THE PHOTOLYTIC instability of riboflavin (I) has been well documented. The intermediates and the reaction products have been isolated and identified, and the mechanistic picture is fairly clearly understood (1–4). This mode of degradation in pharmaceutical systems can, of course, be prevented by use of containers which are opaque to deleterious radiation. Riboflavin and other flavins, however, in aqueous solutions can undergo hydrolytic decomposition involving the isoalloxazine nucleus and which occurs with concomitant loss of biological activity. This latter route of degradation is particularly pronounced in alkaline media, and several studies of both qualitative and quantitative nature have been reported. Among the first investigations were those of Kuhn and Rudy (5). They degraded lumiflavin (II) in alkaline medium and were able to isolate urea and 1,2-dihydro-1,6,7-trimethyl-2-keto-3-quinoxaline carboxylic acid from the reaction mixture. Other reports including those of Surrey and Nachod (6) substantiated these findings. The first detailed kinetic study on the hydrolysis of riboflavin has been reported by Farrer and MacEwan (7). They studied the hydrolysis of riboflavin over the pH range 0.5 to 12.0 and observed the reaction to be general acid-base catalyzed. They also followed the progress of the reaction by paper chromatography and noted transient appearance of lumichrome. Their completely degraded solutions showed the presence of the quinoxaline carboxylic acid and an unidentified compound with mauve fluorescence under ultraviolet light. The presence of several unidentified compounds in degraded solutions of riboflavin and other isoalloxazines has been also reported by other workers. Thus, Svobodova (8), who resolved solutions of lumiflavin which were partially degraded under alkaline conditions, was able to see several unidentified spots on chromatographic paper strips. Similar studies were also conducted by a group of workers led by Wada (9), who reported as many as seven unidentified spots. These reports together with some preliminary studies on 3,9-dimethylisoalloxazine (10) gave some indication as to the complexity of the hydrolytic breakdown and emphasized the need for further work. This communication summarizes the results of the preliminary studies on this problem.

	R_1	R_2	R_3
Riboflavin (I)	Ribityl	CH_3	CH_3
Lumiflavin (II)	CH_3	CH_3	CH_3
9-Methylisoalloxazine (III)	CH_3	H	H

9-Methylisoalloxazine (III), rather than riboflavin, was chosen for the purpose of detailed investigation because of its stability to light and because the absence of ribityl side chain precluded certain complexities observed with riboflavin (11). Like riboflavin, 9-methylisoalloxazine is susceptible to the base-catalyzed degradation and is a useful model for studies on the properties of iso-

Received April 21, 1966, from the Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo 14214.

Accepted for publication June 28, 1966.

Presented to the Basic Pharmaceutics Section, A.PH.A. Academy of Pharmaceutical Sciences, Dallas meeting, April 1966.

This investigation was supported in part by research grant GM-12806 from the National Institutes of Health, U. S. Public Health Service, Bethesda, Md.

alloxazines. The hydrolysis of this compound was investigated under conditions of high pH (0.5 *N* NaOH) and at pH 9.0. In addition, the pH 9 systems were also studied under anaerobic conditions. A chromatographic separation technique was developed to follow the progress of the reaction under different conditions. Identification of the reaction intermediates and the products was accomplished by comparison of their R_f values, fluorescence, and spectral characteristics with those of known compounds.

As it will be seen, spectral and thin-layer chromatographic analysis of solutions of 9-methylisoalloxazine that were degraded under different experimental conditions revealed that different products were formed depending upon the reaction conditions. Thus, in the aerobic systems maintained at high hydroxide-ion concentrations, 1,2-dihydro-1-methyl-2-keto-3-quinoxaline carboxylic acid (IV) was the major product, while at pH 9 and in the presence of air 1,2,3,4-tetrahydro-1-methyl-2, 3-dioxo-quinoxaline (V) was predominantly formed. At the same pH, in the absence of air, the predominant products were the keto carboxylic acid and 1,2-dihydro-1-methyl-2-oxo-quinoxaline (VIII). Evidence was obtained to indicate that the anil of 5-(6-methylaminophenylimino) barbituric acid (VI) and/or 1,2 - dihydro - 1 - methyl - 2 - oxo - quinoxaline-3-carboxyureide (VII) was an intermediate in the reaction under all conditions investigated.

EXPERIMENTAL

Materials.—9-Methylisoalloxazine was obtained as described previously (12).

5-(6-Methylaminophenylimino) Barbituric Acid Anil (VI).—This was synthesized according to the method of Kuhn (13). The anil was purified by dissolving it in water, by adding base, and precipitating the dissolved compound through acidification. The procedure was repeated several times until the precipitated solid was no longer yellowish. Finally, the compound was crystallized from acetone–water to yield silky white needle-like crystals, m.p. 242–244° dec. The anil was titrated potentiometrically under nitrogen atmosphere in DMF, against standard base, and gave a neutral equivalent of 252. Theoretical, based on the molecular formula $C_{11}H_{10}N_4O_3 \cdot {}^1/_2H_2O$ and one titrable hydrogen, was 255.

Anal.—Calcd. for $C_{11}H_{10}N_4O_3 \cdot {}^1/_2H_2O$: C, 51.76; H, 4.31; N, 21.96. Found: C, 52.22; H, 4.77; N, 21.70.

The anil was reported by Kuhn (13) and later by Tishler and co-workers (14) to be yellow in color. It appears that their product was contaminated with the ureide (VII) to which the anil can be easily converted by simple heat or acid treatment. Both Kuhn and Tishler used aqueous acetic acid as their crystallizing solvent and as a result probably obtained a mixture of the anil and the ureide.

1,2-Dihydro-1-methyl-2-keto-3-quinoxaline Carboxylic Acid (IV).—This was synthesized from the anil (VI) in the manner suggested by Kuhn (13). The compound which was obtained as straw-yellow needle-like crystals melted at 176° dec. [King and Clark-Lewis (15) gave m.p. 173–174° dec.] The equivalent weight, determined by nonaqueous titration against methanolic KOH, was 201.6. Theoretical, based on the molecular formula of $C_{10}H_8N_2O_3$ and one titrable hydrogen, was 204.

Anal.—Calcd. for $C_{10}H_8N_2O_3$: C, 58.82; H, 3.92; N, 13.73; O, 23.53. Found: C, 58.97; H, 4.03; N, 13.61; O, 23.53.

1,2-Dihydro-1-methyl-2-oxo-3-quinoxaline Carboxy Ureide (VIII).—This was prepared in the manner suggested by King *et al.* (15), m.p. 246–248° (uncorrected). [Lit. m.p. 248° (15).]

1,2,3,4-Tetrahydro-1-methyl-2,3-dioxo-quinoxaline (V).—This was synthesized according to the procedure described by Miles *et al.* (16). A mixture of equimolar quantities of *N*-methyl-*o*-phenylenediamine hydrochloride and anhydrous oxalic acid was heated at 160° in an oil bath for about 15 min. The melt was cooled and crystallized several times from anhydrous methanol to yield shiny white needle-shaped crystals, m.p. 282–283° (uncorrected).

Anal.—Calcd. for $C_9H_8N_2O_2$: C, 61.36; H, 4.55; N, 15.91. Found: C, 61.22; H, 4.7; N, 15.76.

1,2-Dihydro-1-methyl-2-oxo-quinoxaline (VIII).—This was prepared by sublimation of the keto acid (IV) under reduced pressure at 160° (17). The compound was purified through resublimation, m.p. 119–120° (uncorrected).

Anal.—Calcd. for $C_9H_8N_2O$: C, 67.50; H, 5.00; N, 17.50. Found: C, 67.70; H, 5.08; N, 17.24.

All other chemicals were obtained from commercial sources. The microanalyses were performed by Galbraith Laboratories, Inc., Knoxville, Tenn.

Spectral Studies.—Solutions of 9-methylisoalloxazine and of the anil were completely degraded in pH 9.0 borate buffer and in 0.5 *N* sodium hydroxide. The spectra of the degraded solutions were obtained on a Beckman DB spectrophotometer.

Thin-Layer Chromatographic Studies.—The progress of the hydrolysis of 9-methylisoalloxazine in pH 9.0 borate buffer and in 0.5 *N* base was followed by thin-layer chromatography. Silica Gel G thin-layer plates (4 × 20 cm.²) of 500 μ thickness were used. Sixty-microliter samples were withdrawn at different time intervals and spotted on the plates. Care was exerted to limit the diameter of the spots to about 5 mm. The chromatograms were developed using $CHCl_3$–acetic acid–pyridine (5:1:1). The solvent front was allowed to run 10 cm. from the point of application of samples. The developed plates were warmed to remove the solvent and examined under long-wave ultraviolet light. The different fluorescent spots were identified by comparison of their R_f values with those of authentic samples.

Isolation and Characterization of the Anil (VI) from Partially Degraded Reaction Mixture.—9-Methylisoalloxazine was degraded in 0.5 *N* sodium hydroxide at 45° for 1.5 hr. This partially degraded solution was rapidly cooled and quickly acidified to pH 5.0. The acidified solution was exhaustively extracted with ether. The ethereal solution was dried over anhydrous sodium sulfate, filtered, and the solvent removed under vacuum. The residue was dissolved in 2 ml. of absolute

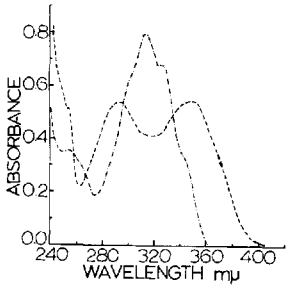

Fig. 2.—Spectrum of the keto acid in 0.5 *N* sodium hydroxide (- - - - - -) and that of the dioxo compound in pH 9.0 borate buffer (-·-·-.)

ethanol and introduced over a silica gel column (10 cm. long and 1 cm. in diameter). Elution was effected with anhydrous ether and the eluate collected in 5-ml. fractions. Earlier studies with synthetic mixtures of the anil (VI), the ureide (VII), and the isoalloxazine (III) showed that such a procedure was effective in separating the anil from the other two compounds. The anil was contained in the first few fractions of eluate.

Anaerobic Studies.—Here the reaction systems containing 9-methylisoalloxazine in pH 9.0 borate buffer were formulated in 10-ml. ampuls. Each ampul was thoroughly flushed with nitrogen and sealed immediately. The sealed ampuls were suspended in a constant-temperature bath adjusted at 45°. The ampuls were opened at different times and the spectrum of each solution was obtained. Concomitant with this, 60-μl. samples were developed on Silica Gel G thin-layer plates using $CHCl_3$–acetic acid–pyridine (5:1:1) solvent system. The developed plates after drying were examined under long-wave ultraviolet light, and the R_f values of different spots were compared with those obtained with known compounds.

RESULTS

Isolation and Identification of Reaction Products.—A preliminary indication of the dependence of the reaction pathways on the hydroxide ion concentrations was obtained by comparison of the spectra of solutions of 9-methylisoalloxazine which were degraded under two different conditions of hydroxide-ion concentration. Figure 1 illustrates such spectra. The striking difference between the spectra clearly indicated that different products were favored depending on the pH of the reaction medium. In Fig. 2 are illustrated the spectra of two possible decomposition products, *i.e.*, the keto acid and the dioxo compound. It can be seen from Figs. 1 and 2 that the spectrum of the isoalloxazine solution degraded at pH 9.0 closely resembled that of the dioxo compound while that of the solution degraded in 0.5 *N* sodium hydroxide corresponded to that of the keto acid. The results of the thin-layer chromatographic studies (see t_∞ samples) summarized in Figs. 3 and 4 revealed that both the keto acid and the dioxo compound were formed under all conditions of pH. However, the relative intensities of the spots corresponding to the two compounds, together with spectral data, demonstrated that the keto acid was the major product at high pH, while at the lower pH, the dioxo compound was mainly formed.

It should be pointed out that the appearance of the dioxo compound as a reaction product was unexpected since the formation of this compound from the parent isoalloxazine must involve both hydrolytic and oxidative reactions. It was the work of Miles *et al.* (16) which presented fluorescence, spectral, and chromatographic properties of a similar compound formed in the bacterial degradation of riboflavin that first drew the authors' attention to the possibility that the dioxo compound was indeed formed.

Thin-Layer Chromatographic Studies.—Fluorescence characteristics under long-wave U.V. light and R_f values for various compounds which could conceivably be formed in the reaction are presented in Table I. It can be seen here and in Fig. 3, which illustrates the progress of the reaction in 0.5 *N* base, that a compound with sky-blue fluorescence and with an R_f approximately 0.38, appeared transiently during the hydrolysis. This R_f value and the fluorescence characteristics agreed with that of a suspected intermediate, *viz.*, the anil compound. The results of a similar study at pH 9.0 are presented in Fig. 4. Only three spots are apparent here, those of the parent compound, the dioxo compound, and a very weak one due to the keto acid.

Isolation and Characterization of the Intermediate from the Reaction Mixture.—A suspected intermediate, the anil, was successfully isolated from partially degraded solution of the isoalloxazine.

Fig. 3.—Chromatograms illustrating the progress of hydrolysis of 9-methylisoalloxazine in 0.5 *N* sodium hydroxide and at 45°. Key: *A*, keto acid; *B*, anil; *C*, isoalloxazine; *D*, dioxo compound.

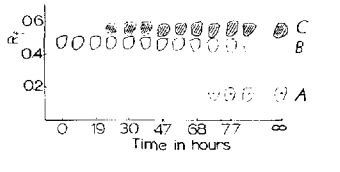

Fig. 4.—Chromatograms illustrating the progress of hydrolysis of 9-methylisoalloxazine in pH 9.0 borate buffer and at 45°. Key: *A*, keto acid; *B*, isoalloxazine; *C*, dioxo compound.

The isolation was achieved through ether extraction of the acidified reaction mixture. Further purification of the isolated material was accomplished through the use of silica gel columns. The spectrum of the isolated compound is shown in Fig. 5 and is identical with that of the pure anil. In addition, the isolated compound exhibited the same fluorescence and chromatographic behaviors as authentic anil. Figure 5 also shows the spectrum of the ureide which could also conceivably be an intermediate in the reaction pathway. It was observed, however, that the ureide in aqueous solution was rapidly and almost quantitatively converted to the anil to form what appeared to be an equilibrium mixture. A typical spectrum of such a mixture in 0.01 *N* HCl is also shown in the figure. The equilibrium was found to be pH dependent, and the anil appeared to be the predominant species in the neutral and alkaline pH range.

Solutions of the anil were formulated in 0.5 *N* NaOH and in pH 9.0 borate buffer and the compound was allowed to degrade. Spectra of the degraded solutions are shown in Fig. 6. These spectra are remarkably similar to those obtained with the parent isoalloxazine.

TABLE I.—R_f VALUES AND THE FLUORESCENCE CHARACTERISTICS OF VARIOUS COMPOUNDS ON SILICA GEL G THIN-LAYER PLATES IN $CHCl_3$–ACETIC ACID–PYRIDINE (5:1:1) SOLVENT SYSTEM

Compd.	Fluorescence Behavior under U.V.	R_f Values
Isoalloxazine (III)	Yellow-green	0.45
Keto acid (IV)	Sky-blue	0.18
Dioxo compd. (V)	Dark blue	0.57
Anil (VI)	Faint sky-blue turning greenish	0.38
Ureide (VII)	Yellow-green	0.78
Quinoxaline compd. (VIII)	Dark blue	0.89
Unidentified compd.	Aquamarine	0.69

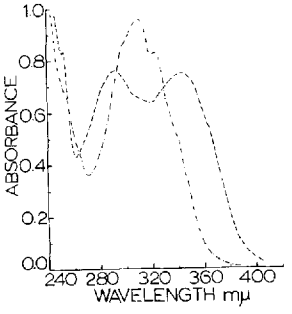

Fig. 6.—Spectra of the solutions of the anil that were degraded in 0.5 *N* sodium hydroxide (- - - - - - -) and in pH 9.0 borate buffer (- · - · -).

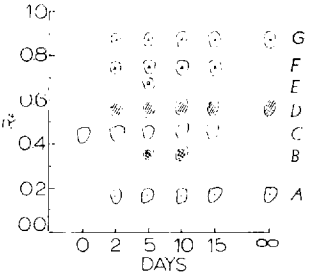

Fig. 7.—Chromatograms illustrating the progress of the anaerobic hydrolysis of 9-methylisoalloxazine in pH 9.0 borate buffer and at 45°. Key: A, keto acid, *B*, anil; *C*, isoalloxazine; *D*, dioxo compound; *E*, unidentified compound; *F*, ureide; *G*, quinoxaline compound.

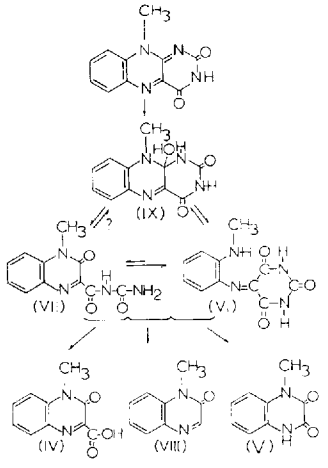
Anaerobic Studies.—Thin-layer chromatographic results of anaerobic hydrolysis of the isoalloxazine at pH 9.0 are presented in Fig. 7. It can be seen here that the degrading solution of the isoalloxazine under these conditions exhibited spots which corresponded to the keto acid and the quinoxaline compound. In addition, it also showed the anil, the ureide, and an unidentified spot exhibiting aquamarine fluorescence under U.V. light and with an R_f of 0.69.

DISCUSSION

The information which has been collected in this study demonstrated that 9-methylisoalloxazine, in aqueous solution, was transformed into a number of different products, and that the anil compound was an intermediate in such transformations. A proposed scheme for the degradation is presented in Scheme I. The isoalloxazine is seen to be initially



Over-All Reaction Mechanism for the Degradation of 9-Methylisoalloxazine.
Scheme I

converted to the anil compound. Such a transformation can possibly result from hydroxide-ion attack at the α carbon to form a carbinolamine (IX), which in turn can rupture to form either the anil (VI) or the ureide (VIII). Evidence, which will be presented in a future communication, has been ob-

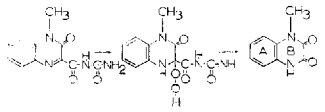
tained to indicate the involvement of such a carbinolamine intermediate. Although the anil compound has definitely been implicated in the reaction scheme, the existence of the ureide is somewhat speculative. As was indicated, however, there is evidence that ureide and anil existed in equilibrium in solution and that the equilibrium favored the anil under the pH conditions which prevailed in this study.

The interesting and somewhat unexpected observation that high pH degradation yielded the keto acid (IV) as the predominant product, while at pH 9.0 the dioxo compound (V) was the main product, can be explained by noting that the anil compound could undergo further reaction by both hydrolytic and oxidative routes and that the relative concentrations of the products would depend on the relative rates of the processes. Thus, at high pH the hydrolytic reaction was much faster than that of oxidation, while at pH 9 the reverse was true. Exclusion of air from the systems at pH 9 markedly decreased the rate of oxidation and made apparent that the hydrolytic reaction which yielded the keto acid was also operant under these conditions. Another reaction pathway which resulted in the formation of the quinoxaline compound (VIII) also became apparent under anaerobic conditions.

The failure to detect the anil in solutions of the isoalloxazine which were degraded at pH 9 in the presence of air can also be explained on the basis of relative reaction rates. It appears that under these conditions, the rate of disappearance of the anil was faster than the rate of its formation from the parent compound. Support of this stems from the fact that solutions of isoalloxazine, which were partially degraded at pH 9 in the absence of air, where the oxidative transformation of the intermediate anil was suppressed, did contain demonstrable concentrations of anil. That the anil was formed as an intermediate under all conditions investigated is also indicated by the spectral studies on completely degraded solutions, which showed that under both conditions of pH the anil yielded the same reaction products as the parent isoalloxazine.

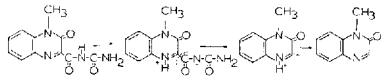
The anaerobic studies with the isoalloxazine also revealed the formation of yet another compound with a weak aquamarine fluorescence under U.V. light and with an R_f value of 0.69 in the solvent system used. This compound has, as yet, not been identified.

Although no definitive evidence was obtained to indicate whether the formation of the final products proceeded through the anil or the ureide, the presence of the intact B ring in the products suggest the latter as the intermediate. Simple hydrolysis would yield the keto acid and urea. It can be speculated that the dioxo compound was formed through a hydroperoxide intermediate such as that depicted in Scheme II, which could undergo homolytic cleavage as shown. Studies on solutions of the keto acid showed that it was stable under the experimental conditions employed and did not undergo any detectable degree of decarboxylation even after prolonged exposure to the reaction conditions. Thus, the quinoxaline compound (VIII) was not derived



A Possible Mechanism for the Formation of Dioxo Compound from the Ureide.
Scheme II

from the keto acid (IV). It could conceivably arise directly from the ureide (VII) which has a weakly acidic imino hydrogen and could be considered to be analogous to a quinaldic carboxylic acid. Such acids are known to decarboxylate readily particularly when unionized (18). A possible mechanism for such a transformation of the ureide is given in Scheme III.



A Possible Mechanism for the Formation of the Quinoxaline Compound from the Ureide.
Scheme III

The formation of an oxidation product analogous to the dioxo compound which was identified in this study, was reported by Stadtman and co-workers (16, 19) to result from bacterial degradation of riboflavin and to involve both hydrolytic and oxidative enzymatic mechanisms. This apparent analogy between chemical and biological systems is interesting and suggests that information on the hydrolytic behavior of isoalloxazines in simple chemical systems might be of significance in gaining a better understanding of certain biochemical reactions involving riboflavin.

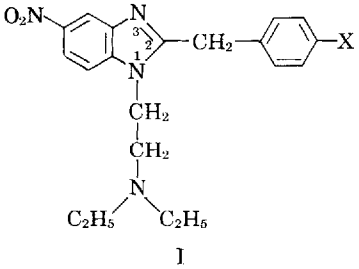
Synthetic Analgesics I

N-(2-Dialkylaminoethyl)-2-phenylacetanilides

By JAMES F. STUBBINS* and TAITO O. SOINE

A series of 24 *N*-(2-dialkylaminoethyl)-2-phenylacetanilides was prepared for testing as potential analgesics. The structure of these compounds can be related to certain nitrobenzimidazole and propionanilide analgesics. The compounds were prepared by treating *N,N*-dialkyl-*N'*-phenyl- or *N,N*-dialkyl-*N'*-(*p*-nitrophenyl)-ethylenediamine hydrochlorides with various phenylacetyl chlorides. The products were obtained as the hydrochloride or perchlorate salts. The previously unknown intermediates—*p*-ethoxyphenylacetyl chloride, *N,N*-dimethyl-*N'*-(*p*-nitrophenyl)-ethylenediamine hydrochloride, and 1-[(*p*-nitroanilino)-ethyl]-piperidine hydrochloride—also are described.

HUNGER *et al.*, in 1957, reported the synthesis of some nitrobenzimidazole derivatives (I) possessing very significant analgesic activity (1). These compounds differ rather radically in structure from other potent analgesics. The degree of activity in this series of compounds is highly dependent upon the *p*-substituent in the benzyl moiety. I*c* and I*d* are 100 and 1000 times as potent as morphine, respectively (2), the latter compound being the most active analgesic known at that time. The unsubstituted (I*a*) or chloro-substituted (I*b*) compounds are only slightly more active than morphine. The nitro group in the 5 position of the benzimidazole ring appears to be an essential feature in this series; if the nitro group is removed or moved to a different position of the ring, activity is markedly reduced or abolished. Another peculiarity of these compounds is that the diethylamino moiety in the basic side chain seems to lead to higher activity than a dimethylamino or heterocyclic amino group.

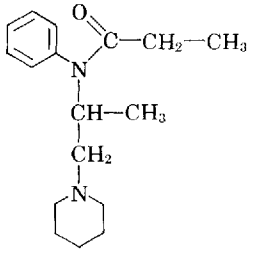


I*a*, X = H
b, X = Cl
c, X = OCH_3
d, X = OC_2H_5

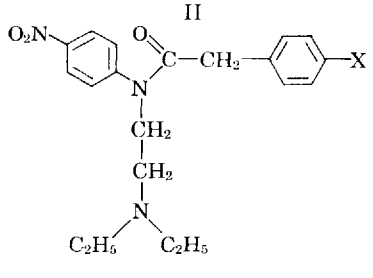
I

Later Wright *et al.* reported that a series of propionanilides showed analgesic properties (3, 4). A typical member of this series is phenampromid (II). These propionanilides resemble the methadone analgesics except that they contain one less phenyl ring and that the usual quaternary carbon atom has been replaced by a tertiary nitrogen atom.

If it is assumed that the carbon-nitrogen double bond of the imidazole ring can simulate a carbonyl group, then the nitrobenzimidazole and propionanilide analgesics may be closely related. Opening of the imidazole ring of I between the benzene ring and the 3 position and replacement of the N^3 nitrogen atom by oxygen leads to compounds of general structure III. This is seen to differ from the propionanilide-type only in the replacement of the propionyl group by the phenylacetyl group and by the added nitro group. Structure III has served as the model for the present series of compounds.



II



III

The structure of III was varied at X to provide compounds for comparison with the active benzimidazoles; thus, X may be a hydrogen, chloro, methoxy, or ethoxy group. In addition, compounds were prepared lacking the nitro group

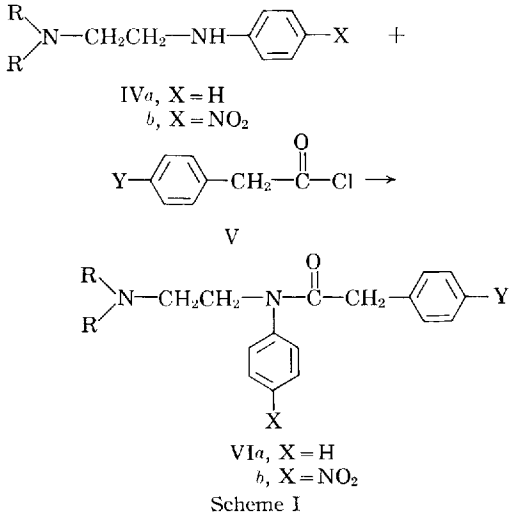
Received September 14, 1965, from the Department of Pharmaceutical Chemistry, College of Pharmacy, University of Minnesota, Minneapolis.
Accepted for publication June 28, 1966.
Presented to the Scientific Section, A.PH.A., Detroit meeting, March 1965.
This investigation was supported in part by a research fellowship (1961–1962) from Rowell Laboratories, Baudette, Minn.
* Present address: School of Pharmacy, Medical College of Virginia, Richmond.

and having dimethylamino or piperidino groups in place of the diethylamino group of the model. It was felt that the special requirements for the nitro and diethylamino groups in the benzimidazole analgesics might be peculiar to that ring system and might be unnecessary in non-benzimidazole analogs.

Thus, all combinations of the variations mentioned yield a set of 24 compounds of general structure (VI). It was hoped that the synthesis and testing of these compounds would establish more structure–activity relationship in this area and that, perhaps, a bridge linking the benzimidazole analgesics to others could be found.

DISCUSSION

In the first attempts to prepare the phenylacetanilides, *N,N*-diethyl-*N'*-phenylethylenediamine (IV*a*, R = C_2H_5) and *N,N*-diethyl-*N'*-(*p*-nitrophenyl)-ethylenediamine (IV*b*, R = C_2H_5) were treated with phenylacetyl chloride in benzene. In both cases large amounts of tar were obtained, and most of the diamine could be recovered. No amide was detected in repeated trials. (Scheme I.)



Scheme I

When phenylacetic anhydride was employed in place of the acid chloride, the desired amides (VI*a* and *b*, R = C_2H_5; Y = H) were obtained in low yield. The products were isolated as the free bases. VI*b* (R = C_2H_5, Y = H) was converted to the hydrochloride salt. All attempts to obtain a salt of VI*a* (R = C_2H_5, Y = H) with various organic and inorganic acids failed to yield a solid until a crystalline perchlorate was prepared according to the method of Caudle *et al.* (5).

The substituted phenylacetic anhydrides required proved to be difficult to obtain in a pure state. Therefore, attempts were made to prepare the amide directly from the acid by use of the "mixed anhydride" methods. Both the sulfonic acid (6) and carbonic acid (7) anhydride methods failed to yield amide. Numerous attempts employing dicyclohexylcarbodiimide (8) as a condensing agent also failed.

When the diamines were treated with the acid chlorides (V), dehydrohalogenation might have occurred in preference to amide formation. To avoid this difficulty, the hydrochloride salt of the diamines (IV) was used in place of the free base. When the various substituted ethylenediamine hydrochlorides were treated with phenylacetyl or *p*-substituted phenylacetyl chlorides in benzene, the phenylacetanilides were obtained as the hydrochloride salts. If the hydrochloride salt would not crystallize, the free base was isolated and converted to the perchlorate salt. All 24 of the desired compounds were obtained by this procedure (Table I). The crude products usually were badly contaminated with the starting material, and purification frequently was difficult. In a few cases the product was soluble in the hot benzene and slowly separated upon cooling, resulting in a much cleaner product.

The structural assignment of the products is supported by the microanalyses and the infrared spectra. All the compounds have a prominent band near 6.0 μ typical of tertiary amides (9). Since this work was started, compound *11* (as the free base) was reported in an Austrian patent (10). It was one of a series of compounds described for use as "narcotic and analgesic drugs," but no pharmacological results were given.

The acid chlorides required were prepared by the method of Elderfield and Meyer (11). *p*-Ethoxyphenylacetyl chloride was the only one not previously known. The intermediate *N,N*-dialkyl-*N'*-phenylethylenediamines were synthesized by condensing dialkylaminoethyl chlorides with aniline according to the method of Stahmann and Cope (12). All the hydrochloride salts have been reported previously (4). However, this method is unsatisfactory for the *N,N*-dialkyl-*N'*-(*p*-nitrophenyl)-ethylenediamines. These were prepared by arylation of *N,N*-dialkylethylenediamines with *p*-nitrochlorobenzene by modification of the method of Mann *et al.* (13). Pyridine was used as solvent and proton acceptor. *N,N*-Diethyl-*N'*-(*p*-nitrophenyl)-ethylenediamine hydrochloride previously has been reported (12).

PHARMACOLOGICAL RESULTS[1]

All of the products were screened initially for possible analgesic activity by the phenyl-*p*-quinone writhing test (14). The compounds were given orally at a dose of 100 mg./Kg. to mice. Compounds *2*, *3*, *5*, *7*, *11*, *14*, *20*, *21*, and *24* (Table I) reduced writhing by at least 50%. These nine compounds were then tested in rats by the D'Amour–Smith procedure (15). At an interperitoneal dose of 25 mg./Kg., only compound *2* increased response time by at least 50%. This is not the compound expected to have the most activity based on comparison with the benzimidazole or propionanilide analgesics. The general lack of activity in the phenylacetanilides is disappointing in view of their close relationship to compounds of significant activity. This would seem to indicate that the benzimidazole ring is an essential feature of that class of analgesics, and that

[a] Solvent: A, methanol; B, ethanol; C, acetone; D, methyl ethyl ketone; E, methyl isobutyl ketone; F, diethyl ether; G, tetrahydrofuran; H, ethyl acetate; I, chloroform; J, benzene; K, hexane. A–B, product dissolved in boiling mixture of solvents A and B. A/B, product dissolved in boiling solvent A and reprecipitated by addition of solvent B.

the activity of that group of compounds is unrelated to other morphine-like analgesics. However, the recent suggestion by Portoghese (16) that analgesics may bind to one site in more than one way must be considered. Thus, the benzimidazole and propionanilide analgesics may bind to the same site by different modes. Then a hybrid structure such as the phenylacetanilide may not be well suited for binding by either mode or may bind by still a third mode which does not lead to the analgesic response.

EXPERIMENTAL

All melting points were obtained on a Thomas-Hoover capillary melting point apparatus and are corrected. All analyses were performed by the University of Minnesota Microanalytical Laboratory or the Scandinavian Microanalytical Laboratory, Herler, Denmark.

p - Ethoxyphenylacetyl Chloride.—*p* - Ethoxyphenylacetic acid (50.0 Gm., 0.280 mole) was dissolved in 100 Gm. (0.840 mole) of thionyl chloride. The solution was stirred at room temperature for 1 hr., then heated on a steam bath for 4 hr. After cooling, the reaction mixture was allowed to stand for 16 hr. more at room temperature. The excess thionyl chloride was removed on a rotary evaporator. The residue was then distilled. The yield was 49.8 Gm. of material boiling at 93–97°/0.7 mm.

N,N - Dimethyl - N' - (p - nitrophenyl) - ethylenediamine Hydrochloride.—To 94.6 Gm. (0.600 mole) of *p*-nitrochlorobenzene suspended in 150 ml. of pyridine was added 52.9 Gm. (0.600 mole) of *N,N*-dimethylethylenediamine. The mixture was stirred and heated under reflux for 24 hr. All of the solid dissolved. The solution was cooled, and most of the pyridine was removed by means of a rotary evaporator. The reddish-brown oil that remained had a bright blue fluorescence. Benzene (200 ml.) was added. The mixture was filtered, and the cake was rinsed with benzene. To the filtrate was added benzene saturated with anhydrous hydrogen chloride in small portions with vigorous stirring. The solid was removed by filtration. The filtrate was again treated with hydrogen chloride in benzene to obtain a further small amount of solid. This solid was filtered off, and the filter cakes were combined and air dried. The yield of crude material was 53.9 Gm.

The product was purified by dissolving it in boiling absolute ethanol, filtering, adding ethyl acetate until precipitation began, and then cooling. Repetition of this process finally yielded bright golden flakes free of any brown coloration. After drying overnight at 110°, the product weighed 32.5 Gm. It melted at 180.5–182.5°.

Anal.—Calcd. for $C_{10}H_{16}ClN_3O_2$: C, 48.88; H, 6.56; N, 17.11. Found: C, 48.77; H, 6.67; N, 17.07.

1 - [2 - (p - Nitroanilino) - ethyl] - piperidine Hydrochloride.—1-(2-Aminoethyl)-piperidine (19.2 Gm., 0.150 mole) and *p*-chloronitrobenzene (23.6 Gm., 0.150 mole) were dissolved in 50 ml. of pyridine. The solution was stirred and heated under reflux for 36 hr. The solution was cooled, and most of the pyridine was removed *in vacuo*. The dark oily residue was dissolved in 100 ml. of benzene. Benzene, saturated with hydrogen chloride, was added in small portions with vigorous stirring until

precipitation was complete. The slurry was filtered, and the filter cake was washed with cold benzene. The crude product weighed 23.6 Gm.

The product was recrystallized once from an ethanol–ethyl acetate mixture, then twice from tetrahydrofuran. The pure material consisted of shiny, golden flakes melting at 207–209°. The yield was 12.8 Gm.

Anal.—Calcd. for $C_{13}H_{20}ClN_3O_2$: C, 54.63; H, 7.05; N, 14.71. Found: C, 54.93; H, 7.23; N, 14.41.

N - (2 - Dialkylaminoethyl) - 2 - phenylacetanilides.—From 0.020–0.030 mole of substituted ethylenediamine hydrochloride was suspended in 100–150 ml. of benzene. The appropriate acid chloride was added in 10–25% molar excess. The suspension was stirred and heated under reflux 24–72 hr. The mixture was cooled and filtered. The crude product was recrystallized from the appropriate solvent (Table I).

In a few instances the product was soluble in the benzene even after cooling. In these cases, an equal volume of petroleum ether was added to force the salt out of solution.

If the crude hydrochloride salt was liquid and could not be induced to crystallize, it was dissolved in dilute hydrochloric acid and neutralized with 10% sodium hydroxide solution. The free base was extracted into ether. The ethereal solution was dried, and the ether was removed *in vacuo*. The residual base was converted to the perchlorate salt by the method of Caudle *et al.* (5).

Synthesis of 4-Substituted-7-methylpyrrolo[2,3-*d*]pyrimidines

By RICHARD H. HAMMER

The reactions of 4-chloro-7-methyl-7H-pyrrolo[2,3-*d*]pyrimidine (IV) with ethanolic ammonia, thiourea, and aqueous sodium sulfhydrate solution to give the 4-amino (V) and 4-thione (VI) analogs are described. Ultraviolet data and pKa values for IV, V, and VI are reported.

TUBERCIDIN (I*a*), a naturally occurring nucleoside in streptomyces species (1, 2), has been assigned the structure 4-amino-7-β-D-ribofuranosyl-7H-pyrrolo[2,3-*d*]pyrimidine (7-deazaadenosine) (3–5). It is an inhibitor of several tumor systems, not cross-resistant to 6-mercaptopurine-resistant line tumor systems (6), and incorporated into both DNA and RNA of mouse fibroblasts and several viruses (7, 8). During structural elucidation studies of tubercidin (I*a*), hydrolysis of I*a* to the aglycone (I*b*) and D-ribose was accomplished by refluxing I*a* in 1–3 *N* HCl for 5 hr. (4). From these data the base ribose bond of I*a* appears to be more resistant to acid hydrolysis than a purine base-ribose bond. Subsequently, resistance of I*a* to enzymatic cleavage by *E. coli* nucleoside phosphorylase was demonstrated while 6-mercaptopurine riboside was observed to be rapidly cleaved (9). Significance of the stability of the pyrrolo[2,3-*d*]pyrimidine base-ribose bond in relation to drug distribution and cancer chemotherapy remains to be explained.

Recent studies by Montgomery and Hewson (10, 11) on the cell culture cytotoxicity of 6-mercaptopurine and 6-mercaptopurine-deaza analogs suggests that deaza structures such as 6-mercapto-7-deazapurine (11–13) are not metabolized by the cells to the ribotide form and consequently are 300–500 times less active than 6-mercaptopurine which is readily converted to the ribotide. This raises the question as to whether antitumor activity for pyrrolo[2,3-*d*]-pyrimidine structures may be dependent on a substituent such as a sugar group, cycloalkyl or alkyl group on the 7-nitrogen (corresponding to the 9-position of purine). This is evident by the fact that tubercidin (I*a*) with a β-D-

ribose moiety on the 7-position is active while II, which is unsubstituted, is inactive. Pyrrolo [2,3-*d*]pyrimidine structures with a methyl group on the 7-nitrogen and amino or mercapto groups at the 4-position (corresponding to the 6-position of purine) are therefore of biological interest and prompted the described synthesis of 4-amino-7-methyl-7H-pyrrolo[2,3-*d*]pyrimidine (V) and 7 - methyl - 7H - pyrrolo[2,3 - *d*]pyrimidine - 4-(3H)-thione (VI) from 4-chloro-7H-pyrrolo[2,3-*d*] pyrimidine (III).

EXPERIMENTAL

Melting points were obtained on a Thomas-Hoover capillary melting point apparatus and are uncorrected. Infrared and ultraviolet analyses were recorded on Beckman IR-5 and model DB spectrophotometers. Titrimetric pKa values (14) were obtained on a Sargent titrator, model D, and spectrophotometric pKa values (15) were obtained using buffered solutions (16) verified with standard buffer solutions on a Beckman expanded scale pH meter, model 76. Microanalyses were conducted by Galbraith Laboratories, Inc., Knoxville, Tenn.

4-Chloro-7-methyl-7H-pyrrolo[2,3-d]pyrimidine (IV) (17).—To a solution of 1.50 Gm. of crude 4-chloro-7H-pyrrolo[2,3-*d*]pyrimidine (III) (12) in 10.0 ml. of dimethylformamide (dried over petroleum ether extracted sodium hydride) cooled to 5° was added 0.492 Gm. of sodium hydride (represents 0.492 Gm. sodium hydride, 50% dispersed in oil, prior to extraction with petroleum ether). The mixture was kept at room temperature until all the hydrogen gas was liberated (4.5 hr.). The reaction mixture was cooled to 5° and 0.60 Gm. of methyl iodide was added. An immediate tan precipitate was observed with agitation in the ice-bath, and after standing for 12 hr., 10.0 ml. of water was added and cooled for an additional 6 hr. Filtration yielded 1.16 Gm. of crude tan product, m.p. 120–122°. The filtrate gave 0.160 Gm. of additional product, m.p. 118–120°. The combined crops were recrystallized from methanol to give light tan crystals (IV). Yield, 1.009 Gm. (62%), m.p. 126–127°. [Reported m.p. 130° (17).] $\nu_{max.}$, cm.$^{-1}$, 3050, 2880 (CH); 1615, 1580, 1530, 1510 (C=C, C=N).

Anal.—Calcd. for $C_7H_6ClN_3$: C, 50.18; H, 3.58; N, 25.08. Found: C, 49.90; H, 3.70; N, 24.84.

4-Amino-7-methyl-7H-pyrrolo[2,3-d]pyrimidine (V).—To 0.20 Gm. of IV in a Parr stainless steel bomb was added 10.0 ml. of ethanolic ammonia solution (prepared by saturating absolute ethanol at 5° with ammonia). The bomb was sealed and maintained at 125–130° with stirring on a combination hot plate-magnetic stirrer. The reported reaction temperature was obtained by simultaneously heating a beaker of mineral oil adjacent to the Parr bomb on the same hot plate. After 10 hr., the mixture was cooled and filtered 5 times to remove decomposition material. The clear brown filtrate was evaporated to dryness yielding a brown crystalline residue which was recrystallized 2 times from hot water to give tan crystals (V). Yield, 0.044 Gm. (25%), m.p. 207–208° dec. $\nu_{max.}$, cm.$^{-1}$, 3280, 3050, 2890 (NH, CH); 1640, 1580, 1550 (NH, C=C, C=N).

	318(19,180)	318(19,450)	306(16,450)	

[a] pH 1.0 (0.1 *N* HCl); pH 7.0 (phosphate buffer) (16); pH 13.0 (0.1 *N* NaOH). [b] Ethanol, absolute (13). [c] Spectrophotometric method (15). [d] Titrimetric method (14). [e] Reported (4): $\lambda_{max.}^{0.01\ N\ HCl}$ 230 (—), 275(10,300); $\lambda_{max.}^{0.01\ N\ NaOH}$ 273(9,400).

Gm. of IV in 8.0 ml. of absolute ethanol was added 0.272 Gm. of thiourea. After 5 min. of refluxing the $\lambda_{max.}$ had shifted from 270 to 325 mμ. Refluxing was continued for an additional 3 hr. at which time the $\lambda_{max.}$ was still 325 mμ. Upon evaporation, the crude residue was recrystallized from methanol (48 hr. at room temperature) to give pale yellow needles (VI). Yield, 0.154 Gm. (52%), m.p. 305–307° dec. $\nu_{max.}$, cm.$^{-1}$, 3125, 3010, 2860 (CH); 1575, 1530 (C=C, C=N).

Anal.—Calcd. for $C_7H_7N_3S$: C, 50.90; H, 4.24; N, 25.44. Found: C, 51.08; H, 4.47; N, 25.20.

Method B.—To a solution of 0.20 Gm. of IV in 10.0 ml. of absolute ethanol was added 30.0 ml. of an aqueous sodium sulfhydrate solution (2.0 *N*). The solution was refluxed for 5 hr. at which time the $\lambda_{max.}$ had shifted from 271 to 319 mμ. The yellow solution was cooled and neutralized to a pH of 7 with 10% acetic acid. After cooling overnight the reaction mixture was filtered to give 0.161 Gm. of a pale yellow residue, m.p. 300–302°. Recrystallization from methanol (48 hr. at room temperature) gave pale yellow needles (VI). Yield, 0.097 Gm. (33%), m.p. 307–308° dec. $\nu_{max.}$, cm.$^{-1}$, 3130, 3000 (CH); 1575, 1545, 1530 (C=C, C=N). (Scheme I.)

Anal.—Calcd. for $C_7H_7N_3S$: C, 50.90; H, 4.24; N, 25.44. Found: C, 50.62; H, 4.27; N, 25.21.

RESULTS AND DISCUSSION

The intermediate compound 4-chloro-7H-pyrrolo-[2,3-*d*]pyrimidine (III) was prepared by a 5-step reaction sequence from starting materials of ethylcyanoacetate and bromoacetal (12). Reaction of III with sodium hydride to form the nucleophile and subsequent reaction with methyl iodide gave the 4-chloro-7-methyl-7H-pyrrolo[2,3-*d*]pyrimidine (IV) compound (17). Nucleophilic displacement of the 4-chloro group of IV by reaction with either thiourea (method *A*) or sodium sulfhydrate (method *B*) gave 7-methyl-7H-pyrrolo[2,3-*d*]pyrimidine-4(3H)-thione (VI). Both reactions proceed smoothly at reflux temperatures. Method *A* gave a yield of 52% of VI compared to 33% by method *B*. Infrared and ultraviolet curves of VI from methods *A* or *B* were superimposable and identical in every respect. Optimum conditions for synthesis of the 4-amino congener (V) required heating IV in ethanolic ammonia for 10 hr. at 125–130° in a stainless steel bomb. The reaction was also run at temperatures of 105–110° and 155–160°. The higher temperature produced more extensive decomposition and the lower temperature gave a lower yield than the 125–130° range. Synthesis of the 4-mercapto analogs of pyrrolo[2,3-*d*] pyrimidines can readily be followed by a bathochromic shift in $\lambda_{max.}$ from 265–275 to 315–325 mμ as previously demonstrated during the synthesis of II (13) and as described here (Table I).

Facile substitution of the 6-chloro group of 6-chloropurine and 6-chloro-9-substituted purines by nucleophilic groups has provided useful synthetic pathways leading to a variety of purine nucleosides and purine analogs. Similarly, 4-chloropyrrolo-[2,3-*d*]pyrimidine moieties, without a 7-nitrogen substituent, are useful intermediates which can be reacted with ammonia (18), alkyl amines and thiourea (12), phosphorus pentasulfide (9), sodium sulfhydrate and sodium methoxide (13), and alkyl mercaptans (19) to give the corresponding 4-substituted derivatives. Even though nucleophilic groups can be substituted in place of the 4-chloro group, on the basis of the conditions required for the amination reactions of III, IV, and 6-chloro-purine compounds, the 4-chloro group appears to be more difficult to displace than the corresponding 6-chloro of purine compounds. Lewis *et al.* (20) reported the synthesis of 6-amino-9-(tetrahydro-2-furyl)purine by treating the 6-chloro precursor with methanolic ammonia at room temperature for 48 hr. However, Hitchings *et al.* (18) reported that to replace the 4-chloro group of III with an amino group it was necessary to heat III in a stainless steel bomb at 155–160° for 20 hr., and as reported here, conversion of IV to V required heating IV in ethanolic ammonia for 10 hr. at 125–130°. For the amination reactions, the reaction conditions indicate that the 4-chloro group of pyrrolo[2,3-*d*]pyrimidines is more difficult to displace than the corresponding 6-chloro group of purines.

The pKa values reported in Table I were obtained by titrimetric (14) or spectrophotometric (15) methods. Due to its insolubility in aqueous perchloric acid, the pKa value for IV was obtained spectrophotometrically. Replacement of the 4-chloro group of IV with an amino group (V) gave an expected shift to a higher pKa which would normally occur when an electron-withdrawing group (Cl) is replaced with an electron-donating group (NH_2). Tubercidin (I*a*) has been reported to have a pKa of 5.3 (4). The pKa of the 4-amino-7-methyl analog (V) was found to be 5.02. Providing V has a favorable partition coefficient, it would be expected to produce high intracellular concentrations. The ratio of unionized to ionized species of V at a pH of 7.4 (plasma) would be 240/1 (pKa 5.02) which should enhance its absorption across cellular membranes. The pKa of the SH group of VI was found to be 9.35. The pKa value was not obtained for the pyrrolo nitrogen of VI.

Screening of these compounds for antitumor properties is being conducted by the Cancer Chemotherapy National Service Center and will be reported at a later date.

Morning Glory Tissue Cultures: Growth and Examination for Indole Alkaloids

By E. JOHN STABA and PAUL LAURSEN*

The seeds and aerial portions of three *Ipomoea violacea* varieties contained significant amounts of indole alkaloids. The roots, callus tissue, and callus medium of these three varieties; the callus tissue and callus medium of *Rivea corymbosa;* and the seeds of three Japanese morning glory varieties contained traces of indole alkaloids.

IT HAS BEEN conclusively established that some *Convolvulaceae* plants contain ergot-type alkaloids. Among them are the seeds of *Argyreia nervosa* (baby Hawaiian wood rose) (1) and *Ipomoea argyrophylla* Vatke (2), *I. coccinea* L. (3), *I. muelleri* Benth. (4), *I. rubro-caerulea* Hook (5) [*I. violacea* (6)]; the seeds (7, 8) and plants (9) of *I. violacea* L. (morning glory, Badoh Negro, *I. tricolor);* and the seeds (7) and plants (10) of *Rivea corymbosa* (L.) Hall. f. (Ololiuqui, wild morning glory).[1]

Certain varieties of *I. violacea* are reported to induce a physiological response similar to lysergic acid diethylamide (11), although a recent study indicates sedation is the principal physiological effect of *I. violacea* and *R. corymbosa* seeds (12). Crude seed extracts of either heavenly blue or pearly gates varieties of *I. violacea* will cause isolated rat uterus muscle to contract (11). Sheep fed dried *I. muelleri* plants for 3 to 6.5 weeks lost weight, became incoordinated, and acquired a rapid panting respiration (4).

The principal objective of this study was to examine three varieties of *I. violacea* and *R. corymbosa* seed callus tissue cultures for indole alkaloids by thin-layer chromatography and spectrophotometry. In addition, the seeds and plants of these three varieties, and the seeds of three varities of Japanese morning glory were examined for indole alkaloids.

MATERIALS AND METHODS

The source of seeds for this study were: *Ipomoea violacea* L. cv. flying saucer (FS), cv. heavenly blue (HB), and cv. pearly gates (PG) (Park Seed Co., Greenwood, S. C.); *Ipomoea nil* (L.) Roth [*Pharbitis nil* Chois, Japanese morning glory (13)] cv. matzukaze, yuki, and chiyo no okina (H. Saier Seedsman, Dimondale, Mich.); and *Rivea corymbosa* (L.) Hall. f. (Prairie Regional Laboratory, Saskatoon, Canada, who purchased them from Atkins Garden and Research Laboratory, Cienfuegos, Cuba). Plants studied were grown from seeds in the Drug Plant Greenhouse, University of Nebraska.

Tissue Cultures.—*Ipomoea* seeds were sterilized in a 5.25% sodium hypochlorite solution (Purex Corp., Ltd., South Gate, Calif.) diluted 1:1 with sterile distilled water for 15 min. in vacuum, and *Rivea* seeds in a 1:3 dilution for 10 min. in vacuum. An unusually strong seed sterilization treatment was required for *Ipomoea* seeds to avoid mold contamination. As the seeds normally germinated within 2 days, they were directly transferred, after thorough rinsing with sterile distilled water, to 1-oz., square glass vials containing 18 ml. of Murashige's and Skoog's tobacco medium (14) with 1.0 p.p.m. 2,4-dichlorophenoxyacetic acid (2,4-D) and 1.0% agar.

Extraction Procedure.—Plant, seed, callus tissue and agar medium were extracted for indole alkaloids by a modification of the procedures published by Taber *et al.* (9) and by Abe and Yamatodani (15).

The aerial and root portions were ground in a Wiley mill to a 40-mesh powder; whereas, the seed and dried callus tissue were ground with a mortar and pestle. The plant samples (seed, 2.0 Gm.; aerial, 3.0 Gm.; root, 6.0 Gm.; callus tissue, amount indicated in Table I) were wetted with 10% ammonium hydroxide and allowed to macerate overnight. The ground seeds were first wetted with ethyl ether to facilitate more thorough wetting of the seeds by alkali. The samples were then extracted with ethyl ether in a Soxhlet apparatus for 24 hr.

The agar media were diluted approximately 3:1 with water, made alkaline with 10% ammonium hydroxide, and extracted for 2 to 3 days with ethyl ether in a liquid–liquid extractor.

Each ethereal fraction was then evaporated to dryness in vacuum and the residue dissolved in 10 ml. of 0.2 *N* sulfuric acid. The acidic solution was washed with 10-ml. portions of ethyl ether to remove residues and color. The acidic solution was then neutralized with an excess of sodium bicarbonate and extracted with three 15-ml. portions of chloroform (fraction A). The aqueous solution was then adjusted to pH 6.8 with 0.2 *N* sulfuric acid and again extracted with three 15-ml. portions of chloroform (fraction B). The remaining aqueous layer was filtered and designated fraction C. Fractions A, B, and C were divided into equal aliquots—A_1 and A_2; B_1 and B_2; and C_1 and C_2. Aliquots A_1, B_1,

[a] Alkaloid content for seeds expressed as mg./Gm. of seed material; for aerial, roots, and tissue cultures as mcg./Gm. wet weight. Average of three samples of seeds and aerial portion; and of one sample of roots, callus, and agar medium. [b] Fraction A: alkaline chloroform extract; fraction B: pH 6.8 chloroform extract. [c] Time interval since callus established in culture.

and C_1 were examined for indole alkaloids spectrophotometrically, and A_2, B_2, and C_2 examined for indole alkaloids by thin-layer chromatography.

Quantitative Alkaloid Assay.—Each aliquot was analyzed colorimetrically by the modified *p*-dimethylaminobenzaldehyde (PDAB)–nitrite procedure of Michelon and Kelleher (16). Total alkaloids present were calculated from an ergonovine maleate standard curve which was measured at 590 mμ in a Bausch & Lomb Spectronic 20 spectrophotometer.

Aliquots A_1 and B_1 (in chloroform) were evaporated to dryness in vacuum. The residue of aliquot A_1 was dissolved in 5.0 ml. of 0.2 *N* sulfuric acid, while the residue of aliquot B_1 was dissolved in 10.0 ml. of 5% aqueous tartaric acid. Aliquot C_1 (the filtered aqueous remainder) was analyzed without further purification. However, a bright yellow color in aliquot C_1 prevented its accurate assay, and the data for it are not reported. For each assay 2.0 ml. of extract was added to 2.0 ml. of 0.1% PDAB dissolved in a concentrated sulfuric acid–water solution (1:1, v/v). After 10 min., 0.1 ml. of freshly prepared 0.1% sodium nitrite aqueous solution was added, mixed, and the absorbance recorded. Each assay was repeated three times.

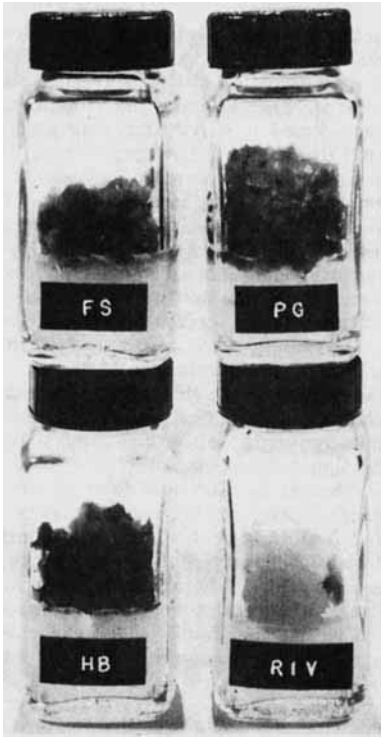

Fig. 1.—Callus tissue cultures after approximately 4 weeks' growth. Key: FS, flying saucer; PG, pearly gates; HB, heavenly blue; RIV, *Rivea corymbosa*.

Qualitative Alkaloid Assay.—Aliquots A_2, B_2, and C_2 were evaporated to dryness in vacuum. The residue of aliquot A_2 was dissolved in 0.5 ml. of 100% ethanol; the residue of aliquot B_2 was dissolved in 0.5 ml. of 95% ethanol; and the residue of aliquot C_2 was dissolved in 1.0 ml. of 95% ethanol. Qualitative comparisons of the alkaloids present in these aliquots were made on thin-layer plates.[2] The plates were spotted with extract amounts ranging from 50 to 200 μl. The solvent system used was a 17:3 mixture of chloroform and methanol (9). Developed plates were sprayed with 1% PDAB in 100% ethanol acidified with concentrated hydrochloric acid, and after 10 min. again sprayed with freshly prepared 0.1% sodium nitrite in 50% ethanol.

RESULTS AND DISCUSSION

Although callus tissue often appeared within 2 weeks on germinated seeds, it required 2 to 3 months before a sufficient size formed for subculture. Once established, callus tissue grew rapidly (Fig. 1) and required subculture approximately every 4 weeks. *Rivea* callus were consistently cream colored, whereas *Ipomoea* callus were considerably darker.

The results of the spectrophotometric assay are shown in Table I, and the chromatographic analysis in Fig. 2. Both analyses reconfirm that fraction A extracts of the seed and aerial portions of *I. violacea* (flying saucer, heavenly blue, and pearly gates) contain alkaloids in the amounts reported by previous investigators (1, 2, 7–9, 11). The authors' results are in agreement with Hofmann (7), but not with Taber *et al.* (9), that alkaloids are present in the plant's roots. Although the three Japanese varieties of *I. nil* seeds assayed contained trace amounts of alkaloids, six domestic varieties are reported not to contain alkaloids (8, 17). Trace amounts of alkaloids remained in most of the alkaline aqueous solutions extracted with chloroform (fraction A). The trace alkaloids were extracted with chloroform

[2] The thin-layer plates were prepared with Adsorbosil-1, Applied Science Lab., Inc., State College, Pa.

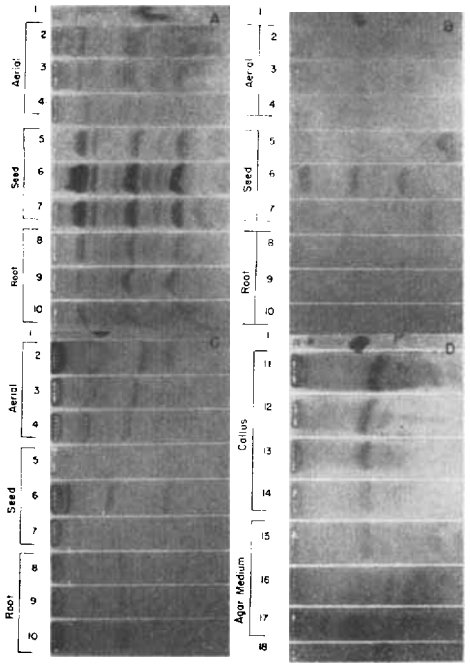

Fig. 2.—Thin-layer chromatograms of morning glory seeds, plants, and tissue cultures. Key: A, plants and seeds: alkaline chloroform extract (fraction A); B, plants and seeds: pH 6.8 chloroform extract (fraction B); C, plants and seeds: pH 6.8 aqueous extract (fraction C); D, tissue culture: alkaline chloroform extract (fraction A). Number code: clymoclavine, 1; pearly gates, 2, 5, 8, 11, 15; heavenly blue, 3, 6, 9, 12, 16; flying saucer, 4, 7, 10, 13, 17; *Rivea corymbosa*, 14; agroclavine, 18. Amounts applied: A, aerial 100 μl.; seed, 50 μl.; root, 150 μl.; B, C, and D, 100 μl. Adsorbent: Adsorbosil-1 (Applied Science Lab., Inc., State College, Pa.). Solvent system: chloroform–methanol (17:3). Spray reagent: PDAB–sodium nitrite.

(fraction B) upon adjustment of the alkaline aqueous solution to pH 6.8 (Table I and Fig. 2, B). The remaining aqueous solution (fraction C) might also contain alkaloids (Fig. 2, C), or indole-type compounds.

Only trace amounts of alkaloids were detected spectrophotometrically in flying saucer, pearly gates, and *Rivea* callus and in flying saucer and pearly gates agar growth medium. No alkaloids were detected spectrophotometrically in heavenly blue tissue cultures (Table I). Although callus tissue cultures more consistently contained alkaloids than their respective medium, the medium extract occasionally gave a more positive and complex pattern than the callus extract on thin-layer plates (Fig. 2, D). Further work is in progress to determine if *Argyreia* and *Ipomoea* suspension cultures produce alkaloids.

Synthetic Approach to Dihydrokavain

By EDWARD E. SMISSMAN, A. NELSON VOLDENG, and JOHN F. MCCARTHY

The preparation of δ-phenylethyl-δ-valerolactone (XII) *via* the alkylation of dihydroresorcinol, followed by a reverse Claisen reaction, and the attempted preparation of dihydrokavain (I), by a modification of this method, are discussed.

FOR CENTURIES the natives of the South Pacific islands have employed the root and rhizome of the kava-kava shrub (*Piper methysticum* Forst.), also known as "ava," "kava," "yangona," and "hoi," to prepare an intoxicating beverage called kava which is consumed at various rituals. The kava beverage, if consumed in sufficient quantity, produces a state of euphoria, followed shortly by muscular relaxation, loss of control of the extremities, and finally a period of dreamless sleep which may last 10 hr. or more. Upon awakening there are apparently no undesirable effects (1–3).

While kava-kava contains a number of components having the pyrone and dihydropyrone

Received April 27, 1966, from the Department of Medicinal Chemistry, School of Pharmacy, University of Kansas, Lawrence. 66045.

Synthetic Approach to Dihydrokavain

By EDWARD E. SMISSMAN, A. NELSON VOLDENG, and JOHN F. MCCARTHY

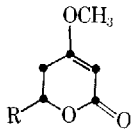
The preparation of δ-phenylethyl-δ-valerolactone (XII) *via* the alkylation of dihydroresorcinol, followed by a reverse Claisen reaction, and the attempted preparation of dihydrokavain (I), by a modification of this method, are discussed.

FOR CENTURIES the natives of the South Pacific islands have employed the root and rhizome of the kava-kava shrub (*Piper methysticum* Forst.), also known as "ava," "kava," "yangona," and "hoi," to prepare an intoxicating beverage called kava which is consumed at various rituals. The kava beverage, if consumed in sufficient quantity, produces a state of euphoria, followed shortly by muscular relaxation, loss of control of the extremities, and finally a period of dreamless sleep which may last 10 hr. or more. Upon awakening there are apparently no undesirable effects (1–3).

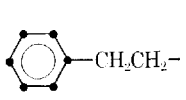
While kava-kava contains a number of components having the pyrone and dihydropyrone

Received April 27, 1966, from the Department of Medicinal Chemistry, School of Pharmacy, University of Kansas, Lawrence. 66045.
Accepted for publication June 14, 1966.
Taken from the dissertation presented by A. Nelson Voldeng to the Graduate School, University of Kansas, in partial fulfillment of Doctor of Philosophy degree requirements.
This investigation was supported by grant NB 02733 from the National Institutes of Health, U. S. Public Health Service, Bethesda, Md.

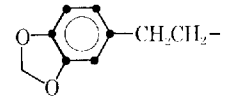
nucleus, only two, dihydrokavain (I) and dihydromethysticin (II), have been shown to produce the characteristic soporific effect (4–6).



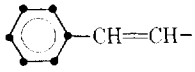
R



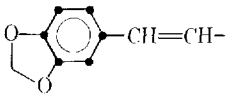
Dihydrokavain (I)



Dihydromethysticin (II)



Kavain (III)



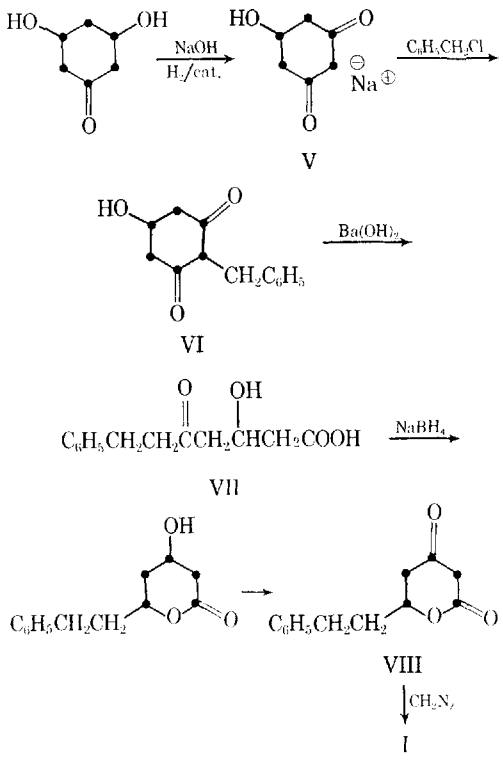
Methysticin (IV)

Dihydrokavain (I) has been synthesized; however, the reaction sequence is lengthy and the yield is low (7). The present source of dihydrokavin (I) and dihydromethysticin (II) is either by isolation from the kava-kava plant or by reduction of kavain (III) and methysticin (IV), respectively.

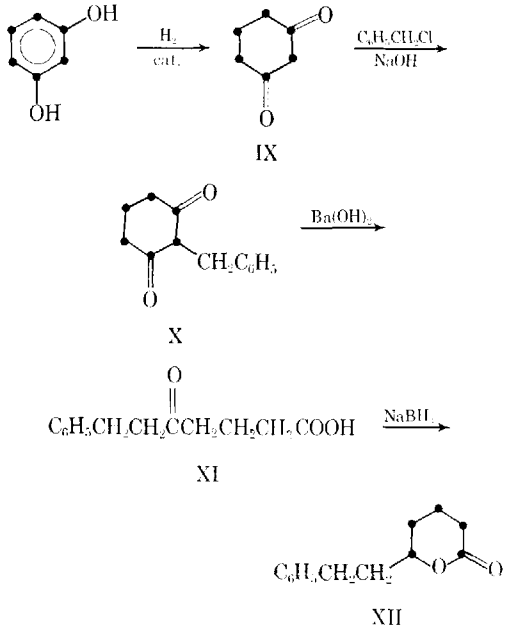
The unique chemistry and pharmacology associated with these dihydropyrones prompted this investigation. It was envisioned that the desired lactones could be prepared by the scheme shown in Scheme I.

Reduction of phloroglucinol followed by alkylation of the monosodium salt (V) would yield the alkylated dione (VI). A reverse Claisen reaction would afford the keto-acid (VII), which in turn could be lactonized and oxidized to the keto-lactone (VIII). Treatment with diazomethane would then afford dihydrokavain (I). Dihydromethysticin (II) and other analogs could be prepared in an analogous manner, using the appropriately substituted benzyl chloride.

Before investigating this approach, it was decided to use resorcinol as a model starting compound (Scheme II). Reduction of resorcinol with Raney nickel catalyst afforded dihydroresorcinol (XI) which was alkylated with benzyl chloride, giving rise to 2-benzylcyclohexane-1,3-dione (X). A reverse Claisen reaction using barium hydroxide as the base, followed by reductive lactonization of the keto-acid (XI) gave rise to the lactone (XII).



Scheme I

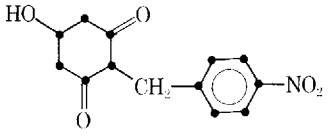


Scheme II

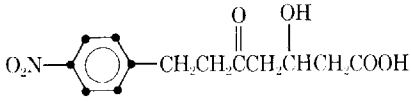
Applying the same sequence of reactions (Scheme I) to phloroglucinol afforded much lower yields of the corresponding compounds. Reduction of phloroglucinol with Raney nickel catalyst yielded monosodiodihydrophloroglucinol

(V) in a 35% yield. When 5% rhodium on alumina was used as the catalyst, the monosodium salt (V) was obtained in 95% yield. Alkylation of the salt (V) with benzyl chloride gave rise to 2-benzyl-5-hydroxycyclohexane-1,3-dione (VI) in 15% yield. Attempts to increase this yield by the use of benzyl iodide, bromide, and tosylate, or by employing various solvents and temperatures were unsuccessful. Formation of the heptanoic acid (VII) from the dione (VI) by means of a reverse Claisen reaction was also unsuccessful. Various temperatures and bases were employed, but the keto-acid was not produced.

The use of a modified procedure of Kornblum (8) in which *p*-nitrobenzyl chloride is used as the alkylating agent, afforded a 30% yield of the nitro dione (XIII). Attempts to open the dione ring (XIII) by means of a reverse Claisen reaction did not afford the keto-acid (XIV).



XIII



XIV

EXPERIMENTAL

Dihydroresorcinol (IX). This material, m.p. 103–104°, was prepared in 90% yield by the procedure of Thompson (9). (Lit. m.p. 103–104°.)

2-Benzylcyclohexane-1,3-dione (X).—This substance, m.p. 184°, was prepared in 70% yield by the procedure of Stetter and Dierichs (10). (Lit. m.p. 184°.)

5-Oxo-7-phenylheptanoic Acid (XI).—This material, m.p. 58°, was prepared in 78% yield by the procedure of Stetter and Dierichs (10). (Lit. m.p. 58°.)

δ-Phenylethyl-δ-valerolacetone (XII).—The procedure for the preparation of this material was patterned after that of Chaikin and Brown (11). Five per cent aqueous sodium hydroxide was added dropwise to 4.3 Gm. (0.019 mole) of 5-oxo-7-phenylheptanoic acid (XI), which was suspended in water, to phenolphthalein end point. This solution was added over a period of 15 min. to 0.23 Gm. of sodium borohydride (0.006 mole) dissolved in 10 ml. of water. The reaction was stirred during the addition and for 1 hr. after the addition was complete. The solution was then acidified to Congo red with 10% hydrochloric acid and stirred for 15 min. at room temperature. The cloudy mixture was then extracted with three 50-ml. portions of ether, the ether dried over anhydrous magnesium sulfate, and evaporated. The resulting oil was distilled under reduced pressure to give 2.8 Gm. (70%) of the lactone, XII, b.p. 140–143° (0.05 mm.); n^{25} 1.5320. The infrared spectrum (liquid film) exhibited strong absorption at 6.75 μ (C=O).

Anal.—Calcd. for $C_{13}H_{16}O_2$: C, 76.44; H, 7.90. Found: C, 76.64; H, 8.38.

Monosodiodihydrophloroglucinol (V).—The procedure for the reduction of phloroglucinol was patterned after a method for the reduction of resorcinol reported by Esch and Schaeffer (12). To a solution of 15 Gm. (0.376 mole) of sodium hydroxide in 100 ml. of water was added 61.0 Gm. (0.376 mole) of phloroglucinol dihydrate and the total volume of the solution was made 200 ml. This solution was placed in a 500-ml. hydrogenation bottle, 4.7 Gm. of 5% rhodium on alumina (Engelhard Industries, Inc.) was added, and the mixture was shaken at room temperature (31°) for 5.5 hr. at an initial pressure of 60 p.s.i. The catalyst was filtered, rinsed with water (2–20 ml.), and the filtrates were combined. After cooling in an ice bath, the filtrate was acidified (pH 6) with 10% hydrochloric acid. The unchanged phloroglucinol was filtered, and water was added to make the total volume of the solution 350 ml. Attempts to obtain the diketone by neutralization of the salt resulted only in polymeric material, so it was necessary to isolate the sodium salt.

Into ten 250-ml. round-bottom flasks was placed 35 ml. of this solution and the water was removed by freeze drying (0.03 mm.) for 18 hr. Fifty milliliters of a solution of 40% ethyl acetate–60% ethyl alcohol was added to each flask, stirred for 30 min., filtered, and the maroon residue was rinsed with a small amount of ethyl acetate–ethyl alcohol mixture. This dark red filtrate was poured with stirring into ethyl acetate (about 1 l.); the sodium salt of dihydrophloroglucinol (V) was filtered rapidly and dried under reduced pressure (0.02 mm.).

Based on the recovered phloroglucinol, the yield of monosodiodihydrophloroglucinol (V) was 98%. This salt is quite hygroscopic and necessitates storage *in vacuo*, $\lambda_{max.}^{EtOH}$ 280 mμ (ε 18,800).

