nitrogen (4), determination of alkali consumed during hydrolysis in strong base (5), and measurement of carbon

[5] Furnished through the courtesy of Varian Associates, Palo Alto, Calif.

dioxide evolved on acidification after alkaline hydrolysis (6). The assays are unsatisfactory for distinguishing intact drug from decomposition products and for the last two assays the results obtained, even with pure trimethadione, are highly dependent on the conditions under which the assay is conducted.

Trimethadione is transparent in the visible and ultraviolet regions of the spectrum but exhibits a distinctive absorption band in the infrared at 5.49 μ. This absorption is similar to that exhibited by lactones (7); this band disappears upon destruction of the cyclic structure.

None of the possible decomposition products of trimethadione show absorption at 5.49 μ. Therefore, determination of absorbance of a chloroform extract of the aqueous reaction medium provides an assay specific for intact drug. Figure 1 shows the infrared spectrum of trimethadione and Fig. 2 shows the standard curve of absorbance *versus* concentration.

Specificity of Assays for Decomposition Products.—The product N-methyl-carbamylo-α-hydroxyisobutyric acid was determined by ether extraction of acidified aqueous solution, followed by evaporation and titration of residue with standard alkali. Presumably a product of further hydrolysis, α-hydroxyisobutyric acid, might also respond to such a procedure. It has been reported (1) that the sodium salt of carbamylo-α-hydroxy acid is not sensitive to alkali even at 100°; however, prolonged exposure to excess alkali did result in further hydrolysis. Below pH 10.8, however, it was found that there was a loss of less than 1% per hour. It would appear that for the duration and conditions of the present studies the carbamylo-α-hydroxyisobutyric acid can properly be considered as a final product.

The possibility of cleavage at the 2,3 position yielding another acid product of equivalent weight identical to N-methyl-carbamylo-α-hydroxyisobutyric acid was eliminated on examination of NMR

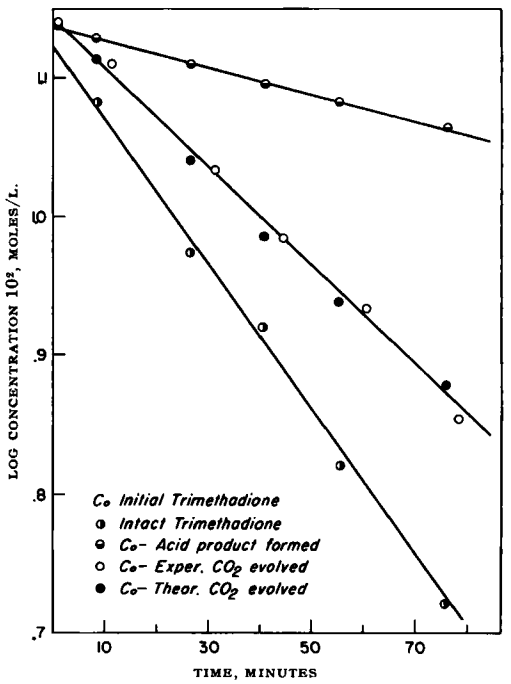

Fig. 4.—First-order disappearance of trimethadione and appearance of products.

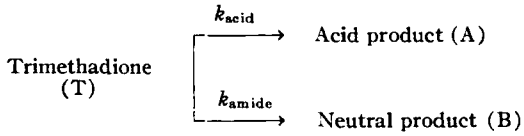
spectra obtained for the acid product. The alternate structure for the acidic component would require the resonance of the N-methyl to be single, since there is no adjacent proton; the resonance is, in fact, doubled indicating that the N atom carries a proton as required for the N-methyl-carbamylo-α-hydroxyisobutyric acid structure. Additional resonance assignments and the integrated intensities confirm the above structural assignment.

Adherence to stoichiometry during the course of the reaction, as illustrated in Fig. 3, supports the acceptability of the determination of liberated carbon dioxide as an indirect means of determining the quantity of N-methyl-α-hydroxyisobutyramide produced.

Order of Reaction with Respect to Trimethadione. —Figure 4 illustrates that overall disappearance of trimethadione is first order with respect to intact drug. The nature of Fig. 3 suggests that at constant hydroxide ion concentration the decomposition occurs by formation of an acid product and an amide *via* two parallel first-order reactions. The proposed reaction is



The symbols T, A, B represent trimethadione, N-methyl-carbamylo-α-hydroxyisobutyric acid, and N-methyl-α-hydroxyisobutyramide, respectively, and k_{acid} and k_{amide} represent the corresponding rate constants. The rate equation at constant hydroxide ion concentration is

$$\frac{-dT}{dt} = \frac{dA}{dt} + \frac{dB}{dt} \qquad \text{(Eq. 1)}$$

or $$-\frac{dT}{dt} = kT = k_{acid}T + k_{amide}T \qquad \text{(Eq. 2)}$$

where $$k = k_{acid} + k_{amide} \qquad \text{(Eq. 3)}$$

and $$ln\ (T_0/T) = kt \qquad \text{(Eq. 4)}$$

or $$T = T_0e^{-kt} \qquad \text{(Eq. 5)}$$

where T_0 is the initial concentration of trimethadione and T is the concentration at any time t. The rate of formation of the acidic product can be expressed as

$$\frac{dA}{dt} = k_{acid}T \qquad \text{(Eq. 6)}$$

$$= k_{acid}T_0e^{-kt} \qquad \text{(Eq. 7)}$$

and by integration

$$A = -\frac{k_{acid}T_0e^{-kt}}{k} + \text{constant} \qquad \text{(Eq. 8)}$$

$$A = A_0 + \frac{k_{acid}}{k}T_0(1 - e^{-kt}) \qquad \text{(Eq. 9)}$$

where A_0 is the initial concentration of the acid product and A is the concentration at any time t. If $A_0 = 0$ (Eq. 10), then

$$A = \frac{k_{acid}}{k}T_0(1 - e^{-kt}) \qquad \text{(Eq. 11)}$$

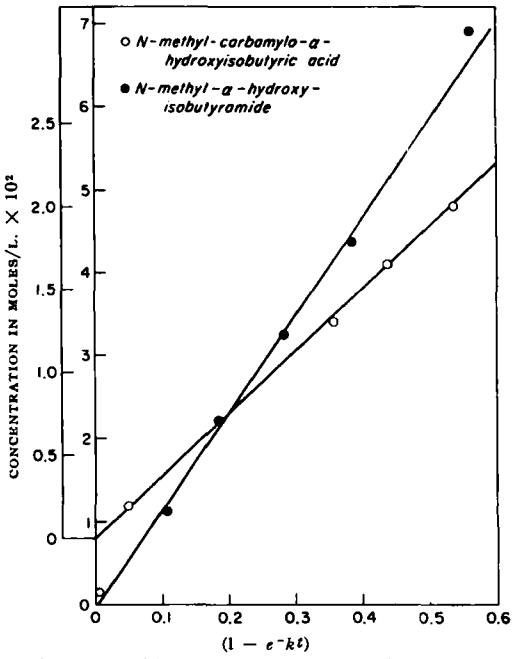


Fig. 5.—Evidence for parallel pseudo-first order reactions for hydrolysis of trimethadione to N-methyl-carbamylo-α-hydroxyisobutyric acid and N-methyl-α-hydroxyisobutyramide at pH 10.0 and 30°.

A similar expression derived for the neutral product is

$$B = \frac{k_{amide}}{k}T_0(1 - e^{-kt}) \qquad \text{(Eq. 12)}$$

Equations 11 and 12 indicate that for the base catalyzed hydrolysis of trimethadione, a plot of the concentration of either A or B against $(1 - e^{-kt})$ should yield a straight line. At zero time the curve should pass through the origin and at infinite time the function should have a value of unity.

The value for k, the overall first-order rate constant, was obtained by plotting logarithm of the concentration of residual trimethadione *versus* time at various hydroxide ion concentrations. It was then possible to check the relationship expressed in Eq. 11 using the concentrations of acidic product formed at various hydroxide ion concentrations. A plot of the acidic product formed in the degradation of trimethadione at pH 10.0 and 30° *versus* $(1 - e^{-kt})$ yielded a straight line through the origin as predicted by Eq. 11 (See Fig. 5). Also shown in Fig. 5 is a linear plot of the neutral or amide product formed at pH 10.0 and 30° *versus* $(1 - e^{-kt})$. The value of k_{acid}, the rate constant for the formation of acidic material, was calculated from the slope by Eq. 11.

$$\text{Slope} = \frac{k_{acid}}{k}T_0 \qquad \text{(Eq. 13)}$$

The value of k_{amide}, the rate constant for the formation of neutral material at pH 10.0 and 30°, was also obtained in the same manner. Values for k_{amide} at other pH values were obtained by evaluat-

ing k_{acid} in the above manner at each pH value and then subtracting k_{acid} from k according to Eq. 3. The data are found in Table I.

Hydroxide Ion Dependency.—The influence of hydroxide ion on the rate constant for trimethadione decomposition is illustrated in Fig. 6. Also shown in Fig. 6 is the influence of hydroxide ion on the rate constants for appearance of the decomposition products, N-methyl-carbamylo-α-hydroxyisobutyric acid and N-methyl-α-hydroxyisobutyramide. All plots show a hydroxide ion dependency of an order that is non-integral but greater than one.

Temperature Dependency.—Rate constants for the overall disappearance of trimethadione were obtained over the temperature range of 30 to 60° at a pH of 9.25. The data are presented as an Arrhenius plot in Fig. 7, and the apparent heat of activation for the process was determined as approximately 26.0 kilocalories per mole.

Mechanism.—Over the pH range studied, the pseudo-first order rate coefficient for the disappearance of trimethadione and the rate coefficients for the parallel pseudo-first order appearance of decomposition products, N-methyl-α-hydroxyisobutyramide and N-methyl-carbamylo-α-hydroxyisobutyric acid, all show hydroxide ion dependencies which are non-integral but of an order greater than one. The amide is the principal product below about pH 8.75, with the acid product becoming increasingly important above pH 9.50.

In postulating a mechanism to satisfy these requirements, the data illustrated in Fig. 8, showing hydroxide ion uptake during the reaction, become extremely useful. Figure 8 indicates an initial uptake of hydroxide ion greater than the equivalent quantity of trimethadione disappearing, followed by a region in which the hydroxide uptake is proportional to the trimethadione disappearing but is less than equivalent to the trimethadione disappearing. This observation suggests a relatively rapid reaction of hydroxide ion with trimethadione to produce a species which is in equilibrium with the trimethadione. On the basis of these observations the mechanism proposed is

TABLE I.—EXPERIMENTAL RATE CONSTANTS FOR THE BASE-CATALYZED HYDROLYSIS OF TRIMETHADIONE AT 30° C.

pH	k, Hr.$^{-1}$	k_{acid}, Hr.$^{-1}$	k_{amide}, Hr.$^{-1}$
10.75	7.314	2.710	4.604
10.50	2.696	0.873	1.823
10.25	1.325	0.359	0.966
10.00	0.676	0.145	0.531
9.75	0.292	0.047	0.245
9.50	0.119	0.019	0.100
9.25	0.0684	...	...
9.00	0.0284	...	...
8.75	0.0141	...	...
8.00	0.00251	...	...

Development of a rate expression can be considerably simplified if it can be assumed that the cyclic structure I is in rapid equilibrium with the acyclic structure III. An equilibrium quotient may then be written as

$$K = \frac{\text{III}}{(\text{I})\,(\text{OH}^-)} \qquad \text{(Eq. 14)}$$

The fraction of total trimethadione present in the cyclic form is

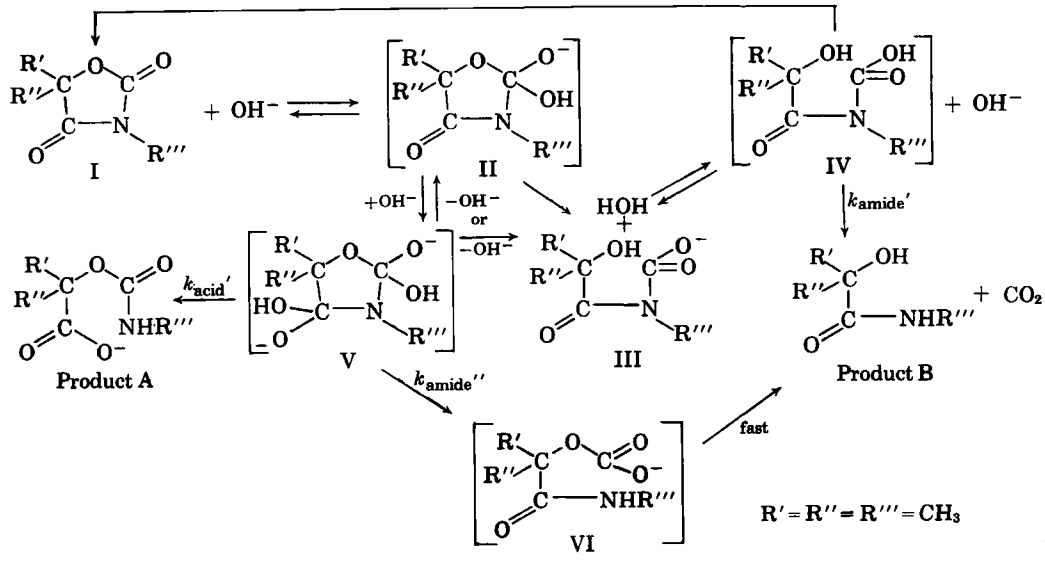
$$\frac{1}{1 + K\,(\text{OH}^-)} \qquad \text{(Eq. 15)}$$

and the fraction of total trimethadione in the acyclic form III is

$$\frac{K\,(\text{OH}^-)}{1 + K\,(\text{OH}^-)} \qquad \text{(Eq. 16)}$$

The existence of this equilibrium could not be verified directly, since at a pH where a significant fraction of trimethadione would theoretically exist in the acyclic structure, hydrolysis is extremely rapid. Structure IV apparently is extremely unstable, for in no case was it possible to isolate this compound after acidification of the reaction mixture.

In the following development, T represents total trimethadione in solution (essentially I + III), K is the equilibrium quotient as defined above, and



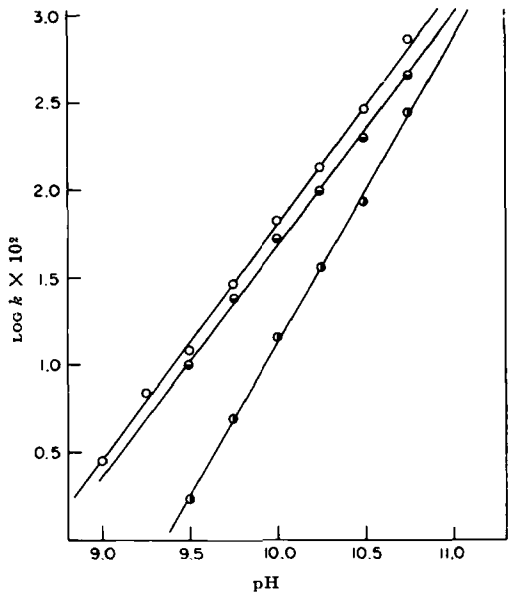


Fig. 6.—Influence of hydroxide ion on the pseudo-first order rate constant for hydrolysis of trimethadione at 30°. Also shown is the effect of hydroxide ion on the rate constants for appearance of products. Key: O, trimethadione; ◒, N-methyl-α-hydroxyisobutyramide; ◑, N-methyl-carbamylo-α-hydroxyisobutyric acid.

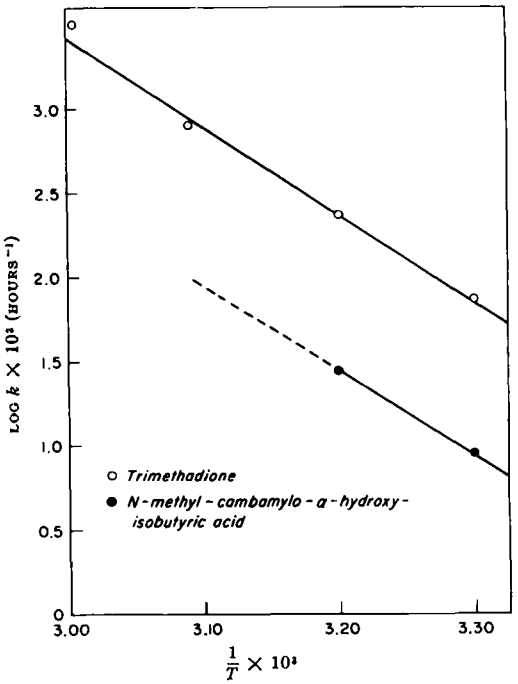

Fig. 7.—Arrhenius-type plots showing the temperature dependency for hydrolysis of trimethadione and appearance of N-methyl-carbamylo-α-hydroxyisobutyric acid at pH 9.25.

$k_{amide'}$, $k_{amide''}$, and $k_{acid'}$ are rate coefficients for formation of decomposition products. The overall rate of disappearance of trimethadione can be represented as

$$\text{Rate} = (\text{III})\,k_{amide'} + (\text{I})\,(OH^-)^2\,k_{amide''} + (\text{I})\,(OH^-)^2\,k_{acid'} \quad \text{(Eq. 17)}$$

When Eqs. 15 and 16 are substituted into Eq. 17, then

$$\text{Rate} = \frac{(T)\,K\,(OH^-)\,k_{amide'}}{1 + K\,(OH^-)} + \frac{(T)\,(OH^-)^2\,k_{amide''}}{1 + K\,(OH^-)} + \frac{(T)\,(OH^-)^2\,k_{acid'}}{1 + K\,(OH^-)} \quad \text{(Eq. 18)}$$

or

$$\frac{\text{Rate}}{T} = \frac{K\,(OH^-)\,k_{amide'}}{1 + K\,(OH^-)} + \frac{(OH^-)^2\,k_{amide''}}{1 + K(OH^-)} + \frac{(OH^-)^2\,k_{acid'}}{1 + K\,(OH^-)} \quad \text{(Eq. 19)}$$

The constants in Eq. 19 are evaluated in the following manner. At any constant hydroxide concentration, the observed pseudo-first order rate coefficients listed in Table I may be expressed as

$$k_{amide} = \frac{K\,(OH^-)\,k_{amide'}}{1 + K\,(OH^-)} + \frac{(OH^-)^2\,k_{amide''}}{1 + K\,(OH^-)} \quad \text{(Eq. 20)}$$

$$k_{acid} = \frac{(OH^-)^2\,k_{acid'}}{1 + K\,(OH^-)} \quad \text{(Eq. 21)}$$

$$k = k_{acid} + k_{amide} \quad \text{(Eq. 22)}$$

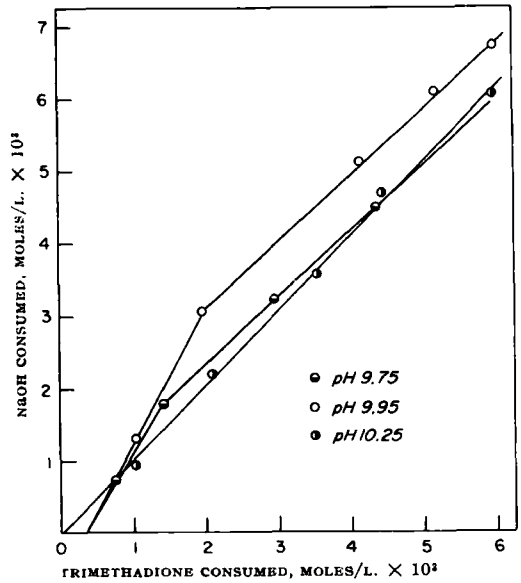

Fig. 8.—Plots showing uptake of hydroxide ion *versus* quantity of trimethadione degrading during hydrolysis reaction.

Using Eq. 21 and substituting observed values for k_{acid} at several hydroxide ion concentrations, it is possible to solve for the two unknowns, $k_{acid'}$ and K. These constants were determined from data obtained in the pH range 9.50 to 10.75. Using Eq. 20 and substituting the known value for K, and selecting values for k_{amide} at several hydroxide ion concentrations from Table I, simultaneous equa-

tions may be employed to determine $k_{amide'}$ and $k_{amide''}$. The coefficients thus calculated are

$$k_{acid'} = 0.965 \times 10^{7}\ \text{hr.}^{-1}$$
$$k_{amide'} = 0.074 \times 10^{1}\ \text{hr.}^{-1}$$
$$k_{amide''} = 1.491 \times 10^{7}\ \text{hr.}^{-1}$$
$$K = 2.564 \times 10^{3}$$

Using the above coefficients in the overall rate equation (Eq. 19) the theoretical rate of disappearance of trimethadione was calculated for the pH range of 7.5 to 11.0. The calculated rate appears as a solid line in Fig. 9. The rate expression predicts that the overall rate for disappearance of trimethadione should be first order with respect to hydroxide ion below pH 8.75 and above pH 11.0, and that the order is non-integral between pH 8.75 and 11.0. The experimentally determined rates are in good agreement with the theoretical and the rate does become first order with respect to hydroxide ion below pH 8.75. It was not feasible to study the reaction above pH 11.0 to examine for first-order hydroxide ion dependency because of the extremely rapid reaction under these conditions.

Comparison of Hydrolysis Rates for Cyclic and Acyclic Compounds.—Trimethadione is much more sensitive to alkaline hydrolysis than are acyclic compounds of similar structure. At pH 10 and 30° trimethadione is hydrolyzed at a rate approximately 10^{6} times that of ethyl-N-methylcarbamate (8), and approximately 10^{5} times the rate at which ethyl carbamate (urethan) (8) is hydrolyzed under similar conditions.

Rekker and Nauta (1) demonstrated that, in the presence of alkali, carbamylo-α-hydroxy esters are not hydrolyzed directly but are first converted to a trimethadione-type cyclic intermediate which then hydrolyzes to produce as products an N-substituted-α-hydroxy amide and the salt of a carbamylo-α-hydroxy acid. (See reaction scheme below.)

The extreme sensitivity of the trimethadione structure to alkaline hydrolysis (when compared with acyclic structures) suggests that the trimethadione structure might be of interest as an enzyme model or as an intermediate in the decomposition or metabolism of related drugs.

Pharmaceutical Significance.—From the theoretical rate equation proposed, half-life values for hydrolysis of trimethadione were calculated as a function of pH and are listed in Table II. It should be noted that these values are for solutions in which constant hydroxide ion concentration is maintained throughout the course of the reaction. Since trimethadione is usually employed in high concentration (5%) and since hydroxide ion is consumed in the hydrolysis reaction, the reaction presumably is self-limiting in unbuffered or weakly buffered solutions.

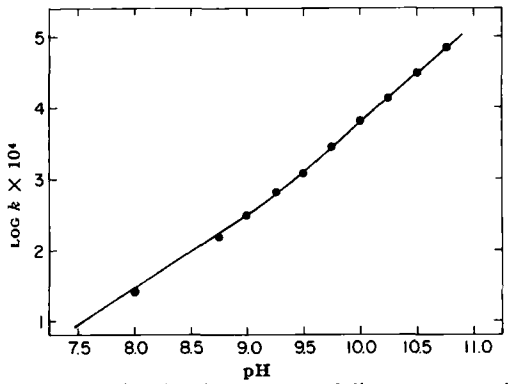

Fig. 9.—Plot showing the rate of disappearance of trimethadione as a function of hydroxide ion concentration over the pH range 8.0 to 11.0. The theoretical curve as calculated from the rate equation is shown as a solid line. The circles are experimental points determined at 30°.

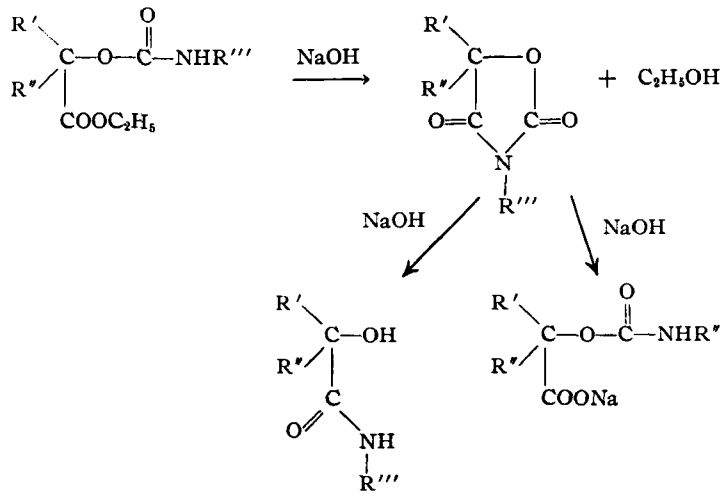
TABLE II.—HALF-LIFE PERIODS, $t^1/_2$, FOR THE DEGRADATION OF TRIMETHADIONE AT CONSTANT pH AND 30° C. CALCULATED FROM THE THEORETICAL RATE EQUATION

pH	Half-life, hr.
7.0	2472
8.0	247
9.0	25.3
10.0	1.11
11.0	0.047

SUMMARY

1. An infrared method is reported for determination of trimethadione in the presence of products of its hydrolytic decomposition.



2. The kinetics of the base catalyzed hydrolysis of trimethadione (3,5,5-trimethyl-2,4-oxazolidinedione) have been determined for the pH range 8.0 to 10.75 at 30°. Pseudo–first order rate coefficients are reported for the disappearance of trimethadione and for the parallel pseudo–first order appearance of the decomposition products N-methyl-carbamylo-α-hydroxyisobutyric acid and N-methyl-α-hydroxyisobutyramide. The amide is the principal product below pH 8.75, with the acid becoming an increasingly important product above pH 9.50.

3. The overall rate of disappearance of trimethadione in aqueous solution, at constant hydroxide ion concentration, was found to be in agreement with a rate equation of the form

$$\frac{\text{Rate}}{T} = \frac{K(OH^-)\,k_{amide'}}{1 + K(OH^-)} + \frac{(OH^-)^2\,k_{amide''}}{1 + K(OH^-)} + \frac{(OH^-)^2\,k_{acid'}}{1 + K(OH^-)}$$

4. A mechanism was proposed in which there exists a rapidly reversible equilibrium between the cyclic trimethadione and an acyclic structure.

5. Trimethadione is much more sensitive to alkaline hydrolysis than acyclic compounds of similar structure. Trimethadione hydrolyzes approximately 1,000,000 times as fast as ethyl-N-methylcarbamate and approximately 100,000 times as fast as ethyl carbamate (urethan) at pH 10 and 30°.

Determination and Identification of *p*-Hydroxyamphetamine as the O,N-Diacetyl Derivative

By LLEWELLYN H. WELSH and A. FRANCIS SUMMA

Therapeutic solutions of hydroxyamphetamine hydrobromide, such as the ophthalmic solution U.S.P. and nasal solution, N.N.R. (N.N.D.), may be assayed gravimetrically by treating with acetic anhydride in the presence of bicarbonate and quantitatively isolating the O,N-diacetylhydroxyamphetamine thus formed. The properties of the readily crystallizable derivative serve to identify the parent substance.

TESTS AND STANDARDS for New and Nonofficial Remedies" (1) includes monographs for a 1% nasal solution and a 1% ophthalmic solution of *p*-hydroxyamphetamine hydrobromide. The assay specified for the former solution involves liberation of hydroxyamphetamine base with potassium carbonate, extraction of the base into ether, addition of excess standard acid to the extract, and back-titration after evaporation of the ether. The assay specified for the latter solution is based on measurement of its absorbance at 225 mμ.

Vincent, Krupski, and Fischer (2) have reported an alkalimetric method in which the solution containing a salt of hydroxyamphetamine is passed through a column of Amberlite IR-45. The base so formed is titrated after being eluted with ethanol. Varga and Vastagh (3) have developed a bromometric assay applicable to therapeutic solutions of hydroxyamphetamine.

The alkalimetric methods and the procedure of Varga and Vastagh are relatively nonspecific. In regulatory work it would be necessary to supplement them with experimental data providing some assurance that consumption of reagent is due only to the substance to be quantitated. The N.N.R. (1) alkalimetric method is, in addition, somewhat tedious. Even with the salting-out effect produced by the specified high concentration of potassium carbonate (15 Gm. for a 20-ml. sample), seven extractions are required, and there are other difficulties related to the low specific gravity and high vapor pressure of ether. The N.N.R. spectrophotometric method, although convenient, is applicable only in the laboratory of the manufacturer since it requires employing as a blank the menstruum used in preparing the solution.

In the course of investigating alternative

Determination and Identification of *p*-Hydroxyamphetamine as the O,N-Diacetyl Derivative

By LLEWELLYN H. WELSH and A. FRANCIS SUMMA

Therapeutic solutions of hydroxyamphetamine hydrobromide, such as the ophthalmic solution U.S.P. and nasal solution, N.N.R. (N.N.D.), may be assayed gravimetrically by treating with acetic anhydride in the presence of bicarbonate and quantitatively isolating the O,N-diacetylhydroxyamphetamine thus formed. The properties of the readily crystallizable derivative serve to identify the parent substance.

TESTS AND STANDARDS for New and Nonofficial Remedies" (1) includes monographs for a 1% nasal solution and a 1% ophthalmic solution of *p*-hydroxyamphetamine hydrobromide. The assay specified for the former solution involves liberation of hydroxyamphetamine base with potassium carbonate, extraction of the base into ether, addition of excess standard acid to the extract, and back-titration after evaporation of the ether. The assay specified for the latter solution is based on measurement of its absorbance at 225 mμ.

Vincent, Krupski, and Fischer (2) have reported an alkalimetric method in which the solution containing a salt of hydroxyamphetamine is passed through a column of Amberlite IR-45. The base so formed is titrated after being eluted with ethanol. Varga and Vastagh (3) have developed a bromometric assay applicable to therapeutic solutions of hydroxyamphetamine.

The alkalimetric methods and the procedure of Varga and Vastagh are relatively nonspecific. In regulatory work it would be necessary to supplement them with experimental data providing some assurance that consumption of reagent is due only to the substance to be quantitated. The N.N.R. (1) alkalimetric method is, in addition, somewhat tedious. Even with the salting-out effect produced by the specified high concentration of potassium carbonate (15 Gm. for a 20-ml. sample), seven extractions are required, and there are other difficulties related to the low specific gravity and high vapor pressure of ether. The N.N.R. spectrophotometric method, although convenient, is applicable only in the laboratory of the manufacturer since it requires employing as a blank the menstruum used in preparing the solution.

In the course of investigating alternative

Received October 23, 1962, from the Division of Pharmaceutical Chemistry, Bureau of Biological and Physical Sciences, Food and Drug Administration, U. S. Department of Health, Education, and Welfare, Washington 25, D. C.
Accepted for publication November 15, 1962.

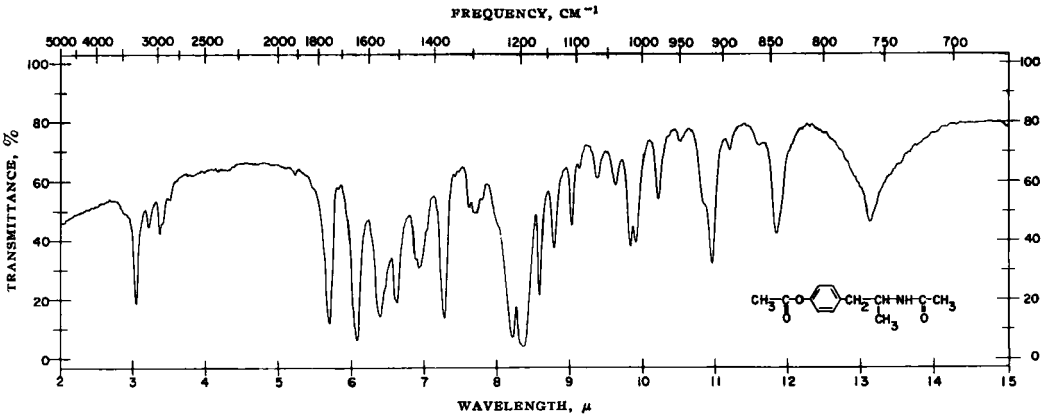

Fig. 1.—Infrared absorption spectrum of crystalline O,N-diacetyl-*p*-hydroxyamphetamine (1 mg.) in 0.5 in. (200 mg.) KBr disk. Recorded with a Perkin-Elmer model 21 spectrophotometer.

methods of assay acceptable for regulatory use, application was made of the general procedure for acetylation which has proved useful in the analysis of other sympathomimetic amines (4–6). Under the conditions of the procedure (dilute solution of the drug in *ca.* 10% aqueous bicarbonate), *p*-hydroxyamphetamine reacts rapidly and quantitatively with acetic anhydride to form the O,N-diacetyl derivative which may be extracted easily into chloroform and weighed after removal of solvent. This is the basis of the assay presently proposed. The method is manipulatively less difficult than the N.N.R. alkalimetric assay, requires one-half as much sample (10 ml.), and is applicable to individual units of the size most commonly marketed (15 ml.).[1] Furthermore, it provides a readily crystallizable derivative, the properties of which serve to identify the drug and give an indication of its purity.[2]

EXPERIMENTAL

Assay.—Pipet 10 ml. of hydroxyamphetamine hydrobromide solution (1%) into a 125-ml. separator. Extract with 15 ml. of chloroform; discard the extract. Rinse the stopper and mouth of the separator with a few drops of water and allow the rinsings to combine with the contents. Add 1.05 Gm. of sodium bicarbonate, preventing it from contacting the mouth of the separator, and swirl until most of the bicarbonate has dissolved. By means of a 1-ml. syringe, rapidly inject 0.50 ml. of acetic anhydride into the contents of the separator, stopper the vessel immediately, and shake it vigorously until the evolution of carbon dioxide has ceased, releasing the pressure as necessary through the stopcock. Allow to stand for 5 minutes and extract the solution with five 10-ml. portions of chloroform; filter each extract through a pledget of cotton (previously washed with chloroform) into a beaker.

Evaporate the combined extracts on a steam bath in a current of air to about 3 ml., completely trans-

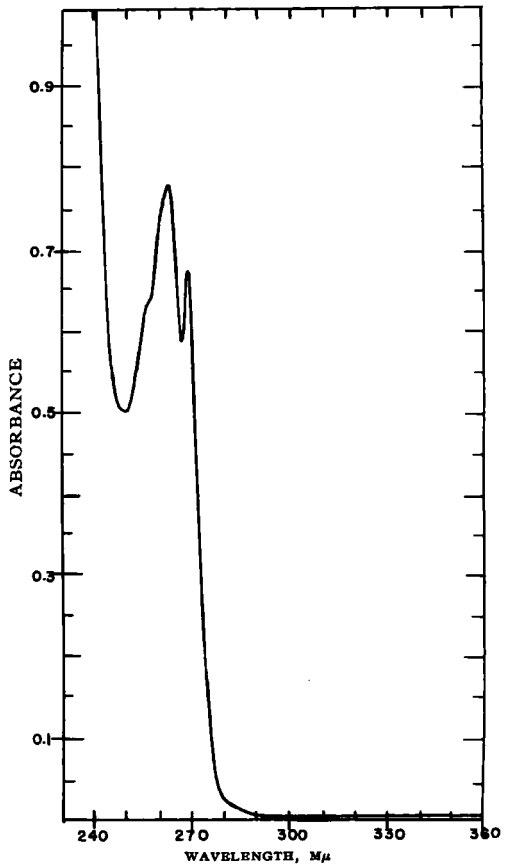

Fig. 2.—Ultraviolet absorption spectrum of O,N-diacetyl-*p*-hydroxyamphetamine in 95% ethanolic solution (400 mg./L., 1-cm. cell). Recorded with a model DK-2 Beckman spectrophotometer: ϵ_{265} = 368, ϵ_{271} = 315.