2-Benzyl-5-hydroxycyclohexane-1,3-dione (VI).—The procedure (9) for the preparation of 2-benzylcyclohexane-1,3-dione (X) was modified as follows. In a 100-ml. round-bottom flask fitted with a condenser and magnetic stirrer was placed 7.7 Gm. (0.057 mole) of monosodiodihydrophloroglucinol, 7.0 ml. (0.06 mole) of benzyl chloride, 8.0 ml. of water, and 0.4 Gm. (0.24 mmole) of potassium iodide. The mixture was stirred for 2 hr. in an oil bath (95°), cooled to room temperature, and 5% sodium hydroxide was added until the mixture was distinctly alkaline (pH 9–10). The gummy mixture was extracted with two 50-ml. portions of ether and the ether solutions were discarded. The dark alkaline solution was cooled to 5° in an ice bath and made acidic (pH 2) with 10% hydrochloric acid. A viscous brown oil separated after the flask stood in the refrigerator for several hours. The aqueous solution was decanted and 25 ml. of chloroform was added to the oil. After standing at room temperature for 12 hr., yellow crystals separated. The crystals were dissolved in a small amount of ethyl acetate, heated to boiling, petroleum ether was added to the cloud point, the mixture was allowed to cool to room temperature, and then placed in a

refrigerator for 2–3 hr. The yellow crystals were recrystallized from ethyl acetate–petroleum ether in the same manner, affording 2.0 Gm. (18%) of the alkylated dione (VI), m.p. 161°; $\lambda_{max.}^{EtOH}$ 263 mμ (ε 12,800), $\lambda_{max.}^{EtOH}$ 289 mμ (ε 23,200). The infrared spectrum (Nujol mull) of this material exhibited a broad band at 3.2 μ (bonded OH) and a sharp band at 14.2 μ (mono-substituted benzene).

Anal.—Calcd. for $C_{13}H_{14}O_3$: C, 71.54; H, 6.47. Found: C, 71.79; H, 6.91.

Attempted Preparation of 3-Hydroxy-5-oxo-7-phenylheptanoic Acid (VII).—The procedure (9) for the preparation of 5-oxo-7-phenylheptanoic acid (XI) was followed using 0.486 Gm. (2.23 mmoles) of 2-benzyl-5-hydroxycyclohexane-1,3-dione (VI), 3.2 Gm. (10.7 mmoles) of barium hydroxide octahydrate, and 10 ml. of freshly distilled water. After stirring for 25 hr. at 105–110° the mixture was cooled in an ice bath and 10% hydrochloric acid was added dropwise to a Congo red end point. The cloudy aqueous solution was extracted with three 25-ml. portions of ether, the combined ether solutions dried over anhydrous magnesium sulfate, and the ether was evaporated. A dark viscous oil (350 mg.) was obtained which had a sweet odor but which would not form a 2,4-DNP derivative.

This oil did not solidify and crystallization could not be induced. It was insoluble in 20% sodium bicarbonate, but was soluble in 5% sodium hydroxide. The infrared spectrum (liquid film) exhibited absorption at 3.0 (OH), 5.9 (C=O), and 14.3 μ (monosubstituted benzene). It was not possible to purify this material.

2-(p-Nitrobenzyl)-5-hydroxycyclohexane-1,3-dione (XIII).—A solution of 4.5 Gm. (0.026 mole) of *p*-nitrobenzyl chloride dissolved in 20 ml. of DMF was added to a stirred solution of 3.5 Gm. (0.026 mole) of monosodiodihydrophloroglucinol in 30 ml. of DMF. After stirring 24 hr. at room temperature (25°) the sodium chloride was filtered and the DMF was removed under reduced pressure. Chloroform was added to the residue, heated to boiling, and decanted from the dark insoluble material. This was repeated twice, and the chloroform extracts were combined. The yellow organic solution was heated to boiling, petroleum ether was added to the cloud point, and the mixture was allowed to cool to room temperature; it was then placed in a refrigerator. The crystals were filtered and the filtrate was treated in the same manner twice again. The three crops of crystals were combined and recrystallized twice from ethyl acetate, affording 2 Gm. (30%) of the dione (XIII), m.p. 184–185°; $\lambda_{max.}^{EtOH}$ 265 mμ (ε 37,400), $\lambda_{max.}^{alk.\ EtOH}$ 287 mμ (ε 64,800). The crystalline material gave a negative Beilstein (halogen) test and exhibited strong bands in the infrared spectrum (Nujol mull) at 6.45 and 7.4 μ (aromatic nitro).

Anal.—Calcd. for $C_{13}H_{13}NO_5$: C, 59.32; H, 4.98; N, 5.32. Found: C, 59.80; H, 5.06; N, 5.28.

Attempts to prepare the keto-acid (XIV) from the dione (XIII) by means of a reverse Claisen reaction using barium hydroxide as the base were unsuccessful.[1]

Anti-Inflammatory and CNS Depressant Properties of 1-(4-Chlorophenyl)-4-{2-[3-(2-pyridyl)acrylyloxy]-ethyl}-piperazine (DA 1529)

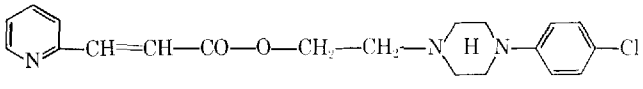
By ERNESTA MARAZZI-UBERTI, CARLA TURBA, and CAMILLO BIANCHI

1-(4-Chlorophenyl)-4-{2-[3-(2-pyridyl)acrylyloxy]ethyl}-piperazine (DA 1529) has been found the most active among 29 alkylpiperazine esters studied. Following oral administration, DA 1529 prevents the edema formation provoked in rats by subplantar injection of carrageenin, formalin, and dextran; it has antinociceptive effect on inflamed (not on normal) foot of rats; it has antipyretic effect in yeast-treated pyrexial rats. DA 1529 is as active or only a little less active than phenylbutazone as anti-inflammatory; it is more active than phenylbutazone as analgesic and antipyretic. The acute toxicity in mice of DA 1529 is similar to that of phenylbutazone. DA 1529 has been found to possess mild CNS depressant properties as evidenced in mice by the results of the barbiturate potentiation test, of the rotarod test, by the reduced spontaneous motility, by analgesia in the hot-plate test, by the hypothermic effect.

AMONG 29 alkylpiperazine esters synthesized (1) and tested for anti-inflammatory, analgesic, and antipyretic activity, the 1-(4-chlorophenyl) - 4 - {2 - [3 - (2 - pyridyl)acrylyloxy]-ethyl}-piperazine (DA 1529) proved to be the more interesting one. Since the completion of the above-mentioned researches, the pharmacological properties of the compound have been explored more fully, and this report is a complete account of the results obtained.

The prevention in rats of the carrageenin-induced edema has been regarded as a reliable method for testing the anti-inflammatory properties of nonsteroid anti-inflammatory drugs (2). Since it has been proved that many compounds unrelated to the anti-inflammatory drugs are very active on this test (3), it was thought advisable to expand the investigation on our drug and look for many other activities in order to draw a clear and correct picture of its pharmacological profile. From this research DA 1529 turned out to be an anti-inflammatory drug with some mild CNS depressant properties.

The compound is a colorless, crystalline material, soluble in water as hydrochloride, and has a molecular weight of 371.86 and the following formula:



METHODS

Male albino mice of 18–22 Gm. and male Sprague-Dawley albino rats of 140–180 Gm. were used in these experiments.

In all the tests, DA 1529 was administered as hydrochloride in aqueous solution at the constant volume of 10 ml./Kg. in rats and 20 ml./Kg. in mice. The control animals received corresponding volumes of saline. The median effective doses (LD_{50} or ED_{50}) were calculated according to Litchfield and Wilcoxon (4) for the quantal responses, and according to Burn (5) for the graded responses. The significance of the differences was estimated using the Student t test as test of significance.

Acute Toxicity.—The acute toxicity tests were performed on mice and rats. The animals in groups of 10 to 20 for each dose tested were treated intraperitoneally or orally and observed for 96 hr. The effects appearing within 3 hr. after treatment were studied according to the scheme suggested by Irwin (6). The doses used ranged from 25 to 200 mg./Kg. for the intraperitoneal route and from 50 to 300 mg./Kg. for the oral route.

Anti-Inflammatory Activity.—The anti-inflammatory activity was estimated in rats following subplantar injection in the left hind paw of formalin (0.1 ml./rat of a 0.75% v/v solution), dextran (0.05 ml./rat of a 6% w/v solution), and carrageenin (0.1 ml. of a 1% w/v suspension in sterile normal saline) (7).

The degree of the edema was expressed as percentage increase of the thickness of the paw after the injection of the edema-provoking agent (measured with a dial thickness gauge) over the thickness of the same paw before injection of the edema-provoking agent. The anti-inflammatory effect was estimated at different time intervals, as specified in the tables, following oral administration of 50 100, and 200 mg./Kg. Phenylbutazone, 200 mg./Kg. orally, was used as reference compound.

Antipyretic Activity.—The antipyretic activity was studied according to the method of Smith and Hambourger (8) in groups of 5 rats for each dose. The animals were housed in a thermostatically controlled room at 23°. The rectal temperatures were measured using a thermocouple applicator before ad-

Received March 14, 1966, from the Research Laboratories, Istituto De Angeli S.p.A., Milan, Italy.
Accepted for publication July 11, 1966.
The authors acknowledge the technical assistance of Mrs. A. Collasco, Mrs. M. Pizzamiglio, and Miss L. Tomasi.

ministration of DA 1529 and at hourly intervals for 5 hr., following intraperitoneal administration of 25, 50, and 100 mg./Kg., and oral administration of 50, 100, and 200 mg./Kg. Phenylbutazone, 100 mg./Kg. intraperitoneally and orally, was used as reference compound.

Analgesic Activity on Inflamed Tissue.—The analgesic activity was tested in rats, according to the technique of Randall and Selitto (9). DA 1529 was administered 90 min. after subplantar injection of brewer's yeast (0.1 ml./rat of a 20% suspension in normal saline); 10 to 15 animals were used for each dose. In evaluating the results, the regression line and the corresponding ED_{50} were calculated correlating the logarithm of the dose with the percentage increase of the pain threshold, 90 min. after treatment, of the inflamed paw and of normal paw in treated animals over the corresponding thresholds in control animals. DA 1529 was administered intraperitoneally at the dose of 25, 50, and 100 mg./Kg. and orally at the dose of 50, 100, and 200 mg./Kg. Phenylbutazone administered intraperitoneally, 100 mg./Kg., and orally, 200 mg./Kg., was used as reference compound.

Analgesic Activity—Hot Plate Method.—The analgesic activity was studied in mice, according to the method previously described in detail in another paper (10). DA 1529 was administered intraperitoneally at the dose of 50, 100, and 200 mg./Kg. and orally at the dose of 50, 100, 150, and 200 mg./Kg. to groups of 29 to 40 mice for each dose. Phenylbutazone administered intraperitoneally, 50 mg./Kg., and orally, 200 mg./Kg., was used as reference compound.

Hypothermic Activity.—The activity on the body temperature was evaluated in mice housed in a thermostatically controlled room at 23°. The rectal temperatures were recorded by means of a thermocouple applicator before treatment and 1, 2, 4, and 6 hr. after intraperitoneal administration of 25, 50, and 100 mg./Kg. and oral administration of 12.5, 25, 50, and 100 mg./Kg. of DA 1529. Twenty animals were used for each dose.

Activity on Spontaneous Motility.—The spontaneous motility was studied in mice, using Dews technique (11). DA 1529 was administered intraperitoneally at the dose of 12.5, 25, 50, and 100 mg./Kg. and orally at the dose of 50, 100, and 200 mg./Kg. 15 min. before the test. Six groups of five animals each were used for each dose and route of administration. Corresponding groups of normal mice were used as controls. The results were evaluated by determining the percentage variations of the motility of the treated groups compared with the controls and calculating the corresponding ED_{50} from the activity-log dose line.

Activity of *Hexobarbital* and *Pentobarbital* Sleeping Time.—Hexobarbital and pentobarbital were injected intraperitoneally in mice, at the respective doses of 100 mg./Kg. and 60 mg./Kg., 15 min. after intraperitoneal or oral administration of DA 1529. When hexobarbital was used DA 1529 was adminstered intraperitoneally at 12.5, 25, and 50 mg./Kg. and orally at 12.5, 50, and 100 mg./Kg. When pentobarbital was used DA 1529 was administered intraperitoneally at 25, 50, and 100 mg./Kg. and orally at 12.5, 25, 50, and 100 mg./Kg. The sleeping time was defined as the interval between the loss and the spontaneous return of the righting reflex. Ten to 20 animals were used for each dose and a group of control animals was always prepared in parallel. In evaluating the results the regression line and the corresponding ED_{50} were calculated correlating the logarithm of the dose with the percentage increase of the sleeping time of the treated group over that of the control group.

Anticonvulsant Activity.—The anticonvulsant activity was tested by means of: (*a*) protection from the tonic phase of convulsions due to maximal electroshock (10 ma., alternating current, 0.2 sec.); (*b*) protection from tonic-clonic type convulsions and from death due to lethal doses of pentamethylenetetrazole (125 mg./Kg. i.p.); (*c*) protection from the convulsive and lethal effects of lethal doses of strychnine (3 mg./Kg. i.p.).

The experiments were carried out on unfasted mice. DA 1529 was administered by the intraperitoneal route, 15 min. before the convulsant, to groups of 10 animals each at the dose of 100 mg./Kg.

Activity on the Movement Coordination.—The muscular activity and coordination were studied in mice, using the following methods: (*a*) Boissier's rotarod test (12). The number of mice which lost the capacity to cling to a rotating rod (2.5 cm. diameter, rough surface, 12 r.p.m.) was determined. Before the experiment the mice were selected so as to reject animals falling within 5 min. (*b*) Traction test described by Boissier (12). The mice were suspended by their forepaws from a horizontally stretched wire. The number of animals which lost the capacity of clinging to the wire with at least one hind paw within 5 sec. was determined. (*c*) Inclined screen test according to Randall *et al.* (13). The number of animals incapable of clinging to a fine mesh wire net inclined at approximately 30° to the horizontal was recorded. (*d*) Paralyzing action test according to Berger (14). The loss of the righting reflex for at least 1 min. was taken as test of paralysis.

The tests were performed 2, 5, and 15 min. after intraperitoneal administration and 5, 15, and 30 min. after oral administration of DA 1529. For the rotarod test the doses used were 25, 50, and 100 mg./Kg. intraperitoneally and orally. For the traction test the doses used were 50, 100, and 200 mg./Kg. intraperitoneally and orally. For the inclined screen and righting reflex tests the doses used were 50, 100, and 200 intraperitoneally and 100, 200, and 300 orally.

Action on the Pinna and Corneal Reflexes.—The changes in the pinna and corneal reflexes were determined in mice, according to the method of Witkin *et al.* (15). The tests were performed 2, 5, and 15 min. after intraperitoneal administration and 5, 15, and 30 min. after oral administration of DA 1529. The doses used were 25, 50, and 100 mg./Kg. intraperitoneally and 200, 300, and 350 mg./Kg. orally, 10–15 animals/dose being used.

Activity on the Cardiovascular System and Respiration.—The effect of DA 1529 on the arterial pressure and respiration was studied in male rabbits weighing 2.3–2.5 Kg. in ethyl-urethan narcosis (750 mg./Kg. i.p.). The blood pressure was recorded at the carotid artery using a mercury manometer, and the respiration by means of a Marey tambour connected to a pneumograph fixed to the chest. DA 1529 was administered to the animal

Phenylbutazone	200	20	82.0 ± 4.05	16[b]

[a] Expressed as percentage increase of the thickness of the inflamed paw compared with the thickness before injection of dextran ± S.E. [b] Change significant at 0.02 level.

through the marginal ear vein at various doses, maintaining constant the volume and rate of administration (1 ml. in 30 sec.). The coronary vasodilator activity of the compound was determined on isolated rabbit heart prepared according to Langendorff and perfused at constant pressure according to the technique described by Setnikar (16); the amplitude and rate of the heart beats were recorded simultaneously.

Activity on Smooth Muscle.—The action on smooth muscle was studied on segments of guinea-pig ileum suspended in oxygenated Tyrode's solution, in a thermostatically controlled bath kept at 34°. The intestine was stimulated with standard doses of acetylcholine (10^{-7} Gm./ml. of chloride), histamine (10^{-6} Gm./ml. of hydrochloride), nicotine (2×10^{-6} Gm./ml. of bitartrate), and 5 HT (10^{-6} Gm./ml. of creatinine sulfate monohydrate).

RESULTS

Acute Toxicity.—The results of the toxicity tests on DA 1529 are given in Table I. The compound showed slight toxicity when administered by intra-

peritoneal and oral route in either mice or rats. The oral LD_{50}/i.p. LD_{50} ratio was found to be 1.64 for mice and 1.54 for rats. These values are almost identical for the two species and indicate good absorption of the substance under test through the digestive tract. The direct observation in mice performed according to the indications of Irwin (4) revealed that DA 1529 at nonlethal doses (100–200 mg./Kg. i.p. and 100, 200, 300 mg./Kg. orally) caused reduction of the spontaneous motility, curiosity, and pain sensitivity as well as muscular hypotonia, a very slight motor deficit, and reduction of the ipsilateral flexor reflex.

Reduced pain sensitivity was still evident at 50 mg./Kg., for both routes of administration.

Anti-Inflammatory Activity.—Tables II, III, and IV report the data relative to DA 1529's oral inhibiting effect of carrageenin, formalin, and dextran-induced edemas. The results of the experiments performed, reported in Table II, indicate the inhibiting effect of DA 1529 on carrageenin-induced edema; this effect is slightly less intense than that exerted by phenylbutazone. As shown by Table III, DA 1529 demonstrated to be capable of significantly reducing formalin-induced edema, exerting an anti-inflammatory action quantitatively superior to that of phenylbutazone. As for dextran-induced edema, DA 1529 exerted a slight anti-inflammatory action only at the 200 mg./Kg. dose; at this dose the action of DA 1529 was slightly less than that of phenylbutazone.

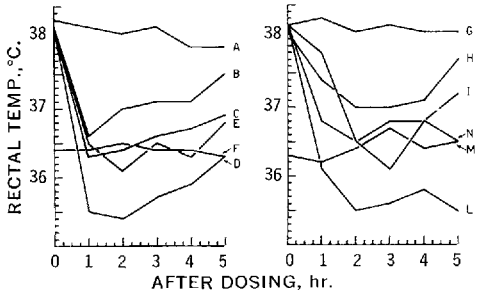

Fig. 1.—Antipyretic activity in rats. Key: A, fevered controls; B, DA 1529, 25 mg./Kg.; C, DA 1529, 50 mg./Kg.; D, DA 1529, 100 mg./Kg.; E, phenylbutazone, 100 mg./Kg.; F, nonfevered controls; G, fevered controls; H, DA 1529, 50 mg./Kg.; I, DA 1529, 100 mg./Kg.; L, DA 1529, 200 mg./Kg.; M, nonfevered controls; N, phenylbutazone, 100 mg./Kg.

Antipyretic Activity.—Figure 1 gives the variations of the rectal temperature. As the graphs show, DA 1529, administered by either the intraperitoneal or oral route, exerted a distinct inhibiting action on experimentally induced pyrexia in rats, the effect still evident, although to a slighter extent, 5 hr. after treatment. The antipyretic effect observed was found to be proportional to the dose administered.

Analgesic Activity on Inflamed Tissue.—Table V summarizes the results of the experiments performed with the gradual pressure method according to Randall and Selitto (19) on the inflamed and controlateral normal paw. The data reported show that DA 1529 exerted a marked effect on the inflamed paw but did not increase the pain threshold in the normal paw.

Under the same experimental conditions phenylbutazone is active only on the inflamed paw. The median effective doses calculated by plotting the percentage increase of the pain threshold in the inflamed paw in function of the logarithm of the dose were found to be 9.5 mg./Kg. for intraperitoneal administration and 40.1 mg./Kg. for oral administration.

Analgesic Activity–Hot-Plate Method.—Table VI summarizes the data relative to the hot-plate analgesic action, and gives the percentage increase of the reaction time (RT) to the heat nociceptive stimulus 1 and 2 hr. after treatment (i.p. and oral) with DA 1529, the total number of mice insensitive to pain during the 2 hr. of the experiment, and the ED_{50} for the two routes of administration. In this test, DA 1529 significantly increased the reaction time to the heat stimulus and provoked an analgesia proportional to the dose administered. The effective dose, producing analgesia in 50% of the animals, was found to be 105 mg./Kg. i.p. and 109 mg./Kg. orally.

Hypothermic Activity.—The results reported in Table VII indicate that after intraperitoneal or oral administration of 100 mg./Kg. of DA 1529, the rectal temperature of mice fell approximately 2°,

	15	os	30	3	298.0[c]
Corneal reflex	5–15	i.p.	60	4	>200[c]
	5–15–30	os	30	3	>300[c]

[a] Dose provoking a 50% reduction in the spontaneous motility compared with controls. [b] Dose provoking a 50% increase in the sleeping time compared with controls. [c] Dose inducing the effect considered in 50% of the animals.

compared with the controls. The compound exerted only a slight hypothermic effect at 50 mg./Kg. by the oral route. No significant change in the temperature was observed for the other doses tested (25–50 mg./Kg. i.p. and 12.5–25 mg./Kg. orally).

Activity on Spontaneous Motility.—As may be seen from Table VIII, DA 1529 administered intraperitoneally or orally, induced a significant reduction of the spontaneous motility.

Action on Hexobarbital and Pentobarbital Sleeping Time.—On both intraperitoneal and oral administration, DA 1529 markedly potentiated the hypnotic effect of hexobarbital and pentobarbital (Table VIII).

Anticonvulsant Activity.—DA 1529 injected intraperitoneally at the dose of 100 mg./Kg. was found to be inactive on convulsions induced by electroshock, pentamethylenetetrazole, or strychnine.

Action on Movement Coordination and Pinna and Corneal Reflexes.—Table VIII gives the results of the test on muscular activity and coordination and on the pinna and corneal reflexes. Table VIII reveals that the compound administered

intraperitoneally or orally exerted a marked effect on the rotarod and traction tests, at doses far from the toxic levels and from those causing behavioral changes. The effect was well marked 5 min. after intraperitoneal administration and 15 min. after oral administration. Fifteen and 30 min. after dosing the mice were normal. DA 1529 had no action on the inclined screen test and righting reflex. As for the alterations of the superficial reflexes, the pinna reflex was markedly influenced when the product was administered intraperitoneally, and only slightly so on oral administration.

By contrast the corneal reflex was not altered at any of the doses tested.

Activity on the Cardiovascular System and Respiration.—DA 1529, administered intravenously to rabbits at doses of 2, 4, and 8 mg./Kg., lowered blood pressure and increased respiration. These phenomena were only temporary and were all the greater the higher the dose. On isolated rabbit heart, DA 1529 perfused at the concentration of 10 mcg./ml., caused a slight increase in the coronary flow, and a slight reduction in the amplitude of the pulse rate and heart beat.

Action on Smooth Muscle.—On guinea pig ileum *in vitro*, DA 1529 exerted a very slight action against acetylcholine, 5-HT, and nicotine, while the antihistamine activity was still apparent, although slight (17% inhibition of histamine-induced contraction), at the concentration of 10^{-8} Gm./ml.

DISCUSSION

DA 1529 prevents the formation of edemas provoked in rats by subplantar injection of formalin, carrageenin, and dextran. More than as an anti-inflammatory, DA 1529 is active as an analgesic and antipyretic. The antinociceptive effect is very marked on the inflamed foot, insignificant on the normal foot. The antipyretic effect is well marked. Relative to phenylbutazone, DA 1529 is more active as an analgesic and antipyretic, as active or only a little less active as an anti-inflammatory. The acute toxicity of DA 1529 is similar to that of phenylbutazone. The data in Table I relative to DA 1529 have to be compared with data relative to phenylbutazone obtained in this laboratory in comparable experimental conditions (LD_{50} in mg./Kg.): 327 and 680 in mice; 215 and 637 in rats. The first value is relative to the intraperitoneal administration, the second one to the oral administration.

The therapeutic indexes (LD_{50}/ED_{50}) are as favorable for DA 1529 as for phenylbutazone. When the analgesic effect is considered the therapeutic index in rats (Randall-Selitto method) is 33 and 11 after intraperitoneal and, respectively, oral administration; in mice (hot-plate method) it is 3.0 intraperitoneally and 4.8 orally.

The anti-inflammatory, analgesic, and antipyretic effects of DA 1529 are apparent at doses provoking in rats only a mild sedation and not overt neural deficit or derangement of the autonomic nervous system or of the neuromuscular system.

DA 1529 has, however, some CNS depressant properties as the results obtained in mice seem to prove. It is active in the barbiturate potentiation test; in the rotarod test, it reduces the spontaneous motility and the sensitivity to painful stimulation. In addition, it has hypothermic properties. As it is well proved (17) that hypothermia, potentiation of the barbiturate depression, and depression of spontaneous motility are strictly correlated, it may be that the depressant effects observed in these experiments performed at 22–23° have been caused or exaggerated by the hypothermic effect. It may be the same as far as the analgesic effect observed in the hot-plate method is concerned since the thermal sensitivity of the feet of the mice is involved. Drugs modifying rectal or superficial temperature are known to have an effect on the response of mice in the hot-plate method (18–23). The analgesic effect, the superficial temperature of the paw, and the rectal temperature may, therefore, be causally related.

In the authors' opinion, however, the mild hypothermic effect is not fully responsible for the effects observed in their experiments since calming effects were still evident following administration of doses not causing hypothermia. Furthermore, the hypothermic effect of the compound was minimal compared with that caused by reserpine or chlorpromazine since, following oral administration of 50 or 100 mg./Kg., the rectal temperature, while lower than normal, was still in the range of normal values of healthy animals.

From what has been said, it is legitimate to think of DA 1529 as a mild CNS depressant agent. This mild depressant effect does not, however, detract from the potential value of the compound as an anti-inflammatory–analgesic–antipyretic agent since the depressant effect is of very short duration, while the duration of the main effect is considerably longer.

Single-Tablet Determination of Reserpine at the Microgram Level

Estimation of Reserpine in the Presence of Protoveratrine A and Other Active Drug Components

By WILLIAM J. WEAVER

Mixtures of reserpine and other drugs can be resolved by thin-layer chromatography on silica gel, following extraction from single tablets with chloroform. Quantitation is accomplished by visual inspection, and is accurate to within 10 per cent.

THE PURPOSE of this investigation was to provide a rapid, sensitive, reliable analytical procedure to measure tablet-to-tablet variation of the active ingredients in tablets containing reserpine, protoveratrine A, and hydroflumethiazide.[1] Each tablet contains:

Reserpine	0.125 mg.
Protoveratrine A	0.200
Hydroflumethiazide[2]	50.000

The small amounts of reserpine and protoveratrine A present in single-dosage forms of drugs of this type cannot be determined by conventional analytical procedures because of interferences by other active ingredients which are present in milligram quantities.

Hydroflumethiazide can be determined spectrophotometrically by measuring the ultraviolet absorbance of a filtered methanolic extract of a single pulverized tablet. Reserpine, protoveratrine A, and tablet excipients do not interfere.

The official U.S.P. method (1) for the determination of reserpine involves solvent extraction of the reserpine and subsequent colorimetric determination. The U.S.P. extraction procedure is designed to eliminate degradation products of reserpine. In the procedure described here these purification steps are not required because the degradation compounds do not interfere in the separation and detection.

Protoveratrine A is currently determined in these laboratories by the colorimetric procedure of Craig and Jacobs (2). This procedure requires a reaction time of 16 hr. for samples, standards, and appropriate synthetic tablet blanks. In addition to eliminating these time-consuming operations, the procedure described in this report permits the simultaneous separation and detection of reserpine and protoveratrine A.

Wimer *et al.* (3) have recently reviewed procedures for the separate determination of reserpine and protoveratrine A. Although some of the methods described are extremely sensitive, they are not applicable to formulations which contain certain interfering ingredients. Levine and Fischbach (4, 5) have employed partition and paper chromatography for the separation of the veratrum alkaloids. More recently Montgomery (6) has separated protoveratrines A and B by thin-layer chromatography on cellulose.

This paper describes a thin-layer chromatographic method for the separation of reserpine and/or protoveratrine A from excipients and from other active ingredients present in several commercial tablet dosage forms. Development of the thin-layer plate with the solvent is rapid, requiring only 30 min. The detection reagent, *p*-dimethylaminobenzaldehyde in concentrated sulfuric acid, produces characteristic color reactions with reserpine and protoveratrine A. Graham (7) has investigated the color reactions between the veratrum alkaloids with this and other reagents.

EXPERIMENTAL

Equipment.—Silica Gel G scored-glass Uniplates (20 × 20 cm.) supplied by Analtech, Inc., Wilmington, Del. Reactivate the plate for 30 min. in an oven at 100° immediately before use. Glass developing-

4	0.125	0.124	0.112 to 0.137	0.200	0.194	0.180 to 0.220

[a] Acceptable concentration limits have been established as ±10% of label claim.

tanks (25.5 cm. in diameter, 25.5 cm. deep) lined with solvent-saturated filter paper. Hamilton, No. 701-N, 10-μl. syringe. Fisher 125-ml. chromatographic indicator spray flask.

Solvent.—Prepare 30 vol. % acetone, ACS, in chloroform, ACS, to serve as the developing solvent.

Spray Reagent.—Dissolve 500 mg. of *p*-dimethylaminobenzaldehyde, Eastman, in 50 ml. of concentrated sulfuric acid.

Stock Protoveratrine A Standard.—Weigh 90 mg. (±0.1 mg.) of standard protoveratrine A into a 10-ml. volumetric flask. Dissolve and dilute to volume with chloroform. This solution is stable for 1 week.

Stock Reserpine and Protoveratrine A Standard.—Weigh 11.25 mg. (±0.1 mg.) of reserpine U.S.P. into a 10-ml. low-actinic volumetric flask. Pipet 2.0 ml. of the stock protoveratrine A standard solution into the flask containing the dry reserpine. Dilute to volume with chloroform. Prepare fresh daily.

Working Reserpine and Protoveratrine A Standard. Dilute 2.0 ml. of the stock reserpine and protoveratrine A standard to 10.0 ml. with chloroform in a low-actinic volumetric flask. Prepare just prior to use. This solution contains 1.125 mcg. reserpine and 1.8 mcg. of protoveratrine A/5 μl., and 1.35 mcg. of reserpine, and 2.16 mg. of protoveratrine A/6 μl. These amounts represent reserpine and protoveratrine A corresponding to 90% and 110%, respectively, of the theoretical reserpine and protoveratrine A content in 5 μl. of the final sample concentrate.

Preparation of Sample and Application to TLC Plate.—Pulverize one Salutensin tablet, and transfer quantitatively to a 50-ml. glass-stoppered, low-actinic conical flask. Add 30 ml. of chloroform, and shake 15 min. in a mechanical shaker. Filter the chloroform extract through Whatman No. 30 filter paper into a 50-ml. serum vial protected from direct light with aluminum foil. Wash the flask and filter paper with two consecutive 2-ml. portions of chloroform. Evaporate the chloroform extract to dryness under a stream of nitrogen, then dissolve the residue in the vial with 0.50 ml. of chloroform. Stopper the vial, and swirl to ensure complete solution of the active ingredients.

Employing a 10-μl. syringe, spot consecutively on a thin-layer plate about 10 mm. apart and 20 mm. from the bottom edge of the plate: 5.0 μl. of the working standard, 5.0 μl. of the sample concentrate, and 6.0 μl. of the working standard. Maintain the diameter of the spot at 3 to 5 mm. Allow the spots to air-dry. Develop the plate with the solvent to a distance of 10 cm. from the origin.

Detection of Spots.—Remove the plates after solvent development, and allow to air-dry. Holding the sprayer 30 cm. from the plate, spray the plates lightly with the spray reagent until green spots become visible. Place the plates in an oven at 100° for 5 to 8 min. Remove the plates from the oven, and observe the positions of the spots. Protoveratrine A is indicated by an elongated, purple spot, R_f = 0.1 to 0.2. Reserpine appears as a greenish-black spot, R_f = 0.3 to 0.35.

Quantitation.—Estimate the concentrations of reserpine and protoveratrine A in the sample by comparing the sizes and intensities of the reserpine and protoveratrine A sample zones with those

obtained from the standards. Distinct differences can be noted between the standards at the 90% and 110% concentrations.

RESULTS

The method has been applied to six commercial dosage forms containing reserpine and other active ingredients. The results are shown in Table I. (The active ingredients, rauwolfia serpentina and protoveratrines A and B,[3] were also separated on a thin-layer plate. Reserpine and the protoveratrines were not quantitated against standard reserpine and protoveratrine mixtures.) The commercial tablets were obtained on the open market in bottles of 50 or 100, and single tablets of each were used for assay. None of the active ingredients or excipients present in the tablets interfered in the determination of reserpine.

Table II shows a comparison of results obtained from the determination of reserpine and protoveratrine A in tablets containing reserpine, protoveratrine A, and hydroflumethiazide[1] by the proposed single tablet method *versus* the U.S.P. method (1) for reserpine and the protoveratrine A procedure of Craig and Jacobs (2), using multiple-tablet extracts.

DISCUSSION

Sensitivity.—From 2 to 6 μl. of the working standard solution was spotted on a plate. The plate was developed and sprayed with the reagent. The lower limits of reserpine and protoveratrine A that can be detected are 0.9 and 1.44 mcg., respectively.

Interferences.—Reserpine was hydrolyzed in an alkaline medium according to the method of Neuss (8). The products, reserpic acid and trimethoxybenzoic acid, were dissolved in chloroform at a concentration equivalent to that of the working standard solution and chromatographed in the usual fashion. Reserpic acid and trimethoxybenzoic acid do not react with the reagent. When the plate is exposed to ultraviolet light, faint fluorescent spots are observed at the origin.

When the standard stock solution of reserpine and protoveratrine A is exposed to bright light for approximately 4 hr., diluted, and chromatographed, fluorescent spots are observed at the origin and at an R_f of 0.5 to 0.58. These spots are not found on a developed plate when freshly prepared, light-protected standard solutions are chromatographed. Excipients and active components found in the seven formulations reported above do not interfere.

Determination of Hydrocortisone and Hydrocortisone Acetate in Antibiotic Mastitis Preparation

By ALFRED BRACEY, LEON GARRETT, and PETER J. WEISS

A modified column partition chromatographic method has been developed for the determination of hydrocortisone and hydrocortisone acetate in antibiotic mastitis preparations. A sodium bicarbonate trap under a methyl alcohol–water stationary phase in Celite is used with two mobile phases. First, the interfering oil is eluted with methylene chloride–isooctane, then the steroid to be assayed by the blue tetrazolium method is eluted with methylene chloride. This procedure shows a marked improvement over the U.S.P. XVII hydrocortisone ointment method in the removal of interferences and results in satisfactory assays for the two steroids in mastitis formulations. Recoveries of the steroids added to blank mastitis preparations ranged from 90.3 to 100.9 per cent. The average percentage of recovery for hydrocortisone and hydrocortisone acetate was 96.9 and 98.2, respectively.

CORTICOSTEROIDS have been incorporated in a large number of drug preparations, primarily for their anti-inflammatory activity. Two of the most common, hydrocortisone and hydrocortisone acetate, are often used in ointments and oils for the treatment of mastitis in dairy animals. These mastitis preparations frequently contain procaine penicillin G and a vegetable oil, *e.g.*, peanut oil, and may contain, in addition, one or more of the following: dihydrostreptomycin sulfate, neomycin sulfate, polymyxin B sulfate, sulfamerazine, sulfamethazine, sulfathiazole, sulfanilamide, methylpara-

Determination of Hydrocortisone and Hydrocortisone Acetate in Antibiotic Mastitis Preparation

By ALFRED BRACEY, LEON GARRETT, and PETER J. WEISS

A modified column partition chromatographic method has been developed for the determination of hydrocortisone and hydrocortisone acetate in antibiotic mastitis preparations. A sodium bicarbonate trap under a methyl alcohol–water stationary phase in Celite is used with two mobile phases. First, the interfering oil is eluted with methylene chloride–isooctane, then the steroid to be assayed by the blue tetrazolium method is eluted with methylene chloride. This procedure shows a marked improvement over the U.S.P. XVII hydrocortisone ointment method in the removal of interferences and results in satisfactory assays for the two steroids in mastitis formulations. Recoveries of the steroids added to blank mastitis preparations ranged from 90.3 to 100.9 per cent. The average percentage of recovery for hydrocortisone and hydrocortisone acetate was 96.9 and 98.2, respectively.

CORTICOSTEROIDS have been incorporated in a large number of drug preparations, primarily for their anti-inflammatory activity. Two of the most common, hydrocortisone and hydrocortisone acetate, are often used in ointments and oils for the treatment of mastitis in dairy animals. These mastitis preparations frequently contain procaine penicillin G and a vegetable oil, *e.g.*, peanut oil, and may contain, in addition, one or more of the following: dihydrostreptomycin sulfate, neomycin sulfate, polymyxin B sulfate, sulfamerazine, sulfamethazine, sulfathiazole, sulfanilamide, methylpara-

ben, propylparaben, papain, chlorobutanol, cobalt sulfate, and polyvinylpyrrolidone. Aluminum monostearate or colloidal silica is frequently used as a gelling agent.

Of the several chemical methods widely used for the assay of steroids (1–4), the blue tetrazolium method, official in U.S.P. XVII and N.F. XII, with minor modifications was chosen for this study.

The U.S.P. XVII method for hydrocortisone ointment proved unsatisfactory for mastitis preparations. Assays for hydrocortisone revealed positive interferences (ranging from less than 1 to 39% and varying with the manufacturer) when blanks were used which contained, in all cases, procaine penicillin in an oil base together with some of the above-mentioned adjuncts. The main interfering substances are procaine penicillin G and the oil.

A Celite chromatographic column with methyl alcohol–water as the stationary phase and methylene chloride–isooctane as the mobile phase is useful for removing fatty alcohols while retaining the steroid; the steroid can then be eluted with methylene chloride (5). This method is applicable to ointments containing steroids and is especially effective for removing the interfering substances contained in lanolin.

A modification of this method is presented for the determination of hydrocortisone and hydrocortisone acetate in antibiotic mastitis preparations. It consists of the following: (*a*) inserting a sodium bicarbonate trap under the methyl alcohol–water stationary phase to prevent procaine penicillin from interfering; (*b*) changing the concentration of methyl alcohol–water (1:1) stationary phase from 1 ml./Gm. of Celite to 0.5 ml./Gm. to improve recovery; (*c*) changing the isooctane–methylene chloride mobile phase to accommodate the polarity range of the two steroids; (*d*) packing the column with Celite support mixture in dry form rather than as a suspension in isooctane–methylene chloride mobile phase, and placing the sample on the column in a Celite mixture rather than in an isooctane–methylene chloride suspension. The Celite mixture technique proved more satisfactory in the authors' experience. Details of the modified assay procedure are as follows.

ASSAY PROCEDURE

Apparatus.—Chromatographic column, 15 mm. i.d., and 450 mm. long with Teflon stopcock.

Reagents.—Celite 545, methyl alcohol, isooctane, methylene chloride, glacial acetic acid, tetramethyl ammonium hydroxide (10% in water), blue tetrazolium (Dajac Laboratories), ethyl alcohol, sodium bicarbonate. All reagents are reagent grade.

Preparation of Column.—Use either glass wool or a fritted disk as the column support. Add 1 ml. of 8% sodium bicarbonate aqueous solution to 2 Gm. of Celite in a small beaker, mix well, and transfer to the column in three portions, gently packing each portion with a tamping rod made of glass or stainless steel. Add 3 ml. of methyl alcohol–water (1 + 1) to 6 Gm. of Celite, mix well, and transfer to the top of the bicarbonate column in several portions, packing gently after each portion.

Preparation of Sample.—Accurately measure or weigh a sample of mastitis preparation containing 2 mg. of steroid into a 150-ml. beaker containing 1 Gm. of Celite and mix thoroughly. Transfer this mixture to the column. Dry wash the beaker with 0.5 Gm. of Celite and add to the column.

Preparation of Standard.—Place into a 150-ml. beaker an aliquot equivalent to 2 mg. of the appropriate steroid reference standard dissolved in ethyl alcohol and evaporate to dryness on a steam bath. Dissolve the residue in 1 ml. of methyl alcohol, add 1 ml. of water, and mix well into 2 Gm. of Celite. Transfer to a column and treat standard and sample alike. This procedural standard gave assay values between 98 and 100% of a direct standard.

Elution of Column.—Add portions of methylene chloride–isooctane (1 + 9) to a sample beaker and transfer to the column. Collect 100 ml. of eluate with a flow rate of 1 drop/sec. Discard the eluate and use the same container to add methylene chloride to the column. Collect 100 ml. of eluate in a volumetric flask at the same rate. This methylene chloride fraction contains the steroid.

Spectrophotometric Assay.—Evaporate a 10.0-ml. aliquot of the methylene chloride fraction in a 50-ml. glass-stoppered conical flask to dryness on a steam bath under a gentle stream of air. Add 20.0 ml. of ethyl alcohol to the flask, swirl to complete solution, and add 2.0 ml. of blue tetrazolium solution (400 mg. in 100 ml. of ethyl alcohol) and 2.0 ml. of diluted tetramethyl ammonium hydroxide (1 ml. to 10 ml. with ethyl alcohol). After 45 min., stop the reaction by adding 1.0 ml. of glacial acetic acid. The color is then stable for 24 hr. Determine the absorbance of the solution against a reagent blank at 520 mμ on a suitable spectrophotometer, and compare with the standard treated in like fashion.

RESULTS AND DISCUSSION

Development of the Assay Procedure.—Initially the column was made with 1 ml. of methyl alcohol–water (1 + 1) per gram of Celite. Incomplete (80–85%) recoveries of steroid were obtained. A change to 0.5 ml. of stationary phase per gram of Celite improved the recoveries to over 95%. The initial mobile phase for removing the oil was a methylene chloride–isooctane mixture (2 + 8). Recovery experiments showed that this solvent was satisfactory for the hydrocortisone alcohol but not for hydrocortisone acetate because of some loss in the initial elution. A change to methylene chloride–isooctane (1 + 9) proved satisfactory, not only in removing the oil but also in yielding satisfactory recoveries of both steroids. In addition to the above steroids, satisfactory recoveries were obtained with prednisolone, prednisolone acetate, and dexamethasone alcohol during the investigational phase of this work. Some interfering substances

from the preparations being tested still passed through the column. On the assumption that the interference was caused by the procaine penicillin G and/or its degradation products, a sodium bicarbonate trap was placed on the bottom of the column. This removed almost all of the interference. A stronger alkaline trap would undoubtedly be satisfactory in holding back the interference but would encourage the degradation of the steroid. A comprehensive study of interference by antibiotics and other pharmaceutical ingredients in the various assay methods (2–4) is in progress.

Hydrocortisone and hydrocortisone acetate carried through this column procedure were examined by thin-layer chromatography (6). No degradation was observed.

Preliminary experiments indicate that this chromatographic system is also applicable to a large number of aqueous preparations, ointments, lotions, and creams containing antibiotics and steroids.

Application of the Assay Procedure.—The interferences caused by blank mastitis preparations, which contained all ingredients except the steroids (obtained through the courtesy of six manufacturers), when tested by the U.S.P. XVII method for hydrocortisone ointment and by the new procedure, are shown in Table I.

As shown in Table II, the recoveries of steroids added to blank mastitis ointments range from 90.3 to 100.0% for hydrocortisone and 95.0 to 100.9% for hydrocortisone acetate. These recovery data were based on direct standards rather than procedural standards.

Table III shows that the hydrocortisone and hydrocortisone acetate content of nine commercial preparations assayed by the new procedure ranged from 91.5 to 112% of label claim.

Dye–Polyethylene Glycol 6000 Interactions in Filmcoating Solutions and Their Effect on Color Uniformity

By D. G. BHATIA*, T. D. SOKOLOSKI†, and V. N. BHATIA

The objective of this study was to evaluate the problems of uneven coloration in tablets filmcoated with solutions utilizing polyethylene glycol (PEG 6000) and cellulose acetate phthalate (CAP) in a solvent system consisting of 65 per cent acetone and 35 per cent absolute alcohol. It was hypothesized that to obtain uniform color the dye needed to be brought into solution due to interaction between it and one of the other ingredients in the solution. Attention was focused on CAP, PEG 6000, and titanium dioxide. The procedures included the following steps: (*a*) study of the interaction between dyes, and PEG 6000; (*b*) study of interaction between dyes and CAP; (*c*) testing of the hypothesis stated above in filmcoating operations; (*d*) study of the function of titanium dioxide in filmcoating solutions. The results show that the interaction of PEG 6000 with the solid dye results in the solubilization of the latter and this is significant in producing uniform color. No interaction was observed between CAP and the dyes. Titanium dioxide was found to act purely mechanically in preventing the aggregation of dye particles.

ONE TYPE of filmcoating solution that is frequently used utilizes a combination of cellulose acetate phthalate (CAP) and polyethylene glycol 6000 (PEG 6000) as the film former in a solvent system consisting of acetone (65%) and absolute alcohol (35%). Such a filmcoating solution was described by Gross and Endicott in 1960 (1). While the formula for such a solution consists of a variety of auxiliary agents such as flavoring agents, sweeteners, etc., the basic ingredients are as follows:

CAP	6%
PEG 6000	14%
Dye	0.05%
Titanium dioxide	2%
Solvent system (acetone 65%, absolute alcohol 35%)	*q.s.* to 100%

The dyes used in this formula are essentially insoluble in the solvent system, and it has been noted that their action is often unpredictable with respect to the uniformity of color deposition. In certain concentrations some of the dyes produce coatings with a mottled appearance, particularly when the filmcoating solution is not rendered opaque by the titanium dioxide.

The objective of this investigation was to study the cause of the lack of uniformity in the color deposition. It was hypothesized that to obtain a uniform color coverage the dye must be brought into solution. This could be achieved only by interaction between the dye and some ingredient in the filmcoating formulation causing the formation of a soluble complex.

Since it was observed that titanium dioxide played some role in obscuring the mottled appearance of the filmcoated tablets, its function in a filmcoating formulation was also investigated.

The procedure adopted in this investigation consisted of the following steps: (*a*) study of any interaction between several dyes and PEG 6000; (*b*) study of any interaction between several dyes and CAP; (*c*) testing of the hypothesis presented above by the use of the interaction data of two of the dyes in actual filmcoating operations; (*d*) study of the function of titanium dioxide in a filmcoating formulation.

EXPERIMENTAL PROCEDURE[1] AND RESULTS

The materials used in this study included the following: dyes (provided by Abbott Laboratories): FD&C Blue No. 1 (brilliant blue), FD&C Yellow No. 5 (tartrazine), FD&C Red No. 1 (Ponceau 3R), FD&C Red No. 2 (amaranth red), FD&C Red No. 4 (Ponceau SX); CAP (Eastman Kodak Co.); PEG 6000 (Union Carbide Chemicals Co.); and titanium dioxide (Fisher Scientific Co.).

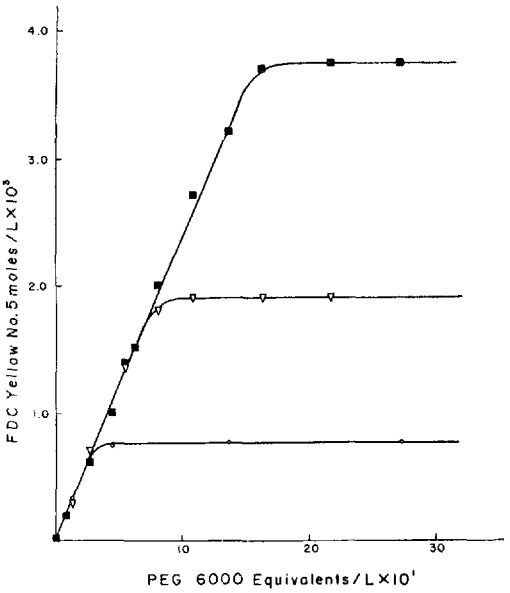

Fig. 1.—Interaction between dye FD&C Yellow No. 5 and PEG 6000. Key: ■, 50 mg.; ▽, 25 mg.; O, 10 mg.

Interaction Studies Between PEG 6000 and Dyes

In this study the following dyes were used: FD&C Yellow No. 5 (mol. wt. = 534.39), FD&C Blue No. 1 (mol. wt. = 792), FD&C Red No. 2 (mol. wt. = 604.49), FD&C Red No. 1 (mol. wt. = 494.46), and FD&C Red No. 4 (mol. wt. = 480).

General Procedure.—All interaction studies between PEG 6000 and dyes were carried out by the phase solubility method (2). A certain amount[2] of the dye under consideration was placed in each of a series of 100-ml. glass-stoppered volumetric flasks. Several stock solutions of PEG 6000 in the solvent system were made. The concentrations of the stock solution were varied, depending on the requirements of a particular experiment. Different volumes of PEG 6000 stock solutions representing different amounts of PEG 6000 were added to each flask. Then, with the aid of a buret, sufficient amounts of the solvent system were added to make up the volume to 25 ml. in each flask. Solutions were shaken in a mechanical shaker at a constant temperature of 25° for 24 hr. to establish dynamic equilibrium. Solutions were then filtered using Whatman No. 2 filter paper, analyzed spectrophotometrically, and the concentrations of the dye were determined from the Beer's law plots.

Three sets of studies using 10 mg., 25 mg., and 50 mg. of dye, respectively, were carried out with FD&C Yellow No. 5 and FD&C Reds No. 1, No. 2, and No. 4. In the case of FD&C Blue No. 1 the amounts of the dye used in the three studies were 200 mg., 250 mg., and 350 mg.

The results of the interaction studies between FD&C Yellow No. 5 and PEG 6000 are shown in Fig. 1. (The interaction between FD&C Blue No. 1 and PEG 6000 gave a similar plot and hence is not illustrated.)

The results of the interaction studies between FD&C Red No. 2 and PEG 6000 are shown in Fig. 2. (The interactions between FD&C Reds No. 1 and No. 4 and PEG 6000 gave similar plots and hence are not illustrated.)

Interaction Studies Between CAP and Dyes

No interaction was noted between CAP and any of the dyes tested.

Filmcoating Studies.—Two of the dyes were selected for this study: FD&C Yellow No. 5 and FD&C Red No. 2. Their selection was based on the fact that they showed two different types of interaction.

Preparation of the Test Tablets.—The test tablets containing equal amounts of sodium bicarbonate and lactose were prepared. Starch paste was used as the granulating agent and magnesium stearate (0.75%) as the lubricant. The tablets were compressed on a Stokes B-2 machine using $^{7}/_{16}$-in. standard concave punches to a pressure of 8–10 Strong-Cobb units. The weight of each tablet was 650 mg. (±5%). The average thickness of the tablets was 5.10 mm.

Preparation of the Filmcoating Solution.—The basic filmcoating formula used in all these studies was:

CAP	6%
PEG 6000	14%
Acetone 65% } q.s.	100%
Absolute ethanol 35% }	

The filmcoating solutions used with the various dyes are presented in Table I (FD&C Yellow No. 5) and Table II (FD&C Red No. 2) and were the modification of the above basic formula.

The test formulations presented above were designed to be of the following two main types.

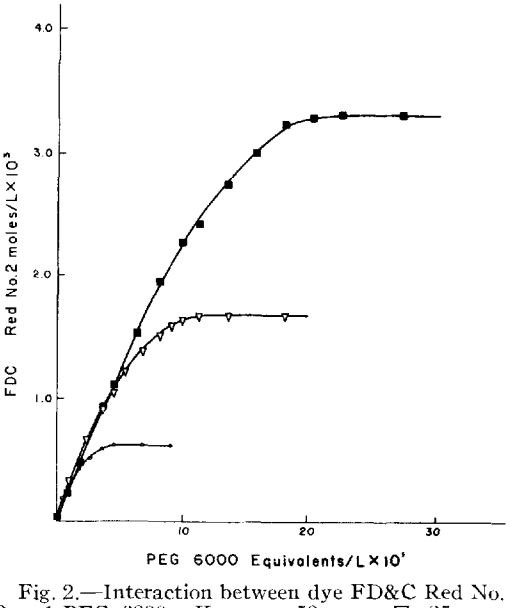

Fig. 2.—Interaction between dye FD&C Red No. 2 and PEG 6000. Key: ■, 50 mg.; ▽, 25 mg.; O, 10 mg.

[2] The amounts used for each dye were chosen on the basis of (*a*) solubility of the dye and (*b*) knowledge of the amount of the dye generally used in the filmcoating formulations.

TABLE I.—COMPOSITION OF TEST FILMCOATING FORMULATIONS USING FD&C YELLOW NO. 5 AND THE OCCURRENCE OF MOTTLING ON THE TABLETS COATED BY THEM

	Formulation No.			
	YI	YII	YIII	YIV
Dye	0.875 Gm.	7 Gm.	0.875 Gm.	7 Gm.
CAP	30 Gm.	30 Gm.	30 Gm.	30 Gm.
PEG 6000	70 Gm.	70 Gm.	70 Gm.	70 Gm.
Titanium dioxide	...	...	10 Gm.	10 Gm.
Acetone, 65% / Absolute ethanol, 35% (q.s.)	500 ml.	500 ml.	500 ml.	500 ml.
Occurrence of mottling	No	Yes	No (Final color lighter than YI)	No (Final color lighter than YII)

TABLE II.—COMPOSITION OF TEST FILMCOATING FORMULATIONS USING FD&C RED NO. 2 AND THE OCCURRENCE OF MOTTLING ON THE TABLETS COATED BY THEM

	Formulation No.			
	RI	RII	RIII	RIV
Dye	0.675 Gm.	5.4 Gm.	0.675 Gm.	5.4 Gm.
CAP	30 Gm.	30 Gm.	30 Gm.	30 Gm.
PEG 6000	70 Gm.	70 Gm.	70 Gm.	70 Gm.
Titanium dioxide	...	...	10 Gm.	10 Gm.
Acetone, 65% / Absolute ethanol, 35% (q.s.)	500 ml.	500 ml.	500 ml.	500 ml.
Occurrence of mottling	No	Yes	No (Final color lighter than RI)	No (Final color lighter than RII)

(*a*) Those containing 4 times (a large excess) the amount of dye that could be solubilized by PEG 6000; *i.e.*, formulation No. YII, YIV, RII, and RIV. (*b*) Those containing half the amount of dye that could be solubilized by PEG 6000; *i.e.*, formulation No. YI, YIII, RI, and RIII.

The determination of the amount of dye used in each formulation was based on the dye–PEG 6000 interaction studies. A typical calculation is shown in the illustration for FD&C Yellow No. 5 (Fig. 1).

On an average, 0.91 equivalents[3] of PEG 6000 (40 Gm.) would completely solubilize 0.0018 equivalents of the dye (1 Gm.). Therefore, 140 Gm. (the amount used per liter of a typical filmcoating formulation) of PEG 6000 would solubilize 3.5 Gm. of the dye.

The two dye concentrations used were $3.5 \times 4 = 14$ Gm./L. (excess dye in suspension) and $3.5/2 = 1.75$ Gm./L. (dye completely solubilized).

In formulations YI, YII, RI, and RII the method of preparation was carried out in the following steps. (*a*) The requisite amount of dye was milled for 24 hr. with 200 ml. of solvent system in a ball mill. (*b*) This mixture was transferred to a bottle containing a solution of 30 Gm. of CAP and 70 Gm. of PEG 6000 in 200 ml. of the solvent system. (*c*) The volume was made up to 500 ml. with the solvent system.

In formulations YIII, YIV, RIII, and RIV, the method of preparation was carried out in the following steps. (*a*) The requisite amounts of dye and titanium dioxide were milled for 24 hr. with 200 ml. of solvent system in a ball mill. (*b*) This mixture was transferred to a bottle containing a solution of 30 Gm. of CAP and 70 Gm. of PEG 6000 in 200 ml. of the solvent system. (*c*) The volume was made up to 500 ml. with the solvent system. All the solutions were kept in a water bath at 55–60°.

[3] Equivalents of PEG 6000 were calculated on the basis of oxyethylene linkages (44 Gm. per equivalent).

Filmcoating Procedure

The filmcoating was carried out using a pear-shaped copper pan of 16 in. maximum diameter with a panload of 5 lb. Four tape-baffles were used to improve the rolling character of the tablets.

Initially a mixture of 50 ml. of the filmcoating solution diluted with 50 ml. of the solvent system was used. This diluted solution was poured in a series of 5 to 10-ml. portions in a thin stream over the tumbling tablets and was added as quickly as possible, making sure that the tablets were perfectly dry between each addition. Then 75 ml. of filmcoating solution (undiluted) was added in a series of 2 to 5-ml. portions. Then the tablets were removed and the pan was washed and dried. The pan was recharged and another 100 ml. of the filmcoating solution (undiluted) was added in a series of 2 to 5-ml. portions. Then the coated tablets were dried and samples were taken.

The results obtained using the various formulations are also shown in Table I (FD&C Yellow No. 5) and Table II (FD&C Red No. 2). It can be seen that mottling occurred only in the tablet coats which contained an excess of the dye and did not contain titanium dioxide. It was also noted that the final color of the tablets coated with formulations containing titanium dioxide was lighter than that of the tablets on which a corresponding formulation without titanium dioxide was used.

Study of the Function of Titanium Dioxide in the Filmcoating Formulation

The following two approaches were used in this study to determine if the presence of titanium dioxide altered the interaction phenomenon between dye and PEG 6000. This study was carried out using FD&C Yellow No. 5 and FD&C Red No. 2.

A.—A constant amount (excess) of the dye under consideration was placed in a series of 100-ml. glass-stoppered volumetric flasks. Amounts of titanium dioxide varying from 0 to 750 mg., in 125-mg. increments, were also placed in the series of flasks. Twenty-five milliliters of the 14% PEG 6000 solution was added to each flask. The solutions were shaken in a mechanical shaker at a constant temperature of 25° for 24 hr. to establish dynamic equilibrium. Solutions were then filtered using Whatman No. 2 filter paper and analyzed spectrophotometrically.

B.—A constant amount (excess) of the dye under consideration was placed in a series of 100-ml. volumetric flasks. Twenty-five milliliters of 14% PEG 6000 solution was added to each flask. The solutions were shaken in a mechanical shaker at a constant temperature of 25° for 24 hr. to establish dynamic equilibrium. Amounts of titanium dioxide varying from 0 to 750 mg., in 125-mg. increments were added to the series of solutions and again the solutions were shaken for another 24 hr. at a constant temperature of 25°. The solutions were then filtered using Whatman No. 2 filter paper and analyzed spectrophotometrically.

The results obtained using the above two approaches were identical to those obtained from experiments conducted under similar conditions without the addition of titanium dioxide.

DISCUSSION

Interaction Studies Between PEG 6000 and Dyes

Interaction Studies Between Dye FD&C Yellow No. 5 and PEG 6000.—The type of interaction between FD&C Yellow No. 5 and PEG 6000 may be explained on the basis of an adsorption phenomenon. It is postulated that there exists an equilibrium between the solid dye, PEG 6000 in solution, and the adsorbed species. Then the adsorbed species goes into solution. The possible scheme of interaction can be represented as:

$$Y + P \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} YP_s \xrightarrow{k_2} YP_l$$

where

Y = FD&C Yellow No. 5,
P = PEG 6000,
YP_s = adsorbed species (solute P adsorbed on solid Y),
YP_l = adsorbed species in solution.

Various approaches were tried to substantiate the existence of the adsorption phenomena mentioned above. These include the use of Freundlich's isotherm (3) and elemental and infrared spectral analysis of the residues from different regions of the interaction curves.

The use of the isotherm could not be applied in the case of FD&C Yellow No. 5 because a method of direct determination of the weight of the solute adsorbed on the dye surface or indirect determination from analyzing the solution at a particular instant for PEG 6000 content was too cumbersome and hence could not be established.

The results obtained from the two analyses did not prove to be definitive and, hence, these experiments neither proved nor disproved the existence of the adsorption phenomenon.

It is observed from Fig. 1 that as the concentration of PEG 6000 is increased, the amount of dye being constant, the curve levels off at some concentration of PEG 6000. Since such a plateau would occur when all the dye molecules are coated by PEG 6000 molecules resulting in the solubilization of the dye, the amount of PEG 6000 (expressed in terms of equivalents of oxyethylene linkages) required to solubilize a mole of dye could be obtained from Fig. 1. For example, in Fig. 1 (10 mg. dye) 4.0×10^{-1} equivalents per liter of PEG 6000 (the point where the curve starts leveling off) are required to solubilize 0.76×10^{-3} moles/L. of dye. Thus,

$$\frac{\text{PEG in equivalents/L.}}{\text{dye in moles/L.}} = \frac{4.0 \times 10^{-1}}{0.76 \times 10^{-3}} = 5.26 \times 10^{2}$$

Similarly, the ratios of 5.26×10^2 and 5.20×10^2 are obtained from 25 mg. dye and 50 mg. dye plots in Fig. 1, respectively. Thus, the average ratio,

$$\frac{\text{PEG in equivalents/L.}}{\text{dye in moles/L.}} = 5.24 \times 10^{2}$$

That is, on an average, 524 equivalents of oxyethylene linkages are required to solubilize 1 mole of FD&C Yellow No. 5.

Interaction Studies Between Dye FD&C Blue No. 1 and PEG 6000.—The type of interaction between FD&C Blue No. 1 and PEG 6000 observed was similar to that observed between FD&C Yellow No. 5 and PEG 6000, and could be explained on a similar basis.

It was found that on an average, 51 equivalents of oxyethylene linkages are required to solubilize 1 mole of FD&C Blue No. 1.

Interaction Studies Between Dye FD&C Red No. 2 and PEG 6000.—The type of interaction between FD&C Red No. 2 and PEG 6000 could also be explained on the basis of adsorption phenomenon and may be represented schematically as:

$$A + P \overset{1}{\rightleftharpoons} AP_s$$

$$AP_s + nP \overset{2}{\rightleftharpoons} AP_{ns} \rightarrow AP_{nl}$$

where

A = FD&C Red No. 2,
P = PEG 6000,
AP_s = primary adsorbed species (solute P adsorbed on the solid A),
AP_{ns} = secondary adsorbed species,
AP_{nl} = secondary adsorbed species in solution.

FD&C Red No. 2 differs from FD&C Yellow No. 5 and FD&C Blue No. 1 in that a shift in the phase solubility curve to the right is observed (Fig. 2) as the initial amount of the dye is increased. Because of this observation the interaction of FD&C Red No. 2 with PEG 6000 was studied in greater detail as shown in Fig. 3. This shift was seen to occur in all the studies shown in this figure. Such a shift indicates that as the dye concentration is

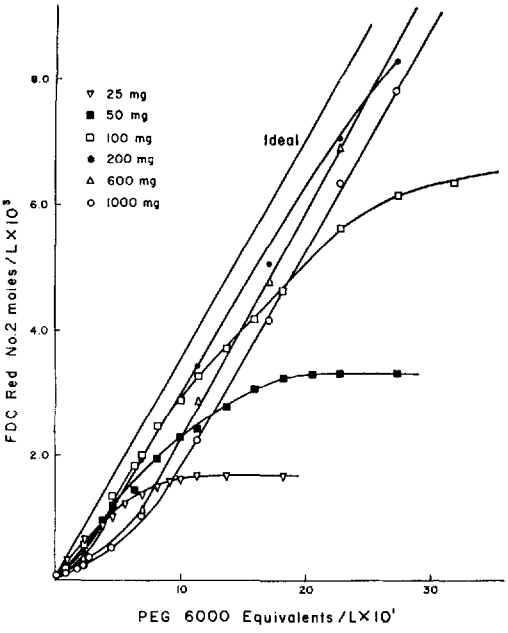

Fig. 3.—Interaction between dye FD&C Red No. 2 and PEG 6000.

increased under conditions in which the PEG 6000 concentration is kept constant, less dye actually enters into solution. This phenomenon could be explained on the basis of the relative insolubility of the primary adsorbed species AP_s (step *1* in the interaction scheme). A greater initial amount of the dye would adsorb more PEG 6000 from its solution forming the insoluble species in relatively larger amounts. Thus a smaller amount of PEG 6000 would be available to form the secondary adsorbed species AP_{ns} (step *2* in the interaction scheme) which leads to solubilization (step *3* in the interaction scheme).

At a lower initial amount of the dye, since less PEG 6000 is required for primary adsorption, more PEG 6000 would be available for secondary adsorption, and, hence, the higher solubility of the dye is observed. It is assumed here that AP_s is practically insoluble and the concentration of dye read at the absorption maximum at any instant is directly proportional to the amount of AP_{nl} in solution.

To substantiate the hypothesis that an adsorption phenomenon (adsorption of solute PEG 6000 from solution onto the solid dye) from solution occurs, the empirical isotherm suggested by Freundlich (3) mentioned earlier may be applied here.

An ideal line, *i.e.*, the line representing no shift due to adsorption phenomenon, is drawn (Fig. 3) passing through the initial point (point representing the saturation solubility of the dye in the absence of PEG 6000) and parallel to the interaction lines in the higher concentration region of PEG 6000.

To apply the Freundlich isotherm, the weight of PEG 6000 adsorbed on the dye is first determined. An illustration to calculate the values of x is as follows:

$$x = x_t - x_i$$

where

x = weight of PEG 6000 (in equivalents per liter) adsorbed,
x_t = weight of PEG 6000 (in equivalents per liter) taken,
x_i = weight of PEG 6000 (in equivalents per liter) required to solubilize the same amount of dye if no shift in the curves occurred.

Referring to Fig. 3 (1000 mg. dye curve which represents the dye in a concentration of 1 Gm./25 ml. or 40 Gm./L.), when $x_t = 0.5$, $x_i = 0.15$, then $x = 0.35$.

Since the plot of log x/m against log C (Fig. 4) yields a straight line, the experimental results conform to the Freundlich expression indicating the existence of adsorption phenomenon.

In the lower concentration region of PEG 6000 and when the amount of dye present is large, the primary adsorption phenomenon would be predominant. However, as the concentration of PEG 6000 in solution is increased, the secondary adsorption and solubilization phenomenon would come into predominance. Approaching the plateau region of the curves, the solubilization process would be predominant in nature.

In case of FD&C Red No. 2 also, the residues from ten different regions of the interaction curves after dynamic equilibrium was established were collected and dried. Here also no definite conclusions could be drawn either from elemental (C, H, N) analysis or infrared spectra (using KBr pellet method) of the residues. The above analyses did not prove or disprove the existence of the adsorption phenomenon. The ratio

$$\frac{\text{PEG in equivalents/L.}}{\text{dye in moles/L.}}$$

for FD&C Red No. 2 is calculated in the same manner as shown with FD&C Yellow No. 5. On an average 721 equivalents of oxyethylene linkages are required to solubilize 1 mole of FD&C Red No. 2.

Interaction Studies Between Dye FD&C Red No. 1 and PEG 6000 and FD&C Red No. 4 and PEG 6000.—These interactions were similar to that ob-

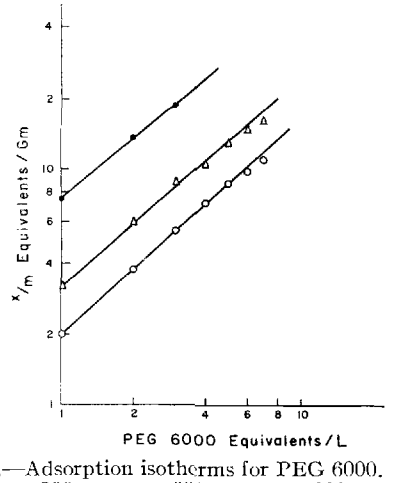

Fig. 4.—Adsorption isotherms for PEG 6000. Key: ●, 200 mg.; △, 600 mg.; ○, 1000 mg.

served between FD&C Red No. 2 and PEG 6000, and can be explained similarly on the basis of adsorption phenomenon. On an average, 700 equivalents of oxyethylene linkages are required to solubilize 1 mole of FD&C Red No. 1, and 450 equivalents to solubilize 1 mole of FD&C Red No. 4.

Filmcoating Studies.—The relative uniformity of color produced by formulations YI (FD&C Yellow No. 5) and RI (FD&C Red No. 2) contrasted with the highly mottled appearance produced by formulations YII (FD&C Yellow No. 5) and RII (FD&C Red No. 2) substantiates the hypothesis presented earlier that to achieve uniform color coverage the dye must be brought into solution. However, the results shown by formulations YIV (FD&C Yellow No. 5) and RIV (FD&C Red No. 2) do not substantiate this hypothesis. Although here the amount of dye is in excess (same as in YII and RII, respectively), the presence of titanium dioxide helps to prevent the expected mottled appearance of the tablets.

Study of the Function of Titanium Dioxide in the Filmcoating Formulation.—The results obtained in the study designed to evaluate the function of titanium dioxide in the filmcoating formulation showed no change in the adsorption curve patterns obtained for PEG 6000–dye interactions. Hence, it is concluded that titanium dioxide does not act as an adsorbent for the dye or PEG 6000 and thus does not aid in preventing mottling by an adsorption process. Furthermore, the studies show that the titanium dioxide does not act in any way to affect the interactions between the dyes and PEG 6000. However, the results in the filmcoating studies show that even when the dye was not completely solubilized by PEG 6000, the mottling was considerably reduced by the addition of titanium dioxide to the filmcoating formula. Therefore, it is concluded that the presence of titanium dioxide promotes color uniformity simply due to "mechanical effect" of its bulk; that is, the larger number of titanium dioxide particles present tends to mechanically prevent the aggregation of the dye particles.

CONCLUSIONS

The results of the present investigation have demonstrated: (*a*) PEG 6000 interacts with the dyes tested (FD&C Red No. 1, 2, and 4; FD&C Yellow No. 5; and FD&C Blue No. 1). The interaction (adsorption of PEG 6000 onto the solid dye) results in solubilization of the dyes which are almost insoluble in the solvent system used (65% acetone and 35% absolute ethanol). (*b*) No interaction is observed between CAP and the dyes tested. (*c*) Presence of titanium dioxide does not alter or affect the adsorption of PEG 6000 onto dyes.

Thus, in a typical basic filmcoating formulation containing dye, PEG 6000, CAP, and titanium dioxide in the nonaqueous solvent system, the interaction between PEG 6000 and dyes plays a significant role in affecting the uniformity of color. In order to assure maximum color uniformity, the amount of dye in a filmcoating formulation should not exceed the amount capable of being brought into solution by PEG 6000. The purely mechanical effect of titanium dioxide in preventing the aggregation of dye particles also plays a significant role in achieving color uniformity.

The information provided by this study gives some insight into methods that may be employed in formulating filmcoating solutions on the basis of scientific data rather than by the use of purely empirical techniques.

compressed to produce tablets with satisfactory physical properties. The term "directly compressed" as used in this text refers to the compression of a mixture of materials which have been subjected to thorough mixing prior to compression in order to obtain a uniform distribution of components of the mixture. By this process, treatments, such as drying the wet granulation, rescreening, and lubricating are not necessary.

Several physical factors appear to influence the direct compression of potassium chloride crystals into modified ball-shaped tablets. This report will relate findings on the influence of particle size distribution, particle shape, apparent bulk density, moisture, drug, and lubricant on the compaction characteristics of potassium chloride crystals.

EXPERIMENTAL

Formulations.—The formula used for screening the direct compressibility of potassium chloride crystals was:

	1000 Tablets
Potassium chloride crystals	1000 Gm.
Stearic acid, powdered	5

Pass the potassium chloride crystals and the stearic acid through a No. 30 mesh stainless steel screen and mix well.

Wet Granulation Formula	1000 Tablets
Potassium chloride crystals	1000 Gm.
Hydrochlorothiazide crystals	50
Gelatin	10
Stearic acid, powder	5

Pass the potassium chloride and hydrochlorothiazide through a No. 30 mesh stainless steel screen and mix well. Dissolve the gelatin in a suitable quantity of deionized water and granulate. Screen the granulation to break up the lumps, dry on trays in a circulating air oven, rescreen, and lubricate.

Direct Compression Formula	1000 Tablets
Potassium chloride crystals	1000 Gm.
Hydrochlorothiazide crystals	50
Polyethylene glycol 6000, powdered	5
Deionized water	1.0 ml.
Colloidal silica	5 Gm.
Stearic acid	5
Talc	10

Pass the potassium chloride, hydrochlorothiazide, and the polyethylene glycol 6000 through a No. 30 mesh stainless steel screen. Mix well and then spray in the water by means of an atomizer or a pressure-actuated spray nozzle. Mix well, then add the colloidal silica, stearic acid, and talc. Mix until blended. The granulation is now ready for compression.