[1] The assay is now part of the monograph for hydroxyamphetamine hydrobromide ophthalmic solution, recently recognized by the U.S.P. (7).

[2] Identification of the product obtained in the assay does not establish unequivocally the identity of the solute since the same substance would be isolated if the solution originally contained *p*-hydroxyamphetamine, its diacetyl derivative, either of the two possible monoacetyl derivatives, or any combination of the four substances. However, the possibility would appear remote that any one of the relatively inaccessible acetylation products would find its way into a commercial preparation either by accident or design.

fer the concentrate by means of small portions of chloroform to a tared 50-ml. beaker, and continue the evaporation until the solvent is completely removed. Heat the residue of diacetyl derivative at 80° for 90 minutes, cool in a desiccator and weigh. (Weight of the residue × 0.9866 = weight of *p*-hydroxyamphetamine hydrobromide.)

O,N - Diacetyl - *p* - hydroxyamphetamine.—The white crystalline substance (m.p. 97.5 to 98.5°) obtained in the assay was recrystallized from carbon tetrachloride (6 ml./Gm.; 95% recovery). Twice-recrystallized material melted at 98 to 98.5° and exhibited the following optical crystallographic properties:[3] (*a*) *habit*–needles, and rods, some in bundles broader at one end than at the other; (*b*) *refractive indices*–α = 1.538, β = 1.548 (common), γ = 1.604 (all ± 0.003); (*c*) *extinction*–parallel and inclined; (*d*) *optic sign*–positive; (*e*) *elongation*–positive and negative; (*f*) 2*V*–moderately small.

The infrared and ultraviolet spectra are shown in Figs. 1 and 2, respectively.

Anal.–Calcd. for $C_{13}H_{17}NO_3$: C, 66.36; H, 7.28; N, 5.95. Found:[4] C, 66.30; H, 7.47; N, 6.03.

RESULTS AND DISCUSSION

Five assays of a 1% standard solution of hydroxyamphetamine hydrobromide[5] gave recoveries in the range of 100.2 to 100.6% (av. 100.5%). Duplicate assays of a solution prepared to contain 1% of the drug, boric acid (2%), and thimerosal (1:50,000) yielded recoveries of 100.6 and 101.0%, whereas five assays of a commercial ophthalmic solution of the same declared composition afforded results corresponding to 101.1 to 101.4% (av. 101.2%) of the declared amount of active ingredient (m.p. of isolated derivative 97.5 to 98.5°).

Coincidence of the infrared spectrum of the derivative with that of authentic diacetyl-*p*-hydroxyamphetamine is, *per se*, sufficient to identify the parent substance within the limitations discussed.[2] If infrared spectrophotometric equipment is not available, the base (8–10) may be extracted from the solution and identified by the classical methods of qualitative organic analysis. In addition to the hydrobromide (10, 11), the following easily prepared derivatives of *p*-hydroxyamphetamine have been reported in the literature: hydrochloride (9, 12–14), hydriodide (8), 2,4-dinitrobenzoic acid salt, and N-benzoyl derivative (15). Color reactions of *p*-hydroxyamphetamine and its behavior with alkaloidal precipitants have been described by Haley (16).

Influence of Organic Groups on the Polarographic Stability of Mercury Compounds

By SISTER M. LAWRENCE O'DONNELL, ANSELMA SCHWARZKOPF, and CORNELIUS W. KREKE

Polarograms of 26 organic mercurials with different R structures were made. The half-wave potentials of these compounds correlate qualitatively with the polarizability of the R structure and the polarities of the mercury-chloride bond in the first wave and the carbon-mercury bond in the second. The polarographic reductive stability of the ring molecules below that of the chain compounds agrees with the greater electronegativity of the rings. Compounds which have found clinical usefulness as diuretics have similar polarographic properties. It is suggested that the electron density of the mercury may be the basis of the biological selectivity of these organic compounds.

IN SPITE OF their great affinity for sulfhydryl groups, organic mercurials show considerable differences in binding with protein. While these differences may be due in some instances to the configurations of the mercurials or to affinities for buffer ions or secondary groups of the protein surface, it seems also that their individual affinities for the sulfhydryl group itself must be a factor.

As an instance of this latter phenomenon it was found that phenylmercuric hydroxide (PMOH) differed from *p*-chloro-mercuribenzoate (PCMB) in its binding on egg albumin (1). Although both have similar configurations and both are known to combine readily with sulfhydryl, PMOH reacted with one SH under the same conditions that PCMB reacted with two. Moreover, under the same conditions, PMOH showed considerable non-sulfhydryl binding while PCMB possessed no affinity for secondary sites.

In this study the half-wave potentials of a series of organic mercury compounds of the type RHgX were determined in order to estimate the influence of a wide assortment of R structures and substituents on the ease of reduction of the mercury-anion bond. It is hoped that this information may suggest some correlation between the binding capacity of organic mercurials for proteins and the electronic influence of the organic moiety, possibly becoming a basis for the interpretation of their biological activity.

The compounds were studied in the supporting electrolyte, 0.1 *M* $NH_4Cl \cdot NH_4OH$, pH 7.4 being present mainly as the chloride species (2), except for 1,1′-oxalyldiiminobis (2-methoxy-trimethylenemercuri) bis-(2,5-dioxo-4-imidazolidineacetic acid, and 2,4-dioxo-3-imidazolidylmercuri-mercaptoacetic acid. In the former compound the mercury is bound to the nitrogen of the imidazolidine ring; in the latter compound the mercury is bound in a mercaptide.

None of these reductions is reversible; nevertheless, the waves are considered to be largely diffusion-controlled as judged by the normalcy of the polarograms at the low concentration levels employed (3) and the agreement between the depolarizing influence of the R groups and the polarographic stability.

METHODS AND MATERIALS

The mercurials studied are listed in Table I. Many were obtained as generous gifts from pharmaceutical houses[1] (PMOH) and phenylmercuric acetate (PMAC) were purchased from Berk and Co.; *p*-chloromercuribenzoate (PCMB) was obtained from Bios Laboratories, and *p*-tolylmercurichloride (PTMC), methylmercurichloride (MMC), and ethylmercurichloride (EMC) were purchased from Delta Chemical Works, Inc.

PMOH, PMAC, and PCMB were recrystallized before using. The other compounds were used as obtained. The purity of these compounds was judged to be sufficient for these studies from the data obtained with the samples.

Stock solutions of the mercurials were made at concentration level of $2 \times 10^{-4} M$. The mercurial was dissolved usually in water. In some cases (as with PCMB) it was necessary to dissolve it in a small amount of concentrated NH_4OH, neutralize with HCl, and dilute with supporting electrolyte solution to the desired concentration. Stock solutions were diluted with 0.2 *M* ($NH_4OH \cdot NH_4Cl$) before use, and the polarographic stability of the mercurial was observed at a concentration of $1 \times 10^{-4} M$. Possible decomposition of the solution was determined from a comparison of the polarograms of older solutions with those of a freshly prepared one. Where necessary, solutions were freshly prepared weekly.

Received August 17, 1962, from the Department of Chemistry, Mount Mercy College, Pittsburgh, Pa.
Accepted for publication December 17, 1962.
Portion of paper presented to the American Chemical Society, St. Louis meeting, 1961.
Supported by Grant No. RG-5947 from National Institutes of Health, United States Public Health Service, Bethesda, Md.

[1] Abbott Laboratories, Ciba Pharmaceutical Products, Inc., Lakeside Laboratories, Inc., Merck Sharp and Dohme Research Laboratories, Parke Davis and Co., The Squibb Institute, Sterling Winthrop Research Institute, The Upjohn Co., and Wyeth Laboratories, Inc.

The polarograms were obtained with an American optical recording electropolarizer model G-1 using a dropping mercury electrode. The drop time of the mercury electrode was 2.5 seconds per drop with a constant pressure of 16.5 cm. of mercury.

The temperature of the mercurial solutions was kept constant at 25° in a water bath. The solutions were deoxygenated by passing in oxygen-free nitrogen for 20 minutes. The solutions were allowed to equilibrate in the water bath for 10 minutes prior to the determinations.

RESULTS

Except for a few compounds—2-hydroxymercuri-3-methoxy-3-phenyl propanoic acid, N-(3-chloromercuri-2-piperidino-propyl) nicotinamide dihydrochloride, 1,1′-oxalyldiiminobis(2-methoxy-trimethylenemercuri)bis(2,5-dioxo-4-imidazolidineacetic acid), 2-acetomercuri-3-methoxy-butanoic acid, and 2,4-dioxo-3-imidazolidylmercuri-mercaptoacetic acid—which exhibited a single reductive wave, all of the mercurials listed in Table I were decomposed irreversibly in a two-step process. Benesch and Benesch (4) and later Wuggatzer and Cross (5) found that PCMB, phenylmercuric chloride (PMC), and phenylmercuric nitrate (PMN) are decomposed polarographically in two-electron steps, resulting in the formation of the organic mercurial radical in the first step and the reduction of this radical in the

[a] Marketed as Mercurhydrin by Lakeside Laboratories. [b] Marketed as Neohydrin by Lakeside Laboratories.

second step to benzene and metallic mercury. This two-step reduction was also observed for a series of phenylmercuric amide and imide compounds (6).

It would be expected that the polarographic stability of PMOH, PMAC, and phenylmercuric glyconate should be identical because of the excess of chloride ion, and this is found to be true within ± 0.02 v. (see Table I). Taking this deviation as an allowable experimental error for all the determinations, it will be observed from the table that the R group of the mercurials has considerable influence on the half-wave potential. The phenyl ring compounds have the lowest and MMC and EMC the greatest negative $E_{1/2}$. Chain compounds with a β-methoxy group and biuret or urea in the chain have intermediate values. The entire range of voltage for the compounds varies from −0.127 v. for the phenyl compounds to −0.490 v. for EMC.

The direction of this change follows closely the depolarization effect of the R groups on the polarity of the mercury-chloride bond resulting in a change in the electron density of the mercury. Compounds in which mercury is attached directly to the benzene ring would be expected to have a higher polarity of the Hg-Cl bond, *i.e.*, a lower electron density on the mercury. The decomposition of these compounds at lower voltage agrees with the known polarizability of the benzene ring or its electronegativity to use Kharash's terminology (7).

The influence of substituents in the ring, on the other hand, seems to have relatively minor effects. The −E and −I effect of the *meta* nitro group is not shown, apparently being offset by the +E effect of the *p*-methoxy as in 1-acetomercuri-3-nitro-4-methoxy-benzene. Compound 2-nitro-3-hydroxy-4,6-diacetomercuritoluene having the same substituents in the ring has a lower decomposition potential. Possibly the electrophilic character of the two chloromercuri groups may be a factor. Compound 2-chloromercuriphenol shows no influence of an *ortho* phenolate ion. The influence of a *para* carboxyl ion in 4-chloromercuribenzoic acid (*p*-chloromercuribenzoate, PCMB) increases the half-wave potential significantly. The *para* methyl group in 1-methyl-4-chloromercuri-benzene (*p*-tolyl-mercurichloride, PTMC) and a substituted sulfonamide group in 1-benzene sulfonamide-4-chloromercuribenzene show considerable polarographic stabilizing influence.

Among the chain compounds the greater polarographic stability of chloromercurimethane (methylmercurichloride, MMC) and chloromercuriethane (ethylmercurichloride, EMC) suggests a large depolarization of the mercury-chloride bond. The influence of a β-methoxy and the other groups on the chain is shown by the lower decomposition potentials of the remaining compounds. Assuming a standard variation of ±0.02 v. compounds N-(3-chloromercuri-2-piperidinopropyl) nicotinamide dihydrochloride to 2-acetomercuri-3-methoxy-butanoic acid of Table I have the same decomposition voltage, −0.270 ± 0.02 v. Compound N-(3-chloromercuri-2-piperidinopropyl) nicotinamide dihydrochloride has a mercury attached to an aromatic pyridine ring with the substituted piperidine ring in the β-position to the mercury. The chain compounds of this intermediate group are all β-methoxy chain compounds which may account for their similarity of decomposition potential.

The decomposition potential, −0.373 v., of 2,4-dioxo-3-imidazolidylmercuri-mercaptoacetic acid is considerably higher than that of the group, −0.270 ± 0.02 v. This high value is obtained because the decomposition potential is that of a mercaptide in which the polarity of the Hg-S bond is less than the Hg-Cl bond (8).

Compound 2-acetomercuri-3-methoxy-butanoic acid is somewhat more stable than the group of methoxy compounds. Its decomposition potential is −0.285 v. It is interesting that the analog of this compound, 2-hydroxymercuri-3-methoxy-3-phenyl propanoic acid, in which the β-methyl is replaced with phenyl, is lower than the group −0.198 v. In both cases there is a carboxyl group bound to the same carbon as the Hg. The higher decomposition potential of 2-acetomercuri-3-methoxy-butanoic acid follows a depolarization effect of the carboxyl ion but a higher electronegativity of the phenyl ethyl group in 2-hydroxymercuri-3-methoxy-3-phenyl propanoic acid may also be a factor in lowering the potential.

Table I gives the decomposition potentials of the second wave for the aromatic ring compounds. Presumably at this potential the phenyl mercury radical is decomposed to benzene or a substituted benzene and mercury. Again using the results obtained with acetomercuribenzene (phenylmercuric acetate, PMAC), hydroxymercuribenzene (phenylmercuric hydroxide, PMOH), and glyconomercuribenzene as an estimate of the variations expected, the range of decomposition voltage obtained is −0.859 v. to −0.924 v. or −0.891 ± 0.03 v. It will be observed that only three of the compounds, 2-nitro-3-hydroxy-4,6-diacetomercuritoluene, 1-acetomercuri-3-nitro-4-methoxy-benzene, and 1-benzene sulfonamido-4-chloromercuribenzene, fall outside this range indicating that influences of substituents such as OH, COOH, or CH_3 are slight. From an electronegativity point of view, a small influence would be expected since the polarity of the mercury-carbon bond is less than that of the mercury-chloride bond. Compounds 2-nitro-3-hydroxy-4,6-diacetomercuritoluene and 1-acetomercuri-3-nitro-4-methoxy-benzene contain a nitro group in the ring and show unusually high polarographic stability. This strange effect is still in agreement with the idea of polarizability of groups when it is remembered that the nitro group is reduced under the conditions of these experiments to hydroxylamine in a four-electron step. This wave was observed at approximately −0.4 v. The +E effect of this reduced group would result in a decreased polarity of the carbon-mercury bond. This is in agreement with the greater negative half-wave potential of the compound.

A similar relationship was observed in a pH study of *o*-chloromercuriphenol. With increased pH there was an increased polarographic stability of the compound in a general correlation with the +E activity of the phenolate ion (see Table II). In this study a measure of the decomposition potential of the first wave gave anomalous results possibly due to bonding of the mercury to the *ortho* phenolate group. No significant change in the potentials of the first wave was observed over the entire pH range (5.07 to 10.23).

A similar relation between depolarization effects

TABLE II.—EFFECT OF pH ON SECOND HALF-WAVE OF *ortho*-CHLOROMERCURIPHENOL

pH	$-IIE_{1/2}$
5.07	0.608
5.98	0.763
6.70	0.776
6.70	0.840
7.73	0.796
8.71	0.884
10.23	0.946
10.23	0.888

and half-wave potentials was also observed in a study of the second decomposition of the chain compounds. The results of this study are given in Table I. Several of the chain compounds, 2-(3-hydroxymercuri-2-methoxy-propyl carbamyl) nicotinic acid; (salyrganic acid) 2-(3-hydroxymercuri-2-methoxypropyl) carbamyl-phenoxy acetic acid; 1-[3-(chloromercuri)-2-methoxy-propyl] biuret; N-(2-methoxy-3-chloromercuripropyl) urea; N,N'-bis-[3-(hydroxymercuri)-2-methoxypropyl] oxamide, diacetate ester; chloromercurimethane (methylmercurichloride, MMC), and chloromercuriethane(ethylmercurichloride, EMC), exhibited maxima with sloping plateaus at the second reduction. This made the estimation of their half-wave potentials difficult and inaccurate. The positions of the maxima are reported along with the approximate $E_{1/2}$. Undoubtedly, these abnormalities are due to adsorption and reactivity of the radicals but the position of the maximal wave is of some interest in terms of the polarization effects of the R groups. With PMOH as standard with a decomposition voltage of -0.891 ± 0.03 v., it will be observed that chain compounds N-(2-methoxy-3-hydroxymercuri-propyl) biuret; 2-{N,N-bis[3-(chloromercuri)-2-methoxy-propyl] carbamyl-phenoxy} acetic acid, and the theophylline salt of N-(2 - methoxy - 3 - hydroxy - mercuripropyl) - N'-succinyl urea are equally stable polarographically. These are β-methoxy chain compounds and the theophylline salt of N-(2-methoxy-3-hydroxy-mercuripropyl)-N'-succinyl urea has, in addition, an added theophylline ring. Compounds chloromercurimethane (methylmercurichloride, MMC) and chloromercuriethane (ethylmercurichloride, EMC) appear again as the most stable, correlating the +I effect of the methyl and ethyl chains, respectively. Compounds N,N-bis(3-chloromercuri-2-methoxy-propyl) biuret; N,N-bis(3-chloromercuri-2-methoxy-propyl) urea; 2-(3-hydroxymercuri-2-methoxy-propyl carbamyl) nicotinic acid; (salyrganic acid) 2-(3-hydroxymercuri-2-methoxy-propyl) carbamylphenoxy acetic acid; 1-[3-(chloromercuri)-2-methoxy-propyl] biruet; N-(2-methoxy-3-chloromercuripropyl) urea, and N,N'-bis[3-(hydroxymercuri)-2-methoxy-propyl] oxamide, diacetate ester are methoxy chain compounds and have an average decomposition potential of -0.983 ± 0.06 v.

As was stated before, 2-hydroxymercuri-3-methoxy-3-phenyl propanoic acid; N-(3-chloromercuri-2-piperidinopropyl) nicotinamide dihydrochloride; 1,1' - oxalyldiiminobis(2 - methoxy - trimethylenemercuri)bis(2,5-dioxo-imidazolidineacetic acid); 2-acetomercuri-3-methoxy-butanoic acid, and 2,4-dioxo-3-imidazolidylmercuri-mercaptoacetic acid appeared anomalous in that they exhibited a single reductive wave. Presumably this reduction may involve the addition of two electrons. An electronic interpretation would require that the two mercury bonds have the same polarity. This cannot be answered with the present data available, but it is interesting that in 2,4-dioxo-3-imidazolidylmercuri-mercaptoacetic acid the mercury is bonded to sulfur and nitrogen and in 1,1'-oxalyldiiminobis-(2-methoxy-trimethylenemercuri)bis(2,5-dioxo-4-imidazolidineacetic acid), to nitrogen and carbon. Possibly, proximate groups may also influence the polarity of the bonds.

DISCUSSION

The relation of the depolarizing influence of the R group structure with the polarographic stability of the compounds at the first wave is consistent in general with a mercury-chloride bond polarity of Hg^{d+}–Cl^{d-}. Those groups attracting electrons decrease the electron density on the mercury and those donating electrons decrease the polarity. Since the polarographic influence of the R group in the second reduction is in the same direction, an electronic interpretation would suggest that the polarity of the carbon-mercury radical bond is C^{d+}–Hg^{d-}. Radical formation does not occur apparently with all the compounds studied. In these cases there may be similar polarities in the two mercury bonds, as for instance in a compound in which the mercury is bonded to nitrogen and sulfur. This situation can be represented as N^{d-}–Hg^{d+}–S^{d-}.

At present, some organic mercurial compounds of the type

$$R—CH_2—\underset{\displaystyle OY}{\underset{|}{CH}}—CH_2—HgX$$

have found clinical usefulness as diuretics. While the X and Y groups have a small influence on activity, it is evident that the nature of the R group is fundamental (9). Compounds of the type R—Hg—X in which R is simply an aromatic ring or an aliphatic chain are not useful because of toxicity. It is interesting that the ring compounds of this type have low polarographic stability (see Table I) and those where R is a simple alkyl have large negative half-wave potentials. Among the intermediate compounds, polarographically speaking, are those which have found some clinical usefulness.

At present, it is impossible to correlate more closely toxicity or diuretic activity with half-wave potentials but this study suggests at least a possible basis for biological selectivity of the mercury compounds. From the demonstrated correlation between polarographic stability and polarizability of groups, it can be concluded that the R, X, and Y groups exert effects on the polarity of the mercury bonds and on the electron density around the mercury atom.

According to Boyer (2) the ease of dissociation of the mercury compound is apparently not of prime importance in biological activity. It seems from the work of Weiner and Müller (10) and others that the intact molecule is involved, at least in diuretic activity. If this is true, then possibly the electron density on the mercury plays the determining role in biological activity. This view is suggested by the rough correlation observed in the present work between polarographic stabilities and clinical usefulness

and by the fact that compounds of different polarographic stabilities exhibited correspondingly different inhibitory activities on trypsin proteolysis (work in progress).

This view of mercury activity proposes a mechanism by which organic groups may produce selectivity by controlling the electron density on the mercury moiety.

A New Oral Gelatinized Sustained-Release Dosage Form

By NOBUO TANAKA, SETSUKO TAKINO, and ISAMU UTSUMI

A new sustained-release micropellet was prepared which takes advantage of the relationship of gelatin solubility to the hardness of the gelatin caused by formalin treatment. This new gelatin micropellet could be produced more easily than the coated micropellet employed in the usual sustained-release dosage forms.

THE SUSTAINED-RELEASE principle has universal application in the field of practical pharmacy. It is generally understood that gelatin is digested in the human gastrointestinal tract and that the rate of hydrolysis of the gelatin can be varied by hardening. This suggested that if medication was dissolved or suspended in a gelating sol and the gelatin treated with formalin-isopropanol, the rate of hydrolysis in the gastrointestinal tract would decrease. In this study, the relationship of the hydrolysis to the grade of gelatin hardening was applied to produce a sustained-release gelatin micropellet.

As described in the *Experimental* section, the technique utilized to produce the gelatin sustained-release micropellet is easier than the more complicated and painstaking process required to produce the conventional coated micropellet. The gelatin micropellet (containing medication) had a diameter of 0.3 to 0.5 mm. To obtain the desired sustained-release effect, the gelatin micropellet was stored in 10% formalin-isopropanol at 2–5° for varying periods of time. From the results of the *in vitro* dissolution test, the treated gelatin micropellet was found to prolong protease hydrolysis.

Urinary excretion, blood concentration, and biological kinetic theory data have been employed to evaluate oral sustained-release dosage forms and such studies have been reported recently in the literature (1–5). We used chemical determinations of the amount of medication in the blood or urine to examine the delay in absorption and urinary excretion of the medication imbedded in the treated gelatin micropellets. As gelatin can be digested in the gastrointestinal tracts of carnivorous and omnivorous animals, five dogs and three humans were used to evaluate the *in vivo* sustained-release of sulfanilamide (SA) and riboflavin (RF) through blood concentration determinations.

EXPERIMENTAL

Preparation of Dosage.—Table I shows the physical properties of gelatin and mineral oil used in the production of the micropellets.

An apparatus to produce the micropellets also is shown in Fig. 1. The apparatus consists of a stainless steel vessel, stirring wing, and motor. Two-hundred grams of water was added to 60 Gm. of gelatin. After the gelatin swelled 40 Gm. of SA powder (less than 50 μ in diameter) was added.

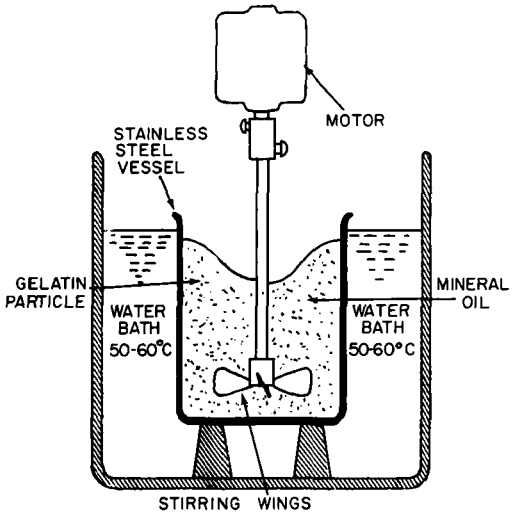

Fig. 1.—Apparatus used to produce gelatin micropellets.

TABLE II.—CHARACTERISTICS OF SA AND RF MICROPELLETS

Size	Yield, %	Content, %
SA		
Less than 24 mesh	7	38.08
24–35 Mesh	72	31.12
35–50 Mesh	17	20.32
More than 50 mesh	4	10.54
RF		
Less than 24 mesh	4	5.15
24–35 Mesh	81	5.10
35–50 Mesh	13	5.25
More than 50 mesh	2	5.30

The mixture was warmed on a steam bath to form a sol. Gelatin sol was poured into 600 Gm. of mineral oil heated previously to about 55–60° and stirred at 18–22 r.p.m. After 5 or 6 minutes, the vessel was steeped in ice water, cooled quickly to less than 5°, and kept at the same temperature until the gelatin microdrops became a perfect gel. After 300 Gm. of about 5° isopropanol was added to the vessel for dehydration, the solution was stirred about 5 minutes; then the gelatin micropellets were separated. The micropellets were then washed two times with 100 Gm. of 5° isopropanol and dried until the alcohol disappeared. The sustained-release effect of micropellets were obtained by immersing 1 Gm. of the micropellets into 10 ml. of 10% formalin-isopropanol in a covered vessel and hardened in a refrigerator at 2–5° for 24 hours and dried.

The method of RF was almost the same as with SA. One-hundred and seventy grams of water was added to 76 Gm. of gelatin. After the gelatin swelled, 4 Gm. of RF powder (less than 50 μ in diameter) was added, and the same procedure with SA was used. The hardening time of the micropellets was 24, 48, or 72 hours. These micropellets are shown in Tables II and III.

In Vitro Dissolution Experiment.—Micropellets equivalent to 100 mg. of SA and 200 ml. of simulated gastric fluid (dissolution medium) were put into a flask and immersed in thermostat adjusted to 37 ± 1°.

At appropriate intervals of time, 20 ml. was removed from the flask for analysis; a similar volume of dissolution medium was added each time to maintain constant volume. Five milliliters of 20% trichloroacetic acid was added to a 20-ml. quantity used for analysis.

Animal Experiment.—Five mongrel dogs weighing approximately 7 Kg. were fasted overnight. The mixture of micropellets and a piece of wet bread were given orally to the dogs. Blood samples of 2 ml. were then withdrawn from the vein after 1, 2, 4, 6, 7, and 24 hours, respectively. Dogs were used repeatedly with a rest period of more than 6 days for their complete recovery.

Method of Analysis for SA.—Tsuda's (6) modification of the Bratton and Marshall (7) method was used. The blood was hemolyzed by spraying into distilled water. Color was developed using 0.1% Tsuda reagent (β-diethylamino-ethylaminophthalene oxalate). Equivalent quantities (2 ml.) of blood were used in the preparation of the standard curve.

Method of Analysis for RF.—The method of analysis for RF was Yagi's method (8). Hemolyzed blood was decomposed with exposure to light. After acidifying by acetic acid, it was extracted with chloroform. Standard lumiflavin solution was prepared using 1 mcg./ml. standard RF solution instead of blood.

RESULTS AND DISCUSSION

As shown in Table IV, it is obvious from the results on various samples *in vitro* that hardened

micropellets have the prolongation of hydrolysis against protease in the simulated gastric fluid. In the RF micropellets, RF could not be measured by the same method as the *in vitro* test of SA micropellets because of the slight solubility of RF in simulated gastric fluid.

Dogs were given Sample I and Sample II orally at a dose of 250 mg. of SA per Kg. of body weight, and SA concentrations in blood were measured at the times shown. Blood concentration of SA reached a peak 3–4 hours after administration of Sample I. On the other hand, in Sample II maximum peak of SA concentration in blood appeared after 16

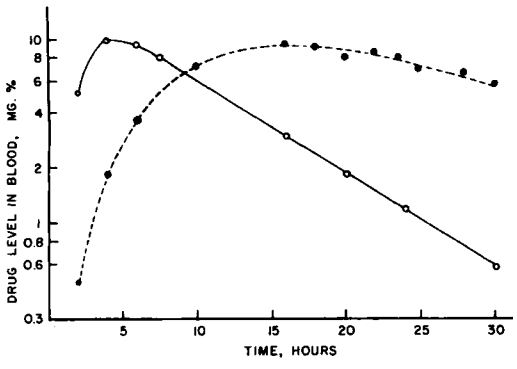

Fig. 2.—Logarithm of SA levels in blood against time after administration of SA gelatin micropellets to dogs. —O—O—, untreated micropellets; —●—●—●—, micropellets treated with formalin-isopropanol for 24 hours.

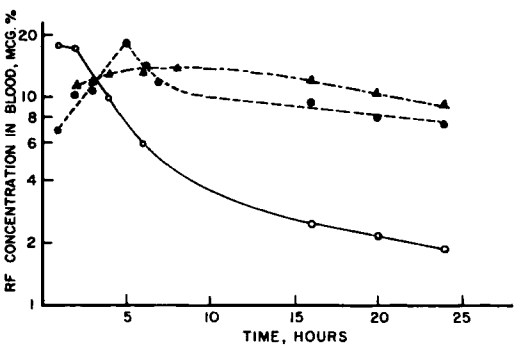

Fig. 3.—Logarithm of RF concentration in blood after administration of RF solution and its gelatin micropellets to dogs. —O—O—, RF solution; —●—●—●—, untreated micropellets; —▲—▲—▲— micropellets treated with formalin-isopropanol for 24 hours.

hours. Since the blood concentration of Sample II decreased more gradually than that of Sample I, it is certain that Sample II fulfills prolongation. The results of these experiments appear in Tables V and VI.

The decline of blood concentration of SA and its homologs after they had reached a maximum concentration, followed a pseudo first-order rate (5,9,10). To examine whether samples stayed in the digestive tracts, the logarithm of SA concentration in blood was plotted as a function of time (Fig. 2). A straight-line relationship of decrease resulted in Sample I after the maximum blood concentration. The possible interpretation is that Sample I almost dissolved in the gastrointestinal tracts in 3–4 hours. Sample II is considered to stay in the digestive tract for a long time since blood concentration increased until the 16th hour and decreased slowly after this. Judging from the above results, it is obvious that

gelatin micropellets hardened with formalin produce a sustained-release effect.

Both medication transport into blood and excretion in urine were determined on RF gelatin micropellets; the urinary excretion of RF is quicker than that of SA. Using the same dogs that were used in the experiment of SA micropellets, 1 mg. of RF per Kg. of body weight was administered to each dog and RF concentration in blood was determined. The results are shown in Fig. 3 and Tables VII–IX.

When Sample III was given to dogs (Fig. 3), the blood concentration gave a maximum level within 1 hour and then dropped quickly.

With Sample IV, RF concentration in blood reached a peak at about 4 hours; even 24 hours after dosing, RF concentration was higher than that of Sample III. In Sample V, a gradual rise occurred through 4 hours, reached a plateau and remained there for 3 hours, and 24 hours after

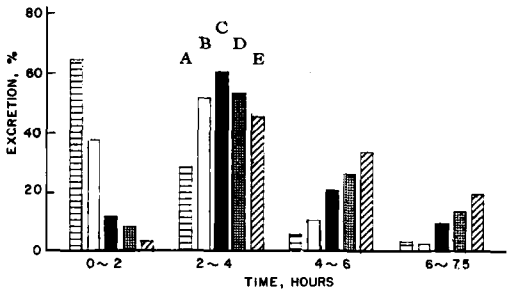

Fig. 4.—Ratio of RF in urine against time (after oral administration to three humans) if amount of accumulative RF excreted into urine for 7.5 hours is presumed 100%. A, RF solution, B, no treatment micropellets, C, micropellets treated for 24 hours, D, micropellets treated for 48 hours, E, micropellets treated for 72 hours.

dosing dropped to a blood concentration similar to Sample IV. Then the behavior of urinary excretion of RF in the load test on humans was examined. Results similar to those of the dogs were expected. The results are shown in Table X and Fig. 4.

When Sample III was administered, RF concentration in urine had a maximum value after 2 hours, but in other cases maximum excretion was shown about 4 hours after dosing. Table X shows that the recovered quantities of Samples VI and VII are lower than those of the other samples. This phenomena is probably due to the delay of excretion since the excreted quantities from 6 to 7.5 hours after administration rose proportionally to the time of treatment by formalin.

In these experiments there was a distinct difference in blood concentration response among Sample III, Sample IV, and Sample V. In the urinary excretion test, peak level of Sample II was observed 2 hours after dosing, while those of the other three samples appeared after 4 hours. Therefore, the sustained release of a certain drug cannot always be determined only by the peak of the urinary excretion, since the quantity excreted in urine is not directly related to blood concentration.

Kinetics of Steroid Effects on Ca^{47} Dynamics in Dogs with the Analog Computer II

By EDWARD R. GARRETT, RICHARD L. JOHNSTON, and ELLIOTT J. COLLINS†

The effect of adrenal steroids on the distribution of intravenously administered Ca^{47} has been studied further by use of an analog computer. A distributive model, consistent with the literature, has been programmed on the computer and has been shown to be in agreement with the fecal and blood serum levels of Ca^{47}. Adrenal steroid effects can be assigned to a decrease in the calcium capacity of the metabolic pool with respect to the calcium capacity of the blood and to enhanced transfer of calcium to the gastrointestinal tract. This distributive model has been correlated with the empirical equations computer-derived for fitting the Ca^{47} data. Blood levels and fecal excretion of Ca^{47} are enhanced by steroid and depressed on recovery. It has been definitely proved that when the quasi equilibria of radioactive calcium among blood, soft tissues, metabolic pool, and contents of the gastrointestinal tract have been achieved, the relatively slow fecal elimination of Ca^{47} at an apparently linear rate is doubled by the steroid administered and relapses to the control values on recovery. The phenomena are consistent with the hypothesis that adrenal steroids not only inhibit the entry of endogenous calcium into the bone and enhance its secretion into the gastrointestinal tract but also promote the resorption of calcium from bone.

THE PREVIOUS PAPER in this series (1) considered the kinetics of adrenal steroid effects in four dogs and fitted the obtained values of intravenously administered Ca^{47} in blood, feces, and urine as functions of time with the analog computer.

It had been observed that steroid regimen increased the amount of Ca^{47} accumulated in the feces and urine with respect to the amounts of a prior control or presteroid period, and that this increase was reversed subsequently on cessation of steroid dosage (1, 2). It had also been observed that Ca^{47} blood levels after intravenous administration of Ca^{47} were generally higher during the steroid regimen than during the prior control period (1, 2).

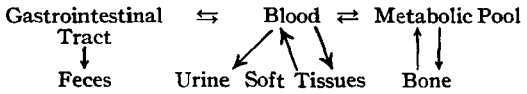
On recovery from steroid administration, a decreased rate in the resorption of Ca^{47} (possibly from the bone) was reflected in the long term fecal and urinary excretion of the radioisotope (1). Unfortunately, long term fecal and urinary excretion studies of Ca^{47} had not been conducted during the prior control periods.

The dogs in these previous studies (1) were relatively unmatched, were treated with antibiotics, and were biopsied. This chemotherapy and possible surgical shock may have had an indeterminate effect on the studies and their results.

In light of these circumstances it was believed that further detailed investigation was warranted to eliminate possible perturbing influences such as antibiotics or surgery, to take full advantage of the knowledge that prolonged studies of Ca^{47} fecal excretion may give insight into the effects of adrenal steroids on the resorption of calcium from bone, to use animals as "matched" as possible to evaluate the consistency of effects in control, steroid, and recovery phases, and to study induced osteoporosis in the fast growth period of the immature dog.