Compaction.—A four-station, single-rotary Colton 204 tablet press, using $^{15}/_{32}$ in. modified ball stainless steel punches, was used to screen the direct compressibility of the different batches of potassium chloride crystals. The batch of crystals which compressed satisfactorily was then formulated with hydrochlorothiazide. The mixtures which produced satisfactory tablets on the Colton 204 were scaled up for compression on a 27-station, double-rotary tablet press. The production-size batches were sufficient to make 240,000 tablets and were compressed on a Stokes 541 double-rotary press, operating at a speed that produced 2000 tablets/min.

The four-station, single-rotary press was used rather than a single-punch machine for the screening studies in order to more closely approximate the compression force distribution encountered when the tablets are compressed in production on a larger rotary press. Furthermore, in a single-punch machine, the lower punch is stationary and only the upper punch exerts the pressure at the time of maximum compression. In a rotary press, both the upper and lower tablet punches approach one another simultaneously up to the point of maximum pressure. Consequently, the strains induced in tablets produced on a single-punch machine would be different than those obtained from a rotary press.

For this investigation, modified ball-shaped tablets were chosen since such tablets provide a minimum volume for a heavy tablet and a narrow edge which facilitates the application of a coating onto the tablets. A tablet compressed with standard concave punches or extra deep concave punches would have a wider edge which is not so easily coated. Figure 1 shows a composite photo of these different shaped tablets.

Friabilator.—A modified Roche friabilator (3) was employed to determine the resistance of the tablet to breaking. Both a plastic and stainless steel frame were used initially for tumbling the tablets. The plastic frame was selected for use after the initial evaluations since it was found that each frame gave comparable results. Twenty tablets were placed in the friabilator which was then set in motion and timed. The test was terminated when one or more tablets were broken. Four minutes was the minimum acceptable time based on experience gained in spray coating of these tablets.

Particle Size Distribution.—Two hundred grams of potassium chloride crystals were sized on 8-in. diameter stainless steel screens (U. S. sieve series) using a Rotap sieve shaker operating for 20 min. The per cent of the crystals retained on each screen was then determined.

Apparent Bulk Density.—A weighed sample of crystals was placed into a graduated cylinder and tamped a given number of times from a uniform height. The volume of the crystals in the cylinder was used to estimate the apparent bulk density.

Moisture Determination.—The potassium chloride crystals were placed into weighing bottles fitted with ground-glass covers and weighed on a Mettler semimicro analytical balance. The bottles were previously exposed to 175° for 20 hr. The samples of crystals were placed in an oven set at 105 ± 1° for 2 hr. to remove surface moisture. The bottles were then stoppered, placed into a desiccator, and weighed when at room temperature. After weighing, the bottles were transferred to the 175 ± 1° for 20 hr., after which they were stoppered, cooled in a desiccator until at room temperature, and reweighed.

Microscopic Examination.—The deformation of crystals following compression into modified ball-shaped tablets was evaluated microscopically. The potassium chloride crystals were lubricated with stearic acid, mixed with a small quantity of activated charcoal, and compressed. The tablets were then cut in half and examined under low power magnification.

Sampling Procedure for the Determination of Inter-Unit Tablet Variability.—Six individual batches of the directly compressible formulation of potassium chloride with hydrochlorothiazide, sufficient to make 240,000 tablets per batch, were prepared and individually processed. Three batches were selected for statistical analysis of the inter-unit variability in tablet weight, drug content, and per cent of drug. Four samples of approximately 100 tablets each were taken systematically at 30-min. intervals from each side of the double-rotary tablet press during the compression operation. The initial sample was taken 30 min. after starting compression. During this period, the production personnel made the routine weight adjustments on the machine which may not have been the same in number or in time for the three batches that were analyzed, nor were they the same for each side of the tablet press. Ten tablets were randomly selected from each sample, individually weighed, and each was placed into a coded bottle, which identified the tablet as to batch, time of sampling, side of machine from which sample was taken, and weight of tablet. Four tablets were randomly selected from each set of 10 tablets for analysis of drug content per tablet. A table of random numbers was employed to facilitate random selection.

RESULTS AND DISCUSSION

The failure of some crystals to compact favorably when compressed into modified ball-shaped tablets may be due to the amount of pressure which can safely be applied to the tablets and to the distributions of the forces in the tablet itself. Table I shows the maximum safe pressure which may be applied with different shaped tablet punches. It will be noted that less than half the amount of pressure can be applied safely when using modified ball punches than when using flat-faced or standard concave punches.

Seth (2) stated that deeply biconvex tablets show a greater tendency toward capping because the applied pressure is not uniformly distributed throughout the tablet granulation in the die cavity during compression. As a result, the more deeply biconvex-shaped tablets are, in general, relatively weaker in strength than flat-faced or conventional biconvex tablets. Because of the convexity of the tablet, the pressures reaching the center of the tablet at its maximum diameter would be expected to be a minimum.

Modified ball-shaped tablets which showed poor friability were split in half and examined under low-

power magnification as shown in Fig. 2. Batch B crystals were used to make the tablet shown in the figure. The crystals at the edges of the tablet, *i.e.*, those crystals in close proximity to the punch face, showed the greatest modification in shape due to the pressure exerted. The crystals in the center of the tablet showed little or no modification from their original shape, indicating that the pressures exerted on the granulation bed were not uniform, a finding which was not unexpected due to the curvature of the punch faces.

Particle Size Distribution.—The particle size distribution of the several batches of potassium chloride crystals is presented in Fig. 3, and it can be seen that there exists a wide range of sizes in the batches. The directly compressible crystals were at least 650 μ or larger at the fiftieth percentile, while the largest crystals at this percentile for those batches that did not exhibit directly compressible properties were no more than 450 μ in size. Approximately 75% of the crystals from the directly compressible batches were 420 μ or larger, while approximately 75% of the nondirectly compressible crystals were 297 μ or larger.

Particle Shape and Appearance.—Examination of the crystals under low-power magnification revealed differences in the appearance and shape of the crystals. The directly compressible crystals (Figs. 4, 5, and 6), batches D, E, and F, respectively, were irregular in shape, frequently having straight jagged edges, often transparent, and appearing to be built up in the form of clusters as a result of growing together in irregular clumps. Other crystals were cubic units built-up in almost pyramid fashion by what appears to be fusion of adjacent crystals. The nondirectly compressible crystals (Figs. 7, 8, and 9), batches A, B, and C, respectively, frequently had rounded surfaces and appeared to lack distinct crystal faces. In addition, these crystals were usually translucent and occasionally opaque in appearance.

Apparent Bulk Density.—The apparent bulk density of the crystals corresponded fairly closely to the particle size distribution of the crystals as shown in Table II. The bulk density represents the packing tendency of the crystals and is a function of the crystal size distribution and the irregularities of the crystal shape. The larger crystals and the highly irregular crystals provide fewer contact points between crystals and create greater void spaces; and if these voids are not filled in by the smaller crystals in the distribution, a low apparent bulk density value will be obtained. It was observed that those crystals which had an apparent bulk density above 1.0 could not be directly compressed.

Moisture Content of Crystals.—When sodium chloride and potassium chloride are crystallized from solution, some water of crystallization may be occluded in the crystals. Smith and co-workers (4) dried sodium chloride and potassium chloride crystals at 140° and then heated them at 550° for 1 hr. A loss in moisture was recorded at the latter temperature. A further loss in occluded moisture was observed when the crystals were heated for 20 min. at 900° which is more than 100° above the fusion point of the crystals. For example, they reported a loss of 0.156% water at 550° and an additional loss of 0.064% water at 900° for potassium chloride crystals prepared by slow evaporation on a hot plate followed by drying to remove surface moisture. In addition, they found that the amount of water occluded varied with the method of precipitating the salts.

The various batches of potassium chloride in the present study were evaluated for the possible presence of occluded moisture, first by drying the crystals at 105° and then at 175° for 20 hr. The 175° temperature was selected because of convenience, no special precautions were necessary to guard against loss by decrepitation, and significant results were apparently attained at this temperature. The data obtained from these drying studies are summarized in Table III. Samples A, B, and C represent crystals which could not be directly compressed or could they be compressed when wet granulated. Samples D, E, and F were directly compressible.

The loss of moisture at 175° was, as one would expect, higher than at 105° which is the usual temperature for removing surface moisture. The loss at 175° which is represented by the difference between total loss of 175° and the observed loss at 105° was generally higher for the directly compressible crystals than for the others.

To determine whether the per cent of occluded water within the crystals varied with the particle size of the crystals, a similar study was performed on different size crystals from several batches, and the results are presented in Table IV. The data in the table indicate that there were generally greater losses in moisture from the larger size crystals than from the smaller crystals. This moisture is not apparently surface moisture because if it were, the small crystals, which have a larger surface area, would be expected to exhibit a greater loss on heating.

The higher percentage of moisture in the larger crystals may be one of the factors that contribute to the compressibility of these crystals. Although these moisture values are small in magnitude, they appear to be of significance when used as a measure

of water of occlusion and are in the same order of magnitude as reported by Smith *et al.* (4).

It is reasonable to assume that the loss in weight observed after heating the crystals represents moisture since the crystals are obtained by evaporation from water. Examination of the crystals, before and after heating, under low-power magnification, preferably with the stereomicroscope, will reveal an apparent increase in the number of air bubbles or cavities following the heat treatment. The air bubbles will be more obvious with crystals which exhibit a greater moisture loss at the higher temperature.

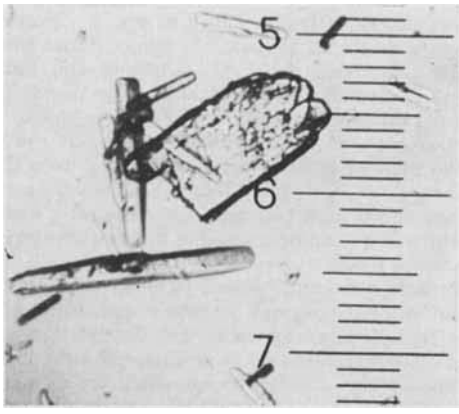

Fig. 10.—Hydrochlorothiazide crystals.

Although batch A crystals had a larger average particle size than B or C and more closely approximated in particle size range the directly compressible crystals, they did not directly compress. This can be attributed to the fact that batch A crystals were compacted on a Chilsonator[1] to attain a larger average particle, and the amount of occluded moisture was low as seen from the data in Table III. The photomicrograph of these crystals (Fig. 7) shows them to be rounded and somewhat opaque with few natural transparent aggregates, unlike the crystals formed by evaporation of solvent and not further subjected to any mechanical compaction process. Since moisture is apparently an important factor in compaction, the crystals should not be subjected to any treatment which will cause excessive loss of moisture.

Lubricant Effect.—The addition of different lubricants was studied in conjunction with the compressibility of the potassium chloride crystals. Stearic acid, magnesium stearate, and calcium stearate were each added in varying amounts to potassium chloride crystals. The magnesium and calcium stearates produced good lubrication, but decreased the bonding characteristics of the salt excessively as seen from the data presented in Table V.

Drug Effect.—The addition of hydrochlorothiazide to the mixture containing potassium chloride and stearic acid reduced tablet hardness and the resistance of the tablets to splitting in the friabilator as evidenced by the data in Table VI. The good bonding properties of the directly compressible potassium chloride crystals were adversely affected as evidenced by the data in this table. The hydrochlorothiazide crystals were essentially needle-like in shape with an occasional flat-platelet and which could be readily fractured and is shown in Fig. 10.

Directly Compressible Formulas.—To overcome the adverse effect of hydrochlorothiazide on the

directly compressible properties of potassium chloride, additives were incorporated in the formulation. The rationale for the use of the various raw materials in the formulation will now be presented.

The polyethylene glycol 6000 powder was used as a water-soluble binder, and the small amount of moisture which is atomized into the mixture most likely activates its binding properties. Since the potassium chloride crystal is well balanced ionically, it does not have ideal surfaces for attracting poorly soluble additives, such as a hydrochlorothiazide. The polyethylene glycol 6000 may act as a bridge to provide the necessary bonding between these two crystals.

The moisture may also act to leak-off electrostatic charges induced by mixing the dry powders in the presence of hydrochlorothiazide. The surface of the potassium chloride crystals may be altered by the addition of moisture through surface dissolution of the salt followed by recrystallization on drying.

The colloidal silica improved the flow of the mixture by its adsorbent properties, particularly when the distribution of the small quantity of moisture added was not absolutely homogeneous. In the presence of the water, the colloidal silica may modify the surface of the potassium chloride by forming a surface film.

In order to overcome picking of the tablets at the monogram, it was found necessary to add talc. Such picking did not occur on nonmonogrammed, smooth-faced punches.

Inter-Unit Tablet Variation.—The directly compressible method (method *2*) required less manufacturing and material handling time than the wet granulation procedure (method *1*). At least 12 material handling steps are involved in method *1* as compared to four for method *2*. The manufacturing time for method *1* is approximately 3.5 manhours, not including the delay for drying time. There is no delay for drying in method *2*, and the manufacturing time is about 1.25 manhours.

The purpose of the statistical analysis was to determine the variation in inter-unit tablet weight and drug content existing in the tablets prepared by method *2* and to compare these results with similar data reported for method *1* (5).

The mean, standard deviation, and coefficient of variation for tablet weight and drug content were estimated for each lot. The contribution to heterogeneity introduced by sampling from two sides of the compressing machine and the different times of sampling were disregarded. The data are presented in Table VII.

The tablets from method *1* show a tendency for larger inter-unit tablet weight variability than do the tablets from method *2* as judged from the values for the coefficients of variation. A stronger tendency for larger variability of drug content exists also in method *1*. In view of these results, one can conclude that the directly compressible formulation is at least as good, if not better, than the wet granulated formula.

SUMMARY

Several factors were found to influence the direct compression of potassium chloride crystals into nonconventional shaped tablets. These were particle size distribution, crystal shape, apparent bulk density, moisture, additives, and punch shape.

A larger particle size distribution was observed for the potassium chloride crystals which could be directly compressed into modified ball-shaped tablets. These crystals had many straight edges, were generally cubic or oblong in shape, or formed clusters from these shapes. Rounded surfaces and smaller particle size distribution were characteristic of the potassium chloride crystals which could not be directly compressed into modified ball-shaped tablets. The larger irregular crystals had an expected lower apparent bulk density and exhibited more occluded moisture. As lubricants, calcium and magnesium stearate tended to produce weaker tablets than stearic acid. Hydrochlorothiazide had a similar effect as the stearates. The development of a directly compressible formulation for hydrochlorothiazide-potassium chloride tablets is described. The inter-unit tablet weight and drug content variability for the tablets prepared from the directly compressible formulation and those prepared by the wet granulation technique were found to be comparable.

Compressibility of Pharmaceutical Solids I

Instrumentation Employed and Preliminary Results Obtained

By JACOB VARSANO and LEON LACHMAN

A description is presented of an Instron physical testing instrument which was adapted to permit its utilization in the evaluation of the compressing characteristics of drug particles and granules. Measurements were performed on a bed of a readily and a poorly compressible solid, as well as granules of these solids made with several commonly used pharmaceutical binding agents. It was found that potassium chloride crystals and granules deformed at lower compression loads than those of potassium citrate. The influence of crystal and granule size and granulating agents on these measurements was found to be relatively small when compared with the inherent properties of each salt. The relationship between the logarithm of the load and the deformation showed a change of slope depending on load range. An attempt was made to obtain a parameter of compressibility having practical implications and leading to a better theoretical understanding of the mechanism of bonding of solids under pressure.

DURING THE past 15 years a considerable amount of research has been performed to elucidate the phenomena and mechanisms involved in the compression of pharmaceutical solids and their granulations.

Higuchi and associates (1–5), using an instrumented single-punch tablet press, were able to demonstrate that a definite relationship existed between compression force and various physical characteristics of the produced tablets, among which were hardness, density, porosity, and specific surface area.

The mechanisms of compaction of powders into pellets and the transmission of the compression forces throughout the powder bed were investigated by Train (6). He also studied the physical changes occurring in the powder undergoing compression by measuring the change of relative volume with respect to load.

Shotton and Ganderton (7) evaluated the relationships between compaction forces and crushing strength, voidage, and ejection forces. The structural changes of granules occurring at different compression levels and the mechanism of bonding were also investigated by these authors (8, 9).

Several pharmaceutical solids were studied for their stress relaxation behavior under constant strain by Shlanta and Milosovich (10). The investigators found a correlation between the relaxation properties of these materials and their bonding characteristics.

Seth and Munzel (11) postulated that particles bind among each other by the formation of surface irregularities during compression. Rumpf (12) investigated the effect of adsorbed water as a factor in the bonding of particles undergoing compression.

In recent years increasing attention has been given to the influences of crystal lattice strength on the bonding characteristics of several pharmaceutical materials. Correlations between crystal hardness and bonding have been demonstrated by Windheuser *et al.* (13). A thorough investigation into the elastic and plastic deformations of some pharmaceutical solids under compression was reported by Höfer and Gstirner (14).

The cohesion between solid surfaces depends on forces of atomic attraction which demonstrate themselves at distances slightly greater than normal interatomic spacing. There exists a direct proportionality between bonding and the contact area of the solid surfaces on which these forces play a role. Solids with a greater tendency for plastic flow will attain a greater contact area when subjected to a given load and, therefore, a higher degree of bonding would result (15). Consequently, the plasticity of the crystal lattice would be a major factor contributing to the bonding of pharmaceutical solids, regardless of the other mechanisms involved.

Although previous reports have considered the importance of this aspect, there is still a need for a systematic evaluation as to the effect of relative crystal and granule hardness on the compression bonding of particulate solids. In light of this, a study was designed to perform hardness measurements on a bed of crystals and granules and determine the effect that particle size and granulating additives have on these measurements. Data accruing from such a study should contribute to the development of

crystal and granule hardness specifications of materials used in tableting, their relative grading in respect to hardness, and permit an estimation of the compressibility characteristics of new drugs before formulation work is initiated.

This report describes the instrumentation and techniques employed toward achieving the aforementioned objectives and presents the preliminary data obtained on two pharmaceutical solids, potassium chloride and potassium citrate. Previous experience obtained with these salts during formulation work indicated that satisfactory tablets could be obtained by direct compression with potassium chloride but not with potassium citrate. These results led to the selection of potassium chloride and potassium citrate for this study as representative of a readily and a poorly compressible solid.

EXPERIMENTAL

Instrumentation.—The Instron Universal testing instrument TM-M, table model[1] shown in Fig. 1 was utilized for this study. This equipment permits an evaluation of the stress-strain characteristics of materials under selected loads applied at varying rates and patterns. The major considerations for selecting the instrument were its accuracy, versatility, operational convenience, and relative compactness. These qualities make it a valuable tool for both investigational and routine measurements.

A brief description of the operational principles of this instrument follows. The vertically moving crosshead (A) is driven by a synchronous system exerting a compression force at constant rates independent of load. A set of interchangeable gears provides a selection of crosshead speeds. The load cell (B) is a bonded wire strain gauge system excited by a stabilized oscillator and is temperature compensated. The load cell output is amplified and fed to the potentiometer-type strip chart recorder (C), driven synchronously with the crosshead at variable speed ratios. The actuation of the crosshead and its direction of motion is controlled from a panel (D) either manually or automatically by preset conditions.

To allow the measurements of deformation occurring in particulate solid beds under varying stress levels, the special fixture shown in Fig. 2 was designed for the instrument. It consisted of two punches and a die resembling a single-punch tablet press. The upper punch (A) was attached to the moving crosshead. The lower punch (B) was seated on a flange (C) which was fastened by set screws to the load sensitive table of a compression load cell (D). A threaded bushing (E) containing the lower punch provided a means for regulating its height. The die (F) was placed on a metal plate (G) which slides vertically along a pair of sturdy steel rods (H) attached to the base of the instrument. The surface of the rods had inscribed scales in 1-mm. increments to allow the positioning of the die plate at desired heights which in turn is

Fig. 1.—Instron universal testing instrument equipped with compression fixture. Key: A, crosshead; B, load cell; C, recorder; D, control panel; E, fixture.

held in place by set screws. A lever (I) served to extrude the compressed compacts from the die by lifting the bushing containing the lower punch. The flat-faced punches employed in this study were of $^{11}/_{32}$-in. diameter. The die and punches were chromium plated to reduce sticking and friction.

The instrument equipped with the fixture described above permitted an evaluation of the deformation properties of solids undergoing compression from the relationship of upper punch travel and the compression force exerted on the lower punch.

Materials Used.—Potassium chloride (Schuylkill

[1] Instron Corp., Canton, Mass.

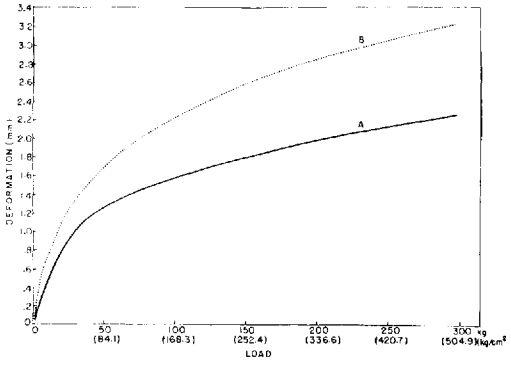

Fig. 3.—Deformation of crystals at varying loads. Key: A, potassium citrate crystals; B, potassium chloride crystals.

Chemical Co.); potassium citrate (Chas. Pfizer and Co., Inc.); cornstarch U.S.P.; acacia U.S.P.; and polyvinylpyrolidone (PVP) (Antara Chemicals).

Procedure.—The potassium chloride and potassium citrate were milled on a Fitzpatrick machine, and granulations of these salts were prepared with water, cornstarch paste 20% w/v, acacia solution 20% w/v, and PVP solution 20% w/v. For each granulation system the ratio of binder to salt was kept at 1.4%. The granulations and the untreated crystalline solids were screened on U. S. standard sieves to obtain the following size fractions:

	Sieve Classification, Mesh
Potassium chloride, crystalline	40–60, 60–80, 80–100, 100–120
Potassium citrate, crystalline	40–60, 60–80, 80–100, 100–120
Granulations	18–20, 20–40, 40–60, 60–80, 80–100

The screened fractions and unscreened material were dried in a 65°-oven until the Karl Fischer test indicated no measurable amount of water.

Compression.—The die wall was dusted with magnesium stearate, and a 300-mg. sample was accurately weighed and fed into the die cavity through a specially designed glass funnel. In order to insure uniform packing of the particles in the die, the funnel was suspended on a vibrating arm operating at a constant frequency.

The instrument was operated on automatic load cycling at a downward crosshead motion of 1 cm./min. until a 300-Kg. (504.9 Kg./cm.^{2}) load was exerted on the lower punch. When this maximum load was reached, the instrument automatically reversed the direction of the crosshead at a speed of 50 cm./min. The ratio of the downward crosshead speed to that of the recorder chart was 1:50. For each screened fraction, five measurements were made, and their mean values were used in subsequent calculations. Corrections were made for the amount of deflection due to the instrument and the fixture.

RESULTS AND DISCUSSION

Figure 3 presents a typical load deformation relationship as replotted from the recorder. It

shows that the deformation of potassium chloride was greater than that obtained with potassium citrate.

Plotting the logarithm of the load against deformation produced a linear relationship over a load range from approximately 50 to 300 Kg. for both potassium citrate and potassium chloride as shown in Figs. 4 and 5. Because of particle reorganization occurring at the load range below 50 Kg., deviation from linearity takes place in the above relationship. The slopes of the plots in Figs. 4 and 5 (Δ log load/Δ deformation), are an index of the relative ease with which the solid bed undergoes deformation.

The compression slopes of the plots in Fig. 4 are summarized in Table I. It is evident from the data in this table that within each salt, the slope values are for the most part of the same magnitude, independent of particle size. However, a comparison of the slopes of the two salts reveals a significant difference between them.

The effect of granulating additives at a constant particle size on the slopes is demonstrated by the plots in Fig. 5. The slopes of such plots are presented in Tables II and III. It can be seen that the slopes of each salt are essentially unaffected by granule size and granulating agent at concentrations normally used in tablet technology.

The values for work expended in compressing the

materials under study over the load range from 50 to 300 Kg. were computed from the areas under the load displacement curves and are presented in arbitrary units in Table IV. The data clearly indicate that in all instances the work done in compressing potassium chloride is greater than that for potassium citrate. This is an indication that potassium chloride has undergone greater deformation at this load level than potassium citrate.

Crushing strength measurements on the compacts obtained in this study were performed on the instrument as illustrated by the photograph shown in Fig. 6. Table V presents the over-all means of these values for each granulation. It is evident from these data that greater apparent bonding was achieved with potassium chloride than with potassium citrate.

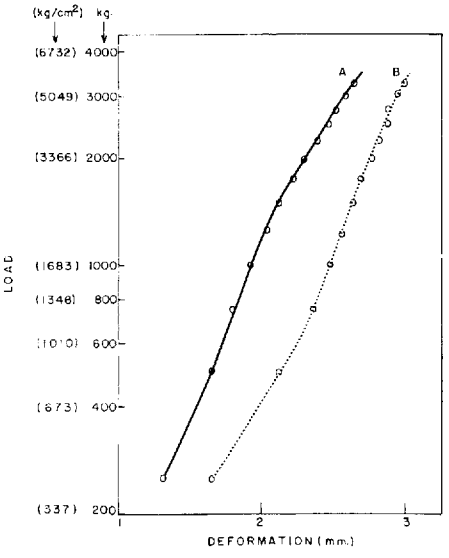

Fig. 7.—Compression curves of potassium citrate (on 80) and potassium chloride (on 80) at high loads. Key: A, potassium citrate; B, potassium chloride.

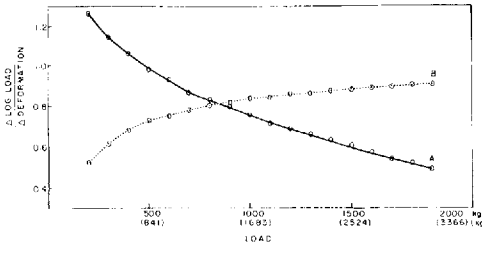

Fig. 8.—Compression slopes of 80-mesh crystals at different loads. Key: A, potassium citrate; B, potassium chloride.

In order to determine whether the slope relationship for the two substances found at lower loads would remain valid at higher loads, a floor model Instron capable of exerting a maximum load of 5000 Kg. was utilized. The data obtained were plotted in Fig. 7, and it is apparent from the nonlinearity of the plots of log load *versus* deformation that the straight line relationship found at the lower loads does not hold true over a wide load range. Because of the curvature of the plots, it is not readily possible to obtain the compression slopes of the two substances. It was felt that if the compression curves were approximated as straight lines, valuable information on the mechanism of compression would be obscured. Instead, the equation of the best fitted line was calculated on a computer by the method of least squares, using the quadratic model $\log y = A_1 + A_2X + A_3X^2$. The slope at each load level of the fitted line was then computed by differentiating the model: $d(\log y)/dx = A_2 + 2A_3X$. This analysis permitted the determination of the compression slopes at any load level. The computer program also recorded the residual sum of squares and the standard deviation. The latter represented the geometric mean of the variations about the fitted line and included both the experimental error and the inadequacy of the model.

The slopes computed in this manner were plotted against load as shown in Fig. 8. This graphical presentation clearly illustrates the influence of varying loads on the compression slopes. From the plot of potassium chloride, it can be seen that the compression slope increases and approaches a plateau with increase in load. This relationship would indicate that the major deformation of the crystal bed took place at the lower load range. As the load increases beyond this range, a greater portion of it is being transmitted through the bed onto the load cell with little further compaction being accomplished. In contrast, for potassium citrate, the major deformation is occurring at the higher load range as evidenced by the considerable decrease in compression slope as the load increases.

The changes occurring in compression slopes at different load ranges provide valuable information about the compression characteristics of a material and permit the selection of the most appropriate load level to obtain optimal compaction. It would be expected that the grading of the relative compressibility of materials could be accomplished by determining the load range at which most active compaction is taking place.

The work expended in compressing potassium chloride and potassium citrate in the load range up

Table VI.—Cumulative Work Expended to Compress 80-Mesh Potassium Citrate and Potassium Chloride Crystals from 50 Kg. to Load Levels Given in Table

	Cumulative Work at Loads in Kg.								
	500	1000	1500	2000	2500	3000	3500	4000	4500
Potassium citrate	281	557	862	1187	1528	1882	2246	2620	3002
Potassium chloride	356	613	870	1129	1388	1647	1906	2166	2425

to 4500 Kg. is given in Table VI. It can be seen from the data in this table that more work is expended on the potassium chloride crystals up to 1500 Kg., while for potassium citrate more work is expended from 1500 to 4500 Kg. This would indicate that the potassium chloride crystals are undergoing greater deformation and compaction at the lower load range while the reverse is true for potassium citrate.

SUMMARY AND CONCLUSION

A description has been presented of a modified Instron physical testing instrument which can be used to obtain a quantitative measure of the compressibility of pharmaceutical solids. Preliminary information is given for potassium chloride and potassium citrate crystals and granulations of these salts which can be summarized as follows.

1. Potassium chloride was found to deform at lower compression loads than potassium citrate.

2. Modifying the two salts by granulating with materials commonly used in tablet technology indicated that the inherent compression properties of the salts predominated. The granulating agents employed were water, acacia, starch paste, and polyvinylpyrrolidone.

3. A linear relationship was found for log load *versus* deformation for both salts at load levels up to 300 Kg. However, at higher loads, this linear relationship did not hold true.

4. In order to permit a measure of the relative compressibility of the materials at high load levels, a computer program was prepared to determine the quadratic equation best fitting the experimental data which were subsequently used to obtain the compression slopes at each load by calculating the derivative.

5. The relationship between compression slope and load can be used to determine the load range at which maximum deformation of the solid bed is taking place.

6. The work expended at different loads can also be used to determine the load range of maximum deformation.

Powder Flow Studies I

Instrumentation and Applications

By GERALD GOLD, RONALD N. DUVALL, and BLAZE T. PALERMO

Several methods have been used to evaluate the flow properties of pharmaceutical formulations. Although these methods give reproducible results, they often measure different factors. Consequently, it is difficult to interpret the data, and it is debatable whether correlation with actual flow of material is possible. A new approach to the measurement of powder flow is presented and involves measurement of the weight of powder per unit time flowing through a hopper orifice. The instrument, a recording powder flowometer, consists of a hopper, strain gauge balance, and recorder. The flow rate can be calculated from the recorder tracing, and in addition, the tracing serves to characterize the flow qualities of a formulation. Various sized hopper orifices with or without vibration can be used. By incorporation of an ionostat into the instrument, the static charge may also be measured concurrently with the flow rate.

FLOW PROPERTIES of pharmaceutical formulations are extremely important to the industrial pharmacist. Increasing complex manufacturing techniques and modern dosage forms require a more thorough and basic understanding of the science and technology of small particles. In tablet and capsule manufacturing, considerable effort is directed toward obtaining and improving free flowing powders and granulations. Recent compendia standards and law enforce-

ment activity relative to intertablet dosage variation have further emphasized the problem. Research in this area has been hindered by the lack of suitable instrumentation, and, until fairly recently, flow properties were often evaluated empirically.

Methods currently in use in an attempt to evaluate powder flow include measurements of the angle of repose or angle of spatula and timed delivery from an orifice. The angle of repose is a measure of the static coefficient of interparticular friction, and is the maximum angle possible between the surface of a pile and the horizontal plane. The angle of spatula is also a measure of interparticular friction. In this method, a spatula is inserted parallel to the bottom of the container and then lifted straight up and out of the material, thereby creating an angle to the horizontal (1). Timed delivery through an orifice has also been used to evaluate flow of materials, with either the volume or weight of powder flowing through the orifice in a specified time period measured (2). Munzel (3) also utilized this principle with a modified Emix powder dispenser. Although, separately, these three methods give reproducible comparative results, they have no specific relation to each other, and are not necessarily influenced by the same factors.

Powder flow problems encountered in this laboratory could not be satisfactorily resolved with the various methods described above. Consequently, an instrumented approach to the problem has been developed and appears to be more closely related to actual flow of materials under production conditions. A recorder tracing of the weight of the powder flowing through a hopper *versus* time is obtained. The tracing serves to illustrate graphically variations or fluctuations in flow patterns. The flow rate through a given hopper orifice with or without vibration is easily calculated from the tracing and, in addition, an ionostat can be used to measure the static charge concurrently with the flow rate. This report describes the recording powder flowometer which should lend itself to basic studies of the flow of powdered or granular materials. An example is presented to illustrate the usefulness of the instrument in identifying the ingredients in a complex formulation which adversely influence flow and in confirming an improved flow of the reformulated material.

EXPERIMENTAL

Materials.—Commercially available materials of either U.S.P., N.F., or pharmaceutical grade were used. The following materials were powders: anhydrous dicalcium phosphate, magnesium stearate, niacinamide, riboflavin, and thiamine. The following were crystalline: ascorbic acid, aspirin, anhydrous citric acid, sodium ascorbate, and tartaric acid. The remaining materials were processed granules.

Description of the Recording Powder Flowometer.—The instrument consisted basically of a strain gauge balance and recorder along with various hoppers. The hoppers were stainless steel, conical in shape, and measured 20 cm. top diameter by 30 cm. in length with orifice diameters of 8.0, 10.0, and 15.0 mm. In order to study poorly flowing materials, a vibrolator[1] was attached to the 10.0-mm. hopper and connected by means of rubber tubing through a pressure regulator[2] to a laboratory air jet. The pressure regulator can be set at any air pressure depending on the amount of vibration desired. In those experiments requiring vibration, a setting of 10 lb./sq. in. was used. The strain gauge balance is shown schematically in Fig. 1. The receiving platform (B) was positioned 11 cm. directly beneath the hopper orifice. This platform was supported by bar (C), the upper of two brass bars mounted horizontally to the wood support. The lower horizontal bar (D), fastened at one end, bends when weight is placed on the platform. Two strain gauges[3] were fastened to this bar. Within the enclosed area (A) were the resistors, resistor controls, and the circuit switch. The electrical diagram indicating the bridge circuit, voltage regulator, and strip chart recorder is also shown in Fig. 1. Voltage regulation was accomplished with a transistorized power supply model 1020[4] set at 8 v. The Brown electronik[5] recorder has a 0–2-mv. range for 25.4 cm. full scale and a chart speed of 0.33 cm./sec.

Calibration of the Instrument.—Due to the change in resistance of the deformed strain gauges when powder flows through the hopper onto the platform, a voltage difference results in the two arms of the bridge circuit. The magnitude of this change in potential, indicated by the recorder, was found to be directly proportional to the weight on the strain gauge balance. The recorder response was calibrated by adding weights to the platform and noting the millivolt response. The linear relationship between recorder response and weight is shown in Fig. 2. The weight of material that has flowed through the hopper at any given time could be ascertained from the calibration curve. In this study, however, an equation based on the method of least squares was used to relate recorder response to weight in grams.

Measurement of Static Charge.—Static charge and flow rate can be measured concurrently if an ionostat described in a previous communication from this laboratory (4) is used and the platform of the strain gauge balance replaces the helipath stand.

RESULTS AND DISCUSSION

Typical results obtained with various materials having different flow rates are illustrated in Fig. 3.

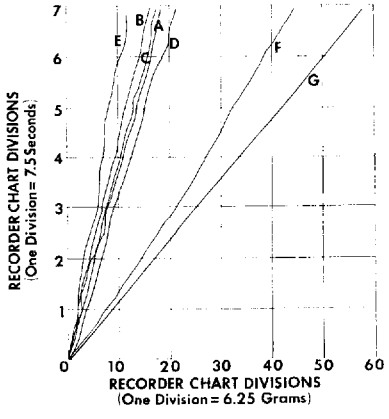

Fig. 5.—Flowometer recording of chewable hexavitamin tablet formulations. Key: A, original formula; the following ingredients were omitted from the original formula: B, magnesium stearate; C, thiamine; D, riboflavin; E, sodium ascorbate; F, niacinamide. Formula G was the reformulated product.

Glass beads, 18–25 mesh, a calcium sulfate granulation, aspirin crystals, and anhydrous dicalcium phosphate powder were used in order to ascertain precision of the instrument over a broad range of flow rates. Flow rates and corresponding standard deviations are shown in Table I.

The results indicate that the instrument is capable of monitoring flow of materials flowing at widely divergent flow rates and of giving good reproducibility. The recorder tracing provides continuous data on such flow with time, a major advantage of this instrument. Fluctuating or irregularly flowing materials can be readily identified. The pulsating character shown by the dicalcium phosphate powder represents alternating periods of flooding and starving. From Fig. 3, it can also be noted that the relative magnitude of the flooding may be estimated from the amplitude of the pulse pattern. This could prove valuable in solving problems relative to tablet weight variation.

The instrument appears to be applicable to basic studies in powder flow. The relationship originally established by Ketchum (5) indicated that the flow rate is directly proportional to the product of a constant, the density of the material, and the cube of the diameter of the orifice. This proved to be an oversimplification, primarily because other factors which affect the rate of discharge were not included (6). However, Fig. 4, although presented only to indicate a potential use for the instrument, does seem to show this relationship between the cube of the orifice diameter and flow rate.

Application of the instrument as an aid in solving flow problems either during the developmental stage of a new product or during production of an existing product appears promising also. To illustrate this point, chewable hexavitamin tablet N.F. formulations containing coated niacinamide, riboflavin, and thiamine, together with fine granular sodium ascorbate, magnesium stearate powder, granules of vitamins A and D, and mannitol were studied. The powder formulation has poor flow properties as illustrated by tracing A in Fig. 5. To analyze the powder mixture for the effect of individual ingredients on flow, five formulations in which a different ingredient was excluded from each were prepared. There appeared to be no significant differences in the flow patterns of the complete formula and of those formulations without either magnesium stearate, thiamine, or riboflavin. The formulation in which sodium ascorbate was omitted, tracing E, had a slower flow rate than the complete formula, indicating that this ingredient had a beneficial effect on the flow rate. When niacinamide was omitted from the formula, recording F, the material had a significantly faster flow rate, thus identifying niacinamide as that ingredient primarily responsible for the poor flow of the original formula. The product was then reformulated with a granulated niacinamide and the resulting formulation, tracing G, showed a marked improvement in flow rate. This example indicates the relative ease by which a poorly flowing formulation may be analyzed and improved through the use of this instrumented approach to the problem. This would be a formidable problem if approached by existing methods of flow evaluation.

The relationship of static charge to flow rate was studied by means of the flowometer modified with an ionostat. Flow rates and static charges of selected organic acids are listed in Table II. The results obtained with two different hopper orifices are the averages of nine determinations. The static charge, read directly from the ionostat, represents the maximum charge resulting from the flow of 500 Gm. of material. Although presented only to illustrate another potential application of the apparatus, it is interesting to note that the increase in flow rate from the larger orifice (15.0 mm.) effected an increase in static charge.

TABLE II.—FLOW RATES AND STATIC CHARGES OF SELECTED ORGANIC ACIDS AS OBTAINED WITH DIFFERENT HOPPER ORIFICES

	Orifice Diam., 8.0 mm.		Orifice Diam., 15.0 mm.

Tartaric acid	5.99	1306	49.37	2289

SUMMARY

A new instrumented approach applicable to the analysis of flow properties of powdered or granular materials has been described. The instrument, a recording powder flowometer, consists basically of various hoppers with or without vibration, a strain gauge balance, and a recorder. A major advantage of the apparatus is the recorder tracing from which the flow rate can be calculated and from which fluctuating or inconsistently flowing materials can be readily detected. In addition, incorporation of an ionostat into the flowometer permits simultaneous measurement of the static charge with the flow rate.

Quantitative Recovery of Radioactivity from ^{14}C-Pentaerythritol Tetranitrate Administered to Rats

By MALCOLM C. CREW, CLAUDE B. COUTINHO, and FREDERICK J. DICARLO

A single dose of ^{14}C-labeled pentaerythritol tetranitrate (PETN) was administered orally to fasted rats, and the level of radioactivity was determined 24 hr. later in the blood, liver, gastrointestinal tract (GIT), urine, and carcass. One group of treated rats was housed to permit collection of expired CO_2 which was also assayed for ^{14}C. It was possible to account for all of radioactivity administered. More than 40 per cent of the drug was absorbed, and about 25 per cent of the ^{14}C was excreted into the urine. The blood, GIT, and urine, were also assayed quantitatively for PETN and its metabolites. The blood contained pentaerythritol and its mono- and dinitrates. Urine contained these metabolites and also a trace of pentaerythritol trinitrate. The GIT contained PETN and pentaerythritol.

A PREVIOUS STUDY (1) examined the absorption and subsequent metabolism of ^{14}C-pentaerythritol tetranitrate (PETN) administered in ligated sections of the rat gastrointestinal tract. The present experiment was undertaken to evaluate the necessity of monitoring the respiratory carbon dioxide in a more general metabolic study of normal (*i.e.*, nonligated) rats. This experiment provided, furthermore, the opportunity to evaluate the efficacy of the extraction methods used in the estimation of PETN and its metabolites.

In the metabolism of PETN the nitrate groups are removed to form PE-trinitrate, PE-dinitrate, PE-mononitrate, and finally pentaerythritol (PE); no breakdown products from the PE have been found (2–5). Although no evidence of expired $^{14}CO_2$ was found in a comparable study using mice (3), this determination was necessary in rats to plan the procedures for animal management in a more complete metabolic study.

For the present experiment, ^{14}C-PETN was administered to six rats housed in glass metabolic cages in such a manner as to provide for the collection of the expired carbon dioxide. After 24 hr. the rats were sacrificed and the ^{14}C content of the carbon dioxide assayed. The blood and some of the tissues were extracted, and the radioactivity of both the extract and the residue was measured to evaluate the efficacy of the extraction. The distribution of the metabolites of PETN in the extracts and the urine was also determined.

METHODS

Radioactive PETN.—^{14}C-PE labeled at C-1 and C-2 was synthesized from acetaldehyde with specific activity of 1.6 mc./mmole and was employed to prepare ^{14}C-PETN, m.p. 140–141.5°. To minimize the danger of working with explosive material, the labeled PETN was mixed with 7 parts by weight of chemically pure lactose. The activity of the lactose–PETN mixture was 0.59 mc./Gm.

CO_2 Collection.—Six white female Wistar rats weighing approximately 180 Gm. each were fasted for a period of 24 hr. prior to the experiment. The rats were dosed orally with 1.8 ml. of a 8.0 mg./ml. suspension of PETN–lactose in propylene glycol (10 mg. ^{14}C-PETN/Kg. body weight) and housed in glass metabolic cages connected to a gas absorption train.

The gas absorption train consisted of a drying tower containing Drierite and Ascarite connected to a source of low-pressure air, followed by a gas-scrubber containing water for rehumidifying the air. The air from the scrubber was passed to a manifold to distribute the air to the six metabolic cages. The effluent air from the cages was recombined in a second manifold and bubbled successively through three containers of 10% sodium hydroxide to trap the expired CO_2 before exhaustion to the atmosphere. A total of 4 L. of 10% NaOH was used in the three collection flasks.

After 24 hr. of CO_2 collection, the combined NaOH solutions were treated with a saturated solution of barium chloride until the precipitation of barium carbonate was complete and crystallization of barium hydroxide was evident. The precipitate was filtered, washed with 4 L. of water, and dried.

The animals were removed from the cages and sacrificed immediately. The blood, liver, gastrointestinal tract, and carcass were extracted with dioxane, and the residues from the extractions assayed for ^{14}C by combustion analysis. The barium carbonate was assayed by gas evolution analysis.

Radioactivity Counting.—Quantitative assays of the urine and the dioxane extracts for ^{14}C were conducted by scintillation spectrometry in a Packard Tricarb using a dioxane solvent for the scintillation solution. The combustion analyses of the residues and the gas evolution analysis of the barium carbonate were conducted by the New England Nuclear Corp.

Received April 22, 1966, from the Biochemistry Department, Warner-Lambert Research Institute, Morris Plains, N. J. 07950.
Accepted for publication June 8, 1966.

Thin-Layer Chromatography.—The assay of the urine and the dioxane extracts for metabolites of PETN was carried out by means of thin-layer chromatography and radioscanning as previously described (1).

RESULTS AND DISCUSSION

Several hours prior to the expiration of the experiment one of the six rats died. The urine and tissue used for this study were, therefore, taken only from the five survivors. The results of the assay for total ^{14}C are given in Table I. The distribution of PETN metabolites in the blood, urine, and gastrointestinal tract is given in Table II. The carcass extract was not assayed qualitatively. The liver extract proved too intractable to produce a satisfactory chromatogram.

TABLE I.—RECOVERY OF ^{14}C 24 hr. AFTER ORAL ADMINISTRATION OF ^{14}C-PETN

Sample	Dose, % Extract	Residue	Total
Blood	0.61	0.02	0.63
Liver	0.24	0.08	0.32
GIT	54.73	3.92	58.65
Urine	25.21	—	25.21
Carcass	15.73	1.20	16.93
CO_2[a]	0.28	—	0.28
	96.8	5.2	102.0

[a] Value from "5.5" rats.

TABLE II.—DISTRIBUTION OF PETN METABOLITES AT 24 hr. POSTADMINISTRATION

Sample	Compn., %[a] PE	PE-Mono-nitrate	PE-Di-nitrate	PE-Tri-nitrate	PETN
Blood	45	27	28	—	—
GIT	58	—	—	—	42
Urine	51	30	17	2	—

[a] Calculated on a molar basis.

The small amounts of radioactivity found in the residues from the tissue extraction confirm the efficacy of the extraction procedure. The one notable exception is the liver extraction which removed only 75% of the radioactivity from the tissue.

The barium carbonate collected weighed 108.6 Gm. A blank with the apparatus using no rats produced 2.9 Gm. of barium carbonate. The difference of 105.7 Gm. of barium carbonate, corresponding to 23.6 Gm. of carbon dioxide, represents the air expired by "5.5" rats in the 24 hr. On this basis it is estimated that each young rat (fasted for 48 hr. as described) exhaled about 24 Gm. of carbon dioxide per kilogram body weight. This quantity is in agreement with data reported by Benedict and MacLeod (6).

From the finding (Table I) that the rats exhaled $^{14}CO_2$ to the extent of only 0.28% of the ^{14}C-PETN administered, it is evident that there was no significant conversion of PETN or its metabolites to carbon dioxide. This observation confirms the finding in mice (3). One possible source of the $^{14}CO_2$ might have been some trace quantity of radioactive impurity in the PETN. Another possibility is that the bacterial flora of the intestine degraded a small quantity of pentaerythritol. There seems to be no information on this point. In their review on the metabolism of tetritols, Carr and Krantz (7) indicated that some microorganisms degrade erythritol. Erythritol, of course, contains two secondary alcohol groups which may render it more vulnerable to enzymatic attack than is the completely symmetrical, primary alcohol-containing pentaerythritol.

Kutscher (8) studied the chronic feeding of pentaerythritol to rats and reported almost 90% of the compound to have been excreted without structural alteration. Considering that Kutscher did not employ radioactive material, his recovery was very high, and inclines one to accept the generalization (9) that compounds containing four alcohol groups are not metabolized by mammals.

More than one-half of the radioactivity of the initial dose was found in the gastrointestinal tract. Of this activity one-third was PETN and two-thirds pentaerythritol; none of the intermediate organic nitrates was detected. One might speculate that the PETN was located in the upper intestinal tract since it was shown previously (1) that the large intestine or its flora is capable of a measurable degradation of the PETN which would result in the detection of the intermediates. The pentaerythritol in the gastrointestinal tract may be the result of this action in the large intestine, although it could be found in the small intestine as a result of bile recirculation or in the stomach as a result of coprophagy. Since the design of the metabolic cages permitted coprophagy, it is not surprising that after 48 hr. of starvation, there were no feces available for collection.

Effects of Some Psychotropic Agents on Peripheral Nerve Conduction Rate

By JACK K. PRUETT* and BYRON B. WILLIAMS

Impulse conduction rates in isolated frog sciatic nerves were reduced significantly by immersion of the nerves in solutions of chlordiazepoxide, 3.4×10^{-3} μm./ml. and prochlorperazine, 5.5×10^{-3} μm./ml. Promazine at a concentration of 3.5×10^{-3} μm./ml. did not significantly alter conduction rates. For chlordiazepoxide the conduction rate reduction increased with increase in drug concentration.

Most of the studies of psychotropic agents center around their effects on the central nervous system. While it has been established that the major component of psychotropic effect involves one or more central sites, there are side effects produced by drugs in this group which are suggestive of peripheral action, *e.g.*, tingling of extremities and impaired association movements (1–4). Plexus anesthesia in frogs induced by chlorpromazine (5) is indicative of the capacity of such a drug to affect peripheral nerve function.

Krivoy (6) reported peripheral nerve effects of several analgetic agents and speculated concerning the relationship of such effects to drug action mechanism. Tasaki (7) has shown that a 1.2% urethan–ringer solution reduced the conduction rate of a large motor fiber approximately 30% after exposure of less than 5 min. Although it may be argued that transmission reduction of such a magnitude by a drug solution at such a concentration would hardly explain the usual pharmacological effects of urethan, it does seem likely that the effects of urethan in large doses might reflect to some extent this peripheral action. It seems reasonable that psychotropic drugs also in high doses might have some of their nervous system activity attributed in part to an effect on peripheral nerve function.

This project was designed to provide preliminary information on the possible effect of some commonly used psychotropic drugs on impulse conduction rate in peripheral nerves. The drugs chosen, chlordiazepoxide,[1] prochlorperazine,[2] and promazine[3] represent two different structural categories.

EXPERIMENTAL

The sciatic nerve of the green frog, *Rana pipiens*, was used in this investigation. The nerve was dissected from the spinal cord to a point near the termination of the peroneal nerve. Care was taken to retain the eighth and ninth roots of the sciatic nerve, and the tibial nerve was trimmed away at the bifurcation of peroneal and tibial nerves. The dissected nerve was maintained in a beaker of frog ringer solution at pH 7.2 for 1 hr. after which time a general state of stability was attained (7). The nerve was then suspended from silver electrodes mounted in the nerve chamber. The proximal end of the nerve trunk was placed on a pair of stimulating electrodes, and the distal end on a pair of recording electrodes. The stimulating electrodes were 53 mm. from the recording electrodes.

Biphasic stimuli were employed to initiate impulses. Stimuli were provided by a Harvard electronic stimulator, model 340, isolated from the nerve chamber by an isolation transformer. The stimulus intensity was 0.5 v. and of 800 μsec. duration. The voltage constituted a submaximal stimulus for A fibers. The recording and measurement of impulse conduction rates were accomplished by standard electrophysiological techniques essentially like those of Krivoy (6) and Stacy (9) with instrumentation differences as described below. An all-purpose conductor-coupled Mark III preamplifier and a d.c. amplifier, both manufactured by E and M Instrument Co., were used in conjunction with a Lavoie Laboratories TS-239 A/UP oscilloscope. A model 800 Polaroid camera with close-up lens was mounted on the oscilloscope to allow photographic recording of the traces. Type 47, 3000 speed Polaroid film was used to insure high-contrast prints. The sweep generator of the oscilloscope was synchronized with the stimulator. An impulse from the stimulator served to start the sweep at the same time the nerve received a stimulus. The nerve, suspended on the electrodes as described above, was stimulated, and the trace with the resulting action potential was recorded photographically by opening the shutter for the duration of the trace. Conduction time was measured from the end of the stimulus artifact to the apex of the action potential spike. Time markers superimposed on the trace eliminated need for separate time signals. Time signals appeared on all traces and were imposed every 100 μsec. along the trace as shown in Fig. 1.

Nerve conduction rates were determined for the treatment groups and one control group. The treatment groups included chlordiazepoxide, 3.4×10^{-3} μm./ml.; prochlorperazine, 5.5×10^{-3} μm./ml.; and promazine, 3.5×10^{-3} μm./ml. Nerves from treatment groups were checked for normal conduction rate then immersed in drug-ringer solution for a period of 60 min., after which they were

removed from the drug solution and a second rate recording made. Nerves in control groups were subjected to the same procedure except that no drug was added to the frog ringer solution. The chlordiazepoxide group comprised 25 nerves, the prochlorperazine group 12, the promazine group 11, and the control group 18.

To establish dose-effect relationship, four higher concentrations of chlordiazepoxide were used. Since some of these concentrations lowered the pH of the drug-ringer solutions, control nerves for these concentrations were treated with frog ringer solutions adjusted to the altered pH values. Drug treatment groups included from six to 12 nerves and all control groups included six nerves. The same general procedure was used as described above except that the period of immersion was 30 sec.

RESULTS

Single Concentrations.—Per cent change from normal conduction rate was determined for each treated nerve, and these data were subjected to statistical analysis. Table I presents data from tests in which single concentrations of each drug were used. Probability values indicate that the conduction rates were significantly lowered in comparison with controls by direct exposure of nerves to chlordiazepoxide and to prochlorperazine. Promazine treated nerves did not differ significantly from control nerves in conduction rate change at the drug concentration used.

Concentration-Effect Relationship.—Table II presents variance analysis data from tests in which four higher concentrations of chlordiazepoxide were used in an attempt to evaluate the concentration-effect pattern. Experimental *F* values were found to exceed table *F* values at 1% probability and, thus, indicated statistically significant difference between effects of the several drug concentrations. Comparison of control data at pH values corresponding to those of drug-ringer solutions revealed that the hydrogen-ion concentration of the solution used did not appreciably affect the conduction rate. Statistical analysis also indicated a significant difference between drug treated and control nerve conduction rates. Figure 2 graphically presents the relationship between concentration and per cent reduction in conduction rate. Data points as well as calculated regression points are shown. Regression analysis indicated no significant deviation from linearity at the 5% probability level.

DISCUSSION

Preliminary determinations of effects of three psychotropic agents on peripheral nerve impulse conduction rates revealed a significant rate reduction by chlordiazepoxide and prochlorperazine. Promazine at the concentration used failed to significantly alter the conduction rate. An investigation of the concentration-effect pattern for chlordiazepoxide indicated that within the limits of concentration used there was evidence of increase in rate reducing effect with increase in concentration of drug.

Although change in conduction rate of the magnitude revealed at these concentrations (10 to 30% reduction) would hardly be expected to account for the major pharmacological effects of these drugs, it would not be unreasonable to assume that there might be some contribution by such an axon effect to the total activity of these drugs at high dose levels. Evidence of this type may be considered of importance also as an indication of a capacity of some psychotropic drugs to exert general effects on nervous tissue in addition to their rather specific central nervous system effects. Such evidence may point also to a need for the consideration,

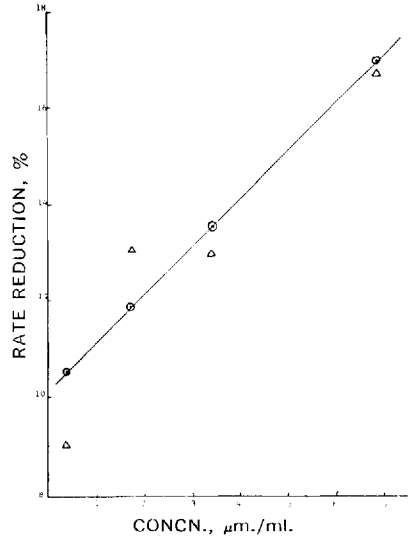

Fig. 2.—Relationship between conduction rate and concentration of chlordiazepoxide. Key: ⊙, calculated point; △, data point.

in mechanism studies, of the possibilities of conductional as well as junctional sites of action for psychotropic agents.

The need to determine site and mechanism of the conduction rate alteration is apparent. The drug concentrations used in this study were near the concentration of chlorpromazine found by Nathan and Friedman (8) to alter the permeability of resting cells of *Tetrahymena pyriformis*. They concluded that this alteration had a lipid site of action. Tasaki (7), in his experiments with saponin, has demonstrated that pharmacological alteration of lipid can change impulse conduction rate. He reported that this agent, by an effect on lipid of the myelin sheath, increased the time required for impulse transmission across the internodal segment. He found, however, that urethan altered conduction rate by a nodal rather than an internodal effect. A study of conduction parameters to provide information as to the site of the rate alteration by these psychotropic agents is planned.

Ion-Exchange Separation and Ultraviolet Spectrophotometric Determination of Dextromethorphan in Pharmaceutical Products

By K. O. MONTGOMERY* and M. H. WEINSWIG

A method for the isolation and determination of dextromethorphan is presented. The dextromethorphan is extracted with strong cation exchange resin, AG 50W-X4, and is subsequently eluted with 1 *N* hydrochloric acid in 60 per cent methanol in water. The dextromethorphan is determined in the eluate by ultraviolet spectrophotometry. The assay is used successfully on several commercial products.

THE POPULAR acceptance of dextromethorphan as an antitussive agent has brought numerous pharmaceutical products to the consumer with this as the main ingredient. There has been very little information reported on the analytical procedures for the determination of dextromethorphan concentrations in liquid dosage forms.

Saques (1) was able to obtain satisfactory results using ultraviolet spectrophotometry and nonaqueous titration on the pure compound but control blanks had to be utilized to overcome interferences from excipients. Lee (2) demonstrated the use of the classical reineckate precipitation and colorimetric determination on the pure compound. Horioka (3) tested a dye complexation and extraction. The official method (4) for the assay of the pure compound and for the official tablets utilizes nonaqueous titration. Ultraviolet spectrophotometry and paper chromatography (5, 6) have also been studied.

The official assay procedure for the syrup requires an involved immiscible solvent extraction and reextraction followed by the determination using ultraviolet spectrophotometry.

The present paper utilizes the ability of strongly acidic cation exchange resins to separate an amine such as dextromethorphan from common dosage form ingredients prior to determination on a spectrophotometer. A weakly acidic solution is used prior to the use of the strongly acidic solution to remove traces of aromatic amines from flavors or coloring agents that may be present in pharmaceutical products. This type of separation using ion-exchange resins has been employed in the determination for phenylephrine by Kelly and Auerbach (7) and by Blake and Nona (8) in the determination for ephedrine salts.

EXPERIMENTAL

Apparatus.—Glass column 20 cm. × 1 cm. with stopcock made of Teflon and containing built in needle valve for control of flow rate. The column is also fitted with a reservoir with a capacity of 250 ml.

A suitable recording ultraviolet spectrophotometer such as the Beckman DK-2A or Spectronic 505 which records in absorbance units.

Reagents.—Cationic exchange resin AG 50W-X4 100–200 mesh in hydrogen form available from Bio-Rad Laboratories, Richmond, Calif. Enough resin, about 3 Gm., is added in the form of a slurry to the glass column and rinsed with water. Hydrochloric acid, 0.05 *N* in 60% methanol in water. Hydrochloric acid, 1.0 *N* in 60% methanol in water.

Standard Solution.—Weigh exactly 150 mg. of dextromethorphan hydrobromide N.F. reference standard and transfer to a 100-ml. volumetric flask. Dissolve and adjust the volume with distilled water to prepare the desired stock standard.

Pipet exactly 10 ml. of the stock standard into a 200-ml. volumetric flask and adjust the volume with 1.0 *N* hydrochloric acid in 60% methanol in water.

Pipet exactly 10 ml. of the stock standard into a 200-ml. volumetric flask and adjust the volume with 1.0 *N* hydrochloric acid in 60% methanol in water.

TABLE I.—ANALYSIS OF PRODUCTS CONTAINING DEXTROMETHORPHAN HYDROBROMIDE

Dextromethorphan Hydrobromide Product No.	Amt. Claimed	Amt. Found	% Label Claim
1[a]	0.9 Gr./fl. oz.	0.906 Gr./fl. oz.	100.7
2[b]	15 mg./5 ml.	14.93 mg./5 ml.	99.5
3[c]	5 mg./5 ml.	5.18 mg./5 ml.	103.6
4[d]	7.5 mg./5 ml.	7.76 mg./5 ml.	103.5

[a] Marketed as Cheracol D by The Upjohn Co., Kalamazoo Mich. [b] Marketed as Robitussin D M by A. H. Robins, Richmond, Va. [c] Marketed as Thorexin by Isodine Pharmacal Corp., New York, N. Y. [d] Marketed as Actin by Chesebrough-Pond's, Inc., New York, N. Y.

Sample Treatment.—Pipet a sample equivalent to 15 mg. of dextromethorphan hydrobromide into the reservoir, rinse the pipet with distilled water, and add to the reservoir.

Add distilled water to the sample to make the volume approximately 100 ml. and mix well.

Allow the sample solution to flow through the resin bed at the rate of 2–3 ml./min. Wash the column by adding 100 ml. of distilled water and allow it to flow through the resin at the rate of 5 ml./min.

Traces of aromatic amines from flavors or coloring agents are removed by allowing 50 ml. of 0.05 *N* hydrochloric acid in 60% methanol in water to flow through the column at 5 ml./min.

Position a 200-ml. volumetric flask under the column and add 190 ml. of 1.0 *N* hydrochloric acid in 60% methanol in water. Allow this to flow through the column at the rate 3 ml./min. The volume is adjusted with 1.0 *N* hydrochloric acid in 60% methanol in water.

Determination.—The ultraviolet spectrum of the sample effluent and of the working standard is recorded with a suitable spectrophotometer. Absorbance units should be used.

Using the baseline technique determine the absorbance at the maximum at about 278 mμ. Calculate the amount of dextromethorphan hydrobromide present from the standard values obtained at the same time the sample is analyzed

DISCUSSION AND RESULTS

Standard solutions, when subjected to the above procedure, yield an average recovery or accuracy of 99.04% with a standard deviation of ±0.52% based on ten determinations. The data for the analysis of marketed products are shown in Table I.

The analytical grade resin used was found to be satisfactory without pretreatment except for washing with a simple water rinse.

A slightly raised baseline was noted with some products where a small portion of the coloring agent was held and eluted with the sample. This did not cause any problem since the baseline technique was used in the calculations.

Other ingredients present in the various formulations included potassium guaiacolsulfonate, ammonium chloride, tartar emetic, sodium citrate, glyceryl guaiacolate, white pine and wild cherry bark extractives, and various common ingredients in syrups and elixirs.

SUMMARY

A method for the isolation and determination of dextromethorphan has been presented. The procedure has been used successfully on commonly available liquid dosage forms and the results are accurate and reproducible.

Effect of Red Cedar Chip Bedding on Hexobarbital and Pentobarbital Sleep Time

By HUGH C. FERGUSON*

Male albino mice, in a red cedar chip environment, show a decreased sleep time to sodium hexobarbital and sodium pentobarbital. The effect appears to be reversible.

THROUGHOUT the years various papers have been published citing controllable factors that modify drug action and toxicity in experimental animals. Examples of these are the age of the animal reported by Petty and Karler (1), cage design by Winter and Flataker (2), exercise and limitation of movement by Hardinge and Peterson (3), strain difference by Weaver and Kerley (4), type of anesthetic and pain response by Gutman and Charmovitz (5), grouping and amphetamine toxicity by Chance (6), and volume of fluid administered by Ferguson (7). Thus, by taking advantage of such knowledge, variations in results might be minimized within this laboratory and from laboratory to laboratory.

In the course of a screening program, control results changed abruptly in one of the author's standard tests. Investigation of all possible varia-

TABLE I.—ANALYSIS OF PRODUCTS CONTAINING DEXTROMETHORPHAN HYDROBROMIDE

Dextromethorphan Hydrobromide Product No.	Amt. Claimed	Amt. Found	% Label Claim
1[a]	0.9 Gr./fl. oz.	0.906 Gr./fl. oz.	100.7
2[b]	15 mg./5 ml.	14.93 mg./5 ml.	99.5
3[c]	5 mg./5 ml.	5.18 mg./5 ml.	103.6
4[d]	7.5 mg./5 ml.	7.76 mg./5 ml.	103.5

[a] Marketed as Cheracol D by The Upjohn Co., Kalamazoo Mich. [b] Marketed as Robitussin D M by A. H. Robins, Richmond, Va. [c] Marketed as Thorexin by Isodine Pharmacal Corp., New York, N. Y. [d] Marketed as Actin by Chesebrough-Pond's, Inc., New York, N. Y.

Sample Treatment.—Pipet a sample equivalent to 15 mg. of dextromethorphan hydrobromide into the reservoir, rinse the pipet with distilled water, and add to the reservoir.

Add distilled water to the sample to make the volume approximately 100 ml. and mix well.

Allow the sample solution to flow through the resin bed at the rate of 2–3 ml./min. Wash the column by adding 100 ml. of distilled water and allow it to flow through the resin at the rate of 5 ml./min.

Traces of aromatic amines from flavors or coloring agents are removed by allowing 50 ml. of 0.05 *N* hydrochloric acid in 60% methanol in water to flow through the column at 5 ml./min.

Position a 200-ml. volumetric flask under the column and add 190 ml. of 1.0 *N* hydrochloric acid in 60% methanol in water. Allow this to flow through the column at the rate 3 ml./min. The volume is adjusted with 1.0 *N* hydrochloric acid in 60% methanol in water.

Determination.—The ultraviolet spectrum of the sample effluent and of the working standard is recorded with a suitable spectrophotometer. Absorbance units should be used.

Using the baseline technique determine the absorbance at the maximum at about 278 mμ. Calculate the amount of dextromethorphan hydrobromide present from the standard values obtained at the same time the sample is analyzed

DISCUSSION AND RESULTS

Standard solutions, when subjected to the above procedure, yield an average recovery or accuracy of 99.04% with a standard deviation of ±0.52% based on ten determinations. The data for the analysis of marketed products are shown in Table I.

The analytical grade resin used was found to be satisfactory without pretreatment except for washing with a simple water rinse.

A slightly raised baseline was noted with some products where a small portion of the coloring agent was held and eluted with the sample. This did not cause any problem since the baseline technique was used in the calculations.

Other ingredients present in the various formulations included potassium guaiacolsulfonate, ammonium chloride, tartar emetic, sodium citrate, glyceryl guaiacolate, white pine and wild cherry bark extractives, and various common ingredients in syrups and elixirs.

SUMMARY

A method for the isolation and determination of dextromethorphan has been presented. The procedure has been used successfully on commonly available liquid dosage forms and the results are accurate and reproducible.

TABLE I.—EFFECT OF BEDDING ON SODIUM HEXOBARBITAL AND SODIUM PENTOBARBITAL SLEEP TIME

Time, hr.	Sodium Hexobarbital Sleep Time ± S.E., min.		Sodium Pentobarbital Sleep Time ± S.E., min.	
	Corncob	Red Cedar Chips	Corncob	Red Cedar Chips
24	32.4 ± 2.7	31.2 ± 2.1	107 ± 8.1	110 ± 9.2
48	34.6 ± 3.1	16.8 ± 1.5	117 ± 9.8	58.3 ± 2.8
72	31.7 ± 2.1	15.9 ± 1.3	105 ± 10.2	62.2 ± 5.8
96	31.1 ± 2.4	14.1 ± 0.9	121 ± 8.7	55.0 ± 2.4
120	34.5 ± 2.3	15.3 ± 1.1	111 ± 11.0	60.0 ± 3.8
144	34.3 ± 1.9	15.0 ± 1.4	109 ± 9.2	57.1 ± 2.8
168	32.8 ± 2.2	16.1 ± 1.5	125 ± 8.7	61.4 ± 4.5

bles showed that the only alteration was in the bedding material employed. Prior to the erratic results, mice were housed in plastic cages with a ground corncob bedding, and this had been changed to red cedar chips. Since further investigation verified the fact that changing the bedding material altered the pharmacologic response, the following study was undertaken.

Similar results were obtained in two different laboratories: Distillation Product Industries, a Division of Eastman Kodak, and the School of Pharmacy, University of Georgia. Two different sources of male albino mice and red cedar chips were employed in these experiments.

MATERIALS AND METHODS

Male albino mice, obtained from Blue Spruce Farms and the National Laboratory Animal Co., weighing 20–25 Gm. were used in all tests. Each animal was used only once and then sacrificed. Upon receipt of a shipment of animals, half were housed in ground corncob bedding and half housed in red cedar chip bedding in a separate room. Animals were allowed a 24-hr. adjustment period before tests were started. The red cedar chips were obtained from a local pet supply store.

Sleep time, for a group of 10 animals, was measured from the time of administration of sodium hexobarbital (100 mg./Kg. i.p.) or sodium pentobarbital (80 mg./Kg. i.p.) until the return of the righting reflex, indicated by two spontaneous righting responses within a 30-sec. period. The average sleep time and the standard error were determined daily for each group of mice, after the 24-hr. adjustment period.

To determine if the effects were reversible, animals that had been housed in red cedar chips for 120 hr. were then changed to the corncob bedding and sleep time again determined daily employing both sodium hexobarbital and sodium pentobarbital.

RESULTS

Table I shows typical results obtained with sodium hexobarbital and sodium pentobarbital in both control group and those housed in red cedar chips. In both cases there is a significant difference between animals housed in the two bedding materials. The sleep time for mice housed in red cedar chips is approximately 50% less than control groups. This difference is evident at 48 hr. and shows no significant change up to 168 hr. Tests run at 24 hr. were not significantly different from control results.

The results in Table II indicate that the effect produced by red cedar chips on sleep time is reversible. An approach to normal is observed sometime between the 24th and 48th hr. after the mice are removed from the red cedar chip environment; thus the change develops with about the same speed as it is lost.

TABLE II.—EFFECT OF SODIUM HEXOBARBITAL AND SODIUM PENTOBARBITAL ON SLEEP TIME AFTER REMOVAL FROM RED CEDAR CHIPS

Time After Removal, hr.	Sleep Time ± S.E., min.	
	Sodium Hexobarbital	Sodium Pentobarbital
0	16.3 ± 1.3	58.8 ± 2.9
24	21.6 ± 1.9	60.8 ± 4.1
48	32.6 ± 3.1	102.6 ± 7.6
72	33.8 ± 3.2	119.0 ± 6.9
96	33.6 ± 3.2	121.0 ± 7.1

DISCUSSION

These results point to another controllable variable that might possibly exist in pharmacologic evaluations. It is conceivable that one might extrapolate to all phases of pharmacologic screening and wonder whether the manner in which these test animals were housed alters other responses and determinations. Further investigation along these lines is in progress, *e.g.*, effect on other classes of drugs and alterations in metabolism and detoxification. Additional experiments are also being carried out to determine if the volatile material in red cedar chips might be responsible for the change reported.

Thus, investigators should be cautious about the use of red cedar chips in animal rooms for the sole purpose of minimizing odors.

SUMMARY

Male albino mice, in a red cedar chip environment, show a decreased sleep time to sodium hexobarbital and sodium pentobarbital. The effect appears to be reversible.

Solubility of Acetanilide and Several Derivatives in Sucrose Solutions

By BHOGILAL B. SHETH, ANTHONY N. PARUTA, and FRED C. NINGER

The solubilities of acetanilide, acetoacetanilide, and the *p*-methyl, *p*-ethoxy, *p*-hydroxy, and *p*-amino derivatives of acetanilide were determined in aqueous sucrose solutions. The solubilities of all solutes were found to change significantly with changes in the concentration of sucrose solutions. The solubility curves indicate the changes probably involve solvent polarity, as indicated by dielectric constant of the solvent, and decrease in the activity of water. The solubility changes obtained for acetanilide and the several *para* derivatives were found to show a fair correlation with respect to the magnitude of solubility in water. This indicates a possibility of predicting solubility changes for the remainder of the compounds if the solubility change for one of the compounds is known.

SEVERAL STUDIES have been carried out in these laboratories to investigate solubility phenomena and their implications in the formulation of pharmaceutical dosage forms. Previous studies indicated the solubility of a given solute in syrup could be significantly different from that in water. This was demonstrated for sulfanilamide, quinine, phenobarbital, and *p*-aminobenzoic acid (1), for xanthines, antipyrine and derivatives (2), and for the *p*-hydroxybenzoic acid esters (3). The fact that increased as well as decreased solubilities were noted and the nature of the solubility curves obtained indicated these changes were probably of complex mechanism. It was thought that the mechanism involved changes in solvent polarity, as indicated by the dielectric constant, and decreased activity of water due to an additive, sucrose, with strong dependence also on the nature of the solute and solvent.

This is the third in a series of investigations of sucrose solutions as solvents of considerable pharmaceutical interest. Solutes were selected for this study to yield information for predicting solubility changes in addition to the solubility curves obtained in the conventional manner. Solubilities of antipyrine and its 4-amino and 4-dimethylamino derivatives (2) in water and in various sucrose solutions indicated a possibility that solubility changes might be predictable.