This paper reports on these investigations and utilizes the analog computer to quantify the blood levels, fecal, and urinary amounts of Ca^{47} as functions of time in accord with the method previously established (1). In addition, analog computer methods and techniques are used to fit a more realistic model for the compartmental transferences of Ca^{47}.

Such a model, variously modified, has been considered by several authors (3–7):



(Eq. 1)

It must be well understood that curve or data fitting with time can be accomplished not only by the model of Eq. 1 but also by kinetically equivalent models (3). For example, the transfer of calcium from the blood to the metabolic pool as mediated through the soft tissues may also fit the data. The amount of Ca^{47} excreted in the urine by the dog is small and would make a

[a] A_i are in per cent of initial total dose of Ca^{47}/ml. of serum and k_i are in sec.$^{-1}$ [b] Study A was the control study; Study B was during 2 mg./Kg./day steroid administration; the recovery Study C was conducted after cessation of steroid administration. [c] The injected doses of Ca^{47} were in c.p.m.–11.01 × 10^6 for A, 8.11 × 10^6 for B, and 14.3 × 10^6 for C.

negligible contribution to the overall balance of compartments and rates.

Reversible first-order expressions for Ca^{47} transfer between gastrointestinal tract and blood, between metabolic pool and blood, and between metabolic pool and bone are gross oversimplifications of complex physiological phenomena. However, such a model as Eq. 1 is most certainly a closer fit to reality than a linear equation of exponentials (1, 8–13).

The apparent first-order rate constants, k_i, which can be derived from analog computer fitting of the Ca^{47} data have an alternative interpretation as r/Ca_i, the fractional amount of calcium Ca_i renewed or turned over in a unit time where r is the turnover rate of calcium, amount/unit time, renewed in the compartment (see *Appendix*) (14, 15).

EXPERIMENTAL AND METHODS

Treatment of Animals.—Four beagles were used in these experiments. The animals were conditioned to the metabolism cages and laboratory routine prior to experimentation. Pertinent data for Dogs 1–4 given as initial age in days and sex are for Dog 1, 227 (F); Dog 2, 222 (F); Dog 3, 213 (M); Dog 4, 213 (M). The methods and procedures of intra-

[a] Where ΣP_i is expressed in terms of per cent total dose and k in sec.$^{-1}$ [b] This is the deviation from the first-order accumulation of Ca^{47}, *i.e.*, P_∞ where m is in per cent total dose/hour and t is in hours. [c] The injected doses of Ca^{47} were in c.p.m.–11.01 × 10^6 for Study A, 8.11 × 10^6 for Study B, 14.3 × 10^6 for Study C, for all dogs. [d] This column relates to per cent of the total dose as Ca^{47} remaining in bone at *ca.* 200 hours and as can be estimated from 100 $-P_\infty$(urine) $- P_\infty$(feces). [e] $R = m/\%\ Ca^{47}_{Bone}$ is an estimate of the resorption rate adjusted for the Ca^{47} content of the bone where $\%\ Ca^{47}_{Bone}$ is defined in *footnote f*. [f] An anomalously high count was obtained for the first urine samples during the control phases that did not appear for other phases or for the same control phase for other studies. Plots of Ca^{47} accumulated in urine for runs A *vs.* time showed an intercept value at zero time. A technological bias is implied. *Ignoring of this first value of the urine for* the control phase, runs A, brought the urine data into the same pattern as the fecal data. These first urine Ca^{47} values in control phase A which were ignored were (in terms of per cent of total Ca_0^{47} dose at zero time): Dog 1, 0.22%; Dog 2, 0.38%; Dog 3, 0.65%; Dog 4, 0.28%.

TABLE III.—ESTIMATED SECOND LINEAR RATE,[a] R' OF RESORPTION OF Ca^{47} FROM BONE DURING RECOVERY PHASE, STUDY C, AFTER CESSATION OF STEROID ADMINISTRATION

Dog	m'[a]	b'	$10^4R'$	t', Hrs.
1	0.0146	22.5	1.89	800
2	0.0117	30.5	1.67	690
3	0.0127	22.5	1.69	760
4	0.0115	20.5	1.45	750

[a] $R' = m'/\%\ Ca^{47}_{Bone}$ is an estimate of the second linear Ca^{47} fecal excretion rate with time after t' hours adjusted for the $\%\ Ca^{47}_{Bone}$ content presumed to be in bone. The $\%\ Ca^{47}_{Bone}$ value is derived from $100 - b'$ at t' hours, *i.e.*, the per cent of the original Ca^{47} dose not excreted in the feces at that time where $b' = \Sigma P_i$ at $t = t'$. The slope, m', is in per cent of total dose/hour of the cumulative Ca^{47} (per cent of original Ca^{47} dose), *i.e.*, excreted in the feces, *i.e.*, ΣP_i after $t = t'$ and $\Sigma P_i = m'(t - t') + b'$. At t', *ca.* 700 hours, a sharp discontinuity in the linear fecal excretion of Ca^{47} observed after 200 hours did occur and these data describe the properties of this new linear relation of the cumulative Ca^{47} excretion, ΣP_i, in the feces with time.

venous administration of Ca^{47} and of the determination of radioactivity in blood serum, urine, and feces have been detailed elsewhere (2).

The studies were conducted in three sequential phases. At the ages cited above 50 μc. of Ca^{47} were administered (control, Study *A*), and the Ca^{47} distribution was studied with respect to time. At "Day 20" after the initial administration of Ca^{47}, 2 mg./Kg./day of a typical corticoid, 6-α-methylprednisolone was administered orally and Ca^{47} was again intravenously injected at "Day 41" and its distribution studied with time (steroid, Study *B*). At "Day 61," the steroid regimen was reduced for each dog at the rate of 1 mg./day so that at "Day 81," steroid administration was ceased. At "Day 131," Ca^{47} was again administered and distribution studied with time (recovery, Study *C*).

The times of blood sampling and urine and feces collection after Ca^{47} administration were as previously given (1), except the feces and urine collections were prolonged for 25 days after Ca^{47} administration during the control and steroid studies and for 58 days during the recovery studies. No antibiotics were administered or biopsies were performed.

Treatment of Data.—The procedures used for calculating and treating the data from the blood serum, urine, and feces were given in detail in the previous publication (1). Sufficient sample was taken and time of counting used so that all counting error was less than 2%. As previously discussed, values were corrected for normal decay from the data obtained by the simultaneous counting of an aliquot of the initial Ca^{47} solution used for injection.

Curve Fitting and the Analog Computer.—The disappearance of labeled Ca^{47} from the blood after intravenous administration can be represented by a four-factor linear homogeneous equation of exponentials (1, 8–13)

$$Ca_B{}^{47} = 100\ Ca^{47}/Ca_0{}^{47} = \Sigma_i A_i e^{-k_i t} = A_1 e^{-k_1 t} + A_2 e^{-k_2 t} + A_3 e^{-k_3 t} + A_4 e^{-k_4 t} \quad \text{(Eq. 2)}$$

where Ca^{47} is the amount of Ca^{47} per ml. of blood

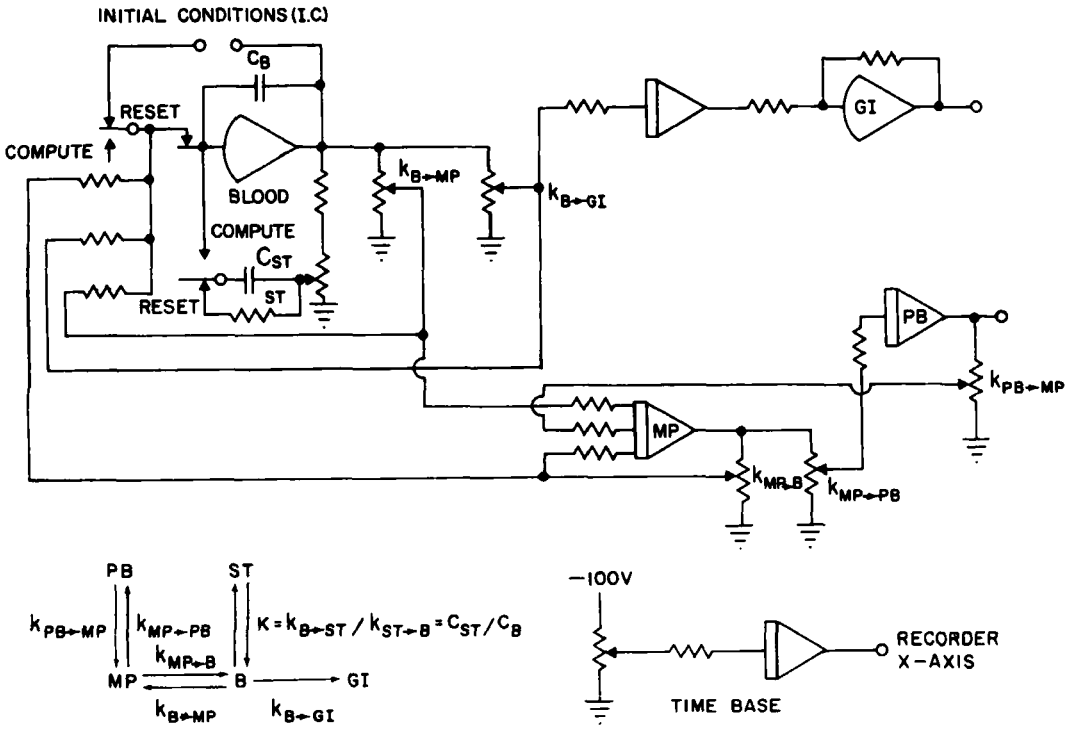

Fig. 1.—The electronic dog. Schemata for the programming of the analog computer for Ca^{47} data in the blood and feces up to 240 hours. The k values represent the respective potentiometers that are varied to obtain the rate constants, the sequence of their respective subscripts represent the directions of transfer of the Ca^{47}. The symbols, *B* (blood), *ST* (soft tissues), *MP* (metabolic pool), *PB* (bone), and *GI* (gastrointestinal tract) represent the various possible depots for Ca^{47} in the animal. The C_{ST} and C_B represent the capacitors for the soft tissue-blood equilibrium.

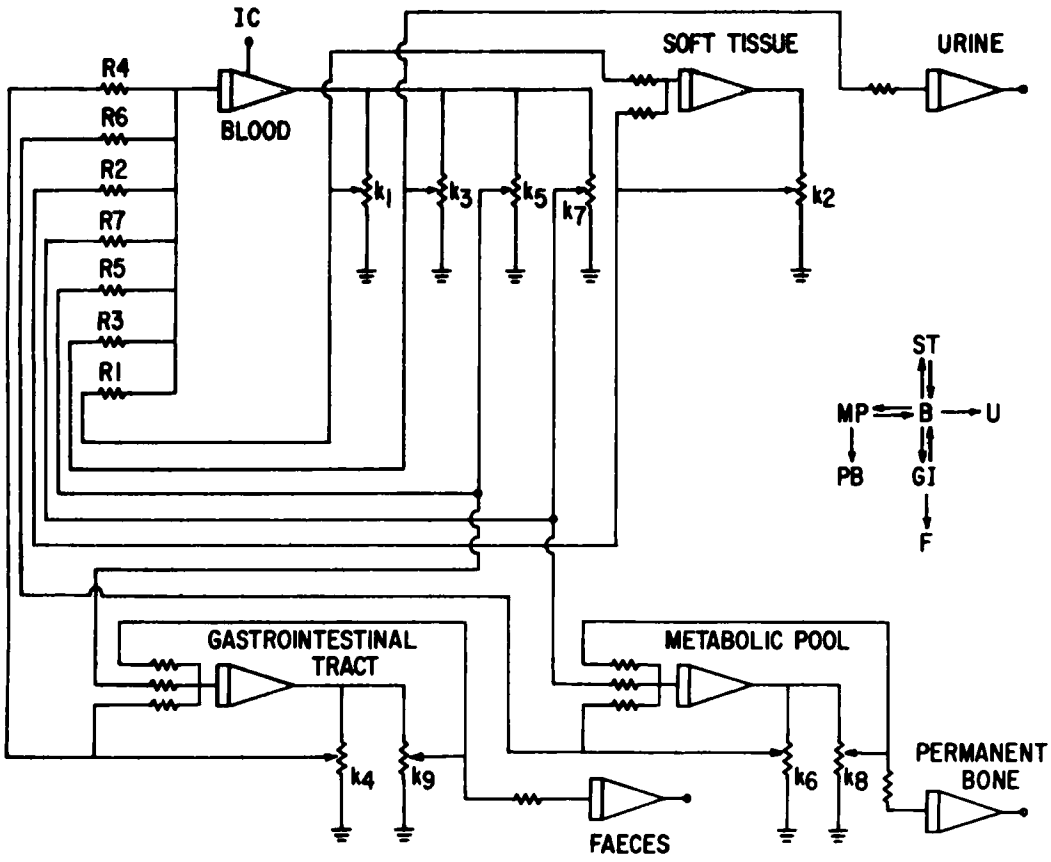

Fig. 2.—The electronic dog. A more complete schemata for the programming of the analog computer and used in part to fit Ca^{47} data up to 11 hours.

serum at any time, t, and Ca_0^{47} is the initial dose, so that Ca_B^{47} is the per cent of total dose administered/ml. of serum.

The significance and limitations of this expression as a reflection of reality and the methods of determination of A_i and k_i by analog and digital computer methods have been previously described (1).

The A_i and k_i values for these studies of four dogs during a control phase A, a steroid regimen, B, and a recovery phase, C, are given in Table I.

The parameters of the curve fitting of the fecal and urinary data by the analog computer are given in Tables II and III in accord with the methods and developments previously given (1).

The Electronic Dog and the Analog Computer

Programming of the Chosen Model for Ca^{47} Distribution.—The basic philosophy of evaluating the consistency of a physiological model with experimental data by means of simulation with an analog computer has been given previously (14). The analog computer setup as finally programmed for all data in excess of 700 minutes is given in Fig. 1. The output voltage of each integrator represents the time variable amount (concentration times a volume factor) of Ca^{47} distributed to a particular portion of the dog's anatomy on the basis of the model chosen, *i.e.*, blood (B), gastrointestinal tract (GI), metabolic pool (MP), and permanent bone (PB).

The integrators are connected by rate setting potentiometers in a conventional manner to simulate the distribution of Ca^{47} on the basis of the chosen model.

The amount of the dosage is represented by the initial condition voltage (IC) applied to the blood

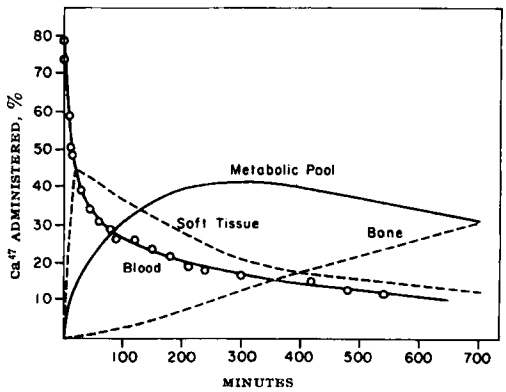

Fig. 3.—Ca^{47} as per cent of intravenously administered dose in the various depots of Dog 1, steroid phase B *vs.* time up to 700 minutes on the basis of a good fit to the plotted blood serum data. The other plots are the "read-out" of the analog computer in accordance with the program of Fig. 2.

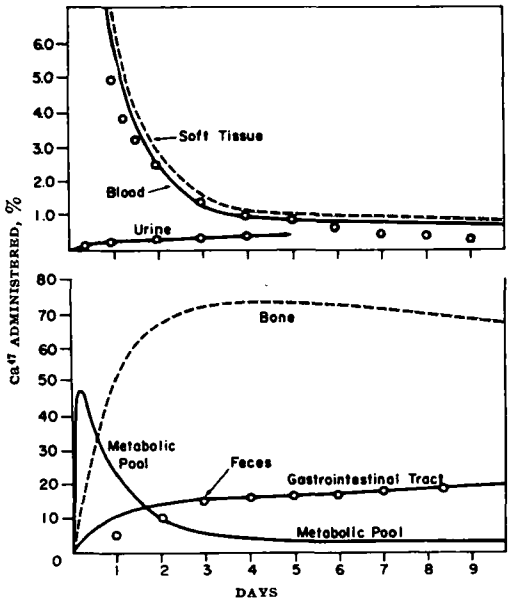

Fig. 4.—Ca^{47} as per cent of intravenously administered dose in the various depots of Dog 1, steroid phase *B vs.* time up to 9 days on the basis of a good fit to the plotted blood serum data and the latter values in the feces. The other plots are the "read-out" of the analog computer in accordance with the program of Fig. 1. A portion of the urine data is plotted for comparison.

(*B*) integrator since the method of administration of Ca^{47} was intravenous.

An additional integrator generates a voltage proportional to time as required by the X-Y recorder used, Fig. 1. The time scale was chosen so that for the 700-minute curves of Figs. 3 and 5, 1 minute of machine time equaled 10^3 minutes of real time; for the 10-day curve of Figs. 4 and 6, 1 minute of machine time equaled 10^4 minutes of real time.

Originally, the more elegant computer program given in Fig. 2 was used in fitting the data. However, drift or leakage resulted over the entire time interval of 10 days with the large number of integrators and with apparent rate constants which varied over four powers of ten. A more expensive computer comprised of precision components (resistors and capacitors) would have been able to simulate without drift. However, with the equipment at hand it was necessary to improvise.

The rate of decrease of Ca^{47} in the blood can be fitted to a linear sum of exponentials and the k_1 value of the first of these, $A_1e^{-k_1t}$, representative of the rapid equilibration between blood and soft tissues, is relatively of high magnitude. The residual exponentials contribute little to Ca^{47} decrease in the blood while the first exponential is operative. Conversely, the equilibration between blood and soft tissue at times in excess of 100 minutes can be considered as instantaneous with respect to the other distributive factors that are rate determining in the loss of Ca^{47} from the blood.

Thus a valid simplification of the program of Fig. 2 in excess of 100 minutes is the removal of the integrator representing the soft tissue (*ST*) and substitution of equilibrating capacitors as in Fig. 1 to account for this rapid equilibration of blood Ca^{47} with soft tissue. The model used can be considered as liquid instantaneously seeking the same level in joined compartments of capacities proportional to the apparent compartmental volumes of blood and soft tissue, respectively, for Ca^{47} or, of course, for calcium since the contents of the compartments would have the same specific activities.

$$Ca_B{}^{47}/Ca_B = Ca_{ST}{}^{47}/Ca_{ST}$$

The integrator representative of Ca^{47} in the feces in Fig. 2 is also absent in Fig. 1 for technological operation of this particular computer system. The Ca^{47} eliminated from the blood by this route is only

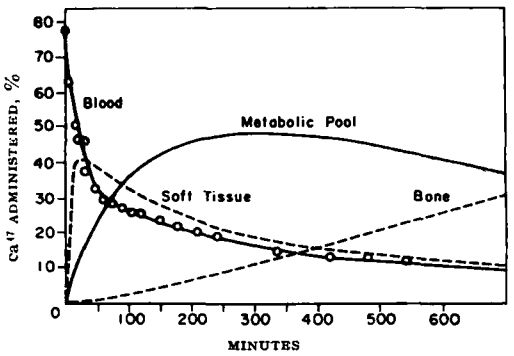

Fig. 5.—Ca^{47} as per cent of intravenously administered dose in the various depots of Dog 1, recovery phase *C vs.* time up to 700 minutes on the basis of a good fit to the plotted blood serum data. The other plots are the "read-out" of the analog computer in accordance with the program of Fig. 2.

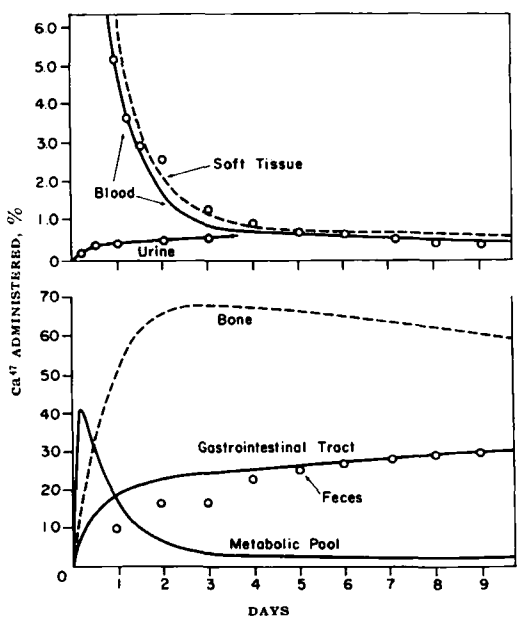

Fig. 6.—Ca^{47} as per cent of intravenously administered dose in the various depots of Dog 1, recovery phase *C vs.* time up to 9 days on the basis of a good fit to the plotted blood serum data and the latter values in the feces. The other plots are the "read-out" of the analog computer in accordance with the program of Fig. 1. A portion of the urine is plotted for comparison.

[a] k_i in sec.$^{-1}$ (See model in Fig. 1.) [b] Study A was the control study; Study B was during 2 mg./Kg./day steroid administration; the recovery Study C was conducted after cessation of steroid administration.

experimentally manifested in fecal elimination. However, the effect on Ca^{47} levels in the blood resulting from the transfer of Ca^{47} into the gastrointestinal fluid most certainly occurs relatively quick in comparison to the lag in the determination of Ca^{47} in the feces.

Also apparent first-order fecal eliminations of Ca^{47} would obviously serve as a gross oversimplification of the complicated processes of absorption into the gastrointestinal tract, including binding with fecal matter and subsequent mechanical displacement down the colon.

The computer used was a modified Heath analog computer and the recorders were Mosely model 4.

Fitting the Model to the Analog Computer.—The blood Ca^{47} for the first 700 minutes (real time, Figs. 3 and 5) where computer drift is not operative is fitted by the computer program of Fig. 2 with the processes from the gastrointestinal tract to the feces omitted. The program was revised for the 10-day scale (Figs. 4 and 6) in accordance with Fig. 1. No discontinuities in the fit were observed.

The equilibration constant K and the rate constants $k_{B\to ST}$ and $k_{ST\to B}$ were derived from the original polyexponential fit. The k_1 of the first exponential (Table I) was considered equal to the sum of the forward and reverse rate constants of the model

$$k_1 = k_{B\to ST} + k_{ST\to B} \qquad \text{(Eq. 3)}$$

The apparent soft tissue (ST) compartment size A_1 is also derived from the first exponential of the polyexponential fit. Thus the equilibrium constant, K, for Ca^{47} distributed between the soft tissue and the blood would be

$$K = A_1/(\Sigma A_i - A_1) = k_{B\to ST}/k_{ST\to B} = C_{ST}/C_B \qquad \text{(Eq. 4)}$$

where ΣA_i is the extrapolated value of the Ca_B^{47} content of the blood at zero time (of intravenous administration).

From the data ΣA_i, A_i and k (given in Table I and Eqs. 3 and 4), $k_{B\to ST}$ and $k_{ST\to B}$ can be derived. These values are given in Table IV and were used in fitting the first 700 minutes of Ca_B^{47} data (Figs. 3 and 5). They were also used to calculate the ratio of the two capacitors (Eq. 4), C_{ST} and C_B, representing blood and soft tissue compartmental size, respectively, as used in the program of Fig. 1 and in the curve fitting of Figs. 4 and 6.

After the insertion of the appropriate values for the capacitors and resistors representative of $k_{B\to ST}$ and $k_{ST\to B}$, the capacitors and resistors associated with the rate constants $k_{B\to MP}$ and $k_{MP\to B}$ representative of the blood $\rightleftarrows$ metabolic pool equilibrium were then adjusted until a reasonable fit for the data over the first 100–150 minutes (Figs. 3 and 5) were obtained. A condition for this initial fit was that the constant, k_2, for the second exponential of the polyexponential fit, $\Sigma_i A_i e^{-k_i t}$ can be defined

$$k_2 = k_{B\to MP} + k_{MP\to B} \qquad \text{(Eq. 5)}$$

The 10-day scale (Figs. 4 and 6) was mounted on the recorder and the machine-time/real-time ratio adjusted accordingly. The extrapolated value of Ca_B^{47} at zero time, $(Ca_B^{47})_0$, *i.e.*, the per cent of total administered Ca^{47} per ml. of serum at the time of intravenous administration, was considered equivalent to 100% of the administered radioisotope. Thus, 100 $Ca_B^{47}/(Ca_B^{47})_0$ could be considered equivalent to the per cent of Ca^{47} intravenously administered that was in the blood at any time. The Ca^{47} fecal content was plotted cumulatively as ΣP_i on this same ordinate as per cent of Ca^{47} administered.

The program of Fig. 1 was then used to obtain appropriate $k_{B\to GI}$ and $k_{MP\to PB}$ values by adjustment of resistors and capacitors. The $k_{B\to GI}$ value was initially chosen so as to fit the Ca_B^{47} data and to be consistent with the P_∞ asymptote approached by the cumulative ΣP_i values of the feces at *ca.* 4–5 days, on the assumption of a first-order fecal elimination of Ca^{47}. The $k_{MP\to PB}$ value was concomitantly chosen to fit the Ca_B^{47} data and account for the Ca^{47} not in the blood or feces.

Subsequently, a $k_{PB\to MP}$ value was chosen to fit the positive linear deviation of Ca^{47} fecal excretion, ΣP_i, from the apparent asymptote, P_∞. Minor readjustments were made to the $k_{B\to GI}$ and $k_{MP\to PB}$ constants when necessary.

The 700-minute (Figs. 3 and 5) and 10-day (Figs. 4 and 6) scales were alternately reinserted in the recorder and since all of these rate constants were interacting, fine adjustments in their values were made to assure consistency with the Ca_B^{47} data of the blood, the amounts excreted in the feces, gastrointestinal tract, GI, (in excess of 5 days), and the amounts of Ca^{47} that would have to be in the permanent bone, PB, and metabolic pool, MP, to account for the stoichiometry.

For ease of fitting, the several per cents of the

administered Ca^{47} that appeared in the urine were ignored (Figs. 4 and 6) since their overall contribution was not of great significance.

The rate constants so determined are given in Table IV. They were calculated from the relation

$$k(\text{sec.}^{-1}) = P/RC \times (\text{machine time})/(\text{real time}) \quad \text{(Eq. 6)}$$

where P is the potentiometer setting, R is the resistance in megohms, and C is the capacitance in microfarads.

The output of each compartment was graphed on the recorder as a function of time after the intravenous administration of Ca^{47}. Typical plots are given in Figs. 3–6.

RESULTS

Empirical Equations Fitted to the Ca^{47} Content of the Blood.—The parameters of the four-factor linear homogeneous equation of exponentials, $\Sigma_i A_i e^{-k_i t}$, given in Eq. 2 and representative of the disappearance of Ca^{47} from the blood of the four dogs during a control phase, A, a steroid regimen, B, and a recovery phase, C, are given in Table I.

As previously noted (1), no specific or consistent patterns appear in the k_i values that can be ascribed to the effect of steroid regimen or steroid recovery.

The major difference within dogs appears in the magnitude of the A_i values, the total amount of the Ca^{47} transferred from the blood to the four hypothetical compartments. This is most readily demonstrated in the plots of $Ca_B{}^{47}$ (as per cent of the total administered dose per ml. of serum) in the blood *versus* time for the four dogs. In general, the curves were similar but displaced along the ordinate. There is a significantly higher concentration of $Ca_B{}^{47}$ in the blood for the steroid phase than for the control phase in all cases.

The $Ca_B{}^{47}$, before the A_4 value of the fourth exponential becomes the determining factor (<750 minutes) and after the fast decrease in $Ca_B{}^{47}$ due to the first exponential (>30 minutes) has been expended, is lower in the recovery phase than in the steroid phase. However, the $Ca_B{}^{47}$ did not reach the lower levels attained with the dog as his own control nor was it as significantly different from the $Ca_B{}^{47}$ values for the steroid phase. The curves of $Ca_B{}^{47}$ against time are similar to those given in the figures of the prior paper in this series (1, 2). Figure 1a of the latter reference (2) is representative of the data.

It has been previously shown (1) that the A_1 (in three out of four dogs), A_2 (in four out of four dogs), and A_3 and A_4 (in three out of three dogs) were all lower for the control period than for the steroid regimen studies. With minor exceptions, these A_1, A_2, and A_3 values decreased for the recovery periods. There were no highly significant differences between the A_4 values of steroid phases and the subsequent recovery A_4 values.

The present study confirmed a good part of these observations (Table I). The major differences in the A_i values that account for the displacement of the Ca^{47} in blood serum curves are in the A_3 and A_4 values. In four dogs out of four the steroid regimen phases have higher A_3 and A_4 values than the control.

The slight decrease in $Ca_B{}^{47}$ values (30 minutes > t < 750 minutes) from steroid to recovery phase may be accounted for by the lessened value of A_3 (for three out of four dogs) (Table I). There were no significant differences in A_4 values between steroid and recovery phase.

The A_1 and A_2 data did not permit conclusions regarding differences among phases of treatments.

Empirical Equations for Ca^{47} Content of the Feces and Urine.—The appearance of Ca^{47} in the feces and urine has been represented by apparent first-order expressions (1)

$$\Sigma P_i = \text{Accumulated } Ca^{47} \text{ in feces (or urine)} = P_\infty(1 - e^{-kt}) \quad \text{(Eq. 7)}$$

where P_∞ is the total per cent of the total dose that should appear in the feces (or urine) over the entire period on the postulate of first-order kinetics. The two pertinent parameters are P_∞ and k, and are given in Table II for all dogs and phases as best fitted by the analog computer (1). Again, as in the previous study (1), the amount of Ca^{47}, *i.e.*, P_∞ appearing in the urine and feces by an assumption of first-order kinetics is greatly enhanced by a steroid regimen, Run B over Run A. (See Fig. 7 for Dog 3.)

In fact, the increase in fecal elimination for these studies on steroid regimen is even more pronounced than previously (1), primarily due to the lower P_∞ values for the dogs in the control phases of the first studies. The P_∞ values for dogs of similar age during the steroid regimen were similar, *ca.* 30% of the total Ca^{47} administered.

The "rebound" effect or decrease in P_∞ for the recovery phase (Table II) was definitely present (Fig. 7) but not as pronounced in the present studies since the P_∞ values for the control phases were so much lower. However, P_∞'s for the recovery phases were of the same magnitude in both sets of studies.

The apparent rate constant, k, for the fecal and urinary elimination among runs for particular dogs did not significantly correlate with the conditions of the run.

As was also demonstrated in other papers of this series (1, 2), the fecal (and urinary) elimination of Ca^{47} deviates from first order by an amount of radioisotope excreted in excess of an expected asymptote,

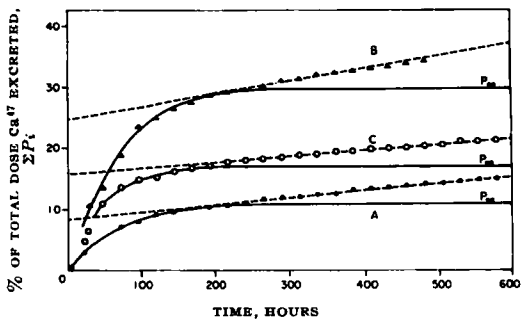

Fig. 7.—Typical example of cumulative fecal excretion of Ca^{47} with time over 600 hours. The data is for Dog 3; A is control study, B is steroid study, and C is recovery study. The solid curves represent the pseudo first-order fecal excretion with time, $\Sigma P_i = P_\infty(1 - e^{-kt})$. The dashed lines represent the apparent linear deviation from the first-order asymptote P_∞, *i.e.*, $\Sigma P_i = mt + b$.

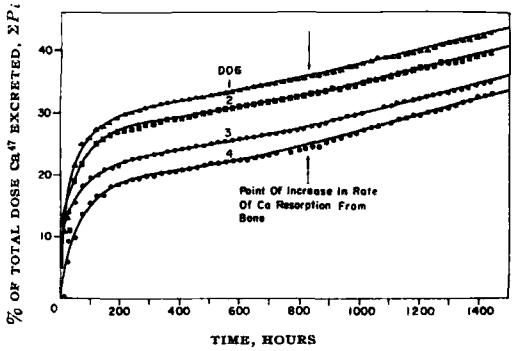

Fig. 8.—Cumulative fecal excretion of Ca^{47} with time for the recovery phases of the dogs over 1500 hours. For reasons of clarity, the data are plotted as Y for Dog 1, Y-4.8% for Dogs 2 and 3, and Y-12% for Dog 4.

i.e., P_∞. This deviation can be approximated by a straight line of slight slope

$$\Sigma P_i = mt + b, \quad t > 200 \text{ hr.} \qquad \text{(Eq. 8)}$$

The slope, m, is the per cent of the total Ca^{47} dose excreted per hour and b is the intercept. The m and b values are given in Table II for both urinary and fecal elimination. Typical plots of this linear deviation are given for the fecal excretion of Dog 3 in Fig. 7.

Since the m values may serve as estimates of the possible rates of reabsorption of Ca^{47} from bone, these values should be adjusted to account for any bias introduced by greater amounts of radioisotope in bone. A reasonable adjustment can be made by dividing m by per cent of the dose of administered Ca^{47} in the bone. This per cent (of the total dose) of Ca^{47} in the bone can be estimated from the difference between 100% and the sum of the apparent first-order asymptotes of Ca^{47} excretion in urine and feces reached at *ca.* 200 hours. Thus

$$R = m/[100 - P_\infty(\text{urine}) - P_\infty(\text{feces})] \qquad \text{(Eq. 9)}$$

where the apparent resorption rate R is the Ca^{47} available for excretion into the feces per unit of Ca^{47} in the bone. This value may be a satisfactory measure of the calcium resorption from bone.

The R data of Table II show that the Ca^{47} reabsorption rate is almost double that of control for all cases of steroid administration and relapses on recovery to at least the rate of the control period and probably less. This phenomenon is also mirrored by the urine data.

Subsequent to this linear deviation from the expected first-order asymptote of Ca^{47} excretion, a further increase in bone resorption rate was observed when the fecal collections were carried out in excess of 700 hours during the recovery phases. The plots are given in Fig. 8.

This new enhancement of resorption rate can be characterized by the linear expression

$$\Sigma P_i = m'(t - t') + b' \qquad \text{(Eq. 10)}$$

where m' represents the new rate and b' is the value of Ca^{47} accumulated in the feces at time $t = t'$, *ca.* 700–800 hours, which represents the time of transition from the old to the new resorption rate.

Again, the m' for the various dogs can be adjusted for Ca^{47} content in the bone, dividing m' by the per cent of total Ca^{47} dose in the bone. The value $100 - b'$ is considered a good estimate of this latter value. Thus

$$R' = m'/(100 - b') \qquad \text{(Eq. 11)}$$

where the R' is the estimated second linear rate of Ca^{47} available for excretion into the feces per unit of Ca^{47} in the bone. This value may be a satisfactory measure of the calcium resorption from bone 700 hours after Ca^{47} administration and during the recovery phase. The m', b', t', and R' values are given in Table III.

Extended studies of fecal elimination during the recovery phase showed that the estimated rates of Ca^{47} resorption subsequently increased by *ca.* 20–40% over the rates of resorption during the 200–700 hour period post-Ca^{47} injection.

Rates of Distribution of Intravenously Administered Ca^{47} as Determined by the Analog Computer.—The apparent first-order rate constants for the compartmental model in Fig. 1 are listed in Table IV. There are no consistent effects of steroid administration and subsequent recovery on the apparent first-order rate constants for the transfer of Ca^{47} from the blood, B, to the soft tissue, ST, *i.e.*, $k_{B\to ST}$ and $k_{ST\to B}$. The relative apparent volume (14) of the soft tissue, V_{ST}, available for Ca^{47} to the blood serum apparent volume, V_B

$$V_{ST}/V_B = k_{B\to ST}/k_{ST\to B} = Ca_{ST}/Ca_B \qquad \text{(Eq. 12)}$$

is of the order 1.2–1.7 (average 1.4) among dogs. This may also be interpreted as the ratios of the calcium contents of both compartments. (See *Appendix.*)

A satisfactory estimate of half the time it would take to reach equilibrium between the blood and soft tissue is 4 minutes, a value which is similar to that previously determined (1).

A definitive decrease in the rate constant assigned to the transfer of Ca^{47} from the blood to the metabolic pool, $k_{B\to MP}$, is observed for steroid over the control period. In three out of four dogs an increase in the rate of return of Ca^{47} from the metabolic pool to the blood, $k_{MP\to B}$, was observed after cessation of steroid.

The ratio of these rates, $k_{B\to MP}/k_{MP\to B}$, may be more indicative of the steroid effect on Ca^{47} distribution. In the control phase the ratio (average 9.4) is twice the value of the ratio while steroid is administered (average 4.6) which is almost equivalent to the value of the ratio during the recovery phase (average 5.2).

An alternate method of appraising this data is by examining the apparent relative volumes or calcium contents of the compartments (14–16). From this perspective, the capacity of the metabolic pool for Ca^{47} and calcium with respect to blood serum may be considered as halved on steroid administration. This relative decrease in the capacity of the metabolic pool remained after cessation of steroid in these studies.

With the model used the major source of the differences in $Ca_B{}^{47}$ values with time within a dog can be attributed to the blood-metabolic pool equilibrium and the blood-gastrointestinal tract transfer, $k_{B\to GI}$.

The values assigned this latter rate constant almost double during steroid phase with respect to the control. On recovery from steroid, they decidedly tend to revert to the control levels.

The introduction of a $k_{PB \rightarrow MP}$ rate constant to account for the return of Ca^{47} from the bone to the metabolic pool is obviously an oversimplification of a complex process. It is significant, however, that the apparent linear increase in Ca^{47} excretion after 5 days (Figs. 4 and 6) can be accounted for by this assumption that Ca^{47} is resorbed from the bone.

DISCUSSION

Most Significant Steroid Effects.—The results of these detailed studies of intravenously administered Ca^{47} in young Beagles support and extend those previously published (1, 2). The most significant effects of steroid radiocalcium metabolism include the increased amounts (more than twice control) of Ca^{47} accumulated in the feces (P_∞ in the Table II) and the increased rate of apparent resorption (*ca.* twice control) of Ca^{47} from a "deep" compartment that may be assigned to bone (R in Table II). Both of these effects are decidedly reversed on the cessation of steroid administration.

Explanation and Correlation of Curve-Fitting.—The fitting of the data by the analog computer (Fig. 1) permits an explanation of these phenomena. It also permits a correlation of the parameters of the model with the sum of exponentials, Eq. 2, fitted to the Ca_B^{47} decrease with time.

The first exponential, Table I, and the $k_{B \rightarrow ST}$ and $k_{ST \rightarrow B}$ (Table IV) values are synonomous in their significance, the presumed fast transfer of Ca^{47} into extravascular spaces and soft tissues. The second exponential (Table I), $A_2e^{-k_2t}$, is largely representative of a slower transfer to the compartment represented as the metabolic pool (Figs. 1, 3, 5). This compartment could be assigned to the reasonably reversible chelation and/or complexation of calcium with bone or matrix.

The analog computer fitting of this model, the ratio $k_{B \rightarrow MP}/k_{MP \rightarrow B} = Ca_{MP}/Ca_B$ (Table IV), which decreases with respect to control on steroid administration, may explain the apparent increase in Ca^{47} blood levels during steroid, *i.e.*, the relative increase in A_3 and A_4 values (Table I). The relative constancy of this ratio between steroid and recovery studies would also explain the fact that the polyexponential A_3 and A_4 values do not appreciably differ between steroid and recovery (Table I).

The model fitting shows that the inhibition of transfer of Ca^{47} from the blood to the metabolic pool, $k_{B \rightarrow MP}$, by a presently unknown mechanism of steroid action, is a plausible explanation for steroid induced osteoporosis. If this metabolic pool represents the sites from which the radioisotope is incorporated into a deep compartment such as bone by the assigned rate constant, $k_{MP \rightarrow PB}$ (Table IV), there does not have to be significant effects of steroid on this latter transfer. This was indicated by the lack of a significant variation of $k_{MP \rightarrow PB}$ with treatment within the dogs. The decrease of Ca^{47} in bone on steroid-induced osteoporosis is a ready explanation on the premise that the amount of calcium in the metabolic compartment necessary for bone incorporation is lessened.

This hypothesis would be consistent with the postulates that an effect of the adrenal steroids is to inhibit the synthesis of protein matrix (17, 18). Thus, less sites would be available for a comparatively reversible binding of calcium with bone precursor as represented by the values for the ratio, $k_{B \rightarrow MP}/k_{MP \rightarrow B}$, as modified by steroid (Table IV).

The recovery period studies again demonstrate reversal of steroid effects in that an increase in the $k_{B \rightarrow MP}$ value is observed on cessation of steroid.

The model used and as fitted (Fig. 1) showed a marked increase with steroid in the apparent first-order rate constant, $k_{B \rightarrow GI}$, for the transfer of Ca^{47} across the intestinal wall or by biliary or gastric secretion as crudely estimated from the fecal excretion data. As has been stated previously (2), this is representative of the excretion of endogenous calcium and is explained by a steroid mechanism that would increase the rate of calcium transfer from the blood to the intestine. The possibility of decreased calcium binding by protein, thereby increasing the amounts of diffusible calcium has already been cited (2, 19) and is consistent with this data. An alternative explanation (2) is the inhibition of calcium return *via* gastrointestinal absorption which is also consistent with recent reports (20).

The analog computer plottings (Figs. 4 and 6) even with an oversimplified first-order process for Ca^{47} transfer from bone to metabolic pool, show that the positive deviation from first-order fecal and urinary eliminations (Table II, Figs. 7 and 8) can be accounted for by a resorption of radioisotope from bone, at least for the data up to 10 days (Figs. 4 and 6).

Limitations of Studies to Date.—The great numbers of fecal, urinary, and blood serum collections necessary to do studies of this kind decidedly limit the number of animals that can be followed experimentally. The major arguments for these experimental designs (within the limitations of the amount of data that can be practicably obtained) are that each dog can be used as its own control and that the relatively short half-life of Ca^{47} permits repetitive radioisotope labeling without interference from the radioisotope administered in the previous study.

The dogs used in this study were in a maximum growth or maturation period and, undoubtedly, hormonal changes occurred in this interval which may have affected their calcium metabolism. It is known that the retention of radioisotopes decreases with increase in age of the dog (21). However, it is felt that such a change would be unidirectional and that when effects of steroid are reversed on recovery, the validity of these effects may be given additional weight. It has been shown that the nature of these effects is similar in the adult dog (1). It is also argued that less variability exists among "litter-mates" during their youth.

Detailed studies should be made with varying steroid dosages to evaluate dose-response relations. Cold calcium assays should be determined simultaneously with Ca^{47} concentrations to correlate changes in specific activity with the influences of adrenal steroid administration and to permit the calculation of exchange rates, r, between compartments rather than the fractional exchange rates, $r/Ca_i = k_i$, which merely permit estimates of relative compartment sizes or the relative calcium content of exchanging compartments. (See *Appendix*.)

The interesting observation of a significant and sudden increase in the apparent resorption rate of Ca^{47} from bone on recovery from steroid should be further investigated. The reproducibility of these Ca^{47} methods without steroid, *i.e.*, the maturation effect on radiocalcium metabolism should be evaluated. Such studies and their results will be reported in a future publication.

Advantages of the Application of the Analog Computer.—The analog computer is an extraordinary tool for the elucidation of the mechanisms and rates of transformations and compartmental exchanges of drugs in the various organs of the body. It permits the establishment of models for gastrointestinal absorption into the blood, diffusion into tissues, incorporation into organs, metabolic pathways, and elimination into the urine and feces. Its use permits the investigation and quantification of distribution and excretion processes for which the application of methods of analytical mathematics is most approximate and difficult.

The philosophy of analog computer programming and application to be consistent with experimental assay, blood level, urinary, and fecal data is based on the use of minimum postulates consistent with physiological reality. The validity of "steady state" approximations and "apparent metabolic half-lives" with respect to the more exact models programmed in the analog computer can be evaluated as is shown in the *Appendix*.

Comparisons of empirical curve fitting and model making by the analog computer were made with respect to Ca^{47} dynamics.

Of course, the digital computer could also be used since numerical methods could approximate the solutions of differential equations established for the appropriate mathematical models. However, the analog computer has the advantages of simpler and more flexible programming for various models. It can generate a series of curves which can be observed by the operator as consistent or inconsistent with the forms and magnitudes of plotted data.

APPENDIX

The total Ca_T^{47} or 100% of the administered dose can be considered as distributed among the various compartments as blood, Ca_B^{47}, soft tissue, Ca_{ST}^{47}, metabolic pool, Ca_{MP}^{47}, gastrointestinal tract, Ca_{GI}^{47}, and bone, Ca_{PB}^{47}, in concurrence with the model of Fig. 1, as

$$100\% = Ca_T^{47} = Ca_B^{47} + Ca_{GI}^{47} + Ca_{ST}^{47} + Ca_{MP}^{47} + Ca_{PB}^{47} \quad \text{(Eq. 13)}$$

where Ca_{GI}^{47} also includes the cumulative amount in the feces and where the negligible amounts in the urine can be ignored. (See Figs. 4 and 6.)

The rates of transfer of Ca^{47} among these compartments before resorption from bone becomes significant can be formulated as

$$d\,Ca_B^{47}/dt = -[k_{B\to GI} + k_{B\to ST} + k_{B\to MP}]\,Ca_B^{47} + k_{ST\to B}Ca_{ST}^{47} + k_{MP\to B}Ca_{MP}^{47} \quad \text{(Eq. 14)}$$

$$d\,Ca_{GI}^{47}/dt = k_{B\to GI}Ca_B^{47} \quad \text{(Eq. 15)}$$

$$d\,Ca_{ST}^{47}/dt = k_{B\to ST}Ca_B^{47} - k_{ST\to B}Ca_{ST}^{47} \quad \text{(Eq. 16)}$$

$$d\,Ca_{MP}^{47}/dt = k_{B\to MP}Ca_B^{47} - (k_{MP\to B} + k_{MP\to PB})Ca_{MP}^{47} \quad \text{(Eq. 17)}$$

$$d\,Ca_{PB}^{47}/dt = k_{MP\to PB}Ca_{MP}^{47} \quad \text{(Eq. 18)}$$

Alternately, these apparent rate constants can be interpreted as fractional turnovers or the fraction of compartmental calcium exchanged in a unit of time as they represent the quotient of an amount of calcium transferred from a compartment in a unit of time, r, and the total amount of calcium, Ca_i, in that compartment, r/Ca_i (14, 15). For example, Eq. 16 can be formulated as the rate of radioisotope transfer proportional to the specific activities of the blood and soft tissue compartments

$$d\,Ca_{ST}^{47}/dt = r[S_B - S_{ST}] = (r/Ca_B)Ca_B^{47} - (r/Ca_{ST})Ca_{ST}^{47} \quad \text{(Eq. 19)}$$

The $S_B = Ca_B^{47}/Ca_B$, $S_T = Ca_{ST}^{47}/Ca_{ST}$ represent the specific radioactivities in the blood and soft tissue compartments, respectively, and Ca_B and Ca_{ST} are the respective total calcium contents of these compartments, so that $k_{B\to ST} = r/Ca_B$ and $k_{ST\to B} = r/Ca_{ST}$. It also follows that $k_{B\to ST}/k_{ST\to B} = Ca_{ST}/Ca_B$ is the ratio of the calcium in the soft tissue to the amount in the blood. It may also be interpreted as the ratio of the apparent effective volumes of soft tissue and blood with respect to calcium if the concentration per unit volume is considered to be the same in the equilibrated compartments.

Inspection of Figs. 4 and 6 indicates that at 1–3 days after the intravenous administration of Ca^{47}, pseudo or quasi steady state conditions can be assumed for the model given in Fig. 1. This assumption implies that the rates of Ca^{47} transfer between blood and soft tissue and blood and metabolic pool are no longer rate determining in the decrease of Ca_B^{47}, and the amounts of radioisotope in these various compartments are proportionately related, as

$$Ca_{MP}^{47} = (k_{B\to MP}/k_{MP\to B})Ca_B^{47} = (Ca_{MP}/Ca_B)Ca_B^{47} \quad \text{(Eq. 20)}$$

$$Ca_{ST}^{47} = (k_{B\to ST}/k_{ST\to B})Ca_B^{47} = (Ca_{ST}/Ca_B)Ca_B^{47} \quad \text{(Eq. 21)}$$

These equations also state that the specific radioactivities, S, in all three compartments are the same in the pseudo or quasi steady state as from Eqs. 20 and 21

$$S = Ca_B^{47}/Ca_B = Ca_{MP}^{47}/Ca_{MP} = Ca_{ST}^{47}/Ca_{ST} \quad \text{(Eq. 22)}$$

The rates of increase of radioisotope in the gastrointestinal tract and bone (Eqs. 15 and 18) may be formulated as equal to the rates of decrease in metabolic pool, soft tissue, and blood (Eqs. 14, 16, and 17) before any return of Ca^{47} from bone to metabolic pool significantly contributes

$$d\,Ca_{GI}^{47}/dt + d\,Ca_{PB}^{47}/dt = -d[Ca_{MP}^{47} + Ca_{ST}^{47} + Ca_B^{47}]/dt = k_{B\to GI}Ca_B^{47} + k_{MP\to PB}Ca_{PB}^{47} \quad \text{(Eq. 23)}$$

Substitution of Eqs. 20 and 21 into Eq. 23 and rearranging gives

$$-d\,Ca_B^{47}/dt = \left[\frac{k_{B\to GI} + k_{MP\to PB}\,k_{B\to MP}/k_{MP\to B}}{1 + k_{B\to MP}/k_{MP\to B} + k_{B\to ST}/k_{ST\to B}}\right] Ca_B^{47} = k_4 Ca_B^{47} \quad \text{(Eq. 24)}$$

The estimated apparent first-order rate constant for the pseudo or quasi steady state elimination of radioisotope from the blood could also be expressed as

$$k_4 = \left[\frac{r_{B,\,GI} + r_{MP,\,PB}}{Ca_B + Ca_{MP} + Ca_{ST}}\right] \quad \text{(Eq. 25)}$$

by substituting the appropriate r_i/Ca_i for the k_i of Eq. 24 and simplifying the result. The r_i values are the calcium exchange rates between the two compartments given in the subscripts of the k_i; the Ca_i values are the total calcium in the compartments identified by the subscript.

It can also be shown (16, 22) from Eqs. 13, 20–22 that on pseudo steady state conditions

$$d\,Ca_{GI}{}^{47}/dt + d\,Ca_{PB}{}^{47}/dt = k_4[Ca_T{}^{47} - Ca_{GI}{}^{47} - Ca_{PB}{}^{47}] \quad \text{(Eq. 26)}$$

This estimated apparent first-order rate constant, k_4, for the pseudo steady state elimination of radioisotope from the blood could also be expressed in terms of apparent compartmental volumes (16, 22, 23).

The term, k_4 (as used in Eqs. 24–26) should be analogous to the k_4 in Table I, the apparent decay constant for the fourth exponential of the polyexponential fit of the $Ca_B{}^{47}$ *versus* time data. Substitution of the k_i values given in Table IV for the model of Fig. 1 will give calculated k_4 values from Eq. 23 of 3×10^{-6} sec.$^{-1}$, whereas the k_4 values of 5×10^{-6} sec.$^{-1}$ are listed in Table I.

The model used in the programming of the computer was necessarily a simplification of the physiological reality. The estimates of $k_{B\to GI}$ representative of apparent rates of radioisotope transfer from the blood to the gastrointestinal tract were actually determined by analog computer fitting to the cumulative fecal Ca^{47} at 5–10 days since no actual data were available for the amount in the intestine. The true value of $k_{B\to GI}$ is undoubtedly greater than the first approximation from fecal data since intestinal capacity for Ca^{47}, possible fecal and mucosal binding of radioisotope, and lag in defecation would contribute to an underestimation of the rate of removal of $Ca_B{}^{47}$ from the blood to the intestine.

An increased value of $k_{B\to GI}$ in Eq. 23 would estimate a k_4 value more consistent with the listed values of Table I. Further, the model and program of Fig. 1 ignore the probable equilibration of Ca^{47} in the intestinal tract with that of the blood as was indicated in the more complex model given in Fig. 2.

Psychopharmacological Studies of Some 1-(Chlorophenyl)-2-aminopropanes I

Effects on Appetitive-Controlled Behavior

By JOHN E. OWEN, JR.

A series of 1-phenyl-2-aminopropanes with chloro substitutions on the 2,4, 3,4, and 4 positions on the phenyl ring and their optical isomers were compared with *dl*- and *d*-amphetamine and methamphetamine on a fixed-ratio (FR) procedure. The subjects were rats that had been trained to press a lever 30 times for 0.25-ml. reinforcement of sweetened condensed milk. Each session consisted of 40 reinforcements. With unsubstituted amphetamines, rats showed a slight reduction in response rates with long pauses following reinforcement. This effect was similar to the effect seen with onset of normal satiation. After chloro compounds, the rats produced irregular and slowed response rates with frequent short pauses between and following reinforcement. The minimum effective doses of all compounds used in this study ranged from 1–3.2 mg./Kg. Except for *d*-1-(4-chlorophenyl)-2-aminopropane, the *l*-isomers of chloro-substituted compounds were more active suppressants of FR behavior than the *dl* or *d* compounds.

COMPOUNDS THAT stimulate the central nervous system and also have appetite-suppressing activity, such as amphetamine and methamphetamine, have be enreported to alter performance of trained experimental animals working for food reinforcement on fixed-ratio (FR) schedules (1–3). Specifically, *dl*-, *d*-, and *l*-amphetamine and methamphetamine (4) changed FR behavior in rats by slowing the response rate, increasing the frequency and duration of pauses between and following reinforcements, and inducing temporary cessation of responding following drug administration. Some chloro substituted 1-phenyl-2-aminopropanes in a series of phenylalkylamines studied for central-nervous-system activity by Rathbun (5) exhibited appetite suppression with minimum stimulation. Rathbun estimated the appetite suppressing ED_{50}'s of these compounds in carefully controlled studies on the food intake of hungry rats under the influence of the drugs. Four of these chloro-substituted compounds and their optical isomers were selected for comparison with *dl*- and *d*-amphetamine and methamphetamine on an FR schedule for food reinforcement. The changes in the appetitive controlled behavior of rats after the administration of the drugs is described.

EXPERIMENTAL

Materials.—The compounds and doses used in this investigation as well as the oral ED_{50} doses (5) are listed in Table I. The compounds were dissolved in distilled water and administered subcutaneously.

Method.—Male rats of a Wistar-derived strain, initially weighing 400–450 Gm., were used in this study. With controlled food deprivation their body weights were gradually reduced to 70% of the initial weights. They were trained on an FR-30 schedule in which 30 lever pressing responses were reinforced with 0.25 ml. of a mixture of sweetened condensed milk, water, and homogenized multiple vitamins,[1] in proportions of 1:1:0.01.

The apparatus and procedure have been described in detail elsewhere (4). Briefly, two experimental cages, each 9 × 9 × 7.5 in. were used. Each contained a lever, a modified telephone-type switch (6), a small pilot light over the lever, and a motor-driven dipper for delivery of the reinforcement. The cages were contained in light-proof, sound resistant, ventilated boxes isolated from the control equipment. The procedure, controlled by appropriate electrical relay circuits, was designed to give the rat a reinforcement upon completion of 30 responses. Illumination inside the cage was provided during a session by the small light over the lever. During the 8-second interval that the reinforcement was available to the rat, the light over the lever was extinguished and another small light illuminated the dipper cup.

Each rat was given daily sessions of 40 reinforcements to maintain stable performance. For sessions when drugs were tested, a rat was given ten reinforcements before drug administration as a "warm-up" and to establish that he was working normally that day.

In a previous study (4) the clinically used amphetamines and methamphetamines had been shown to produce maximum suppression of FR responding within 20 to 30 minutes after administration. Therefore, the animal was placed in a small observation cage for 30 minutes following drug administration to allow the drug to be absorbed. The animal was returned to the experimental cage and permitted to work for 40 reinforcements. The compounds were given once to each rat at each dose.

Data.—The data were collected on electrical impulse counters, running-time meters, and cumula-

tive recorders. Two variables of this appetitive controlled FR behavior were studied: the running response rates, *i.e.*, the sustained constant rate (7), and the total time used to complete each session. The response rates of the individual rats were determined as responses per second. Because this investigation was concerned with the running response rate in contrast to the overall response rate (4, 7, 8), pauses in responding of more than 5 seconds were not included in the response-rate calculations. Since each rat acted as its own control, *i.e.*, normal behavior *versus* behavior with drug, the data from each rat were calculated as ratios of response rates with drug to response rates without drug. Also, ratios of total time to complete a session with drug to mean total time to complete a session without drug were calculated.

The cumulative recorders produced direct recordings of responses related to time. Thus, a visual record of behavior was available at any point of an experimental session. In these records vertical movement of the pen is related to the number of

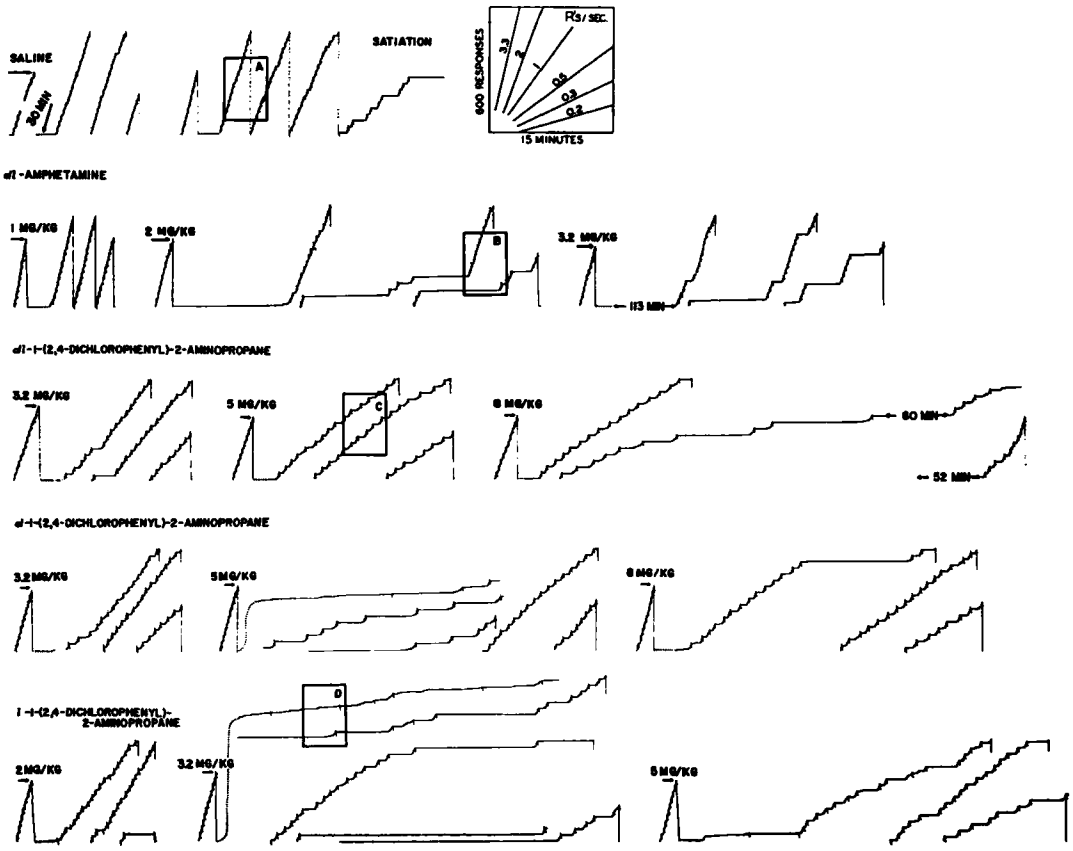

Fig. 1.—Cumulative records of responses of Rat 84 showing patterns of normal behavior and behavior under the influence of the drugs used in this study.

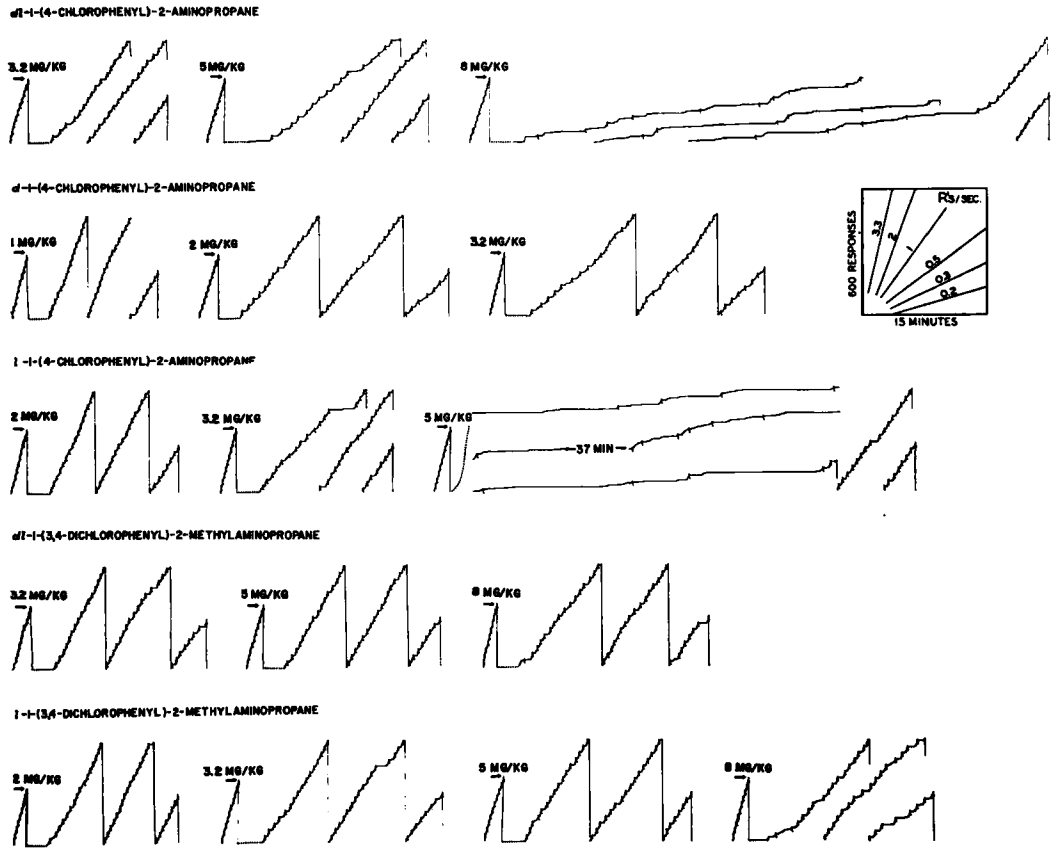

Fig. 2.—Cumulative records of responses of Rat 84 showing patterns of behavior under the influence of drugs used in this study.

responses and horizontal paper movement indicates time. The angle of the line or any segment of the ine is indicative of the individual's response rates. Short vertical marks on the response line show when reinforcements occurred.

RESULTS

The data from this behavioral study of chloro-substituted 1-phenyl-2-aminopropanes, as recorded on the cumulative response recorders, demonstrated that these compounds influence appetitive-controlled FR behavior differently than do *dl*- and *d*-amphetamine and methamphetamine. In general, the deschloro drugs influenced the behavior by causing only a slight depression of response rates with a marked increase in the frequency and duration of the post-reinforcement pauses. At the higher doses some rats also failed to resume responding immediately upon being returned to the cage after the 30-minute period following drug administration.

Figures 1 and 2 present typical cumulative response curves of one rat showing a session with saline; a session during which an unlimited number of reinforcements was made available to the rat (satiation); the effects of *dl*-amphetamine; and the effects of eight of the chloro-substituted compounds. With *dl*-amphetamine there was little variation in the response rate when the rat was working. This rate appeared constant from dose to dose. Shown

3,4-diCl	CH_3	*l*	7	0.86	0.68	0.56	−0.151 ± 0.048	<0.05

here are the long pauses that occasionally followed a reinforcement and protracted periods of time when no response occurred following return to the experimental cage.

With the chloro-substituted compounds, the rat's response rate appeared irregularly depressed. Pauses between and after reinforcement became more frequent and were shorter than those with the unsubstituted amphetamines. These phenomena present an overall "scalloped" effect on the cumulative records. The depression of rate appeared more pronounced with the larger doses. A detailed comparison of segments of the records showing the differences between normal running rates, rates with *dl*-amphetamine, and rates with *dl*-1-(2,4-dichlorophenyl)-2-aminopropane is presented in Fig. 3.

The effects of the compounds on the response-rate ratios are shown in Table II. The average response-rate ratios of individual rats were computed for each dose of each drug. The slope values are relative, based on three equally spaced doses and do not represent numerically the dose-response slopes (*cf.*, Table I for actual doses used). They serve the purpose of indicating whether or not there was a change in the rate ratio and whether or not the change was significant. With *dl*- and *d*-amphetamine and methamphetamine, the rats produced lower than normal rates but showed little change from dose to dose. The chloro-substituted compounds, with the exception of *d*-1-(3,4-dichlorophenyl)-2-aminopropane, caused the rats to work at rates that decreased significantly as the doses were increased.

As shown in Table III, the length of time to complete the 40-reinforcement sessions with all of the drugs studied was longer than normal. The means and standard errors of the time ratios are presented for each dose of each drug. In general, the mean time to complete a session increased as the dose was increased. The increases appeared greatest with *dl*- and *d*-amphetamine, methamphetamine, the 4-chlorophenyl, and the 2,4-dichlorophenyl compounds. The variability among animals was high as evidenced by the rather large standard error terms.

DISCUSSION

In animals trained on FR procedures for food reinforcement the response rate normally will remain unchanged once it is established. The development of post-reinforcement pauses, however, is dependent upon several controllable variables (7, 8). If the size of the FR is increased, *e.g.*, from 30 to 100 responses, post-reinforcement pauses become pronounced and in some instances the rat stops responding entirely. If the size of the reinforcement is decreased, the post-reinforcement pauses become more frequent and of greater duration. The state of

deprivation and/or satiation of the animal influences the character of the post-reinforcement pause, *i.e.*, the more satiated the animal the longer the pauses. Generally, the response rates remain relatively unchanged despite the length of the post-reinforcement pause. The phenomenon of pausing has been termed "fixed-ratio strain" (4). Rats with stable FR behavior showing little or no ratio-strain responded with frequent and sometimes very long pauses when under the influence of amphetamine compounds. The overall effect of the amphetamines in this situation was considered to be a lowering of the threshold for fixed-ratio straining that resembled, in many respects, a premature onset of satiation.

The chloro-substituted compounds used in this study depressed the rats' FR behavior by causing an irregular decline in response rate that appeared different from the depression seen with the unsubstituted amphetamines as shown in Fig. 3. The cumulative record data indicate numerous relatively short pauses occurred with the slowed response rates. Even segments of the cumulative records that appear as long pauses, on closer inspection, reveal the presence of occasional short bursts of 2–3 or more lever presses. This random, intermittent responding is illustrated in part *D* of Fig. 3. At the doses used, the 4-chlorophenyl and 2,4-dichlorophenyl compounds produced the most marked depression of the FR behavior in regard to response rate and prolongation of total time to complete sessions.

Except for the 1-(4-chlorophenyl)-2-aminopropane compounds, the *l* isomers of the chloro compounds appeared more potent than the *dl* and *d* members. This observation suggests that the presence of dichloro substitutions on the phenyl ring reverses the relative potency of the isomers seen with *d*- and *l*-amphetamine as reported in a previous study (4). Monochloro substitution on the 4 position seemingly failed to cause this reversal since the *d*-1-(4-chlorophenyl) compound appeared more potent than either of the *dl* or *l* compounds.

ADDENDUM

None of the new compounds tested could be considered a clinically useful drug.[2] In one double blind study with 16 moderately obese subjects, 20 and 30 mg. of *l*-1-(2,4-dichlorophenyl)-2-aminopropane was compared with placebo and a marketed anorectic drug. When the patients received the chlorinated compound they reported poor appetite control. Several patients mentioned a sense of agitation associated with inability to work effectively; others complained of nausea, nightmares, irritability, and lack of tolerance for the usual difficulties at work and at home. In general, both the patient and his family disapproved of the experimental compound. The placebo and known drug were well tolerated and the active known compound could be shown to cause significant weight loss in a 1-week period. No patient preferred the chlorinated compound but 15 preferred the active drug to placebo. It would appear that the pseudo-satiation-type of suppression of the FR preformance seen after the rats were given amphetamine is consistent with suppression of appetite clinically. The decrease of rate with the scalloped appearance resulting from frequent short pauses seems to indicate a different, and probably undesirable, type of clinical activity.

Psychopharmacological Studies of Some 1-(Chlorophenyl)-2-aminopropanes II

Effects on Avoidance and Discrimination Behavior

By JOHN E. OWEN, JR.

A series of 1-(chlorophenyl)-2-aminopropanes previously shown to suppress appetitive-controlled behavior were compared with *d*-amphetamine and methamphetamine on an avoidance procedure. Rats trained to press a lever to avoid intermittent electroshocks were used. In alternate 10-minute periods, a rat received a time-out (TO) when no responding on the lever was necessary. The discrimination between the two periods was cued by appropriate visual stimuli. The two lowest doses that suppressed the appetitive-controlled behavior were studied. With the unsubstituted amphetamines, the rats produced high response rates during both the avoidance and TO periods with a reduction in the number of shocks received. On the whole, the chloro-substituted compounds produced relatively small increases in the rats' response rates with little or no change in the number of shocks received. These results indicate that, at the doses used, the chloro-substituted compounds produced less CNS stimulation than did *d*-amphetamine or methamphetamine.

AN OPERANT-BEHAVIOR avoidance procedure originally described by Sidman (1) has been employed to study the effects of drugs of the amphetamine class on conditioned avoidance responding (2–5). Rats, trained to press a lever (respond) to avoid or postpone brief, intermittent electroshocks, produced higher than normal response rates with the drugs in this study. Verhave (4) introduced a time-out contingency (TO) to the Sidman procedure. Rats were trained to avoid electroshock in the presence of a 433-c.p.s. tone stimulus. They were then taught to discriminate between tone-on avoidance periods and tone-off TO periods when no electroshocks would occur and responding was not necessary. As the discrimination developed the rats did not respond in the absence of the tone stimulus. With the amphetamines the animals had a tendency to continue responding during the TO. This effect with the drugs was considered as a breakdown of the tone stimulus control that maintained the acquired discrimination. In a previous study Verhave (3) had shown that, in the absence of established avoidance behavior, methamphetamine did not cause rats to produce high response rates with or without shock.