EXPERIMENTAL

Materials.—The compounds used in this study were as follows: acetanilide N.F. (Mallinckrodt); acetoacetanilide (Eastman No. 1239); *p*-acetotoluidide (Eastman No. 425); phenacetin U.S.P. (Nepera Chemical Co.); acetaminophen N.F. (Nepera Chemical Co.); 4-aminoacetanilide (Eastman No. 13); sugar, granulated U.S.P. These materials were used without further purification.

Solubility Determinations.—Solubility determinations of each material were made in water and in the following sucrose solutions: 18.6, 31.6, 46.0, and 63.4% w/w sucrose. The 63.4% sucrose solution corresponds to syrup U.S.P. Deionized water was used throughout this study. The dielectric constants of these solutions ranged from 78.5 for water to 58.5 for syrup U.S.P. The solubility determinations were made as described previously (4–6). Equilibration time was 72 hr. All determinations were made at 25°. Sample volumes diluted for analysis were 1 ml. for 63.4% sucrose solutions and 5 ml. for all other samples. After appropriate dilutions, all samples were analyzed spectrophotometrically. The final dilutions and absorbance maxima for each compound were as follows: 1:1000 dilution at 237 mμ for acetanilide, 1:100 dilution at 241 mμ for *p*-acetotoluidide, 1:100 dilution at 245 mμ for phenacetin, 1:1000 dilution at 241 mμ for acetaminophen, 1:2000 dilution at 250 mμ for 4-aminoacetanilide, 1:1000 dilution at 240 mμ for acetoacetanilide.

Dielectric Constant.—The dielectric constants of saturated solutions of the compounds investigated in this study were measured on a WTW Multidekameter, model DK-06 (Kahl Scientific Instrument Corp.), as previously described (2). Previously determined values of the dielectric constants of the sucrose solutions were used, as these were in agreement with the values reported by other workers (7, 8).

RESULTS AND DISCUSSION

The solubility data of the solutes investigated in this study are shown in Table I. The values represent an average of three determinations in all cases, except phenacetin, where two values were determined.

The solubility ratios, *i.e.*, solubility in 63.4% sucrose solution relative to that in water, are shown in Table II. It is noted that significant solubility changes were obtained in going from water to 63.4% sucrose solution. For drawing solubility curves, the solubility is plotted against both sucrose concentration and dielectric constant of the corresponding sucrose solution used as solvent.

In general, the dielectric constant scale squeezes in the *x*-axis. The solubility curves are shown in Figs. 1–6.

Acetoacetanilide shows the largest relative change in solubility, with a solubility ratio of 0.5. Its solubility curve is linear in relation to both sucrose concentration and dielectric constant (DEC) of the solvent. The decrease in solubility is 0.25 mg./ml./DEC unit. The solubility curves of acetanilide and the *p*-methyl derivative (*p*-acetotoluidide) are smooth, nonlinear functions. However, it is interesting to note that for the *p*-ethoxy derivative (phenacetin) and the *p*-hydroxy derivative (acetaminophen), there is a considerable change in solubility going from 46.0 to 63.4% sucrose. The solubility ratio of the *p*-aminoacetanilide is 0.88, showing the least change in this series of solutes.

46% Sucrose	4.63	0.81	0.76	11.63	14.74	6.17
63.4% Sucrose	4.25	0.77	0.59	9.80	14.02	4.96

TABLE II.—SOLUBILITY RATIOS FOR ACETANILIDE AND SEVERAL DERIVATIVES

Solute	Solubility Ratio: (mg./ml. in 63.4% w/w Sucrose Soln.)/(mg./ml. in Water)
Acetanilide	0.66
p-Methylacetanilide	0.73
p-Ethoxyacetanilide	0.63
p-Hydroxyacetanilide	0.71
p-Aminoacetanilide	0.88
Acetoacetanilide	0.50

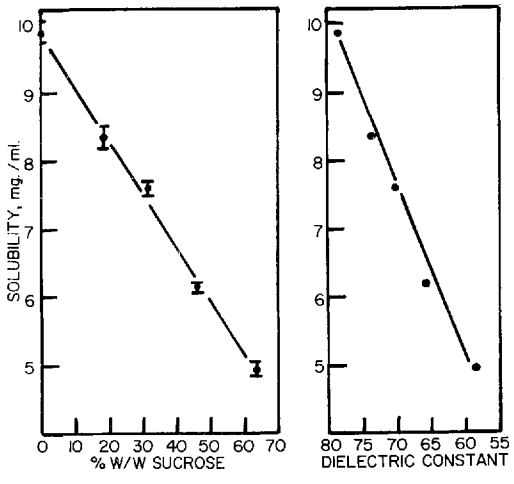

Fig. 1.—Plot of solubility of acetoacetanilide, mg./ml. at 25°, as a function of sucrose concentration and dielectric constant of solvent.

This series of solubility curves is generally in agreement with previous findings (2, 3). The curves indicate the observed changes in solubility probably involve complex mechanisms.

The decrease in solubility, going from water to 63.4% sucrose solution, is shown in Table III, for acetanilide and the *p*-methyl, *p*-ethoxy, *p*-hydroxy, *p*-amino, and the aceto derivatives. It is seen that the solubility change is fairly constant relative to the solubility in water for the first four compounds. These results indicate the possibility of predicting solubility and are in agreement with similar observations made for antipyrine and two derivatives (2). Thus, knowing the solubility change that occurs for acetanilide, the expected change for the derivatives could be approximately calculated.

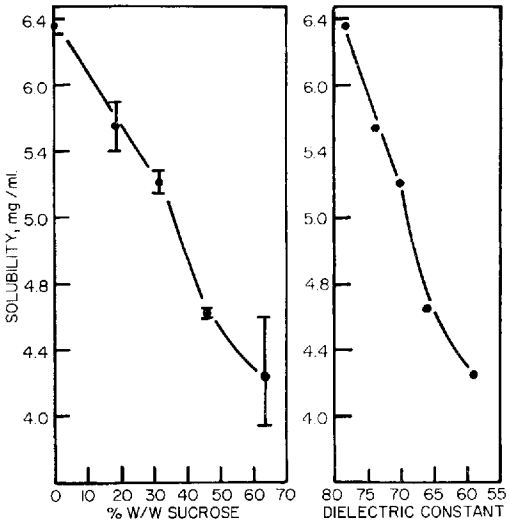

Fig. 2.—Plot of solubility of acetanilide, mg./ml. at 25°, as a function of sucrose concentration and dielectric constant of solvent.

The *p*-amino derivative differs from the rest of the solutes in this regard. This may be due to the fact that the amine substitution may cause a much stronger change in the polarity of the molecule.

It should also be noted that the *p*-amino derivative has the highest magnitude of solubility in this series of solutes. Acetoacetanilide, showing about a 50% decrease in solubility, was not expected to correlate since the substitution was directly on the functional group of the parent compound.

It again indicates the dependence on the nature of the solute and solvent. However, the apparent correlation noted in the change in solubility with two sets of derivatives may be of value if it is further substantiated.

The dielectric constants of the saturated solutions followed, in general, the shape of the dielectric constant curves of the solvents. There was no indication of any specific correlation. This may partly be due to the low solubilities of the solutes.

SUMMARY AND CONCLUSIONS

The solubilities of acetanilide and five related compounds were determined in water and in sucrose solutions containing from 18.6 to 63.4% sucrose. The solubility of all solutes changed significantly in going from water to syrup. The solubility curves obtained in this study again indicate that observed changes are of complex mechanism probably in-

volving solvent polarity, as indicated by the dielectric constant of the solvent, and decrease in the activity of water due to the additive sucrose. A strong dependency on the nature of the solute and the solvent is also indicated.

The decrease in solubility relative to the solubility in water, in going from water to syrup, was found to be fairly consistent for several of the derivatives studied. This further indicated the possibility of predicting solubility changes. These conclusions should be considered within the type and range of systems investigated.

This and previous studies show that the formulator, in considering solubility or applying solubility data, needs to take into account the solvent as represented by the total system of interest. It is the authors' view that an appropriate recognition of solubility phenomena is necessary if the formulator is to use solubility differences of the type reported in this and other studies either to his ad-

vantage in achieving solubility or in avoiding problems due to increased or decreased solubility.

Although there is no sweeping involvement of the dielectric constant as either the parameter of choice or the mechanism involved, it may be a useful tool to the formulator in considering solubility problems.

Metabolism of ^{14}C-Labeled Glutamic Acid and Pyroglutamic Acid in Animals

By WINTHROP E. LANGE and EDWARD F. CAREY*

A useful method has been developed for the paper chromatographic separation and identification of certain amino acids found in biological fluids. A synthetic route to ^{14}C-labeled pyroglutamic acid was developed. The ^{14}C-labeled glutamic acid and pyroglutamic acid were given orally to mice and rabbits. The drug concentration in various tissues was determined utilizing a chromatogram scanner or a liquid scintillation counter. Experimental data indicated that the metabolic products formed following glutamic acid therapy were pyroglutamic acid, γ amino butyric acid, and glutamine. Animals to which the labeled pyroglutamic acid had been administered showed radioactivity present as γ amino butyric acid and glutamic acid.

GLUTAMIC ACID is an important amino acid. Although it is not essential for growth, it has been known for many years to be a major constituent of body protein and to take part in many metabolic processes. In clinical therapy the monosodium salt has been used in place of the free acid because L-glutamic acid is only slightly soluble in water and is absorbed slowly by ingestion. On the other hand the monosodium salt, which is soluble to the extent of over 70% at room temperature is readily absorbed (1, 2). Monosodium glutamate has been tested in many types of neurological and psychiatric cases with positive results (3, 4) and with negative results (5). However, glutamic acid therapy is a problem from two points of view. First, large doses are required; and second, its taste is difficult to mask.

In 1944, Ratner demonstrated the formation of D-pyroglutamic acid in rats fed DL-glutamic acid (6). Wilson and Koeppe determined labeled carbon dioxide excretion, pyroglutamic acid formation, and tissue glutamic acid concentrations after the administration of D- and L-glutamic acid-2-^{14}C and DL- or D-glutamic acid-5-^{14}C (7). They found that when labeled D-glutamic acid was administered in small doses, intraperitoneally or by stomach tube, more than 50% of the radioactivity was excreted in the urine in 24 hr., most of it as D-pyroglutamic acid. There has been a great deal of investigation of the metabolism of pyroglutamic acid in animals and man. Bethke and Steenboek found that it was converted to glutamic acid and postulated that it was an enzymatic transformation (8). However, no reports of the presence of pyroglutamic acid in brain tissue were found. Thus, it is proposed to develop a micro-method which could accurately determine the distribution of glutamic acid or a metabolic product in various tissues following oral administration of glutamic and pyroglutamic acid. If the oral administration of pyroglutamic acid shows the same compound or compounds are crossing the blood–brain barrier then possibly it can be used in place of glutamic acid to give a similar therapeutic response at a lower dosage.

Received April 26, 1966, from the Department of Pharmacy, Massachusetts College of Pharmacy, Boston.
Accepted for publication July 1, 1966.
Presented to the Pharmacology and Biochemistry Section, A.PH.A. Academy of Pharmaceutical Sciences, Dallas meeting, April 1966.
Abstracted from a thesis submitted by Edward F. Carey to the Massachusetts College of Pharmacy in partial fulfillment of Master of Science degree requirements.
This investigation was supported in part by a research grant from The Purdue Frederick Co.
* Present address: Atlantic Gelatin, Division of General Foods Corp., Woburn, Mass.

METHODS AND PROCEDURES

The paper chromatographic procedure described below is based on a method reported by Clayton and Strong (9).

Paper Chromatography.—Standard solutions were prepared of various amino acids. Known quantities of the solutions were spotted on strips of Whatman No. 1 chromatographic paper. The strips were

Acetoacetanilide	9.87	4.96	50

vantage in achieving solubility or in avoiding problems due to increased or decreased solubility.

Although there is no sweeping involvement of the dielectric constant as either the parameter of choice or the mechanism involved, it may be a useful tool to the formulator in considering solubility problems.

Metabolism of ^{14}C-Labeled Glutamic Acid and Pyroglutamic Acid in Animals

By WINTHROP E. LANGE and EDWARD F. CAREY*

A useful method has been developed for the paper chromatographic separation and identification of certain amino acids found in biological fluids. A synthetic route to ^{14}C-labeled pyroglutamic acid was developed. The ^{14}C-labeled glutamic acid and pyroglutamic acid were given orally to mice and rabbits. The drug concentration in various tissues was determined utilizing a chromatogram scanner or a liquid scintillation counter. Experimental data indicated that the metabolic products formed following glutamic acid therapy were pyroglutamic acid, γ amino butyric acid, and glutamine. Animals to which the labeled pyroglutamic acid had been administered showed radioactivity present as γ amino butyric acid and glutamic acid.

GLUTAMIC ACID is an important amino acid. Although it is not essential for growth, it has been known for many years to be a major constituent of body protein and to take part in many metabolic processes. In clinical therapy the monosodium salt has been used in place of the free acid because L-glutamic acid is only slightly soluble in water and is absorbed slowly by ingestion. On the other hand the monosodium salt, which is soluble to the extent of over 70% at room temperature is readily absorbed (1, 2). Monosodium glutamate has been tested in many types of neurological and psychiatric cases with positive results (3, 4) and with negative results (5). However, glutamic acid therapy is a problem from two points of view. First, large doses are required; and second, its taste is difficult to mask.

In 1944, Ratner demonstrated the formation of D-pyroglutamic acid in rats fed DL-glutamic acid (6). Wilson and Koeppe determined labeled carbon dioxide excretion, pyroglutamic acid formation, and tissue glutamic acid concentrations after the administration of D- and L-glutamic acid-2-^{14}C and DL- or D-glutamic acid-5-^{14}C (7). They found that when labeled D-glutamic acid was administered in small doses, intraperitoneally or by stomach tube, more than 50% of the radioactivity was excreted in the urine in 24 hr., most of it as D-pyroglutamic acid. There has been a great deal of investigation of the metabolism of pyroglutamic acid in animals and man. Bethke and Steenboek found that it was converted to glutamic acid and postulated that it was an enzymatic transformation (8). However, no reports of the presence of pyroglutamic acid in brain tissue were found. Thus, it is proposed to develop a micro-method which could accurately determine the distribution of glutamic acid or a metabolic product in various tissues following oral administration of glutamic and pyroglutamic acid. If the oral administration of pyroglutamic acid shows the same compound or compounds are crossing the blood–brain barrier then possibly it can be used in place of glutamic acid to give a similar therapeutic response at a lower dosage.

Received April 26, 1966, from the Department of Pharmacy, Massachusetts College of Pharmacy, Boston.
Accepted for publication July 1, 1966.
Presented to the Pharmacology and Biochemistry Section, A.PH.A. Academy of Pharmaceutical Sciences, Dallas meeting, April 1966.
Abstracted from a thesis submitted by Edward F. Carey to the Massachusetts College of Pharmacy in partial fulfillment of Master of Science degree requirements.
This investigation was supported in part by a research grant from The Purdue Frederick Co.

METHODS AND PROCEDURES

The paper chromatographic procedure described below is based on a method reported by Clayton and Strong (9).

Paper Chromatography.—Standard solutions were prepared of various amino acids. Known quantities of the solutions were spotted on strips of Whatman No. 1 chromatographic paper. The strips were

dried and developed by the descending techniques in chromatographic tanks containing a solution consisting of methyl ethyl ketone, propionic acid, and water (75:25:20). The strips were developed at 25° for 8 hr., removed from the tanks, and air dried. The strips were then sprayed with a 0.2% solution of ninhydrin in alcohol and activated in an oven at 80°. All of the amino acids appeared as characteristic pink to purple colored spots on the paper except for pyroglutamic acid. The strips were placed in an atmosphere of chlorine vapors for 5 min., allowed to hang in a hood overnight, and then sprayed with a starch–potassium iodide solution to show the pyroglutamic acid as a blue-black spot on a light blue background (10). The R_f values calculated for the various amino acids of interest were:

DL-Glutamine	0.22
DL-, L-, and L(+) Glutamic acid	0.29
γ Amino butyric acid	0.52
Glutathione	0.55
Pyroglutamic acid	0.68

Synthesis of Labeled Pyroglutamic Acid.—A measured solution of glutamic acid-1-^{14}C, buffered to a pH of 2.0 with hydrochloric acid, was sealed in a glass ampul, and placed in an oven at 130° for 72 hr. After the ampul was cooled, it was opened and a sample subjected to paper chromatographic examination. The paper strips, after chromatography, were run through a chromatogram scanner, model RSC-160 by Atomic Accessories, Inc., at a rate of 1.5 in./min. with a constant flow of Geiger gas. The rate meter attachment was a Tracermatic by Tracer Labs. Standard curves of glutamic and pyroglutamic acid were obtained by plotting for a scan of a given number of counts per minute the area under the curve in centimeters against the number of gamma's of isotope spotted. The conversion of glutamic acid to pyroglutamic acid was nearly quantitative.

Liquid Scintillation Detection.—To increase the sensitivity for the detection of micro quantities of the amino acids in the tissue samples, the paper strips were cut into small portions and placed in scintillation fluid. The fluid used consisted of 0.1 Gm. of 1,4-di-2-(5-phenyloxazolyl)-benzene, 14 Gm. of 2,5-diphenyloxazole, 100 Gm. of naphthalene (C.P.), and sufficient dioxane to make 2 L. The liquid scintillation counter was from Baird Atomic, Inc. From the R_f values for the various amino acids, the activity found in various portions of the paper strips could be identified.

Comments on the Analytical Procedures.—It was found that the paper strip could not be chlorinated before spraying with ninhydrin if the ninhydrin-positive amino acids were to be detected. It was also noted that the chlorination step could not be speeded up without a loss of sensitivity. Thin-layer chromatography was tried. Satisfactory separation of the amino acids was not obtained.

BIOLOGICAL TESTING

Investigation with Rabbits.—A fasted rabbit was fed 200 μl. of glutamic acid-1-^{14}C, which contained 20 μc. of activity in 20 Gm. of glutamic acid carrier. After administration of the drug, 2-ml. samples of blood were obtained from the rabbit by cardiac punctures at 0.5, 1, 2, 3, 4, 6, 18, and 24-hr. intervals. One milliliter of a 10% solution of trichloroacetic acid was added to the blood sample, the suspension mixed, centrifuged, and the clear supernatant fluid separated. A 100-μl. sample of the supernatant was spotted on a strip of Whatman No. 1 chromatography paper and the strips chromatographed in the previously described developing system. The strips were allowed to develop for 6 hr., dried, and run through the chromatogram scanner with a rate meter attached. A 250-μl. sample of the supernatant fluid was added to 15 ml. of scintillation fluid in low ^{40}K vials, the mixture shaken, and counted in a liquid scintillation counter to give the total activity for the sample. Portions of the chromatographed strips were treated with scintillation fluid and the resulting solutions counted as before. From the R_f values found for the various amino acids, the source of radioactivity found in the samples could be identified.

The pyroglutamic acid-1-^{14}C, which had been prepared from the labeled glutamic acid, was fed to a 2.5-Kg. rabbit. The procedure followed was the same as for the labeled glutamic acid study except that 300 μl. of pyroglutamic acid-1-^{14}C in a 3-Gm. carrier solution of pyroglutamic acid was used as the dose.

Investigation with Mice.—Three white mice, each weighing approximately 20 Gm., were fed 1 ml. of a glutamic acid carrier solution which contained 1 μc. of glutamic acid-1-^{14}C. After 3 hr., the mice were heparinized and sacrificed. The blood from the three mice was pooled, the protein precipitated with trichloroacetic acid, the mixture centrifuged, and the supernatant fluid separated. The brain was enucleated from each mouse and washed with three portions of sterile saline solution at 5°. The brains from the three mice were pooled, homogenized with 2 ml. of cold saline solution, the mixture centrifuged, and the clear liquid collected. The kidneys of each mouse were treated in a similar manner. Control tissues were similarly prepared from untreated mice. Fifty microliters of the three different tissue samples were spotted on strips of Whatman No. 1 chromatography paper. The strips were developed in the previously described manner. The chromatographed strips after drying were run through the chromatogram scanner. No clearly defined areas of radioactivity could be detected. The strips were then cut into sections and placed in ^{40}K free glass vials, each containing 15 ml. of scintillation fluid. Radioactivity was detected in some of the vials. Knowing the area (R_f) of the

strip associated with the vials having radioactivity, it was possible to predict the amino acids involved.

The entire procedure was repeated with groups of three mice being fed pyroglutamic acid-1-^{14}C. The dosage was the same as for the glutamic acid study.

RESULTS AND DISCUSSION

In the synthesis of the labeled pyroglutamic acid from the labeled glutamic acid, it was found that the 72-hr. heating at 130° gave better than a 98% conversion of glutamic acid to pyroglutamic acid. Heating for 24 hr. at the same temperature gave about a 95% conversion, while heating at 100° for 24 hr. gave only about an 80% conversion.

Tables I and II summarize the distribution of the different labeled amino acids found in the various tissues after the oral administration of labeled glutamic and pyroglutamic acid to rabbits and mice. No attempt was made to determine absorption rates. However, when the total concentration of labeled pyroglutamic acid and labeled glutamic acid in the tissues studied are compared it can be seen that at the 3 hr. sampling time, despite a lower dose being given, the pyroglutamic acid is more completely absorbed.

The paper strips which contained the chromatographed samples from the blood of the rabbits fed labeled glutamic acid showed only the presence of glutamic acid and pyroglutamic acid when they were run through the chromatogram scanner. The acids were identified by their R_f values on the paper, as well as their color following spraying of the strips with the described indicator solutions. The presence of labeled glutamine in the blood samples was not detected until the strips were cut into sections and examined with the liquid scintillation counter. The highest radioactivity levels in the blood were found between 2 and 4 hr. after oral administration of the labeled glutamic acid. These activity levels were found to be equivalent to approximately 4% of the administered dose of labeled drug. The chromatogram scanner did not differentiate the radioactivity source on paper strips prepared from the blood of rabbits fed the labeled pyroglutamic acid. It was possible, however, to differentiate the amino acids containing the radioactivity using the liquid scintillation counter.

In the mice, the highest tissue concentration of radioactivity was found to be between 2 and 4 hr. after administration of the labeled acids. In all of the studies with mice, the chromatogram scanner was not able to differentiate the sources of radioactivity in the tissues examined. After 3 hr., the mice which had been fed the labeled glutamic acid were found to have the greatest concentration of radioactivity in the kidney, while after pyroglutamic acid adminstration the highest activity was found in the blood.

Attempts to obtain autoradiograms from contact of the chromatographed strips with X-ray film were not successful. Various concentrations of the tissue fluids were chromatographed as well as various development times were tried for the X-ray film. It was thought that the autoradiograms might give a second method for checking R_f values for the labeled amino acids.

SUMMARY

It has been found that the metabolism of labeled glutamic acid and pyroglutamic acid in mice can be followed using a combination of paper chromatography and liquid scintillation counting. Labeled pyroglutamic acid was found to be absorbed after oral administration and converted to glutamic acid. The labeled glutamic acid was further found to be present in brain tissue while the pyroglutamic acid was not found in the brain tissue at any time. Thus, it might be possible to obtain a therapeutic response similar to that of glutamic acid after oral administration of pyroglutamic acid.

Alkaloids of *Scopolia carniolica*

By SANTO W. ZITO and JOHN D. LEARY

The alkaloid composition of the rhizomes of *Scopolia carniolica* Jacq. has been investigated and the identification of six alkaloids is reported. Three of these alkaloids have been reported previously and are confirmed in this report. Moreover, the authors report here for the first time the presence of 3-α-tigloyloxytropane in the genus *Scopolia;* in addition, pseudotropine and cuscohygrine are reported in this plant for the first time. One other alkaloid could not be identified at this time.

SCOPOLIA CARNIOLICA Jacq., a member of the family *Solanaceae*, is well known for its content of the tropane ester alkaloids hyoscyamine and scopolamine, and for the hydramine, tropine (1). Evidence for the existence of alkaloids other than those mentioned is without firm foundation. Bendik *et al.* (2) detected the presence of scopine in addition to the previously mentioned bases, and Schreiber (3) reported on the presence of solanidine in this plant as well as in many other members of the nightshade family; neither of these bases could be confirmed in this work. Another report suggests the presence of alkaloids which were not identified (4).

The dried rhizomes were extracted by two different methods, subjected to preliminary purification, and were analyzed for the presence of alkaloids by paper partition and thin-layer chromatographic procedures. Examination of the chromatograms revealed the presence of seven alkaloids, three of which were previously identified.

EXPERIMENTAL

Extraction.—The dried rhizomes[1] were extracted by two different procedures. The first method involved continuous extraction with methanol in a Soxhlet apparatus (5) until devoid of alkaloids when tested with Mayer's reagent. The methanol extract was concentrated to a viscous solution at 40° *in vacuo*, diluted with water, and acidified to pH 2 with hydrochloric acid. The aqueous solution was exhaustively extracted with chloroform (fraction A). The aqueous phase was then adjusted to pH 10 with 20% sodium hydroxide solution and extracted anew with chloroform (fraction B). Each of these fractions was submitted to analysis by paper and thin-layer chromatography.

In the second method the drug was moistened overnight with water and was then intimately mixed with calcium hydroxide according to the method of Evans and Stevenson (6). The basified drug was stirred with solvent ether during the next 2 hr.; the supernatant liquid was decanted, and the marc was further percolated with solvent ether until the percolate gave a negative test for the presence of alkaloids. The ether extracts were combined and concentrated at 40° *in vacuo;* the viscous extract was fractionated on a buffered kieselguhr column.

Column Partition Chromatography.—The concentrated extracts from Evans' method were placed on a column of kieselguhr (30 Gm.) loaded with phosphate buffer (15 ml.; pH 6.6). Elution was carried out with successive portions of petroleum ether, solvent ether, chloroform, and chloroform saturated with concentrated ammonium hydroxide solution. Petroleum ether gave an oily material which gave a questionable Dragendorff-positive spot of high R_f value on paper and thin-layer chromatograms (see below). Ether eluted hyoscine followed by 3-α-tigloyloxytropane; chloroform removed hyoscyamine and an unidentified material. The ammoniacal chloroform afforded tropine, pseudotropine, and cuscohygrine. Identifications were based on elution patterns on the buffered column which coincided with previously reported results (6), as well as by comparison of the extracts with known compounds in the chromatographic systems mentioned later.

Paper Partition Chromatography.—Whatman No. 1 paper was impregnated with 0.5 *M* KCl solution, air dried, and used for the separation of the various extracts and reference compounds,[2] used singly and in mixtures. Development of the chromatograms was achieved with the solvent system of Rother *et al.* (7) which consisted of *n*-butanol–concentrated hydrochloric acid (98:2) saturated with water. Revelation of the alkaloids was effected with modified Dragendorff's reagent (8). Two other partition systems were used but were not as successful in complete resolution of the mixtures.

Thin-Layer Chromatography.—A matrix of aluminum oxide G (Brinkmann) was prepared by the standard procedure (0.250 mm.), and the plates were activated at 110° for 30 min. Extracts of the plant in addition to reference compounds, singly and admixtures, were developed with a solvent system of benzene–methanol (9:1); extracts suspected of containing cuscohygrine were developed with a mixture of benzene–methanol–diethylamine (99:1:5). Revelation of the alkaloids was achieved with modified Dragendorff's reagent.

The data for the chromatographic studies are summarized in Table I.

RESULTS

Extracts of the rhizomes of *S. carniolica* obtained by two different methods have yielded fractions which were analyzed by several paper and thin-layer chromatographic procedures. Maximum resolution was achieved in the two systems which are reported. The development of purple spots in the case of tropine and pseudotropine-containing extracts aided materially in their identification. Identification was effected by means of elution patterns on a kieselguhr-phosphate buffer column,

Hyoscyamine	0.48	0.43
3-α-Tigloyloxytropane	0.84	0.63

[a] Whatman No. 1 paper (0.5 *M* KCl); *n*-butanol–HCl (98:2) water-saturated. [b] Aluminum oxide G; benzene–methanol (9:1). [c] Aluminum oxide G; benzene–methanol–diethylamine (99:1:5).

comparison of R_f values of compounds in extracts when analyzed by paper and thin-layer chromatographic procedures with authentic compounds, and color reactions.

The data indicate the presence of at least seven alkaloids. Identification of hyoscyamine, scopolamine, and tropine corroborates the studies of previous workers. This work has succeeded in the tentative identification of 3-α-tigloyloxytropane, the first reported occurrence of this compound in the genus *Scopolia;* it extends the distribution to still another genus of the family *Solanaceae* along with *Datura* (6), *Withania* (5), and *Physalis* (9). It also broadens the knowledge of the existence of cuscohygrine in plants containing tropane alkaloids. Pseudotropine was the sixth alkaloid to be identified. One other alkaloid remains to be identified. Failure to confirm the presence of scopine and solanidine in this sample was due to a lack of authentic reference compounds.

Work is continuing and complete details on the extraction, isolation, and characterization will be published at a later date.

Synthesis of *N,N'*-Haloacyl Analogs of *p,p'*-Oxydianiline as Potential Antineoplastic Agents

By WILLIAM D. ROLL

A series of eight new haloacetyl and halopropionyl derivatives of *p,p'*-oxydianiline have been synthesized for evaluation of anticarcinogenic activity.

AS AN INTEGRAL part of this continuing cancer chemotherapy research project, another series of bis-haloamide analogs of a parent diamine molecule have been prepared. Based upon the screening data obtained in this laboratory (1–3) and that from others in the field (4–7), the chemotherapeutic activity of such compounds is deserving of further study. This report concerns itself with the synthesis of a series of bis-haloacetyl and bis-halopropionyl derivatives of *p,p'*-oxydianiline (I).

This type of alkylating agent may inhibit the growth of cancer cells through selective inhibition of vital metabolic activities within tumor cells (8–15). By varying the carrier moieties of these active, relatively nontoxic compounds, it is hoped that some insight will be gained as to structure–activity relationships as regards their alkylating abilities.

DISCUSSION

An anhydrous chloroform solution of the diamine, *p,p'*-oxydianiline[1] (I), was treated with a chloroform solution of chloroacetyl chloride, 2-chloropropionyl chloride, and 3-chloropropionyl chloride to form,

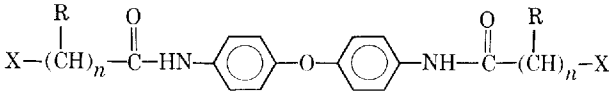
A series of eight new haloacetyl and halopropionyl derivatives of *p,p'*-oxydianiline have been synthesized for evaluation of anticarcinogenic activity.

AS AN INTEGRAL part of this continuing cancer chemotherapy research project, another series of bis-haloamide analogs of a parent diamine molecule have been prepared. Based upon the screening data obtained in this laboratory (1–3) and that from others in the field (4–7), the chemotherapeutic activity of such compounds is deserving of further study. This report concerns itself with the synthesis of a series of bis-haloacetyl and bis-halopropionyl derivatives of *p,p'*-oxydianiline (I).

This type of alkylating agent may inhibit the growth of cancer cells through selective inhibition of vital metabolic activities within tumor cells (8–15). By varying the carrier moieties of these active, relatively nontoxic compounds, it is hoped that some insight will be gained as to structure–activity relationships as regards their alkylating abilities.

DISCUSSION

An anhydrous chloroform solution of the diamine, *p,p'*-oxydianiline[1] (I), was treated with a chloroform solution of chloroacetyl chloride, 2-chloropropionyl chloride, and 3-chloropropionyl chloride to form,



X = Br, Cl, and I
R = H, n = 1,2
R = CH_3, n = 1

respectively, *N,N'*-bis(chloroacetyl)-*p,p'*-oxydianiline (II), *N,N'*-bis(2-chloropropionyl)-*p,p'*-oxydianiline (III), and *N,N'*-bis(3-chloropropionyl)-*p,p'*-oxydianiline (IV). Similarly, the reaction of I with bromoacetyl bromide, 2-bromopropionyl bromide, and 3-bromopropionyl chloride gave the corresponding diamides, compounds V, VI, and VII, respectively. Compounds V and VII were converted into the iodoamides, compounds VIII and IX, respectively, by treating the former with sodium iodide in acetone.

EXPERIMENTAL

The procedure used for the synthesis of these compounds has been previously related (2). Reference may be made to Table I for the results of this synthetic work and properties of the compounds prepared. The melting points were determined with a Fisher-Johns melting point apparatus and are corrected. The infrared spectra were obtained with a Perkin Elmer Infracord.

Growth of Callus Tissue of *Catharanthus roseus* in Suspension Culture

By DAVID P. CAREW

The successful suspension culture of *Catharanthus roseus* (L.) G. Don callus tissue for an indefinite period of time has been accomplished. The growth rates of the suspension cultures, which were grown in media with and without growth substances, are reported. Alkaloids were detected in both the tissue and the media.

THE IMPORTANCE of *Catharanthus roseus* (L.) G. Don (*Vinca rosea* L.) as a source of anticancer alkaloids is well established (1). The report of the 1964 Symposium on the Chemistry and Biological Activity of Catharanthus, Vinca, and Related Indole Alkaloids (2) provides considerable information on this subject. The literature also contains reports on the growth of *C. roseus* as a tissue culture (3–7) and of the presence of alkaloids in *Catharanthus* callus tissue. Previous tissue culture studies of *C. roseus* have been concerned with growth on solid media. This paper reports a study of *C. roseus* tissues grown in suspension culture over a period of several months.

EXPERIMENTAL

Plant Tissues and Media.—Callus cultures of *C. roseus* which had been growing on solid media for more than 3 years provided the source of tissue for initiation of suspension cultures. The solid nutrient medium was a modified White's formula containing 15% coconut water and 3 mg./L. of 2,4-dichlorophenoxyacetic acid (2,4-D) (3). A preliminary study revealed that while a modified White's medium provided excellent nutrition for the growth of *C. roseus* tissues cultured on solid media, a modified Wood and Braun medium (5) was preferable for suspension culture. The modified Wood and Braun medium as reported previously (5) was used as a basal medium throughout this study.

Inoculation, Growth, and Transfer Procedures.—Suspension cultures of *C. roseus* were initiated by aseptically inoculating 100 ml. of Wood and Braun's modified medium contained in 500-ml. conical flasks, with approximately 3 Gm. of callus tissue which had been growing on solid media. The inoculated flasks were placed on an Eberbach rotating shaker which operated at 160 r.p.m. on a 1.5 in. circle. The shaker was located in a dark room maintained at a temperature of 26°. Once suspension cultures were successfully established these tissues were used as inocula for initiating continuing suspension culture studies. A circular metal scoop with a perforated base, 1 cm. in diameter and 0.7 cm. in depth, was constructed and used to transfer suspension cells to fresh liquid media. The scoop was attached to the handle of a conventional inoculating needle and the unit was easily sterilized by flaming. Numerous transfers of tissue were made and their weights determined in order to find the approximate average weight of tissue contained in one scoop. The average figure was found to be 255 mg.

In an attempt to determine the effect of naphthaleneacetic acid (NAA) and kinetin on the growth of continuing suspension cultures, two media formulations were studied. One medium consisted of Wood and Braun's basal medium without the presence of either kinetin or NAA. A second formula contained the basal medium plus NAA, 1 mg./L., and kinetin, 0.5 mg./L.

The procedure for inoculating and subsequently continuing growth of the suspension cultures was the following. The appropriate medium was prepared and adjusted to pH 5.8 and placed in conical flasks (100-ml./500-ml. flask). The flasks were plugged with cotton and sterilized by autoclaving for 15 min. at 15 p.s.i. One hundred milliliters of media was inoculated by the aseptic addition of five scoops of suspended cells (approximately 1.275 Gm.). The inoculated flasks were placed on a rotating shaker. The suspension cultures were observed daily and at the end of the growth period the flasks were removed from the shaker. At that time some of the suspended cells were aseptically removed for the purpose of inoculating new media. The remainder of the suspended cells were collected on filter paper as the cell-media suspension was passed through a Büchner funnel. The fresh weight of the tissue from each flask was determined and recorded. In each case the tissue which had been removed for inoculation of new media was included in the total fresh weight figure. The tissue which was collected on the filter paper was wrapped in aluminum foil and frozen for later chemical investigation. The results of the growth rate study are recorded in Tables I and II. As noted in these tables, five series of suspension cultures, each series consisting of from 10 to 20 cultures, were grown on media with NAA and kinetin, while 10 series of cultures were grown on the basal medium without the addition of any growth substance.

In a separate experiment suspension cultures of *C. roseus* were grown in 250-ml. conical flasks, some of conventional design and others containing three baffles in the base of each flask. The baffled flasks are a product of Bellco Glass Co. The purpose of this experiment was to determine if increased agitation and aeration of cells would have any effect on the growth rate. The 250-ml. conical flasks each contained 50 ml. of sterile Wood and Braun medium with kinetin, 0.5 mg./L., and NAA, 1 mg./L. A suspension culture inoculum of approximately 765 mg. was aseptically placed in each flask of sterile medium. Both the conventional and the triple-baffled flasks were placed on an Eberbach rotating shaker which operated at 160 r.p.m. Two growth cycles were evaluated and the growth rates of tissues

cultured in the two types of flasks were compared. In each case the tissue was harvested after 54 days.

RESULTS AND DISCUSSION

It has been demonstrated that *C. roseus* tissue cultures can be grown under submerged conditions and it appears, that providing proper subculturing procedures are performed, growth can be carried on indefinitely. In the experiment employing growth substances, the concentration used in liquid media was considerably less than that employed previously in solid media. In fact, it was found in one experiment with suspension cultures that the tissue required no added growth substance in the medium. The mean fresh weight, per flask, of tissue grown in a medium without NAA and kinetin was 17.646 Gm. while the average fresh weight of tissue grown on a medium with these growth factors was 17.938 Gm. In each instance the weight of inoculum was about 1.3 Gm. Several previous attempts to maintain *C. roseus* tissue cultures on solid media without growth substances met with only limited success. The tissue grew very slowly, especially in comparison to tissue grown on media with growth substances.

In the flasks of media without growth substances there was never evidence of tissue differentiation. Furthermore, on several occasions suspension cells were transferred to solid nutrient media without growth substances and in no instance was there evidence of differentiation which has been reported under similar circumstances with other tissues.

Despite the fact that the suspension cultures were conditioned to the media over a considerable period of time, very little growth appeared in the first 3 weeks after cells were transferred to new media. After this 3-week "lag" period growth occurred at a rapid rate for approximately 3 weeks. In flasks in which the cells remained as clumps or clusters, as opposed to those flasks in which the cells were finely dispersed, there was much slower growth. In a few flasks very little growth occurred and the clumps of cells at the end of the growth period appeared about the same as at the beginning. Problems of microorganism contamination were encountered as are indicated in Tables I and II. No growth rates were determined for flasks of tissue which became contaminated.

In the experiment concerned with cultures in conventional and baffled flasks it was found that suspension cultures in conventional conical flasks grew at a significantly faster rate than did cultures in the triple-baffled flasks. Apparently the increased agitation and aeration does not improve the growth rate but in fact may be detrimental to growth.

A qualitative examination of the tissues and the spent media from this study revealed the presence of several alkaloids in both the tissue and the media. The suspension culture of *C. roseus* is presently being scaled up from 500-ml. flasks to multiliter fermentors.

Molecular Interaction of Stereoisomers When in Solid State

By A. H. BECKETT and N. H. CHOULIS

Studies of acid-base association of asymmetric molecules in the solid state, involving the determination of melting points of the formed diastereoisomeric salts, their infrared spectra, and for a number of examples, X-ray diffraction powder photography, have been carried out. In these examples, in which crystalline salts were obtained using optically active acids and bases, the diastereoisomeric salts prepared from components of the same configuration had higher melting points than those of different configuration. Although infrared measurements could not be used to indicate configuration of the components, definite differences in the spectrum of salts formed from isomers of like configuration from those of unlike configuration have been observed; likewise, the X-ray diffraction pattern was different.

JAROWSKI AND Hartung (2), working with the mandelates of ephedrine-type molecules, showed some correlation between chemical structure and physiological properties; they also reported the melting points of the salts formed. However, no attempt was made to interpret the differences in melting points in terms of differences in the geometry of the components of these diastereoisomeric salts.

Ricci (3) discussed the principles of the quasi-racemic method of configurational assignment and concluded that molecular interactions in a system of two substances of opposite configuration cause negative deviation from ideality as compared to the phase equilibrium in the corresponding system between related configurations.

Differences observed in infrared spectra of diastereoisomeric salts have already been the subject of another paper (1).

The X-ray method has been used by Bijvoet *et al.* (4) to deduce configurations and also by examining X-ray photographs (5–7), the degree of association of the molecules within the diastereoisomeric salts.

In the present investigation, melting point measurements, infrared spectra evaluations, and X-ray diffraction powder photographs of a number of different diastereoisomeric compounds have been examined.

EXPERIMENTAL

Materials.—The optically active acids and bases used are these recorded in Table I.

The signs D- and L- refer to the absolute configuration of the compounds used.

Preparation of the Salts.—Equimolar quantities (about 0.5 Gm.) of the appropriate acid and base were dissolved in an appropriate solvent (*e.g.*, methyl or ethyl alcohol, ether, etc.) under reflux. The solution was cooled and placed in the refrigerator until crystals separated. These crystals were filtered off, dried under vacuum, and melting points were taken; these salts were recrystallized to constant melting points.

The substance (small quantity in a melting point tube) was placed in the melting point apparatus when the temperature was about 10° below the melting point. Heating at a rate of about 2°/min. was then carried out.

Received April 25, 1966, from the School of Pharmacy, Texas Southern University, Houston.

Accepted for publication July 11, 1966.

Presented to the Drug Standards, Analysis and Control Section, A.PH.A. Academy of Pharmaceutical Sciences, Dallas meeting, April 1966.

This work was carried out at Chelsea School of Pharmacy, London, England, as partial requirement for a Ph.D. thesis under a grant from the Greek Foundation Scholarships.

For the infrared spectra Nujol mulls of the salts were prepared (1). The same salts were sent for X-ray diffraction powder photographs.[1]

Instruments.—The following instruments were used: (*a*) the Townson and Mercer melting point apparatus and (*b*) the Unicam S.P. 200 spectrophotometer.

RESULTS

Melting Point Measurements.—The results (Table I) indicate that salts formed from optically active acids and optically active bases, and possessing the same configuration, had a higher melting point than those formed from the corresponding acids and bases of opposite configuration. The latter salts in some cases could only be obtained in the form of oils.

As expected, the melting points of D-acid/D-base salts were similar to those of the corresponding L-acid/L-base salts; L-acid/D-base salts also had the same melting points as D-acid/L-base salts.

X-Ray Diffraction Powder Photography.—The results (Table II) indicate that *d*-values, calculated from the application of Bragg's law (Eq. 1), were not the same for both diastereoisomers (*i.e.*, between D/D and D/L or between L/L and L/D).

$$n\lambda = 2\,d \sin \vartheta^\circ \qquad \text{(Eq. 1)}$$

where

n = order of reflection
λ = wavelength
d = interplanar spacing
ϑ° = angle of deviation from the direct X-ray beam.

DISCUSSION

The results indicated that in the series studied, diastereoisomeric salts, formed from compounds of the same configuration (*e.g.*, D-amphetamine–D-mandelate or L-amphetamine–L-mandelate) have a different arrangement of the molecules, and consequently a difference in association between the isomers, from that of diastereoisomeric salts from compounds of unlike configuration (*e.g.*, D-amphetamine–L-mandelate or L-amphetamine–D-mandelate).

This dissimilarity between the D/D (or L/L) and D/L (or L/D) diastereoisomeric salts was observed in differences in melting points (*e.g.*, D-amphetamine–D-mandelate, m.p. 166°, D-amphetamine–L-mandelate, m.p. 162°), differences in their spectra, and also

[1] The X-ray diffraction powder photographs were carried out by Mr. G. H. Hunt, Overseas Geological Surveys, London, England.

differences in *d*-values in X-ray diffraction powder photographs.

Because of the observed influence of the geometry of the components of diastereoisomeric salts on the melting points of the latter, the use of melting point differences of salts to assign configuration to acids and bases may become possible. For example, the configuration of a base isomer may be determined if an isomer pair of acids of known configuration are available and crystalline salts can be prepared from the base and these two isomeric acids; the higher melting point diastereoisomeric salt will have components of the same configuration (*i.e.*, if a mandelic acid isomer forms a salt, m.p. 166°, with D-amphetamine and one, m.p. 162°, with L-amphetamine, the mandelic acid isomer used would have the D-configuration).

The infrared spectra also showed significant differences between the diastereoisomeric salts formed from stereoisomers of unlike and of like configuration.

However, infrared spectra cannot be used to allocate the configuration of the components (1).

X-Ray diffraction powder photography also showed differences between diastereoisomeric salts, formed from stereoisomers of unlike and of like configuration (*e.g.*, D-amphetamine–D-mandelate and D-amphetamine–L-mandelate) (Table II).

Since these differences were observed between the interplanar spacing (*d*) of the diastereoisomeric salts, it is suggested that there is a difference of packing between the stereoisomers in the crystals.

Smaller *d*-values for the diastereoisomeric salt formed from stereoisomers of like configuration as compared with the diastereoisomeric salt with stereoisomers of unlike configuration, suggested closer packing of the crystals and, therefore, better association. However, the number of examples studied for the X-ray method was not enough to show that this method could be used for configurational assignment and further work is needed.

REVIEWS

Methods in Drug Evaluation. Proceedings of the International Symposium on Methods in Drug Evaluation, Milan, Italy, September, 1965. Edited by P. MANTEGAZZA and F. PICCININI. North-Holland Publishing Co., Amsterdam, The Netherlands, 1966. xii + 580 pp. 16 × 23 cm. Price $16.80.

A number of books discussing the area of drug evaluation have recently been published. These fulfill a need in pharmacology that has been long standing. This newest book has as its stated purpose a critical evaluation of proposed testing methods, not just a long list of literature quotations. This would allow the scientist to choose the method best suited to his requirements. The volume is based upon papers presented at the International Conference on Methods in Drug Evaluation and this may contribute to some of its faults. The book does not have the consistency of structure between chapters that should be present. Many of the chapters (i.e. cardiac glycosides, FFA, anti-inflammatory drugs, etc.) are excellent with the required depth and breadth necessary for accurate reader evaluation, but in contrast other chapters do not fulfill the aims of the book in that they only discuss a limited number of methods that are used by that particular author. This could mislead the fledgling scientist who desires a critical discussion of a particular area in pharmacology. The book does not discuss all areas of pharmacology, although there has been an attempt to include areas of recent interest. It discusses new areas such as radioprotectives, calcitonin, etc., but neglects anticholinergics, antihistamines, anticoagulants, anticonvulsants, etc. The excellence of certain of its chapters, when compared to other published works, suggests the book's usefulness to a school or industrial library, but its partially restricted scope limits its place in the library of the individual scientist.

Textbook of Biochemistry. 9th ed. By BENJAMIN HARROW and ABRAHAM MAZUR. W. B. Saunders Co., West Washington Square, Philadelphia, Pa., 19105, 1966. ix + 648 pp. 17 × 25.5 cm. Price $9.

This new edition of the *Textbook of Biochemistry*, like previous editions, is designed for introductory courses in biochemistry. It contains a clear and precise presentation of biochemistry as it exists today coupled with a flexible course outline rendering it highly adaptable for students in a variety of disciplines. Particularly commendable is the desire of the authors to keep abreast of the rapidly changing developments in the science of biochemistry.

Biochemistry developed first as an outgrowth of organic chemistry, gradually incorporated certain principles of physical chemistry, and, more recently, began to develop unifying concepts of its own. These concepts have emerged from the application of theories and techniques of biology, chemistry, and physics to the study of living systems. This 9th edition incorporates recent significant advances in biochemical thought with an excellent fundamental presentation of biochemically important compounds and their reactions. The reader is provided early in the text with a review of elementary chemical principles as they apply to biochemically significant compounds; these may be considered the unifying concepts of biochemistry. This presentation is followed by an introduction to several more specialized areas of biochemistry and shows certain relationships that exist between chemical structures, their reactivities, and their biological functions. Some of the newer concepts which have resulted in the modification of portions of this edition are the recent elucidation of the structure of cellular macromolecules, proteins, and nucleic acids; newly proposed mechanisms for the regulation of the synthesis of vital cellular compounds; and biochemical genetics.

This well-illustrated, well-documented textbook should provide the student with an excellent introduction to the science of biochemistry. For scientists in allied fields, it should serve as a useful basic reference.

Organic Chemistry. By L. O. SMITH and S. J. CRISTOL. Reinhold Publishing Corp., 430 Park Ave., New York, N. Y. 10022, 1966. xv + 966 pp. 15.5 × 23.5 cm. Price $12.50.

Professor Smith, of Valparaiso University, and Professor Cristol of the University of Colorado, both teachers of chemistry, have prepared a text especially for a full-year organic chemistry course. Their organization differs from that of most other texts on the subject. Traditionally the material is organized by functional groups; some of the more recent books are based on reaction types and mechanisms. In this text, the authors have combined what they felt were the best features of both presentations. The book is divided into five major sections, with the first devoted to introduction and a review of general principles. The second section covers constitution of compounds, nomenclature, fundamental chemical properties, classical methods for determining structure, and structure and physical properties. The third presents the theory and mechanisms of organic reactions. The fourth covers physical principles of measurement. The fifth section provides topics of special interest from which the teacher may select those of pertinence to his courses. Each chapter is followed by study questions and problems.

REVIEWS

Methods in Drug Evaluation. Proceedings of the International Symposium on Methods in Drug Evaluation, Milan, Italy, September, 1965. Edited by P. MANTEGAZZA and F. PICCININI. North-Holland Publishing Co., Amsterdam, The Netherlands, 1966. xii + 580 pp. 16 × 23 cm. Price $16.80.

A number of books discussing the area of drug evaluation have recently been published. These fulfill a need in pharmacology that has been long standing. This newest book has as its stated purpose a critical evaluation of proposed testing methods, not just a long list of literature quotations. This would allow the scientist to choose the method best suited to his requirements. The volume is based upon papers presented at the International Conference on Methods in Drug Evaluation and this may contribute to some of its faults. The book does not have the consistency of structure between chapters that should be present. Many of the chapters (i.e. cardiac glycosides, FFA, anti-inflammatory drugs, etc.) are excellent with the required depth and breadth necessary for accurate reader evaluation, but in contrast other chapters do not fulfill the aims of the book in that they only discuss a limited number of methods that are used by that particular author. This could mislead the fledgling scientist who desires a critical discussion of a particular area in pharmacology. The book does not discuss all areas of pharmacology, although there has been an attempt to include areas of recent interest. It discusses new areas such as radioprotectives, calcitonin, etc., but neglects anticholinergics, antihistamines, anticoagulants, anticonvulsants, etc. The excellence of certain of its chapters, when compared to other published works, suggests the book's usefulness to a school or industrial library, but its partially restricted scope limits its place in the library of the individual scientist.

Husa's Pharmaceutical Dispensing. 6th ed. Edited by ERIC W. MARTIN. Mack Publishing Co., Easton, Pa., 1966. vii + 903 pp. 18 × 26 cm. Price $12.00.

More than 30 pharmaceutical authorities have participated in the revision adding new material to make this sixth edition nearly 200 pages longer than the fifth. The format of the book and the topics included are similar to those of the previous edition. However, new information has been incorporated in those areas where it has become available. A section on emulsion stability has been added, several new suspension stabilizers are evaluated, the information on flavors has been expanded, an entire new chapter covers aerosols, and the chapter on drug stability has been updated. Adverse drug reactions are recognized and discussed from the viewpoint that they are a therapeutic incompatibility. Specific organic incompatibilities are included for many recently marketed drugs. Like its predecessor, Husa's sixth edition is a useful reference for both student and practicing pharmacist.

Reaction Mechanisms in Organic Chemistry. By BIANCO TCHOUBAR. American Elsevier Publishing Co., Inc., 52 Vanderbilt Ave., New York, N. Y. 10017, 1966. 197 pp. 14 × 22 cm. Price $8.75.

This work is intended as an introduction to this special field of organic chemistry. It was published originally in France by Dunod and titled "Les Mecanismes Reactionnels el Chimie Organique," and was modified slightly; certain areas have been amplified. The first section of the book covers fundamentals of electronic theory of chemical structure. This includes modern theory of molecular structure, covalency and electron density, polarity and polarizability of covalent bonds, conjugation or mesomerism, and acids and bases. The second part of the book covers reaction mechanisms and rates and deals with the application of electronic theory to the study of reaction mechanisms.

Experimental Pharmaceutical Technology. 2nd ed. By E. L. PARROTT and WITOLD SASKI. Burgess Publishing Co., 426 S. Sixth St., Minneapolis, Minn. 55415, 1965. iv + 276 pp. 21 × 28 cm. Price $5.75. Paperbound.

To bridge the gap between a pharmaceutical preparations course and physical chemistry, the authors have designed a manual which correlates the two. It is designed to acquaint the student with the theoretical, mathematical, and physical relationships, and the practical skills and techniques which characterize various pharmaceutical systems. Solids, solutions, polyphasic systems, and plastic systems are presented. Within each physical state classification, the traditional pharmaceutical classes are considered. As an example—in preparing a suspension, particle size, interfacial tensions, adsorption, stability, viscosity, Stoke's law, and drug solubility must all be considered. The authors use this manual for a three-semester course in pharmaceutical technology, preceded by an orientation course and followed by dispensing pharmacy.

Reaction Mechanisms in Organic Chemistry. By BIANCO TCHOUBAR. American Elsevier Publishing Co., Inc., 52 Vanderbilt Ave., New York, N. Y. 10017, 1966. 197 pp. 14 × 22 cm. Price $8.75.

This work is intended as an introduction to this special field of organic chemistry. It was published originally in France by Dunod and titled "Les Mecanismes Reactionnels el Chimie Organique," and was modified slightly; certain areas have been amplified. The first section of the book covers fundamentals of electronic theory of chemical structure. This includes modern theory of molecular structure, covalency and electron density, polarity and polarizability of covalent bonds, conjugation or mesomerism, and acids and bases. The second part of the book covers reaction mechanisms and rates and deals with the application of electronic theory to the study of reaction mechanisms.

Experimental Pharmaceutical Technology. 2nd ed. By E. L. PARROTT and WITOLD SASKI. Burgess Publishing Co., 426 S. Sixth St., Minneapolis, Minn. 55415, 1965. iv + 276 pp. 21 × 28 cm. Price $5.75. Paperbound.

To bridge the gap between a pharmaceutical preparations course and physical chemistry, the authors have designed a manual which correlates the two. It is designed to acquaint the student with the theoretical, mathematical, and physical relationships, and the practical skills and techniques which characterize various pharmaceutical systems. Solids, solutions, polyphasic systems, and plastic systems are presented. Within each physical state classification, the traditional pharmaceutical classes are considered. As an example—in preparing a suspension, particle size, interfacial tensions, adsorption, stability, viscosity, Stoke's law, and drug solubility must all be considered. The authors use this manual for a three-semester course in pharmaceutical technology, preceded by an orientation course and followed by dispensing pharmacy.

Drug Effects on Animal Performance and the Stress Syndrome

By HERBERT BARRY, III, and JOSEPH P. BUCKLEY

CONTENTS

INTRODUCTION

STRESS is the response of an organism to a variety of challenging and threatening events which inevitably occur and recur throughout life. Each individual's health and survival depend on effective physiological and behavioral responses to stressors on repeated occasions. Many compounds, including those classified as tranquilizers, sedatives, and antidepressants, are used for the purpose of aiding an adaptive response to stressors. The actions of these drugs, administered under stress, may depend partly on their interactions with endocrine and other systems which are stimulated by stressors.

Stressors and Stress Responses.—The environmental stimulus which constitutes the stressor is generally distinguished from the physiological reactions which have been described as the stress syndrome or general adaptation syndrome (1–3). The existence of a stressor is generally inferred from the strength of the noxious stimulus and confirmed by observation of the stress reaction. All environmental events and changes are stimuli which threaten the organism's state of biological equilibrium or homeostasis (4). Those stimuli which merely require slight and well-established adjustments are not considered to be stressors, but any stimulus, if sufficiently intense, may evoke the stress syndrome. Many types of stressors have been classified as biological drives, including hunger, thirst, pain, and excessive heat or cold. The physiological reaction of fatigue, during or after exertion, and the mental state of fear or anxiety, aroused by

Received from the Department of Pharmacology, School of Pharmacy, University of Pittsburgh, Pittsburgh, Pa. 15213.

realistic or unrealistic anticipation of a threatened stressor, likewise are stressors. Deprivation of environmental stimulation for several hours may also be stressful (5). Different types of stressors require different behavioral responses and physiological changes to maintain or restore homeostasis. However, all stressors, if sufficiently intense and prolonged, evoke the general adaptation syndrome, with the successive stages of alarm reaction, adaptation, and exhaustion.

The various physiological and endocrinological changes in different stages of the general adaptation syndrome are accompanied by behavioral responses which the stressed animal learns and performs. The alarm reaction generally includes vigorous muscular movements of attack or flight to destroy or escape the stressor. If the stress situation cannot be terminated by the initial violent reaction, the animal eventually resumes a more normal response, thus conserving energy and prolonging resistance to exhaustion by means of behavioral as well as physiological adaptation. The initial agitated behavior tends to improve the animal's ability to destroy or escape the stressor but curtails its survival in a situation of severe, inescapable stress. The choice of a therapeutic compound may depend on whether it is needed to enhance the initial alarm reaction or to prolong resistance to exhaustion.

Purposes of This Review.—The present paper attempts to review and evaluate the experimental techniques which have been used to test effects of compounds on behavioral responses to pain, threat of pain, and other stressors. The most frequently used test situations may be classified as measures of avoidance, escape, or approach-avoidance conflict. The physiological and endocrinological reactions involved in the stress syndrome are also summarized and related to the effects of drugs on behavioral performance during stress. The principal purpose of this review is to identify the features of the test situations which influence drug effects on behavioral performance. In order to enable such comparisons, emphasis is placed on techniques which have been used most frequently, such as the conditioned avoidance response, and on those compounds, notably chlorpromazine, whose effects have most commonly been tested with these techniques.

A series of excellent reviews of behavioral effects of drugs (6–10) have included various stressful test situations. Their coverage of the literature was necessarily selective and abbreviated. A comprehensive review of drug effects on the conditioned avoidance response (11) was limited to this one major technique and was primarily concerned with identifying the effects of a wide variety of drugs rather than comparing the various techniques with respect to their measurement of drug effects. Other articles (12–14) have described and evaluated certain selected techniques for testing drug effects on behavioral performance but without any attempt at a comprehensive coverage. Many of the studies described or cited in these prior articles are included in the present review, which aims to provide a new summary and interpretation of accumulated findings rather than merely bringing the literature up to date. Two collections of abstracts, available from the U. S. Public Health Service, have provided a number of useful references: "Psychopharmacology Handbook," vols. 1–3, for publications in 1954–1961, and "Psychopharmacology Abstracts," vols. 1–4, for publications in 1961–1964.

In spite of the fact that the preponderance of studies on behavioral drug effects have been published since 1953, the high and rapidly accelerating rate of output since that time has accumulated several thousand articles, only a small proportion of which can be cited in the present paper. The main criterion for including an article in this review was the description and use of an important behavioral technique for measuring drug effects in a stressful situation. Preference is given to large-scale studies, testing a number of doses of several compounds on a sizable number of animals. Most of the studies have tested drug effects on performance of a previously established avoidance, escape, or conflict response, but some have tested drug effects on acquisition of the response or on persistence of the avoidance during extinction, when removal of the threatened stressor has made it unnecessary for the animal to continue responding to the warning signal. Painful electric shock has been used as the stressor in most studies; objective records of performance have been ensured by automatic recording in almost all of the studies cited, and automatic programming of the experimental events was also used in many of them. The majority of the experiments were performed on rats, but many other species have been used, including mice, dogs, cats, and monkeys in a substantial number of the studies. This review excludes the few pertinent studies on humans. The use of infrahuman animals permits much greater control of the stress conditions and also has the advantage that the data are free from variations due to verbal learning and cultural expectations of the

subjects. The behavioral tests on animals were usually designed to measure general features of motivation and performance which are common to all species, including humans. Certain types of stressful situations have been discussed in the Review Article in the October 1966 issue of *J. Pharm. Sci.* (15) and are not included here. These include the relatively mild stress of exposure to a novel environment, measured by defecation and locomotor activity in the open field test, and test methods which involve manually pinching or otherwise stimulating the animal to elicit a reaction which is observed and rated rather than being automatically recorded. Measurements of forced locomotor activity, also included in this prior review (15), are stressful situations but have generally been used as tests of muscular coordination.

The present review is expected to be particularly useful for those who conduct, direct, or evaluate experiments on animal behavior. The comparisons among commonly used techniques are intended to help in the choice of experimental methods and in the interpretations of the findings, whether the purpose is basic scientific knowledge or screening for clinically useful compounds. However, the authors hope that this review will also be read with appreciation by those with a purely clinical interest in the drugs and by those with a scientific desire for further understanding of the interrelations between drugs and behavior in stressful situations.

MANIPULATIVE RESPONSE

A frequently used test situation is a chamber (Skinner box) equipped to deliver painful electric shocks to the grid floor; the animal is trained to escape or avoid the stressful shocks by means of an "operant" manipulative response, usually pressing a lever or rotating a wheel attached to one of the walls. This situation is generally used for testing drug effects on performance in test situations which last several hours, after the avoidance or escape response has been thoroughly established in a number of prior sessions. Most animals readily learn to press a lever to escape the shock, but many fail to perform the same response consistently in order to avoid the shock. The manipulative avoidance response must compete with an immobile, crouching response to the threat of shock. The test session comprises an inescapable, chronic stress situation in which crouching is a strong behavior tendency; thus, the animal's normal performance and the drug effects show the outcome of a conflict between opposing response tendencies rather than measuring the strength of a simple avoidance response.

Continuous Avoidance.—The procedure of continuous avoidance without a warning signal is one of the most recent of the commonly used behavioral tests. It was devised by Sidman (16) in 1953, at approximately the same time as the beginning of the recent upsurge in rate of publications on behavioral drug effects. The animal receives a brief electric shock at a fixed interval of once every few seconds. Each lever press postpones the next shock by a fixed interval, so that the animal can avoid the shock indefinitely by pressing this lever before the expiration of the fixed interval between shocks. Several different studies on rats (17–20) showed that a low dose of chlorpromazine (CPZ) substantially decreased the rate of avoidance lever presses, thus increasing the number of shocks received. The number of shocks is a more valid measure of the drug effect than the avoidance rate; one of these studies (18) showed an increase in shocks and an increase in the rate of lever presses with a low CPZ dose, because of a tendency for the animal to make a rapid burst of lever presses after each shock. Low doses of reserpine or tetrabenazine likewise markedly impair avoidance, thus increasing the number of shocks received by rats (21, 22) and by monkeys (23). The doses at which these compounds prevent avoidance are too small to cause any marked analgesia or ataxia; however, it is possible that the drugs intensify the immobile, crouching response which competes with the lever-pressing avoidance. Relatively high doses of chlordiazepoxide (17) and alcohol (24) caused only a moderate decrement in lever pressing by rats, and half the anesthetic dose of pentobarbital was required to impair avoidance in monkeys (23).

The avoidance performance of rats improved after injection of adrenocorticotropic hormone (ACTH) or dexamethasone (25). Lysergic acid diethylamide (LSD) improved performance at a low dose and impaired it at higher doses (26). Administration of amphetamine or one of its isomers, at low or moderate doses, increases the rate of lever pressing under a variety of continuous avoidance conditions (19–21, 27–30). A toxic depression of responding is produced by doses only slightly above those inducing maximal stimulation of lever pressing. Even at low doses, there is generally little or no decrease in the number of shocks received; an analysis of lever-pressing inter-response times (21) showed that amphetamine increased the incidence of responses in rapid succession while decreasing the incidence

of the more effective avoidance responses at times shortly before the next shock was scheduled. Two alternative schedules, requiring rats to lick a water tube at a high or low rate for shock avoidance, were used to demonstrate that low doses of amphetamine improved avoidance performance on either schedule, whereas higher doses caused the animals to lick at a faster rate on either schedule (31). Amphetamine greatly increased the rate of lever pressing during nonshock time-out periods which were designated by a visual signal (29). In a procedure with omission of shocks for 0.5-hr. periods without any signal (19), response rates decreased during the nonshock period in nondrug tests but not under dextroamphetamine. Three anticholinergic compounds (scopolamine, atropine, and benactyzine) generally produced an elevation in lever-pressing rate with no consistent effect on the number of shocks received (19, 20); thus, as in the case of amphetamine, efficiency of performance was impaired. Likewise, monkeys responded to scopolamine and atropine with a marked increase in avoidance lever presses and in unnecessary responses during a signaled nonshock period. Much larger doses of methyl scopolamine and methyl atropine were required for equivalent activity, suggesting that the behavioral effects were mediated by central rather than peripheral anticholinergic action (32).

The fact that the continuous avoidance schedule does not require any signals for experimental events facilitates the use of this procedure as one component of a multiple schedule, in which different experimental events are associated with different signals, at different times during the same session. This has the advantage of permitting a comparison of shock avoidance with food-rewarded or other types of performance, in the same animal and session. Drug effects on a continuous avoidance component of a multiple schedule appear to agree well with drug effects reported in other studies on a simple avoidance schedule. CPZ impaired avoidance in rats (33) and in dogs (34) at doses which produced no decrement in other components of the multiple schedule. Doses of amphetamine which greatly increased lever presses during the food-reinforced and time-out stages of the multiple schedule had no consistent effect on the number of shocks received during continuous avoidance (33). A high dose of pentobarbital was required to increase the number of shocks received by rats (33) and by rhesus monkeys (35). Low doses of scopolamine increased the rate of avoidance lever presses, and high doses depressed food-reinforced much more than shock-avoidance lever pressing, in rats (36) and in monkeys (35).

A method for differentiating avoidance from escape performance is through the use of a two-lever system whereby depression of the escape lever terminates the shock, while the separate avoidance lever is ineffective during this shock period. In tests with a variety of compounds (37), low doses of CPZ consistently increased the number of shocks received, indicating impairment of avoidance. Other compounds reliably increasing the occurrence of shocks at low doses include morphine and chlordiazepoxide, whereas high doses were required for detrimental effects of barbiturates, alcohol, and meprobamate. The animals always escaped the shock in nondrug sessions, and much higher doses of CPZ, morphine, and chlordiazepoxide were required to cause escape failures than to impair avoidance, whereas the compounds which required a high dose to impair avoidance were found to cause escape failures at slightly higher doses. An increase in rate of avoidance responses was produced by low doses of dextroamphetamine, cocaine, and anticholinergic compounds. In general, the drug effects in this study (37) agree well with the findings obtained with other continuous avoidance procedures. Detailed analysis of inter-response times, shock escape latencies, and other measures of performance on this two-lever avoidance schedule is feasible with a recently reported system for punched paper tape records and computer analysis (38). With the use of this system, the probability of avoidance responses shortly before shock is scheduled was greatly decreased by CPZ at doses which had little effect on the bursts of response in rapid succession (39).

Warning Signal for Avoidance.—If the continuous avoidance schedule is modified by presentation of a signal several seconds before the shock, rats (40, 41) and monkeys (42) generally do not perform the response until the signal appears. In most studies, the warning signal is presented at fixed or varied intervals, according to a schedule determined by the experimenter rather than by the animal, and lever presses during the intertrial interval have no effect. Generally, the same response which terminates the signal and avoids the shock also terminates the shock if the animal fails to avoid, so that it is possible to compare the drug dosage which impairs avoidance with the higher dose which impairs escape. A crouching tendency interferes with the lever-pressing avoidance response, so that typically only a minority of animals acquire consistent

avoidance performance (43), but the warning signal apparently has a stimulating effect which results in greater resistance to disruption by drugs than is found in continuous avoidance. Six depressant compounds (tetrabenazine, CPZ, chlordiazepoxide, diazepam, meprobamate, and pentobarbital) all impaired continuous avoidance at a lower dose than that which impaired the avoidance response to a warning signal (44, 45). The differential sensitivity of these testing methods was apparently greatest for chlordiazepoxide and smallest for meprobamate and pentobarbital (45). The fact that CPZ and thiopropazate, another phenothiazine, had similar magnitudes of effect on continuous avoidance and on avoidance with a warning signal (46) might be explained by the fact that the continuous avoidance was measured throughout 90 min. after drug administration, whereas avoidance with a warning signal was measured only for the 30 min. of maximum drug effect. Doses of scopolamine and atropine causing a large increase in shocks received by monkeys in a continuous avoidance schedule had less effect on avoidance by monkeys which were required to perform or inhibit an avoidance response by discriminating between two warning signals (32). The drugs produced a much greater detrimental effect with warning signals which were more difficult to discriminate.

Differential drug effects on avoidance with a warning signal in general appear to agree well with findings in continuous avoidance situations. A wheel-turning avoidance response was impaired at much lower doses of CPZ than secobarbital (47) or pentobarbital (48), and the dose required to prevent shock-escape was much greater than the avoidance-blocking dose for CPZ but not for the barbiturates. Morphine appeared to be intermediate in these respects (49). The ratio between escape-blocking and avoidance-blocking doses was reported to be highest for CPZ, intermediate for chlordiazepoxide, diazepam, and meprobamate, and lowest for pentobarbital (45). Avoidance in response to a warning signal was decreased by low doses of anticholinesterase drugs (50, 43, 51) and was increased by dextroamphetamine (52) at a dose which generally caused a toxic decrement of responding in the continuous-avoidance situation. A "trace" avoidance procedure consists of following the 5-sec. warning noise by 5 sec. of silence before the shock is delivered. A dose of chlordiazepoxide, diazepam, and meprobamate, which prevents avoidance during the signal, permits avoidance in the postsignal period, indicating that these drugs tend to delay rather than block the response to the warning signal, whereas in CPZ, pentobarbital, and nondrug tests, the animal generally responds either during the warning signal or not at all (45).

A lever-pressing avoidance response to a warning signal has been used as one component of a multiple schedule, compared with a milk-reinforced approach response in the same sessions. Low doses of CPZ, which greatly decreased avoidance in rats, had little effect on the approach response. Similar differential effects, requiring rather high doses, were induced by meprobamate and reserpine, whereas a high dose of pentobarbital had almost equal effects on avoidance and approach (53). In contrast, LSD, mescaline, serotonin, dextroamphetamine, and iproniazid impaired approach with a much smaller detrimental effect on avoidance (54). In a similar schedule, reserpine had a much greater inhibitory effect on lever pressing by cats for shock avoidance than for milk reward (55). These findings with a multiple schedule agree well with each other and with drug effects on avoidance in other situations.

LOCOMOTOR RESPONSE

Animals may avoid or escape shocks by the more naturally occurring response of running or jumping. Such a procedure has the advantage of enabling quicker and easier training of the avoidance response, with few animals being discarded due to insufficient performance. Drug effects on various locomotor responses have been investigated in many studies.

Avoidance by Running.—A test apparatus which has been widely used, for many years prior to its recent extensive application to drug research, is the two-compartment shuttle box. The animal avoids or escapes the shock by running into the other compartment, usually through a door or across a hurdle; successive trials can be programmed automatically, shifting the shock from one compartment to the other. In a shuttle box for continuous avoidance by mice, low doses of CPZ were found to decrease performance, with one of three strains tested being much more resistant to the drug effect than were the other two (56). A number of investigators have tested drug effects on shuttle-box avoidance by rats or other species in response to a warning signal. Low or moderate doses of CPZ decreased avoidance in rats (57–59), mice (60), and monkeys (61), with much higher doses being required to affect escape. The same doses of CPZ had a greater inhibitory effect on the escape response when shocks were delivered on the same schedule

without the warning signal (indicating a function of the signal in arousing the animal and thus facilitating the escape response) at doses which prevented the avoidance response (57). Reserpine likewise produced a great decrement in shuttle-box avoidance of mice (62, 63), rats (62, 64), cats (65–68), and monkeys (69). A very high, ataxia-inducing dose is required for ethyl alcohol (70) or pentobarbital (61) to impair avoidance. Amphetamine or its congeners effectively improved shuttle-box avoidance of rats (71–73) and cats (68), apparently by decreasing the crouching tendency (72). Performance was also improved by a low dose of benactyzine or LSD (71) and by a high dose of benactyzine, which reduced various rated measures of tension (74), but not by scopolamine, which likewise reduced tension (75). A general excitatory or disinhibitory effect of some compounds which improve avoidance is indicated by the finding that amphetamine and several anticholinergic compounds increased the frequency of incorrect, shuttling responses to a second warning signal which indicated punishment if the animal crossed to the other compartment, whereas it would not be shocked if it remained in the same one (76). Another procedure required animals to remain motionless on the grid floor in order to avoid shock; this response was readily learned in the nondrug condition, and activity was increased by CPZ, imipramine, and methylphenidate in test sessions when shocks were omitted (77). Nearly all other experiments have used some form of active behavior as the avoidance response, so that it is difficult to distinguish the specific drug effect on avoidance performance from a general stimulant or depressant effect.

In general, the shuttle-box avoidance seems to be more readily improved by stimulants and less easily impaired by depressants than is a lever-pressing avoidance response. A higher dose of CPZ was required to block a shuttle-box than lever-press avoidance response in rats (78). Contrary to this finding, the same doses of CPZ, secobarbital, and morphine appeared to produce a greater decrement in avoidance and escape for a shuttle-box than for a wheel-turning response, perhaps because the wheel-turning response was extensively trained to a high level of performance (79). Avoidance performance in the shuttle-box may be impaired by the fact that the animals on each trial are required to return to the compartment in which they previously received shock (13). A four-compartment box (80), permitting the animals to progress in a clockwise or counterclockwise direction, has been shown to improve performance. A still more effective method for increasing the attractiveness of the escape or avoidance response might be a safety compartment where the animals are never shocked, from which they are manually removed before being placed into the starting compartment at the start of each trial.

Rats (81) which were manually placed in the same compartment of a two-compartment shuttle-box, thus never receiving shock in the other compartment, required rather high doses of CPZ and reserpine for inhibition of avoidance. The same conclusion appears to be valid for other studies on effects of CPZ and reserpine in rats (82) and mice (83). Barbiturates, anticholinergics, and meprobamate were even less active in this situation. Drug-induced inhibition of avoidance may have been enhanced in one of these studies (82) by the use of a long, 60-sec. interval before shock, without any warning signal other than placement in the starting compartment of the test box. Rats which have learned to avoid shock by running to a safe compartment at the end of an alley are highly resistant to inhibiting effects of CPZ (84, 85) and other compounds (85). Different groups were trained to run down an alley for food reward, shock escape, or shock avoidance, using a higher shock intensity for the avoidance than escape group in order to equalize nondrug running speed. Most of the compounds had similar effects on the three groups, but amobarbital caused the greatest decrease in avoidance and the smallest decrease in approach speed (85). CPZ does appear to inhibit avoidance performance at relatively low doses in locomotor response situations involving a multiple schedule or a discriminative choice. CPZ greatly impaired avoidance with very little effect on approach, whereas reserpine impaired approach with very little effect on avoidance, in rats trained to avoid shock or approach food during different trials in the same runway (86). Effects of compounds have been studied in a situation with a visual stimulus identifying the correct exit for avoidance or escape from shock (87–91). CPZ decreased avoidance at a low dose, with a higher dose being required to decrease the percentage of correct choices during escape. Benzquinamide, chlordiazepoxide, meprobamate, and hydroxyzine likewise had greater effects on avoidance than on discrimination. In contrast, reserpine and pentobarbital affected both measures of performance almost equally, and alcohol had a greater detrimental effect on discrimination than on avoidance. All of the

compounds required higher doses to suppress escape from the shock than to inhibit avoidance.

Avoidance by Jumping.—When shock is delivered to a grid floor, a response of jumping up to a safe area may provide quicker escape than running across the electrified grid. A rather high dose of CPZ but a fairly low dose of meprobamate was required to inhibit an avoidance response of rats trained to jump onto a stand (92). A relatively high dose of CPZ was required to inhibit a similar avoidance response in rats (93). In mice, an avoidance response of jumping onto a net was not affected by amphetamine and required high doses of CPZ to impair this response (94). Other studies on mice indicated that a jumping avoidance response was more resistant to inhibition by meprobamate and barbiturates than by CPZ, reserpine, and chlordiazepoxide (95–97).

Many investigators have tested drug effects on an avoidance response of jumping onto a vertical pole, which is usually constructed of wood with a rough surface, so that the animal can cling to it and must be removed manually. A number of investigators have shown that rather high doses of CPZ were required to inhibit the pole-jumping avoidance response of rats (98–103). The dose which prevented escape from shock was generally much higher than the avoidance-inhibiting dose. A comparison of pole-jumping with shuttle-box avoidance has been reported in *Peromyscus maniculatus gracilis*, an arboreal species of mice (104). Animals trained in the pole-jumping apparatus acquired a higher percentage of avoidances and were more resistant to suppression of avoidance by CPZ and pentobarbital than animals trained in the shuttle-box. A similar conclusion may be drawn from the report (105) that a much higher dose of a cholinesterase inhibitor was required to suppress avoidance by rats in a pole-jumping than lever-pressing situation.

Pole-jumping avoidance was inhibited in rats by cholinergic compounds (106) and by benzoquinolizine derivatives, monoamine oxidase inhibitors, and catecholamines (107), generally at much lower doses than those required to prevent the escape response. Morphine has also been reported to inhibit the pole-jumping avoidance at a much lower dose than escape (98, 99, 103), whereas pentobarbital and meprobamate impair both avoidance and escape at very high doses, which usually also induce ataxia (98, 99). In general, pole-jumping avoidance was highly resistant to the effects of the above compounds, reserpine (99), and other drugs (103). However, the "secondary conditioned response" of jumping onto the pole as soon as the animal was placed into the chamber, prior to the warning signal, was inhibited by much lower doses, especially by CPZ, meprobamate, and morphine (99). The drug effect on this unnecessarily early avoidance response may be primarily an index of general central nervous system depression.

Avoidance trials have been programmed automatically at regular intervals, using a metal (108) or plastic (109) pole which causes the animals to slide down to the grid floor. With this procedure, avoidance is inhibited by CPZ at lower doses, reserpine at approximately the same doses, and pentobarbital only at higher doses in comparison with brief pole-jumping sessions (108, 109). A finding that CPZ at low doses inhibited pole-jumping avoidance, with very brief intertrial intervals (110), suggests that rapidly repeated trials, in addition to a continuous session, may enhance the inhibitory effect of CPZ. However, even under these conditions a jumping avoidance response seems to be more resistant to inhibition by CPZ than is a lever-pressing avoidance response.

Flinching and Fighting.—A leg-flexion avoidance response by dogs requires only a slight movement, is performed very reliably, and is highly resistant to inhibition by CPZ, meprobamate, phenobarbital, and morphine (111). The dose necessary to prevent shock-escape is much higher than the avoidance-inhibiting dose for CPZ but not for meprobamate and phenobarbital, indicating differential effectiveness of these drugs on performance despite the high dose of each compound necessary to inhibit avoidance. An increase in heart rate during the warning signal (found in nondrug tests) was blocked by the doses of chlorpromazine, phenobarbital, and meprobamate which suppressed avoidance. Morphine, which failed to suppress avoidance, also failed to alter the heart rate response to the warning signal (112). A similar leg-flexion avoidance response in cats (113) was inhibited by cholinergic drugs, and this technique was described as showing an all-or-none effect in comparison with a shuttle-box avoidance response in a different group of cats. When an i.v. injection of *l*-epinephrine was used as the warning signal 30 sec. before shock (114), the leg-flexion avoidance response in dogs was inhibited by a low dose of chlorpromazine which did not block the usual physiological effects of the epinephrine. The conditioned avoidance response may have been weakly established, with the use of a drug as warning signal and the unusually long interval until shock.

Pain threshold is generally measured by gradually increasing the intensity of a painful stimulus until the animal performs an escape or other response. It is difficult to specify whether a drug alters the motivation, the intensity of the stimulus, or the capability for performance, in this as in other behavioral tests. A number of compounds require higher doses to inhibit the initial flinch response to electric shock on a grid floor (115, 116) or foot-licking response on a hot plate (117) than to inhibit the subsequent response of jumping. The effects of several doses of the same compounds have been compared in a test of pain threshold (response to electric stimulation of the tail root) and pole-jumping avoidance in rats (118, 119). Much higher doses of CPZ were required to increase the pain threshold than to decrease the probability of avoiding. A similar differential effect was found with pentobarbital, bulbocapnine, and reserpine. Morphine, and to some degree dextroamphetamine, showed opposite differential effects, with higher doses being required to decrease the probability of avoiding than to increase the pain threshold. Several cholinergic compounds had a similar magnitude of effect on both measures. In mice, a much higher dose of CPZ than morphine was required to inhibit the response of squeaking when electric shock was applied to the tail (120) and to inhibit the reaction when heat was applied on a hot plate (100) or to the tail (121). Contrary to these findings of analgesic effects of morphine, higher doses of morphine were required to inhibit the reaction to these two types of heat stimulation in rats than to inhibit the pole-jump avoidance response (122). Rats which had been trained to terminate a progressively increasing tail shock by turning their head in one direction required a higher dose of morphine than CPZ to cause an elevated shock intensity threshold at which this response occurred (123). In general, tests of pain threshold appear to be rather insensitive to drug effects, requiring high doses of morphine and even higher doses of most other compounds to produce reliable changes. However, analgesic effects with low doses of morphine have been reported using grid shock (124) and ultrasonic pain stimulation (125) in rats and with the jaw-jerk response to electrical stimulation of the tooth pulp in dogs and cats (126). Sympathomimetic compounds have shown analgesic effects, with ACTH and cortisone causing an elevated pain threshold, measured by thermal stimulation of mice on a hot plate (127), and with amphetamine and norepinephrine (NE) likewise causing an elevated pain threshold, measured by the inflamed-foot method in rats (128) and by electric shock to the tooth pulp in guinea pigs (129). Most tests of analgesia have been based on a motor response of flinching, withdrawal, or vocalization. However, a well-trained lever-pressing response has been used successfully in several experiments. With progressively increasing shock on a grid floor, the threshold for a lever-pressing escape response by rats (130) or for an active motor reaction by mice (124) was increased by moderate doses of morphine, sodium salicylate, and acetylsalicylic acid, whereas a sizable dose of pentobarbital had no effect (130). A similar procedure likewise showed analgesic effects with low doses of morphine in monkeys (131).

The startle response to a loud noise associated with painful shocks may be a sensitive measure of anxiety or fear, but there have been few tests of drug effects on this response because of the technical difficulties in constructing and using an appropriate measuring device. Alcohol (13) and amobarbital (132) reduced the motor response to a loud sound when it occurred during a visual warning signal for shock, at doses which had little effect on the startle response to the sound alone. Amobarbital was even more effective in reducing the startle response to shock, without loud noise or warning signal; however, fear rather than pain may have been the principal reaction to the mild shock used (132). A variety of severe stressors have been used for the measurement of drug effects on escape. The speed with which rats escaped from electric shock in a runway was slightly increased by dextroamphetamine and slightly decreased by pentobarbital and chlordiazepoxide (133, 134). Swimming has been used as an escape response, and drug effects may be influenced greatly by variations in the procedures. Barbital (135) and amphetamine (136) greatly slowed swimming of rats to an escape ramp when they were required to pull a weight, at doses with little effect on swimming time under normal conditions. CPZ and meprobamate also decreased swimming speed at fairly low doses, especially when the animals were required to pull a weight, with generally smaller effects on a shuttle-box avoidance response tested in the same rats during the same session (137). Escape of rats from audiogenic stimulation was inhibited by fairly low doses of CPZ but not by high doses of phenobarbital and meprobamate (138, 139). Rats housed and tested in isolation generally fail to escape audiogenic stressors, and amphetamine or other stimulant drugs enabled a substantial proportion of them to escape (140). A lever-pressing escape response has also been used in tests of drug

effects. Amphetamine increased the rate of lever pressing by rats to terminate loud noise (141) and moderate doses of amphetamine increased, CPZ decreased, and pentobarbital briefly decreased rate of lever pressing by rats to turn on a heat lamp in a cold environment (142).

Painful electric shocks on the grid floor may induce pairs of animals to attack each other, indicating that a stressor is likely to elicit aggression if the test situation permits this response. Fighting in rats was inhibited by high doses of CPZ and benactyzine; however, high doses of meprobamate and reserpine had no effect (143, 144). Fighting of mice in response to grid-floor shocks is suppressed by meprobamate and to a lesser degree by CPZ, barbiturates, and chlordiazepoxide (145–147). Another method for inducing aggressive behavior in mice is to house the animal in isolation for several weeks prior to testing with another mouse. Suppression of attack behavior was found at approximately the same dose of CPZ for both techniques, but much higher doses of phenobarbital and meprobamate were necessary to inhibit isolation-induced than shock-induced fighting (148). Isolation-induced aggression of mice was also suppressed by a moderate dose of benactyzine and a very high dose of reserpine (149). A comparison of aggression with analgesia and other behavioral measures showed that isolation-induced fighting was suppressed at a lower dose by CPZ, other phenothiazines, and morphine, but not by barbiturates and meprobamate (150). In a comparison of aggression with shuttle-box avoidance, isolation-induced attack was suppressed at a lower dose by chlordiazepoxide, at the same dose by CPZ, and at a higher dose by pentobarbital and meprobamate (97). The doses of pentobarbital and meprobamate required to suppress aggression also prevented escape from shock in the shuttle-box. Isolation-induced attack has been reported to be inhibited by high doses of LSD, psilocybin, and mescaline (151, 152). The aggressive response to stressors generally appears to be highly resistant to effects of most compounds, even in one study (97) in which it was characterized as being weak and unstable in nondrug tests. A different type of attack behavior, found in a minority of rats, is to kill a mouse placed into the rat's cage. This has been described as aggression but may be related to predatory or feeding behavior, and is highly resistant to drugs. A variety of depressant compounds inhibited this behavior only at severely ataxic doses; hydroxyzine was the only drug tested which abolished the mouse-killing response at a moderate dose (153, 154). However, low doses of several antidepressant compounds effectively inhibit the mouse-killing response (155).

APPROACH–AVOIDANCE CONFLICT

A conflict may readily be established by punishing the animal for responses which procure a desired goal. The stress of the punishment is augmented by the thwarted need for food or other reward formerly obtained, and the conflict itself may be an additional stressor (13). The strength of the opposing approach and avoidance tendencies can be measured only in relation to each other, but this disadvantage is offset by the advantage that the opposing tendencies are likely to be affected equivalently by any drug-produced changes in activity or freezing. This equivalence is not complete, because the approach response is generally acquired first, is more strongly established, and requires more active behavior. Whereas the active lever-pressing or locomotor response is motivated by fear of shock in the usual avoidance test situation, in the conflict test it is the suppression of an active response which is motivated by fear. Therefore, the conflict situation may indicate whether CPZ and other compounds suppress performance of an avoidance response during a warning signal because they intensify an incompatible freezing tendency or because they decrease the fear-producing effect of the signal.

Manipulative Response.—One technique for measuring conflict is to present a signal, terminated by inescapable electric shock, while an animal is pressing a lever for food reward. The "conditioned emotional response" to this stimulus includes "conditioned suppression" of the lever-pressing response. Reserpine, in doses which decreased normal lever-pressing rate, increased the number of responses during the aversive stimulus in rats and monkeys (156, 157) but not in guinea pigs (158). Procedures which caused almost complete suppression of responding by rats during the signal (159–161) prevented any substantial recovery under reserpine. On the other hand, when rats were trained to press a lever in response to a signal that food was available, instead of on the usual free-operant schedule, reserpine greatly increased the rate of suppressed lever pressing during a concurrent signal for inescapable shock (162). Lauener (163) trained rats on a fixed-interval schedule, with water reward obtained by the first lever press 5 sec. or more after the last reward, instead of using the more customary variable-interval schedule. The high, stable performance rate generated is very resistant to disruption by drugs and thus is advantageous for

testing drug effects on conditioned suppression. The responding during the signal was greatly increased by chlordiazepoxide, several barbiturates, and to a lesser degree by meprobamate, but not by CPZ, morphine, ethanol, and amphetamine. Morphine has been reported to increase suppressed responding (164), but most of Lauener's findings are supported by other studies, which show that suppressed responding was greatly increased by amobarbital (165, 166), increased by meprobamate in one study (167), but not in another (162), not increased by CPZ (160, 162), and decreased by amphetamine (156, 157).

A more direct conflict procedure is to punish the animal only when it presses the lever, so that the aversive shock is associated specifically with the food-rewarded lever-pressing response. Comparisons between these procedures have given evidence that reserpine increases responding during a signal for inescapable shock but not when the animal is punished for pressing the lever (156, 157); whereas, meprobamate increases responding during a signal for punishment but not inescapable shock (168). Effects of several compounds have been tested in a conflict situation where lever presses by rats are rewarded on the average of once every 2 min. on an unpredictable, variable-interval schedule, and at periodic intervals a tone is presented for 3 min., during which every lever press is punished by shock and rewarded by food (169–172). The number of lever presses during the conflict signal was increased greatly by meprobamate, substantially by barbiturates and chlordiazepoxide, slightly by reserpine, and decreased by CPZ and morphine, at doses which had little effect on the lever-pressing rate during the unpunished portion of the schedule. Another conflict procedure (173), for rats trained to press a lever for milk in response to a signal, is to accompany this reward signal with an additional stimulus indicating that each of the next four lever presses will be rewarded and also punished. The number of lever presses during the conflict signal was increased by meprobamate and pentobarbital and not by CPZ and reserpine. Punished responding was likewise increased by a barbiturate (amobarbital) but not by CPZ in pigeons pecking a key for food reward on a variable-interval schedule and punished by shock for every response during the conflict signal (174).

When every response is punished during the conflict period, as in the above studies, drug effects might be due to changes in the aversiveness of the shocks, based on the immediately preceding experience with shocks in the same session, rather than being due to changes in fear or avoidance of the threatened shocks. A procedure for measuring fear rather than pain, by omitting shocks during the conflict signal in some test sessions, showed a large increase in lever pressing during the conflict signal under amobarbital but not under the other compounds tested (175). Contrary to the failure of CPZ to increase suppressed responding, in several of the above studies, CPZ produced a slight but reliable increase in lever pressing during the conflict signal in this situation with shocks omitted (175). CPZ produced a large increase in lever pressing during the conflict signal in a study using similar procedures (176) but with a more prolonged duration of the conflict signal.

Drug effects on conflict have been tested in situations without a signal for punishment. Alcohol and amphetamine decreased rate of rewarded and punished lever pressing by rats (177), in agreement with the effects of these drugs during the conflict signal in another study (175). Morphine greatly increased the number of punished water-drinking responses by rats during a prolonged conflict session (178); a similar effect of CPZ during a prolonged conflict signal (176) suggests that the duration of the conflict period may be a factor in the drug effect. In two other studies on rats (179, 180), the frequency of punished drinking responses was increased by meprobamate, amobarbital, and methylpentynol, decreased by CPZ, and not significantly changed by benactyzine. A measure of agitated approach-withdrawal responses showed a decrease under benactyzine (179).

Locomotor Response.—Conditioned suppression of a running response was tested in rats previously trained to obtain water reward by shuttling back and forth in a two-compartment box (181). In this situation, the signal for an inescapable shock caused slightly less suppression of the running response in animals injected with CPZ than in a control group. However, conflict has generally been induced by direct punishment of the locomotor approach response. The use of a long runway permits measures of speed and distance of approach, and provides a test of drug effects on fear of punishment as well as on the immediate effects of punishment. Conger (182) showed that alcohol restored the approach response in rats which had been shocked at the food cup. Measures of strength of pull in the same apparatus showed that alcohol greatly reduced the vigor of running in a shock-avoidance group but not a food-approach group. A further demonstration of the avoidance-reducing effect of alcohol was with a method of omitting shocks after alcohol injection for one group and after

placebo for another group; approach in the nonshock condition was more rapidly learned by the group for which shocks were omitted under alcohol rather than placebo. Barry and Miller (183) devised a "telescope alley" in which progressive changes in runway length signaled increases in shock intensity delivered at the food or water cup, during several trials of the same day. This technique measured drug effects on normal approach speed and on the intensity of punishment or fear of punishment required to prevent the approach response, with repeated tests of the same animals under different drugs on successive test days. Amobarbital and alcohol generally decreased approach speed in the initial safe trial of the day but consistently increased speed and probability of approach in the series of trials with increasing shocks, whether the shocks were delivered or omitted (183–185). Other compounds tested (CPZ, morphine, cocaine, methamphetamine) tended to decrease approach speed, generally with a greater effect in the safe trial than in the conflict test (183). One study gave evidence that CPZ increased approach during trials with shock but decreased approach during trials when shocks were omitted (184).

Drug effects on conflict in a runway or other locomotor situation have also been studied in other species. Amobarbital effectively restored the approach response of cats in a runway (186). In a more complex situation, designed to induce neurotic behavior (187), alcohol restored food-approach responses of cats and had other beneficial effects in the conflict test. A series of studies on cats and monkeys in the same situation (188) showed even greater beneficial effects of barbiturates but little or no effect of reserpine, CPZ, and mephenesin. A similar procedure (189) was used to test effects of several compounds (190) on conflict behavior of cats after food deprivation of only a few hours instead of 24 hr. Approach responses were increased by benactyzine, by related anticholinergic agents, and by alcohol, with no beneficial effect of CPZ and scopolamine. Cats which were punished by electric shock when they seized a mouse resumed the punished response under the influence of a low dose of meprobamate, but high doses of benactyzine and CPZ were required to elicit the response (191). Dogs resumed a punished food-approach response under the influence of barbiturates, alcohol, and meprobamate but not benactyzine (192).

The most consistent finding in the locomotor conflict studies is that barbiturates and alcohol increased approach performance of all species tested, in all of the situations which included tests of these compounds. The failure of alcohol to increase approach in a lever-pressing conflict (175, 177) may be due to the greater detrimental effect of alcohol-induced ataxia on this type of response. CPZ fails to increase approach in both lever-pressing and locomotor conflicts, with a few exceptions (175, 176, 184, 191). Other tranquilizing agents (meprobamate, benactyzine) apparently increase approach responding in some situations but not in others.

Other Conflict Tests.—An approach-avoidance conflict occurs during "experimental extinction," when the cessation of rewards for a learned approach response results in a conflicting avoidance response motivated by the aversive experience of frustration (193, 194). In this situation, the inhibited approach response is increased by amobarbital (193, 195) and by alcohol (193); this drug effect has been attributed to a reduction in frustration-motivated avoidance (193, 194). Likewise, amobarbital gives evidence of counteracting inhibition due to a frustrating schedule in which many of the responses are not rewarded (194, 196, 197) or due to a portion of a schedule associated with nonreward (198). These findings have been reported for locomotor responses of rats (193–197) and for lever pressing by pigeons (196, 198). Responding of rats inhibited by a signal for nonreward was increased by amobarbital in a runway but not in a lever-pressing situation (166), indicating a stronger drug effect for the locomotor response. A temporary increase in lever pressing by rats during the first few minutes of nonreward, attributed to frustration-produced emotionality, was enhanced by CPZ (199). A comparison of this compound with phenobarbital (200) showed that the barbiturate elicited a larger number of unrewarded responses, following a smaller initial increase in lever pressing at the beginning of extinction. Scopolamine and other anticholinergic compounds have been shown to increase preservation and to retard the inhibition caused by nonreward under a wide variety of conditions (201–203). However, scopolamine gave no evidence of diminishing the aversive effects of punishment (201), and the effects of anticholinergic drugs were attributed to a specific antagonism of the inhibitory effects of nonreward (203).

Drugs may help or hinder performance in a conflict situation by affecting the specific motor actions which are required. An example is found in the requirement that a pigeon hold its head for a specified duration in a restricted spot, intersecting two photocell beams, in order to receive food reinforcement (204). The birds were observed to be very excited and agitated in this situation, and the time they were able to remain sufficiently immobile was increased by CPZ and decreased by

pentobarbital. This conflict situation, in which the obstacle to the necessary response is the animal's own motor activity, is one of the few instances in which CPZ has been found to improve the performance of animals.

Drug effects on performance of rats in a complex conflict situation have been reported in a series of studies (205–209). The Lashley jumping apparatus is used to induce a maladaptive, perseverative-choice response during a long series of test sessions. The hungry animal jumps from a platform to one of two windows in a situation where the chosen window has an equal probability of opening to give access to food reward or of punishing the choice by failing to open so that the animal falls into a net below. An electric shock, delivered to the platform after 30 sec., forces the animal to make a choice and adds a further stressor to the situation. These procedures are highly stressful as shown by frequent urination and defecation on the platform and by the fact that the hungry animal usually does not eat on the trials when the door opens to make the food available (205, 206). The maladaptive, perseverative-choice response developed in this situation is highly resistant to therapeutic modification by drugs, but chlordiazepoxide (205, 206) and diazepam (206) gave evidence of reducing emotionality and improved the performance of some animals after a number of days of drug treatment. Under certain conditions, however, the reduced motivation under the influence of chlordiazepoxide prevented animals from acquiring an adaptive choice response (207). The other compounds tested did not have any therapeutic effect in this situation; high doses of CPZ, reserpine, and meprobamate but not phenobarbital gave evidence of reducing avoidance of the shock on the platform by causing the animals to delay jumping to one of the windows under some conditions until the shock was administered (205, 208). The therapeutic effectiveness of a guidance method for breaking a maladaptive, perseverative choice was apparently enhanced by amphetamine and retarded by CPZ and meprobamate (209). The maladaptive, perseverative-choice behavior seems to resemble certain types of neurotic behavior in humans, but this test situation has the disadvantage of being extremely complex, and the behavior was apparently resistant to the rather high drug doses used in these studies.

PERSISTENT BEHAVIOR ALTERATION

Most of the studies reviewed thus far tested the acute effect of a single drug administration on performance which had previously been well established and stabilized. Drug effects on acquisition, extinction, and relearning of responses are also of interest, especially for potential applications to therapy in humans.

Drug Effects on Acquisition.—CPZ (82, 210–214) and reserpine (82, 212) impair performance during acquisition of various types of avoidance responses in rats, but the magnitude of these drug effects does not appear to exceed their inhibitory effects on a well-established avoidance response. The magnitude of the drug effects may depend partly on the test situation; for example, CPZ caused slight decrement in acquisition of runway avoidance, but when the test was made more difficult by requiring the animal to select the lighted one of two adjacent compartments, this compound produced a much greater decrement (213). Likewise, CPZ but not pentobarbital reduced the percentage of rats learning to make the correct choice in a swimming escape situation which was made more stressful by forced immersion for 30 sec. prior to the start of each trial (215).

A variety of depressant drugs have been found to facilitate acquisition of an avoidance response in rats. These include reserpine at low doses (216), amobarbital (212, 217), meprobamate (218), alcohol (219, 220), chlordiazepoxide (221), and benactyzine (222). Some of the drugs which improved shuttle-box avoidance during the warning signal also were shown to increase the frequency of intertrial crossings from one compartment to the other (217–219) indicating that these ordinarily depressant compounds apparently decreased the tendency for immobile, freezing behavior in this stressful situation. These drug effects are influenced by certain characteristics of the test situation. Acquisition of a pole-jumping avoidance response was impaired by amobarbital (223); another pole-jumping situation where amobarbital facilitated acquisition (212) differed in several procedural conditions, including a longer interval between onset of the warning signal and the shock, and a longer intertrial interval. The same dose of benactyzine which improved acquisition of a shuttle-box avoidance response (222) impaired acquisition of a lever-pressing continuous avoidance response (224). On the other hand, a dose of scopolamine which improved acquisition of a lever-pressing continuous avoidance response (225) impaired acquisition of a pole-jump avoidance response (226). Various stimulant compounds have been shown to facilitate acquisition of avoidance, including amphetamine (212

223), pipradol (224), epinephrine (227), and ACTH (228–230).

Acquisition of an approach-avoidance conflict response was studied with the use of a signal that a lever press would deliver water reward to the thirsty rat, with a painful shock being delivered 15 sec. after onset of the signal (231). Inability to control the shock duration apparently enhanced its stressful effect, as indicated in a comparison of rats which escaped the shock by pressing a lever with matched animals which received the shock for the same length of time; after several days of training the latency of drinking was much shorter for the escapable-shock animals than for their paired inescapable-shock controls. A phenothiazine (thioridazine), administered chronically throughout training, substantially decreased the latency of responding, with a greater effect on the inescapable-shock than on the escapable-shock animals. This technique thus gives evidence for a tranquilizing effect of a phenothiazine not usually found with the more commonly used tests of conditioned suppression.

Drug Effects on Extinction.—An animal which always makes the avoidance response when the warning signal is presented will continue to respond unnecessarily even if failure to avoid is no longer punished by shock. Therefore, occasional failures to avoid serve an adaptive purpose, and when the warning signal is repeatedly presented without shocks, in a test of extinction of the avoidance response, excessive persistence of the learned response is maladaptive. However, if animals acquire the avoidance response in a nondrug condition followed by extinction trials under a drug, their performance may be influenced not only by the drug itself but also by the novelty of their drugged condition. It is necessary to have separate drugged and nondrugged groups in acquisition, so that the effects of the drug and of a change in condition can be equalized by changing half the animals of each group to the other condition at the start of extinction (13). The change in condition may have an important effect, as indicated by an experiment in which rats, following punishment for a lever-pressing food-rewarded response, resumed pressing and obtaining food without punishments under the influence of amobarbital but failed to continue pressing the lever in a subsequent placebo test (232). A decrease in avoidance response, due to a change from drugged to placebo or from placebo to drugged condition, has been shown in rats with amobarbital (185), phenobarbital (233), chlordiazepoxide (221), and CPZ (214).

A dose of CPZ which produced a moderate decrement in acquisition of avoidance response also moderately decreased the number of extinction trials before the animals stopped responding to the warning signal (210). CPZ decreased the probability of an avoidance response to the warning signal during extinction (234); all of the animals were in the nondrug condition throughout acquisition, so that the drug effect was associated with a change in condition, but phenobarbital had no effect on extinction performance after nondrug acquisition. CPZ had little effect on extinction of a runway avoidance response (213), but the requirement of a choice response almost completely eliminated avoidance responses during extinction under CPZ. A dose of phenobarbital which had no effect on speed of shock escape in a runway decreased persistence of the response during extinction, when shock was omitted (233). Other compounds have the opposite effect of increasing persistence of avoiding after shocks are omitted. Extinction of shuttle-box avoidance was greatly retarded by a dose of ACTH which had very little effect on acquisition (228). A dose of demeton,[1] which greatly reduced brain cholinesterase also retarded extinction of a platform-jumping avoidance response, with little effect on acquisition (235). Anticholinergic drugs have likewise been shown to increase persistence of avoidance responses in a variety of situations (202, 203).

A passive instead of active avoidance response may be tested by placing a rat in a box which it has previously explored without shock and measuring the amount of time spent in an adjoining, smaller compartment where it previously received painful shock (236–238). Drug effects have been reported with a similar procedure adapted for mice (239). This technique has generally been used as a measure of impairment in the passive avoidance response, presumably due to loss of memory, after administration of anticholinergic drugs. However, prolonged or repeated test sessions would provide a measure of extinction of avoidance.

There have been some studies of drug effects on extinction of avoidance in conflict situations. Rats trained to press a lever for water and punished for this response by shocks normally resumed pressing the lever in subsequent nonshock tests but not if ACTH was administered during punishment and subsequent test sessions (240). A higher level of performance found in animals punished under ACTH and tested without drug than in the placebo group might be due to the

[1] Marketed as Systox by the Chemagro Corp., New York, N. Y.

change in condition (13). Jumping or running was measured as the response to a signal for inescapable shock in mice (241), shocked under CPZ or placebo and all given nonshock extinction trials under placebo. Fewer extinction trials were required to abolish this active response to the signal in the animals which had been given acquisition under CPZ. This might indicate a tendency for CPZ to cause the acquisition of a freezing rather than active response to the signal for inescapable shock. Drug effects on learning to reverse a choice response were tested in rats which were trained to turn their head in one direction to turn off a gradually increasing shock, followed by trials in which only the opposite direction of head-turn escaped the shock (123). The reversal learning was greatly impaired by phenobarbital (123) and by meprobamate (242).

Prolonged Drug Effects.—Most of the studies have investigated the acute effects of a single dose of a compound. The chronic effects of repeated administrations may result in decreased drug effect on behavior, indicating tolerance, or else increased effect, indicating sensitization. Behavioral tolerance to the effect of a high dose of CPZ is shown in the finding (243) that there was progressively less suppression of a locomotor avoidance response on successive test days under the drug. A progressive development of tolerance is indicated by the finding that CPZ produced less decrement in a lever-pressing continuous avoidance response (244) if progressively higher doses were given, starting with a very low dose, than if the doses were given in a descending sequence. A more acute instance of behavioral tolerance is shown by the finding (245) that CPZ caused less decrement in a shuttle-box avoidance response if the test session began immediately after injection, providing a gradual onset of drug effect, rather than at the time of peak drug action. These and other factors influencing behavioral tolerance or sensitization to drug effects may alter the results of experiments, especially those which use repeated administrations of a drug. Furthermore, test compounds themselves are stressors if given in high doses or if they impair the performance of avoidance or escape in a stressful situation. Thus, the development of behavioral tolerance to the drugs may represent the stage of resistance to a chronic stressor.

A different type of response, suitable for measurement of the chronic effects of a prolonged stressor, is an increase or decrease in voluntary consumption of certain drugs. A number of the behavioral tests are designed to assess drug effects in alleviating or intensifying anxiety in a stressful situation. If animals could be trained to consume a drug in order to relieve their anxiety, this might confirm the tranquilizing drug effect and also provide a method for measuring the stress response to various experimental situations. A tendency for an increase in choice of an alcohol solution, during or after stress, has been found in cats (187), rats (246, 247), and monkeys (248). This behavioral response generally seems to be slight, with no resemblance to the human alcoholic's craving for liquor, but it apparently does occur in several species of animals in spite of the obstacles of the delayed pharmacological effect after drinking, the unpleasant effects of excessive quantities, the unpalatability of alcohol solutions except at low concentrations, and the difficulty of inducing consummatory behavior in stressful situations. A technique for self-injection, which may overcome most or all of these obstacles, was used in a study with rats, showing that inescapable electric shocks caused an increase in rate of lever presses which injected amobarbital into their jugular vein (249). Diminution of this response after several 1-hr. sessions indicates the possibility of habituation to the drug or aversive physiological effects of the injected substance. Tests in rats showed that stress failed to increase the choice of a solution containing reserpine (246) and actually decreased the choice of a solution containing chlordiazepoxide (250).

THE STRESS SYNDROME

Selye (1–3) has postulated that organisms subjected to alarming stimuli will respond in a given manner, which he termed "the general adaptation syndrome" or "stress syndrome." Briefly, the general adaptation syndrome (GAS) can be divided into three distinct stages. The first is the alarm reaction, associated with the discharge of adrenocorticotropic hormone (ACTH), cortical steroids, and catecholamines, plus various other physiological changes. The second is the stage of resistance, in which adaptation to the stressor results in a diminished reaction and thus increased resistance. The third is the stage of exhaustion, during which adaptation can no longer be maintained because of prolonged overexposure to the stressor. Different homeostatic adjustments may be aroused by various types of stressors, such as the contrasting stimuli of excessive heat or excessive cold. However, in the case of severe stressors the universal, nonspecific stress syndrome is generally the most prominent response.

Acute Exposure to Stress.—The following physiological responses to stress have been suggested by Selye (3). The stressor (stimulus) acts on the target (the body or some part of it) directly and by way of the pituitary and adrenals. An immediate discharge of ACTH stimulates the release of corticoids from the adrenal cortex. If the stress is extremely severe, the adrenal cortex shows morphologic changes characteristic of hyperactivity. Simultaneously, the animal's corticoid requirement markedly increases and there is an increase in the blood concentration and urinary excretion of corticoids and their metabolites. There is a general stimulation of the sympathetic division of the autonomic nervous system and the splanchnics induce the adrenal medulla to discharge epinephrine (E) and norepinephrine (NE), thus increasing the discharge of NE at various peripheral receptor sites and causing the cardiovascular responses of vasoconstriction and hypertension. Other marked physiological changes include alterations in water and electrolyte metabolism, gluconeogenesis and increased blood sugar levels, alteration in both red and white blood cell counts, and increased renin production by the kidney.

Some of these components of the stress syndrome have been measured in animals which were subjected to painful electric shocks in behavioral test situations. Elevated plasma 17-hydroxycorticosteroid (251) and NE levels (252) have been found in monkeys after sessions of pressing a lever on a continuous shock-avoidance schedule. There was also an increase in plasma steroid and NE levels after sessions of pressing a lever for food rewards in which no shocks were delivered but a conditioned emotional response was aroused by presentation of a clicking noise previously associated with shocks. Aceto *et al.* (109) reported that rats subjected to the pole-climbing avoidance test developed hypertension within 4 weeks. A recent study (253) showed that corticosterone concentration is elevated in rats at the end of a session of inescapable shocks, and an adaptive behavioral function of this physiological response is suggested by the further finding that the animals successfully acquired a shuttle-box avoidance response if they were trained immediately following their exposure to the warning signal paired with inescapable shocks; the animals did not acquire this response if the avoidance training began 1 to 4 hr. afterward, at which time the corticosterone had dropped to a normal level. Inescapable shocks delivered to the grid floor at regular intervals, for 1.5 hr., caused a 38% reduction in brain NE of guinea pigs (254). Another measure of sympathetic activation is the skin resistance of the paws, which was lowered in rats by a severe, single 5-sec. shock to the grid floor (255).

Compounds Altering Acute Stress Response.—There is potential clinical value as well as basic scientific information to be gained by identifying compounds which alleviate or aggravate the components of the stress syndrome. Several compounds have shown evidence of protective effects, with somewhat conflicting findings for CPZ. The large decline in brain-stem NE in rats, resulting from the stressor of inescapable electric shocks on the grid floor, was partly reversed by large doses of CPZ and pentobarbital but not by morphine (256). In another study, the decrease in adrenal ascorbic acid in rats due to the stressor of excessive heat or cold was partly counteracted by a moderate dose of CPZ and by a low dose of reserpine (257). A large CPZ dose had a similar effect on rats subjected to restraint at room temperature (258). The increase in blood glucose after rotation stress was partly counteracted by methylpentynol but not by CPZ (259). Sedative doses of CPZ and other phenothiazines have been reported to stimulate secretion of ACTH, mimicking the effect of exposure to cold temperature (260).

Stress increases the urinary excretion of catecholamines, especially E (261–263). Although E is the main catecholamine excreted in the urine during stress, a more important component of the stress response might be the general stimulation of the sympathetic nervous system and the increased discharge of NE at the peripheral receptor sites. Since the uptake of NE at the peripheral receptor site is very rapid, a more prolonged physiological change may be preferable as a measure of the stress response. Maickel *et al.* (264) reported that adipose tissue lipase was stimulated and plasma free fatty acid (FFA) elevated in rats by catecholamines, ganglionic stimulants, and exposure to cold, but plasma FFA was unaffected by cold exposure in the absence of a functional sympathetic nervous system. Gilgen *et al.* (265) found that an intact sympathetic nervous system was essential for increasing the output of FFA and glucose on exposure to cold and concluded that NE at peripheral nerve endings was essential for this reaction. Plasma FFA levels in rats are significantly increased by inescapable electric shocks delivered to the grid floor, and the degree of increase in plasma FFA is proportional to the duration of the stress. The effect of the stressor (electric shock) on plasma FFA was either blocked

or markedly attenuated by CPZ and meprobamate (266). The elevation of plasma FFA in rats by a similar schedule of inescapable electric shocks was effectively blocked by several tranquilizers (reserpine, benzquinamide, CPZ, meprobamate, hydroxyzine, and chlordiazepoxide). Two sedative compounds (pentobarbital and ethanol) were only partially effective; however, rather small doses were given. Two stimulants (dextroamphetamine and caffeine) elevated plasma FFA, in both shocked and nonshocked rats (267).

Since the stress syndrome may have an adaptive function in preparing the animal to resist a stressor, compounds which diminish the physiological reactions do not necessarily have beneficial effects. A more valid criterion for a protective effect of a compound might be a prolonged survival time during exposure to an acute stressor which is severe enough to cause rapid death. CPZ prolonged survival of rats subjected to combined heat and vibration stress (268) and of pigs subjected to combined heat and restraint stress (269). Survival of mice subjected to rapid mechanical vibrations was prolonged after pretreatment with large doses of chlordiazepoxide, reserpine, pentobarbital, and phenobarbital, and curtailed after large doses of iproniazid, dextroamphetamine, and morphine (270). Swimming time of mice in agitated cold water was prolonged by meprobamate (271) and by morphine (272), with no beneficial effect of hexobarbital or of several stimulants (271).

The generalized increase in sympathetic outflow, occurring in the alarm reaction to acute stressors, rapidly elicits a reciprocal stimulation of the parasympathetic nervous system. This reciprocal activation is not usually included in descriptions of the stress syndrome, but it adds a high level of internal stimulation to the effects of the original stressor and in some situations may be the immediate cause of the sudden lethal effect sometimes observed in cases of intense, acute stress. Richter (273) described this type of reaction, which is almost invariably lethal when wild rats are forced to swim in a vertical position with their whiskers clipped. In this situation, there is a marked slowing of heart rate, accompanied by decreased respiration and hypothermia, and at the time of death the heart is stopped in diastole, indicating a massive overstimulation of the parasympathetic nervous system. The lethal effect is aggravated by cholinergic drugs and retarded by atropine. This stress reaction may be influenced by the animal's experience with the situation, producing variations in the arousal of hopelessness or helplessness as a component of the perceived situation. Animals are much more resistant to the lethal effects if they are allowed to escape from the situation a few times instead of being maintained in the situation continuously.

Another consequence of excessive parasympathetic stimulation during stress may be the development of gastric ulcers. Reserpine has been shown to increase the incidence of ulcers in rats subjected to physical restraint for a number of hours (274–277). In one study (277), pretreatment with reserpine for several days prior to the restraint lowered the incidence of ulcers to the level of the nondrugged controls; this effect of more extensive premedication was attributed to the tranquilizing action of the drug. The incidence of ulcers after restraint stress has been found to be decreased by imipramine (275, 276, 278), thalidomide (279), cortisone (280), and a variety of other compounds, including anticholinergics, barbiturates, and CPZ (276, 281). A method for inducing ulcers without physical restraint is to immobilize rats for 24 hr. by punishing every motion with electric shock; ulcers were prevented by an extremely low dose (5 mg./Kg.) of meprobamate, but higher doses (10 and 20 mg./Kg.) were less effective, perhaps because they reduced the animal's ability to remain sufficiently immobile to avoid the shocks (282).

Chronic Exposure to Stress.—The alarm reaction cannot be maintained for long, and the process of adaptation or habituation enables most of the physiological reactions to return to their normal homeostatic level of functioning, even if the stressor continues unabated. This is identified as the stage of resistance, which continues until the stressor ceases or until exhaustion overcomes the adaptation. Mice forced to swim in cold, agitated water (272) were described as showing within the first 6 min. the agitated reactions of alarm reaction followed by the slower, energy-conserving behavior of the resistance stage and finally exhaustion when they sank beneath the surface. However, a much longer time span is generally required as a criterion for the stage of resistance.

Not all of the components of the stress response appear to return to normal levels of functioning during this stage. Aldosterone production increases, whereas corticosterone production is normal (283, 284), giving evidence that the renin–angiotensin II–aldosterone complex is involved in the response of the organism to chronic stress. Investigators (285–287) have

shown that the kidney is the source of an aldosterone-stimulating hormone and that the renin–angiotensin II system is involved in the stimulation of aldosterone production by the zona glomerulosa of the adrenal cortex. Miller (288) has shown that the glomerular zone increases in weight and hypertrophies by stress in hypophysectomized rats. Feldberg and Lewis (289) have reported that angiotensin is one of the most potent compounds inducing a release of catecholamines from the adrenal medulla, and other investigators (290–294) have provided evidence that there is an interrelationship between the activity of angiotensin II and the sympathetic division of the autonomic nervous system.

In a chronic stress situation, gastric ulcers have developed in monkeys performing a continuous shock-avoidance lever-pressing response for 6-hr. sessions, alternating with 6-hr. rest periods (295). The ulcerogenic effect was apparently a consequence of the chronic rather than the acute stress situation, because the gastric acid secretion was suppressed during the test sessions and greatly elevated in the rest periods. In rats, a chronic approach-avoidance conflict situation lasting 18 days gave rise to gastric ulcers which were greatly increased in animals given reserpine (296).

Gastric ulcers are not the only consequences of chronic stress. Friedman and Ader (297, 298) delivered inescapable electric shocks to the grid floors of the home cages of mice for 15 hr. per day, during a span of 7 days. The most stressful experimental condition, as indicated by the greatest loss in body weight (297) and the greatest susceptibility to the effects of injected coxsackie virus (298), was the presentation of the 2-sec. shock once every 15 min., at regular instead of irregular intervals, and with a stimulus light being presented for 15 sec. immediately before each shock instead of at different times. These conditions are similar to the typical schedule for a conditioned avoidance response. In another study (299), reduced weight gain and enhanced susceptibility to a toxic virus (herpes simplex) were found in mice after 28 days of 6-hr. sessions in a shuttle-box conditioned avoidance response. Animals tested for 1 or 14 days did not differ significantly from nonstressed controls. Measurements of blood pressure in rats tested for 42 weeks in a pole-climbing conditioned avoidance response (109) showed a rapid hypertensive response within the first few weeks on this schedule, persisting at approximately the same elevated level thereafter.

Rats subjected to a chronic variable stress program consisting of visual, auditory, and mechanical stimulation (flashing bright light, noxious intermittent sounds, and 120 oscillations per minute) for 4 hr. per day developed hypertension and had a high incidence of mortality within 20 weeks (300). Rosecrans *et al.* (301), using a similar stress protocol, also induced experimental hypertension in rats and found significant increases in both urinary NE and E following a single stress exposure, with a return to normal range by the eighth week of chronic stress. After the initial increase in secretion of adrenal E, adaptation occurred within 8 weeks. In contrast to acclimation of the sympathetic nervous system, the pituitary-adrenal axis appeared to continue to function maximally throughout the study, as indicated by high plasma steroid levels. The authors suggested that adrenal medullary activity appeared to be more important in acute stress situations, whereas the pituitary-adrenal axis appeared to play a more important role in adaptation during the long-sustained phase of chronic stress.

In spite of the great clinical importance of identifying protective or harmful drug effects in chronic stress, little research has been reported on drug effects in prolonged stress situations. Moderate doses of reserpine and CPZ failed to counteract the hypertension induced by chronic stressors but, on the contrary, potentiated the lethal effects of the stressors, apparently by the action of these compounds on the anterior pituitary-adrenocortical system (302). When reserpine treatment was begun after the seventh week of stress, blood pressures dropped to the control level but there was some indication of a higher mortality rate among the reserpinized than nondrugged animals (303). Acetylsalicylic acid failed to reduce blood pressures and greatly increased mortality of rats subjected to this chronic stress program; the deaths were apparently due to perforated gastric ulcers (303). The stress of physical restraint for 3 hr. per day caused 50% mortality within 32 days in rats pretreated with a large dosage of reserpine compared to successful adaptation and no mortality in nondrugged animals (304).

Drug Effects Modified by Stress.—In view of the physiological alterations involved in the stress response, the effects of some exogenous compounds may be expected to differ, depending on whether they are administered to a stressed or tranquil animal. Such differential effects have been found in a behavioral test situation in which rats turn a wheel to terminate a progressively increasing electric shock delivered to the grid

floor. There was an exaggerated stimulant effect of methamphetamine and caffeine and an exaggerated depressant effect of CPZ on escape performance of a group of animals previously given severe, inescapable shocks in the same apparatus. In contrast, alcohol had less depressant effect on the stressed animals than on the control group (305, 306). Another study has also provided evidence that the stress reaction potentiates the effects of stimulant drugs and of CPZ. With the use of a method of rating various measures of fright in rats introduced to a novel situation, animals whose fear was aroused by loud noises and by a bright, flashing light showed a greater increase in fright under the influence of E and a greater decrease under the influence of CPZ than did the low-fear controls (307). The finding that stress counteracted the depressant effect of alcohol (306) is convincingly supported by a report that rats under the influence of alcohol were better able to cling to a tilted plane after the stress of forced swimming or, to a lesser degree, after exposure to inescapable electric shocks or loud noise compared to nonstressed control animals. Amphetamine and E also improved performance under the influence of alcohol. Forced swimming likewise improved the performance of hypophysectomized rats, indicating that the depressant effect of alcohol was counteracted by a general arousing mechanism rather than by adrenocortical secretion activated in the stress reaction (308).

Reports have shown that stress may markedly alter the activity and toxicity of compounds. The survival time of guinea pigs administered emetine hydrochloride (a cardiotoxic agent) was reduced in animals which had been trained in a shuttle-box conditioned avoidance response and was further reduced in animals which, after training, had been subjected to conflict by being punished with shock when they made the conditioned avoidance response (309). The LD_{50} for amphetamine is less than one-tenth the dosage for mice or rats after receiving a brief severe inescapable shock every 8 or 10 sec. for 3 hr. than for nonshocked control animals (310). Rats being trained in a lever-pressing avoidance may be killed by normally sublethal doses of dextroamphetamine (19). Aggregation in a confined space may be a stressor, and there have been many replications of the original report (311) that aggregation greatly increases toxicity of amphetamine in mice. However, this effect depends partly on genetic factors, with some strains of mice showing little or no difference in amphetamine toxicity between the aggregated and isolated conditions (312). The toxicity of amphetamine in aggregated mice is greatly reduced if the animals have had 40 hr. of previous habituation to the same group of three in which they are placed after amphetamine administration (313). A study of the effects of several variables showed that amphetamine toxicity was increased by the stressors of elevated environmental temperature and forced activity as well as aggregation. Aggregation failed to increase toxicity under conditions in which motor activity was not stimulated (314).

A variety of other stressors have also been found to potentiate toxicity and pharmacological effects of compounds. Amphetamine toxicity was greater in mice after 4 weeks of chronic isolation stress, whether they were isolated or placed in a group after amphetamine injection (315). A similar result was reported after only 13 days of isolation, beginning at weaning (316). Isoproterenol toxicity was likewise found to be greater in rats after 13 weeks of isolation (317). The pentylenetetrazol seizure threshold in mice was lowered by restraint for a very brief (15-sec.) period immediately prior to the test (318). A subsequent study in the same laboratory showed similar effects on seizure threshold after more prolonged body immobilization (for 7.5 to 60 min.) and also after 20 presentations of inescapable electric shocks, at 1-min. intervals (319). In both studies, there was evidence for adaptation to the effects of more prolonged restraint. A study of the effects of three environmental temperatures on acute toxicity of a number of compounds showed the greatest toxicity at the hottest temperature (37°) for amphetamine and most of the other compounds tested, with the least degree of toxicity at 28° for the tranquilizers and at the coldest temperature (18°) for the stimulants (320). The lethal effects of scorpion and rattlesnake venom were potentiated by either cold (2°) or heat (35–38°) stress, with the greatest resistance being found at normal room temperature (321).

Contrary to these reports on the potentiation of drug effects in stressed animals, rats subjected to unilateral hindleg ligation showed shorter sleeping time after injection of hexobarbital, meprobamate, or zoxazolamine (322). This stressor was shown to lower the blood levels of hexobarbital, pentobarbital, and meprobamate (323). However, phenobarbital produced no significant difference in sleeping time (322) and blood levels (323) between the stressed and nonstressed animals. Shorter sleeping time was reported after injection of pentobarbital or a com-

bination of pentobarbital and CPZ, in rats which had been isolated for 4 weeks previously (315). The writhing response of mice to benzoquinone may be inhibited by electric shocks prior to the drug injection (324).

These studies, showing various ways in which a stressful situation influences the action of compounds, indicate that the physiological and endocrinological components of the stress syndrome interact with the administered compound. It would be useful to determine for each important drug whether its effects are potentiated, counteracted, or unaffected by stress, as an aid in determining appropriate doses during stress and normal conditions and also as an addition to scientific knowledge about the drug's mechanisms of action. The drug effects might also be influenced differentially by different intensities or types of stressor or at different stages of the stress syndrome. In contrast to the finding that severe stress potentiates the depressant effect of CPZ on behavior of rats (305–307), evidence has been reported (325) that the mild stress of exposure to a novel environment counteracts the depressant effect of CPZ on spontaneous motor activity of mice.

DISCUSSION

During stress, the physiological and behavioral alterations occur in an attempt to maintain or restore homeostasis. The marked increase in endocrine secretions and activation of the autonomic nervous system during the alarm reaction prepare the animal for violent fighting or flight. The energetic behavior may succeed in terminating the stressful situation and also discharges the excess energy potential, thus helping to restore the organism to its normal, homeostatic state. If the stressor continues, as in an inescapable situation, the best chance for survival is to conserve strength, with most of the physiological and behavioral responses returning to normal during the stage of resistance. The freezing, crouching reaction, often seen during prolonged stress, may also occur during the alarm reaction if the initial attempt to destroy or escape the stressor is unsuccessful. Violent, agitated behavior very quickly leads to exhaustion; the rigid, tense posture of crouching conserves energy and also keeps the animal alert to the environment and in a good posture for springing forward as soon as there is an opportunity for escape or attack. Another adaptive value of freezing in small animals is that a moving object is more likely to be seen by an enemy; furthermore, a predator is less likely to attack an animal that is immobile (326).

Summary of Drug Effects.—The findings reviewed in this paper may be classified as showing either a decrease (−), an increase (+), or no change (0) in the behavioral and physiological responses to stressors. Table I shows a classification of the effects of the compounds most commonly included in these studies for several of the most frequently used measures of behavior. The number of plus or minus symbols (one or two) indicates the degree of consistency with which the effect has been reported in the various studies. All species and routes of administration are included in the compilation of Table I, although the sample doses are specified as i.p. in rats. The absence of a symbol (+, −, or 0) indicates that the information is lacking. The behavioral tests of pain threshold and pain-induced aggression are not included here because almost all of the compounds have effects only at higher doses than those cited here. The data forming the basis for this table are rather meager and often inconsistent for most of these compounds; CPZ is the only one of these which has been

tested by more than one investigator for each of the six measures shown.

In spite of deficiencies in the available information, some meaningful patterns are apparent. The performance of an avoidance response is inhibited by several tranquilizing and general depressant drugs, unaffected by therapeutic doses of a muscle relaxant and hypnotic, and is increased by anticholinergic and adrenergic agents. Drug effects on acquisition of avoidance show a less consistent pattern, perhaps because drug effects on learning of a new response are more complex than drug effects on performance of a well-established response. Drug-produced decrements in avoidance performance cannot reasonably be attributed to a specific reduction of avoidance motivation, because the compound which most consistently inhibits avoidance (CPZ) has no effect in the approach-avoidance conflict situation, whereas the compounds which reduce avoidance of the shock in conflict tests (meprobamate, pentobarbital, and alcohol) have no effect on performance of avoidance and actually improve acquisition of an avoidance response. The two additional compounds which generally increase an animal's willingness to accept avoidable shocks, in a conflict situation where the food-rewarded responses are punished by shock (chlordiazepoxide and benactyzine), likewise improve acquisition of an avoidance response. Three compounds which reduce performance of avoidance (CPZ, reserpine, chlordiazepoxide) reduce physiological components of the alarm reaction, and dextroamphetamine increases both the behavioral and physiological responses, but the other compounds do not show much correspondence between behavioral and physiological effects.

These drug effects cannot be adequately explained in terms of general stimulation or depression. The first seven compounds listed in Table I might all be classified as depressants, but they show very different patterns of effects. A distinction between sympathetic and parasympathetic dominance may explain why the effects of reserpine, which depletes catecholamines, and of CPZ, a centrally acting α-adrenergic blocker, are generally opposite to the effects of the sympathomimetic agent, dextroamphetamine. Scopolamine and benactyzine, which reduce cholinergic stimulation, tend to resemble dextroamphetamine and differ from CPZ and reserpine in certain respects. The few studies on effects of cholinergic drugs, such as physostigmine, have shown profound decrements in avoidance. Five of the compounds listed in Table I (chlordiazepoxide, morphine, meprobamate, pentobarbital, and alcohol) do not have a marked preponderance of adrenergic or cholinergic effects. However, the balance or imbalance of the two divisions of the autonomic nervous system is a critical factor in the stress syndrome, as shown by the adrenergic stimulation characterizing the alarm reaction, followed by reciprocal parasympathetic stimulation which may lead to sudden death (273) or gastric ulceration. Some behavioral drug effects have been convincingly attributed to central sympathetic or parasympathetic stimulation. Avoidance is greatly enhanced by the combination of an adrenergic and anticholinergic compound (28); many other behavioral effects of drugs have been attributed to their central adrenergic or cholinergic activating or blocking effects.

The choice of drugs for protective or therapeutic effects may be expected to depend on certain features of the stress situation. Adrenergic or anticholinergic compounds may enhance and prolong the alarm reaction, helping the animal to destroy or escape the stressor. Termination of the stress situation is the purpose of the vigorous alarm reaction, and if successful this eliminates the need for adaptation to the stressor. However, in most cases the organism's own mechanisms provide sufficient adrenergic stimulation. Administration of certain compounds is likely to be disruptive, as indicated by the lethal effect of moderate doses of amphetamine in acute stress situations (19, 310). The most conspicuous behavioral effect of adrenergic or anticholinergic compounds is the persistence of unnecessary avoidance responses (203). Anticholinergics can be beneficial in counteracting the parasympathetic overstimulation which may cause sudden death (273) or gastric ulcers. However, therapeutic effects are found more often with tranquilizing drugs which prolong the stage of resistance. This might be due to the fact that in most experimental test situations the stressor is inescapable, so that survival is prolonged by physiological and behavioral adaptation rather than by increasing efforts to escape. In nature both escapable and inescapable stress situations occur, and the adrenergic and cholinergic systems apparently provide a mechanism for an appropriate response in either type of situation. Drugs influence simultaneously the behavioral and physiological responses to stress, but our knowledge of these effects is severely limited by the fact that drug effects on behavior have usually been tested in animals previously subjected to the stress situation repeatedly, for

many days or even weeks, whereas drug effects on physiological stress responses have usually been measured by restraint or some other acute stress procedure during a single session of several hours.

Variations in Test Procedures.—Each compound has a wide variety of effects in addition to the stimulant, depressant, adrenergic, or cholinergic action by which it is often classified. Differential effects may be analyzed by comparing drug effects in situations which differ in a particular specified feature. An important methodological aid for such comparisons is to measure effects of several doses in order to estimate the effective dose, usually defined as the dose which causes a definite change in the behavior of half of the animals (ED_{50}). This measure of the response to a drug is concise and may be standardized and used for comparing data obtained in different laboratories. Unfortunately, a wide range of variations in ED_{50} values has been reported by different investigators, even when using apparently the same procedures for the same compound, administered by the same route in the same species. Similar wide variation is found also in measurements of lethal dose (LD_{50}). Since the variations among laboratories which influence the toxicity or effectiveness of a compound would generally be expected to influence other compounds in the same way, the relationship among compounds in ED_{50} or LD_{50} might be expected to show more consistent results than the levels found for each compound singly. Table II compares the effective doses of CPZ with meprobamate for inhibiting avoidance in three different situations. A CPZ effect was found at a much lower dose in the chronic, continuous avoidance situation than when the extra stimulation of a warning signal was provided, and the pole-jumping response, which was least compatible with a crouching response, was least readily affected by this compound. Meprobamate affected avoidance only at doses which caused marked skeletal muscle relaxation; with this compound the warning signal had very little stimulating effect, and the pole-jumping response was most readily impaired, presumably because it required the highest degree of muscular coordination. These differential situations indicate some specific drug actions which may be identified; a great deal more could be learned from large-scale studies in which a number of different compounds are tested in several different situations, using the same species and route of administration. Unfortunately, such information is apparently very scarce at the present time.

The experimental findings reviewed in this paper permit some additional conclusions about interactions between drug effects and behavioral test situations. Generally, a lever-pressing avoidance response was most susceptible to drug effects, whereas avoidance by jumping on a pole or platform was most resistant to drug effects, with a running response being intermediate in this respect. The lever-pressing response was generally the most difficult to train, whereas the jumping response was usually the quickest way to escape the electrified grid and was readily learned. In the lever-pressing situation, it is probable that the usual procedure of training the animals to a stable level of avoiding over a long period of time somewhat counteracted the tendency to be more readily affected by the compounds. CPZ appeared to block avoidance at lower doses in rodents than in cats; this species difference might be interpreted as showing that the crouching reaction, which is potentiated by this compound, is a stronger response tendency in rodents. However, reserpine showed no such species difference, suggesting a different mechanism for the action of this compound in decreasing avoidance. A much greater decrement in a locomotor avoidance was caused by CPZ when the animal was required to select the correct one of two exits rather than being able to avoid by either route (213); perhaps the process of choice or decision potentiates the inhibitory crouching tendency. In an approach-avoidance conflict, alcohol has been shown to decrease the avoidance response in a runway (183, 184) but not in a lever-pressing test (175, 177), perhaps because the drug causes greater muscular interference with the manipulative than with the locomotor response. Some substantial differences in drug effects have resulted from seemingly minor procedural variations. Studies which isolate and experimentally manipulate the situational features influencing drug effects may contribute valuable information about drugs and behavior through the measurement of their interactions.

Recommendations for Experimenters.—Effective research in behavioral pharmacology requires testing several doses of each drug, to

obtain an ED_{50}. In order for this measure to be reliable it should be determined over a wide time range after administration, on a sizable number of animals. The value of an experiment is greatly increased by the use of several drugs in the same test situation and by a comparison of several measures of performance and several related procedures. These requirements can only be fulfilled by large-scale studies. It is often possible to use the same animals in testing different time intervals, doses, and compounds. This use of each animal as its own control reduces the number of animals needed, increases the sensitivity of the statistical comparisons, and also saves time in preliminary training. However, these advantages can only be obtained if drug effects are tested on performance of an already learned response, rather than on the process of acquisition or extinction. Also, the experimenter must be alert to the possibility that the nondrug performance may change during repeated tests, and that a test under a particular drug condition may influence performance in the following test session. In addition, the possibility of cumulative drug effects and development of tolerance should be taken into consideration.

Experimenters are encouraged to select test techniques which have already been used in a number of previous drug studies, such as the lever-pressing, shuttle-box, and pole-jumping avoidance. Most of the meaningful conclusions in this review have been based on results reported with the most frequently used techniques. If novel procedures are used, the data are greatly increased in value when the investigator also obtains comparable data from a related, commonly used technique. Some of the most novel techniques, such as immobility as an avoidance response (77) and lever-pressing escape from cold temperature (142), are potentially valuable methods which deserve and need a great many more studies to establish a pattern of drug effects under these experimental conditions. The characteristics of the test situation to be used may depend on the purposes. Performance that is difficult to acquire, such as a lever-pressing avoidance response, may have the advantage of being a measure of learned rather than innate behavior that is readily altered by drugs. On the other hand, a pole-jumping avoidance response has the advantage of being easier to train, and its similarity to natural behavior tendencies may be advantageous for certain clinical applications.

It is to be hoped that the findings on drug effects in animals will lead to useful clinical applications. This is a necessary and challenging task, with many complex factors to be taken into account in applying results to a different species under varied conditions. However, the experimenter should select techniques which are simple and yield readily understandable results. The complex, multiple-conflict situation tested in a series of studies with a jumping-stand discrimination (205–209) does not permit isolation and identification of the determinants of behavior. Even though the drugs may be used to alleviate multiple conflicts and complex neuroses, the preclinical tests should measure simple, prototype components of the naturalistic situation. A preliminary step is to obtain more data and gain better understanding of the drug effects in animal test situations. Some glib assumptions, such as the belief that CPZ decreases avoidance performance because of reducing fear of the shock, have been based on an inadequate amount of data. At present we still do not fully understand the crouching response pattern and the situations and drugs which influence it. The collection of further data will greatly increase the validity and usefulness of theories about drug effects on animal behavior and thus provide a firm basis for clinical applications. It would be easy to deplore the shortcomings of behavioral pharmacology research to date, but it is more constructive to emphasize its recency, with nearly all of the studies having been published since 1953. It is inevitable that such a new field of scientific knowledge is largely characterized by diverse methods, conflicting findings, and small-scale studies. Already the research seems to show improvement in scope and methods as well as a rapid increase in number of published studies. We can expect very rapid advance in the next few years.

The stress syndrome includes both behavioral and physiological components, which should be measured concurrently, such as by testing effects of drugs on behavior and also on brain amines, blood pressure, and other physiological measures in the same situation. Most of the behavioral tests currently being used to investigate centrally acting compounds involve a stress reaction to the animal. Cardiovascular, endocrine, and a variety of biochemical changes most likely occur; however, the quantitative changes will vary from animal to animal and will also depend upon the intensity of the stressor involved. Effects of the psychotropic compounds on animal behavior may in reality be effects on stress-induced alteration in one or more of the biological systems within the organism. The behavioral and physiological components of the stress syndrome interact with each other and with experimentally administered

compounds. The inclusion of both behavioral and physiological measures adds a new element of difficulty to pharmacological studies, but the value of the additional information may be expected to outweigh the disadvantage of the extra work required.

Thermodynamics of Chelation by Tetracyclines

By LESLIE Z. BENET* and JERE E. GOYAN

Thermodynamic data were determined for the complexation of five tetracycline analogs with cupric ion. Free energy values were calculated from data previously published by the authors. Enthalpy determinations were made in a Dewar calorimeter. Entropy values were determined from ΔG° and ΔH° at 25°. For the formation of 1:1 complexes, ΔH° was approximately −12 Kcal./mole and ΔS° was approximately −4 e.u. for the three chlor-analogs studied (4-epi-chlor-, demethylchlor-, and chlortetracycline), while a ΔH° of −7.6 Kcal./mole and a ΔS° of +10.2 e.u. was obtained for tetracycline. It is suggested that all of the analogs studied form inner sphere 1:1 complexes with cupric ion but that the chlorine at C-7 compels the three chlor-derivatives to undergo a more severe conformational change than tetracycline in order to reach a favorable configuration for chelation. All of the above analogs showed a small negative enthalpy change and a large positive entropy change for 2:1 complex formation. It is suggested that all four analogs form outer sphere or ion-pair complexes during 2:1 complexation.

IN A PREVIOUS paper (1), the authors calculated the thermodynamic dissociation and stoichiometric stability constants for five tetracycline analogs with cupric ion. In light of the experimental evidence presented, it was felt that all five analogs investigated, tetracycline·HCl, chlortetracycline·HCl, demethylchlortetracycline·HCl, 4-epi-chlortetracycline·HCl, and 4-epi-anhydrotetracycline·HCl, formed 2:1 (ligand–metal) complexes with cupric ions. The present study was undertaken to further elucidate the thermodynamic relations involved in this complexation.

In order to reach accurate conclusions regarding the nature of the forces operating within complexes during their formation in solution, it is necessary to know the energy changes accompanying the reactions in question. Stability constants are related directly only to the change in free energy.[1]

$$\Delta G^\circ = -2.303\ RT \log \beta_i \qquad \text{(Eq. 1)}$$

Where β_i is the over-all stability constant. The values for the change in free energy for the tetracycline chelations studied may be calculated from the data presented in *Reference 1*.

A knowledge of the entropy change during the complexation reaction allows the investigator to estimate the effects of certain steric factors which may be involved in complex bonding. In order to calculate the entropy of complexation, the enthalpy of complexation must also be determined as seen in Eq. 2.

$$\Delta S^\circ = (\Delta H^\circ - \Delta G^\circ)/T \qquad \text{(Eq. 2)}$$

The enthalpy of complexation was determined by direct calorimetry. Although this method requires more experimentation than the determination of enthalpy by the variation of stability constants with temperature, the accuracy gained in the calorimetric method justifies the work expended, especially in this study where the maximum heat evolved for any one measurement was only 0.5 cal. Rossotti (2) presents an enlightening discussion as to the accuracy of the two methods.

EXPERIMENTAL

Materials.—Tetracycline · HCl, chlortetracycline · HCl, demethylchlortetracycline · HCl, 4-epi-chlortetracycline · HCl, and 4-epi-anhydrotetracycline · HCl were donated by Lederle Laboratories. All solutions were prepared as described in *Reference 1*.

Calculation of Dissociation and Stability Constants.—Dissociation constants and concentration of tetracycline present were determined by the method of nonlogarithmic titration curves (1, 3).

Received April 25, 1966, from the School of Pharmacy, University of California, San Francisco.

Accepted for publication July 13, 1966.

Presented to the Basic Pharmaceutics Section, A.PH.A. Academy of Pharmaceutical Sciences, Dallas meeting, April 1966.

This investigation was supported in part by training grant 5 TO1 GM 0728 05 from the Division of General Medical Sciences, National Institutes of Health, U.S. Public Health Service, Bethesda, Md.

* Fellow of the American Foundation for Pharmaceutical Education, 1963–1965. Present address: College of Pharmacy, Washington State University, Pullman. 99163.

[1] The choice of the standard state is of great importance in determining ΔG°, ΔH°, and ΔS°. Many authors choose as the standard state a hypothetical 1 molal solution with the properties of an infinitely dilute solution. This choice of standard state eliminates the effect of ionic strength and the ambiguity which arises when comparing values with other work. However, this advantage is usually outweighed by the inaccuracy inherent in the extrapolation of data to values at zero ionic strength. In recent years, therefore, use has been made of a less hypothetical molar solution of a given ionic strength (μ = constant) at 25°. This choice of standard state was used in this work. However, it must be pointed out that all determinations, calculations, and comparisons of thermodynamic functions must be made with reference to the same standard state.

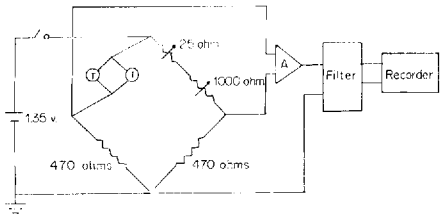

Fig. 1.—Circuit diagram for thermistor bridge. Key: T, 1000-ohm thermistor; A, amplifier.

Stability constants were determined as described in *Reference 1*. All determinations were carried out at an ionic strength of 0.01.

Calorimetry.—The design of the calorimeter was influenced by the desire to measure the heat of complexation for the same reactions from which the stability constants were determined. The work of Atkinson and Bauman (4, 5) was of special interest since they had used very dilute solutions. Therefore, modifications were made on a basic Wheatstone bridge in order to improve on the accuracy which they reported. A circuit diagram of the "thermometer circuit" is shown in Fig. 1. The bridge was driven by a Mallory 1.35-v. mercury battery (RM-12-R) which could be switched in and out of the circuit. Two arms of the bridge were fixed with matched 470-ohm, 0.5-w. carbon resistors. The temperature-sensing arm contained two 1000-ohm thermistors (Fenwall GB 31 P2) connected in parallel. The fourth arm contained two 10-turn wire wound potentiometers in series, the first a 1000-ohm potentiometer and the second a 25-ohm potentiometer. These potentiometers were used to zero the voltage output of the bridge at the beginning of a titration run. The voltage output of the bridge then goes to a model 1755 low-noise d.c. instrumentation amplifier[2] which is operated as a differential amplifier. The voltage output of the amplifier then passes through a model 7500 d.c. active filter[2] which attenuated all signal frequencies above 0.1 c.p.s. The voltage output was then fed into a Varian model G-10 graphic recorder.[3]

The calorimeter was constructed with a Dewar flask, based on the design proposed by Schlyter (6) as modified by Bauman (5), and was equipped with a thermostated buret for enthalpy titrations. The buret device was constructed from a microburet identical with the one utilized in the potentiometric procedures (1, 3). The entire device holds approximately 1.7 ml. of titrant, of which 1 ml. may be delivered to the solution. A micro-heater was utilized to calibrate the Dewar flask and its contents (7). The procedure was as follows.