Rats given drugs of the amphetamine type show stimulated avoidance behavior only in a limited range of doses (3, 6). Doses above certain optimal levels (the level depending on individual variation from rat to rat) cause the animals to produce erratically depressed response rates. In some cases responding ceases entirely and the animal dies at much less than normally toxic doses of the drugs with normally nonlethal electroshock. Weiss, *et al.* (7), in a study of this phenomenon reported that rats and mice exposed to aversive electroshock died at much lower doses of amphetamine than animals that were not shocked. Also, the mode of death appeared different from that seen with lethal doses of the drug.

The investigation reported here utilized a Sidman-type avoidance TO procedure to study the influence of some 1-chlorophenyl-2-aminopropanes and their optical isomers on avoidance and discrimination behavior. These compounds were reported (8) to suppress appetitive-controlled fixed-ratio behavior. This study was undertaken as an extension of Rathbun's observations (9) of these compounds in mouse activity studies. He found that, although the 1-(4-chlorophenyl)-2-aminopropane compounds were more active central nervous system stimulants than the dichloro compounds, all caused little or no increased activity in the mice at dose ranges that induced appetite suppression in rats on food-consumption, weight-loss studies.

EXPERIMENTAL

Materials.—The compounds and doses used are listed in Table I. The compounds were dissolved in distilled water and administered subcutaneously.

Methods.—The subjects were six male rats of the Long-Evans strain, weighing 300–450 Gm. By means of a modification of the procedure described by Sidman (1) they were trained to press a lever to avoid brief intermittent electroshocks.

Two experimental cages were used in this investigation. Each measured 10 × 5 × 9 in. and was designed with four electrically isolated metal walls and a grid floor made of parallel $^3/_{16}$-in. diameter stainless steel rods. A response lever, a

modified telephone-type switch (10), was mounted on one end wall of each cage. A small 24-volt pilot light was mounted in the wall above the lever and another below the level of the grid floor. The cages were contained in light-proof, sound-resistant, ventilated boxes isolated from the control equipment.

Brief electroshocks of 0.2-second duration were given to the rat through the grid floor and walls of the cage at 2-second intervals (SS). A response on the lever postponed the next shock for 20 seconds (RS). Responses within this 20-second interval produced another 20 seconds without shock. Thus, with a steady rate of responding the rat avoided being shocked. The shock was provided by a constant-current generator passing half-wave 60-cycle d.c. at 1 milliamp. The shock was delivered to the cage through a "grid scrambler" that, in a random fashion, rapidly changed the current polarity on the individual grid rods and walls. The rat was thus unable to avoid shock by standing on rods or leaning against a wall of similar polarity.

Appropriate electrical relay circuits and timers were used to control the procedure and record the data on impulse counters and cumulative recorders.

After several training sessions, when the rats began developing stable avoidance behavior, the TO contingency was introduced. During alternate 10-minute periods the light over the lever went out and the light below the cage floor came on, signifying the TO when no shocks would occur. The rats learned to discriminate between the avoidance

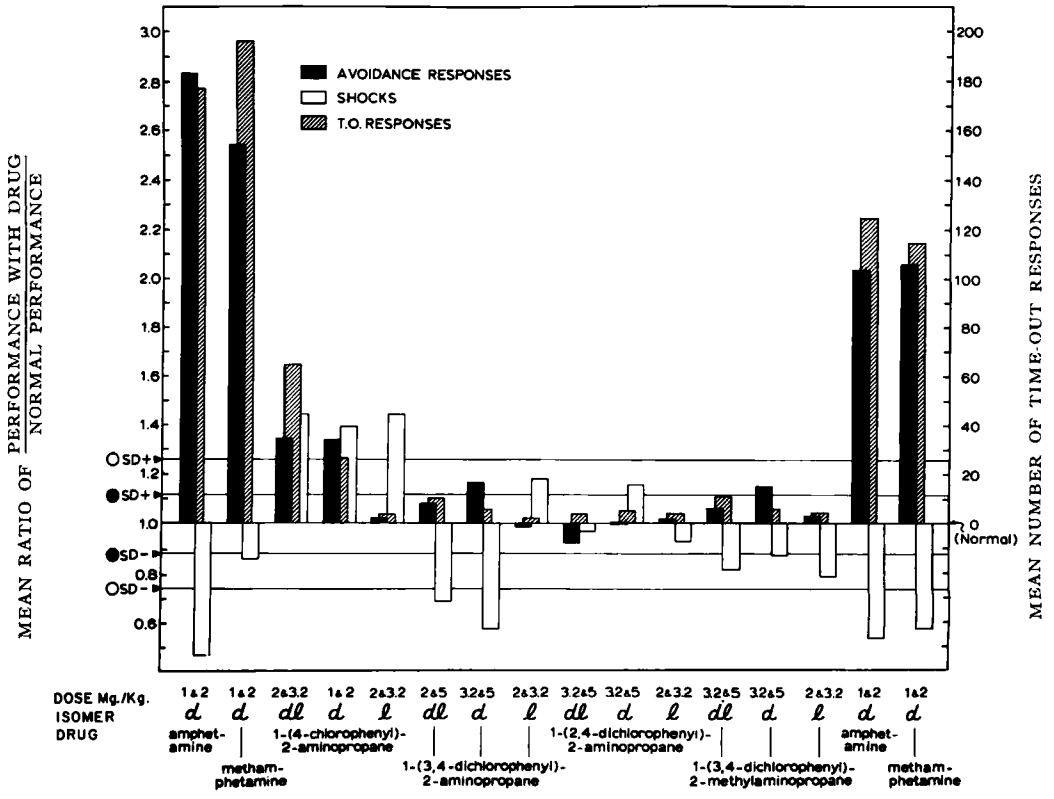

Fig. 1.—Summary of combined dose drug effects of compounds used in this study on avoidance discrimination behavior.

periods and TO by the change in the source of cage illumination. As the rats developed discrimination they no longer responded during the TO. Each avoidance-TO session lasted for 3 hours. When drugs were tested, each rat was given a 1-hour "warm-up" before drug administration. The animal then was returned to the experimental cage for a 3-hour session.

Only the two lowest doses of each compound that suppressed appetitive-controlled fixed-ratio behavior were used (8). *d*-Amphetamine and methamphetamine were tested at the beginning and again at the end of the investigation. The chloro-substituted compounds were run only once at each dose in a random order. Non-drug sessions run at 24 and 48 hours after a drug session failed to show residual drug activities on either avoidance or TO behavior. Thus, a time lapse of at least 48 hours was allowed between sessions for the individual animals.

Data.—The number of avoidance responses, the number of responses during TO, and the number of shocks received were recorded for each hour of each session. The means and standard deviation of avoidance responses and shocks received for the second hour of 11 non-drug sessions that were run during the study were calculated for each rat. Only non-drug sessions were used when at least 48 hours had elapsed since a previous drug session. The avoidance response and shock data from the second hour after drug administration of each drug session were used to calculate ratios of performance with drug to normal performance. Since TO responding normally was nonexistent in non-drug runs, no ratios were determined for this contingency of the procedure. Only the actual number of responses was counted.

Cumulative records of responses were made of each session to provide graphic data of the character and distribution of the responses and shocks.

RESULTS

The results of this investigation have been summarized by combining the data from both doses of each compound—presented in Fig. 1 as means of the ratios of avoidance responding and shocks received and the means of the TO responses. The data were combined because relatively little difference was seen between dose levels of each compound. This was especially true of the chloro-substituted drugs. The normal baseline (ratio of 1.0) and the means of normal standard deviations of the avoidance responses and shocks received have been included in Fig. 1.

At the beginning and at the end of the study with *d*-amphetamine and methamphetamine, the rats showed increased avoidance and TO responding with a decrease in the number of shocks received. With the *dl* and *d*-1-(4-chlorophenyl)-2-aminopropane

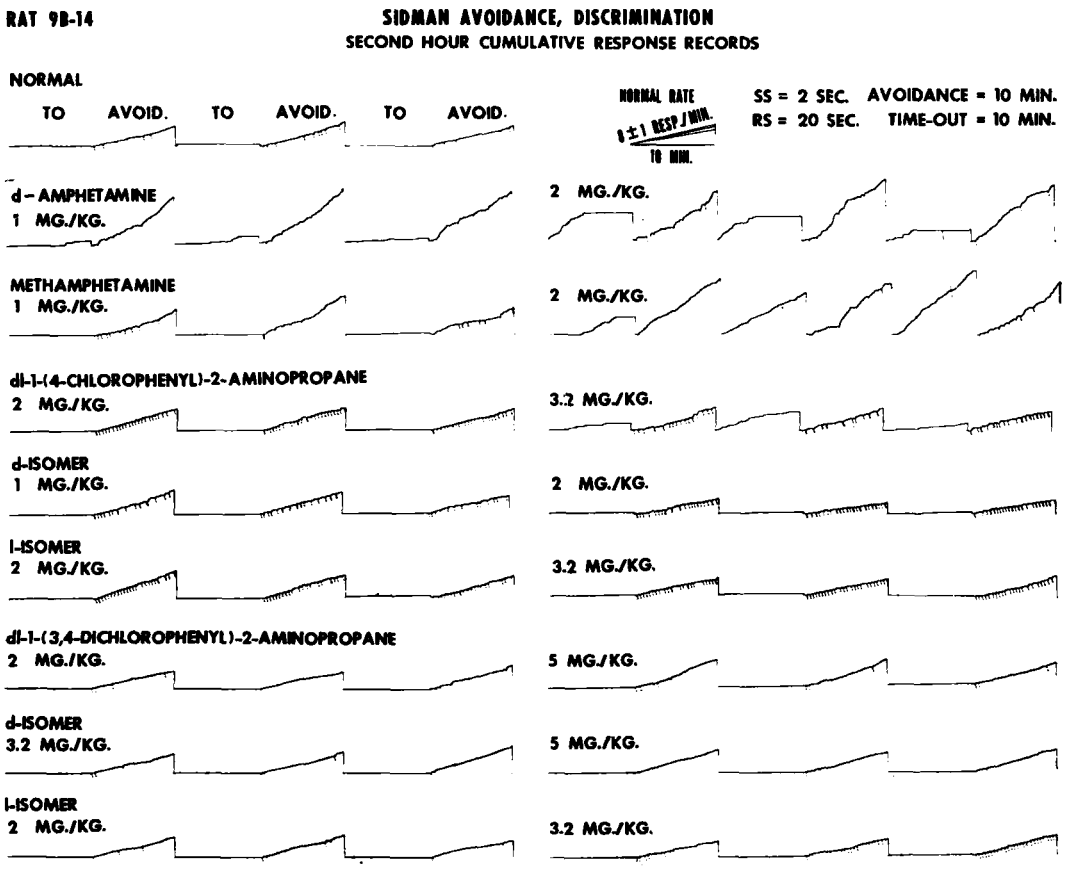

Fig. 2.—Cumulative response records of a rat comparing effects of drugs on avoidance discrimination behavior to normal behavior.

rats showed increased responding during the avoidance and TO periods with an increase in the number of shocks received. The magnitude of the response increases appeared to be one-third to one-half that of the des-chloro-compounds. The *l* isomer showed a marked increase only in the ratios of shocks received. Except for the *dl* and *d*-1-(3,4-dichlorophenyl)-2-aminopropanes, the remainder of the compounds produced ratios that fell well within the limits of normal standard deviation of avoidance responses and shocks, and near the normal of TO responding. The shock ratios of the *dl* and *d*-1-(3,4-dichloro)-2-aminopropane compounds appeared below the lower standard deviation limit.

Figures 2 and 3 show the cumulative response records of one typical rat. Included are examples of records of the second hour of non-drug sessions and records of the second hour after drug administration of *d*-amphetamine and methamphetamine and the 12 chloro-substituted compounds. This rat had a normal avoidance response rate of 8 ± 1 responses per minute, which has been drawn in the figures as the normal rate. The short vertical pen marks on the avoidance segments indicate points when the animal was shocked. Significant TO responding in these records appeared only after the administration of *d*-amphetamine, methamphetamine, and the higher doses of *dl* and *d*-1-(4-chlorophenyl)-2-aminopropane. The increased avoidance responding was apparent with the administration of the amphetamine compounds. The stimulated avoidance responding can be described as erratic and is illustrated with the *d*-amphetamine and methamphetamine and the 3.2 mg./Kg. dose of the *dl*-1-(4-chlorophenyl)-2-aminopropane. The animal received several successive shocks with only one or two responses between shocks and then responded in very rapid bursts of lever pressing. The overall effect produced very irregular appearing cumulative response records.

DISCUSSION

Data from this study have confirmed Verhave's observations (4) that the administration of amphetamine compounds to rats that have well developed avoidance and discrimination behavior causes the animals to show a stimulation of avoidance responding with a loss of ability to discriminate between the two contingencies of the procedure. The *dl* and *d*-1-(4-chlorophenyl)-2-aminopropane, unlike the dichloro-substituted compounds, more nearly resembled *d*-amphetamine and methamphetamine with regard to the rats' avoidance and TO responding. The magnitude of effect was somewhat less. However, qualitatively the *dl* and *d*-4-chloro compounds differed from all of the others since the animals received more shocks in spite of the increased avoidance responding. The *l* isomer of the 4-chloro compounds also showed high shock ratios

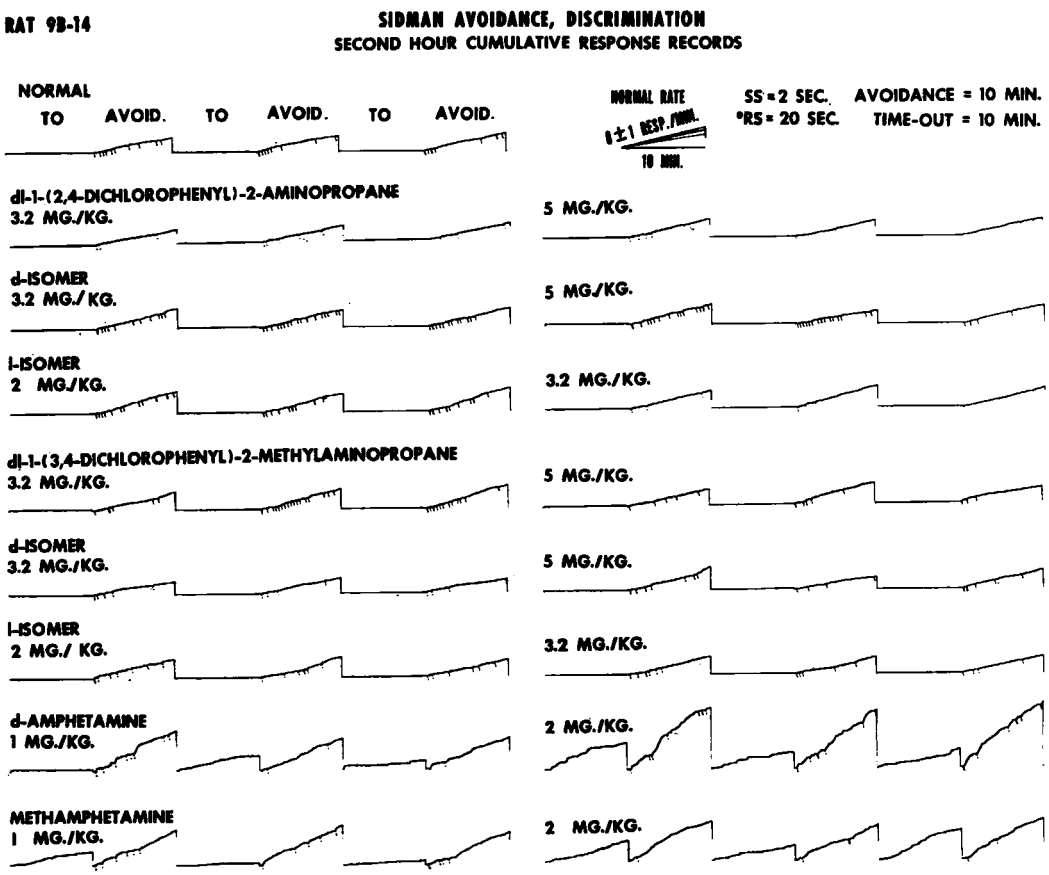

Fig. 3.—Cumulative response records of a rat comparing effects of drugs on avoidance discrimination behavior to normal behavior.

in the rats. Dichloro substitutions on the 2,4 and 3,4 positions of the phenyl ring of 1-phenyl-2-aminopropane structures, at the doses used, inhibited the behavioral stimulation effects seen with the parent structure. The general lack of responding during the TO contingency after administration of the dichloro-substituted compounds showed that the stimulus control of the changing light sources was maintained. The lowered shock ratios seen in the rats with the *dl* and *d*-1-(3,4-dichlorophenyl)-2-aminopropanes could be termed as an increase in efficiency since the avoidance ratios were only slightly raised, *i.e.*, more protection for the same work output.

Although the *d*-amphetamine and methamphetamine response rates were approximately 30% less at the end than at the start of the study, the mean avoidance response-rate ratios and TO responses with the chloro-substituted compounds were well below those of the amphetamine compounds. For the most part, the chloro compound data fell close to or within the normal standard deviation limits. The difference in the amphetamine data could be due to a development of tolerance to the 1-phenyl-2-aminopropane structure or more probably to a gradual strengthening of the behavior over the period of time covered by the investigation to provide a resistance to drug action.

SUMMARY

Some 1 chlorophenyl-2-aminopropanes have been compared with *d*-amphetamine and methamphetamine for effects on avoidance and discrimination behavior in rats. The doses used were the two lowest that caused suppression of an appetitive-controlled behavior.

After *d*-amphetamine, methamphetamine, and *dl* and *d*-1-(4-chlorophenyl)-2-aminopropane, rats showed increased avoidance response rates as well as responding during time-out periods when it was not necessary. This latter effect was considered as a loss of ability to discriminate. The rats when given dichlorophenyl-2-aminopropanes showed little or no change from normal in avoidance or discrimination behavior.

several solvent systems, different adsorbents, and appropriate developing reagents. Rules similar to those in paper chromatography apply also to the determination of R_f values, preparation of chambers, etc. Finally, additional criteria of identification by various physical methods should always be supplemental whenever this is practical.

Since a bibliography on TLC, which also includes several excellent reviews (9), deals with practically all the phases of this technique and its applications, we shall limit our discussion to a description of the experimental details necessary for the reproducibility of our results.

Preparation of Plates

Alumina.—Our studies were conducted on plates prepared with Fluka[3] special alumina for thin-layer chromatography. Thirty grams of this adsorbent were shaken with 75 ml. of distilled water for 30 seconds, poured into the Desaga[4] applicator, and spread on plates. They were then allowed to dry in the air for about 1 hour and activated in an oven at 110–120° for 15 minutes. Immediately afterward, the plates were allowed to cool in a desiccator and stored for varying lengths of time in a wooden cabinet over drying reagents (Drierite and calcium chloride).

Silica.—The plates were prepared using Merck[4] silica gel in the following manner: Twenty-five grams of the adsorbent was shaken with 50 ml. of distilled water for 30 seconds and applied using the applicator. They were used after having been allowed to air dry for at least 2 hours. These plates are also stored in a wooden cabinet over drying reagents.

Application of Alkaloids

Most of our studies, except where noted, were done using a concentration of 50 mcg. of alkaloid per spot (5 μl. of a 10 mg./ml. solution) in a suitable solvent (in most cases CH_2Cl_2 or $CHCl_3$).

When mixtures of alkaloids were investigated, quantities of 100–200 mcg. were used. Spots were marked 1.5 cm. from the lower edge of the plates. No more than nine samples were applied per plate (10 × 10 cm.).[4]

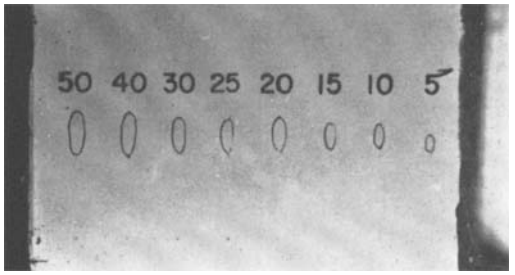

Plate 1—Different concentrations of catharanthine (5–50 mcg): adsorbent silica; solvent system, ethyl acetate.

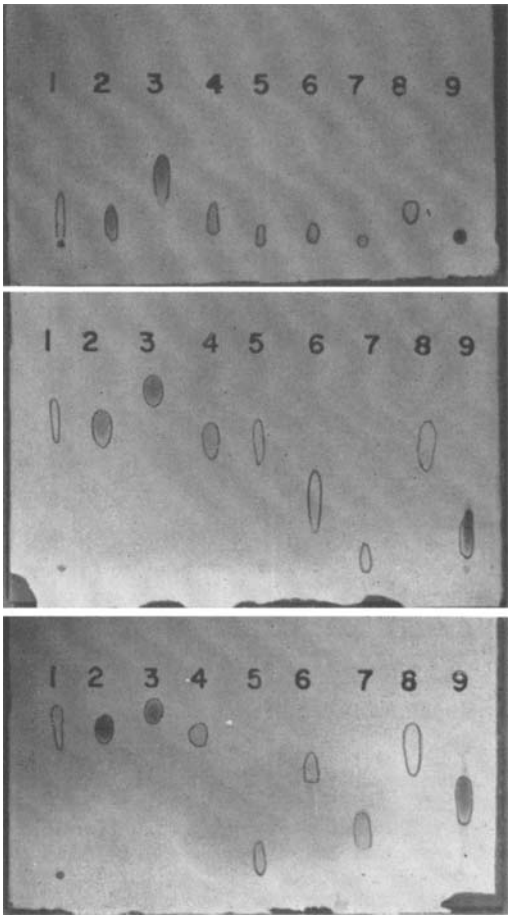

Plates 2, 3, 4—Dimeric alkaloids on silica adsorbent. Key: carosidine *1*, catharicine *2*, carosine *3*, catharine *4*, pleurosine *5*, neoleurocristine *6*, neoleurosidine *7*, vincarodine *8*, vindolidine *9*. Solvent systems used were ethyl acetate for plate 2 (top); ethyl acetate–ethanol (3:1) for plate 3 (middle); and ethyl acetate–ethanol (1:1) for plate 4 (bottom).

[a] Numbers refer to solvent systems listed in Table I.

Development of Plates

One-hundred milliliters of the developing solvent system were placed in the bottom of the chamber to insure a 5–7 mm. layer of the solvent. Two 15 × 25-cm. rectangular pieces of Whatman No. 1 filter paper were immersed in the solvent and placed on the two long sides of the chamber. Proper saturation of the system was assured by waiting 30 minutes before using the chamber. After this time the plates were placed in the chamber and rested on a 50-ml. graduate cylinder as a support. Time of development (when the solvent front reached a line marked 10 cm. from the point of application) was about 30 minutes for silica plates and 45 minutes to 1 hour for alumina plates.

TABLE IV.—SEPARATION OF CLOSELY RELATED DIMERIC ALKALOIDS

Compounds	Suitable Systems for Separating
Leurosine VLB Isoleurosine	No. 2 or No. 8
Leurosidine Leurocristine VLB or Leurosine	Develop first in No. 10; air dry 10 min.; then develop in No. 3
Leurosidine Sulfate Leurocristine Sulfate VLB Sulfate or Leurosine Sulfate	No. 11

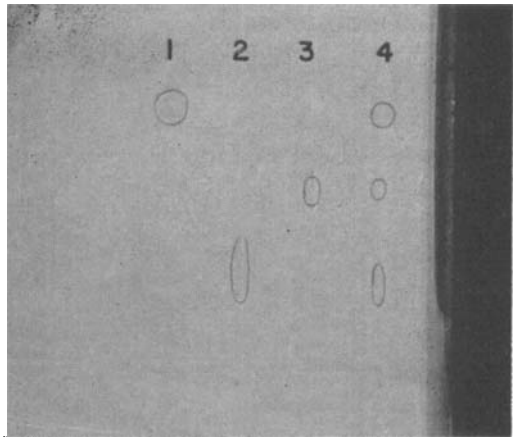

Plate 5.—Oncolytic alkaloids on alumina adsorbent (See Table IV for solvent system.) Key: VLB *1*, leurosine *2*, leurocristine *3*, and mixture *4* of 25 mcg. each of *1*, *2*, and *3*.

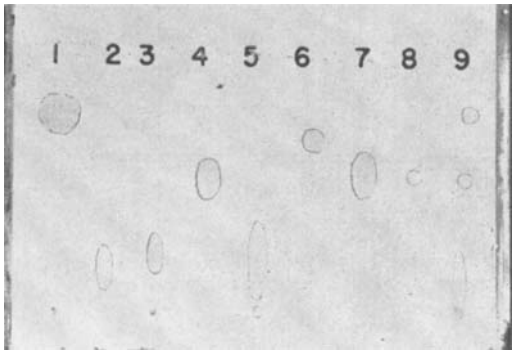

Plate 6.—Monitoring of elution chromatography on alumina. Comparison of an early fraction with several alkaloids known to occur in alkaloidal extract (Fraction A) (4). Key: catharanthine *1*, VLB *2*, isoleurosine *3*, ajmalicine *4*, leurosine *5*, tetrahydroalstonine *6*, vindoline *7*, vindolinine *8*, fraction No. 2 from fraction A *9* (100 mcg.).

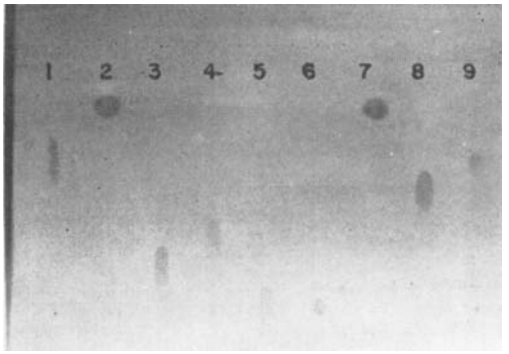

Plate 7.—Examples of results from Table IV on alumina with a chloroform-ethyl acetate (1:1) solvent system. Key: ajmalicine *1*, catharanthine *2*, catharine *3*, leurosine *4*, perivine *5*, serpentine *6*, tetrahydroalstonine *7*, vindoline *8*, vindolinine *9*.

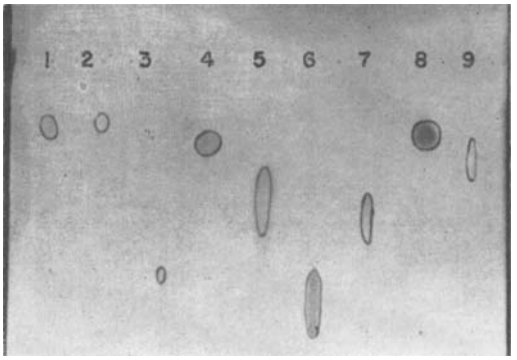

Plate 8.—Examples of results from Table IV on silica with a ethyl acetate-absolute ethanol (3:1) solvent system. Key: catharine *1*, lochnericine *2*, lochneridine *3*, lochnerine *4*, perivine *5*, serpentine *6*, vincamicine *7*, vindolicine *8*, virosine *9*.

Solvent Systems

The solvent systems used in this study are listed in Table I.

Alkaloidal Standards

The alkaloids[5] used in our study had physical characteristics in accordance with those described in the literature (4) and the "Lilly Collection of Physical Data of Indole and Dihydroindole Alkaloids" (10).

Spraying Reagents

Dragendorff's Reagent.—A stock solution is prepared using 2.6 Gm. of bismuth subcarbonate, 7.0 Gm. of dry sodium iodide, and 25 ml. glacial acetic acid. This solution is boiled about 4 minutes and allowed to cool overnight. It is then decanted or filtered from any insoluble material. For every 25-ml. solution obtained, 100 ml. ethyl acetate is added to make the stock solution. The reagent is made fresh daily with 24 ml. ethyl acetate, 10 ml. glacial acetic acid, 4 ml. stock solution, and 2 ml. distilled water, added dropwise.

Ceric Ammonium Sulfate Reagent.[6]—A 1% solution is prepared by dissolving 1 Gm. of ceric ammonium sulfate in 99 Gm. of syrupy phosphoric acid. It is necessary to heat the mixture on a hot plate 5–10 minutes before solution is complete.

DISCUSSION OF RESULTS

The results are tabulated in Tables II, III, and IV. Table II is self-explanatory. From Tables III and IV one can find a system and an adsorbent suitable for the separation of given alkaloids. As far as the reproducibility of R_f values is concerned, we noted that it varies with differences in concentration (Plate 1), the nature of the mixture, the quality of plates used, temperature, and related factors. This has been observed before by Stahl and others (9).

A few examples were chosen which indicate an efficient separation of certain dimeric alkaloids (see Plates 2–5). Plate 6 illustrates the use of thin-layer chromatography to monitor chromatographic fractions. Plates 7 and 8 are representative of the chromatograms which were used to compute the R_f values found in Tables II and III.

[5] We thank Drs. G. H. Svoboda and M. Gorman for authentic samples of several of the alkaloids used in this study and Mr. W. E. Kruse for art and photographic work.

[6] This reagent was introduced for the analysis of Vinca alkaloids by I. Jakovljevic, from the Lilly Control Laboratories, whom we thank for permission to use it in our studies.

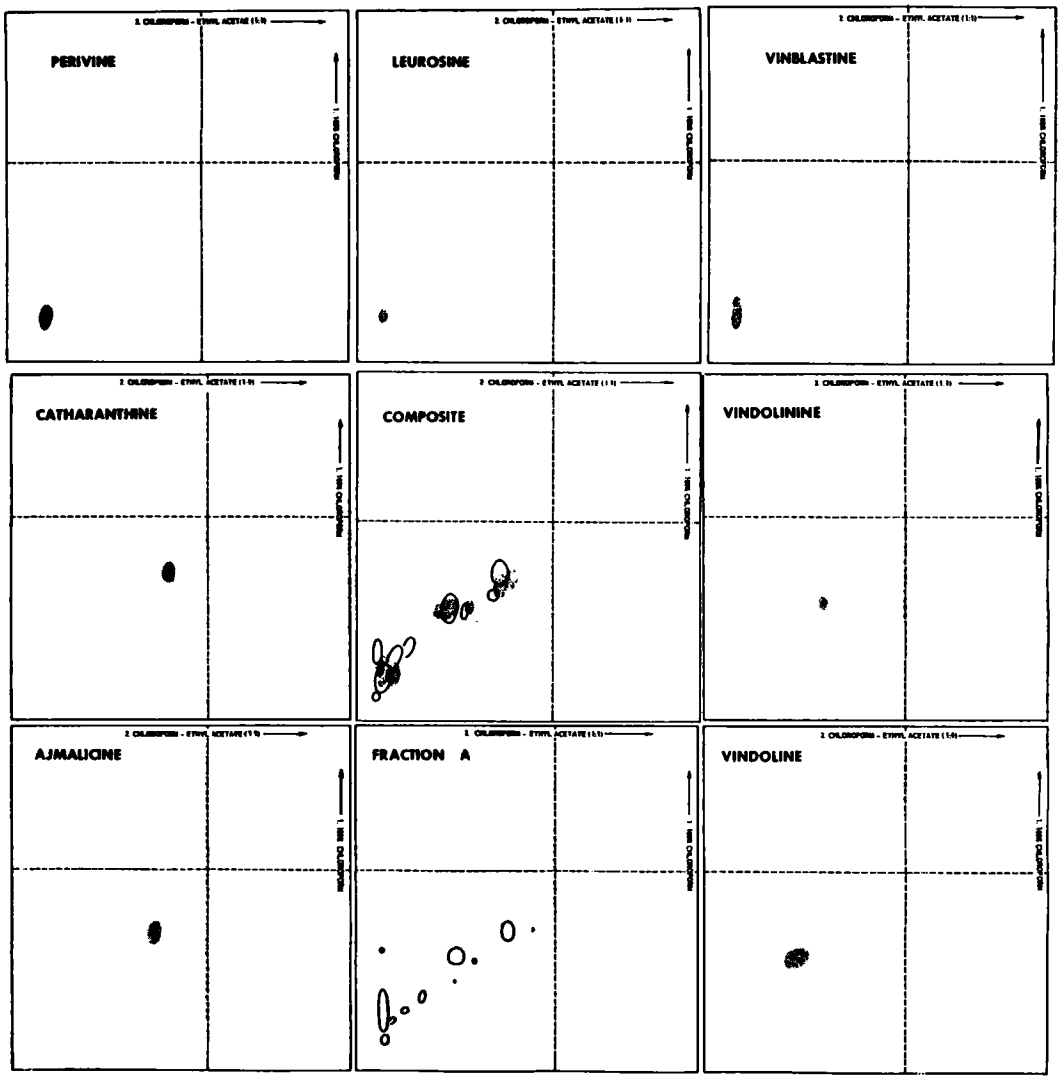

Fig. 1.—Didimensional chromatography on alumina using 1, chloroform (100%) and 2, chloroform-ethyl acetate (1:1) solvent systems. The concentration of Fraction A was 100 mcg. and for the composite 50 mcg. of the following alkaloids applied: ajmalicine, catharanthine, leurosine, perivine, VLB, vindoline, and vindolinine.

When complex mixtures (*e.g.*, Fraction A) (4) were subjected to solvent systems Nos. 1–6 in one dimension, separation was unsatisfactory. A better resolution was obtained by the use of didimensional chromatography on either alumina or silica.

Comparison of the position of spots from individual alkaloids in didimensional chromatograms with the position of spots in the mixture, run under identical conditions, gives a good indication of the nature of the mixture's different components. This procedure is illustrated in Fig. 1. The use of the ceric ammonium sulfate reagent, which gives specific color reactions, was also found to be very useful in this particular technique.

The figure, however, also illustrates that it is not possible to identify spots in the composite unequivocally. Even under similar conditions the location of spots is not always reproducible. Many materials, such as the dimeric alkaloids used in this composite, occur at nearly the same location; it is not possible to distinguish between them in this system.

Assay for Iodochlorhydroxyquin in Iodochlorhydroxyquin Ointment

By JACK COHEN† and ELMER KLUCHESKY

The U.S.P. assay for iodochlorhydroxyquin in iodochlorhydroxyquin ointment was found, in our laboratories, to be unworkable with either hydrocarbon or hydrophilic ointment bases. A colorimetric method was developed which is rapid, reproducible, accurate, and applicable to various ointment formulations. It is believed that this procedure is superior to the official assay presently in use.

THE U.S.P. XVI (1) assay for iodochlorhydroxyquin in ointment formulations involves the precipitation of iodochlorhydroxyquin as a copper chelate from an acetone extract of the ointment and subsequent gravimetric determination by weighing the precipitate.

Attempts were made without success to utilize this assay method in the determination of iodochlorhydroxyquin in two ointment formulations —one an oil-in-water emulsion and the other a hydrocarbon base. The ointment base ingredients do not remain in solution during precipitation of the iodochlorhydroxyquin complex thus seriously contaminating the precipitate on the filter.

Therefore, a method was sought for the assay of iodochlorhydroxyquin in ointment formulations which would circumvent these difficulties and, at the same time, find application to a variety of different types of ointment bases. A colorimetric assay based on the reaction described by Haskins and Luttermoser (2) was developed and found to be applicable to both of the formulations studied. The method depends upon the formation of a colored complex between iodochlorhydroxyquin and ferric ion at a pH between 1.0 and 2.0. Table I demonstrates the application of the method to quantitatively prepared standard samples.

TABLE I.—RECOVERIES OF IODOCHLORHYDROXYQUIN FROM STANDARDS

Hydrophilic Base, %	Hydrocarbon Base, %
100.0	99.4
98.5	99.1
101.5	98.8
101.0	101.0

EXPERIMENTAL

Apparatus and Reagents.—A Beckman DU spectrophotometer with tungsten light source and 1-cm. cells; acetone, reagent grade; methyl cellosolve, reagent grade; and iron reagent (prepare by adding 1 Gm. of ferric chloride, reagent grade, and 1 ml. concentrated hydrochloric acid to a 1-L. volumetric flask and diluting to volume with water) were utilized in this study.