The solutions to be titrated were placed in the Dewar flask, the pipet was filled with titrant, the calorimeter was closed and placed in a constant-temperature bath maintained at 25.00 ± 0.005°. The solution was either cooled or heated as was required to bring the temperature of the solution to 25°. At this time the bridge was balanced and a constant drift rate was established on the recorder. Heat was added by applying a voltage across the known resistance of the heater for a period of time which was electronically recorded (7). A steady drift rate is again obtained and the number of spaces between the two drift lines is measured. The heat sensitivity per space (C_s) can then be calculated from Eq. 3.

$$C_s = \frac{E^2 t}{(4.1840 \text{ joules/cal.})\, R\, (\Delta \text{ spaces})} \qquad \text{(Eq. 3)}$$

where C_s = calories per space,
E = voltage across heater,
R = heater resistance, 120.39 ohms,
t = heating time in sec.,
Δ spaces = number of spaces drift curve is displaced.

In the beginning of the calorimetric work, electrical calibrations were made before and after each addition of titrant. The average of the two calibrations was then taken as the C_s for that particular addition of titrant. However, when following this procedure, the time spent in joule calibrations in any one run was well over an hour, which was undesirable since epimerization takes place during the titration. Therefore, the average values of C_s for 49 calibrations with 158-ml. volume and 25 calibrations with 153-ml. volume were calculated.[4]

$C_s = (1.551 \pm 0.039) \times 10^{-2}$ cal./space for 158 ml.

$C_s = (1.504 \pm 0.037) \times 10^{-2}$ cal./space for 153 ml.

During the course of the work sample determinations of C_s were run to ascertain that the calculated values had not changed.

Most titrations were carried out with a total volume change of less than 0.6 ml.; therefore, it was felt that any change in C_s due to volume change would be imperceptible considering the size of the standard deviation. All joule calibrations were made on solutions with $\mu = 0.01$, so that it was assumed that C_s was the same no matter which tetracycline was being titrated.

To test the reliability of the calorimeter, the heat of neutralization of HCl by KOH was examined. The average of 27 determinations at 0.01 N HCl gave a value of 13.95 ± 0.46 Kcal./mole, which when corrected to infinite dilution (8) was 13.76 ± 0.46 Kcal./mole. Because the range was slightly higher than those values reported by calorimetry for very dilute solutions (9), all the parameters used in the determination were carefully rechecked. Since the heat of neutralization of hydroxide ions is used in the enthalpy determinations to be presented, it was decided to use the value obtained in this calorimeter, since any systematic error would then be carried through all of the calculations.

For each addition of titrant, the heat evolved, Q, in cal./L., is given by Eq. 4.

$$Q = \frac{C_s\,(\Delta \text{ spaces}) - (\text{heat of dilution of KOH titrant})}{\text{total vol., L.}} \qquad \text{(Eq. 4)}$$

The heat of dilution for 1 ml. of 0.4405 M KOH added to 158 ml. of ionic strength 0.01 was cal-

[2] California Electronic Mfg. Co., Inc., Alamo, Calif.
[3] Varian Associates, Palo Alto, Calif.

[4] Calibrations were necessary at both of these volumes, since all calorimetric determinations were carried out under identical conditions as the potentiometric determinations for the stability constants, which were carried out at both of these volumes.

culated from the values tabulated by Rossini (8) and found to be 7.3×10^{-2} cal./ml. of titrant.

The heat evolved in the titration of a solution of tetracycline·HCl and cupric ions is the sum of the heats evolved in the five reactions listed below.

$H_3T^+ + OH^- \rightleftharpoons H_2T + H_2O \quad \Delta H^\circ_1$ Reaction *1*

$H_2T + OH^- \rightleftharpoons HT^- + H_2O \quad \Delta H^\circ_2$ Reaction *2*

$HT^- + Cu^{++} \rightleftharpoons Cu(HT)^+ \quad \Delta H^\circ_3$ Reaction *3*

$HT^- + Cu(HT)^+ \rightleftharpoons Cu(HT)_2 \quad \Delta H^\circ_4$ Reaction *4*

$H^+ + OH^- \rightleftharpoons H_2O \quad \Delta H^\circ_5$ Reaction *5*

If $\Delta[\ ]$ is defined as the concentration initially minus the concentration after titrant (base) is added, and noting that multiplying the enthalpy for each reaction times the change in one of the reactants gives the heat evolved by this reaction, we can write Eq. 5.

$$Q = \Delta[H_3T]\,(\Delta H^\circ_1) - \{\Delta[HT^-] + \Delta[Cu(HT)^+] + \Delta[Cu(HT)_2]\}\,(\Delta H^\circ_2) - \{\Delta[Cu(HT)^+] + \Delta[Cu(HT)_2]\}\,(\Delta H^\circ_3) - \Delta[Cu(HT)_2]\,(\Delta H^\circ_4) + \Delta[H^+]\,(\Delta H^\circ_5) \quad \text{(Eq. 5)}$$

Before the values of interest in this work ΔH°_3 and ΔH°_4 can be calculated, the heats of reaction ΔH°_1 and ΔH°_2 must be determined. These heats can be found by measuring the heat of reaction for the titration of a pure tetracycline·HCl with base. This was done for each of the five tetracycline analogs studied here. The calorimeter was filled with a solution of the particular tetracycline hydrochloride. Simultaneously an exact duplicate of the solution in the calorimeter was titrated potentiometrically. To obtain a larger number of values for ΔH°_1 and ΔH°_2 the concentrations of the tetracycline analogs used in the titrations without metal were about 3 times as great as those used for the work reported in *Reference 1*. This procedure gave good values for all the tetracyclines except 4-epianhydro-, which is considerably less soluble than the other four derivatives.

The heat of reaction for Reactions *1* and *2* may be determined from Eq. 6.

$$Q = \Delta[H_3T^+]\,(\Delta H^\circ_1) - \Delta[HT^-]\,(\Delta H^\circ_2) + \Delta[H^+]\,(\Delta H^\circ_5) \quad \text{(Eq. 6)}$$

From the parallel potentiometric titration, $[H^+]$, $[H_3T^+]$, and $[HT^-]$ may be determined as described in *Reference 1*. Since the first and second dissociation constants for the tetracyclines are widely separated, $[HT^-]$ will be negligible at high hydrogen-ion concentrations and ΔH°_1 may be determined. At lower $[H^+]$, ΔH°_2 may be determined.

The Q values were calculated from the experimental data by use of Eq. 4. A sample determination for ΔH°_1 and ΔH°_2 is given in Table I for tetracycline·HCl. Due to overlap of the second and third dissociation constants, there are fewer determinations for ΔH°_2 and consequently these answers are not as accurate as those for ΔH°_1.

Once ΔH°_1 and ΔH°_2 are known, it is necessary to run two simultaneous titrations of tetracycline with metal—calorimetrically and potentiometrically.

Since the chelation steps of tetracycline with cupric ion are separated sufficiently, it was assumed that when $\bar{n} < 1$ only $Cu(HT)^+$ is formed and therefore, the $Cu(HT)_2$ terms may be dropped from Eq. 5. Using the calculations described in *Reference 1*, the concentrations of H^+, H_3T^+, HT^-, and $Cu(HT)^+$ may be calculated after each addition of base.

At $\bar{n} > 1$, $\Delta[Cu(HT)_2] = -\Delta[Cu(HT)^+]$ so that the only chelate term remaining in Eq. 5 will be $-\Delta[Cu(HT)_2]$ (ΔH°_4), and thus the heat of chelation for the second ligand may be calculated by determining $[H^+]$, $[H_3T^+]$, $[HT^-]$, and $[Cu(HT)_2]$ after each addition of titrant. A sample calculation of ΔH°_3 and ΔH°_4 is presented in Table II for tetracycline·HCl.

It should be noted that the ΔH°_3 and ΔH°_4 values show a wide range of individual points, yet when the averages of two different titrations of a particular analog were compared, the average values were very close. This was also noted in the joule calibrations. Since the calorimeter had no way to lose heat except by diffusion through the Dewar, it seemed that the calorimeter sometimes compensated by giving alternate low and high readings. Yet the average was a good measure of the actual heat evolved. Stability constants calculated from the data as presented in Table II showed good agreement with those values reported earlier (1).

RESULTS

As previously explained, the calorimetric work had to be carried out in two parts. Initially the heats of deprotonation for the first and second dissociating hydrogens were determined. The thermodynamic parameters of the first dissociating hydrogen are designated with a subscript *6*; the thermodynamic parameters of the second dissociating hydrogen are designated with a subscript *7*. The values for these parameters are presented in Table III. The values for K_1 and K_2 are the stoichiometric dissociation constants determined in the parallel potentiometric titrations (*vide supra*) and correspond to the thermodynamic dissociation constants reported previously (1). The values for ΔH°_1 and ΔH°_2 are determined experimentally as demonstrated in Table I. The value for ΔH°_5 is taken as −13.95 Kcal./mole as explained above.

The actual heat evolved in each determination of ΔH°_1 is about 0.5 cal., and the ΔH°_1 values calculated from these results are accurate to about ±5%. The ΔH°_1 values are approximately equivalent for all five tetracycline analogs, as is reflected in the agreement of the ΔH°_6 values in Table III. The epi-derivatives have ΔS°_6 values which are slightly more negative, indicating that the change in pK_1 (1) is an entropy effect as would be expected for a stereochemical change (compare chlortetracycline with 4-epi-chlortetracycline).

The actual heat evolved in each determination of ΔH°_2 is about 0.25 cal. Due to the overlap of pK_2 and pK_3 there are fewer determinations for ΔH°_2, and consequently, these values are not as accurate as the ΔH°_1 values. Due to the low solubility of the isoionic form of 4-epi-anhydrotetracycline, no accurate values of ΔH°_2 could be obtained for this analog.

Once ΔH°_1 and ΔH°_2 had been determined, tetracycline–metal titrations were run to find ΔH°_3, the heat of 1:1 chelation, and ΔH°_4, the heat of 2:1 chelation. These values are presented in Table IV. Particular notice should be directed toward the values determined for tetracycline·HCl where the exothermic heat of chelation, ΔH°_3, is significantly less than those values determined for the chlor-derivatives. Since the ΔG°_3's for the four analogs are reasonably similar, the large difference in ΔH°_3 for tetracycline·HCl, appears as an entropy effect causing ΔS°_3 to be +10.5 for tetracycline and about −4 for the chlor-analogs.

Before attempting to explain this difference, let us take a further look at ΔH°_4, the heat of complexation for the second ligand. The actual heat given off for each addition of titrant in ΔH°_4 determinations was in many cases below 0.2 cal. Also the number of determinations for ΔH°_4 in each titration was limited to the lower pH ranges to

TABLE V.—THERMODYNAMIC DATA FOR THE COMBINED REACTION *2 + 3*

$$Cu^{++} + H_2T + OH^- \rightleftharpoons Cu(HT)^+ + H_2O$$
$$\Delta G^\circ_{2+3} = -1.364 (\log K_1 + \log \beta_1 - \log Kw)$$

Analog	ΔG°_{2+3} (Kcal./mole)	ΔH°_{2+3} (Kcal./mole)	ΔS°_{2+3} (e.u.)
Chlortetracycline·HCl	−18.90	−18.92	−0.01
Demethylchlortetracycline·HCl	−20.00	−18.70	+4.4
Tetracycline·HCl	−19.23	−13.3	+19.9
4-Epi-chlortetracycline·HCl	−19.11	−18.91	+0.7
4-Epi-anhydrotetracycline·HCl	−19.90	−14.0	+19.8

insure that the third dissociable hydrogen from the chelated tetracycline was not present to a significant extent. For 4-epi-chlortetracycline only one value of ΔH°_4 could be calculated per titration before precipitation began in the calorimeter. This could easily be seen on the recorder as irregular bursts of heating replaced a smooth drift curve. Even with all the errors inherent in measuring such a small heat change and the pyramiding of effects of inaccurate ΔH°_1 and ΔH°_2 values, it is possible to get some idea of ΔH°_4, at least qualitatively. The ΔH°_4 values listed in Table IV show a reasonable degree of consistency, as do the ΔS°_4 values. In this case all four derivatives, the chlor-analogs and tetracycline itself, show a high positive ΔS°_4.

As mentioned previously, ΔH°_1 is the most accurate enthalpy determined in this work. Therefore, to prove that the difference in ligational entropy was not just a factor of an incorrect ΔH°_2, it was decided to examine the entropy of the over-all Reaction *2 + 3*.

$$Cu^{++} + H_2T + OH^- \rightleftharpoons Cu(HT)^+ + H_2O$$
$$\Delta H^\circ_{2+3} \quad \text{Reaction } 2 + 3$$

$$\Delta G^\circ_{2+3} = -1.364 (\log K_1 + \log \beta_1 - \log K_w) \quad \text{(Eq. 7)}$$

The ΔH°_{2+3} can be calculated, using only one predetermined value, ΔH°_1. In addition, Reaction *2 + 3* is a good approximation to what is actually happening in solution, since below $\bar{n} = 1$ [*i.e.*, where $Cu(HT)^+$ is forming] the concentration of free ligand (HT^-) is negligible and the addition of titrant (OH^-) results in pH changes (Reaction *5*), neutralization of H_3T^+ (Reaction *1*), and the conversion of H_2T to $Cu(HT)^+$. Therefore,

$$\Delta H^\circ_{2+3} = \frac{Q - \Delta[H^+](\Delta H^\circ_2) - \Delta[H_3T^+](\Delta H^\circ_1)}{\Delta[Cu(HT)^+]} \quad \text{(Eq. 8)}$$

The thermodynamic values obtained from such a calculation are illustrated in Table V. Since ΔH°_{2+3} can be calculated without knowledge of ΔH°_2, this calculation may also be made for 4-epi-anhydrotetracycline. Calculating ΔS°_{2+3}, a value of +19.8 is obtained for 4-epi-anhydrotetracycline, +19.9 for tetracycline, and much lower values for the three chlor-analogs.

DISCUSSION

Rossotti (10) has suggested that from a simple viewpoint, the entropy change on complex formation would be expected to be negative (about −25 e.u.) due to the conversion of translational to vibrational and rotational entropy, accompanying the decrease in the number of particles in solution. However, the role of the solvent must also be estimated in rationalizing ligational entropy changes. Association of a metal ion with a charged ligand in aqueous solution will bring about a decrease in the numbers of ions, (partial) neutralization of electrical charge, attenuation of the remaining charge, and displacement of water from the hydration spheres of the reactant (10). The last term is a major factor and has brought about a differentiation between inner and outer sphere complexes. An inner sphere complex is formed when a ligand is able to replace a water molecule from the hydration sphere of the metal. An outer sphere complex does not replace water from the metal hydration sphere but is rather an ion pair complex. A less favorable entropy change will be expected from the formation of an outer sphere complex than from the corresponding inner sphere complex.

However, it should be noted that the magnitude of the enthalpy of complexation must also be considered, and that judgment concerning the sphere of complexation cannot be made strictly from an entropy viewpoint. Outer sphere complexes with Cl^- or SO_4^{--} as ligands usually show a slight *endothermic* heat of formation (11), whereas inner sphere complexes presuppose the formation of strong covalent bonds, which show large exothermic heats of formation. It should also be expected that a ligand of the size and complexity of tetracycline would show large conformational changes during chelation which would be reflected in the entropy changes.

Therefore, in considering what type of complexation takes place, no set rule for entropy values may be established, but rather an over-all view of all the processes listed above by Rossotti must be taken, with special emphasis for tetracycline on the conformational changes expected. On the basis of the high negative ΔH°_3 values obtained for the 1:1 complexes, it would seem that the two tetracycline analogs and the three chlortetracycline analogs all form inner sphere complexes with cupric ions. However, there is a significant difference between the ΔH°_3 values obtained for tetracycline and 4-epi-anhydrotetracycline[5] as opposed to the ΔH°_3 values for chlortetracycline, demethylchlortetracycline, and 4-epi-chlortetracycline. Since the ΔG°_3 values for tetracycline and the three chlor-derivatives are approximately the same, the difference in enthalpy is probably a function of the conformational changes required for tetracycline and the chlortetracyclines to reach a favorable complexing configuration.

As a system becomes more ordered, the entropy

[5] Although ΔH°_3 has not actually been determined for 4-epi-anhydrotetracycline, it seems reasonable to assume, on the basis of the data presented in Table V, that ΔH°_3 for 4-epi-anhydrotetracycline will be very close to ΔH°_3 for tetracycline.

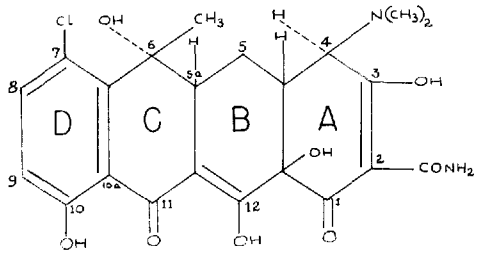

Fig. 2.—Configuration for chlortetracycline after Donohue *et al.* (12). Other authors (15) show the configuration for the enantiomorph.

of the system decreases. Therefore, the chlortetracycline analogs with negative $\Delta S°_3$ values seem to be required to undergo a more severe conformational change than tetracycline in order to reach a favorable configuration for chelation. From the data presented in Tables IV and V it would be expected that the requirement for a more severe conformational change would be dependent on the presence of the chlorine atom at carbon 7 (see Fig. 2). These ideas were tested by constructing framework molecular models[6] of the various tetracyclines using the bond lengths and configuration for chlortetracycline as determined by Donohue *et al.* (12) from X-ray data. The hydrogens on 6-methyl and 6-hydroxyl and the chlorine at carbon 7 were so constructed that the van der Waals radii for these atoms (13) were physically represented. From the model it is seen that the C ring can readily flip from a "boat" conformation where the 6-methyl is axial to the ring, to a "boat" conformation where the 6-methyl is equatorial to the C ring (while the 6-hydroxyl group goes from equatorial to axial positions) and that this flipping would be influenced greatly by the steric hindrance occurring between the chlorine at carbon 7 and either the 6-methyl or 6-hydroxyl.

On the basis of the data presented, it seems most likely that the first tetracycline ligand forms an inner sphere complex with cupric ions and that this complexation takes place with the formation of a chelate ring involving the cupric ion, oxygen 10, carbons 10, 10a, and 11, and oxygen 11, in which case it is necessary that all of the above atoms and ions lie in a plane (14). To accomplish this it is necessary that the C ring be essentially planar with the D ring, and in this case there would be considerable steric interaction between the chlorine atom and probably both the methyl and hydroxyl groups on carbon 6. Donohue *et al.* (12) point out that the Cl . . . CH_3 distance for this conformation is 2.99 Å. which is much less than 3.8 Å., the sum of the van der Waals radii. Obviously, if the chlorine at carbon 7 was not present as for tetracycline, the steric problem would be decreased and the entropy change would essentially depend on the replacement of water from the hydration spheres of copper.

In light of the above reasoning, it is hypothesized that the difference in the entropy of formation for 1:1 complexes of chlortetracycline and tetracycline is due to the strained steric requirement that chlortetracycline must undergo. If this hypothesis is true, it follows that there should be little difference between $\Delta S°_3$ for chlortetracycline and 4-epichlortetracycline, since the 4-dimethylammonium group would not be involved in complexation. This is found to be true in Table IV, and lends support to the idea that chelation takes place at oxygens 10 and 11.

It might seem that demethylchlortetracycline should have a $\Delta S°_3$ which is more positive than $\Delta S°_3$ for chlortetracycline, since demethylchlortetracycline has no 6-methyl group available for steric interaction with the chlorine. However, it seems reasonable to assume that for demethylchlortetracycline the 6-hydroxyl would generally be found axial to the C ring, since there would be much less steric interaction between the 6-hydrogen (equatorial) and the 7-chlorine. Therefore, it might be reasoned that it would be less favorable for the C ring in demethylchlortetracycline to become planar (bringing about steric interaction between chlorine and hydroxyl) than for the C ring in chlortetracycline, where there is no specially favored conformation for the hydroxyl (or methyl) group, and, thus, it could be hypothesized that a slightly more severe conformational change is required for demethylchlortetracycline than chlortetracycline in order to bring about complexation.[7]

In the case of 4-epi-anhydrotetracycline, it would be expected that the entropy of chelation would be similar to that of tetracycline (as is seen in Table V) for two reasons. First, there is no chlorine present at carbon 7 to cause steric interactions with the 6-methyl; and second, since chelation seems to occur at oxygens 10 and 11, entropy of chelation should not depend on whether the 4-dimethylammonium group is epimerized. In addition, for an anhydrotetracycline analog, the C ring is initially in a planar configuration due to the additional double bond at C_{5a}—C_6. Thus, it might be expected that all anhydrotetracyclines would have a $\Delta S°_3$ similar to tetracycline, regardless of whether a chlorine was present at carbon 7.

The results obtained for Reaction *4*, the formation of the 2:1 chelate from the 1:1 chelate and the free ligand, are generally similar for all four compounds, but considerably different from the results obtained for Reaction *3*. In the previous discussion it was hypothesized that the first ligand forms strong covalent bonds with the cupric ion. As a simple picture, we may consider a small cupric ion surrounded by the much larger tetracycline molecule, and although the C and D rings of the ligand are in a fixed position, the A and B rings and the bulky groups attached to them are still free to rotate. Now another large, negatively-charged tetracycline molecule complexes with the copper ion. It is very difficult to visualize a second tetracycline as being capable of approaching the cupric ion close enough to form a covalent ligand bond. This is confirmed by the low values obtained for $\Delta H°_4$ for all of the compounds studied, and thus it may reasonably be presumed that the second tetracycline forms an outer sphere or ion-pair complex.

[6] Prentice-Hall, Inc., Englewood Cliffs, N. J.

[7] An alternate hypothesis, suggested by the reviewer, proposes that the conformation in unchelated demethylchlortetracycline is the same as in chlortetracycline, perhaps due to hydrogen bonding to the 7-chlorine. Therefore, a similar conformational change occurs upon chelation leading to the observed similar entropy change. It should also be pointed out that the above explanations are only valid if chelation actually does take place at oxygens 10 and 11 as would be expected from the protonation scheme determined by Rigler *et al.* (16).

In this reaction $\Delta S°_4$ has a high value (see Table IV) for all of the analogs studied, both tetracycline and chlor-derivatives. This may be explained by the fact that when the second ligand attaches to the metal, the over-all charge of the complex becomes zero, and the number of ions in solution is decreased. This neutralization of charge and decrease in the number of ions is common to all the analogs studied and would be expected to give a positive entropy change. In addition, the conformational entropy changes between tetracycline and the chlor-analogs is not significant here, since little conformational change is needed to form an ion-pair complex bond.

Ionization of Bases with Limited Solubility

Investigation of Substances with Local Anesthetic Activity

By IVO SETNIKAR

The deionization process of six local anesthetics, *i.e.*, procaine, lignocaine, cocaine, Rec 7-0518, Rec 7-0544, and Rec 7-0591, was investigated. The compounds are weak bases with a low or a very low solubility of the unionized form. The effects of this property on the deionization process were studied and an explanation of the irregularities of the deionization curve suggested. A method for plotting the deionization process as a straight line is described. Temperature markedly affects the ionization constant. A limited solubility of the unionized base influences its buffering capacity. Both phenomena may be relevant to tissue tolerance for solutions of these substances.

It is essential to know the ionization curve of a local anesthetic in aqueous solution in order to choose a pH of the injectable solution that is optimal both for pharmaceutical stability and for local tissue tolerance.

Ionization curves may be plotted by the conventional method (1) which, for monoprotic species, leads to the well-known S-shaped curve. Other expressions of the results lead to straight-lined representation of ionization, with the advantage of showing more clearly experimental errors or deviations from theory.

Methods of obtaining straight-line representation of ionization of weak acids or bases were presented by Hofstee (2), by Benet and Goyan (3, 4), and by Leeson and Brown (5). The methods involve recalculations of the results and are strongly influenced by experimental errors (4). More immediate and easier to apply is the method proposed by Druckrey (6, 7), based on the use of a specially designed scale for the titrant, which yields a straight-line expression of the law of mass action. This method may also be adapted for expressing with a straight line the ionization process of weak acids or bases in which the unionized form is sparingly soluble, a fact which limits its availability for the ionization equilibrium.

THEORY

The ionization of a proton acceptor, B, is represented by

$$B + H^+ \cdot H_2O \rightleftarrows BH^+ + H_2O \quad \text{(Eq. 1)}$$

Since in a diluted aqueous solution the concentration of H_2O remains practically constant, the equilibrium of the ionization process is expressed by Eq. 2.

$$\frac{[BH^+]}{[B][H^+ \cdot H_2O]} = K' \quad \text{(Eq. 2)}$$

where K' is the apparent ionization constant, valid

In this reaction $\Delta S°_4$ has a high value (see Table IV) for all of the analogs studied, both tetracycline and chlor-derivatives. This may be explained by the fact that when the second ligand attaches to the metal, the over-all charge of the complex becomes zero, and the number of ions in solution is decreased. This neutralization of charge and decrease in the number of ions is common to all the analogs studied and would be expected to give a positive entropy change. In addition, the conformational entropy changes between tetracycline and the chlor-analogs is not significant here, since little conformational change is needed to form an ion-pair complex bond.

Ionization of Bases with Limited Solubility

Investigation of Substances with Local Anesthetic Activity

By IVO SETNIKAR

The deionization process of six local anesthetics, *i.e.*, procaine, lignocaine, cocaine, Rec 7-0518, Rec 7-0544, and Rec 7-0591, was investigated. The compounds are weak bases with a low or a very low solubility of the unionized form. The effects of this property on the deionization process were studied and an explanation of the irregularities of the deionization curve suggested. A method for plotting the deionization process as a straight line is described. Temperature markedly affects the ionization constant. A limited solubility of the unionized base influences its buffering capacity. Both phenomena may be relevant to tissue tolerance for solutions of these substances.

It is essential to know the ionization curve of a local anesthetic in aqueous solution in order to choose a pH of the injectable solution that is optimal both for pharmaceutical stability and for local tissue tolerance.

Ionization curves may be plotted by the conventional method (1) which, for monoprotic species, leads to the well-known S-shaped curve. Other expressions of the results lead to straight-lined representation of ionization, with the advantage of showing more clearly experimental errors or deviations from theory.

Methods of obtaining straight-line representation of ionization of weak acids or bases were presented by Hofstee (2), by Benet and Goyan (3, 4), and by Leeson and Brown (5). The methods involve recalculations of the results and are strongly influenced by experimental errors (4). More immediate and easier to apply is the method proposed by Druckrey (6, 7), based on the use of a specially designed scale for the titrant, which yields a straight-line expression of the law of mass action. This method may also be adapted for expressing with a straight line the ionization process of weak acids or bases in which the unionized form is sparingly soluble, a fact which limits its availability for the ionization equilibrium.

THEORY

The ionization of a proton acceptor, B, is represented by

$$B + H^+ \cdot H_2O \rightleftarrows BH^+ + H_2O \quad \text{(Eq. 1)}$$

Since in a diluted aqueous solution the concentration of H_2O remains practically constant, the equilibrium of the ionization process is expressed by Eq. 2.

$$\frac{[BH^+]}{[B][H^+ \cdot H_2O]} = K' \quad \text{(Eq. 2)}$$

where K' is the apparent ionization constant, valid

for the particular system in which ionization takes place. Equation 2 describes with sufficient approximation the ionization equilibrium of a weak base, except at the boundaries of almost total ionization or unionization of the base. Without approximations the ionization equilibrium is expressed by Eq. 3, derived from Clark (8).

$$\frac{[A^-] - [H^+ \cdot H_2O] - [D^+] + [OH^-]}{([S] - [A^-] - [OH^-] + [H^+ \cdot H_2O] + [D^+]) \cdot [H^+ \cdot H_2O]} = K' \qquad \text{(Eq. 3)}$$

in which A^- and D^+ are the ions of strong acids and bases present in the solution and S is the total quantity of the base, *i.e.*,

$$[S] = [B] + [BH^+] \qquad \text{(Eq. 4)}$$

In the range of its validity Eq. 2, in logarithmic terms and substituting K_B' for $1/K'$, becomes

$$pH = pK_B' + \log \frac{[B]}{[BH^+]} \qquad \text{(Eq. 5)}$$

If B has a limited solubility, at a certain point of titration the excess of B precipitates and the concentration of the dissolved B remains constant during the rest of titration. When this phenomenon happens Eq. 5 describes the deionization process only up to the point at which B starts to precipitate. Above this point the deionization is described by:

$$pH = pK_B' + \log \frac{[C]}{[BH^+]} \qquad \text{(Eq. 6)}$$

where C is the concentration of dissolved B on saturation.

In the conditions described by Eq. 5, a straight line is obtained by plotting the pH on the ordinate and log $[B]/[BH^+]$ on the abscissa, or using charts in which the abscissa is graded to a special scale, corresponding to the values of log $[B]/[BH^+]$. Furthermore, it may be convenient to substitute $[B]/[BH^+]$ with the titrated fraction F, where F is given by $[B]/[S]$. Since $[B]$ is equal to $[A^-]$, *i.e.*, the titrating strong acid, F is also given by $[A^-]/[S]$.

Similarly, Eq. 6 is expressed by a straight line when the pH is plotted on the ordinate and log $1/[BH^+]$ on the abscissa, or using a chart in which the abscissa is graded to a special scale corresponding to the values of log $1/[BH^+]$. In this case too $1/[BH^+]$ may be substituted by the titrated fraction F. The correspondence of the logarithmic scales, with these special F scales is represented in Fig. 1. The LR scale of Fig. 1 (log $[B]/[BH^+]$) refers to Eq. 5. The L scale (log $1/[BH^+]$) refers to Eq. 6.

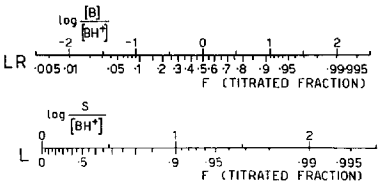

Fig. 1.—Scales of F (titrated fraction), which yield a straight-line relationship between F and pH for deionization processes of weak proton acceptors. Key: LR, scale equivalent to units of log $([B]/[BH^+])$ according to Eq. 5; L, scale equivalent to units of log $([S]/[BH^+])$ according to Eq. 6.

Equation 5 shows that $pK_B' = pH$ when $[B]/[BH^+] = 1$ or $F = 0.5$. Therefore the pK_B' can easily be found, either from the point at which $[B]/[BH^+] = 1$, or from any other point on the ionization line, since its slope, for monoprotic species, is the same on a pH *versus* LR diagram.

On the contrary Eq. 6, which may also be written as

$$pH = (pK_B' + \log C) + \log \frac{1}{[BH^+]} \qquad \text{(Eq. 7)}$$

does not yield the pK_B' value, unless C, the concentration of B at saturation, is determined.

EXPERIMENTAL

Investigated Substances.—The investigated substances were: procaine; lignocaine; cocaine; Rec 7-0518, *i.e.*, ketocaine or 2-(*N*-diisopropylaminoethoxy)-1-butyrophenone; Rec 7-0544, *i.e.*, 1-(*N*-diisopropylaminoethoxyphenyl)-butan-1-ol; and Rec 7-0591, *i.e.*, 2-(*N*-diisopropylaminoethoxy)-3-amino-1-butyrophenone. Rec 7-0518, Rec 7-0544, and Rec 7-0591 are three new local anesthetics described by Setnikar (9, 10).

The hydrochlorides of these substances were dissolved in CO_2-free glass-distilled water at a 0.1 and 0.01 M concentration and submitted to titration with 2 N and, respectively, 0.2 N carbonate-free NaOH.

Apparatus and Procedures.—The pH was measured with a Beckman Zeromatic model 96 meter, standardized against 0.05 M potassium hydrogen phthalate (pH = 4.0) and 0.01 M sodium borate (pH = 9.2). NaOH was added from a 3-ml. microburet, calibrated to 0.01 ml. Measurements were taken at 20.0° and at 37.0° on 50 ml. of the solutions of the local anesthetics under continuous and uniform agitation (magnetic stirrer). After each addition of NaOH, the pH was read when the meter had reached a stable value. The meter was read

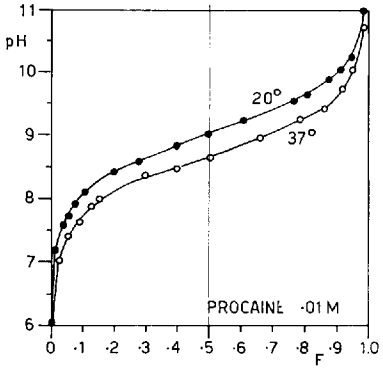

Fig. 2.—Ionization curve of 0.01 M procaine plotted by the conventional method. The titration was performed at 20.0° and at 37.0°, yielding two S-shaped deionization curves.

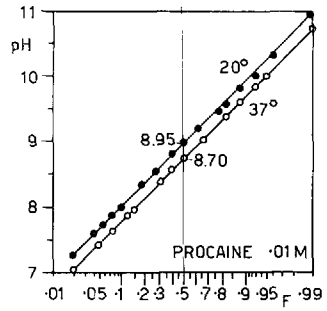

Fig. 3.—Procaine 0.01 *M*. Same data as in Fig. 2 plotted on a LR scale yielding straight-line relationships between pH and titrated fraction F. The pK_B' can be estimated from the whole titration and not only from the central data, as by the conventional method.

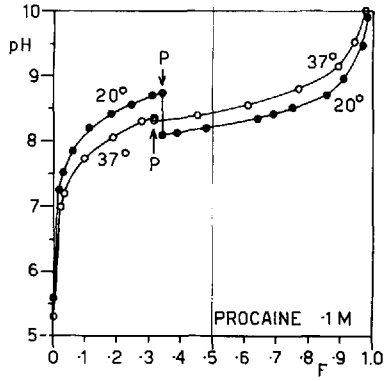

Fig. 4.—Ionization curve of 0.1 *M* procaine plotted by the conventional method. At the arrows, P, the undissociated base, starts to precipitate, markedly altering the deionization process. At this point the pH drops considerably, particularly on the curve obtained at 20°.

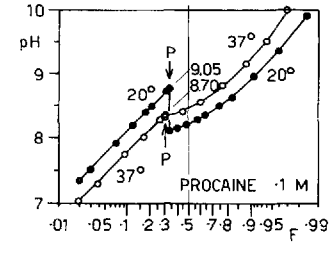

Fig. 5.—Procaine 0.1 *M*. Same data as in Fig. 4, but plotted on a LR scale for F. The initial straight-line part of the deionization process enables one to find the pK_B' values by extrapolation (9.05 at 20.0° and 8.70 at 37.0°). The data beyond the precipitation point are on a curved line, demonstrating a deviation from the theory described by Eq. 5.

10 min. after addition of the titrant when the titration was associated with precipitation.

The amounts of NaOH, corrected according to Parke and Davis (1), were expressed as fractions of the quantity necessary to titrate the whole base present in solution, and plotted on the charts *versus* the pH values.

Solubility of the Unionized Base.—Solutions of the hydrochlorides of the investigated substances, at a concentration of 0.1 *M* for procaine and lignocaine, and 0.01 *M* for the others, were deionized with a 5% excess of NaOH, filtered, or centrifuged, and the clear filtrate or supernatant acidified with HCl. These procedures were performed at 20° and at 37°. The concentrations of the substances in these acidified solutions were determined spectrophotometrically.

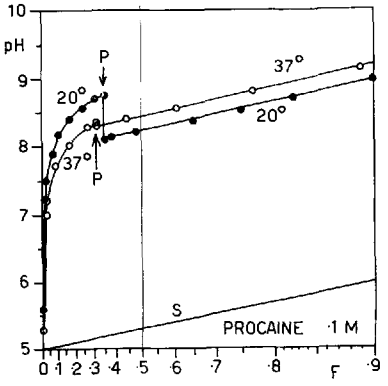

Fig. 6.—Procaine 0.1 *M*. Same data as in Figs. 4 and 5, but plotted on the L scale for F, which shows a straight-line deionization process after the precipitation point. Beyond this point the theory described by Eq. 6, therefore, applies. The line marked with S on the bottom of the figure shows the theoretical slope in these conditions.

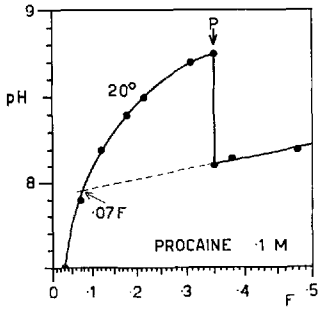

Fig. 7.—Detail of Fig. 6 showing a part of the deionization process at 20.0°. The arrow marks the point at 0.07 titration which corresponds to the maximum solubility of the unionized base in these conditions. This value is found by extrapolating the measurements after precipitation. From 0.07 F to 0.35 F, however, the base in unionized form remains still in solution, due to a phenomenon of hypersaturation. Phenomena of hypersaturation are often present, transiently as in this case or even during the whole titration, interfering with the evaluation of the maximum solubility and of the pK_B' values. They are not seen in back-titrations, *i.e.*, of the unionized base with a strong acid. In this case the dotted line is followed and the solution becomes clear only at the point in which the dotted line meets the first part of the titration curve.

RESULTS

The ionization curve for the tertiary amino group of 0.01 *M* procaine, plotted by the conventional method, is given in Fig. 2, yielding the well-known S-shaped curve. The same data plotted on the LR scale (*cf.* Fig. 1) yield a straight line with a slope of 45° (Fig. 3). In both instances the pK_B' value (second apparent ionization constant of procaine) is easily found.

The shape of the deionization curve of 0.1 *M* procaine is different, since between 0.3 and 0.4 F the unionized base precipitates and the deionization curve changes markedly. Particularly at 20.0° the pH drops by about 0.6. Then, proceeding in the titration, the pH raises again, first slowly, and then more rapidly, the final (right) part of the curve closely resembling the S-shaped deionization curve of soluble bases.

Wehr and Koelzer (11) noted that other bases with local anesthetic activity behaved in a similar complex way, but they offered no explanation.

The same data for 0.1 *M* procaine were plotted on a chart with the titrated fraction F expressed on the LR scale of Fig. 1. They yield a straight-line relationship between F and pH up to the precipitation point, *i.e.*, as far as the requirements of Eq. 5 are fulfilled (Fig. 5). Then the pattern departs markedly from the straight line and the theoretical pattern is approached again toward the end of titration.

By using a chart which yields a straight-line relationship between titrated fraction and pH when the requirements of Eq. 6 are fulfilled, it may be shown that, after precipitation, the theory described by Eq. 6 applies (Fig. 6) since the data are now on a straight line which has the theoretical slope.

The irregularities of the deionization curve of 0.1 *M* procaine shown by Fig. 4 are, therefore, related to the limited solubility of the unionized base and to the constant concentration of [B] in solution.

In the example given by 0.1 *M* procaine the solubility of B is limited but not very low. The estimation of pK_B' obtained in Fig. 5 by extrapolation of the straight-lined part of the deionization curve before precipitation may be considered reasonably precise, and so is the estimation of the maximum solubility of unionized procaine (Fig. 7).

For substances with a low solubility of the unionized base precipitation occurs after the addition of a very small amount of titrant and, due to the interference of transient hypersaturation phenomena, the evaluation of the pK_B' by extrapolation becomes rather arbitrary. An example of this is given by by the deionization curves obtained with 0.01 *M* and 0.1 *M* Rec 7-0518, which, in the unionized form, has a solubility lower than 1 mmole/L. (Figs. 8 and 10 and Table I). As shown by Figs. 9 and 11 the deionization of the Rec 7-0518 fits the theory of Eq. 6 throughout titration. In fact the relationship of the titrated fraction *versus* the pH on a chart with F on the L scale is straight-line and has the slope required by Eq. 6. Furthermore, the pH of the deionization lines of 0.1 *M* Rec 7-0518 is 1 unit higher than that of 0.01 *M* Rec 7-0518, due to the fact that log S and, therefore, also log $[BH^+]$ differ by one unit in the two conditions.

For substances with such properties both the pK_B' and the maximum solubility values may be estimated only with rough approximation. Un-

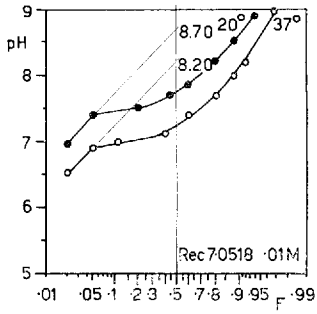

Fig. 8.—Deionization curve of 0.01 *M* Rec 7-0518 plotted on a LR scale for F. Owing to the very low solubility of the unionized form the process of precipitation starts at the very beginning of titration (in the range of 0.05 F). Taking account of the possible presence of hypersaturation phenomena, it becomes difficult to evaluate exactly the maximum solubility of Rec 7-0518. Since the calculation of the pK_B' value depends on the maximum solubility of the unionized base, the pK_B' can be estimated only with rough approximation. The figure shows how the pK_B' was estimated as 8.70 at 20.0° and as 8.20 at 37.0°.

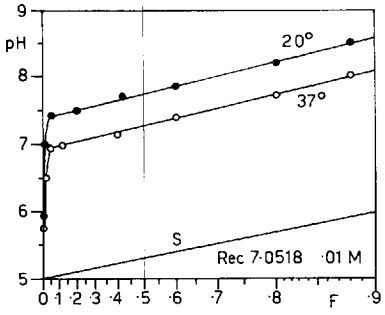

Fig. 9.—Rec 7-0518 0.01 *M*. Same data of Fig. 8 plotted on a L scale of F. After the precipitation point the theory described in Eq. 6 applies. At the bottom the theoretical slope (S) of the deionization process according to Eq. 6 is shown.

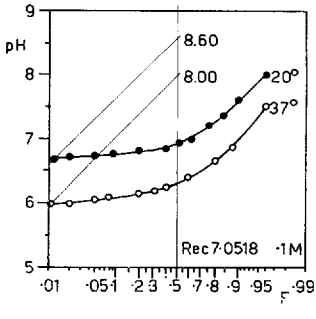

Fig. 10.—Deionization curve of 0.1 *M* Rec 7-0518 plotted on a LR scale for F. At this concentration it becomes still more difficult to evaluate the maximum solubility of the unionized form, since the precipitation obviously occurs at a lower titration point than for 0.01 *M* Rec 7-0518. Therefore, the calculation of the pK_B' value becomes still more approximate.

TABLE I.—APPARENT IONIZATION CONSTANTS OF THE INVESTIGATED BASES AND MAXIMUM SOLUBILITY OF THEIR UNIONIZED FORM AT 20.0° AND AT 37.0°[a]

		pKB′		Maximum Solubility, mmoles: From the Deionization Curves		Maximum Solubility, mmoles: Spectrophotometrically Determined			
		20°	37°	20°	37°	20°		37°

	0.1 *M*	?	?	?	?	...	..	...	..
	BE	9.4	9.4	0.8	0.2	0.5	..	0.7	..

[a] BE = best estimate, based on the most reliable values; D = obtained directly, without extrapolation; S = soluble at the investigated concentration; procaine II = second deionization of procaine; lignocaine II = second deionization of lignocaine; Rec 7-0591 I = first deionization of Rec 7-0591; Rec 7-0591 II = second deionization of Rec 7-0591; H = a substantial amount of procaine (about 20%) hydrolyzes at the high pH values of some steps of the experimental conditions.

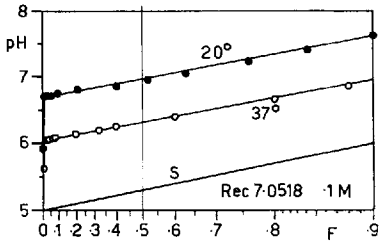

Fig. 11.—Rec 7-0518 0.1 *M*. Same data of Fig. 10 plotted on a L scale for F, in order to check the theory of Eq. 6. Besides by the straight-line alignment and by the slope of the data, the theory of Eq. 6 is verified also because the lines of Fig. 9 (Rec 7-0518 0.1 *M*) are higher by 1 pH unit than the corresponding lines of Fig. 11, as required by Eq. 6, since log S differs by 1 in the two conditions. Figure 9 becomes thus a right-hand continuation of Fig. 11.

fortunately, interference by hypersaturation phenomena and other technical difficulties make the estimation of maximal solubility by other methods problematic too. Therefore, the pK_B' values and the maximum solubility values of bases with a very small solubility of the unionized form, obtained by the described methods, must anyway be considered as very rough estimates.

The comments on Rec 7-0518 apply also to Rec 7-0544, since the solubility of its unionized form is also very low.

Rec 7-0591 has two basic radicals which ionize: one is the 3-amino group, with a pK_B' value of 4.6 at 20° and of 4.3 at 37°, and the other is the tertiary amino group in the *N*-diisopropylaminoethoxy chain, whose chemical-physical features are similar to those of the same radical in Rec 7-0518.

The results obtained with the investigated substances are summarized in Table I which leads to the following grouping.

(*a*) Substances soluble enough in the unionized form to remain in solution during the whole titration when the titration is performed on solutions with a concentration approximating that of the pharmaceutical solutions and in the range of pharmacological activity. This category includes procaine and lignocaine at 0.01 *M* concentration and Rec 7-0591 with regard to their properties during the first deionization process. The theory of Eq. 5 applies and the pH *versus* log $[B]/[BH^+]$ is a straight-lined relationship (*cf.* Fig. 3 of 0.01 *M* procaine). The pK_B' values can be determined directly.

(*b*) Substances with a more limited solubility of the unionized base. The theory of Eq. 5 applies until full saturation of the solution with the unionized base. Then the unionized form starts to precipitate and the theory described by Eq. 6 applies. This group includes 0.1 *M* procaine (Figs. 4–6), 0.1 *M* lignocaine, and 0.01 *M* and 0.1 *M* cocaine.

Maximum solubility of the unionized base and pK_B' values must be determined indirectly but still may be estimated with good approximation. Phenomena of hypersaturation are often present and can be demonstrated by plotting the data on an abscissa with a LR or L scale of Fig. 1. By the linearization so obtained it becomes possible to determine the actual concentration of soluble B during the remaining part of titration, when the excess of the unionized form precipitates.

(*c*) Substances with a low solubility of the unionized base. This group includes Rec 7-0518, Rec 7-0544, and Rec 7-0591, the last with regard to its properties during the second deionization process,

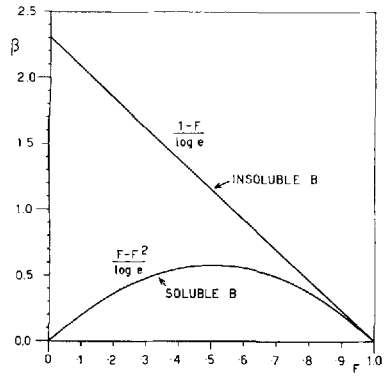

Fig. 12.—Buffering capacity β *versus* titrated fraction F of bases with insoluble unionized form or with soluble unionized form. The curves were calculated from the differential $\beta = dM/d\text{pH}$ and substituting for pH the right-hand member of Eq. 5 or, respectively, of Eq. 6. At a given concentration, the buffering capacity of bases with insoluble unionized form is much higher than that of bases with soluble unionized form. Furthermore, the maximum buffering capacity for the first type of bases is at the initial part of titration, whereas it is at the medial part of titration for the second type of bases.

Solubility of the unionized base and pK_B' values may be determined only with rough approximation.

DISCUSSION

Drop of pH Concomitant with Precipitation.—This behavior is frequently seen with substances whose unionized base is sparingly soluble, *e.g.*, 0.1 *M* procaine in Figs. 4–6. It is related to phenomena of hypersaturation of the unionized base, so that an excess of base provokes the precipitation of a part of [B] in Eq. 5, and the pH drops according to the new equilibrium described by Eq. 6. The maximum solubility of the unionized base, therefore, cannot always be deduced from the titrated fraction at the moment of precipitation, but must be calculated from the curve found after precipitation, extrapolating it in the direction of the first tract of the deionization curve, as exemplified in Fig. 7. This abrupt change of pH is never seen during the back-titration of the unionized base with a strong acid. In the back-titration the ionization curves follow the pattern of the dotted line of Fig. 7 and the solution becomes clear at the point in which the dotted line meets the first part of the ionization curve, which is then followed. This holds good for procaine and for all weak bases generally, which show the abrupt drop of pH during during deionization.

Buffering Capacity.—The tissue-tolerance for solutions with a pH different from that of the tissues depends partly on the buffering capacity of the solution, since possible damage to the tissues is related to the quantity of basic or acid radicals needed for re-equilibrating the pH. The buffering capacity is given by

$$\beta = \frac{d\,M}{d\,\text{pH}} \qquad \text{(Eq. 8)}$$

where M is the quantity of base or acid which provokes a change in pH.

For a base soluble in its unionized form, the buffering capacity β *versus* the titrated fraction F is given by the lower curve of Fig. 12 and is equal to:

$$\beta = \frac{F - F^2}{\log e} \qquad \text{(Eq. 9)}$$

The maximum value of β is at 0.5 titration, *i.e.*, when the pH = pK_B'.

A base which is insoluble in its unionized form has a much higher buffering capacity, equal to

$$\beta = \frac{1 - F}{\log e} \qquad \text{(Eq. 10)}$$

as shown by the higher curve of Fig. 12. The maximum value of β in this case is at zero titration. At a given concentration, a buffering system formed by a base with limited solubility of the unionized form is, therefore, more damaging for the tissues than a system formed by a base with a good solubility of the unionized form, when the pH differs from that of the tissues by the same degree. This explains the observation of Wehr and Koelzer (11) that low precipitation points on the pH or on the titration scale are correlated with low tolerance.

Effect of Temperature.—Conventionally pK_B' values are determined at 20° or at other temperatures close to room temperature.

As shown by Table I the pK_B' at 37° is usually lower, by a value up to 0.6, than the pK_B' at 20°. This phenomenon is related to the influence of temperature on the ionization constant of water which is 14.167 at 20.0° and 13.620 at 37°, with a drop of more than 0.5 unit.

The investigated bases have, therefore, a stronger proton-accepting property at 37° than at 20° and measurements taken at 20° or 25° can be misleading with regard to any inference on the tolerance of solutions for tissues at 37°.

It is interesting to note that for bases with a limited solubility of the unionized form an increase of the solubility of this form has an effect comparable to an increase of pK_B', *i.e.*, a shift toward a higher pH region of the whole deionization curve. The increase of temperature has, therefore, two opposite effects on the position of the deionization curve: due to the increase of the solubility of the unionized base, the deionization curve is shifted toward the top (*cf.* Eq. 6) and due to the decrease of the pK_B', the curve is shifted toward the bottom. The second effect seems usually to prevail over the first.

Interaction of Di- and Tricarboxylic Acids with Glutaric Anhydride in Aqueous Solution

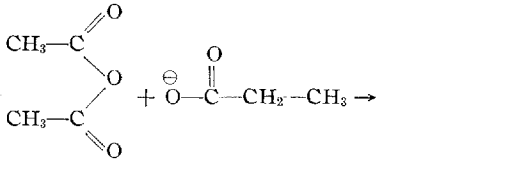
By JOSEPH R. ROBINSON, ARNOLD J. REPTA, and TAKERU HIGUCHI

Anionic forms of polycarboxylic acids such as succinic, citric, etc., interact reversibly and rapidly with glutaric anhydride in aqueous solution at room temperature to produce species which undergo subsequent hydrolysis. The species formed *in situ* from citrate was reacted with aniline and the resulting products isolated by column chromatography. Results of the chromatographic study suggested a mechanism based on the initial formation of a mixed anhydride which cleaved to produce an anhydride of the attacking anionic species. Spectrophotometric investigations have shown that the rate of formation and subsequent hydrolysis of the anhydride are dependent upon the pH and the buffer concentration. These reactive species are presumed to be formed to a varying extent in any formulation containing citrate, particularly under autoclaving conditions.

MANY BIOCHEMICAL systems as well as pharmaceutical formulations contain polycarboxylic acids. Citric acid, tartaric acid, malic acid, aconitic acid, and succinic acid are examples of food acids which occur naturally and are also often used in pharmaceutical preparations. In an earlier report (1) it was shown that these acids exist in solution in equilibrium with their corresponding cyclic acid anhydride forms which are capable of reacting with any nucleophilic species present. The present communication is concerned with results of studies designed to determine the rate and mechanism of transference of this anhydride character in a mixture containing two of these polycarboxylic acid species. Specifically, the interaction of citrate species with glutaric anhydride was investigated.

In aqueous solution, since water is a weak but an effective nucleophile, acid anhydrides undergo relatively rapid hydrolysis with half lives of the order of minutes. In the presence of other more potent electron donors, which are often constituents of frequently used pharmaceutical buffers, other reactions may take place preferentially. Thus, it has been suggested that acetic anhydride reacts with propionate ions with subsequent formation of a mixed anhydride (2).

Scheme I as written would be expected to be largely irreversible in the presence of a large excess of the attacking carboxylate species. If an analogous reaction takes place between a cyclic anhydride and a polycarboxylic acid species, on the other hand, an equilibrium system such as



Scheme I

that shown in Scheme II may be expected to take place (3).[1]

Formation of citric anhydride probably results from intramolecular attack from the neighboring carboxyl group of the citrate moiety on a carbonyl carbon in the mixed anhydride. The mixed anhydride may also revert back to glutaric anhydride by the same mechanism and is probably present only in relatively low concentration.

The present investigation was designed to determine whether the postulated reactions would occur and to establish the individual rates and products of the system. This was done by observing spectrometric changes in the reacting systems and by chromatographic analysis and identification of the end products.

RESULTS AND OBSERVATIONS

Spectrophotometric Studies.—Glutaric anhydride has a characteristic ultraviolet absorbance spectrum that can be utilized to follow its hydrolysis in aqueous solution. When citric acid is employed as a buffer at a pH where substantial quantities of the di-ionized species are present, a change in ultraviolet absorbance is observed. This interaction can be conveniently followed since the reactants, intermediate species, and the final products apparently

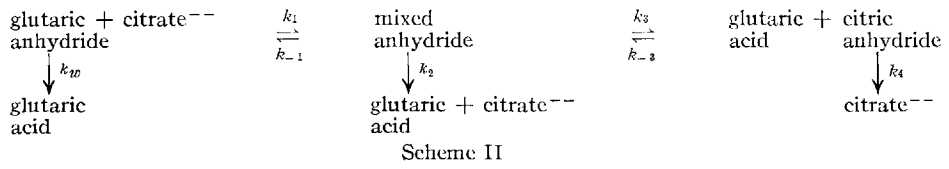
This investigation was supported in part by grants from the American Chicle Co., Warner-Lambert Pharmaceutical Co., Long Island, N. Y., the Research Committee, Graduate School, University of Wisconsin, from funds supplied by Wisconsin Alumni Research Foundation.

[1] Higuchi *et al.* (3) have also shown that acyl exchange of this type takes place with great facility. Their paper should be consulted for specific details.



Scheme II

possess sufficiently different ultraviolet molar absorptivities to permit observation of the various reactions. A typical absorbance change at 248 mμ with time for a system containing initially 7.05 × 10^{-3} moles of glutaric anhydride in 0.3 *M* citrate buffer at pH = 5.0 is shown in Fig. 1. There is a small increase in absorbance initially, followed by a logarithmic approach to an equilibrium value. This corresponds presumably to a G + B ⇌ C → D type relationship where species C possesses a slightly higher molar absorbance than the reactants or the final product. The experimental observation noted above is in agreement, at least in form, to the reactions implicit in Scheme II.

It is apparent from the proposed reaction scheme that there are two possible species which could correspond to species C, the mixed anhydride and citric anhydride. Similarly, the deterioration of the species could be attributable to decomposition of the mixed anhydride or hydrolysis of citric anhydride.

If one assumes $k_3 \gg k_1$, k_{-1}, k_2, k_2, and k_w, and that k_{-3} is negligible,[2] the concentration of species such as citric anhydride can be expressed as:

$$[CA] = \frac{k_1[B]\ [GA]_0}{k_1[B] + k_w - k_4} \times [e^{-k_4 t} - e^{-(k_1[B] + k_w)t}] \quad \text{(Eq. 1)}$$

where [CA] = citric anhydride, [GA] = glutaric anhydride, and [B] = citrate buffer. If the absorbance of a reacting system initially containing glutaric anhydride and citrate is followed at 248 mμ, a plot of log $[A_T - A_\infty]$ against time (where A_T is the absorbance at any time, t, and A_∞ is the limiting absorbance) will yield a straight line in the terminal phase, provided $(k_1[B] + k_w) \gg k_4$. This is because under such a circumstance $(A_T - A_\infty)$ will be expected to be essentially proportional to the concentration of citric anhydride when the total anhydride concentration becomes very small. The slope of the logarithmic plot would then be equal to $-k_4$. Extrapolation of this line will give an imaginary $(A_0' - A_\infty)$ value (which is proportional to [CA]) at time zero. A semilogarithmic plot of $[(A_T' - A_\infty) - (A_T - A_\infty)]$ against time will yield a linear relationship with a slope equal to $-(k_1[B] + k_w)$.

The rates of appearance {corresponding to $(k_1[B] + k_w)$} of the strongly absorbing intermediate species (citric anhydride?) were determined from plots of $(A_T' - A_T)$ for systems at several pH values and different buffer concentrations. Results are shown in Fig. 2. The data suggest that the initial reaction between the anhydride and citrate probably involves the di- and/or tri-ionized form of citric acid.

The apparent rates of loss of the active species (k_4) determined as outlined above are shown in Fig. 3 for several values of pH and various buffer concentrations. The pH range studied was limited to that where citrate behaved effectively as a buffer. Based on the proposed mechanism of relatively rapid formation of citric anhydride followed by a slower hydrolysis, the apparent pH dependency could be ascribed to a slower rate of formation of citric anhydride at lower pH values and buffer concentrations. The relationship presented above permitting separation of the individual rate constants requires that $(k_1[B] + k_w)$ be at least 4 to 5 times larger than k_4. Since in the lower pH range this minimum ratio in the reaction velocities is not apparently obtained, the limiting slopes do not reflect the true magnitude of k_4 in this range. The terminal slopes above pH = 4.5 are considered to reflect the true values of k_4 in that at these pH values, the rate of formation is considerably faster than the subsequent hydrolysis. In Fig. 3, above pH = 4.5, the lines connecting the experimental points extrapolate back to a common value of 11.5 × 10^{-3} sec.$^{-1}$. This is assumed to be the rate constant for hydrolysis of citric anhydride in water.

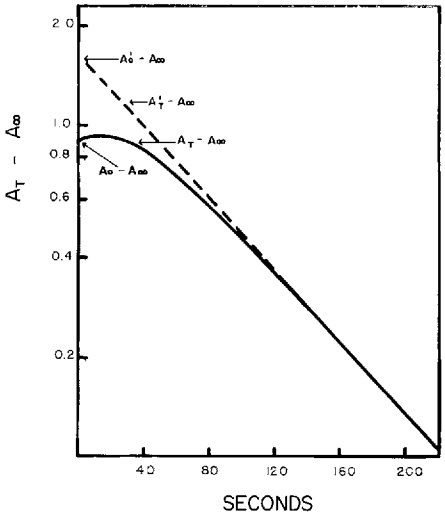


Fig. 1.—Semilogarithmic plot of absorbance change at 248 mμ for the system glutaric anhydride in citrate buffer. pH = 5.0, 0.3 *M* citrate; T = 25°.

The observed decrease in absorbance may also be attributed to slow disappearance of the mixed anhydride (to form citric anhydride) followed by rapid hydrolysis of citric anhydride. A mechanism such as this would require that the glutaric–citric mixed anhydride would be a relatively stable species which would not be expected based on the structure. Direct hydrolysis of the mixed anhydride is also a possibility, but again a stable mixed anhydride could be required. Further work is

[2] Pseudo first-order conditions were maintained and there was always at least a sixtyfold excess of citrate buffer.

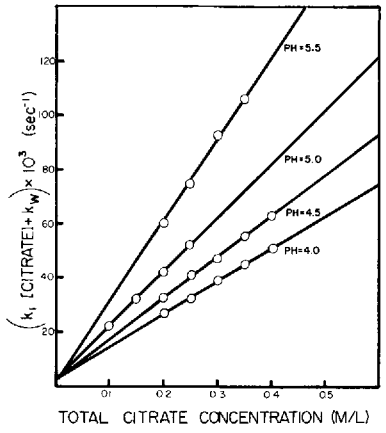

Fig. 2.—Rate of formation of the species formed from the glutaric–citric system at various pH values and different buffer concentrations.

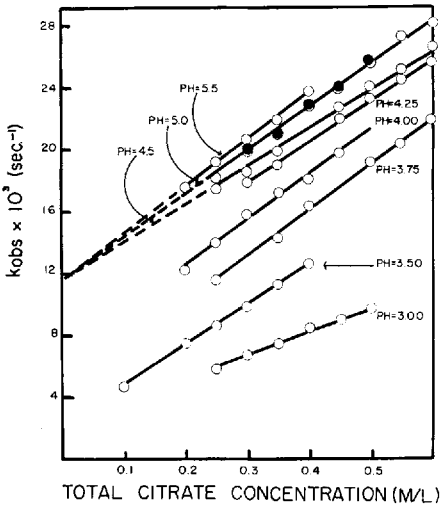

Fig. 3.—Observed rate of hydrolysis of the species formed from the interaction of glutaric anhydride in citrate buffer at various pH values and different buffer concentration. Key: ●, 1 *M* KCl; ○, H_2O.

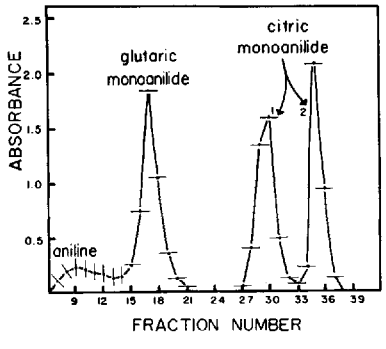

Fig. 4.—Typical chromatogram for the anilides formed by addition of aniline to the reaction mixture. The reaction was quenched with aniline after 30 sec. The eluate was extracted with 0.1 *N* NaOH and the alkaline solution analyzed spectrophotometrically at 241 mμ.

required to definitely establish which mechanism is correct, but intuitively the scheme involving rapid formation of citric anhydride followed by a relatively slow hydrolysis would seem the more likely.

Chromatographic Studies.—Although results of rate studies were strongly indicative of formation of citric anhydride species from mixtures of glutaric anhydride and citrate buffers, the data were not considered definite by themselves. Attempts were made to substantiate these findings by direct chemical examination of the reacting systems. The procedure adopted was isolation and quantification of the reaction products resulting from addition of aniline to the anhydride mixture, all anhydride species present presumably reacting extremely rapidly with the strong nucleophile aniline.

Separation of reaction products following addition of aniline to the reacting systems are evident in the chromatogram shown in Fig. 4. The particular run contained initially 0.3 *M* pH = 5 citrate buffer and 3.95×10^{-5} moles of glutaric anhydride with a trace of dioxane. The reaction was quenched with aniline after 30 sec. and separated by column partition chromatography and analyzed by ultraviolet spectrophotometry as described earlier (4). The double peak ascribed to citric monoanilide corresponds to the isomeric forms as previously suggested (4). Elemental analysis, equivalent weight, ultraviolet spectrum, and infrared spectrum of the compounds corresponding to peaks 1 and 2 were determined and found to be compatible with that of citric monoanilide.

Supportive evidence to corroborate the postulate that the two peaks correspond to the isomeric forms of citric monoanilide was obtained by hydrolyzing citranilic acid[3] and chromatographing the resultant products. Random hydrolysis of this citric acid imide will produce the two isomeric monoanilides of citric acid. Chromatographic separation of this mixture in the same manner as that employed for the anilides formed in the glutaric anhydride–citric acid mixture gave two peaks. The retention volume required for these two peaks was the same as that required for the two peaks in the glutaric–citric case.

It is conceivable that citric monoanilide could have formed through a lactone intermediate. However, previous work with the lactones of tartaric acid (5) has shown them to be unreactive toward aromatic amines under the conditions employed here, and therefore, this was ruled out as a possible pathway.

Citric monoanilide theoretically could have been formed through a mixed anhydride as well as citric anhydride. Previous work has shown (6) that addition of aniline to a mixed anhydride usually gave anilides of both compounds. Depending upon the nature of the mixed anhydride, the yield of one of the anilides may be favored over the other. When aniline was added to the reaction mixture where the pH of citrate buffer was 2.0, citric monoanilide could not be isolated.[4]

[3] Citranilic acid was prepared according to Higuchi *et al.* (4), m.p. 187–188° (literature values vary from 185–189°). Molecular weight determined by direct titration with sodium hydroxide was found to be 253 (calculated 249).

[4] At pH = 2.0, the fraction of aniline in the protonated form is quite high and therefore a large excess was employed. Isolation of glutaric monoanilide from the reaction mixture indicated that sufficient unprotonated aniline was present to react with anhydrides in the system.

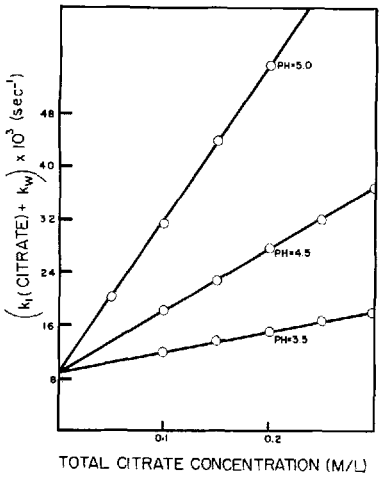

Fig. 5.—Disappearance of phthalic anhydride at 302 mμ as a function of pH and buffer concentration.

At a pH = 2.0, using 3.08 and 4.74 as the respective first and second ionization constants of citric acid (7), the monoionized and free acid would be present almost exclusively with very little of the di-ionized species present. If the monoionized citrate species can attack glutaric anhydride, and since citric monoanilide was not isolated, it is reasonable to assume that either the mixed anhydride is present in a very low concentration or that glutaric monoanilide is exclusively favored in this system.

An additional system that was tried was glutaric anhydride in a pH = 5.5 acetate buffer. Addition of aniline to this reaction mixture did not produce any acetanilide. This would indicate that this system, like the previous one, hydrolyzes *via* an unstable mixed anhydride or formation of glutaric monoanilide is exclusively favored. An alternative possibility is that acetate ion serves as a general base in this system.

To demonstrate the generality of the reaction, phthalic anhydride was used in place of glutaric anhydride. Phthalic anhydride hydrolysis was followed at 315 mμ in citrate buffer. Unlike the glutaric case, there was no apparent anomaly observed in the ultraviolet spectrum, indicating that if a new species was being formed in solution, it had less absorbance at this wavelength than the reactants. The rate of hydrolysis of phthalic anhydride as a function of pH and buffer concentration is shown in Fig. 5. Apparently this system, like glutaric anhydride, is sensitive to the di- and/or tri-ionized species of citric acid. Addition of aniline to the reaction mixture in a manner the same as before gave substantial quantities of citric monoanilide. This indicates that phthalic anhydride like glutaric anhydride is capable of reacting with citrate to form a species in solution which has anhydride properties.

DISCUSSION

Polycarboxylic acids are often used in combination as buffer components; in light of the findings of this study an exchange of anhydride character also presents a possible pathway for drug loss from solution. Equally important is the possibility that a myriad of products could result.

EXPERIMENTAL

Equipment and Reagents.—A Cary model 11 M.S. recording spectrophotometer was utilized for the spectrophotometric determinations. All pH measurements were made with a Beckman Zeromatic pH meter with an expanded scale.

Aniline was purified by repeated distillation and was stored under nitrogen prior to use. Dioxane was purified according to Vogel (8). Glutaric anhydride was recrystallized from ether until a m.p. of 56–57° was obtained. All other chemicals were of analytical or reagent grade.

Procedure for Kinetic Runs on Citric Acid–Glutaric Anhydride Reactions.—Citrate buffers of appropriate concentration and pH were prepared. One-hundred microliters of a 0.450 *M* glutaric anhydride in dioxane solution was mixed with 6 ml. of citrate buffer in a 2-cm. photometer cell. The reaction was followed spectrophotometrically at 248 mμ. All reaction solutions were equilibrated at 25 ± 0.1° prior to use. The concentration of dioxane used in all cases was determined to have a negligible effect on the rate constants.

Procedure for Kinetic Runs on Citric Acid–Phthalic Anhydride Reactions.—Citrate buffers of appropriate concentration and pH were prepared. Fifty microliters of a 0.0338 *M* phthalic anhydride in dioxane solution was mixed with 6 ml. of citrate buffer in a 2-cm. photometer cell. The reaction was followed spectrophotometrically at 302 mμ. All reaction solutions were equilibrated at 25 ± 0.1° prior to use.

Chromatographic Separation of the Reaction Mixture.—The chromatographic columns were prepared as outlined in a previous communication (4). The reaction mixture was prepared by adding 15 ml. of citrate buffer to 100 μl. of a 1.58 *M* glutaric anhydride in dioxane solution. The reaction was allowed to continue the requisite period of time and was quenched with 4 ml. of a 0.33 *M* aqueous aniline solution. The pH was adjusted to 3.13 with HCl and a 5-ml. sample was placed on the column with 5 Gm. of silicic acid. The eluting solutions consisted of 100 ml. each of chloroform, 1.5% butanol in chloroform, 10% butanol in chloroform, and 30% butanol in chloroform; each solution was saturated with the internal phase prior to use. The eluate was collected in 10-ml. fractions; the collecting vessel was rinsed with 10 ml. of chloroform and added to the 10-ml. fraction. Each sample was extracted with 20 ml. of 0.1 *N* NaOH.

Preparative Chromatography of the Reaction Mixture.—A chromatographic column with the following dimensions was employed: length = 60 cm., i.d. = 3.40 cm. Three-hundred grams of silicic acid was utilized as the support and 300 ml. of pH 3.13 phosphate buffer was employed as the internal phase. The eluting solutions consisted of 500 ml. each of chloroform, 1.5% butanol in chloroform, 5% butanol in chloroform, 15% butanol in chloroform, and 35% butanol in chloroform; each solution was saturated with the internal phase prior to use. The reaction mixture was prepared by mixing 100 ml. of 0.3 *M* pH = 5 citrate buffer

with 3.2 ml. of 1.58 *M* glutaric anhydride in dioxane solution. The reaction mixture was quenched at the end of 30 sec. with 16 ml. of a 0.33 *M* aqueous aniline solution. The pH of the resulting solution was adjusted to pH 3.13 with HCl and 30 ml. of this solution was placed on the column with 30 Gm. of silicic acid. The eluate was collected in 50-ml. fractions. The solvent was removed from each sample under reduced pressure and a mixture of chloroform–petroleum ether added to precipitate the compounds.

Characterization of Reaction Compounds.—*Glutaric Monoanilide.*—This was recrystallized from methanol–water, m.p. 129–130°. Molecular weight found by direct titration against standard NaOH was 205 (calculated 207). Known glutaric monoanilide was prepared by adding glutaric anhydride dissolved in dioxane to an aqueous solution of aniline. The sparingly soluble anilide precipitated and when recrystallized gave a m.p. 129–130°. Both known and unknown compounds gave identical infrared and ultraviolet absorption spectrums.

Citric Monoanilide.—1.—This was recrystallized from chloroform, m.p. 136–137°.

Anal.—Calcd. for C, 53.94; H, 4.87; N, 5.23. Found: C, 53.90; H, 4.94; N, 5.3.

Molecular weight determined by direct titration against NaOH was 269 (calculated 268). Infrared and ultraviolet spectra were characteristic of an anilide. NMR spectrum strongly suggested this to be the symmetrical isomer, 2-hydroxy-2-*N*-phenylcarbamide-1,3-propanedicarboxylic acid.

Citric Monoanilide—2.—This was recrystallized from chloroform, m.p. 127–128°. Molecular weight determined by direct titration against sodium hydroxide solution was 270 (calculated 268).

Anal.—Calcd. for C, 53.94; H, 4.87; N, 5.23. Found: C, 53.87; H, 4.85; N, 5.20.

Infrared and ultraviolet absorption spectra were characteristic of an anilide. NMR spectrum suggested this to be the unsymmetrical isomer, 2-hydroxy - 1 - *N* - phenylcarbamide - 2,3 - propanedicarboxylic acid.