Procedure.—Using a hypodermic syringe with a needle large enough to easily accommodate the ointment, add approximately 3 Gm. of ointment to a tared 100-ml. volumetric flask and weigh to determine the sample weight. Add 50 ml. of acetone to the contents of the flask and heat the mixture on a steam bath with occasional swirling until the ointment melts. Stopper the flask, shake vigorously for a short while, and allow to cool to room temperature. Dilute to volume with acetone and mix thoroughly. Add a 3-ml. aliquot to a 25-ml. volumetric flask, using a pipet with a cotton pledget over the tip. Evaporate the acetone from the flask on a steam bath and chill the residue briefly in an ice bath until it solidifies. To the residue add 20 ml. of methyl cellosolve and swirl to disperse the solid material (do not shake vigorously). Add 2 ml. of iron reagent, dilute to volume with methyl cellosolve, and mix thoroughly. Prepare a reagent blank solution by diluting 2 ml. of iron reagent to 25 ml. with methyl cellosolve. Insert a cotton swab on the end of a glass rod into the solution in the neck of the flask and withdraw it to remove most of the oil globules from the surface of the solution. Fill a 1-cm. Pyrex cell using a 4-ml. pipet with a cotton pledget over its tip. The solution at this point must be clear. Determine the absorbance of the solution against the reagent blank at 650 mμ on the spectrophotometer.

Calculations.—Calculate the amount of iodochlorhydroxyquin in the sample by

mg. iodochlorhydroxyquin per Gm.

$$\text{of ointment} = \frac{A}{K \times \text{Gm. of sample}}$$

where A = absorbance at 650 mμ, and K = absorbance index in terms of mg. of drug per 100 ml. of sample solution.

Absorbance Index.—Prepare three standard solutions of iodochlorhydroxyquin reference standard in methyl cellosolve to contain approximately 30, 50, and 70 mg. per 100 ml. Develop the color for each standard as follows. Add a 3-ml. aliquot to a 25-ml. volumetric flask and add 17 ml. of methyl cellosolve. Add 2 ml. of the iron reagent, dilute to volume with methyl cellosolve, and mix thoroughly. Prepare a reagent blank by diluting 2 ml. of the iron reagent to 25 ml. with methyl cellosolve. Determine the absorbance at 650 mμ using the 1-cm. cells and the reagent blank solution in the reference cell. Calculate the absorbance index K by the equation $K = A/c$, where c is the concentration of standard in mg. per 100 ml. and A is the observed absorbance for the corresponding colored solution. Table II shows the results for three such standards using the Beckman DU spectrophotometer.

TABLE II.—DETERMINATION OF ABSORBANCE INDEX ($K = A/c$)

Concn. c, mg. per 100 ml.	Absorbance A	Absorbance Index K
34.8	0.218	0.00626
52.0	0.320	0.00615
69.5	0.427	0.00614

CONCLUSIONS

The U.S.P. method for iodochlorhydroxyquin in ointment preparations presents many difficulties. It is practically impossible to obtain a precipitate free of ointment base materials from an acetone extract of most ointment preparations.

The method described in this paper offers several advantages over the official method in that it is simple, rapid, reproducible, and accurate. The color formed by the reaction of ferric ion and iodochlorhydroxyquin in methyl cellosolve has been shown to be stable over a period of at least 1.5 hours. The application of the assay to two different types of ointment bases was demonstrated.

Preparation of Parenteral Dispersions

By THOMAS J. MACEK

Parenteral dispersions of medicinal products may take the form of parenteral colloids, parenteral emulsions, or parenteral suspensions. The paper defines these categories and discusses problems of manufacture and stability and illustrates with practical examples.

THE TERM "dispersion" is very general and may have several meanings. A simple solution of a salt or sugar in water can be considered an aqueous dispersion. As such, it occupies a position at one end of a scale describing various states of matter. Heterogeneous admixtures of a liquid and relatively large fragments of another immiscible liquid or solid, on the other hand, are described as emulsions or suspensions and occupy a place at the opposite end of that scale. The state of matter between these two extremes, and more particularly when the dispersed phase consists of particles between 1 and 100 mμ in size is that intermediate range called the "colloidal state." This region frequently is subdivided further by the term "colloidal solution" or "sol" as in the case of a solution of gelatin or of silver iodide, and colloidal dispersions, as in the case of colloidal gold having solids suspended in the submicron form. The term "hydrosol" is employed when the solvent is water, and the term "aerosol" refers to a colloidal dispersion in air or another gas.

Actually, the line of demarcation between a true solution and the colloidal state is not really very sharp. Solids dissolve in a liquid such as water when there is complete or near complete intermingling of solute and solvent molecules or ions. The ionic bonds of salts such as exist between Na^+ and Cl^- must be fractured in the process of dissolving, the energy being derived from the polarity of the solvent. At best, solute to solute and solvent to solvent bonds have to be broken and new solute to solvent bonds formed. If the forces—such as

Preparation of Parenteral Dispersions

By THOMAS J. MACEK

Parenteral dispersions of medicinal products may take the form of parenteral colloids, parenteral emulsions, or parenteral suspensions. The paper defines these categories and discusses problems of manufacture and stability and illustrates with practical examples.

THE TERM "dispersion" is very general and may have several meanings. A simple solution of a salt or sugar in water can be considered an aqueous dispersion. As such, it occupies a position at one end of a scale describing various states of matter. Heterogeneous admixtures of a liquid and relatively large fragments of another immiscible liquid or solid, on the other hand, are described as emulsions or suspensions and occupy a place at the opposite end of that scale. The state of matter between these two extremes, and more particularly when the dispersed phase consists of particles between 1 and 100 mμ in size is that intermediate range called the "colloidal state." This region frequently is subdivided further by the term "colloidal solution" or "sol" as in the case of a solution of gelatin or of silver iodide, and colloidal dispersions, as in the case of colloidal gold having solids suspended in the submicron form. The term "hydrosol" is employed when the solvent is water, and the term "aerosol" refers to a colloidal dispersion in air or another gas.

Actually, the line of demarcation between a true solution and the colloidal state is not really very sharp. Solids dissolve in a liquid such as water when there is complete or near complete intermingling of solute and solvent molecules or ions. The ionic bonds of salts such as exist between Na^+ and Cl^- must be fractured in the process of dissolving, the energy being derived from the polarity of the solvent. At best, solute to solute and solvent to solvent bonds have to be broken and new solute to solvent bonds formed. If the forces—such as

hydrogen bonding—between these new associations are great, solubility is favored. In that special situation where these forces are equal or cancel previously existing forces between individual particles of solute and individual particles of solvent, there is a free intermingling and we have a case of an ideal or perfect solution. On the other hand, the forces between the dissimilar particles much more frequently are not as great as the forces between the similar individual components; hence solubility will not be favored, but dispersion may occur. The dispersion may assume colloidal or suspension proportions, sometimes followed by precipitation or flocculation or both.

In accordance with this concept, the terms "hydrophilic" and "hydrophobic" are used to describe the tendency of a surface, a particle, or a functional group to establish bonds of association with the solvent, water. In colloidal systems, stable colloids are always referred to as lyophilic or hydrophilic. Unstable colloids are always lyophobic or hydrophobic. They represent those that are readily flocculated by small amounts of electrolytes.

Some examples will serve to illustrate. Albumin and other proteins dissolve in water, forming hydrophilic sols. Polyvinylpyrrolidone, dextran, the carbohydrate gums, and other synthetic gums behave similarly. In spite of the large size of the protein or gum molecules, they form remarkably stable colloidal solutions. This is because of their state of hydration (the so-called watery envelope) and of their electrostatic charge. To precipitate a hydrophilic sol, one must first remove the charge. This usually is accomplished by adjusting the pH to the isoelectric point at which there is electrical neutrality. Then the watery envelope is removed by dehydration, as with alcohol or a dehydrating salt, such as ammonium sulfate. The protein or gum precipitates under these rather special conditions.

Hydrophobic sols behave quite differently. If an insoluble substance is ground long enough and fine enough in water, a hydrophobic sol may form. This colloidal state will not be very stable, however. The particles, continually in motion, bombard each other, energy is reduced in the process, and there is a great tendency toward coalescence and flocculation. Hydrophobic sols are stabilized by reducing interfacial tension which changes the energy at the particle surface. The process of transforming an insoluble substance into the colloidal state frequently is referred to as "peptization." However, even this colloidal state is easily broken by the simple addition of an electrolyte.

When the extent of the stabilization by reduction of surface forces is great enough, a hydrophobic material can be rendered seemingly water-soluble. This process is called "solubilization," or solubilization through micelle formation. It differs from hydrotropy, another solubilization process which is distinguished by the absence of colloidal material. In the latter case, solubilization is accomplished through the use of aqueous solutions of salts or organic ions, the so-called "salting in" effect, or through the use of water-diluted organic solvents or mixtures of solvents. Emulsification is distinguished from both solubilization and hydrotropy principally by the size of the dispersed phase. An emulsion generally also is opaque, whereas the other phenomena produce solutions which are transparent, at least to the naked eye. Furthermore, an emulsion comprises a dispersion of one immiscible liquid in another. When the process describes solids instead of liquids, the system is a suspension.

Over the years, numerous parenteral formulations have been developed for medicinal use which span the entire range of these different states of dispersion. Much could be said about the properties of surface-active agents, about the hydrocolloids, and about techniques and theories involved in the dispersion and emulsification processes. However, inasmuch as industrial pharmacists constantly are faced with practical problems of development and manufacture, this paper concerns itself with some practical considerations pertaining to parenteral colloids, emulsions, and suspensions. It is hoped that observations and experiences in the development of these dispersion products may prove interesting while illustrating principles and problems which are encountered when working in this field.

MATERIALS AND FACILITIES

The choice of active form of the drug for the preparation of parenteral dispersions is limited largely by pharmacological considerations. Therefore, in most cases the industrial research pharmacist is confronted with a form of a drug that is active biologically with which he must prepare safe and acceptable parenteral products. Quite often, this may be the only active form of the drug known at the time. In some cases, only insoluble forms of the drug possess desirable properties such as prolongation of activity, stability, lack of irritation, etc.

Such was the case at first with the insoluble derivatives of the corticosteroids. Several years elapsed before stable, biologically active, and completely water-soluble derivatives of the adrenocortical steroids were discovered. As a general rule, when biological properties are equal, it is far more desirable and economical to search out water-soluble forms of new drugs for parenteral administration than to attempt the more difficult formulation of physically less stable parenteral dispersions. In the case of methyldopa,[1] exactly this course was pursued, resulting in the development of the water-soluble and biologically active ethyl ester hydrochloride derivative specifically for parenteral use. Other well-known examples of this approach have occurred among the antibiotics. The sodium methanesulfonate of colistin provides a water-soluble parenteral. The ethanol-ammonium-magnesium complex of oxytetracycline is soluble in a propylene glycol-water vehicle employed for injection. The ethyl succinate of erythromycin has been dissolved in a polyethylene glycol vehicle for intramuscular administration. A 10% solution of the sodium succinate derivative of chloramphenicol proved useful for both intravenous and intramuscular injection. Similar examples are found among other classes of therapeutic compounds.

On the other hand, the natural oil form of vitamin K_1 proved much superior therapeutically to syn-

[1] Marketed as Aldomet by Merck and Co., Rahway, N. J.

thetic analogs of K and had to be dealt with even though water-insoluble. For reasons of stability, the insoluble salts of penicillin had to be employed to formulate ready-to-use aqueous suspensions of this antibiotic. The insoluble dibenzylethylenediamine salt of penicillin had to be used to achieve the sought-after prolongation of blood levels. And so the problems of preparing parenteral dispersions persist.

Agents which are employed to prepare and stabilize parenteral dispersions have to meet at least three principle criteria. The first is that they must be safe. This requires that they be nontoxic, nonantigenic, nonpyrogenic, nonirritating, and nonhemolytic. The second is that they must be potent dispersants and/or stabilizers so that only small amounts are required. Third, the agents should be stable, especially upon prolonged storage, and preferably under the conditions of higher temperatures which one would like to employ for positive sterilization. One might add a fourth criteria—namely, known acceptability to the federal Food and Drug Administration. Otherwise, the burden of proof of safety, which today if not attainable without considerable expenditure of time and money, rests entirely upon the user. These are very rigid specifications and rule out many agents that are perfectly satisfactory for oral use in pharmaceuticals and even in foods. A partial list of agents which have been employed in commercial parenteral products is shown in Table I.

The preparation of parenteral dispersions often presents difficult or unusual problems of manufacture because of the requirements for sterility and freedom from pyrogen contamination. In this regard, the efficiency of dispersing and mixing equipment sometimes must be comprised to achieve completely aseptic operation. The alternative is to reconstruct such equipment to withstand heat sterilizing conditions, also a job not easily accomplished. Totally enclosed systems have had to be designed for large-scale aseptic production operations. In such instances assurance was needed to show that the dispersions could be adequately mixed and kept in a state of uniform suspension throughout all preparative, transfer, and subdividing operations. This has been a task to engage the best thinking and ingenuity of both pharmacists and engineers in many industrial plants. Apart from the facilities and techniques for sterile formulation, the development and production of parenteral dispersions would not have been possible without considerable attention to the physical properties of the starting materials, particularly in dealing with suspensions.

In this regard the first gram of cortisone acetate ever produced was processed by aseptic milling with aqueous vehicle employing a glass bottle and glass beads. Milling continued until 90% of the particles were smaller than 10 μ. Although the procedures changed drastically as the scale of operation increased, the requirement for the particle size was retained and, indeed, established a standard for most of the corticosteroid suspensions that followed. Today cortisone acetate and other corticosteroids for parenteral use are crystallized using methods and facilities which produce a sterile solid having a particle size smaller than 10 μ. In addition, the crystallization of cortisone acetate is conducted in a way which produces that polymorphic form which experience has shown to be stable upon prolonged storage in aqueous suspensions. Such starting material requires no subsequent milling. It is simply suspended in a sterile aqueous vehicle by a process which lends itself readily to large-scale operation under strictly aseptic conditions.

The manufacture of other parenteral suspensions presents somewhat different problems. Nonetheless, detailed attention is required to specifications of crystal form and particle size in order to achieve physical and therapeutic uniformity in the final parenteral dispersions.

PARENTERAL COLLOIDS

The area of biological products provides numerous examples of parenteral dispersions in the colloidal state. These include serum albumin, fibrinogen, various immune globulins, human fibrinolysin, insulin, corticotropin, and other hydrophilic protein or peptide products derived from human blood and natural sources.

Several parenteral solutions of iron are actually colloidal dispersions of complexes of iron with carbohydrate materials. This category includes an iron-dextran complex,[2] a high molecular weight iron-carbohydrate,[3] and a saccharated iron oxide.[4]

Perhaps of greater interest, however, are those colloidal dispersions prepared by micellular solubilization involving smaller organic molecules that are essentially hydrophobic. Parenteral products in this category include a product containing water-solubilized vitamin A,[5] an aqueous dispersion of a synthetic vitamin K,[6] and an aqueous colloidal

solution of vitamin K_1[7] made using Emulphor EL-620 as solubilizing surfactant.

The theory of solubilization by micelle formation was first postulated in 1913 by McBain (1). It described the phenomenon wherein particles of a colloidal substance such as potassium stearate functioned to incorporate the insoluble materials within themselves. In the process the original solid or oil particles disappeared into the organized structure of the stable colloid. This process today has been extended to include a wide variety of surface-active agents, some of which are acceptable for parenteral dispersions.

To be effective the surfactants themselves must be soluble in water and form the proper micellular environment for solubilization. The concentration at which micelle formation begins to occur is known as the critical micelle concentration. This can be measured in various ways and has been observed to decrease as chain length of surfactant increases, regardless of its basic organic structure. Sometimes the surface-active solubilizer may have other effects which enhance its activity, such as cosolvency and specific complex formation. However, in spite of many excellent studies on solubilization which have brought about a better understanding of some of the mechanisms involved, it still is necessary to conduct empirical research to arrive at practical answers in most cases.

Some generalizations are available, however, and are worth noting. In 1949, Griffin (2) devised a hydrophile-lipophile balance (HLB) system for classifying surfactants which is helpful in selecting solubilizers. Moore and Bell (3) later listed some useful observations based upon the studies of a number of workers which are helpful in laboratory problems of solubilization. For example, it has been observed that in a homologous series of compounds the amount of solubilizer needed increases directly with the polarity, cyclization, and unsaturation of the hydrophobe and inversely with chain length. The addition of inorganic salts to a solubilized system increases the amount of nonpolar or hydrocarbon-like substances solubilized, but decreases the amount of polar substances solubilized. The more lipophilic nonionic surfactants favor maximum solubilization of low polar substances, and the more hydrophilic nonionic surfactants favor solubilization of the more polar hydrophobes.

From a formulator's viewpoint, it is often found that a mixture of two or more surfactants proves better for solubilizing a compound than does one alone. In addition, a co-solvent sometimes also helps to attain a clear solubilized solution. Once a solubilizer or mixture of solubilizers shows promise, the effect should be studied over a range of ratios of solubilizer and solubilizate. And finally, a mixture of water, solubilizer, and hydrophobic solubilizate often has to be heated to obtain a solution. The optimum heating time may vary with different systems. In some cases, mixtures may show a negative solubility. In other words, their solutions may be cloudy at higher temperatures and clear at room temperature. Clarification may develop slowly in these instances and the solution therefore should be allowed to stand. Slightly opalescent solutions sometimes may be made crystal clear by rapid cooling.

Even though the list of parenteral products made by solubilization using surfactants is still small, this area of formulation offers interesting possibilities. It not only provides a means for preparing aqueous parenteral forms of hydrophobic drugs, but also provides the opportunity for stabilization of some sensitive drugs in parenteral products as well. In this regard, Riegelman (4) observed that micelles of cationic or anionic surfactants shielded certain esters against hydrolysis.

In a 5% sodium lauryl sulfate solution, the half-life of benzocaine against base-catalyzed hydrolysis was extended some eighteenfold. This is a very profound change and is worth noting. Although sodium lauryl sulfate may be unsuitable for parenteral use in these quantities, other surfactants need to be studied. The ampholyte, Emulphor EL-620, by comparison is much less toxic, and also nonhemolytic in rather substantial concentrations.

PARENTERAL EMULSIONS

Until now only two commercially-available parenteral emulsions have enjoyed extensive medical use. Both of these were specifically for intravenous administration. However, parenteral emulsions of fats, either alone or supplemented with amino acids or vitamins, attracted considerable research and clinical interest some time ago and occupied the attention of pharmacists for several years.

An emulsion of a natural vitamin K_1 in an aqueous vehicle made with a purified form of lecithin as emulsifier is described in the U.S.P. as sterile phytonadione emulsion.[8] Considerable care is taken during manufacture and testing of this parenteral to assure that all of the emulsified oil droplets conform to a rigid particle size specification in the range of 1 to 5 μ. This state of subdivision is achieved by an emulsification process involving the use of an intermediary solvent. The emulsion is sterilized by autoclaving while in bulk; it is then filtered and subdivided aseptically into the final ampul containers.

The second product is a parenteral fat emulsion[9] containing 15% cottonseed oil and 4% dextrose, with 1.2% lecithin and 0.3% of an oxyethylene-oxypropylene polymer as emulsifying agents. The product is administered in volumes of 250 to 500 ml. by intravenous infusion to supply dietary fat in debilitating diseases, post surgery, etc. Most of the dispersed droplets in this product are less than 1 μ in size and none can be greater than 5 μ. The product presumably is sterilized in the final container by autoclaving. Like sterile phytonadione emulsion, it must be protected against freezing.

Inasmuch as parenteral emulsions are intended for intravenous administration, absolute assurance of sterility is required, and sterilization in the final container by autoclaving is virtually essential.

[7] Marketed as Aquamephyton by Merck Sharp and Dohme, West Point, Pa.

[8] Marketed as Mephyton by Merck Sharp and Dohme, West Point, Pa.

[9] Marketed as Lipomul I. V. by The Upjohn Co., Kalamazoo, Mich.

Elevated temperature, however, tends to cause increased coalescence of fat globules; hence, parenteral emulsions must be designed to withstand heat sterilization. In this connection, nonantigenic gelatin has been explored for use both as an emulsifier and emulsion stabilizer for intravenous products. Unfortunately, solutions of gelatin hydrolyze upon autoclaving, and this change can result in alterations in emulsion stability. Small concentrations of methylcellulose appear to stabilize fat emulsions against separation or creaming, but one encounters a problem during autoclaving because of the insolubility of methylcellulose at elevated temperatures. Dextran also has been examined as an emulsion stabilizer.

The stability of fat emulsions is no small problem. Apart from the potential development of rancidity of the oil phase, fat emulsions are subject to adverse physical changes. Excessive shaking of parenteral fat emulsions has been observed to accelerate the rate of separation ("creaming") and to cause a greater tendency toward particle coalescence. This change probably is caused by rupture of the film of emulsifier about the particles of dispersed oil. It has been also observed that bottles half full of fat emulsion "creamed" at a faster rate upon prolonged storage than full bottles. Such change was thought to be due to decomposition of the film of emulsifying agent by oxidation.

It is apparent, then, that the preparation of parenteral emulsions is troublesome. It is made more difficult by rigid requirements regarding particle size for reasons of safety, without much latitude in the choice of emulsifiers and stabilizers and stringent requirements for stability upon exposure to both high and low temperatures.

PARENTERAL SUSPENSIONS

One of the earliest commercial parenteral suspensions was sterile bismuth subsalicylate suspension in oil. The product still is described by U.S.P. monograph and is employed as an antiprotozoal and antisyphilitic agent. Among other early parenteral suspensions were those of the estrogens, androgens, and progestational hormones, some of which still are very valuable therapeutic agents.

However, it was the discovery of the adrenocorticol stercids, of penicillin, and the broad spectrum antibiotics that gave renewed impetus to the development of new compositions and technology for the preparation of parenteral suspensions.

The method employed for preparing the first quantities of cortisone acetate was mentioned previously. Glass bead milling to reduce particle size was conducted in a portion of the vehicle containing polysorbate 80 as surfactant to facilitate wetting of the water-insoluble, hydrophobic crystals of the steroid. The wetting agent was effective in this case because it favored the replacement of the solid-air interface by a solid-liquid interface. This is the property expected of a good dispersing agent. However, this alone was insufficient to produce a physically stable suspension. Hence, there was a need for a compatible dispersion stabilizer, protective colloid, or agent to bridge the gap between the continuous phase of the aqueous vehicle and the essentially hydrophobic particles which it enveloped. For this purpose sodium carboxymethylcellulose was employed. This is a safe parenterally acceptable hydrocolloid which had an affinity for the continuous phase. It could be employed effectively in concentrations which produced only a small change in viscosity; it was stable and could be sterilized by autoclaving. In the presence of sodium carboxymethylcellulose, to a large extent the dispersed particles of steroid lost many of the properties which normally identified them as hydrophobes—namely, surface charge, water repellency, and tendency toward agglomeration. Instead they assumed some of the properties of the protective colloid and of the continuous phase. Thus, the suspension was stabilized, settling was reduced, and resuspension by shaking was readily accomplished. Sodium chloride was added to adjust isotonicity. Benzyl alcohol was employed as a preservative. This example illustrates one of the fundamental ways available to the pharmacist for preparing suitable suspensions of a hydrophobe for parenteral use—namely, dispersion using a wetting agent in conjunction with a compatible protective colloid.

A brief digression for a moment will serve to highlight another potential problem. During the period that parenteral suspensions of cortisone acetate were made by bead milling, no problems with polymorphic changes were encountered. It is apparent today that phase changes were being experienced, inasmuch as the starting solid was later shown to be a physically unstable variety in contact with water. However, if a change occurred, this happened during the course of the extended milling cycle and without evidence of significant changes in particle size. Difficulties with polymorphism were encountered when dry, premilled solid of the wrong crystal form was rapidly suspended in the aqueous vehicle by mechanical agitation and the resulting suspensions were allowed to stand undisturbed. The change to a more stable crystal form invariably was associated with crystal growth, the intermingling of these crystals, and the formation of a cake or lumpy suspension. Usually these changes occurred in the final vials so that little could be done to recover the product. The possibility of polymorphic change, therefore, should be anticipated in many parenteral suspensions of new compounds, especially of the steroid type.

Recently, with some steroids, particularly the highly water-insoluble tertiary-butylacetate esters of hydrocortisone and prednisolone, it was possible to replace sodium carboxymethyl cellulose in the aqueous vehicle with sorbitol. This additive functioned as a suspension aid by increasing the density of the aqueous vehicle rather than as a protective colloid. The rate of settling of the suspended solid was readily decreased as the density of the aqueous phase increased by addition of graded increments of sorbitol.

The preparation of aqueous parenteral suspensions of procaine penicillin both in the ready-made and dry-mix forms presented some very different and interesting dispersion problems. Where concentration of suspended solids did not exceed 5% in the case of the corticosteroids, the problem now was one of preparing essentially fluid, syringeable, and injectable suspensions containing up to about 35% solids. Without effective dispersing agents, it

was very difficult even to wet this much solid adequately with the limited volume of water. Surfactants such as lecithin and Pluronic F-68, which proved very effective for purposes of wetting, produced highly dispersed suspension systems exhibiting extremely poor physical stability. Such systems settled slowly but ultimately sedimented to a very dense cake which was exceedingly difficult to resuspend. When viewed under the microscope, disperse suspensions of this type were seen to consist of individual particles, each in random and haphazard motion in relation to others having no apparent association between themselves. The dispersion could be likened to a suspension of sea sand in a bottle of water. Each particle was free to move in any direction at any speed even after colliding with another. When gravity sedimentation occurred, the volume occupied by the solid was small. The dense cake which formed, however, was resuspended again only by peeling a thin layer of particles off the top, one after another, until finally all solid was resuspended.

With procaine penicillin dispersions, it was found that not enough protective colloid could be added to improve adequately the sedimentation properties without also significantly altering their viscosity, flow, syringeability, and other physical properties, usually in an undesirable way. This is not to say that hydrocolloids, like sodium carboxymethylcellulose or gelatin, did not produce a favorable result in aqueous suspensions of procaine penicillin. If the products had been for oral use where high viscosity was not of great importance, they probably would have been quite acceptable. Indeed, the addition of gums is a common way of stabilizing oral suspensions. However, in the parenteral suspension the properties sought included a high degree of product fluidity, little or no foaming, quick restoration with water when in the dry form, a rapid break from the surface of the siliconed vial, a thin suspension for easy syringeability, and a product with good injectability through small bore hypodermic needles. Such properties could not be achieved readily in suspensions of high solids content by the classic method of using a protective colloid alone in conjunction with a wetting agent. Some other method for suspension stabilization had to be found. In this connection partial flocculation by the addition of selected inorganic ions proved to be highly successful.

Flocculation of the dispersed solid was achieved in increasing magnitude by monovalent, divalent, and trivalent ions, respectively. Indeed, flocculation of procaine penicillin dispersions by the addition of even very small amounts of trivalent aluminum, as the chloride, would occur to such an extent that the suspensions acquired an unsightly, nonuniform appearance. However, such suspensions could always be resuspended by gentle shaking. In practice, a partially flocculated dispersion made with monosodium citrate proved most practical. A small amount of the protective colloid, or the use of sorbitol to increase vehicle density, also proved of benefit.

According to Michaels and Bolger (5), in the partially flocculated system, the floc, or the associated colony of a number of particles, becomes the basic flow unit in low shear processes such as gravity sedimentation. These flocs can be regarded as rigid spheres which tend to cluster together in weak aggregates. The aggregates grow by collision, are broken down by low shear forces such as gentle shaking or by flow through a small orifice of a hypodermic syringe or needle, yet they are able to reform easily the extended networks which give the suspension its structural properties with virtually no increase in viscosity. The partially flocculated suspension will settle rapidly, but to a high sedimentation volume and is easily resuspendable. Most important from our standpoint, they can be produced easily under sterile conditions, using materials which are fully acceptable for parenteral formulation.

Wood Products, Corncob, and Cellulose as Tablet Disintegrating Agents

By TAGHI A. FAKOUHI, NORMAN F. BILLUPS,† and ROBERT W. SAGER

A comparative study of certain powdered wood products, corncob, and cellulose has been made for their tablet disintegrating properties. A brief description for preparing the powdered disintegrating agents from the natural products is given. The various disintegrating agents were incorporated into lactose granulations, compressed, and subsequently tested for tablet disintegration time. Powdered corncob was found to be superior to starch and the wood products as a tablet disintegrating agent. The results of the disintegrating action of powdered corncob proved to be reproducible. Powdered redwood bark was as good as starch but not as effective as powdered corncob. The three physically distinctive layers of corncob—chaff, woody substance, and pith—were separated and incorporated in lactose tablets as disintegrating agents. Significant differences were seen among the disintegration times produced by the three layers of corncob. The pith showed superiority over the chaff and woody portion. A series of tests was conducted to study the separate and combination effects of cellulose and starch—the two main constituents of corncob—on tablet disintegration. Cellulose was found to be a better tablet disintegrating agent than starch. The combination of cellulose and starch indicated better results than the separate action of either agent alone. The possible mechanism of action for tablet disintegration is discussed.

THE IMPORTANCE of proper tablet disintegration cannot be overemphasized. To be effective, it is necessary for the tablet to break apart within a desirable period of time so that the medication may be absorbed. To accomplish this, a substance is added to the tablet granulation that will react when brought into contact with fluids and cause the tablet to break apart. Such a substance is termed a disintegrating agent. Disintegrating agents generally fall into three classes, according to their mechanism of action: (*a*) agents which react with moisture to constitute a foam, (*b*) effervescent substances which react with moisture to form a gas, (*c*) substances which react with moisture and swell. Those of the "absorb moisture and swell" type are by far the most commonly employed in research and industry today (1–8), and the present study is confined to this group.

Disintegration time is a function of many factors (4): (*a*) the particular characteristics of the tablet machine, (*b*) the basic formula used in preparing the granules, (*c*) the size, shape, weight, hardness, and age of the tablet, (*d*) the particle size of the medicament, and (*e*) the method of measuring tablet disintegration.

In addition to these variables Ward and Trachtenberg have included (9): (*f*) the moisture content of the granules, (*g*) the particle size of the granules, and (*h*) the particle size of the disintegrants.

Research paper 446, Oregon State University, School of Pharmacy, Corvallis.

In this study each of these factors was held constant or minimized to reduce experimental error.

Billups and Cooper (2) introduced wood flour and powdered wood bark as possible tablet disintegrating agents. In an attempt to continue their work, this research was originally based on testing a large number of wood products for their tablet disintegrating effects. It was during this phase of the research that powdered corncob, one of the agents included in the preliminary study, produced significantly rapid tablet disintegration times. Because of the superior results obtained with powdered corncob, intensive study was conducted with this substance.

This paper presents the results of a comparative study of several wood products, powdered corncob, and cellulose for their potential tablet disintegrating properties. These products were compared with cornstarch, the classical and still one of the best tablet disintegrating agents known. The objectives of the study were to discover new products with superior tablet disintegrating ability and to propose a mechanism of action for the disintegrating agents tested.

EXPERIMENTAL

Selection of Disintegrating Agents.—The selection of various disintegrating agents and the reason for their selection was of primary importance.

Cornstarch was chosen because of its popularity and extensive use. Many authorities still consider this classical agent as the best tablet disintegrating agent in use today (2, 10, 11). A U.S.P. grade of cornstarch was employed in this study.

Powdered redwood bark was included as a new

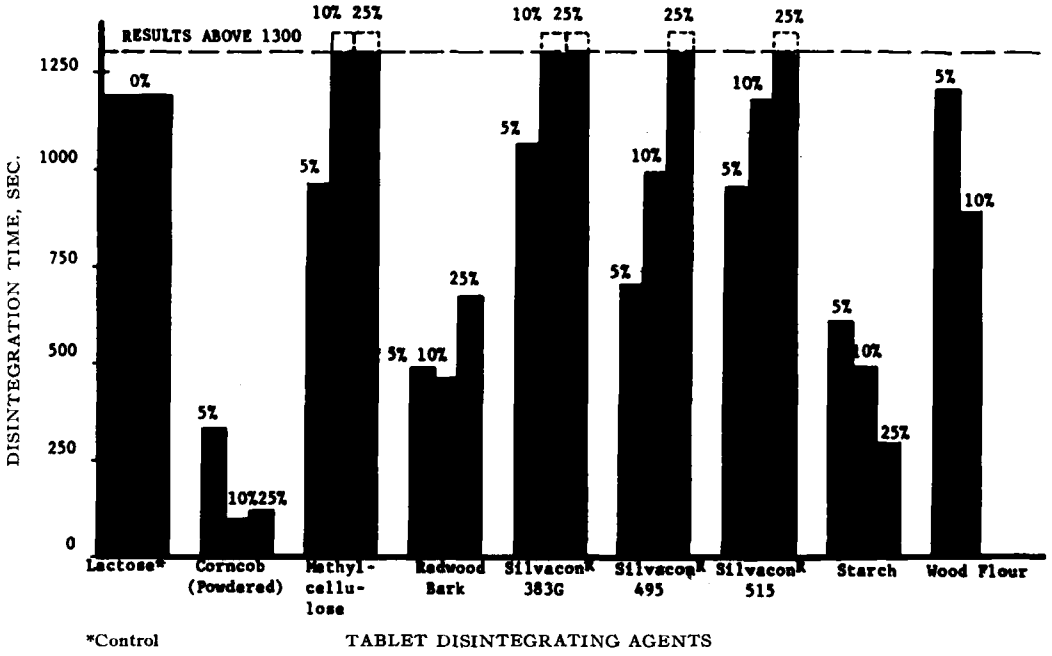

Fig. 1.—Disintegration times of tablets containing various disintegrating agents.

agent to be tested for tablet disintegrating properties. This agent is the powdered bark from the coniferous timber tree (*Sequoia sempervireus*) of California, found only on the Coast Range. The powdered bark was prepared by passing bark specimens, dried 2 months at 80° F., through a Wiley mill until the powder was sufficiently fine to pass through a No. 40 sieve.

Wood flour (2) was used in this study to compare with other wood products. Wood flour is the powdered inner wood from Douglas fir (*Pseudotsuga taxifolia*), a tall evergreen tree of the western United States, often known in the lumber trade as red fir or Oregon pine. The wood flour was obtained locally from the Forest Products Research Laboratories, Corvallis, Oreg.

Silvacon[1] is powdered bark from Douglas fir species. The three basic types of Silvacon are pliable, spongy flakes 383-G, tough needle-like fibers 515, and fine amorphous powders 495. Billups and Cooper used only Silvacon 383-G in their study. All three forms of Silvacon were used in this research. Silvacon products are natural plastics containing the plasticizers, cellulose, and resins found in Douglas fir bark (12).

Methylcellulose was included for comparison with the wood products. Methocel,[2] having a viscosity of 4000 cps. was used.

Powdered corncob, *Zea mays* Linné (Fam. *Gramineae*), was chosen because of its similarity to the other woody products. Corncob, considered a waste product of corn, is used only in small quantities to feed cattle, fertilize land, act as a fuel in remote farming areas, and form chemical by products. The corncob used in this study was obtained locally from the Department of Farm Crops, Oregon State University. A 50-pound randomized sample of corncob was dried for 2 months at 80° F. and powdered with a Wiley mill. Both field corncob and popcorncob were used in the preliminary tests, and since there was an indication that field corncob was slightly better as a disintegrating agent than popcorncob, the former was used throughout this study.

Lactose, a substance with no apparent tablet disintegrating property, was used as the control. Lactose is regarded as a good diluent or inert base for many tablet preparations and was used as a diluent throughout this work.

Procedure for Manufacture of Tablets.—The method of wet granulation was used to manufacture all of the tablets in this study. Tablets were prepared containing lactose as the diluent, 1% magnesium stearate as the lubricant, and syrup U.S.P. as the granulating agent. The finished granulation was separated into "fines" or particles smaller than No. 40 mesh[3] and "granules" or larger particles ranging between No. 14 and No. 40 mesh. According to the amount of disintegrating agent used, an appropriate quantity of "fines" was replaced in the granulation so that all tablets were derived from mixes containing similar proportions of "fines" and "granular" material. A ratio of 30% "fines" to 70% "granules" was used throughout this study. Since the disintegrating agents were added as "fines" to the finished granulation, they were never in contact with moisture during tablet manufacture.

The tablets were compressed on a Stokes model B-2 rotary tablet machine using $^3/_8$-in. diam. punches and dies. Each tablet batch consisted of 500 tablets. An average theoretical weight of 500 ± 10 mg. was maintained using an exact weight shadow-

[1] Marketed by Weyerhauser Timber Co.
[2] Marketed by Dow Chemical Co.
[3] All of the sieves employed in this study compiled with the standards specified in the U.S.P.

graph calibrated periodically with a torsion balance. This average tablet weight was obtained by selecting five samples from each 500-tablet batch. Each sample taken consisted of ten tablets.

Measurement of Hardness and Disintegration Time.—Tablet hardness was determined on a Strong-Cobb hardness tester for ten tablets randomly selected from each tablet batch. Preliminary studies indicated that a tablet hardness of 10 ± 1 Strong-Cobb units gave the least variation in tablet disintegration time and was used unless otherwise specified. Tablets in this hardness range were found to be more resistant to breaking and chipping when subjected to friability tests simulating the most extreme handling conditions. Finally, a hard tablet was felt to reveal better the disintegra ing ab lity of the agents selected for study.

The disintegration tests were conducted on a Gershberg-Stoll (13) type disintegration apparatus in accordance with the official U.S.P. method (14). The reported disintegration time for each batch of tablets represents an average time for 12 tablets. Distilled water was used as the disintegration medium.

RESULTS AND DISCUSSION

The research was divided into three parts: the comparative disintegration tests of wood products and other tablet disintegrating agents, the disintegrating effects of powdered corncob, and the role of cellulose in the disintegrating activity of powdered corncob.

Comparative Disintegration Tests.—The first phase of this research concerned a comparative study of the wood products and other agents for their tablet disintegrating ability. Accordingly, each of the selected agents was incorporated into a standardized lactose granulation in 5, 10, and 25% concentrations. The tablets were compressed and tested for disintegration time immediately after manufacture. The results (summarized in Fig. 1) indicate a significant variation in disintegration time among the various agents. Powdered corncob had the shortest disintegration time of all agents tested. All concentrations of corncob gave better results than starch. A 10% concentration of powdered corncob was the best disintegrating agent of the entire test series. Concentrations of 10% wood flour, 5 and 10% Silvacon and 5, 10, and 25% redwood bark gave improved disintegration times compared to the control. Methylcellulose and the Silvacon products in higher percentages gave longer disintegration times than the control. The use of these substances as disintegrating agents is questionable. Similar results for Silvacon, wood flour, and methylcellulose have been reported (2).

[a] Difficulties encountered in manufacture of tablets.

Normally it would be expected that the 10% concentration would produce a faster disintegration time than the 5% concentration. This was evidenced with corncob, starch, and wood flour. A reversal of this normality was observed with methylcellulose, redwood bark, and the Silvacon products. Billups and Cooper (2) have suggested that these substances possessed adhesive or binding properties which retard disintegration as the concentration is increased. They indicate that this effect may be because of the tendency of these substances to form adhesive gels when hydrated. This suggests that there may be an optimum or maximum quantity of these substances beyond which tablet disintegration will be retarded.

Disintegrating Effects of Powdered Corncob.—The second phase of this study concerned the disintegrating action of powdered corncob. A second lactose granulation was prepared to test the reproducibility of the first test series. A comparison of these results to those of earlier tests is shown in Fig. 2. From these data, no significant difference was indicated between the two tests employing powdered corncob, but significant differences were noted between powdered corncob, lactose, and starch.

Once the reproducibility of corncob had been established, a series of tests was conducted to determine the optimum particle size of powdered corncob. Tablets were made using a lactose granulation with 10% powdered corncob in No. 60, 40, 20, and 14-mesh sieves. All these tablets were readily compressed except the No. 14 mesh. The tablets in this batch were soft because of the large particle size of the powdered corncob and were easily broken before they could be subjected to the disintegration test. Results of these tests are reported in Table I. Since particles of No. 40 mesh produced the fastest

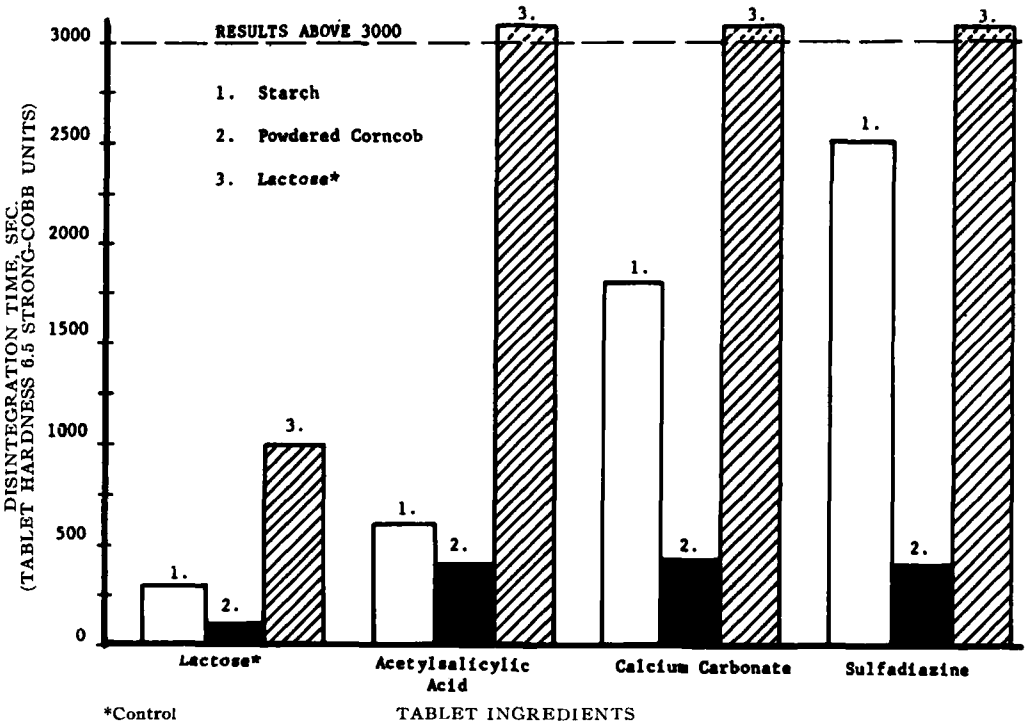

Fig. 3.—Comparison of corncob and starch as disintegrating agents in tablets containing acetylsalicylic acid, calcium carbonate, or sulfadiazine.

tablet disintegration times, this size was employed throughout the remainder of this research.

Thus far, powdered corncob had shown favorable results when used as a disintegrating agent in lactose tablets. Although these results are significant, it remained to be determined if the same results would be obtained in tablets containing active ingredients. Accordingly, powdered corncob was incorporated into granulations of acetylsalicylic acid, calcium carbonate, and sulfadiazine. Lactose was used as the control. A summary of these results is reported in Fig. 3. From these data powdered corncob appeared to be superior to starch in all tablets tested.

Disintegration Effects of Different Parts of Corncob.—The physical appearance of corncob reveals that it is composed of three distinctive parts: the inner area or pith, the middle section or woody substance, and the outer layer or chaff. Burke (15) separated the three layers of corncob and analyzed each layer both quantitatively and qualitatively. His findings, reported in Tables II and III, indicate that starch and cellulose are the two major constituents of corncob. These constituents were further found to vary among each of the three layers. Because of this variability, it was considered necessary to test each of the three parts for tablet disintegrability. The chaff was scraped off with a grater, the pith was bored out with an electric drill, and the remainder of the corncob was ground in a Wiley mill to be used as the wood substance. Each of the separated parts was ground to a fine powder and passed through a No. 40-mesh sieve. The parts were then incorporated into lactose granulations and manufactured into finished tablets. Results shown in Table IV indicate significant differences among the

tablet disintegration times when using different parts of corncob. The three parts of corncob in order of decreasing disintegrating action are pith, woody substance, and chaff. These results raised the question of whether the disintegrating action of powdered corncob or its parts was due solely to the activity of its starch content. It was evident that cellulose must have played an active part since the pith, with the lowest starch content and the highest

cellulose content of all parts, showed the best tablet disintegration time by a large margin.

Role of Cellulose in the Disintegrating Activity of Powdered Corncob.—The third phase of this study was conducted to find the role that cellulose played in the disintegrating activity of powdered corncob. The results from previous tests indicated that cellulose was partially or fully responsible for the disintegrating activity of corncob. To test cellulose as a tablet disintegrating agent, three batches of lactose tablets containing cellulose,[4] starch, and a combination of cellulose and starch were manufactured. Granulations containing 10% starch, 10% cellulose, and a 10% mixture of equal parts of cellulose and cornstarch were incorporated into three tablet formulations. The disintegration times for these three batches are summarized in Table V. These data indicate that cellulose has better disintegrating action than cornstarch. It further shows that a combination of equal parts of cornstarch and cellulose is superior to either of the separate agents. Thus a mutual potentiating effect is shown on the disintegrating action of starch and cellulose. In an earlier study, Crisafi and Becker (16) noticed the same potentiating effect of starch on the disintegrating action of powdered sponge. The potentiating effect of cellulose and starch could be a reasonable explanation for the improved tablet disintegrating activity of powdered corncob over either agent alone.

Mechanism of Disintegrating Action of Powdered Corncob.—The mechanism through which powdered corncob, starch, or cellulose accomplish their disintegrating action is most likely the same. These agents appear to swell when in contact with water and as a result are capable of rupturing tablets in which they are incorporated. Since moisture absorption is an important factor in this action, tests were conducted on powdered corncob, starch, cellulose, a combination of equal parts of starch and cellulose, and lactose (control) to determine the comparative rate of moisture absorption by these agents. One-gram samples of the materials were dried to constant weight at 120 °F. and then placed in a humidity chamber for a 24-hour period. Using a Vapor-Temp[5] humidity chamber the weight gain was calculated by reweighing each sample after the 24-hour interval. A summary of these tests is reported in Fig 4. These results indicate a slight negative correlation between water absorption and tablet disintegration time. Generally, the disintegrating agents which absorbed the most water were those which, when incorporated into tablets, required the shortest times for tablet disintegration.

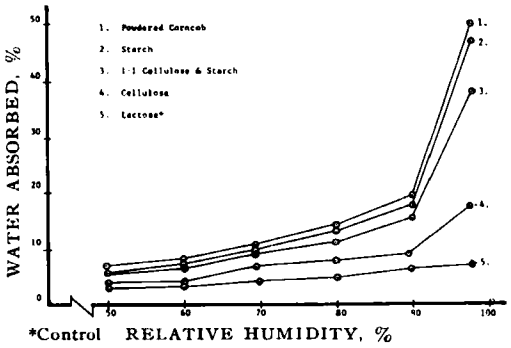

Fig. 4.—Absorptive properties of various disintegrating agents.

It is likely that "swellability" is ultimately the most important single factor in tablet disintegration. In order to swell, however, an agent must first absorb considerable amounts of moisture (17). Figure 4 indicates that powdered corncob, starch, and cellulose each absorbed significant amounts of moisture. Visual examination of these agents indicated considerable swelling compared to the control. Accordingly, each of these agents gave superior tablet disintegration times compared to the control.

CONCLUSIONS

1. Four new substances (powdered corncob, powdered redwood bark, Silvacon 495, and Silvacon 515) have been tested as tablet disintegrating agents and compared to other agents previously reported in the literature. Powdered corncob was shown to be a superior disintegrating agent to starch and the other substances tested. In 5 and 10% concentrations powdered redwood bark was shown to be as good as starch. The Silvacon products were better than the control in 5 and 10% concentrations but not as effective as starch.

2. The disintegrating action of corncob was superior to that of starch in tablets containing soluble, partially soluble, and insoluble material.

3. Results obtained with powdered corncob were reproducible in both placebo and ingredient-containing tablets.

4. The three physically distinct layers of corncob (chaff, woody substance, and pith) were shown to produce significantly different disintegration times. Pith showed superiority over the other two parts.

5. Cellulose was found to be a better tablet disintegrating agent than cornstarch in lactose tablets.

6. Separate and combined effects of starch and cellulose as tablet disintegrating agents were studied.

[4] Stanocel brand of microcrystalline cellulose supplied by the Stanley Drug Co., Portland, Ore., was used in this study.

[5] Marketed by Blue M Electric Co., Blue Island, Ill.

The combined action was shown to be superior to the separate action of either agent alone. This indicates a potentiation effect between these two agents.

7. The mechanism of action through which powdered corncob, starch, and cellulose accomplish their disintegrating action is most likely the same. These agents swell when in contact with water and will rupture the tablets in which they are incorporated. To swell, however, it would appear that an agent must first absorb considerable amounts of moisture. Powdered corncob, starch, and cellulose-starch combinations were shown to absorb significant amounts of moisture. Cellulose absorbed less moisture than starch and corncob but more moisture than the control.

Rapid Visual Assay for Penicillinase Concentrates

By FRANCES W. BOWMAN

Enzyme activity is measured by the time required to solubilize procaine penicillin G.

THE LITERATURE abounds with assay methods for enzyme penicillinase, but most are complicated and time consuming. Among these are the microbial assay of Bowman and Holdowsky (1) and various iodometric titrations (2–4). The manometric (5) and optical rotation (6) procedures are accurate but require special equipment. Pollock (7) suggested a rapid approximate assay based on the time required to decolorize a known quantity of iodine in the presence of sufficient penicillin substrate. Ghosh and Borkar (8) recently described an assay incorporating this idea.

A new and simple assay for penicillinase activity has been developed by using a different approach. Enzyme activity is measured by the time required to solubilize completely 300 mg. crystalline procaine penicillin G in pH 7.0 buffer solution. The procaine salt of penicillin G has a solubility in buffer of about 5 mg./ml.; but as quickly as the soluble portion is converted by the enzyme to penicilloic acid, more penicillin goes into solution until finally it is all dissolved.

No requirements of potency have been established for penicillinase concentrates, but for sterility testing of preparations containing penicillin (9) a solution of the enzyme should have at least 4000 Levy units per ml. One Levy unit of penicillinase inactivates 59.3 units (35.6 mcg. or 10^{-7} moles) of penicillin G in 1 hour when the substrate is in sufficient concentration to maintain a zero-order reaction. The test to be described can measure the penicillinase potency of solutions containing approximately 4000–40,000 Levy u./ml., and within this range the solubilization time is a linear function of the dose.

Received September 18, 1962, from the Division of Antibiotics, Food and Drug Administration, U. S. Department of Health, Education, and Welfare, Washington, D. C.
Accepted for publication October 9, 1962.

EXPERIMENTAL

Reagents.—U.S.P. procaine penicillin G, Clark and Lubs 15% buffer, pH 7.0: potassium dihydrogen phosphate, 150 Gm.; 10 *N* sodium hydroxide, 47.9 ml., *q.s.* to 1 L. with distilled water. Distilled water. Penicillinase solutions. Equilibrate all reagents at 25° before use.

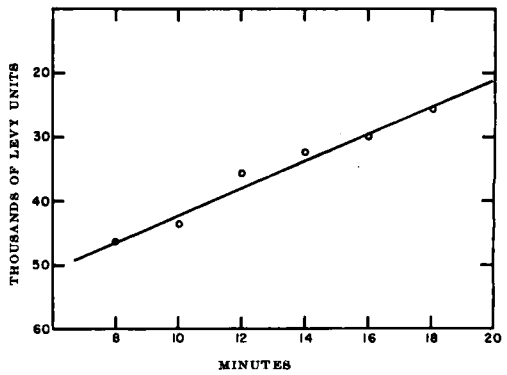

Fig. 1.—Solubilization time for 300 mg. procaine penicillin when tested with various amounts of penicillinase.

The combined action was shown to be superior to the separate action of either agent alone. This indicates a potentiation effect between these two agents.

EXPERIMENTAL

Reagents.—U.S.P. procaine penicillin G, Clark and Lubs 15% buffer, pH 7.0: potassium dihydrogen phosphate, 150 Gm.; 10 *N* sodium hydroxide, 47.9 ml., *q.s.* to 1 L. with distilled water. Distilled water. Penicillinase solutions. Equilibrate all reagents at 25° before use.

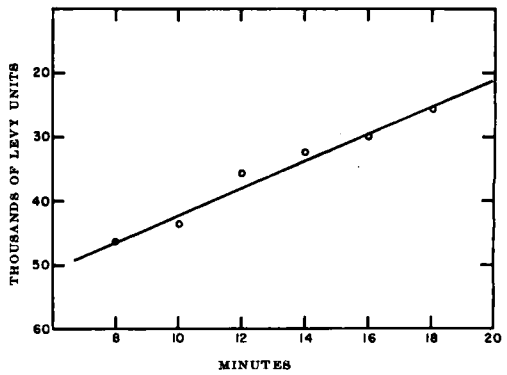

Fig. 1.—Solubilization time for 300 mg. procaine penicillin when tested with various amounts of penicillinase.

TABLE I.—PENICILLINASE ASSAY RESULTS BY TWO METHODS

Levy Units per ml.		Ratio
NaOH Titration Method	Solubilization Method	Col. 2/Col. 1, %
43,296	44,258	102.2
21,075	20,485	97.2
51,676	50,580	98.0
43,415	46,365	106.8
43,836	44,258	101.0
8,430	8,767	104.0
8,430	9,189	109.0
17,703	18,968	107.0
43,346	46,365	106.8
21,075	21,075	100.0
50,580	49,147	97.3
29,505	31,613	107.2
16,860	13,632	81.0
51,170	50,580	98.8
9,273	9,020	97.3
54,205	54,795	101.0
27,145	27,398	101.0
31,613	29,927	94.7
39,452	37,935	96.1
44,848	44,528	99.4
Average		100.1

Assay Procedure.—Suspend 300 mg. of procaine penicillin G in from 9.0–13.0 ml. water in a 20–ml. clear glass bottle with stopper. The volume of water depends on the volume of enzyme sample to be tested. Add 1.0 ml. of the pH 7.0 buffer. Add 1.0–5.0 ml. of the penicillinase test sample to bring the volume to 15.0 ml. and mix. Watch the cloudy suspension and note precisely the time required for it to become completely clear. (A rare small particle or two may be ignored if the solution is substantially clear.) If the time is less than 7 minutes, repeat the test using less enzyme. Samples requiring longer than 20 minutes when 5.0 ml. of enzyme solution is tested contain less than 4000 Levy u./ml. Calculate the Levy units in the sample as follows: Levy units = 63,100–2100 t where t is the solubilization time in minutes. (This relationship is shown graphically in Fig. 1.) Calculate the Levy units per ml. by dividing by the number of ml. of enzyme tested.

Assay of Low Potency Preparations.—Enzymes having very low activity may be assayed by modifying the method. Determine the time required for the enzyme sample to solubilize 300 mg. of procaine penicillin G. A number of hours may be necessary in some cases.

Dilute a previously standardized enzyme concentrate until a dilution is found that requires the same time as the sample to solubilize the same amount of penicillin. Estimate the potency of the unknown from this information. For example, 1.0 ml. of an enzyme solution took 25 hours to solubilize 300 mg. procaine penicillin G. Several dilutions of a stock penicillinase containing 8430 Levy u./ml. were tested by the same method. The dilution requiring 25 hours to solubilize the penicillin contained 422 Levy units per ml. Therefore, it was concluded that the unknown enzyme preparation also contained 422 Levy u./ml.

Application of Assay Method.—A number of penicillinase preparations were tested by the rapid visual method and by a sodium hydroxide titration method (10). The latter is based on the principle that penicilloic acid formed by penicillinase acting on the substrate penicillin may be titrated with sodium hydroxide (11). A solution of soluble sodium or potassium penicillin is adjusted to pH 7.0, the penicillinase (also adjusted to pH 7.0) added, and 0.1 N sodium hydroxide solution added dropwise from a buret, with stirring, to maintain pH 7.0. The reaction is allowed to proceed for 25 minutes and the rate of penicillin destruction calculated from the amount of sodium hydroxide consumed. The rate of inactivation is used to calculate the Levy units.

Results.—As shown in Table I the assays of penicillinase activity by the rapid visual method compare favorably with the results obtained by the sodium hydroxide titration method.

CONCLUSIONS

A simple rapid visual method for determining the enzyme activity of penicillinase concentrates has been presented. The method can be modified to get an approximate assay of low titer preparations. The procedure for enzyme concentrates is especially useful in screening enzyme yields during production runs. It also can be used to estimate the amount of a given enzyme solution to be used in various laboratory tests. When a more precise method with a limited working range is to be used to assign enzyme potency, this method may serve as a preliminary test to establish the approximate activity.

Acetylation of Sulfamethylthiadiazole

By SHUN-ICHI NAITO† and EINO NELSON

PREVIOUS studies with several sulfonamides, after absorption of a dose and attainment of an apparent equilibrium between drug in blood and drug in other fluids of distribution, show the disposition of the drugs can be described by competing first-order processes (1–4). One of these processes is acetylation of the sulfonamide and the other is excretion of free drug. With those sulfonamides that are excreted in part as N-glucuronides, the rate constant for excretion of free drug includes the rate constant for formation of the N-glucuronide (4–5).

This communication is specifically concerned with the magnitude of the rate constant for acetylation of sulfamethylthiadiazole found in studies conducted in Japan in comparison to the magnitude of this constant found in studies conducted in the U. S. The data from the latter studies has been previously published (2).

EXPERIMENTAL

Normal adult humans ingested 0.5-Gm. tablets of sulfamethylthiadiazole in the morning on overnight fasted stomachs. No food was taken until 2 hours after ingestion of the doses. Preingestion blank urines were obtained and after ingestion of the tablets urine collections were made at appropriate times and assayed for free and total drug by the method of Bratton and Marshall (6). This is the same assay as used in the work done in the U. S. (2). The sulfamethylthiadiazole tablets were 9 mm. in diameter and made with standard concave punches. The tablets were made of finely powdered drug and had the following formula

Sulfamethylthiadiazole	25 parts
Dried potato starch	5 parts
Polyvinyl pyrrolidone 5% in 50% isopropanol	10 parts
Calcium stearate	0.5 per cent

The tablets disintegrated on the average in about 1 minute when tested by the U.S.P. method.

Excretion data were subjected to mathematical analysis by methods previously described (1) to determine the values for the following constants: K, hr.$^{-1}$, the overall rate of removal of drug from the body; k_1, hr.$^{-1}$, the rate constant for acetylation; and k_3, hr.$^{-1}$, the rate constant for excretion of unchanged drug; and f, the fraction of a dose ultimately excreted in the urine as unchanged drug.

TABLE I.—VALUES OF RATE AND OTHER CONSTANTS (TESTS IN JAPAN)

Constant	Subjects H	W	S	T	Mean
K, hr.$^{-1}$	0.589	0.567	0.589	0.658	0.601
k_1, hr.$^{-1}$	0.226	0.225	0.249	0.236	0.234
k_3, hr.$^{-1}$	0.363	0.342	0.340	0.422	0.367
f	0.617	0.604	0.577	0.642	0.610

TABLE II.—MEAN VALUES OF RATE AND OTHER CONSTANTS (TESTS IN THE U. S.)

Constant	Value	Ratio (Japan/U. S.)
K, hr.$^{-1}$	0.514	1.17
k_1, hr.$^{-1}$	0.046	5.11
k_3, hr.$^{-1}$	0.468	0.78
f	0.911	0.670

RESULTS AND DISCUSSION

Table I lists the values of the various constants determined in the experiments.

For the sake of comparison, the mean values of constants found in previously published work with sulfamethylthiadiazole (2) are listed in Table II.

An examination of Table II will show that a more than five-fold difference existed between the values of the rate constant for acetylation obtained in the two sets of experiments. The t test showed a highly significant difference ($P < 0.01$) between the two sets of values of the rate constants. However, there was significantly greater variance in the set obtained in the studies conducted in the U. S. as compared to the variance in the set obtained in Japan.

It is difficult to assign a reason for the difference in k_1 found in the two sets of tests. In the tests conducted in the U. S. (2), two of the test subjects were of Japanese ancestry but their rate constants for acetylation were of the same order as for subjects of Caucasian ancestry. The average age of the test subjects in the U. S. tests was 30 years and in the Japan tests, 20 years. It does not seem likely that the difference could be attributable to this small difference in average age. Both sets of tests were conducted in the spring of the year. Differences in diet seem the most likely explanation, but it is difficult to accept this since first-order kinetics were followed.

Accepted for publication October 1, 1962.

† Present Address: Kyoto College of Pharmacy, Kyoto, Japan.

Note Added in Proof.—It recently came to the attention of one of us (E.N.) that 90% of Nisei Japanese and presumably native Japanese are rapid phenotypes with respect to the rate with which they inactivate isoniazid [Harris, H. W., Knight, R. A., and Selin, M., *J., Amer. Rev. Tubercul.*, **78**, 944(1958)]. Inactivation of this drug is mainly by acetylation. Further, humans may be grouped in rapid and slow categories with respect to the rate with which they acetylate sulfadimidine and rapid acetylators of sulfadimidine are rapid inactivators of isoniazid [unpublished work of D. A. Price Evans, Department of Medicine, University of Liverpool; cited by Clark, C. A., *J. Pharm. Pharmacol.*, **14**, (Suppl.), 20T(1962)]. The possibility exists that the results we report might represent the same phenomenon. Absence of difference in acetylation rate in the earlier U.S. tests may have been due to chance.

Isolation of β-Sitosterol, β-Sitosteryl-D-Glucoside, and Palmitic Acid from Coastal Bermuda Grass and Orchard Grass

By E. D. WALTER

β-Sitosterol and β-sitosteryl-D-glucoside were isolated from coastal Bermuda grass and from orchard grass, and identified by infrared spectra and physical constants on the sterol and the acetate. Palmitic acid was isolated from the saponifiable fractions. No saponin was detected.

BERMUDA grass and orchard grass were investigated for saponins by means of the procedure used to isolate saponin from ladino clover (1). Material was obtained which gave a Liebermann-Burchard color test suggesting sterols rather than saponin. A study of this material showed that it contained β-sitosterol, β-sitosteryl-D-glucoside, and palmitic acid. Repeated experiments were carried out on 1-Kg. quantities of dehydrated meal to accumulate enough material for identification. Results were practically identical with either of these grasses. No saponin was obtained by this method from these grasses.

EXPERIMENTAL

The dehydrated meal (1 Kg.) was soaked with about 4 L. of warm water for 2 hours. The water was filtered through cloth with suction and discarded. The hydrated meal was covered with 95% alcohol (5–6 L.) and allowed to stand for a day or more. The extract was filtered with suction, and the alcohol extraction was repeated. The combined alcohol extracts were clarified with charcoal (10 Gm./L.), and concentrated to about 1.5 L. The concentrate was extracted with ether in a separator. The ether was evaporated and the residue was saponified with alcoholic potassium hydroxide. The alkaline mixture was extracted with ether, and the ether solution was evaporated to near dryness.

β-Sitosteryl-D-glucoside.—To the unsaponifiable residue from the ether extract, about 100 ml. of skellysolve-B was added. A small quantity of the material was insoluble and was filtered. The residue was washed with acetone, leaving a white product, m.p. 280°. Yield, 90 mg./Kg. dry meal. The material recrystallized from methanol, m.p. 296° (with dec.), showed an infrared spectrum that was in good agreement with that presented by Morris and Lee (2) for β-sitosteryl-D-glucoside.

Hydrolysis of the glucoside with 2% sulfuric acid by the method of Thornton, *et al.* (3), gave β-sitosterol, m.p. 137°, with an infrared spectrum in good agreement with that reported in the literature (2), and glucose which was detected by paper chromatography after the acid had been removed by barium carbonate.

β-Sitosterol.—The skellysolve-B-soluble part of the unsaponifiable material was put on a column of deactivated alumina. The sterol was eluted with 3% acetone in skellysolve-B, and the solvent removed. The sterol crystallized from methanol yielded about 200 mg./Kg. of dry meal, m.p. 137° [lit. 136–137° (4)]. The infrared spectrum was in agreement with that reported (2) for β-sitosterol.

β-Sitosteryl Acetate.—The sterol was heated with acetic anhydride for 30 minutes. The mixture was poured into ice water, and the fluffy product was filtered and washed with water. The dried product was recrystallized from methanol, m.p. 127°; $[\alpha]_D^{25}$ − 38.4° (in chloroform, c = 1.11, *l* = 2), [lit. (4) $[\alpha]_D$ − 38° in chloroform].

Anal. Calcd. for $C_{31}H_{52}O_2$: C, 81.52, H, 11.48. Found: C, 81.6, H, 11.4.

Palmitic Acid.—After ether extraction of the sterols, the aqueous saponifiable portion was acidified with hydrochloric acid and again extracted with ether. The acid was washed out of the ether extract with water and the ether solution was clarified with charcoal. The solution was concentrated to near dryness, then dissolved in methanol. On standing, a white crystalline solid separated. Recrystallization from methanol gave white flakes, m.p. 63°. Titration with 0.1*N* sodium hydroxide gave an equivalent weight of 260 (palmitic acid, 256.32). A gas chromatogram showed that the retention times of this material and that of authentic palmitic acid were identical. Likewise, the infrared spectra of this material and that of authentic palmitic acid were identical.

A minute quantity of material, m.p. about 90°, was obtained before saponification of the ether extract, which suggests that at least part of the sterol occurred as β-sitosteryl palmitate.

Stabilization of Tetrazolium Blue Assay for Triamcinolone

By PETER ASCIONE and CARL FOGELIN

The substitution of chloroform to the extent of 60 per cent for the pure ethanol normally used in performing the tetrazolium blue assay of triamcinolone produces a stable color in both the sample solution and the reagent blank. Stable color development is achieved within 20 minutes for triamcinolone and its acetonide and diacetate derivatives. The reagent blank reaches a constant value within 10 minutes. In addition, stabilization of the tetrazolium blue reaction overcomes the major objection to its general use and results in a more favorable comparison with triphenyl tetrazolium as the reagent of choice. While the work reported is confined to triamcinolone (9α-fluoro-11β,16α,17α,21-tetrahydroxy-1,4-pregnadiene-3,20 dione) and two of its derivatives, it appears reasonable to assume that the technique described could be extended to the assay of other ketol steroids.

THE APPLICATION of tetrazolium salts for the determination of ketol steroids was presented by Mader and Buck (1). Smith and Halwer (2) applied this reaction to the determination of triamcinolone alcohol, acetonide, and diacetate. Tetrazolium blue was the specific reagent used in this work. Johnson, King, and Vickers (3) reported that the use of tetrazolium blue as an analytical reagent is complicated by the fact that neither the reagent blank nor the sample achieve a stable color within a reasonable time. The problem was regarded as serious enough by these authors to state a general preference for triphenyl tetrazolium since their observations indicated that this compound did not have this undesirable characteristic. However, tetrazolium blue does show better resistance to attack by oxygen (3) and is approximately twice as sensitive a reagent as triphenyl tetrazolium (1). The work described below allows one to take advantage of the desirable features of tetrazolium blue by eliminating the continuous increase in absorbance of the sample and reagent blank.

DISCUSSION

Origin of Investigation.—The use of chloroform to stabilize the blue-colored formazan produced during the reduction of tetrazolium blue by triamcinolone originated as a result of the application of this solvent to the extraction of triamcinolone acetonide from ointment preparations. The use of chloroform for such extractions is not uncommon (4, 5). However, the chloroform is removed by evaporation prior to assay. While attempting to reduce assay time by eliminating this step, it became obvious that not only could the color reaction be carried out in the presence of chloroform, but also the resulting solutions exhibited better stability than when the chloroform was absent. Subsequent work was carried out to investigate systematically this observation.

Effect of Chloroform on Color Development.—Samples of triamcinolone alcohol, acetonide, and diacetate were dissolved in ethanol. Equal aliquots were transferred to a series of flasks for each of the steroids tested. Varying amounts of chloroform were then added to each sequence and the tetrazolium blue assay completed. Table I gives the data obtained. After examination of these data, it was concluded that a 60% chloroform content represented the concentration of chloroform that would yield the maximum color response consistent with the primary purpose of stabilizing the reaction.

Rate of Color Development in 60% Chloroform.—Assays were performed using the 60% chloroform level to determine the amount of time needed for each of the compounds in question and for the reagent blank to reach a plateau in their absorbance values. An identical set of assays was performed in ethanol alone to provide comparative data between the two solvents. Table II summarizes the results obtained.

It was concluded that the absorbance values obtained between 20 and 30 minutes (after color development was initiated in the chloroform–ethanol mixture) could safely be regarded as having achieved a stable maximum value. This should conservatively estimate the span of time suitable for accurate quantitation. For example, data in Table I indicate at least 1 hour of color stability when triamcinolone alcohol is being tested, and 2 hours' stability for the reagent blank. In addition, 20 minutes is more than sufficient time for maximum color development except for triamcinolone alcohol as shown in Table II.

Linearity of Response.—Standard calibration curves were prepared for all three steroids tested. Typical Beer's law plots were obtained over the concentration range of 1 mcg./ml. to 5 mcg./ml. for all three compounds. The data are presented in Fig. 1.

Effect of Light.—Sensitivity to light remains a problem in the performance of this assay. The use of low actinic glassware as noted by Johnson, *et al.* (3), or storage in the dark until the absorbance values are to be determined, is necessary.

EXPERIMENTAL

Assay Reagents.—(a) Tetramethylammonium hydroxide, supplied as a 10% aqueous solution. Prepare a working solution by diluting 10 ml. to 50 ml. with 95% ethanol; (b) Tetrazolium blue, dissolve 350 mg. in 100 ml. of 95% ethanol; (c) 95% ethanol, essentially aldehyde-free; (d) chloroform, reagent grade.

Assay Procedures.—Prepare a chloroform solution of the steroid to be assayed using a concentration of 5 mcg./ml. for triamcinolone alcohol[1] and diacetate or 10 mcg./ml. for the acetonide. Transfer 15 ml. of the chloroform solution to a 25-ml. low actinic volumetric flask. At the same time prepare a standard of the steroid being assayed to carry through the test. A reagent blank is also prepared by adding 15

ml. of chloroform to a third 25-ml. volumetric flask. All three flasks are taken through the following procedure.

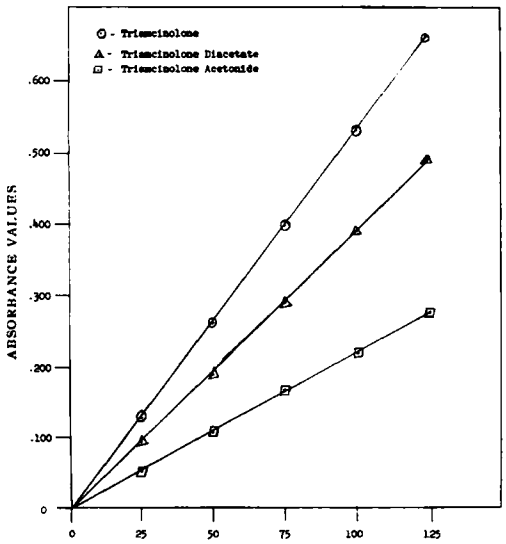

Fig. 1.—Standard calibration curves for triamcinolone, triamcinolone diacetate, and triamcinolone acetonide.