Interaction of Acetic Anhydride with Di- and Tricarboxylic Acids in Aqueous Solution

By ARNOLD J. REPTA, JOSEPH R. ROBINSON, and TAKERU HIGUCHI

Earlier studies have shown that cyclic anhydrides, such as succinic, glutaric, etc., interact with citrate ions in aqueous solution to form what appears to be a citric anhydride species. These interactions have been assumed to be highly reversible through intermediate formation of a mixed anhydride. The present studies were concerned with a comparable system which was expected to be essentially irreversible. Spectrophotometric investigations have shown that acetic anhydride apparently reacts with citrate in aqueous solution to form a new species which undergoes rapid hydrolysis. The rate of the initial reaction and the rate of the subsequent step appear to depend on the citrate concentration and pH. Results of chromatographic studies on products obtained by reaction with aniline at different phases of the reaction are presented.

IN AN EARLIER report (1), experimental evidence was presented which suggested that glutaric and presumably other cyclic anhydrides formed an equilibrium system in the presence of a large excess of citrate buffer in which the total anhydride concentration was distributed among glutaric anhydride, citric anhydride, and perhaps glutaric–citric anhydride. An attempt has been made in the present study to obtain a clearer picture of the reacting system by employing acetic anhydride to furnish the initial anhydride concentration; the noncyclic anhydride not being expected to participate effectively in any reversible process.

If the forward reaction pathway remains essen-

Interaction of Acetic Anhydride with Di- and Tricarboxylic Acids in Aqueous Solution

By ARNOLD J. REPTA, JOSEPH R. ROBINSON, and TAKERU HIGUCHI

Earlier studies have shown that cyclic anhydrides, such as succinic, glutaric, etc., interact with citrate ions in aqueous solution to form what appears to be a citric anhydride species. These interactions have been assumed to be highly reversible through intermediate formation of a mixed anhydride. The present studies were concerned with a comparable system which was expected to be essentially irreversible. Spectrophotometric investigations have shown that acetic anhydride apparently reacts with citrate in aqueous solution to form a new species which undergoes rapid hydrolysis. The rate of the initial reaction and the rate of the subsequent step appear to depend on the citrate concentration and pH. Results of chromatographic studies on products obtained by reaction with aniline at different phases of the reaction are presented.

IN AN EARLIER report (1), experimental evidence was presented which suggested that glutaric and presumably other cyclic anhydrides formed an equilibrium system in the presence of a large excess of citrate buffer in which the total anhydride concentration was distributed among glutaric anhydride, citric anhydride, and perhaps glutaric–citric anhydride. An attempt has been made in the present study to obtain a clearer picture of the reacting system by employing acetic anhydride to furnish the initial anhydride concentration; the noncyclic anhydride not being expected to participate effectively in any reversible process.

If the forward reaction pathway remains essen-

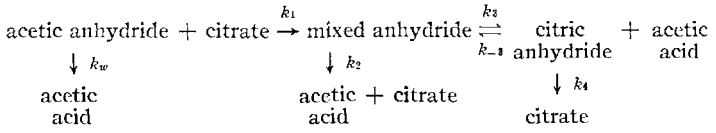
This investigation was supported in part by grants from the American Chicle Co., Warner-Lambert Pharmaceutical Co., Long Island City, N. Y., the Research Committee, Graduate School, University of Wisconsin, from funds supplied by the Wisconsin Alumni Research Foundation.



Scheme I

tially the same as in the cyclic anhydride case, a mixed acid anhydride species would be formed by interaction of acetic anhydride and citrate ion. The loss of the acetate in this step would, however, make formation of the mixed anhydride irreversible. The net effect of this would be to drive the reaction to the right. The proposed reaction is shown in Scheme I.[1]

In the present investigation the differences in the characteristics of this irreversible system from those of the previously studied reversible system have been explored.

RESULTS AND OBSERVATIONS

Spectrophotometric Studies.—Although acetic anhydride hydrolyzes rather rapidly in cold water ($t_{1/2} \cong 5$ min. at 25°), it appears to be capable of reacting with nucleophilic species such as citrate anions. When the hydrolysis is followed spectrophotometrically at 248 mμ in citrate buffer, at pH values where there is an appreciable quantity of di-ionized citrate, a species appears to be formed which has an ultraviolet absorptivity greater than the original anhydride. The absorbance–time profile observed for a system initially containing 1.08×10^{-3} M acetic anhydride in 0.3 M citrate buffer, pH = 5 and 25°, is shown in Fig. 1. The shape of the plot suggests that the reaction involves relatively rapid formation and subsequent hydrolysis of some intermediate species.

As shown previously (1), the concentration of citric anhydride can be expressed[2] as:

$$[CA] = \frac{k_1[B][AA]_0}{(k_1[B] + k_w - k_4)} [e^{-k_4 t} - e^{-(k_1[B] + k_w)t}]$$

If $(k_1[B] + k_w) \gg k_4$, a semilogarithmic plot of $(A_t - A_\infty)$ against time (where A_t is the absorbance at any time t and A_∞ is the limiting absorbance) will have a terminal slope equal to $-k_4$. Extrapolation of this terminal line to zero time will give a value $(A_0' - A_\infty)$ which corresponds to the imaginary absorbance of the new species at time zero. A semilogarithmic plot of $[(A_t' - A_\infty) - (A_t - A_\infty)]$, at various times, against time will yield a linear relationship with a slope equal to $-(k_1[B] + k_w)$.

The rates of appearance $(k_1[B] + k_w)$ of the more strongly absorbing species in the system are influenced by both hydrogen-ion concentration and buffer concentration as shown in Fig. 2. As is evident from the plots, the rate of formation appears to

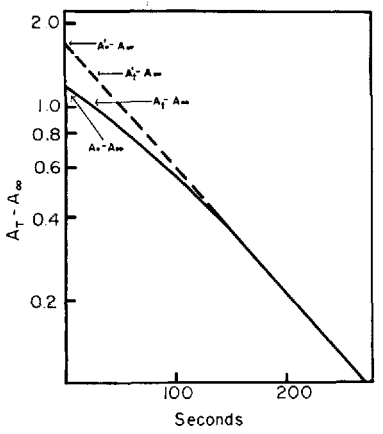


Fig. 1.—Semilogarithmic plot of absorbance change at 248 mμ for the system acetic anhydride in citrate buffer. pH = 5.0; T = 25°.

depend upon either the di- and/or the tri-ionized form of citric acid. It should be noted here that the apparent transfer of anhydride character was observed only at a pH = 3 or greater where the concentration of di-ionized citrate was appreciable.

The observed rates of loss (k_4) of the new species, found from the terminal slopes as described above are shown in Fig. 3 for various pH values and different buffer concentrations. From the proposed reaction Scheme I, if $k_4 \gg k_3$, one would be essentially observing the rate of loss of the mixed anhydride. Similarly, if $k_3 \gg k_4$, the observed hydrolysis would be that of citric anhydride. It is felt that the latter situation probably exists and that acetic anhydride reacts with the citrate buffer to produce citric anhydride which subsequently undergoes hydrolysis.

The apparent dependency upon hydrogen-ion concentration observed in Fig. 3 can be explained on the basis that if the rate of formation of citric anhydride is slow at low pH values and low buffer concentration, extrapolations of the terminal slope does not reflect the true hydrolytic rates for the disappearance of the species. It is suggested, therefore, that only above pH = 6 is the terminal slope representative of the true hydrolytic rate of citric anhydride.

The pH dependency is similar to that observed in the glutaric anhydride–citric acid case (1). The extrapolations of the higher pH values to zero buffer concentration would be expected to yield the uncatalyzed hydrolytic rate for citric anhydride. Since in both systems citric anhydride is apparently formed, the extrapolated rate value should be the same. The value of 11.5×10^{-3} sec.$^{-1}$ obtained in

[1] The reaction steps k_w, k_2, and k_4 are considered irreversible, since under the conditions employed here (25°, aqueous solution) the reverse reaction would be negligible (2).

[2] The assumptions involved in this derivation are the same as previously reported (1). The reaction step, k_3, is considered irreversible since at least a sixtyfold excess of buffer was employed at all times.

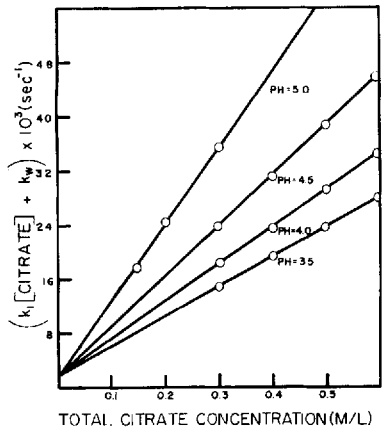

Fig. 2.—Rate of formation of the species formed from the acetic anhydride–citrate system at various pH values and different buffer concentrations.

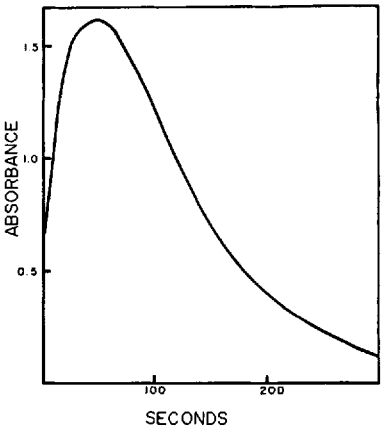

Fig. 4.—Absorbance-time profile for acetic anhydride, initial concentration 4.5×10^{-3} *M*, in 0.5 *M* phthalate buffer. The absorbance change was followed at 315 mμ. pH = 5.5; T = 25°.

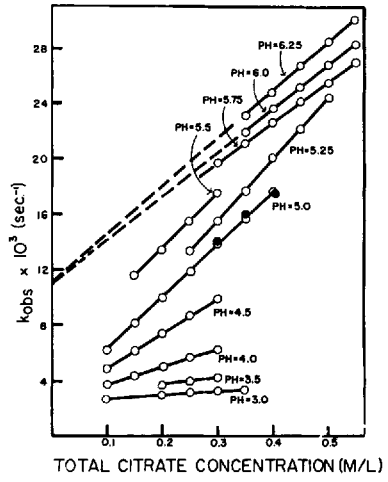

Fig. 3.—Observed rate of hydrolysis of the species formed from the interaction of acetic anhydride in citrate buffer at various pH values and different buffer concentrations. Key: ●, 1 *M* KCl; ○, H_2O.

this investigation is in good agreement with that reported in the earlier work (1).

Apparently the pH values, necessary to obtain a limiting maximum rate constant upon extrapolation to zero buffer at a given pH, are higher (pH = 6.0) for the present case than those found for the glutaric–citrate case (pH = 4.5). This dependence may be rationalized on the basis of steric effects. Since both glutaric and acetic anhydrides have approximately the same rate of hydrolysis in water, one cannot ascribe the observed phenomenon singly to the different sensitivities of the two species to nucleophilic attack.

As previously mentioned (1), the data presented can also be rationalized by an alternate pathway. This essentially requires that the rate-determining step corresponds to the decomposition of the mixed anhydride. A mechanism such as this requires that acetic–citric anhydride be a relatively stable species which seems unlikely. It should be pointed out that direct hydrolysis of the mixed anhydride is also possible, but the slow rate of hydrolysis observed would again require that the mixed anhydride be a relatively stable species.

The catalytic effect of citrate buffer on the hydrolytic rate of the assumed citric anhydride has been observed with other anhydrides. An example of this is the catalytic hydrolysis of acetic anhydride by acetate ions. The most acceptable theory for this catalysis is a general base effect, since nucleophilic attack would result in an identical anhydride (3). A general base effect might be a satisfactory explanation in the citrate case, but it should be pointed out that attack of citrate ions on citric anhydride would produce an intermediate citric–citric anhydride which could undergo hydrolysis at a faster rate than citric anhydride.

Supportive evidence for the formation of citric anhydride rather than the mixed anhydride was obtained by using phthalate as the buffer rather than citrate. Addition of acetic anhydride to phthalate buffer produces a species which can be followed at a wavelength where there is no interfering absorbance from the acetic anhydride. As shown in Fig. 4, a species forms and subsequently undergoes hydrolysis. Applying the same kinetic treatment as was described for the citric case allows for separation of the individual rate constants. Figure 5 shows the rate of disappearance of this species as a function of phthalate concentration and pH. The proposed mechanism for this interaction is relatively rapid formation of phthalic anhydride, followed by a somewhat slower hydrolysis. The apparent pH dependency observed here is explained on the same basis as the acetic anhydride–citrate case, *i.e.*, at low pH values and low buffer concentrations the rate of formation is slow, and, therefore, extrapolation of the terminal slope does not reflect the true hydrolytic rate. Above pH = 5.5 the limiting intercepts at zero buffer concentration value giving

an uncatalyzed velocity constant of 9.3×10^{-3} sec.$^{-1}$ which is in good agreement with reported work (4).

Because of the sparingly soluble nature of phthalic anhydride, it was possible to isolate it from the reaction mixture. Addition of excess acetic anhydride to the phthalate buffer gave a copious precipitate which redissolved upon standing. Isolation and characterization of this precipitate showed it to be phthalic anhydride, lending support to the hypothesis that the mixed anhydride has only a transitory existence in systems containing acetic anhydride and various carboxylic buffers.

Chromatographic Studies.—The presence of a citrate species possessing anhydride properties can be demonstrated by addition of aniline to the reaction mixture as has been previously noted (5). The anilides that are produced can be separated by chromatography as shown in Fig. 6. The typical chromatography run demonstrated in Fig. 6 was carried out using a 0.3 M, pH = 5 citrate buffer, and 8.0×10^{-5} moles of acetic anhydride; the reaction was quenched with aniline after 40 sec. The double peak corresponding to the two isomers of citric monoanilide is again in good agreement with earlier work (5). Verification that the peaks correspond to the two isomeric forms of citric monoanilide was carried out as previously described (1).

Determination of the Citric Anhydride-Time Profile by the Aniline Method.—The citric anhydride concentration in a mixture containing initially only acetic anhydride and citrate buffer can be estimated by quenching the reaction system with aniline and determining the concentration of the total citric monoanilide products. The anilides formed from samples drawn at different times during the course of the reaction were separated by column partition chromatography and the total yield of citric monoanilide determined. The results are shown in Fig. 7. The indicated concentration of citric anhydride as reflected by the total yield of citric monoanilide apparently increased initially with time. The data suggest that the hydrolysis of citric anhydride resulted in a decrease in the amount of the anilides formed in the terminal phase of the reaction. The yield of citric anilide was calculated based on a molar absorptivity for the citric monoanilide of 11,000.

It is apparent in this system that the anilide could have been formed from the mixed anhydride or from citric anhydride, although the spectrophotometric evidence presented supports citric anhydride rather than a mixed anhydride.

DISCUSSION

These studies indicate that, although the irreversible interactions of acetic anhydride with citrate

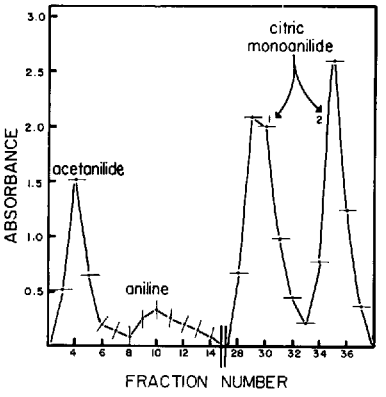

Fig. 6.—Typical chromatogram for the anilides formed by addition of aniline to the acetic anhydride–citrate system. The reaction was quenched with aniline after 40 sec. The eluate was extracted with 0.1 N NaOH and the alkaline solution analyzed spectrophotometrically at 241 mμ.

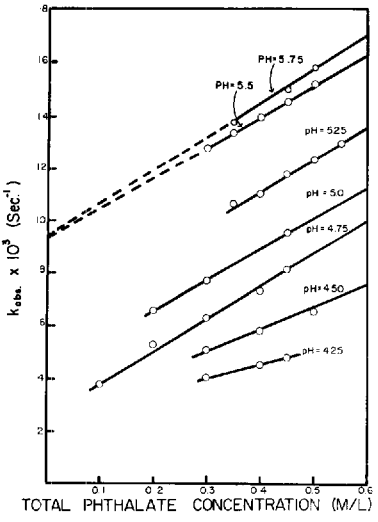

Fig. 5.—Observed rate of hydrolysis of the species formed from the interaction of acetic anhydride in phthalate buffer at various pH values and different buffer concentrations.

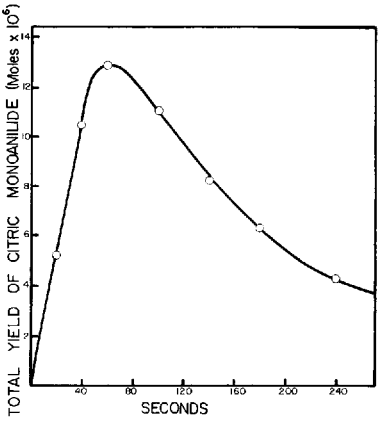

Fig. 7.—Total yield of citric monoanilide for the acetic anhydride–citrate system. The various points were obtained by withdrawing samples from the reaction mixture at various times and quenching the reaction with aniline. The total citric monoanilide present was then determined. pH = 5, 0.5 M.

differ markedly in character from the reversible reaction observed for the glutaric anhydride–citrate system, the apparent kinetic behaviors are surprisingly similar. The primary observation, aside from the irreversibility of the system, seems to be that the acetic anhydride reaction with citrate proceeds at a substantially slower second-order rate than that observed for the cyclic anhydride.

The experimental observations again strongly suggest intermediate formation of a reactive citric anhydride species. Although the compound was not isolated in these studies, the data suggest that acetic anhydride can be employed to produce substantial concentrations of citric anhydride which, in turn, can be conveniently employed for synthesis of citric acid derivatives in aqueous solutions.

EXPERIMENTAL

Reagents and Equipment.—Commercial acetic anhydride was purified by distillation. Dioxane was purified according to Vogel (6). Aniline was purified by repeated distillation and was stored under nitrogen prior to use. All other chemicals were of analytical or reagent grade.

All pH measurements and adjustments were made with a Beckman Zeromatic pH meter with an expanded scale.

Kinetic Procedure for the Reaction of Acetic Anhydride with Various Buffers.—Fifty microliters of a 1.08 *M* solution of acetic anhydride in dioxane was introduced together with 6 ml. of the buffer into a 2-cm. photometer cell. The reaction was allowed to proceed and was followed directly on a Cary model 11- M.S. recording spectrophotometer. All solutions were equilibrated at 25 ± 0.1° prior to use.

The dioxane concentration employed in these runs was determined to have a negligible effect on the rate constants.

Chromatographic Separation of Reaction Mixture.—The chromatographic columns were prepared as outlined in a previous communication (5). The reaction mixture was prepared by adding 15 ml. of the appropriate citrate buffer to 300 μl. of a 1.08 *M* acetic anhydride in dioxane solution. The reaction was allowed to proceed the requisite period of time and was quenched with 4 ml. of a 0.33 *M* aqueous aniline solution. The pH was adjusted to 3.13 with HCl and a 5-ml. sample was placed on the column with 5 Gm. of silicic acid. The eluting solutions have previously been described (1).

Blank determinations were made following the same procedure as above using (*a*) acetic acid, citrate buffer, and aniline solution, and (*b*) acetic anhydride, water, and aniline solution.

Preparative Chromatography of the Reaction Mixture.—A chromatographic column was prepared as previously reported (1). The reaction mixture was prepared by adding 100 ml. of pH = 5.0, 0.3 *M* citrate buffer to 4 ml. of a 1.08 *M* acetic anhydride in dioxane solution. At the end of 60 sec. the reaction mixture was quenched with 27 ml. of a 0.33 *M* aqueous aniline solution. The reaction mixture was placed on the column in the previously outlined manner and the eluate was collected and treated as reported (1).

Characterization of Compounds.—*Acetanilide.*—This was recrystallized from methanol, m.p. 114–115°. Commercial acetanilide was recrystallized from methanol and gave a m.p. 114–115°. A mixture of the known and unknown sample gave no depression of the melting point. In addition, both known and unknown samples gave identical infrared and ultraviolet absorption spectra.

Citric Monoanilide.—1.—Anal.—Calcd. for C, 53.94; H, 4.87; N, 5.23. Found: C, 54.09; H, 4.92; N, 5.22.

Molecular weight determined by direct titration against NaOH was found to be 271. (Calcd. 268.) Infrared and ultraviolet absorption spectra were characteristic of an anilide. The NMR spectrum strongly suggested this to be the symmetrical isomer, 2-hydroxy-2-*N*-phenylcarbamide-1,3-propanedicarboxylic acid.

Citric Monoanilide.—2.—This was recrystallized from chloroform, m.p. 127–128°. Molecular weight determined by direct titration against sodium hydroxide solution was 270. (Calcd. 268.)

Anal.—Calcd. for C, 53.95; H, 4.87; N, 5.23. Found: C, 53.98; H, 4.92: N, 5.19.

Infrared and ultraviolet absorption spectra were characteristic of an anilide. NMR spectrum suggested this to be the unsymmetrical isomer, 2-hydroxy-1 - *N* - phenylcarbamide - 2,3 - propanedicarboxylic acid.

Phthalic Anhydride.—This was recrystallized from chloroform, m.p. 130–131°. Commercial phthalic anhydride was recrystallized from chloroform and a mixture of the known and unknown compounds gave no depression of the melting point. Both known and unknown samples gave identical ultraviolet absorption spectra.

Quantitative Studies of Urinary Excretion of Chlorpromazine Metabolites in Chronically-Dosed Psychiatric Patients

By A. G. BOLT, I. S. FORREST, and M. T. SERRA

A method was developed for the routine assay of conjugated and unconjugated chlorpromazine metabolites in human urine. The method could be adapted to excretion studies of related drugs, *e.g.*, other phenothiazines and imipramine derivatives. The unconjugated drug metabolites were extracted from alkaline urine into dichloromethane and assayed spectroscopically in 50 per cent sulfuric acid at 530 mμ. The conjugated chlorpromazine metabolites were determined after passing a sample of urine through an ion-exchange resin to remove the unconjugated metabolites and contaminating endogenous urinary constituents. The eluate was made up to 50 per cent sulfuric acid content, and drug metabolites estimated spectroscopically at 550 mμ. The total urinary drug excretion of 15 chronic mental patients receiving chlorpromazine in doses of 100 to 1400 mg. per day, varied from 21.1 to 70 per cent of the daily dose. The conjugated drug metabolites formed the major fraction of urinary metabolites. The ratio of conjugated to unconjugated drug metabolites ranged from 2.1 to 11.

ESSENTIALLY two groups of chlorpromazine metabolites are observed in human urine (1–6)—namely, (*a*) the unconjugated fraction consisting of unchanged drug, desmonomethylchlorpromazine, desdimethylchlorpromazine, their sulfoxides, and chlorpromazine-*N*-oxide; (*b*) the conjugated fraction containing the greater number and amount of urinary chlorpromazine metabolites (6, 7). The metabolites in this fraction are the *O*-glucuronides (and small amounts of ethereal sulfates) of the mono- and dihydroxy derivatives of chlorpromazine, their demethylated derivatives, and of the corresponding sulfoxides (6, 8). Trace amounts of other unknown conjugates may also be present.

The unconjugated metabolites have been consistently reported in the literature and represent from 5 to 10% of the daily dose. There are, however, discrepancies in the estimates in the major drug fraction containing the conjugated metabolites which may be due to the different methods used (4, 9, 10). Other methods reported in the literature involve chemical or enzymatic hydrolytic procedures which are time consuming and give low recoveries. The authors have previously described a method (11), using a strong cationic resin, which was less satisfactory than the present method. When the earlier procedure was proposed, hydroxlyated or methoxylated derivatives of chlorpromazine were not available as reference compounds for conjugated metabolites; in fact, these metabolites were later shown to be incompletely estimated.

Since significant inter-patient (7) and interspecies (12, 13) differences in urinary chlorpromazine metabolites have been noted, especially with regard to the large group of conjugated drug metabolites (7), simple and rapid procedures are needed for the separate estimation of the two groups of drug metabolites.

EXPERIMENTAL

Materials.[1]—Dichloromethane, ACS; 97% sulfuric acid, ACS; 0.1 *N* sulfuric acid solution; Sørensen's phosphate buffer (pH 6); 2 *N* sodium hydroxide solution; 2 *N* hydrochloric acid solution; 30% hydrogen peroxide solution; ion-exchange resin[2] IRC-50, analytical grade, 20–50 mesh; chlorpromazine HCl; 7-hydroxychlorpromazine; 7-methoxychlorpromazine HCl; chlorpromazine-5-oxide HCl.

Apparatus.—U.V. spectra were obtained using a Beckman DB recording spectrophotometer. The Beckman Zeromatic pH meter was used for pH measurements.

Determination of Unconjugated Drug Metabolites.—A 10-ml. aliquot of urine was adjusted to pH 9–9.5 and extracted with 3 × 10 ml. of dichloromethane (14). The extract was evaporated on a water bath under a stream of nitrogen, the residue was dissolved in 5 ml. of 0.1 *N* sulfuric acid solution, and the acid solution transferred to a 10-ml. volumetric flask. The flask was immersed in an ice bath and 5 ml. of concentrated sulfuric acid was added very slowly down the wall of the flask. The sulfuric acid mixture was heated for 15 min. at 65°, brought to room temperature, 1 drop of 0.1% H_2O_2 was added, stood for 15 min., and adjusted to 10 ml. with cold 50% sulfuric acid solution. The

[1] The authors express appreciation to Smith Kline & French Laboratories, Philadelphia, Pa., and Dr. A. Manian, Psychopharmacology Service Center, National Institutes of Mental Health, Rockville, Md., for the phenothiazine derivatives used in this study.

[2] Marketed as Amberlite IRC-50 by Rohm & Haas, Philadelphia, Pa.

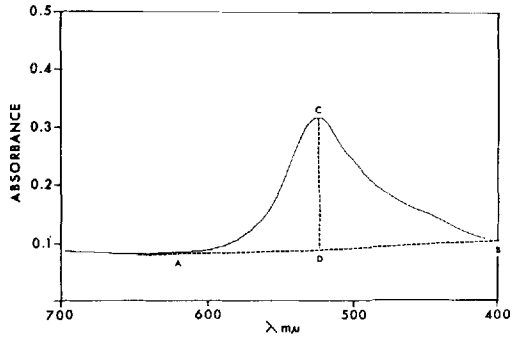

Fig. 1.—The spectrum of a typical dichloromethane urine extract after treatment with 50% sulfuric acid solution. Reading of absorbance at 530 mμ by the background cancellation method.

absorption spectrum of the acid solution was recorded between 400–700 mμ (see Fig. 1). Absorbance was measured at 530 mμ by a background cancellation technique as follows. A straight line AB was drawn between the points of minimum absorption on either side of the peak and a perpendicular line was drawn from the point of maximum absorbance, C, to intersect AB at D; the line CD was measured in absorbance units. A standard calibration curve was prepared from aqueous solutions of chlorpromazine sulfoxide hydrochloride. The absorbance of chlorpromazine sulfoxide after reaction with 50% sulfuric acid was proportional to concentrations up to 5×10^{-5} *M*.

Determination of Conjugated Drug Metabolites.—Chromatographic columns were prepared from the ion-exchange resin in the Na^+ form. One gram of resin was used for each ml. of urine, depending upon the quantity of metabolites in the urine.[3] The column was washed with a few ml. of Sørensen's pH 6 buffer which was discarded. From 0.5 to 2.0 ml. of urine[3] was then passed through the column, and the effluent was collected in a 10-ml. volumetric flask. The column was washed with pH 6 buffer to yield an effluent volume of 5 ml. The effluent was treated with concentrated sulfuric acid as described previously and maximum absorption read at 550 mμ by the background cancellation method. A standard calibration curve was prepared from aqueous solutions of 7-methoxychlorpromazine hydrochloride after treatment with 1 drop of 30% hydrogen peroxide (to form the corresponding sulfoxide). Absorption of the standard compound was read at 567 mμ after addition of concentrated sulfuric acid to give a final acid concentration of 50% by volume. Absorbance was proportional to concentration up to 5×10^{-5} *M* in 50% sulfuric acid.

Procedure.—Twenty-four hour urine collections from male chronic mental patients, receiving 100 to 1400 mg. of chlorpromazine hydrochloride per day, were assayed for conjugated and unconjugated chlorpromazine metabolites. Each determination was made in duplicate. At least two collections, about a week apart, were obtained from each patient. Additional collections were made in those cases in which urinary concentrations of chlorpromazine metabolites varied between samples. The patients were thoroughly supervised, both with regard to ingestion of medication and collection of 24-hr. specimens.

[3] An estimate of the quantity of urine to be used can be made according to a rapid urine color test (15); use 2 ml. of urine for a 1+ color reaction, 1 ml. for 2+, and 0.5 ml. for 3+ and 4+.

RESULTS

The results are summarized in Table I. Total urinary excretion of the combined groups of drug metabolites varied from 21.1 to 70%. Conjugated and unconjugated metabolites ranged from 16 to 51%, and 2.1 to 19% of the daily dose, respectively. All patients excreted much larger amounts of conjugated than unconjugated chlorpromazine metabolites; the ratio of the conjugated to the unconjugated drug metabolites varied from 2.1 to 11.

DISCUSSION

Method.—Since *O*-glucuronide derivatives of 7-hydroxychlorpromazine (II) were not available, 7-methoxychlorpromazine (I) was chosen as the reference compound for the determination of the conjugated metabolites, although the $\lambda_{max.}$ of 7-methoxychlorpromazine after reaction with 50% sulfuric acid was 567 mμ, compared with 550 mμ for the conjugated metabolites. 7-Methoxychlorpromazine was used for the following reasons.

(*a*) The absorptivity of 7-hydroxy- (the aglycone of 7-methoxy-) and 7-methoxy-chlorpromazines are nearly identical. (*b*) The conjugated drug metabolites consist mainly of *O*-glucuronides (II), in which the glucuronic acid residue is attached to the phenothiazine nucleus *via* an ether linkage (6) at the 7-position (16, 17). Thus, the structure of the chlorpromazine *O*-glucuronides is more closely related to that of 7-methoxychlorpromazine than to 7-hydroxychlorpromazine. (*c*) Under the experimental conditions 7-methoxychlorpromazine and the *O*-glucuronides of chlorpromazine reach maximum color development in 50% sulfuric acid solution faster than 7-hydroxychlorpromazine. (*d*) 7-Methoxychlorpromazine is more stable than 7-hydroxychlorpromazine and is more readily available.

In 50% sulfuric acid, the colored reaction products form more rapidly from the chlorpromazine and 7-methoxychlorpromazine sulfoxides than from the corresponding sulfides (11, 18), and therefore the sulfoxides were used as reference compounds.

The present method was rapid and reproducible to 5%. Studies using thin-layer chromatography showed that all unconjugated drug metabolites were absorbed onto the exchange resin and that only conjugated drug derivatives remained in the effluents. These studies also showed that all unconjugated chlorpromazine metabolites were extracted into dichloromethane.

The present method determines approximately 95% of the chlorpromazine derivatives normally present in the patient's urine. However, the assay procedure does not estimate all the drug metabolites in urine. 7-Hydroxychlorpromazine, its demethylated derivatives, and corresponding sulfoxides, and the dihydroxychlorpromazine derivatives are not measured by the present procedure. 2-Chlorophenothiazine and its sulfoxide and other nonbasic (deaminated) metabolites are not completely extracted from urine into dichloromethane. However, only trace amounts of deaminated and hydroxylated metabolites are normally present in

Chlorpromazine (7)-*O*-Glucuronic Acid

urine. The authors have estimated that deaminated chlorpromazine metabolites represent less than 1% of the daily drug dose, and Goldenberg and Fishman (12) conclude that the unconjugated 7-hydroxy derivatives represent about 0.1% of the daily drug dose. However, the 7-hydroxy group of drug metabolites occur in somewhat larger amounts in patients (21) with chlorpromazine-induced skin pigmentation (20).

The procedures used to separate the chlorpromazine metabolites from urine do not exclude all the urinary constituents that give colored products in 50% sulfuric acid. However, the nonspecific background absorption of these interfering constituents was eliminated by the use of the background cancellation method previously described.

Other drugs derived from phenothiazine or imipramine produce colored radical ions in 50% sulfuric acid, and the biotransformation products derived from these drugs could presumably be measured by an assay procedure similar to the one reported here provided that appropriate reference compounds are available.

Results.—The excretion of chlorpromazine and its conjugated and unconjugated metabolites was not related to drug dose (100–1400 mg. per day). Thus, it was shown (Table I) that a patient receiving 100 mg. and another 1200 mg. chlorpromazine per day, both excreted 45% of the administered dose. These results differ markedly from those of Nadeau and Sobolewski (9), who reported earlier that the limits of urinary drug excretion were reached at a dose of 200 mg. per day.

In the present study total drug excretion varied from 21.1 to 70% of the administered dose, with an average excretion calculated at 37%. Previous data of Posner *et al.* (4), who had used methods similar to those of Nadeau and Sobolewski (9), showed recoveries of 7.2 to 24.7%. These authors also stated that there was a trend toward decreasing urinary excretion with increasing drug dose. Using an assay procedure employing biologically derived reference compounds, Huang *et al.* (10) recently studied seven patients receiving 300 to 1200 mg. of chlorpromazine per day, and recovered an average of 58% of the administered dose in urine. These recoveries were higher than those obtained in the present study, and the authors also observed a tendency toward decreased urinary excretion of

conjugated metabolites with increasing drug dose. The present study differs from earlier ones (4, 9, 10) by not showing any dose-excretion correlation, and by yielding per cent excretion values substantially higher than those of Posner *et al.*, considered less than comprehensive, but lower than those of Huang *et al.*, believed to include normal urinary contaminants.

The reported results (Table I) could not be expected to show a definite correlation between drug excretion and such clinical parameters as diagnosis, drug response, or mental status of the patients; this group of patients was selected only to establish the spread of urinary excretion over a large range of chronic doses. The population sample, though small, included members of the three major ethnic groups with the most diverse psychiatric diagnoses. However, preliminary data on the correlation between side effects of drug therapy and urinary drug metabolism were recently reported for the initial phases of drug administration (19) as well as for drug-induced skin hyperpigmentation (22, 23).

The method is currently being used to study the time required to reach a steady excretion rate, to determine the effect of simultaneously administered compounds on the biotransformations and urinary excretion of chlorpromazine, and to elucidate species differences in chlorpromazine metabolism.

When studying the urinary drug excretion in mental patients, a number of factors not readily controlled in a normal hospital setting may affect the reproducibility of the chemical results. They are variations in diet, and intake of food and liquids. Most patients were found to increase their urinary output by a factor of 2 or 3 under chronic administration; the volumes eventually became reasonably stable at this higher level. Large fluctuations in consecutive 24-hr. specimens tended to yield erratic results. Therefore, rigorous surveillance of controllable parameters like drug intake (preferably in liquid form) and of 24-hr. urine collections cannot be overemphasized.

Solubility of Parabens in Syrup Vehicles

By ANTHONY N. PARUTA* and BHOGILAL B. SHETH

The solubilities of methyl, ethyl, propyl, butyl, and benzylparabens have been determined in sucrose vehicles of varying concentration. These syrup vehicles possess dielectric constants less than pure water, their respective dielectric constants decreasing with increasing sucrose concentration. The effect of both the concentration of sucrose added and the dielectric constant upon the solubility of the subject compounds is presented. The solubilities of these materials were seen to change to a relatively small degree with increasing sucrose concentration. Although these changes in solubility are minute, they would appear to be positive in character. The only definitive change noted was for benzylparaben where a relatively large change in solubility was noted.

THE GENERAL use and application of sucrose solutions of varying concentration for liquid pharmaceuticals is still widespread. In an effort to continue (1, 2) to determine the solvency characteristics of these media, the present study was undertaken. It was felt judicious that a study of a set of solutes of varying polar character be undertaken so that the effect of methyl, ethyl, etc., groups upon the solubility in common dissolution media could be studied. In this way, a tendency or characteristic effect of substituent groups could be delineated implying an effect that has been termed "solute polarity."

It has been found that relatively dramatic

Solubility of Parabens in Syrup Vehicles

By ANTHONY N. PARUTA* and BHOGILAL B. SHETH

The solubilities of methyl, ethyl, propyl, butyl, and benzylparabens have been determined in sucrose vehicles of varying concentration. These syrup vehicles possess dielectric constants less than pure water, their respective dielectric constants decreasing with increasing sucrose concentration. The effect of both the concentration of sucrose added and the dielectric constant upon the solubility of the subject compounds is presented. The solubilities of these materials were seen to change to a relatively small degree with increasing sucrose concentration. Although these changes in solubility are minute, they would appear to be positive in character. The only definitive change noted was for benzylparaben where a relatively large change in solubility was noted.

THE GENERAL use and application of sucrose solutions of varying concentration for liquid pharmaceuticals is still widespread. In an effort to continue (1, 2) to determine the solvency characteristics of these media, the present study was undertaken. It was felt judicious that a study of a set of solutes of varying polar character be undertaken so that the effect of methyl, ethyl, etc., groups upon the solubility in common dissolution media could be studied. In this way, a tendency or characteristic effect of substituent groups could be delineated implying an effect that has been termed "solute polarity."

It has been found that relatively dramatic

solubility effects occurred with the xanthine drugs, antipyrine, and several derivatives in syrup vehicles (2). In these cases, both increased and decreased solubility was noted with increasing sucrose concentration up to simple syrup. The parabens find wide use as preservatives in pharmaceutical liquid preparations as well as syrup vehicles, and it was felt desirable to determine their solubility in these vehicles. It was thought that if solubility effects, especially decreased solubility, occurred as extensively as with materials previously studied, the possibility of untoward effects such as preservative precipitation may occur.

EXPERIMENTAL

Materials.—The solutes used in this study were used directly as supplied by the manufacturer. The methyl and propylparabens were obtained from the Nepera Chemical Co. The ethyl and benzylparabens were obtained from Heyden Chemical Corp., lots 113 and 59, respectively. Butylparaben was obtained from Eastman Kodak, catalog No. EK 4574. Syrup vehicles were prepared from commercial granulated sugar and deionized or distilled water. Mixtures of absolute ethanol and either deionized or distilled water were used for dielectric constant calibration.

Equipment.—A WTW DK-06 multidekameter was used for dielectric constant determinations, a Bantam (mixed resin bed) demineralizer for producing deionized water. A Bausch & Lomb 505 spectrophotometer was used to determine sample absorbance and a water bath and attendent temperature controller was used for equilibration at 25°.

Dielectric Constant Determination.—The dielectric constants were determined by the use of a WTW multidekameter DK-06. Calibration curves were prepared from condenser readings and known dielectric constants (3) using ethanol–water mixtures. The dielectric constant values obtained for the syrup vehicles prepared gave excellent agreement with values of previous workers (4, 5). The accuracy of these determinations is about ±0.3 of a dielectric constant unit.

Solubility Determinations.—The protocol used in solubility determinations has been described previously (1, 2). Seventy-two hours was the time determined for equilibration at 25° ± 0.1°. All solubility runs were done at least four times, however, seven replicates were needed for the propyl and butylparabens in order to delineate the range of the magnitude of solubility for each given sucrose vehicle. Methylparaben caused some experimental difficulty since nonfilterable suspensions formed in syrup vehicles. It was found that allowing the methylparaben samples to lie quiescent in the water bath for several hours, clear samples were readily obtained.

RESULTS AND DISCUSSION

In Fig. 1, the solubility of methylparaben in mg./ml. *versus* both the concentration and the di-

electric constant of the syrup vehicles is shown. The solubility is seen to decrease as a function of both increased sucrose concentration and decreased dielectric constant. The rate of change is approximately linear having values of about −0.1 mg./10% w/w sucrose and about −0.1 mg./10 dielectric constant units. The solubility of methylparaben in simple syrup relative to water has a value of about 0.9. The variation in solubility in mg./ml. in Fig. 1 and subsequent figures is shown as a vertical line through the point of the average value. The variation is shown as the highest and lowest solubility in mg./ml. over the number of runs for pure water or any particular syrup vehicle. The variation has only been shown on the sucrose concentration axis, since once the nature of the curve has been defined on this basis, the dielectric constant scale retains the same shape, accentuated to some degree due to the "squeezing-in" on a shorter x-axis scale. The latter is especially true in the case of ethylparaben shown in Fig. 2. Again the solubility in mg./ml. is plotted in the usual fashion. In this case, an approximately sigmoidally disposed and decreasing solubility curve is observed. The solubility ratio, the solubility in simple syrup relative to water has a value of about 0.9. Repetitive runs in the 20–40% w/w sucrose range showed small variation and it is felt that the curve shown is a true reflection of the solubility pattern. It should also be pointed out that the solubility curve on a dielectric constant basis accents the sigmoidal nature of this curve.

In Figs. 3 and 4, the solubility curves obtained for the propyl and butylparabens, plotted in the usual fashion, are shown. As can be seen from these plots, the variation of solubility over a number of runs is quite wide, and this is due to the very low solubility of these materials. It would seem that one can only simply describe these solubility curves in approximately quantitative terms. Thus, the solubility of propylparaben decreases

Table I.—Summary of the Average Solubility in mg./ml. for the Parabens in the Systems Noted

System	Solubility, mg./ml. Methylparaben	Ethylparaben	Propylparaben	Butylparaben	Benzylparaben
Water	2.26	1.06	0.516	0.145	0.092
7.5% w/w sucrose	2.24	1.04	0.510	0.149	0.116
18.5% w/w sucrose	2.21	1.02	0.500	0.150	0.131
31.5% w/w sucrose	2.15	1.01	0.497	0.153	0.140
41.5% w/w sucrose	2.12	1.00	0.493	0.150	0.143
46% w/w sucrose	2.11	0.99	0.491	...	0.149
63.5% w/w sucrose	2.02	0.95	0.484	0.153	0.153
Solubility ratio: mg./ml. syrup / mg./ml. water	0.89	0.90	0.94	1.06	1.7

Table II.—Summary of the Solubility Ratios (mg./ml. Syrup/mg./ml. Water) Found for the Paraben Derivatives

	Run, No. 1	2	3	4	5	6	7	Av.
Methylparaben	0.89	0.91	0.92	0.86	0.91	0.88	...	0.90
Ethylparaben	0.93	0.89	0.89	0.91	0.87	0.89	...	0.90
Propylparaben	0.90	0.93	0.95	0.96	0.97	0.93	0.93	0.94
Butylparaben	1.04	1.03	1.06	1.09	1.05	1.04	1.06	1.05
Benzylparaben	1.7	1.4	1.7	1.9	1.6	...	...	1.67

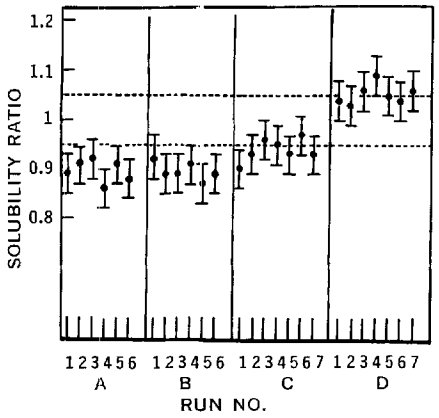

Fig. 6.—A plot of the solubility ratios for the *n*-alkyl parabens over repetitive runs including the determined variation. Key: A, methylparaben; B, ethylparaben; C, propylparaben; D, butylparaben.

slightly and has a solubility ratio of about 0.94. Butylparaben, on the other hand, increases slightly, the solubility ratio having a value of 1.06.

For both propyl and butylparaben, a nonlinear solubility curve has been drawn through the points of average value. Since the experimental values varied to such a large extent, the nature of the curve is considered arbitrary.

In Fig. 5, the solubility of benzylparaben in mg./ml. is plotted in the usual manner. For this derivative, having very low solubility in water, the solubility is seen to increase to a rather large extent, the solubility ratio having a value of about 1.7.

The average solubility in mg./ml. for each of the parabens studied in the syrup vehicles noted is given in Table I.

Although the solubility effects in syrup vehicles for the parabens are small, there is good consistency in the solubility ratios over a set of multiple runs. The value for independent solubility ratios for the number of runs stated is given in Table II.

The dielectric constants of the syrup vehicles were known, and it would be desirable to note any changes in this parameter for the saturated solutions of the parabens. The dielectric constants of the saturated solutions were measured at 25° on the DK-06 dekameter. As was found previously (2) no discernible patterns of change were found for the parabens. The dielectric constants for the saturated solutions, however, did follow the solubility curve and no sudden changes or aberrations in these values were noted for the range studied.

The solvency characteristics of sucrose vehicles can be viewed in two ways, the first being the decrease in the activity of water. With increasing sucrose concentration less water is available to interact with solute molecules, causing dissolution.

Second, the dielectric constants of syrup vehicles decrease with increasing sucrose concentration, implying decreased "polarity" of the dissolution media. The solubility of any given solute may then increase or decrease according to the mechanism or combination of mechanisms operative. The increase or decrease in solubility probably depends upon the nature of the solute and the original magnitude of the solubility in water.

It would be well to consider that a noted change in solubility should be outside or greater than 5%. In other words, it is presumed that a direction of change can only be classified as positively increased or decreased when all the data on repetitive runs fall outside this 5% limit.

In this regard, the solubility ratios for the *n*-alkyl parabens over repetitive runs (Table II) have been plotted in Fig. 6 using the largest variation observed for the solubility in simple syrup for each of the parabens.

The line unity represents 100% of solubility (of the value in water) and the dashed lines are the 5% limit described above. The vertical lines through the average data points represent the determined variation.

From the spread of values for the methyl and ethylparabens, it would seem that the solubility of these materials is affected to a very slight degree, *i.e.*, about 5%. For propyl and butylparabens, the descriptive term of "essentially linear" would apply, especially in view of the wide variation of solubility in the vehicles studied.

The only definitive change observed in the magnitude of solubility was for the benzylparaben where an average increase of about 70% in solubility was observed.

These results are perhaps not completely unexpected since the solubility parameter values given by Martin (6) are quite close to one another. This would indicate that the asymptotic right-handed portion of the solubility distribution curve over a small portion of the dielectric range (syrup vehicles ϵ = 60–75) for the parabens are very close to one another. This would be especially true in solvent systems such as sucrose in water relative to a hydroalcoholic solvent system where it might be expected that discriminatory differences in solubility would occur.

In conclusion, the solubility effects noted with the parabens of general interest are slight or nonexistent in contrast to previously noted effects with other materials (2).

Since large solubility effects have been noted for the xanthines and antipyrine (2) and small or no effect was noted for the parabens, it is felt judicious to continue this type of work. In this regard, the solubility of acetanilide and several derivatives are presently being studied in syrup vehicles.

The parabens are an important class of materials in pharmacy. Future work on the dielectric solubility profiles of these materials is presently under way and the authors' results will be given in a future communication.

Simple Method for Determination of $^{14}CO_2$ from Expired Air

By S. Y. YEH, JOHN H. CAVANAUGH*, and L. A. WOODS

Two simple procedures for preparation of homogeneous $^{14}CO_2$ samples for liquid scintillation counting are described. In one procedure (*A*), the carbon dioxide absorbing agent and the carbonate solution are placed in one tube. Carbon dioxide is released from the carbonate solution by sulfuric acid and absorbed by phenethylamine directly. Added $NaH^{14}CO_3$ (16–8000 dpm/ml.) is recovered nearly quantitatively in the amine phase. Similar results are obtained with another procedure (*B*), with which $^{14}CO_2$ is released from the carbonate solution and flushed with nitrogen into a counting vial containing absolute methanol and phenethylamine.

COMMON METHODS for measuring expired $^{14}CO_2$ involve trapping by passage of the expired air through sodium hydroxide solution and subsequent reprecipitation as $BaCO_3$. The radioactivity of the preciptated $BaCO_3$ can be determined either on planchets in a gas-flow counter or as suspensions in agents such as thixicin (1), or silica[1] (2) in a liquid scintillation spectrometer. Preparation of planchets or suspensions involves precipitation, filtration, drying and/or powdering, and weighing a portion of the powdered sample, all of which are time-consuming procedures.

Dilute sodium ^{14}C-carbonate solution has also been suspended in silica (3) and radioactivity quantitated in a liquid scintillation spectrometer. The latter procedure is limited to a highly radioactive carbonate solutions and is inadequate to measure low levels of radioactivity in carbonate solutions collected from drug metabolism studies.

Another common method for measuring $^{14}CO_2$ involves acidification of the carbonate solution, diffusion of the generated $^{14}CO_2$ to an organic amine such as hyamine, primine, ethanolamine, ethylene amine, and phenethylamine, and determination of radioactivity with a liquid scintillation spectrometer (4–8).

Phenethylamine is reported to be superior to other amines because it provides (*a*) high capacity for absorption of CO_2 and (*b*) minimal quenching (9). Carbon dioxide reacts with phenethylamine to form phenethyl ammonium phenethylcarbamate and with sufficient stoichiometric excess (about 3 moles of amine per mole of CO_2), the reaction is rapid (9).

To insure complete absorption of CO_2 by diffusion following acidification of the carbonate solution, a period of 4–24 hr. is required. The duration depends on (*a*) the diffusion apparatus and (*b*) the shaking of the reaction flasks (4–8). Twenty minutes were reported to be adequate if a special diffusion apparatus under reduced pressure (100 mm. Hg) was used. Carbon dioxide was reported to be quantitatively absorbed, but no data were presented (9).

Since all of the above procedures require complicated apparatus, extreme care, and much time, two simple procedures for preparation of homogeneous $^{14}CO_2$ containing samples for liquid scintillation counting have been developed. The details are described in this paper. The procedures require simple apparatus and are practical for the routine simultaneous handling of a large number of samples.

EXPERIMENTAL

Reagents.—All reagents are analytical reagent grade. (*a*) Alcohol–amine solution; *n*-amyl alcohol in freshly distilled phenethylamine 1:1 v/v. (*b*) 9 *N* sulfuric acid. (*c*) 5.3 *N* NaOH solution. (*d*) Standard $NaH^{14}CO_3$ solution ($^{14}CO_2$ was bubbled into 5.3 *N* NaOH solution). A series of solutions containing $NaH^{14}CO_3$ was prepared by diluting the $NaH^{14}CO_3$ solution with 5.3 *N* NaOH solution which contained 5% sodium bicarbonate. (*e*) Phosphor toluene; 300 mg. [1,4-bis-2(5-phenyloxazolyl)benzene (POPOP)], and 9 Gm. of 2,5-diphenyloxazole (PPO) per liter of toluene.

							32.2 ± 0.9(S.D.)		

[a] A 100-μl. aliquot of a solution prepared by diluting the stock $NaH^{14}CO_3$ solution with 5.3 *N* NaOH solution was added directly to a counting vial. The counting efficient of ^{14}C-toluene in the sample containing 100 μl. of $NaH^{14}CO_3$ solution is 56%. [b] An amount of 2.5 ml. of the diluted $NaH^{14}CO_3$ solution (see *Footnote a*) was used. [c] The air in tube was flushed with nitrogen and trapped in a counting vial containing the alcohol–amine and radioactivity determined. The counts obtained are not significantly different from identical blanks ($P < 0.5$).

Procedure A.—Exactly 2.5 ml. of the diluted $NaH^{14}CO_3$ solution is placed in a 43-ml. glass-stoppered centrifuge tube. Ten milliliters of the alcohol–amine solution is added to each tube. A 1.1 equivalent of sulfuric acid, 1.7 ml. of 9 *N* H_2SO_4, is slowly added *via* a buret to the centrifuge tube. The tube is cooled with ice water during the period of neutralization. Following neutralization, the stoppered tubes are shaken for 10 min. in an International shaker at 280–300 oscillations/min., and centrifuged at 1700 r.p.m. for 10 min. A 10-ml. aliquot of the organic layer, 2 ml. of absolute methanol, and 5 ml. of the phosphor toluene solution are pipeted into a clean counting vial and counted for three 10-min. periods in a Nuclear-Chicago series 720 liquid scintillation spectrometer. Samples are counted for three 10-min. periods to provide a 0.95 counting error of less than 2% for gross counts (10). Radioactivity in a given sample is considered significant when a value of 6 net c.p.m. or greater is obtained. The remaining alcohol–amine and aqueous solutions are drawn (with the aid of a propipet) into a 5-ml. graduated pipet. The volume of the alcohol–amine phase is estimated in the pipet after the organic and aqueous layers have separated.

Procedure B.—Exactly 2.5 ml. of the diluted $NaH^{14}CO_3$ solution is placed in a 43-ml. glass-stoppered centrifuge tube. Ten milliliters of absolute methanol in phenethylamine (1:1 v/v) solution is placed in a counting vial. The tube is stoppered with a rubber stopper which has previously been punctured with a No. 17 gauge needle and connected with a small Chieftain intravenous plastic tubing ($^1/_8 \times {}^1/_{32}$ in.).[2] The other end of the tubing is connected to a 6-in. glass tip,[3] in which a plug of glass wool is inserted. The tip of the Dispo-pette is immersed in the methanol–amine solution. The arrangement of the apparatus is shown in Fig. 1. Two milliliters of 9 *N* sulfuric acid is slowly added to the tube *via* a 5-ml. syringe while the solution is stirred with a magnetic stirrer. Following acidification, the generated CO_2 and the air in the tube is flushed 10 min. with about 0.5 lb./sq. in. pressure of nitrogen. The Dispo-pette and the magnetic stirring bar are rinsed with 1 ml. of absolute methanol each, and 5 ml. of the phosphor toluene is then added. The mixture is counted

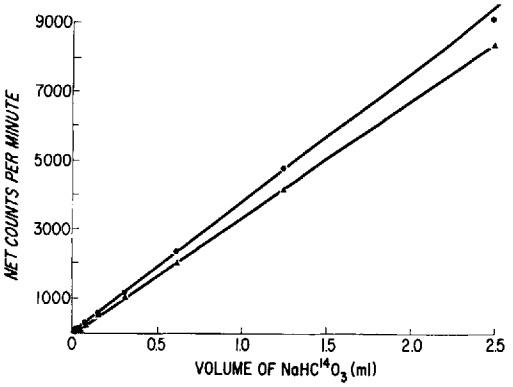

Fig. 2.—Plot of net c.p.m. *versus* volume of standard $NaH^{14}CO_3$ solution added. Key: ●, flushing with nitrogen; ▲, absorption by phenethylamine.

as described under *Procedure A*. The specific radioactivity of the standard $NaH^{14}CO_3$ is determined by first mixing a 100-μl. or a 50-μl. aliquot of the solution with two milliliters of absolute methanol, and then with 10 ml. of the alcohol–amine solution, and 5 ml. of the phosphor toluene.

All samples are corrected for quenching by addition of ^{14}C-toluene as an internal standard. Paired *t* tests were used to compare values obtained from samples and those of identical blanks.

RESULTS

The percentage recovery of $^{14}CO_2$ from sodium hydroxide–carbonate solution by procedure *A* is 104 ± 2.2 (S.D.) as shown in Table I. No significant radioactivity is found in the aqueous layer and in the air of the tube (Table II). A linear relationship is found between the mean of the net counts per minute (c.p.m.) obtained and the volume of $NaH^{14}CO_3$ solution added to the sample as shown in Fig. 2. The counting efficiency of ^{14}C-toluene in the sample containing 10 ml. of the alcohol–amine, 2 ml. of absolute methanol, and 5 ml. of phosphor toluene is approximately 60% of the ^{14}C-toluene in phosphor toluene alone.

The percentage recovery of $^{14}CO_2$ from sodium hydroxide–carbonate solution by procedure *B* is 105 ± 3.5 (S.D.) as shown in Table I. A linear relationship is found between the mean of the net c.p.m. obtained and the volume of $NaH^{14}CO_3$ in the sample as illustrated in Fig. 2. The counting efficiency of ^{14}C-toluene in the sample containing 10 ml. of the "trapping" methanol–amine solution, 2 ml. of absolute methanol, and 5 ml. of phosphor toluene is approximately 60% of the ^{14}C-toluene in phosphor toluene alone.

DISCUSSION

Procedure A.—The theory used in procedure *A* is based on the fact that dissociation of strong acids and strong bases is greater than that of weak bases. If sulfuric acid is mixed with a strong base such as sodium hydroxide–carbonate solution and a weak base such as phenethylamine, the sulfate ions will replace the hydroxide and carbonate ions in preference to reacting with the amine. Preliminary studies gave identical results whether sulfuric acid was added above or below the amine phase.

The result suggests that the affinity of sulfate ions for sodium ions is stronger than both the affinity of sulfate ions for amine ions and carbonate ions for sodium ions.

The higher recovery of $^{14}CO_2$ from known samples was presumably due to the inaccuracy of the micropipet used. The data indicate that $^{14}CO_2$ is recovered quantitatively from $NaH^{14}CO_3$ solutions by both procedures *A* and *B*.

Varying amounts of sulfuric acid (from 113 to 200% necessary to neutralize the NaOH solution) in studies on the recovery of $^{14}CO_2$ from sodium hydroxide–carbonate solution give identical results (Table II). The low recovery of $^{14}CO_2$ while the acid is just 100% equivalent (calculated) to the NaOH solution might have resulted because the actual strength of the acid was not sufficient (the acid and alkali solutions were not standardized by titration). Both the acid and alkali solutions were standardized for routine use. As progressively greater volumes of acid were used, there occurred an increase both in the volume (from 11.5 to 13.2 ml.) and the quenching of the amine–CO_2 phase.

The above procedure was also studied as to (*a*) the possible loss of $^{14}CO_2$ to air *via* diffusion through the alcohol–amine layer using the techniques of procedure *B*, and (*b*) the retention of radioactivity in the aqueous phase. The data shown in Table II indicate that there is no $^{14}CO_2$ loss to air [the air in the tube given 31–33 gross c.p.m. which is not significantly different from the counts obtained on identical blanks (32 gross c.p.m.) ($P < 0.5$)]. The radioactivity in the aqueous phase, determined by counting an 0.25-ml. aliquot with 10 ml. of the methanol–amine, 2 ml. of absolute methanol, and 5 ml. of phosphor toluene, is not significantly different from the identical blanks (Tables I and II, $0.2 < P < 0.1$).

Procedure B.—If one prefers to avoid shaking, centrifuging of the mixture, and transferring of the alcohol–amine-CO_2 to a counting vial in procedure *A*, procedure *B* is suitable. Varying the flushing time from 10 to 30 min. results in identical recovery of added $^{14}CO_2$ (Table III). It is believed that a shorter flushing period than 10 min. may be sufficient if a smaller flask is used.

Table III.—Effect of Flushing Time with Nitrogen on the Recovery of $^{14}CO_2$ Generated from Carbonate Solution

Some Physicochemical Properties of the Montmorillonites

By KEE-NENG WAI and GILBERT S. BANKER

The swelling, moisture sorption, particle size, cation-exchange, and drug adsorption properties of selected montmorillonites were studied. The swelling of montmorillonite was found to depend on both adsorptive and osmotic phenomena. The study of the sorption of alkaloidal drugs by the clay showed that brucine was sorbed by both adsorption and ion-exchange reactions, forming a monomolecular layer on the interior surface of the clay; methapyrilene and triethylamine were sorbed by an ion-exchange reaction; and niacinamide was neither adsorbed nor ion-exchanged.

THE HYDROUS magnesium aluminum silicate minerals, montmorillonites, because of their unusual properties and widespread occurrence have attracted the attention of workers in many fields of application. These clays are extremely plastic when moist, swell in the presence of water, and can be dispersed in water forming thixotropic gels. Bentonite U.S.P. is a mineral composed of 90% montmorillonite (1).

The applications of the montmorillonites in the pharmaceutical field have been explored extensively. Magnesium aluminum silicate[1] and bentonite, alone or in combinations with other common suspending agents, have been studied for their use as suspending agents (2–5). Guth *et al.* prepared different types of bentonites by saturating the clay with Na^+, K^+, Ca^{2+}, Mg^{2+}, and H^+. They used these various cation saturated bentonites to conduct a series of studies on the buffer capacity, cationic-exchange properties, and drug binding and release properties of bentonite (6–10). Many studies of montmorillonites as tablet disintegrants have been made, with the work of Feinstein and Bartilucci (11) being the most recent.

Although the montmorillonite class of clay minerals is widely used in the field of pharmacy, little has been reported in the pharmaceutical literature concerning their basic physical and chemical properties and the relation between such properties and pharmaceutical applications and utility. It was, therefore, the purpose of this work to conduct a pharmaceutically oriented study of the physicochemical properties of the montmorillonites, so that the various present applications and limitations or restrictions of the clays might be better understood and future applications more accurately determined.

EXPERIMENTAL

The three commercial montmorillonites studied in this work were magnesium aluminum silicate, magnesium aluminum silicate F, and WG.[2] These three types of clay will be referred to as clay I, II, and III, respectively, in the remainder of this paper.

Magnesium aluminum silicate has a composition of 61.1% silicone dioxide, 13.7% magnesium oxide, 9.3% aluminum oxide, 2.9% sodium oxide, 2.7% calcium oxide, and smaller amounts of titanium, ferric, and potassium oxides, 1.8% carbon dioxide, and 7.2% water of combination (12). The moisture content of the material will increase if exposed to moist atmospheres. The various grades of

magnesium aluminum silicate have the same general composition of plain magnesium aluminum silicate, but differ primarily in mechanical treatments which have been employed to affect color, rehydration properties, aggregate particle size, and other gross properties of the various grades.

Magnesium aluminum silicate WG is a high viscosity grade of magnesium aluminum silicate in finer than 50-mesh powder form, which is easier to rehydrate than other grades (13). Magnesium aluminum silicate F is a microatomized (325 mesh) grade (13).

The magnesium aluminum silicates were selected for study from the montmorillonite class, based on their high relative purity and light color for clay minerals, small lot-to-lot variation, and the availability of grades of clay varying in aggregate particle size and other properties. The clays studied were all oven dried at 50° for 24 hr. prior to use to remove nonbound moisture which may have been sorbed by the materials during storage. The moisture content of the clays as supplied was between 6.2 and 7.5% and after drying was 3.4, 2.4, and 4.3% for clays I, II, and III, respectively. The starch contained 9.4% moisture before drying and 5.2% after. The physicochemical properties studied included swelling volume, moisture sorption, particle size, ion-exchange capacity, and drug binding.

Particle Size.—Electron microscopy[3] was used to determine the particle-size distribution of the clays.

Three samples of each of the three grades of clay were used for the electron micrographic analysis. One picture, at a magnification power of 4000×, was taken of each sample, and the negative films were used to prepare 8 × 10-in. photographs. The Martin's diameters (14) of all the particles were measured on the enlarged photographs. The cumulative per cent of the particles was plotted on a probability scale against the logarithm of the Martin's diameter of the particles. The geometric mean diameters and the geometric standard deviations of the weight distribution were obtained from the graphs.

Swelling Volume.—The swelling of the montmorillonites was studied in media containing sodium chloride in 0, 0.005, 0.010, 0.025, 0.050, 0.10, 0.25, 0.50, and 1.00 *N* concentrations. Clay samples, weighing 2.00 Gm. each, were placed in 100-ml. amber glass jars. Fifty milliliters of medium was added to each jar, and the jars were capped and shaken for 2 hr. on a mechanical shaker. The contents of each jar were then transferred to a 100-ml. graduated cylinder, and additional saline medium was used to wash the jar and fill the graduated cylinder to volume. After 12 hr. of undisturbed hydration in the cylinders, the volume occupied by each hydrated clay gel was measured. This gel height volume was called the swelling volume. Each swelling volume was calculated from the average of three replicate determinations. For the purpose of comparison, the swelling of starch U.S.P. in each medium was also measured.

Moisture Sorption.—Three constant relative humidities were obtained by placing saturated solutions of calcium sulfate, sodium nitrite, and magnesium chloride, respectively, in 9-in. evaporating dishes in separate chromatographic chambers sealed with glass sheets and stop-cock grease (15). The relative humidities in these chambers, measured by a Sedex hygrometer,[4] were 98, 66, and 35%, respectively. The temperature in the chambers was 26 ± 2°. The moisture absorption of the clay samples, as commercially supplied and as compressed disks, and starch U.S.P. in the form of powdered material was studied. Starch could not be compressed as a disk. The disks, 0.5 in. in diameter and 0.5 Gm. in weight, were compressed with a force of 10,000 lb. (50,000 p.s.i.) for 3 min. with a Carver press.[5] The moisture content of all samples was determined gravimetrically, initially, and after 7, 14, and 21 days of storage at each condition. The thickness and diameter of the disks were measured at the same time intervals and disk volumes were calculated.

Determination of the Exchangeable Cation of Montmorillonite with Radioactive Sodium.—A modified, inverse dilution technique was used to measure the amounts of exchangeable cation and free electrolyte in the clays. The experimental procedure was as follows.

(*a*) The ^{22}Na (10 μc.), in the form of a solution of NaCl in hydrochloric acid, was added to enough distilled water to make 1 L.

(*b*) The solution was divided into four 250-ml. portions in volumetric flasks. To these solutions was added enough sodium chloride to produce the equivalent of 0, 30, 60, and 100 mg. of Na_2O in 100 ml. of solution (plus the 1 μc. of ^{22}Na/100 ml.).

(*c*) The samples of the clays, weighing 1 Gm. each, were placed in 100-ml. dry-square bottles which had previously been soaked in dilute hydrochloric acid for 12 hr., washed, and dried.

(*d*) Fifty milliliters of the radioactive saline solutions were added to each bottle and the bottles capped and sealed with tape.[6] The bottles were placed in a mechanical shaker and agitated for 3 hr.

(*e*) The clays were separated from the media by ultracentrifugation,[7] with a force 100,000 times gravity.

(*f*) Three samples, each containing 2 ml. of the clear medium, were placed in 4-ml. sample vials. The radioactivity of each vial was measured with a crystal-well counter.[8]

Montmorillonite Reaction with Cationic Drugs.—Four cationic drugs were used to study the ion-exchange activity of the clays. They were methapyrilene hydrochloride, brucine sulfate, triethylamine hydrochloride, and niacinamide hydrochloride. The methapyrilene hydrochloride and brucine sulfate were analytical grade chemicals. The triethylamine and niacinamide hydrochlorides were prepared from the respective bases by reaction with hydrochloric acid followed by purification by recrystallization from alcohol, acetone, and ethyl acetate.

The alkaloidal salt was dissolved in alcohol U.S.P. The concentration of the alkaloid in the solution was adjusted so that the alkaloid in 50 ml. of solu-

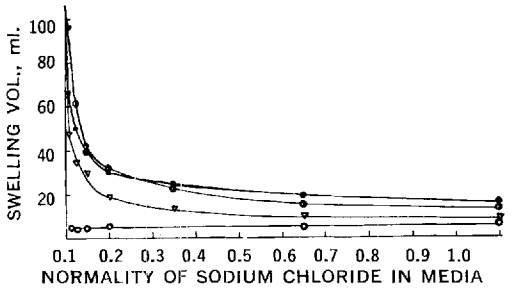

Fig. 1.—The swelling volumes of montmorillonites and starch in aqueous media containing various concentrations of sodium chloride. Key: ◑, clay I; ●, clay II; ▽, clay III; ○, starch.

tion would be completely removed by 1 to 3 Gm. of clay by the ion-exchange reaction. The solution was divided into ten 50-ml. fractions. To these fractions were added different quantities of clay II, varying from 1 to 8 Gm. The clay was removed from the solution by centrifugation after it had been shaken for 3 hr. with the solution. Ten milliliters of the clear alcoholic fraction was pipeted into an aluminum weighing pan and evaporated to dryness on a hot plate at 50°. The weight of residue was plotted against the weight of clays added.

RESULTS

Particle Size.—The particle size (geometric mean diameter) of the discrete clay particles of clays I, II, and III was 0.15, 0.11, and 0.12 μ, respectively, with a geometric standard deviation of 2.4 to 2.5 in each case. This does not reflect a significant difference between the discrete particle size of the various clay materials, although the aggregate particle size of each material as described earlier is quite different.

The surface area of each clay was also estimated using a gravimetric glycerol retention method (16). Based on an average of three replicate determinations for each clay, which were reproducible within $\pm 10\%$ for clay I and $\pm 5\%$ for clays II and III, the respective surface areas of the clays was 371, 339, and 300 M.²/Gm. This finding indicates that clay III, with the largest aggregate particle size (50 mesh), had the smallest available surface, and that microatomization of clay II also reduced its surface compared to clay I, according to the sorption procedure used.

Swelling Volume.—Figure 1 is a plot of the swelling volume of the three grades of clays and starch against the concentration of sodium chloride in the media. The swelling of the clays decreased as the concentration of electrolyte increased. This finding tended to substantiate the hypothesis of Norrish (17) that the second stage of swelling of a montmorillonite is essentially an osmotic one, since the increase in osmotic pressure of the medium caused a rapid decrease in the swelling of the clay. This could be a significant property when the clays are used as disintegrating agents for tablets and as suspending agents. In tablets containing large doses of strongly ionized chemicals, the chemicals might influence the swelling of the clay which, in turn, could decrease the disintegration rate; in suspensions, the strong electrolytes may affect the gel formation of the clays. The swelling of starch did not apparently depend on osmotic pressure and was

not affected by the concentration of sodium chloride in the medium.

Moisture Sorption.—The hygroscopicity of a solid matrix has a direct effect on the stability of many active pharmaceutical ingredients. The hygroscopicity of clays may be influenced by their chemical composition, the amount and type of exchangeable cation present, the particle size, and the surface area of the clay sample.

The results of the moisture sorption study are summarized in Tables I and II. At the same relative humidity condition, all three grades of montmorillonite sorbed approximately the same amount of moisture, although, physically each clay represents a different state of aggregation of the colloidal particles—flake, powder, and fine powder. The aggregate condition of the clays did not appear to affect the moisture sorption of the clays as supplied or as compressed disks. The clays in original powder form and the clays which had been compressed with a pressure of 50,000 p.s.i. for 3 min. also sorbed approximately the same amount of moisture in a period of 7 days or longer. This shows that moisture penetrates the compressed clay rather rapidly. The montmorillonites were found to swell (Table II)

in a humid atmosphere, with the volume of swelling approximately equal to the volume of the water absorbed.

Determination of the Exchangeable Cation of Montmorillonite with Radioactive Sodium.—Consider the case of a clay sample suspended in distilled water containing a trace of $^{22}NaCl$. The free electrolyte in the clay sample dissolves freely in the medium while the exchangeable cations attach to the clay particles. The ^{22}Na, being chemically identical to natural sodium, exchanges indiscriminately with the exchangeable sodium and the sodium in the medium. At equilibrium the relationship in Eq. 1 would exist.

$$\frac{\text{free Na in clay}}{\text{total Na in clay}} = \frac{\text{radioactivity in soln. at equilibrium}}{\text{initial radioactivity}} = \text{free electrolyte in clay, \%} \quad \text{(Eq. 1)}$$

Consider another sample of clay suspended in saline solution containing a trace of $^{22}NaCl$ and x moles of NaCl. The free electrolyte in the clay sample dissolves freely in the medium and mixes with the sodium chloride originally in the medium. The ^{22}Na exchanges indiscriminately with the exchangeable sodium and the sodium in the medium. At equilibrium, the relationship in Eq. 2 is obtained.

$$\frac{\text{free Na} + x \text{ moles of Na}^+}{\text{total Na} + x \text{ moles of Na}^+} = \frac{\text{radioactivity in soln. at equilibrium}}{\text{initial radioactivity}} \quad \text{(Eq. 2)}$$

Solving Eqs. 1 and 2, one can estimate the amount of exchangeable sodium and the amount of soluble electrolyte in the clays.

Table III expresses the radioactivity, in terms of c.p.m. and percentage of initial activity, of 2 ml. of the solutions of radioactive sodium chloride which had been mixed and ion-exchanged with the clays according to the procedure previously outlined.

Utilizing the data in Table III, the free electrolyte and exchangeable electrolyte contents were calculated and are summarized in Table IV.

This experiment shows that the sodium in montmorillonite exists as exchangeable cation as well as free electrolyte. The presence of free electrolyte in the clays may be due to the presence of electrolyte in natural water which is used to wash the clays. Comparing the ion-exchange property and the swelling volume of the clays, it appears that the ion-exchange capacity of the clay is not the major factor that influences the swelling of the clay.

Considering that the cation-exchange capacity of clay II is 0.583 (Table IV) and that the surface area of the same clay is 339 M.²/Gm., the average distance between two ionized sites can be calculated to be about 10 Å. This is a reasonable estimation. It shows that the ion-exchange sites are distributed throughout the internal surface of the clay, and the cation-exchange activity takes place at the interior of the clay particles.