Add 1 ml. of tetrazolium blue solution to each of the flasks, followed immediately by 1 ml. of the tetramethylammonium hydroxide working solution. Bring all flasks to volume with 95% ethanol. Mix well and allow the flasks to stand 20 minutes. Determine the absorbance values for each of the solutions at 520 mμ in any suitable spectrophotometer using ethanol as the reference solution. The value of the steroid content of the unknown samples may then be calculated by comparison with the standard after the reagent blank is subtracted from both.

APPLICATION OF PROCEDURE

This procedure has been applied to routine determination of the steroidal content of a wide variety of pharmaceutical formulations of all three steroids. Tablets, creams, ointments, and suspensions have been successfully assayed using this method. The chloroform often serves a dual purpose by assisting in extracting the steroid from the formulation as well as stabilizing the color reaction.

Estrogenic Strength of 5-(*p*-Hydroxyphenyl)-cyclohexanedione-1,3

By PHILIPPOS E. PAPADAKIS† and THEODORE J. URBAN

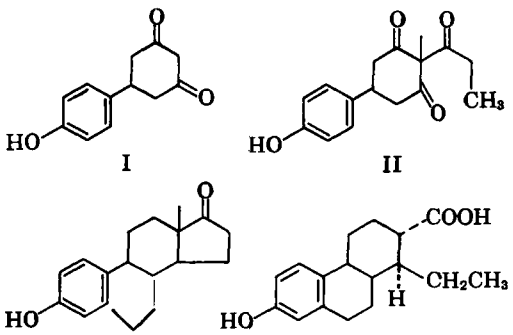
A technique is described for detecting the estrogenic activity of a nonsteroidal compound, 5-(*p*-hydroxyphenyl)-cyclohexanedione-1,3. Under the conditions of this experiment, the uterine weight assay indicated that 0.25 mg./ml. of this compound has estrogenic activity of 5.0 I.U. and 0.75 mg./ml. of the same compound has estrogenic activity of 15 I.U. Vaginal smears indicated that this compound gave a positive response.

BESIDES the natural estrogenic substances, there are synthetic compounds which, although they do not have the steroid ring system, exhibit estrogenic activity. Examples of such synthetic compounds which differ considerably in structure from the natural estrogens are stilbestrol, hexestrol (1), doisynolic acid and its stereoisomers (2–4).

This paper presents the bioassay of an estrogenic compound, 5-(*p*-hydroxyphenyl)-cyclohexanedione-1,3 (I) (5), surnamed by students at Creighton "papadakisone."

Derivatives of I having similarities to compounds of physiological importance have been synthesized. Some of these have been reported (6–8). A C-acyl derivative (7), represented by II, may be considered as an incomplete ring system of estrone (III). Doisynolic acid (IV) is also an incomplete ring system of estrone (III). Since papadakisone (I) is an incomplete ring system of estrone, it seemed reasonable to investigate first its estrogenic activity and then in later experiments proceed to examine the activity of other derivatives which have closer structural resemblance to estrone ex. (II).

The assay of papadakisone is based on an increase of the uterine weight of rats. A typical vaginal smear technique was also used, but since Stob, *et al.* (9), and Rubin, *et al.* (10), indicate that the uterine weight assay is more sensitive than the vaginal smear method, the estimation of estrogenic strength in this experiment is based on the uterine weight assay.



MATERIALS AND METHODS

The test animals used for assay purposes were ovariectomized Holtzman white rats. After the gonads were removed, 14 to 21 days elapsed to allow for uterine atrophy. The rats were killed 24 hours after the last subcutaneous injection of the test material. The rats received 0.1-ml. injections of the aqueous solution of papadakisone every day for 6 days. The solution was made by adding 1 ml. of 6 *N* sodium hydroxide which converts the compound to its soluble salt. The strength of the solution of the dosages used corresponded to 0.25 mg./ml. and 0.75 mg./ml., respectively. The commercial estrogen[1] was used daily in dosages of 10, 25, and 50 I.U. per injection for 6 days (see Table I). The volume of the oil solution of estrogen used for each injection was 0.1 ml. The uteri were weighed using a Roller-Smith precision balance. The uterine weights of the test animals treated with various dosages of commercial estrogen and the increase in uterine weight was used to indicate estrogenic activity.

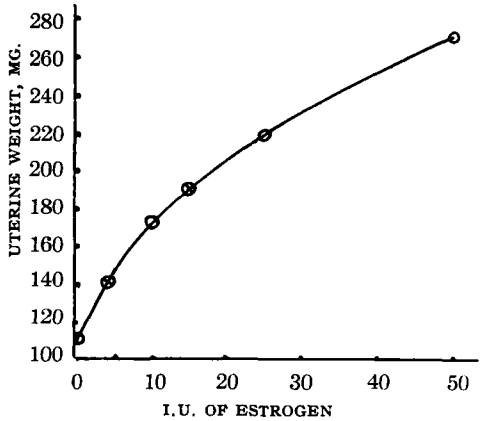


Fig. 1.—Uterine weight response to various dosages of estrogenic substances. ○ = Urestrin; ⊕ = papadakisone.

RESULTS

Data on the changes in uterine weight due to different dosages of estrogen and papadakisone are presented in Tables I and II. Data showing vaginal smear responses are presented in Table III.

In order to establish a means of reference for papadakisone-induced increases in uterine weight, a standard response curve (Table I) was determined using subcutaneous injections of estrogen. The rats receiving papadakisone all exhibited uterine weights that were heavier than the weights of the controls, and these differences also applied when the uterine weights were expressed as a percentage of body weight.

The work with vaginal smears indicates that papadakisone gives a positive response (Table III).

DISCUSSION

It seems quite safe to say that the nonsteroidal compound (called papadakisone here) has estrogenic activity. This is evidenced by positive vaginal smears and an increase in uterine weights. Comparing the responses of the experimental substance to the responses of I.U. of estrogen, the results indicate that 0.25 mg./ml. of papadakisone has an estrogenic activity in the neighborhood of 5.0 I.U. (Fig. 1). The dose of 0.75 mg./ml. of papadakisone causes a uterine weight response about that of a 15 I.U. dosage of estrogen. In searching the literature it was found that Lespagnol and Schmitt (11) compared the estrogenic activity of 5-(*p*-methoxyphenyl)-cyclohexanedione-1,3 to that of estrone and found the ratio of 1/500.

When treated with sodium hydroxide solution structure I is converted to its sodium salt, so that the estrogenic activity measured should be considered as due to the sodium salt of I.

Isolation of Lupeol from *Sweetia panamensis*

By THOMAS J. FITZGERALD, JACK L. BEAL, and JULES B. LAPIDUS

SWEETIA PANAMENSIS Benth. is one of several medicinal Central American plants currently being investigated in this laboratory. For the purpose of facilitating subsequent extractions, the bark of this plant was defatted with skellysolve B, and from this extract the triterpene, lupeol, was isolated. Thus *S. panamensis* may be added to the already extensive list of plants in which this compound is found.

The isolation of lupeol from this particular source is of some historical interest. Thompson (1) reported the isolation from *S. panamensis* of a compound which according to his description is quite similar to lupeol. Indeed, when we repeated his work, lupeol was isolated from an ethanolic extract of the bark. Inasmuch as Thompson's investigation was reported in 1884 this would seem to constitute the first known isolation of lupeol rather than that of Schulze and Steiger in 1889 (2).

Also, this investigation has shown that the lupeol occurs in the bark of this plant as the free alcohol. The triterpene was characterized through formation of the acetate, benzoate, and by use of infrared spectra.

Received October 9, 1962, from The Ohio State University College of Pharmacy, Columbus 10.
Accepted for publication November 7, 1962.
This investigation was supported by a research grant from the A. H. Robins Co., Richmond, Va.

EXPERIMENTAL

Isolation of Lupeol.—The bark[1] was powdered

[1] Obtained from S. B. Penick and Co.

in a Wiley mill, and 1000 Gm. was extracted to exhaustion in a Soxhlet apparatus with 2.5 L. of skellysolve B. The light green solution was reduced to dryness *in vacuo* and yielded a light greenish-yellow residue weighing 20.1 Gm. The residue, when subjected to the Liebermann-Burchard test, gave the characteristic red color of lupeol.

Ten grams of this residue was refluxed for 3 hours with 250 ml. of alcohol containing 12 Gm. of sodium hydroxide. After cooling, the brown solution was poured into 300 ml. of water, and a flocculent yellow precipitate formed. The alcohol was evaporated on a steam bath, and after filtering the suspension, the precipitate was washed with 500 ml. of water. After drying at 105° for 12 hours the crude unsaponifiable material weighed 5.7 Gm. Recrystallization from ethanol gave needles, m.p. 212–213°.[2] When this material was mixed with an authentic sample of lupeol[3] (m.p. 214.5°) and melted, no depression occurred. Further purification was achieved by preparing the acetate and saponifying. This procedure gave a product, after recrystallization from ethanol, m.p. 214 to 214.5°; lit. value, 215° (4). The infrared spectrum of this material was identical with that of an authentic sample.

[2] Melting points are uncorrected.

[3] The authentic samples of lupeol and its derivatives were provided by Dr. Jack L. Beal from a previous investigation (3).

Lupeol Acetate.—The acetate was prepared according to Wagner (5). Recrystallization from ethanol gave the compound as needles with a melting point range of 217 to 217.5°; lit. value, 218° (4).

Lupeol Benzoate.—The benzoate was also prepared according Wagner (5). This material was obtained as small platelets when recrystallized from benzene-ethanol (1:5) and gave a melting point range of 264–266°; lit. value, 273–274° (4). The infrared spectrum of this compound was identical with that of an authentic specimen of lupeol benzoate.

Presence of Free Lupeol.—A portion of the skellysolve residue was washed with methanol and then dissolved in chloroform. The needle-shaped crystals which formed on evaporation of the solvent at room temperature, m.p. 211–213°, gave an infrared spectrum which was identical with that of the material obtained by saponification.

Communications

Absence of 6-Methoxybenzoxazolinone in Uninjured Maize Tissue

Sir:

The peculiar phenomenon has been demonstrated (1) that many living plants contain stable precursors which after the crushing of plants are enzymically decomposed to substances which (or after further chemical or enzymic decomposition) have different biological activities. One of the typical cases is the formation of benzoxazolinone (BOA) and its 6-methoxy derivative (MBOA) in crushed rye and maize plants, respectively. When these compounds were isolated and characterized chemically in this laboratory, it was at first believed that they were present in the intact plants (2). Later on we could relate their formation to the precursors present in these plants. The reaction series is:

precursor, glucoside of 2,4-dihydroxy-7-methoxy- —enzymic→ aglucone —chemical→ 1, 4-benzoxazin-3-one —chemical→ 6-methoxybenzoxazolinone (3, 4).

The last step in the reaction is of an unusual type—a six-membered ring is transformed into a five-membered one by the splitting of formic acid. When hydrolysis of the glucoside is completely prevented in the intact plant, we have never detected any formation of BOA or MBOA.

Smissman, *et al.* (5), recently reported that they found MBOA as an original substance in maize tissue. Quantitative data were not given. Their procedure was complicated, however, and involved some steps during which the formation of MBOA from the aglucone can take place. If the aglucone was already present in the ground plants when they were placed in 95% ethanol, the formation of some MBOA would be expected. Kinetic studies in this laboratory have shown that aglucone of the rye glucoside is converted into BOA at a much higher rate in 80% ethanol than in aqueous solution (6). The rapid conversion of the aglucone of the maize glucoside into MBOA in 95% ethanol solution at 40° is shown in Fig. 1.

The other step at which MBOA could surely be formed from the maize aglucone is the fractiona-

in a Wiley mill, and 1000 Gm. was extracted to exhaustion in a Soxhlet apparatus with 2.5 L. of skellysolve B. The light green solution was reduced to dryness *in vacuo* and yielded a light greenish-yellow residue weighing 20.1 Gm. The residue, when subjected to the Liebermann-Burchard test, gave the characteristic red color of lupeol.

Ten grams of this residue was refluxed for 3 hours with 250 ml. of alcohol containing 12 Gm. of sodium hydroxide. After cooling, the brown solution was poured into 300 ml. of water, and a flocculent yellow precipitate formed. The alcohol was evaporated on a steam bath, and after filtering the suspension, the precipitate was washed with 500 ml. of water. After drying at 105° for 12 hours the crude unsaponifiable material weighed 5.7 Gm. Recrystallization from ethanol gave needles, m.p. 212–213°.[2] When this material was mixed with an authentic sample of lupeol[3] (m.p. 214.5°) and melted, no depression occurred. Further purification was achieved by preparing the acetate and saponifying. This procedure gave a product, after recrystallization from ethanol, m.p. 214 to 214.5°; lit. value, 215° (4). The infrared spectrum of this material was identical with that of an authentic sample.

[2] Melting points are uncorrected.

[3] The authentic samples of lupeol and its derivatives were provided by Dr. Jack L. Beal from a previous investigation (3).

Lupeol Acetate.—The acetate was prepared according to Wagner (5). Recrystallization from ethanol gave the compound as needles with a melting point range of 217 to 217.5°; lit. value, 218° (4).

Lupeol Benzoate.—The benzoate was also prepared according Wagner (5). This material was obtained as small platelets when recrystallized from benzene-ethanol (1:5) and gave a melting point range of 264–266°; lit. value, 273–274° (4). The infrared spectrum of this compound was identical with that of an authentic specimen of lupeol benzoate.

Presence of Free Lupeol.—A portion of the skellysolve residue was washed with methanol and then dissolved in chloroform. The needle-shaped crystals which formed on evaporation of the solvent at room temperature, m.p. 211–213°, gave an infrared spectrum which was identical with that of the material obtained by saponification.

Absence of 6-Methoxybenzoxazolinone in Uninjured Maize Tissue

Sir:

The peculiar phenomenon has been demonstrated (1) that many living plants contain stable precursors which after the crushing of plants are enzymically decomposed to substances which (or after further chemical or enzymic decomposition) have different biological activities. One of the typical cases is the formation of benzoxazolinone (BOA) and its 6-methoxy derivative (MBOA) in crushed rye and maize plants, respectively. When these compounds were isolated and characterized chemically in this laboratory, it was at first believed that they were present in the intact plants (2). Later on we could relate their formation to the precursors present in these plants. The reaction series is:

precursor, glucoside of 2,4-dihydroxy-7-methoxy- —enzymic→ aglucone —chemical→ 1, 4-benzoxazin-3-one —chemical→ 6-methoxybenzoxazolinone (3, 4).

The last step in the reaction is of an unusual type—a six-membered ring is transformed into a five-membered one by the splitting of formic acid. When hydrolysis of the glucoside is completely prevented in the intact plant, we have never detected any formation of BOA or MBOA.

Smissman, *et al.* (5), recently reported that they found MBOA as an original substance in maize tissue. Quantitative data were not given. Their procedure was complicated, however, and involved some steps during which the formation of MBOA from the aglucone can take place. If the aglucone was already present in the ground plants when they were placed in 95% ethanol, the formation of some MBOA would be expected. Kinetic studies in this laboratory have shown that aglucone of the rye glucoside is converted into BOA at a much higher rate in 80% ethanol than in aqueous solution (6). The rapid conversion of the aglucone of the maize glucoside into MBOA in 95% ethanol solution at 40° is shown in Fig. 1.

The other step at which MBOA could surely be formed from the maize aglucone is the fractiona-

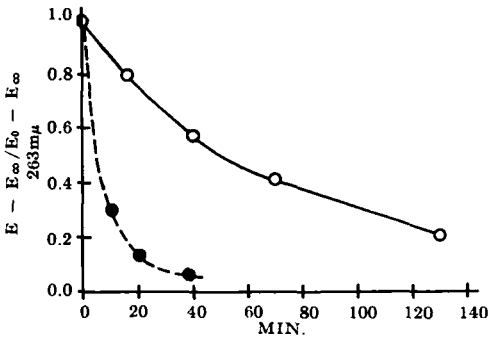

Fig. 1.—Decomposition of 2,4-dihydroxy-7-methoxy-1,4-benzoxazin-3-one to 6-methoxybenzoxazolinone in 95% ethanol (solid line) at 40°C. and in 20% ethanol in ether in the presence of Woelm's acid aluminium oxide at 20°C. (broken line).

tion of the ethanol solution after ether extraction on an aluminium oxide (Merck) column. We have observed very rapid decomposition of the aglucone in the presence of this oxide (Woelm's preparation). The result is seen in Fig. 1. If the aglucone was present in the ether solution, MBOA was formed in the experiment of Smissman, *et al.* (5).

A simple and reliable method of inactivating the glucosidase and completely preventing the enzymic hydrolysis of the glucoside is to place the intact plant in ethanol solution (final ethanol concentration 70 to 80%) either at 0° or at a lower temperature for 24 hours. The temperature of the mixture is then allowed to rise to room temperature, after which the mixture is ground in a Waring Blendor and the alcohol evaporated in a vacuum. We made some new estimations of MBOA by immersing intact maize plants (Early Albert and a sugar maize variety) in a carbon dioxide–ethanol mixture (−76°) for 24 hours. The dry residue was extracted with ether, and the ether solution evaporated at about 0°. The residue was dissolved in a small volume of acetone and the solution mixed with a threefold volume of 2% acetic acid in water. The mixture was poured onto a small cellulose powder column and eluted with 2% acetic acid until 70 ml. of eluate was collected. The eluate was freeze-dried, and the residue dissolved in acetone and chromatographed on Whatman No. 1 paper with 2% aqueous solution of acetic acid as solvent. The aglucone has the R_f value 0.74 and MBOA 0.49 (ascending). The spots were detected by U. V. absorption, the aglucone spot also by the formation of the blue-colored complex on spraying with alcoholic ferric chloride solution. Using these methods, we found neither the aglucone nor MBOA in young maize plants (about 2 weeks old). In older plants (1 to 2 months old) grown in the laboratory greenhouse under artificial light, when the tips of many of the leaves were already yellow, small amounts of aglucone (20 mcg./Gm. fresh wt.) were detected (about the amount of aglucone after enzymic hydrolysis see below), but no MBOA. It is possible, but not proved, that the aglucone was formed in the withered parts of the leaves, or that it is generally present in older plants.

When the enzymic hydrolysis of the glucoside was needed for the estimation of the aglucone and glucoside, the plants were ground in a mortar at about 10°. After standing for 1 hour the mixture was evaporated at low temperature and the dry residue extracted with ether and subsequently treated as described above. Five-hundred micrograms of aglucone was found per Gm. fresh wt. in 2-week-old maize plants (Early Albert), and 100 mcg. of aglucone per Gm. fresh wt. in 2-month-old plants. In 1-month-old sugar maize, the amount of aglucone was 200 mcg. per Gm. fresh wt. No MBOA could be detected in these plants either.

On the basis of our previous and present findings, we still consider that uninjured maize plants do not contain MBOA. The presence of free aglucone in small amounts in older maize plants is possible but requires additional evidence.

Received April 4, 1963.
Accepted for publication May 10, 1963.

This research has been financed in part by a grant from the Agricultural Research Service, U. S. Department of Agriculture, Washington, D. C.

Book Notices

Aids to Biochemistry. By S. P. DATTA and H. H. OTTAWAY. Bailliere, Tindall and Cox, 7 & 8 Henrietta St., London, W. C. 2, 1962. Exclusive U. S. Agent: The Williams & Wilkins Co., 428 East Preston St., Baltimore 2, Md. viii + 327 pp. 10 × 16 cm. Price $3.75.

As an aid to the preclinical medical student (the primary objective of this book), this reference on biochemistry should prove to be as handy as a pocket secretary. The general usefulness of the book, however, will not be limited to medical students. In one petit volume, the authors present somewhat detailed information in a concise manner which should make a handy reference for pharmacists and others who can benefit by a better understanding of biochemistry. Very little material on plant and microbiological chemistry and no literature references are included. However, the book assumes that a review of some details and principles is all that is needed and for more extensive requirements, standard reference works will be employed.

Resistance of Bacteria to the Penicillins. Edited by A. V. S. DE REUCK and MARGARET P. CAMERON. Little, Brown and Co., 34 Beacon St., Boston 6, Mass., 1962. viii + 125 pp. 18.5 × 12 cm. Price $2.95.

This report of a one day conference of a Ciba Foundation study group presents a great deal of current information and a look at areas needing additional study in the realm of penicillin resistance. Five papers were reported: Penicillin-resistant penicillins and the problem of the penicillin-resistant staphylococci, Mode of action of the penicillins, Penicillinase, Different types of resistance to different penicillins, and Coagulase-positive staphylococci resistant to benzyl penicillin, methicillin, and other penicillins. Pharmaceutical scientists will find this report helpful in appraising the progress of work in this area and pharmacists in community or hospital practice will find this information helpful in performing their consultant and public health responsibilities.

The Biochemical Bases of Psychoses. By D. W. WOOLLEY. John Wiley & Sons, Inc., 440 Park Ave. South, New York 16, N. Y., 1962. xii + 331 pp. 15 × 22.5 cm. Price $11.95.

In this book, the author proposes that schizophrenia, manic-depressive psychosis, and a variety of other severe mental disorders arise primarily from a disturbance in the production and function of serotonin. He states that related contributing causes for these diseases are disturbances in the hormones. Detailed experimental evidence is presented to support the hypothesis. Every person working with psychopharmacological drugs should examine the materials presented carefully. The remarkable Dr. Woolley is especially qualified in this area because of his long continued interest in and work with serotonin and LSD. His theories will undoubtedly have a substantial impact on scientific thought on the biochemistry of mental disorders.

Transplantation. Edited by G. E. W. WOLSTENHOLME and MARGARET P. CAMERON. Little, Brown and Co., 34 Beacon St., Boston 6, Mass., 1962. xii + 426 pp. 13.5 × 20 cm. Price $12.

The Ciba Foundation has produced, in this volume, another important work in an area of timely interest to both scientist and layman alike. This conference report appears to be a supplement to the last transplantation conference held about eight years ago and serves to review and highlight the more important developments during the intervening period. Included in this report are papers on transplantation antigens, cheekpouch skin homografts in the Syrian hamster, transplantation tolerance and immunity in relation to age, homograft sensitivity in human beings, and role of the thymus in transplantation tolerance and immunity, among others. As with previous volumes, author and subject indexes are appended permitting rapid reference to items of particular interest.

Introduction to Pharmacology. By J. J. LEWIS. The Williams and Wilkins Co., 428 East Preston St., Baltimore 2, Md., 1963. xii + 926 pp. 14 × 21.5 cm. Price $13.

While pharmacology texts generally must contain considerable information on site, mode and type of action, and chemical structure–action relationships, this aspect is especially emphasized here. The significance of chemical structure in relation to the pharmacological action provides a logical approach to the subject. For a detailed and comprehensive discussion of various aspects, standard reference sources will have to be consulted. However, this book will assist in those areas where great detail is not necessary or desirable. The second edition essentially updates the earlier edition published in 1960.

Ion Exchange Separations in Analytical Chemistry. By OLOF SAMUELSON. John Wiley & Sons, 440 Park Ave. South, New York 16, N. Y. 474 pp. 15 × 23 cm. Price $9.50.

Under three main divisions, the fundamental properties of ion exchange resins along with principles and mechanisms of such separations, the techniques of general usefulness in ion-exchange chromatography, and applications of the process to separations in determinations of inorganic substances are presented. Methods of calculation for use in analytical work are also presented and discussed.

Advances in Organic Chemistry: Methods and Results. Vol. III. Edited by RALPH RAPHAEL, HANS WYNBERG, EDWARD TAYLOR. Interscience Publishers, 440 Park Ave. South, New York 16, N. Y. 333 pp. 15.5 × 23.5 cm. Price $13.75.

Four contributors present a critical appraisal and evaluation of recent developments in the field of organic chemistry. Boissonnas, R. A., of Sandoz, Ltd., Basle, Switzerland, has contributed a section on selectively removable amino protective groups

Book Notices

Aids to Biochemistry. By S. P. DATTA and H. H. OTTAWAY. Bailliere, Tindall and Cox, 7 & 8 Henrietta St., London, W. C. 2, 1962. Exclusive U. S. Agent: The Williams & Wilkins Co., 428 East Preston St., Baltimore 2, Md. viii + 327 pp. 10 × 16 cm. Price $3.75.

As an aid to the preclinical medical student (the primary objective of this book), this reference on biochemistry should prove to be as handy as a pocket secretary. The general usefulness of the book, however, will not be limited to medical students. In one petit volume, the authors present somewhat detailed information in a concise manner which should make a handy reference for pharmacists and others who can benefit by a better understanding of biochemistry. Very little material on plant and microbiological chemistry and no literature references are included. However, the book assumes that a review of some details and principles is all that is needed and for more extensive requirements, standard reference works will be employed.

Resistance of Bacteria to the Penicillins. Edited by A. V. S. DE REUCK and MARGARET P. CAMERON. Little, Brown and Co., 34 Beacon St., Boston 6, Mass., 1962. viii + 125 pp. 18.5 × 12 cm. Price $2.95.

This report of a one day conference of a Ciba Foundation study group presents a great deal of current information and a look at areas needing additional study in the realm of penicillin resistance. Five papers were reported: Penicillin-resistant penicillins and the problem of the penicillin-resistant staphylococci, Mode of action of the penicillins, Penicillinase, Different types of resistance to different penicillins, and Coagulase-positive staphylococci resistant to benzyl penicillin, methicillin, and other penicillins. Pharmaceutical scientists will find this report helpful in appraising the progress of work in this area and pharmacists in community or hospital practice will find this information helpful in performing their consultant and public health responsibilities.

The Biochemical Bases of Psychoses. By D. W. WOOLLEY. John Wiley & Sons, Inc., 440 Park Ave. South, New York 16, N. Y., 1962. xii + 331 pp. 15 × 22.5 cm. Price $11.95.

In this book, the author proposes that schizophrenia, manic-depressive psychosis, and a variety of other severe mental disorders arise primarily from a disturbance in the production and function of serotonin. He states that related contributing causes for these diseases are disturbances in the hormones. Detailed experimental evidence is presented to support the hypothesis. Every person working with psychopharmacological drugs should examine the materials presented carefully. The remarkable Dr. Woolley is especially qualified in this area because of his long continued interest in and work with serotonin and LSD. His theories will undoubtedly have a substantial impact on scientific thought on the biochemistry of mental disorders.

Transplantation. Edited by G. E. W. WOLSTENHOLME and MARGARET P. CAMERON. Little, Brown and Co., 34 Beacon St., Boston 6, Mass., 1962. xii + 426 pp. 13.5 × 20 cm. Price $12.

The Ciba Foundation has produced, in this volume, another important work in an area of timely interest to both scientist and layman alike. This conference report appears to be a supplement to the last transplantation conference held about eight years ago and serves to review and highlight the more important developments during the intervening period. Included in this report are papers on transplantation antigens, cheekpouch skin homografts in the Syrian hamster, transplantation tolerance and immunity in relation to age, homograft sensitivity in human beings, and role of the thymus in transplantation tolerance and immunity, among others. As with previous volumes, author and subject indexes are appended permitting rapid reference to items of particular interest.

Introduction to Pharmacology. By J. J. LEWIS. The Williams and Wilkins Co., 428 East Preston St., Baltimore 2, Md., 1963. xii + 926 pp. 14 × 21.5 cm. Price $13.

While pharmacology texts generally must contain considerable information on site, mode and type of action, and chemical structure–action relationships, this aspect is especially emphasized here. The significance of chemical structure in relation to the pharmacological action provides a logical approach to the subject. For a detailed and comprehensive discussion of various aspects, standard reference sources will have to be consulted. However, this book will assist in those areas where great detail is not necessary or desirable. The second edition essentially updates the earlier edition published in 1960.

Ion Exchange Separations in Analytical Chemistry. By OLOF SAMUELSON. John Wiley & Sons, 440 Park Ave. South, New York 16, N. Y. 474 pp. 15 × 23 cm. Price $9.50.

Under three main divisions, the fundamental properties of ion exchange resins along with principles and mechanisms of such separations, the techniques of general usefulness in ion-exchange chromatography, and applications of the process to separations in determinations of inorganic substances are presented. Methods of calculation for use in analytical work are also presented and discussed.

Advances in Organic Chemistry: Methods and Results. Vol. III. Edited by RALPH RAPHAEL, HANS WYNBERG, EDWARD TAYLOR. Interscience Publishers, 440 Park Ave. South, New York 16, N. Y. 333 pp. 15.5 × 23.5 cm. Price $13.75.

Four contributors present a critical appraisal and evaluation of recent developments in the field of organic chemistry. Boissonnas, R. A., of Sandoz, Ltd., Basle, Switzerland, has contributed a section on selectively removable amino protective groups

Ion Exchange Separations in Analytical Chemistry. By OLOF SAMUELSON. John Wiley & Sons, 440 Park Ave. South, New York 16, N. Y. 474 pp. 15 × 23 cm. Price $9.50.

Under three main divisions, the fundamental properties of ion exchange resins along with principles and mechanisms of such separations, the techniques of general usefulness in ion-exchange chromatography, and applications of the process to separations in determinations of inorganic substances are presented. Methods of calculation for use in analytical work are also presented and discussed.

Advances in Organic Chemistry: Methods and Results. Vol. III. Edited by RALPH RAPHAEL, HANS WYNBERG, EDWARD TAYLOR. Interscience Publishers, 440 Park Ave. South, New York 16, N. Y. 333 pp. 15.5 × 23.5 cm. Price $13.75.

Four contributors present a critical appraisal and evaluation of recent developments in the field of organic chemistry. Boissonnas, R. A., of Sandoz, Ltd., Basle, Switzerland, has contributed a section on selectively removable amino protective groups

used in the synthesis of peptides; Brown, D. M., of the University Chemical Laboratory, Cambridge, England,—phosphorylation; McOmie, J. F. W., of the University, Bristol, England,—protective groups; and Reed, R. I., of The University, Glasgow, Scotland,—mass spectrometry as a structural tool. An extensive bibliography follows each section. Author and subject indexes, as well as a cumulative index for volumes 1–3 are included.

Methods of Biochemical Analysis. Vol. XI. Edited by DAVID GLICK. Interscience Publishers, 440 Park Ave. South, New York 16, N. Y. ix +442 pp. 15.5 × 23.5 cm. Price $14.50.

Chemical, physical, microbiological, and animal assays, as well as basic techniques and instrumentation for biochemical determinations are presented. The entire volume deals with well-established methods or techniques which have undergone sufficient improvement to render recapitulation or reappraisal beneficial and relatively new approaches which have shown promise of being potentially useful in biochemical analysis. The materials presented should be of particular value because the contributors of the various sections are either workers who have originated or have had intimate personal experience with the methods which they discuss. Additionally, experimental details are given in a manner which will furnish the laboratory worker with the complete information required to carry out the analyses discussed.

Progress in Drug Research. Vol. IV. Edited by ERNST JUCKER. Interscience Publishers, 440 Park Ave. South, New York 16, N. Y. 606 pp. 17 × 24.5 cm. Price $30.

Subjects presented in this fourth volume of this survey series discussing the chemical, pharmacological, and clinical aspects of pharmaceutical research include recent developments in therapeutically useful organic sulfur compounds, drug latentiation, antihypertensive agents, structure-activity relationships of local anesthetics, and molecular geometry and mechanism of action of chemical carcinogens. The subjects are presented in the language of the contributor, either English or German. The subject index, also in the language of the respective contributions, includes trade names as well as chemical and trivial names—an excellent feature of the work.

A Survey of Drugs. By HAKIM ABDUL WAHID and H. H. SIDDIQUI. Institute of the History of Medicine and Medical Research, Hamdard Buildings, Delhi 6, India. xv + 168 pp. 16 × 24 cm. Price $1.

A systematic classification of information on indigenous drugs of India and the surrounding regions is presented to bring together available information of the drugs used in Indian systems of medicine which may be of interest to pharmaceutical investigators. The classification is effected through different lists, 19 in all. The lists classifying the indigenous drugs added by Unani physicians to their materia medica, vegetable drugs used exclusively in Unani medicine and the comparable information for Ayurvedic medicine, and drugs according to their uses and action in Unani medicine may be of particular interest. A brief textual section covers the background of the different systems of medicine of the area and helps the reader orient himself when considering the various classifications established.

First International Pharmacological Meeting. Vol. VI. General Editor: BORJE UVNASS. The Macmillan Company, 60 Fifth Ave., New York 11, N. Y. xiii + 330 pp. 16 × 24 cm. Price $15.

A symposium covering biochemistry and pharmacology is reported. The list of 41 author-participants from this and other countries is composed of eminently qualified scientists. The first part is devoted to enzymes that metabolize drugs—excluding, however, antitumor drugs. The second part of the program concerns factors that influence the amount of drug available to the enzymes and factors which change their activity. Specific topics presented include: detoxication mechanisms *in vivo*, demethylation and methylation of drugs and physiologically active compounds, desulfuration, urinary excretion of drugs, duration of action of drugs as affected by tissue distribution, and species differences and individual variations in drug metabolism.

First International Pharmacological Meeting. Vol. VIII. Edited by W. D. M. PATON. The Macmillan Company, 60 Fifth Ave. New York 11, N. Y. xvi + 330 pp. 15.5 × 23 cm. Price $15.

A symposium designed to concentrate on the mechanism of action and analytical aspects of drugs active on the central nervous system and various approaches to central nervous system pharmacology is reported. Thirty-one papers fitting within the format described above were selected for publication and these include: inhibitory factors in the brain; central amines and behavorial states: a critique and new data; unusual central depressant properties of a new piperidine compound; drug-induced changes in behavior; and controlled environment: a method of measuring the drug response–behavior in humans.

Encyclopedia of Chemical Technology. Vol. 1. Edited by ANTHONY STANDEN. John Wiley & Sons, Inc., 440 Park Ave. South, New York 16, N. Y. xvi + 990 pp. 19 × 27 cm. Price $45.

The first volume of the second edition promises to be as useful a resource and reference work as the first edition. The aim of this thorough revision, volume by volume, is to provide a comprehensive summary of knowledge on the industrial methods, materials, processes, and equipment of chemical technology. The second edition will be broadened in scope to include information from abroad as well as the United States. The encyclopedia will contain articles on pharmaceuticals and cosmetics. About one-half of the articles deal with single or compound chemical substance.

Infrared Absorption Spectroscopy, Practical. By KOJI NAKANISHI. Holden-Day, Inc., 728 Montgomery St., San Francisco 11, Calif. ix + 233 pp. 18 × 26 cm. Price $8.

Actual infrared curves are presented to acquaint the reader with the range of absorption of the various characteristic absorption bands. Factors which influence band positions and intensities are discussed. The work is a translation of a Japanese book first published in 1960.

used in the synthesis of peptides; Brown, D. M., of the University Chemical Laboratory, Cambridge, England,—phosphorylation; McOmie, J. F. W., of the University, Bristol, England,—protective groups; and Reed, R. I., of The University, Glasgow, Scotland,—mass spectrometry as a structural tool. An extensive bibliography follows each section. Author and subject indexes, as well as a cumulative index for volumes 1–3 are included.

Methods of Biochemical Analysis. Vol. XI. Edited by DAVID GLICK. Interscience Publishers, 440 Park Ave. South, New York 16, N. Y. ix +442 pp. 15.5 × 23.5 cm. Price $14.50.