Montmorillonite Reaction with Cationic Drugs.—Figures 2 to 5 describe the sorption of the four drugs by montmorillonite. At first the drug concentration decreased very rapidly with the increased quantity

Drug adsorbed by clay, meq.	−0.017	0.201	0.002	...

of clay added. Finally, when all drug in the solution was removed by the clay, the weight of the residue-exchange product from the clay ceased to exchange with further addition of the clay. Each curve shows two distinct straight segments. The intersection at which the extensions of these two straight portions meet shows the weight of clay required to pick up all the drugs from the solution.

Table V illustrates the amounts of drug exchanged with the cations of the clay and the amount of drug adsorbed by the clay. The "initial concentrations of the drugs" and the amount of "clay required to absorb all of the drug in 50 ml. of solution" are obtained from Figs. 2–5. The "ion-exchange capacity of the clays" is obtained from the previous experiment. The "drug exchanged with the cation of the clay" is calculated by multiplying the "ion-exchange capacity" by "the amount of clay required to absorb all of the drug in 50 ml. of solution."

Table V shows that the clay quantitatively picks up methapyrilene and triethylamine by an ion-exchange reaction, and brucine partly by ion-exchange and partly by an adsorption reaction. Niacinamide was neither adsorbed by nor exchanged with the cations of the clay.

Brucine sulfate, being a large molecule, is picked up by the clay to an extent of 35% above the cation-exchange capacity of the clay; yet, triethylamine hydrochloride, being a small molecule, is picked up by the clay quantitatively with respect to the ion-exchange capacity of the clay. This is a further strong indication that the absorption of triethylamine by the clay is not a surface phenomenon of the clay. It is, instead, ion exchange.

Niacinamide, being an extremely weak acid, may dissolve in the alcohol in the form of niacinamide base, rather than the ionic form of its hydrochloride salt. Another possibility may be that the positive charge on the niacinamide cation may resonate and spread throughout the molecule, and weaken the charge of the cations, so that they cannot replace the original cations on the clay which are strongly charged. This may explain why niacinamide was not bound by the clay.

DISCUSSION AND CONCLUSIONS

The swelling of montmorillonite depends upon two main mechanisms—namely, adsorption and osmosis. The swelling by adsorption is illustrated by the adsorption of moisture, glycerol, and brucine by the clay. The swelling of montmorillonite by osmosis can be illustrated by the depression of the swelling volume of the clays by electrolytes.

The data on the measurements of specific surface area of the clays are the best proof of particle swelling of clays by adsorption. The glycerol and brucine actually penetrate into the interior of the clay particles. The adsorption of glycerol, moisture, and brucine to the internal surface of the clay particles results in swelling of the particles of the clay. Since the initial swelling of the clay is essentially by adsorption, the disintegrating activity of the clay on tablets may be hypothesized as primarily due to the adsorption swelling rather than osmotic swelling of the clay. If this hypothesis is true, then, many other clays which are good adsorbants may also be good disintegrating agents.

The cation-exchange activity of montmorillonite occurs at the internal surface of the clay particles. The physical entrapment of the organic molecules between the silica–alumina–silica layers may explain the strong and partial irreversible binding of organic molecules by clays. One can further theorize that the entrapment of cationic drugs in the interior of the clay particles may be applied to stabilize some unstable drugs and to produce sustained-release medications.

Modification of Polyethylene Glycol Ointment U.S.P. XVI

By WINITA CHANDRANONDNAIWINIT and E. BLANCHE SOMMERS

The hydrophilic capacity of official polyethylene glycol ointment, modified by the addition of 0.5 per cent of dry unneutralized carboxypolymethylene compound, was increased 48 per cent. The relative effectiveness of the modified ointment as a vehicle for yellow mercuric oxide (1 per cent) and potassium penicillin G (1000 u./Gm.) using *Staphylococcus aureus* PS 81 as the test organism was determined. Antistaphylococcal activity was increased 23.3 and 31.3 per cent, respectively. The stability of penicillin in the modified and official bases was checked for 23 days. Antistaphylococcal activity declined to 18.8 and 13.5 per cent, respectively.

POLYETHYLENE glycol ointment U.S.P. XVI possesses such advantages as esthetic appearance, washability, inertness, and the ability to form an emollient base. However, its high degree of solubility precludes the addition of aqueous solutions much in excess of 5% of the total formula (1).

One of the criteria of an ideal ointment base is that of hydrophilic capacity. According to Beeler (2), various authors have described an ideal ointment base as being capable of holding at least 50% of water.

Due to the lack of this ability on the part of all of the polyethylene glycols, various additives have been tried with limited degree of success. For example, the addition of 5% of cetyl alcohol to the anhydrous base containing 47.5% each of polyethylene glycol (PEG) 4000[1] and polyethylene glycol 400 has been recommended (3). This addition increased the water absorption ability of the base 10%.

Since the official ointment in most respects is pharmaceutically and dermatologically acceptable except for its lack of water capacity, further study was prompted in regard to this characteristic. Different substances were tried in varying concentrations and carboxypolymethylene compound[2] proved to be the most satisfactory in regard to increasing the hydrophilic capacity of official polyethylene glycol ointment.

EXPERIMENTAL

Addition of Carboxypolymethylene Compound.—Polyethylene glycol ointment U.S.P. XVI was prepared and samples of the official ointment were modified by the addition of carboxypolymethylene compound in concentrations of 0.5, 0.75, 1, 2, and 5%. Aseptic techniques were observed and finished ointments were stored in closed jars at room temperature. The polymer was added according to the following methods.

Method 1.—One-half gram of unneutralized carboxypolymethylene compound reduced to a fine powder was thoroughly triturated into enough polyethylene glycol ointment to make 100 Gm. This process was repeated using 0.75, 1, 2, and 5 Gm. of the polymer.

Carboxypolymethylene compound owes much of its exceptional ability to thicken, suspend, and emulsify to its hydrophilic nature or affinity for water (4). It was used dry and unneutralized in an effort to increase its water absorption ability when present in the ointment base.

Method 2.—Method *1* was varied by adding the respective portions of unneutralized carboxypolymethylene compound to enough liquid polyethylene glycol 400 to make each portion weigh 60 Gm. The powder was first levigated with a small amount of the liquid glycol and successive portions of the latter were added until thorough incorporation was accomplished. Each 60-Gm. portion of the PEG 400 containing its respective concentration of the polymer was then heated with 40 Gm. of PEG 4000 on a water bath to 65°. The preparation was allowed to cool and was stirred until it congealed.

Method 3.—Carboxypolymethylene compound (0.5 Gm.) was neutralized with a solution of sodium hydroxide (10%). In order to avoid the presence of water to the greatest possible degree, the dry polymer was mixed with 10 ml. of the official ointment before it congealed. One milliliter of the sodium hydroxide solution was added and the mixture was allowed to stand for 30 min. It became very gelatinous, but readily liquefied when placed on a water bath, and it was then incorporated into the remaining liquid official ointment to make a total of 100 Gm.

The resulting preparation was darker and considerably stiffer than the official ointment. For this reason further modification of the official ointment by the addition of increased concentrations of the neutralized carboxypolymethylene compound was not attempted. Products of methods *1* and *2* were evaluated. The 0.5% formulation prepared by trituration of dry unneutralized carboxypolymethylene compound into the official ointment was

Received January 17, 1966, from the College of Pharmacy, University of Oklahoma, Norman.
Accepted for publication August 3, 1966.
Presented to the Industrial Pharmacy Section, A.PH.A. Academy of Pharmaceutical Sciences, Dallas meeting, April 1966.
Abstracted in part from a thesis submitted by Winita Chandranondnaiwinit to the Graduate College, University of Oklahoma, Norman, in partial fulfillment of Master of Science degree requirements.

selected as the most cosmetic in texture and appearance.

Hydrophilic Properties.—The official ointment and that modified with 0.5% of carboxypolymethylene compound were tested for hydrophilic capacity. Distilled water was added dropwise with trituration from a calibrated dropper to samples of each ointment until the point of flow was reached. Standardized point of flow was attempted in each instance by the delivery of a specified volume of the sample in a specified time from the same container.

After the initial hydration, the ointments thickened on standing. When this occurred, water was again added to the ointments in the same manner until they did not change consistency on standing for 30 days. Results of the initial hydration are shown in Fig. 1.

Relative consistency of the ointments was determined by the use of a rheostat connected to an electrically driven stirring device. The blades of the latter were submerged in the ointment under standardized conditions. The electrical power was slowly increased and the rheostat reading was taken at the first perceptible indication of the ointment's yield to the blades of the stirring device. Repeated experimental determinations gave values that differed within acceptable limits.

After the initial hydration, the samples of polyethylene glycol U.S.P. XVI containing an average of 19.6% of distilled water regained their original consistency in an average of 5.5 days on standing in tightly closed containers at room temperature. When compared to samples of the modified ointment containing the same amount of distilled water, the latter regained their original consistency in an average of 1 day. Distilled water was again added to the samples of the official ointment containing 19.6% of distilled water until each reached the point of flow. This time an average of 10.4% water/sample was required making a total of 30% of distilled water that was added. After standing 30 days, thickening occurred to a very slight degree.

The samples of the ointment modified by the addition of 0.5% of carboxypolymethylene compound, that contained an average of 29% water when initially hydrated to the point of flow, were stored in the same manner for 30 days. They thickened considerably but did not regain their original consistency.

Using fresh samples of the modified ointment, distilled water was added to each sample to the point of flow. This was repeated using the same samples until, on standing 30 days, these preparations did not thicken. A total of 34% water was required.

Evaluation as Vehicles for Yellow Mercuric Oxide.—The official and the modified ointments were tested to determine their relative effectiveness as bases for yellow mercuric oxide. One per cent of the latter was incorporated into samples of each

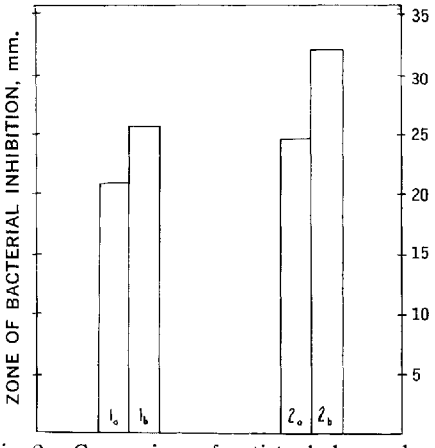

Fig. 2.—Comparison of antistaphylococcal activity. Key: 1_a, PEG ointment U.S.P. with mercuric oxide, 1%; 1_b, PEG dry unneutralized carboxypolymethylene compound ointment with mercuric oxide, 1%; 2_a, PEG ointment U.S.P. with potassium penicillin G, 1000 u./Gm.; 2_b, PEG dry unneutralized carboxypolymethylene compound ointment with potassium penicillin G, 1000 u./Gm.

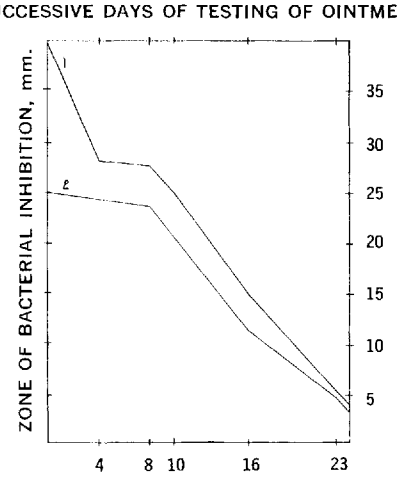

Fig. 3.—The rate of decline of potency of (*1*) PEG dry unneutralized carboxypolymethylene compound ointment with potassium penicillin G, 1000 u./Gm.; (*2*) PEG ointment U.S.P. with potassium penicillin G, 1000 u./Gm.

of the ointments by trituration until homogeneous composition was obtained. Aseptic techniques were observed.

A solution of nutrient agar in distilled water (2.3%) was prepared, autoclaved, and cooled to 45°. Each of 20-ml. samples of this solution was inoculated with 0.2 ml. of *S. aureus* PS 81 which had previously been incubated for 18 hr. at 37° in an aqueous solution of thioglycollate (1%). The 20-ml. samples were then poured into sterile Petri dishes and allowed to harden, after which 0.5 Gm. of the official ointment containing yellow mercuric oxide (1%) was placed in the center of the nutrient agar in each plate. This procedure was repeated using the modified ointment containing yellow mercuric oxide (1%).

These preparations were incubated at 37° and read after 48 hr. Bacterial inhibition zones were measured from the edge of the ointment to the edge of the zone of complete inhibition. Controls consisting of the nutrient agar, the official, and the modified ointments were prepared. They showed no zones of bacterial inhibition. Results are shown in Fig. 2.

Evaluation as Vehicles for Potassium Penicillin G.—Ointments of potassium penicillin G (1000 u./Gm.) were prepared using the official and the modified bases. The penicillin was incorporated into the bases by the same method used in the preparation of the mercuric oxide ointments.

Effectiveness of the two bases as vehicles for the penicillin was tested by the same method used for testing the yellow mercuric oxide ointments. Results are shown in Fig. 2.

Stability Studies.—The stability of potassium penicillin G in the official and in the modified bases was tested. The ointments, after preparation, were immediately stored in tightly closed containers at room temperature. Using *Staphylococcus* PS 81 as the test organism and the previously described media and techniques, the ointments were tested at 1, 4, 8, 10, 16, and 23-day intervals for potency of their contained penicillin. Results are shown in Fig. 3.

DISCUSSION AND CONCLUSIONS

Hydrophilic Capacity.—According to this investigation, the initial hydrophilic capacity of the official polyethylene glycol ointment (19.6%) is greater than that of 8–10% reported by the literature, and the addition of 0.5% of carboxypolymethylene compound increased this capacity to 29%.

However, a total of 30% water was added to the official ointment at successive times before it ceased to thicken when stored 30 days. When 29% water was initially added to the modified ointment, it thickened on standing, but did not regain the original consistency on standing for the same period of time. The addition of a total 34% of water was required before the modified base showed no change when stored for 30 days.

The changes that occurred in the consistency of the ointments on standing might be considered as thixotropic in nature. However, thixotropy is customarily demonstrated by a 2-phase system. Polyethylene glycol ointment is an organogel and thus exists as a 1-phase system (5).

It is important to note that total hydration (30%) of the official ointment and the initial hydration (29%) of the modified ointment were approximately the same. Also, the total hydration of the latter was 34%. It is probable that apparent increased hydration of the official ointment when carboxypolymethylene compound was added was predominately due to increased rate of hydration caused by the polymer.

Incomplete hydration (8–10%) could account for the observation by King and Sheffield (6) that "The polyethylene glycol ointments are not completely satisfactory cosmetically . . . ."

Evaluation of Bases for Yellow Mercuric Oxide and Potassium Penicillin G.—Polyethylene glycol ointment U. S. P. XVI and its modified form containing 0.5% carboxypolymethylene compound were suitable bases for mercuric oxide (1%) and potassium penicillin G (1000 u./Gm.). When the anti-infective agents were added to the official and the modified bases and the finished preparations were tested, both produced zones of bacterial inhibition; however, the modified base was superior to the official base.

Controls of the official ointment and of the modified ointment containing 0.5% carboxypolymethylene compound did not demonstrate anti-infective activity. The polymer did not possess anti-infective activity in this instance, but when it was added to the official ointment containing mercuric oxide or penicillin, the anti-infective activity of the ointment was increased. These results suggest that increased anti-infective activity that occurred when the polymer was present was not due to the polymer alone but to direct relationship of the polymer to the anti-infective agent.

Thus, the superiority in regard to anti-infective activity of the modified base when compared to the official base could be due to the ability of the polymer to act as an emulsifying agent and in this manner increase the ratio of anti-infective/bacteria exposure.

Stability of Potassium Penicillin G in the Official and Modified Bases.—The PEG's have useful roles as vehicles for penicillins (7). However, there is difference of opinion concerning the effect of these compounds on the penicillins. Some investigators (8, 9) have reported that the presence of these compounds hastens the decomposition of the antibiotic, while others (10) have found it to be remarkably stable in PEG bases. In studying this problem, Ferlanto and Clymer (11) found that penicillin stability varies with the vehicle and with the particular salt used.

Numerous references are found in the literature in regard to the stability of penicillin in polyethylene glycol bases. However, none of these was concerned with the effect of carboxypolymethylene compound when present as a component of the polyethylene glycol base. It was decided to determine that effect.

According to the data of this investigation, the potency of the penicillin in the official and the modified bases when stored at room temperature declined to 18.3 and 13.5% of their original activity at the end of 23 days. This decline was fairly gradual and consistent except for the rapid decline of the penicillin potency of the modified base during the first 4 days. On further testing, this occurred again and remains unexplained.

Investigation of Factors Influencing Release of Solid Drug Dispersed in Inert Matrices II

Quantitation of Procedures

By SAURABH J. DESAI*, PARVINDER SINGH, ANTHONY P. SIMONELLI, and WILLIAM I. HIGUCHI

Recently a number of factors governing the rate of release of drug from plastic matrices were investigated. This study showed that while the experimental results were generally in agreement with Higuchi's relationship, they were not always quantitative. The present paper describes a refined experimental procedure for quantitatively studying the various factors. Matrix porosities are determined in two ways so that available and inaccessible pores can be differentiated. Diffusion coefficients are independently determined. The matrix tortuosity can now be quantitatively determined independently of the solid drug release rate data. In addition to these experimental refinements, the limitations of the theory are reviewed and some useful modifications proposed.

A PREVIOUS communication (1) discussed preliminary results on the investigation of the factors influencing drug release from solid drugs dispersed in inert matrices. An attempt was made in that study to compare experimental release rate data to the Higuchi relationship (2). While it was found that qualitative and semiquantitative comparisons between theory and data could easily be made, considerable difficulty was generally encountered when a quantitative test of the theory with data was attempted.

It was believed that much of the difficulty was due to the porosity and the tortuosity of the matrix not being independent of the other variables and changing from experiment to experiment. For example, these studies (1) showed that a small amount of surfactant in the solvent phase could markedly increase the release rate from the polyethylene plastic matrix. It was shown that this was not an increased solubility effect, and therefore, must be related to the porosity or tortuosity factors.

It has now become apparent that, in order to clearly understand the basic mechanisms involved, a more systematic study must be undertaken. Wherever possible, each of the parameters in the theory should be quantitated independently and then incorporated into the theory to see whether the equation accurately predicts the rate. Then when discrepancies occur, real or apparent, physical interpretations that are meaningful may be assigned.

The purpose of this paper is to present details of methods, both theoretical and experimental, designed for the quantitative physical evaluation of the various factors involved in drug release from nondisintegrating matrices. It will be shown that these techniques should permit the unambiguous interpretation of release rate data in most instances.

Investigation of Factors Influencing Release of Solid Drug Dispersed in Inert Matrices II

Quantitation of Procedures

By SAURABH J. DESAI*, PARVINDER SINGH, ANTHONY P. SIMONELLI, and WILLIAM I. HIGUCHI

Recently a number of factors governing the rate of release of drug from plastic matrices were investigated. This study showed that while the experimental results were generally in agreement with Higuchi's relationship, they were not always quantitative. The present paper describes a refined experimental procedure for quantitatively studying the various factors. Matrix porosities are determined in two ways so that available and inaccessible pores can be differentiated. Diffusion coefficients are independently determined. The matrix tortuosity can now be quantitatively determined independently of the solid drug release rate data. In addition to these experimental refinements, the limitations of the theory are reviewed and some useful modifications proposed.

A PREVIOUS communication (1) discussed preliminary results on the investigation of the factors influencing drug release from solid drugs dispersed in inert matrices. An attempt was made in that study to compare experimental release rate data to the Higuchi relationship (2). While it was found that qualitative and semiquantitative comparisons between theory and data could easily be made, considerable difficulty was generally encountered when a quantitative test of the theory with data was attempted.

It was believed that much of the difficulty was due to the porosity and the tortuosity of the matrix not being independent of the other variables and changing from experiment to experiment. For example, these studies (1) showed that a small amount of surfactant in the solvent phase could markedly increase the release rate from the polyethylene plastic matrix. It was shown that this was not an increased solubility effect, and therefore, must be related to the porosity or tortuosity factors.

It has now become apparent that, in order to clearly understand the basic mechanisms involved, a more systematic study must be undertaken. Wherever possible, each of the parameters in the theory should be quantitated independently and then incorporated into the theory to see whether the equation accurately predicts the rate. Then when discrepancies occur, real or apparent, physical interpretations that are meaningful may be assigned.

The purpose of this paper is to present details of methods, both theoretical and experimental, designed for the quantitative physical evaluation of the various factors involved in drug release from nondisintegrating matrices. It will be shown that these techniques should permit the unambiguous interpretation of release rate data in most instances.

THEORY

The basic Higuchi relationship (2) for the rate of diffusional release of drug incorporated as solid drug in an insoluble matrix, from one surface of the matrix, is

$$Q = \left\{\frac{D\epsilon}{\tau}(2A - \epsilon C_s)C_s t\right\}^{1/2} \quad \text{(Eq. 1)}$$

where Q is the grams of drug released per unit area of surface at time, t, D is the diffusion coefficient of drug in the release medium, ϵ is the porosity of the matrix, C_s is the solubility of drug in the release medium, τ is the tortuosity of the matrix, and A is the concentration of drug in the tablet expressed as Gm./ml.

Some comments are now appropriate regarding Eq. 1. Most of these were pointed out in the original work (2).

The porosity, ϵ, refers to the volume fraction that is permeated by the solvent and available for diffusion in the already leached portion of the matrix. Therefore, in general,

$$\epsilon = \epsilon_d + \epsilon_{\text{air}} + \epsilon_{\text{other}} \quad \text{(Eq. 2)}$$

Here $\epsilon_d = \frac{A}{\rho_d}$ is the contribution to the porosity from the dissolved drug where ρ_d is the drug crystal density. The other two terms in Eq. 2 are the contributions to porosity from released air and from the leaching of other soluble additives in the mixture. As we shall see later, ϵ_{air} available for solvent penetration and drug diffusion, is very sensitive to the presence of surfactants with certain matrices.

The tortuosity factor, τ, corrects for the lengthened diffusional path caused by the necessary lateral excursions. In other words, it accounts for, or corrects for the additional distance a molecule must travel due to its circuitous path within the tablet. A straight channel will have a tortuosity of 1, whereas a spherical glass bead column will have a τ value of about 2 to 3.

It will be seen later that in some situations extremely large τ values ($\sim 10^3$ to 10^4) are encountered. In these cases the concept of the average porosity and the average tortuosity does not adequately describe physically the pathways and resistances for diffusion, and a more detailed consideration of the microscopic matrix permeability factors becomes desirable.

As was originally stressed (2), the model leading to Eq. 1 should fail when $\epsilon C_s \gtrsim 2A$. To derive a general analytical expression which includes the large ϵC_s cases appears to be extremely difficult because the pseudo steady-state assumption cannot be made. It appears safe to state that, as long as $2A$ is more than about 3 times greater than ϵC_s, the model should be quantitatively meaningful. The authors' initial quantitative studies of Eq. 1 will therefore be limited to those cases involving solutes of low to moderate solubilities.

Another limitation of Eq. 1 is that it does not explicitly account for the effects of the diffusional movement of the solvent or for the possibility that the solute diffusion coefficient may be concentration dependent in the diffusion barrier. Both of these factors could become important when C_s is moderate to large, say $\gtrsim$ 0.1 Gm./ml. The modified equation (see *Appendix* for the derivation) taking these factors into account may be written

$$Q = \left\{\frac{D'\epsilon C_s}{\tau} t\left[2A - 2\epsilon\int_0^{C_s}\frac{DC\,dC}{D'C_s - KC}\right]\right\}^{1/2} \quad \text{(Eq. 3)}$$

where D' is the effective (or apparent) diffusion coefficient that takes into account both of the effects mentioned above. As will be shown later D' may be conveniently determined by a single run in a conventional diffusion cell.

The term in Eq. 3 involving the integral has the same physical meaning as the $\frac{1}{2}\epsilon C_s$ term in Eq. 1. It represents, therefore, the solution holdup of solute in the leached matrix. This integral term has a value between $\frac{1}{2}\epsilon C_s$ and ϵC_s and may be approximately evaluated by methods discussed in the *Appendix*.

It should be pointed out that Eq. 3, like Eq. 1, breaks down when

$$\epsilon C_s \gtrsim 2A$$

However, it should extend the quantitative applicability of the theory to much larger C_s values than Eq. 1.

The effect of solute binding has not been included in Eq. 1. For the case in which binding to the matrix is linear, *i.e.*, constant partition coefficient, a modified equation may be derived by the same mathematical procedure used previously (2). One has in this case

$$Q = \left\{\frac{\epsilon DC_s}{\tau}[2A - C_s(\epsilon + K - K\epsilon)]t\right\}^{1/2} \quad \text{(Eq. 4)}$$

where $K = \dfrac{\text{(drug in matrix phase)}}{\text{(drug in solvent)}}$ at equilibrium.

Equation 4 assumes equilibrium binding and takes into account the same factors included in Eq. 1. The cases for time dependent binding or nonlinear binding would be much more difficult to handle mathematically.

It can be seen from Eq. 4 that unless the product, KC_s, is a significant fraction of A, the effect of binding should not be very important.

EXPERIMENTAL METHODS

Diffusion Coefficient.—The method used in these studies is, in principle, the same as that employed by McBain (3). Essentially, it involves measurement of the solute transfer rate through a sintered glass disk from one chamber to another.

The apparatus is shown schematically in Fig. 1. It consists of a porous sintered glass disk (E) mounted between two 150-ml. conical flasks (C) with side arms. One of the flasks is closed with a ground glass stopper, and the other with a special adapter (B). Stirring of the solution is achieved by using magnetic stirring bars (D). The entire apparatus is water jacketed (F) to maintain constant temperature.

The following procedure was followed. Before the beginning of each experiment, the glass disk was flushed with water to remove entrapped air. This was accomplished by filling one of the flasks with water and then applying pressure over it or by applying vacuum to the other flask. This step was an important one because it was assumed that identical conditions were maintained from one experiment to another.

Also, a few minutes before the experiment the drug solutions were heated in a flask to boiling and then cooled rapidly to within 10° of the temperature of the experiment. This step greatly helped to eliminate the development of gas bubbles in the solution chamber during the experiment.

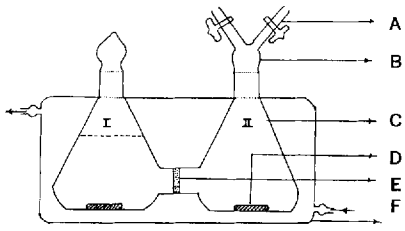

Fig. 1.—Schematic diagram of apparatus used to determine diffusion coefficients. Sintered glass disk diameter = 30 mm., thickness = 2.5 mm., and pore size = 4.0–5.5 μ. (See text for detailed description.)

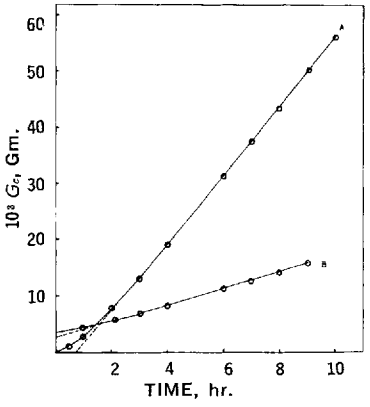

Fig. 2.—Typical diffusion runs with the apparatus. Curve A gives data for 6.8% sodium salicylate solution in flask II and water in flask I initially. Curve B gives data for saturated caffeine solution in flask II and water in flask I initially.

A measured amount of water was added to flask I, and simultaneously the drug solution was added to flask II keeping the levels of the liquids in the two flasks approximately the same. When the water addition to flask I was completed, flask II was quickly filled to the top and the adapter (B) was placed in position. More solution was added through one of the arms (A) keeping the stopcock of the other arm open for air displacement. Because the last traces of air were difficult to remove, the last few milliliters of solution were added by means of a fine-tipped pipet passed through the bore of the stopcock. After all of the visible air had been removed, the stoppers of the adapter were closed tightly and the magnetic stirring bars were started in both flasks. Samples were withdrawn at various time intervals for analysis.

The solution concentration in flask II was determined before and after each experiment. In most instances the changes, as expected, were negligible during the runs.

The cell constant, L, was determined using KCl solutions and the following relationship,

$$L = \frac{G_{KCl}}{D_{KCl}(C_2 - C_1)}$$

where C_2 and C_1 (with $C_1 \approx 0$) were the KCl concentrations in flasks II and I, respectively, D_{KCl} is the diffusion coefficient for KCl, and G_{KCl} is the KCl transport rate in the experiment.

A D_{KCl} value of 2.09×10^{-5} cm.^{2} sec.$^{-1}$ (4) was used with 0.10 M KCl solutions. G_{KCl} was determined by K^+ analysis using the Perkin-Elmer atomic absorption spectrophotometer model 303.

For the present apparatus it was found that at 30°

$$L = 2.45 \pm 0.10 \text{ cm.}$$

This value was also checked with benzoic acid solutions and the agreement was satisfactory using King's value for the diffusion coefficient for benzoic acid (5).

For the unknown solutes the diffusion coefficients were calculated from the data using the equation

$$D_e = \frac{G_e}{L\Delta C} \qquad \text{(Eq. 5)}$$

where G_e is the rate of solute transport and ΔC is the concentration difference between the two flasks.

It must now be pointed out that the D_e value obtained by means of experiment and Eq. 5 is the appropriate apparent diffusion coefficient to be used in either Eqs. 1 or 3 when $\Delta C = C_s$. This identity can easily be seen (Eq. 17a in *Appendix*) by examining the theory for the diffusion cell experiment in the same way as was done in the derivation of Eq. 3.

The direct use of the experimentally obtainable diffusion coefficient, D_e, in the theory for drug release from the matrix conveniently allows the absolute test of Eqs. 1 or 3 when ϵ and τ values are available from the measurements described later.

In Fig. 2 are given typical diffusion cell experimental data for two experiments. If the linear portions of the curves are extrapolated, it can be seen that in one curve (B) a positive intercept is obtained, while in the other curve (A) the intercept is negative. The magnitude of the intercept and whether it is positive or negative depends upon how the diffusion experiment is started. In the calculation of D_e the intercept is disregarded and only the straight line, steady-state portion of the data, is used.

Table I presents some D_e values determined by this method.

Solubility Determination.—An amount of drug, in excess of its reported solubility was placed in

each of several 100-ml. volumetric flasks and 50 ml. of solvent was added. The flasks were shaken in a Burrell wrist action shaker for 24 hr. and immersed in a water bath maintained at 30°. These were then filtered with a Millipore filtering unit and the filtrate was analyzed spectrophotometrically. A rapid filtering process was adopted to prevent the precipitation of drug from the saturated solution during filtration. Solubility of the compounds investigated are reported in column 2 of Table I.

Drug-Matrix Partition Tendencies.—Where distribution of drug in the matrix was suspected, saturated solutions of the drug were shaken overnight with the matrix material. High slurry densities were generally employed to increase the sensitivity of this method for estimating K (Eq. 4).

Porosity.—In order to have a porosity value that could be reliably used in Eqs. 1 or 3, two independent methods were used to estimate this quantity. The first method involved calculating the maximum possible contribution to ϵ by air in the tablets. The resulting ϵ value would be the correct one to use in Eqs. 1 or 3 only if all of the air spaces were permeated by the solvent and became available during the drug release process.

From knowledge of the tablet volume, the densities of the drug and matrix material (and other additives, if any), and the weight percentages of all the components, these calculations were carried out. The tablet volumes were computed from tablet dimensions determined with a micrometer and the densities were determined with the Beckman air compression pycnometer.

Some typical data for polyethylene matrix–drug tablets are presented in Table II. The last column gives the porosities calculated by this procedure.

In the second method for estimating ϵ the tablets were completely leached of the solute, and the empty matrices were equilibrated with a dilute solution of a known concentration. The equilibration times depended upon the matrix permeabilities, but usually 1 to 2 weeks was adequate. These resaturated matrices were then exposed to fresh solvent after a brief rinse, and the total amount of solute released determined from the release time data (Figs. 3 and 4). These steps were carried out as described under *Tortuosity*.

Table III presents some of the data with the polyethylene plastic matrix. Columns 4 and 5 of Table

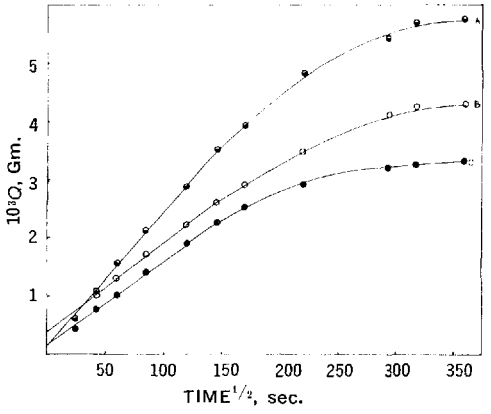

Fig. 3.—Solute release data from polyethylene plastic matrices used in the calculations of porosity and tortuosity. Solute release into 0.2% benzalkonium chloride of sodium salicylate from matrices equilibrated with 5% sodium salicylate solutions. Curves A, B, and C correspond to disks that originally contained 20, 10, and 5% solid sodium salicylate, respectively, and which were leached completely in 0.20% benzalkonium chloride solution.

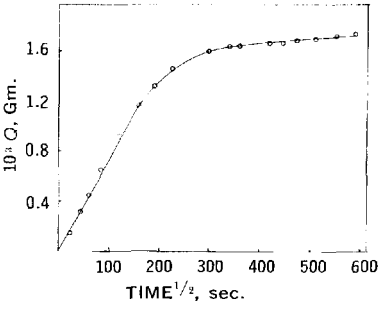

Fig. 4.—Release of caffeine into 0.10% dioctyl sodium sulfosuccinate (AOT) from a polyethylene plastic matrix which was equilibrated with a saturated caffeine solution. The matrix originally contained 20% solid caffeine which was leached completely in 0.10% dioctyl sodium sulfosuccinate (AOT) solution.

TABLE III.—POROSITY AND TORTUOSITY VALUES FOR SOME DRUG–POLYETHYLENE SYSTEMS DETERMINED BY RELEASE FROM SOLUTION SATURATED MATRIX METHOD

5% Sodium salicylate in polyethylene	3.92	5.12	0.130	0.113	4.8

III compare the two methods for determining ϵ. The agreement of this instance was very satisfactory.

As will be seen in a later communication, the agreement between the two procedures is not always so good. In these cases incomplete displacement of air appears to be the cause of the discrepancies.

It should be pointed out that good agreement between these two methods does not guarantee correctness of the ϵ value for the solid leaching process because air release may occur but only slowly during the solid release experiment. Good agreement between the two methods for determining ϵ does assure, however, a good reference point for evaluating the data by means of Eqs. 1 or 3.

Tortuosity.—The procedure for the determination of the tortuosity, τ, has been described previously (1). It is based upon the use of the following equation for the release of solute from one planar surface of a solution-saturated matrix

$$Q' = 2\epsilon C_0 \left(\frac{Dt}{\tau\pi}\right)^{1/2} \qquad \text{(Eq. 6)}$$

Here Q' is the amount of solute released per cm.^{2} at time, t, ϵ is, as before, the porosity defined by Eq. 2 and determined by the procedures described above, D is the diffusion coefficient obtainable by the experiment described earlier, and C_0 is the solution concentration.

Equation 6 was deduced for the present situation from the general equation for the release from a semi-infinite medium (6). Therefore, it would be quantitatively applicable for initial rates ($\simeq$ up to 30% release) only.

From the slopes of the initial linear portions of the Q' *versus* $t^{1/2}$ plots, τ may be calculated by means of Eq. 6 as

$$\tau = \frac{4\epsilon^2 C_0^2 D}{\pi\,(\text{slope})^2} \qquad \text{(Eq. 7)}$$

A typical plot is presented in Fig. 3 and some calculated τ values are given in the last column of Table III.

APPENDIX

Derivation of Eq. 3.—When steady-state diffusion takes place from a region of relatively high solute concentration toward essentially pure solvent, the movement of the solvent must be considered also in the problem. In the present problem when the solute is diffusing from $X = s$ to $X = 0$, the solvent, which is usually water in the authors' studies, will set up a concentration gradient, $\frac{dC_w}{dX}$ in the opposite direction and a tendency for solvent diffusion will be established.

However, the net movement of the solvent, G_w, must be zero, because at $X = s$ the solvent is not diffusing into the unleached region at steady state. Consequently, this must result in a bulk solution flow in the channels of velocity, v, from $X = s$ to $X = 0$. The important consequence of this bulk flow is that the solute transport rate is greater by $\frac{\epsilon}{\tau} vC$ than that given by Fickian diffusion alone. Mathematically we may write

$$0 = G_w = \frac{\epsilon}{\tau} D_w \frac{dC_w}{dX} + \frac{\epsilon}{\tau} vC_w \qquad \text{(Eq. 1}a\text{)}$$

and

$$G = \frac{\epsilon}{\tau} D \frac{dC}{dX} + \frac{\epsilon}{\tau} vC \qquad \text{(Eq. 2}a\text{)}$$

Here G is the solute transport rate, D_w is the diffusion coefficient of the solvent, C_w and C are, respectively, the solvent and the solute concentrations at X, and the other terms have already been defined.

Let us solve these equations assuming that both D and D_w are concentration dependent. The final results would then be more general and applicable even when appreciable viscosity changes are encountered or when significant solute–solute interactions occur.

Integrating Eq. 1a from $X = 0$ to $X = s$ one obtains

$$v \int_0^s dx = -\int_{C_w^0}^{C_w^s} D_w \frac{dC_w}{C_w}$$

whence,

$$vs = \int_{C_w^s}^{C_w^0} \frac{D_w dC_w}{C_w} = K \qquad \text{(Eq. 3}a\text{)}$$

where C_w^0 and C_w^s are the solvent concentrations at $X = 0$ and $X = s$, respectively. K is constant for a given solvent–solute pair at a given temperature when diffusion takes places from a saturated solution into pure solvent—the situation which is of most interest.

Equation 2*a* may now be solved after substituting for v from Eq. 3*a*. Integrating Eq. 2*a* from $X = 0$ to $X = s$ where $C = 0$ and $C = C_s$, one obtains

$$\int_0^s dX = \frac{\epsilon}{\tau}\int_0^{C_s} \frac{DdC}{G - \frac{\epsilon K}{\tau s}C} \qquad \text{(Eq. 4a)}$$

Since the left side of Eq. 4*a* becomes s, we have

$$s = \frac{\epsilon s}{\tau}\int_0^{C_s} \frac{DdC}{Gs - \frac{\epsilon}{\tau}KC} \qquad \text{(Eq. 5a)}$$

The s cancels, and

$$1 = \frac{\epsilon}{\tau}\int_0^{C_s} \frac{DdC}{Gs - \frac{\epsilon}{\tau}KC} \qquad \text{(Eq. 6a)}$$

For Eq. 6*a* to be true the product Gs must not be a function of C. Therefore,

$$Gs = K', \text{ a constant}$$

Now we may proceed as was done previously (2) for the derivation of Eq. 1. The amount of solute release from the matrix per unit area, Q, is

$$Q = As - M \qquad \text{(Eq. 7a)}$$

where M is the amount of drug in the pores from $X = 0$ to $X = s$ as solution. M then is given by

$$M = \epsilon\int_0^s CdX \qquad \text{(Eq. 8a)}$$

Since from Eq. 2*a*, dX is given by

$$dX = \frac{\epsilon D\,dC}{\tau\left(G - \frac{\epsilon K}{\tau s}C\right)} \qquad \text{(Eq. 9a)}$$

$$M = s\epsilon\int_0^{C_s} \frac{\epsilon DCdC}{\tau\left(sG - \frac{\epsilon K}{\tau}C\right)} \qquad \text{(Eq. 10a)}$$

Therefore,

$$Q = s\left\{A - \epsilon^2\int_0^{C_s} \frac{DCdC}{\tau\left(sG - \frac{\epsilon}{\tau}KC\right)}\right\} \qquad \text{(Eq. 11a)}$$

Differentiation of Eq. 11*a* with respect to time gives

$$\frac{dQ}{dt} = \left\{A - \epsilon^2\int_0^{C_s} \frac{DCdC}{\tau\left(sG - \frac{\epsilon}{\tau}KC\right)}\right\}\frac{ds}{dt} \qquad \text{(Eq. 12a)}$$

But

$$\frac{dQ}{dt} = G = \frac{K'}{s} \qquad \text{(Eq. 13a)}$$

Now Eqs. 12*a* and 13*a* may be solved by integrating from $t = 0$ to $t = t$ and from $s = 0$ to $s = s$ to give

$$Q = \left\{2K't\left[A - \frac{\epsilon^2}{\tau}\int_0^{C_s} \frac{DCdC}{K' - \frac{\epsilon}{\tau}KC}\right]\right\}^{1/2} \qquad \text{(Eq. 14a)}$$

If Eq. 14*a* is compared to Eq. 1, we find that K' may be associated with the factor $\frac{D\epsilon}{\tau}C_s$ of Eq. 1. Therefore, an effective (or an apparent) diffusion coefficient, D', may be defined as

$$D' = \frac{K'\tau}{\epsilon C_s} = \frac{Gs\tau}{\epsilon C_s} \qquad \text{(Eq. 15a)}$$

Therefore, Eq. 14*a* becomes

$$Q = \left\{\frac{D'\epsilon C_s}{\tau}t\left[2A - 2\epsilon\int_0^{C_s} \frac{DCdC}{D'C_s - KC}\right]\right\}^{1/2} \qquad \text{(Eq. 16a)}$$

Because Eq. 15*a* is general, this relation may be used to calculate D' from experimental data obtained with a conventional diffusion cell. Thus,

$$D' = \frac{G_c S_c \tau_c}{\epsilon_c C_s} \qquad \text{(Eq. 17a)}$$

where G_c is the measured solute transport rate per unit area of the barrier in a diffusion chamber with a diffusion barrier of thickness, S_c, porosity ϵ_c, and tortuosity, τ_c.

To accurately determine the value of the term involving the integral may be difficult unless accurate D *versus* C data are available. If such data are available and if ϵ and τ are known, then K should first be determined by means of Eq. 6*a* by a numerical integration procedure. Then, again by numerical integration, the integral term in Eq. 16*a* could be computed.

A reasonably accurate estimate of the integral term in Eq. 16*a* could frequently be made by employing a constant D value obtained from a diffusion experiment at low concentration.

Investigation of Factors Influencing Release of Solid Drug Dispersed in Inert Matrices III

Quantitative Studies Involving the Polyethylene Plastic Matrix

By SAURABH J. DESAI*, PARVINDER SINGH, ANTHONY P. SIMONELLI, and WILLIAM I. HIGUCHI

The procedure described in the previous paper has been applied to a number of cases. Release of sulfanilamide, caffeine, and potassium acid phthalate from polyethylene matrix disks into aqueous media were studied. The results show that in these cases the absolute tortuosity values are relatively small when all pores are accessible to the solvent. This situation is achieved, for example, when there is surfactant in the solution permitting adequate wetting of the channels. A direct correlation between surfactant activity and the rate of release has been found. Even when there was a relatively small amount of inaccessible pores, the tortuosities in these cases were found to be considerably greater. The results were obtained when surfactant was not incorporated in the release medium. It is proposed that these findings are consistent with an "encapsulated" drug particle model.

A PREVIOUS INVESTIGATION (1) showed that the Higuchi equation can be utilized to describe drug release from polyethylene matrices. The results of experiments which investigated the effects of drug type, concentration of drug in tablet, solvent media, etc., indicated that the above factors not only altered release rates directly as predicted by theory, but also indirectly by altering other parameters. Before a quantitative evaluation of the polyethylene system could be made, it was therefore necessary to establish experimental procedures to determine independently all parameters for the conditions of each study. In this way the interdependence of all parameters can be eliminated.

Experimental procedures to determine the diffusion coefficient, drug solubility, and matrix porosity were reported in a previous communication (2). These parameters can then be used in the equations which describe the release rates from matrices containing solid medicament and from matrices saturated with a solution of drug.

The release rate of drug imbedded in an insoluble matrix obeys the following equation:

$$Q = \sqrt{\frac{D\epsilon}{\tau}(2A - \epsilon C_s)C_s t} \qquad \text{(Eq. 1)}$$

where

D = diffusion coefficient of the drug in the permeating fluid,
ϵ = the porosity of the matrix,
τ = tortuosity of the matrix,
A = the total amount of drug present in the matrix per unit volume,
C_s = the solubility of the drug in the release medium,
Q = grams of drug released per unit area of surface.

If the same matrix is saturated with a solution, the release rates would obey the following relationship:

$$Q = 2\,C_0\epsilon\left(\frac{Dt}{\tau\pi}\right)^{1/2} \qquad \text{(Eq. 2)}$$

where C_0 = concentration of the solution in the matrix. The other terms have the same meaning as in Eq. 1.

Once the parameters of the matrix have been established, one can use Eq. 1 to determine the remaining parameter, tortuosity, from release data obtained using the matrix containing the solid drug. Equation 2 can also be used to calculate the tortuosity of the same matrix, but the release data obtained from the resaturated matrix must be used. If the tortuosities independently calculated by these methods agree well with each other, this would provide strong evidence that this method of attack can be used to quantitatively study the effect of experimental conditions on the release rates of drugs from inert matrices. Using this approach, this paper reports the effect of drug concentration, drug solubility, and other factors upon the parameters—tortuosity, porosity, and diffusion coefficient.

EXPERIMENTAL

The release rates from polyethylene matrices containing solid drug as well as solutions were studied using the techniques described previously (1). The parameters were evaluated as described in the subsequent paper (2).

RESULTS AND DISCUSSION

If a given matrix is studied by both the solid and saturated solution methods, it must be established that all parameters remain constant during the experiments. Since the addition of surfactant to the aqueous solvent media greatly increases the rate of drug release from polyethylene matrices, it had been postulated that all of the maximum possible matrix porosity is made available by the surfactant. This was verified by the fact that the porosity determined by the liquid leaching method (2) was equal to the combined porosity of drug and air. The latter was calculated by the physical measurement method (2). This was not true in nonsurfactant experiments. It was, therefore, decided to use surfactant solutions as the release medium to establish the quantitative applicability of the theory.

Quantitative Application of Theory.—Polyethylene matrices containing 20% sulfanilamide, caffeine, and potassium acid phthalate were studied. Both the solid and liquid leaching experiments were performed utilizing surfactant solutions. It should be pointed out that the compounds were selected on the basis of their suitability for establishing basic physicochemical points rather than their therapeutic value; similarly, the surfactants used were selected on the basis of their surfactant activity and system compatibility. All surfactant solutions used were above their critical micelle concentration to provide maximum surfactant activity.

The surfactant solution used in the sulfanilamide and caffeine studies was 0.1% dioctyl sodium sulfosuccinate[1] (AOT) but 0.1% hexadecyl trimethylammonium bromide solution (HTAB) was used with the potassium acid phthalate studies since the latter was not compatible with AOT.

The solid release curves of these systems are shown in Figs. 1, 2, and 3. Solid leaching curves in water are also included to show the magnitude of the surfactant effect which will be discussed later. Liquid leaching curves of the same matrices are shown in Figs. 4 and 5. To demonstrate the applicability of the solid and liquid leaching concepts, calculations of τ values using Eqs. 1 and 2, respectively, will be shown and compared.

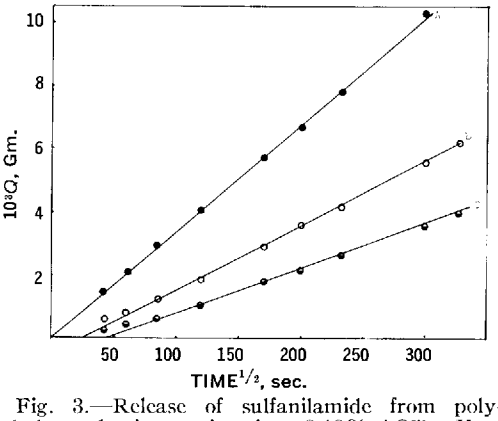

Fig. 3.—Release of sulfanilamide from polyethylene plastic matrices into 0.10% AOT. Key: A, 20% drug in matrix; B, 10% drug; C, 5% drug.

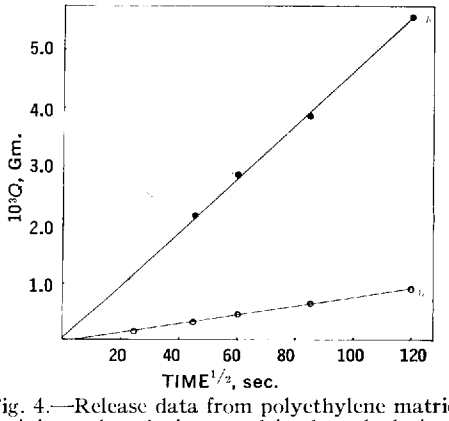

Fig. 4.—Release data from polyethylene matrices containing only solutions used in the calculation of tortuosity. Key: A, tablets originally contained 20% solid potassium acid phthalate which was released completely in 0.10% HTAB, was then equilibrated with a saturated potassium acid phthalate solution, and then released in 0.10% HTAB; B, same as A, except caffeine was used instead of potassium acid phthalate and 0.10% AOT was used instead of HTAB.

The following calculations using the data of a polyethylene matrix containing 20% sulfanilamide

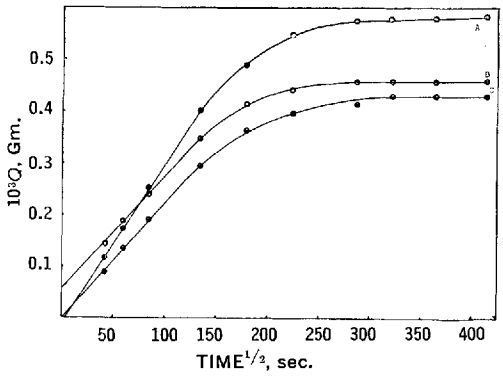

Fig. 5.—Solute release data from polyethylene plastic matrices used in the calculations of porosity and tortuosity. Key: A, tablets originally contained 20% sulfanilamide which was released completely in 0.10% AOT, was then equilibrated with a saturated sulfanilamide solution, and then released in 0.10% AOT; B, same as A, except tablets contained 10% drug; C, same as A, except tablets contained 5% drug.

in a surfactant medium will serve as an illustrative example.

weight of the tablet = 0.300 Gm.

volume of tablet = $\pi r^2 h$ = 0.328 ml.

$C_s = 1.08 \times 10^{-2}$ Gm./ml.

$C_0 = 0.95 \times 10^{-2}$ Gm./ml.

$$A = \frac{\text{wt. of drug}}{\text{vol. of tablet}} = \frac{0.060 \text{ Gm.}}{0.328 \text{ ml.}} = 0.182 \text{ Gm./ml.}$$

$D = 12.9 \times 10^{-6}$ cm.^{2}/sec.

$$\text{volume of plastic} = \frac{0.240}{0.960} = 0.250 \text{ ml.}$$

$$\text{volume of drug} = \frac{0.06}{1.500} = 0.040$$

volume of air = 0.328 − 0.290 = 0.038 ml.

$$\epsilon = \frac{0.038 + 0.04}{0.328} = 0.237$$

$Q/t^{1/2}$ = slope of solid leaching (Fig. 3) = 3.30×10^{-5} Gm./sec.$^{1/2}$

$Q/t^{1/2}$ = slope of liquid leaching (Fig. 5) = 0.303×10^{-5} Gm./sec.$^{1/2}$

Solving Eq. 1 for the value of τ and substituting the values of above parameters one obtains the following

$$\tau = \frac{D\epsilon(2A - \epsilon C_s)C_s}{(\text{slope})^2}$$

$$= \frac{(12.9 \times 10^{-6}) \times (0.237)\,(2 \times 0.182 - 0.237 \times 1.08 \times 10^{-2})(1.08 \times 10^{-2})}{(3.30 \times 10^{-5})^2}$$

$$= 10.7$$

and similarly Eq. 2 yields

$$\tau = \frac{4C_0^2\epsilon^2 D}{\pi\,(\text{slope})^2}$$

$$= \frac{4 \times (0.95 \times 10^{-2})^2 \times (0.237)^2 \times 12.9 \times 10^{-6}}{3.142 \times (0.303 \times 10^{-5})^2}$$

$$= 9.1$$

Comparison of the above values of τ shows excellent agreement and thereby indicates that the theory and the parameters employed are valid. Similar agreement was obtained with caffeine. A similar study with potassium acid phthalate showed a reasonably good agreement; the relatively higher τ value obtained for potassium acid phthalate by the solid leaching experiment may be due to the poorer wetting properties of HTAB compared to AOT. These results are summarized in Table I.

Examination of the ϵ due to air in Table I shows that it does not remain constant, although the same concentration of different drugs is used. This may be a reflection of the relative flow properties of the drug and plastic when under compression.

The above approach was also used to study polyethylene matrices containing 5 and 10% sulfanilamide. The curves are shown in Figs. 3 and 5, and the calculated parameters are listed in Table II.

Examination of Table II clearly shows that the ϵ of the matrix is not a direct function of the drug percentage. Although the porosity contribution from the drug increases with increasing concentration of drug, the porosity contribution from air is decreasing. In addition, there seems to be a slight increase in τ. Again, it should be noted that excellent agreement was shown between the tortuosities calculated from the solid leaching and solution leaching data.

These results explain why the release rates in an earlier study (1) did not follow the predicted rates assuming all parameters were constant and confirm the hypothesis that the porosity was not proportional to A.

Mechanism of Surfactant Action.—The surfactant seems to be instrumental in making available the maximum possible porosity. It was felt, therefore, that the effect should be investigated further. To eliminate the possibility that surfactant may

solubilize some component of the plastic material, the polyethylene powder was shaken in the presence of excess of surfactant solution overnight. This slurry was then filtered and the polyethylene was washed with hot and cold water. Twenty per cent potassium acid phthalate tablets were made using this washed and then dried polyethylene powder. The release rates in water and surfactant were then studied; results were identical with the unwashed plastic indicating that the surfactant does not solubilize any of the plastic component.

The increase in release rates of drugs from a polyethylene matrix by surfactants seems to be a general effect. It has been shown that not only is this effect present with all the compounds studied but also that it is independent of the chemical nature of the surfactant. This is demonstrated by the identical release behavior of 20% potassium acid phthalate in polysorbate and HTAB solutions (Fig. 1).

The release rates of 20% sulfanilamide tablets were studied in several solution concentrations of AOT. The results obtained are presented in Fig. 6. In order to compare these results with the surfactant property of these solutions, plots of both the release rate and surface tension *versus* the surfactant concentration are shown together in Fig. 7. The data reveal an excellent correlation between the release rates and the surface tension of the release media. It was expected that the release rates would increase with increasing concentration of surfactant because of increased wetting power of surfactants with increased concentration in regions below the critical micelle concentration (CMC). It is interesting that the reported (3) CMC for AOT is 0.08% which is near the point in Fig. 7 where the plateau of the release rate curve begins.

If the above-proposed mechanism of surfactant action is true, then the presence of surfactant either within the tablet matrix or in the release medium could give essentially the same results. On the basis of the same principle, a drug with inherent surfactant activity may yield identical release rates in the presence and in the absence of a surfactant in the release medium.

Release rates of 20% potassium acid phthalate tablets containing 2% HTAB were studied in water. These results are plotted in Fig. 8 along with the results of 20% potassium acid phthalate determined in a solution of 0.1% HTAB. As expected, the release rates were about the same. The slightly higher release rate observed with the former case might be accounted for by small porosity differences due to the incorporation of the surfactant.

To study the second premise, hexadecylpyridinium

10% Sulfanilamide	4,700	1,700
20% Sulfanilamide	1,500	740

chloride was selected as the drug with inherent surfactant properties. Release rates were obtained in water and in 0.1% HTAB solution. The results are shown in Fig. 9. The release rates in both experiments were essentially the same as indicated by their slopes. The intercept in the data for the release in surfactant is probably due to the better initial wetting of the tablet surface when the surfactant was used in the release medium.

Nonsurfactant Release Rates.—As previously noted and illustrated in Figs. 1 and 2, the release rates in water are considerably slower than those obtained in surfactant solutions. Analysis of the parameters and the release rates strongly suggest that the wetting of all pores and the release of air from them are not achieved in nonsurfactant solutions. To further complicate matters, it appears that removal of air is slowly but continuously occurring as indicated by the slight curvature of several release rates observed in nonsurfactant solutions.

Attempts to apply Eq. 1 to both initial and limiting slopes of these curves yielded a very high value for the apparent tortuosity. Calculations were made assuming the two limiting cases—all air removed or no air removed. This seems to indicate that the air remaining in the tablets blocks pathways leading to drug particles and in this way effectively encapsulates them.

To further study this effect, the release rates of matrices containing 5, 10, and 20% sulfanilamide were studied in water. The results are shown in Fig. 10. The slopes in all these cases initially decreased with time and then exhibited a constant value. It is believed that the initially greater rate is due to the surface drug that is readily accessible to the solvent. The magnitudes observed are consistent with this assumption.

Using Eq. 1 and applying it to the constant slope portions of these curves, tortuosities were calculated using the two porosity values. The results of these calculations are shown in Table III.

The apparent tortuosities calculated in this manner are extremely high. These results suggest that drug is indeed effectively encapsulated by the polyethylene plastic. The increase in the calculated τ values with decreasing A is consistent with this type of model because the more dilute the internal (drug) phase the greater the likelihood of isolation of a drug particle in a sea of plastic. Then, if the wetting of the channels in the plastic itself is insufficient, the permeability of the media is largely determined by the low permeability of the plastic itself and not by a simple average of the void space and the plastic permeabilities.

It is believed that situations such as these may be best defined physically by the use of concepts other than the "average porosity" and the "average tortuosity" as are implied by Eq. 1. Preliminary theoretical studies based on the use of mixture relationship such as the Clausius-Mosotti and the Bruggeman equations (4) have yielded effective τ values of the order of magnitudes given in Table III when reasonable assumptions were made. A future communication will describe in detail comparisons of data with these theories for encapsulation.

SUMMARY

The interpretation of data based upon the quantitative determination of the parameters, ϵ, τ, and D, and their use in Eqs. 1 and 2 was shown to be valid for studies in which the porosity was known throughout the experiment. The results were excellent and showed that these methods can be quantitatively used to study the effect of various variables on the release rates of drugs from inert matrices.

Investigation of Factors Influencing Release of Solid Drug Dispersed in Inert Matrices IV

Some Studies Involving the Polyvinyl Chloride Matrix

By SAURABH J. DESAI*, PARVINDER SINGH, ANTHONY P. SIMONELLI, and WILLIAM I. HIGUCHI

The mechanism of drug release from tablets made from mixtures of drug and polyvinyl chloride particles was investigated. Experimental data were evaluated by means of the Higuchi relationship for the process. The S-shaped nature of the amount released *versus* (time)$^{1/2}$ plots was studied, and it appears that this behavior was the result of the relatively slow release of air from the tablets. Matrix tortuosities ranging from about 1.5 to 3.0 were found for these polyvinyl chloride matrices.

IT HAS BEEN previously shown that polyvinyl chloride (PVC) matrices have exhibited peculiar behavior compared to those of polyethylene (1). The drug release from the PVC tablets showed S-shaped curves which are contrary to the predicted linear plots when the amount of release is plotted *versus* the square root of time. In addition, the PVC matrices did not show the surfactant effect observed with those of polyethylene. Finally, the PVC release rates were 4–6 times faster. These plots are shown in Fig. 1. Since this behavior may be representative of a general class of matrices, it was felt that this phenomenon should be thoroughly investigated.

Comparison of PVC and polyethylene powders reveals that the PVC powder has a much higher density (about 50%), a larger particle size (50–200 mesh as compared to smaller than 270 mesh), and a larger particle size distribution. This suggested that their respective matrices may also differ. The PVC powder should produce a more compact tablet due to its higher density and should be better bonded due to its wider particle-size distribution. Examination of their respective matrices shows that, although PVC is more compact, it exhibits poorer bonding. Polyethylene produces a tablet which has a very smooth surface, appearing as a fused solid, but PVC tablets seem rather friable and are easily repowdered by scraping.

EXPERIMENTAL

The release rates from PVC matrices containing solid drug as well as solutions were studied using the techniques and the evaluation of parameters described previously (1, 2). All studies were conducted using water as the release medium unless specified otherwise, and all percentages reported are on a w/w basis.

RESULTS AND DISCUSSION

The relatively poorer bonding characteristics of PVC may be partly responsible for its behavior. In an effort to improve its bonding characteristics, the effect of pressure was studied. Tablets containing 10% sodium salicylate were made at compressional forces of 2000-lb. increments between 4000 and 20,000 lb. Their release rates were independent of the compressional force. Figure 2 displays the curve obtained from the composite of all data and shows the range of random variations for each point. These results indicate that PVC is elastic throughout this range of compressional forces, and, therefore, its porosity should remain constant in these tablets. This was confirmed by the constancy of the dimensional measurements of all tablets.

Physical measurements of PVC tablets not only showed the presence of air, but also that the amount was considerably higher than in a similar matrix of polyethylene. The porosity of a 500-mg. 20% sodium salicylate tablet in PVC was 0.37, whereas the corresponding tablet made using a polyethylene matrix had a porosity of 0.22. The relatively large amount of air in the PVC tablet theoretically suggested that a large surfactant effect on the release rates might be observed. However, no such effects were found. This lack of surfactant effect implies that the surfactants used did not increase the wetting characteristics of PVC and that the removal of air was not facilitated. The discussion of this aspect will be deferred to a later portion of this paper.

The S-shaped curves exhibited by PVC tablets show that the slopes are not constant with time, but initially increase, then become constant, and then finally decrease with time. The beginning of the last phase corresponds to where essentially all of the solid drug in the matrix had just dissolved.

Several possible explanations were considered and investigated for the initial curvature of the S-shaped curves. One possible explanation may

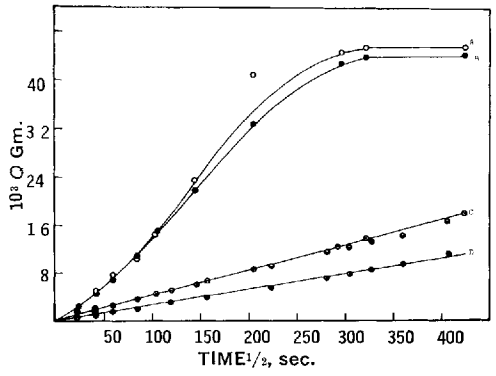

Fig. 1.—Effect of surfactants on sodium salicylate release rates. Key: A, 5% w/w sodium salicylate in PVC matrix using water as solvent; B, 5% w/w sodium salicylate in PVC matrix using 0.2% w/w benzalkonium chloride as a solvent; C, 5% w/w sodium salicylate in polyethylene matrix using the following solvents: ⊙, 0.2% benzalkonium chloride and ⊖, 0.2% sodium lauryl sulfate; D, 5% w/w sodium salicylate in polyethylene matrix using water as a solvent.

be the partitioning of drug between the PVC and the release medium. Theoretical considerations have shown (2) that the release dependence remains linear with respect to the square root of time if reversible drug partitioning should occur. If, however, the rate of partitioning is slow, then the linearity may be disturbed and the S-shaped curve may result. This possibility was ruled out on the basis of liquid leaching experiments using the same tablets which showed linear release plots. If partitioning was the cause of the S-shaped curve, the same result would be expected to occur in both solid and liquid leaching experiments.

This S-shaped curve can be due to any factor which governs the release rates not remaining constant as required, but changing as a function of time. A critical examination of all these factors clearly indicated that porosity would most likely be a variable. As an example, any swelling of the matrix due to the presence of water would alter the porosity, decreasing it with time. This possibility was investigated by accurately measuring the dimensions of tablets prior to and after soaking overnight in water. Blank PVC tablets and PVC tablets containing 10% sodium salicylate were used for these experiments. No change was noted in their dimensions due to the water exposure, and swelling was clearly eliminated as a factor in this system.

Another possibility for porosity variation may be due to a difference in the physical properties of the surface and interior portions of the matrix. This can be brought about by a difference in the flow properties of the matrix components during compression. If there is poor flowability, the effective pressure is not uniformly distributed throughout the matrix. As a result, the surface portion would be subjected to a greater pressure. This would produce smaller porosities and larger tortuosities at the surface and account for initial rates being slower.

If the above is true, it would predict that the release rate of a matrix whose surface was removed by scraping would yield a more rapid initial release of drug and would display linear behavior. For this purpose, matrices containing 10% sodium salicylate were compressed from the same mixture and then treated in the following manner. From one tablet about 6% w/w was scraped from the surface (surface to be exposed to the leaching action of the solvent) so that a uniform layer was removed and a new surface produced. Another had 12.5% w/w removed, and from a third 25% w/w was removed. As a control, one tablet utilized its original surface. Examination of Fig. 3 reveals that the release rates were not affected by the above treatment. This indicated that the physical properties of the surface and interior layers are not different, and that this is not an important factor in the experiments.

To further confirm this finding, the effect of lubri-

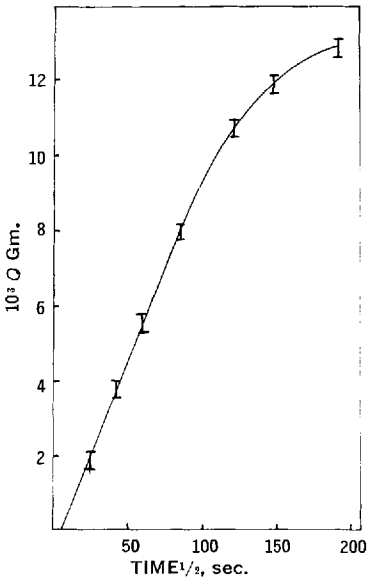

Fig. 2.—Effect of compressional force on release of 10% sodium salicylate–PVC tablets in water. Range of random spread of the data is indicated by the bars.

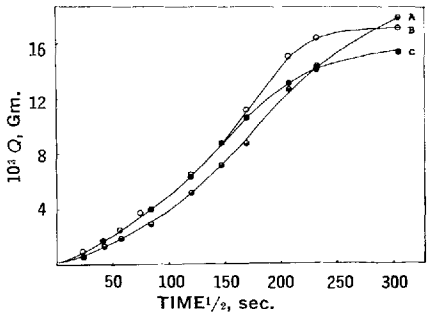

Fig. 3.—Effect of removal of the tablet surface layers on the release rates of 5% sodium salicylate tablets in PVC. Key: A, 6% w/w tablet surface removed; B, 12.5% w/w tablet surface removed; C, 25% w/w tablet surface removed.

cant addition to the matrix was studied. If the flowability of the PVC powder–drug mixture is not adequate, the addition of lubricant would improve flowability under compression and alter the matrix release profile. Figure 4 shows the release of 10% sodium salicylate matrices containing 3% talc or magnesium stearate. Comparison of these curves with the included plot of the matrix not containing any lubricant confirm the previous finding of sufficient flowability of the powder mixture under pressure.

It was finally reasoned that the initial incomplete removal of air from the matrix may be the cause of the S-shaped curves. This view was supported by the fact that a resaturated matrix yielded a linear plot. Such a matrix would have been exposed to solvent for a sufficient length of time to allow for the complete removal of air.

It is believed that the availability of air channels

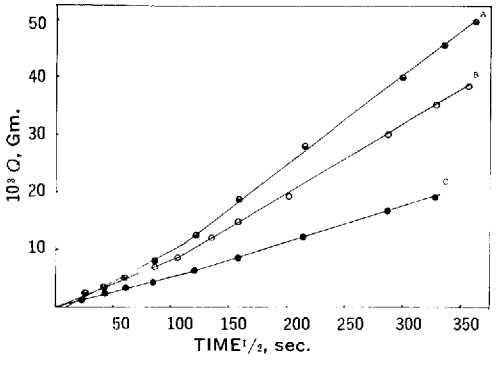

Fig. 5.—Release of 20% calcium benzoate (A), 20% caffeine (B), and 20% sulfanilamide (C) from PVC matrices into water.

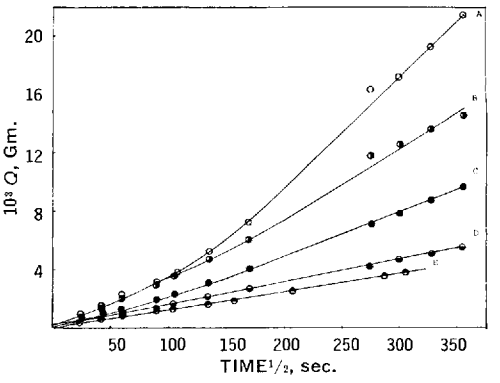

Fig. 6.—Effect of K_2HPO_4 concentration on release of 10% salicylic acid in PVC tablets. Key: A, 1.00 *M* K_2HPO_4; B, 0.50 *M* K_2HPO_4; C, 0.10 *M* K_2HPO_4; D, 0.01 *M* K_2HPO_4; E, water.

to the solvent depends on the rate of liquid boundary movement which should be a function of the drug solubility and would be expected to increase with an increase in solubility. If the drug is poorly soluble, the movement of the liquid boundary may be sufficiently slow to permit the prior removal of air. This would provide the linear plots predicted by theory. If the drug is very soluble, on the other hand, the drug solution boundary may move faster than the process of air removal, producing an increasing porosity with time and causing the observed curvature.

To test this concept, the release rates of sulfanilamide, caffeine, and calcium benzoate tablets were obtained and the corresponding data are shown in Fig. 5. The respective solubilities are 1.08×10^{-2}, 2.50×10^{-2}, and 3.08×10^{-2} Gm./ml., as compared to 65.0×10^{-2} Gm./ml. for sodium salicylate. In agreement with the previous discussion, the curves in Fig. 5 show the expected correlation between solubility and degree of curvature. As the solubility increased, nonlinearity also increased showing the most marked change for sodium salicylate.

This correlation can be shown in another way. The solubility of a drug can be varied by using different concentrations of buffer in the release medium. In this manner, the solubility of the drug can be varied and yet have the identical matrix properties operative in all cases.

The release rate of 10% salicylic acid dispersed in PVC was studied in different concentrations of K_2HPO_4 solutions. The results are given in Fig. 6, and they show that the release rates increase as the concentration of K_2HPO_4 is increased. In the presence of K_2HPO_4, salicylic acid in solution is converted to salicylate ion, the extent of the conversion being essentially proportional to the concentration of K_2HPO_4. Again, as the effective solubility increases, each plot displays increasing curvature in the release patterns. The rates are linear in water and at low K_2HPO_4 concentrations.

If the rate of air removal is the controlling factor, then the complete removal of air by vacuum before exposing the matrix to solvent should produce a linear square root of time dependence. To test

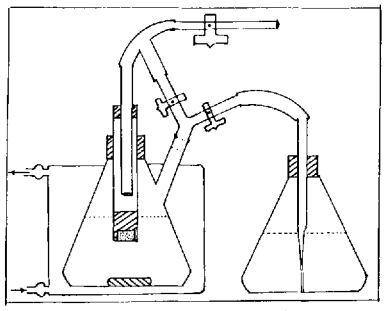

Fig. 7.—Schematic diagram of the apparatus used to study release rates after vacuum treatment.

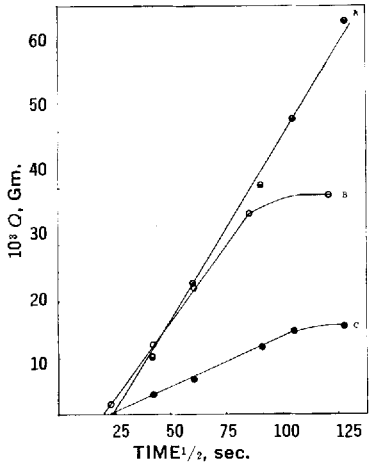

Fig. 8.—Release of 5, 10, and 20% sodium salicylate in PVC tablets into water after vacuum treatment. Key: A, 20% sodium salicylate; B, 10% sodium salicylate; C, 5% sodium salicylate.

this, a modified apparatus was made, and its schematic diagram is shown in Fig. 7. A tablet inserted in a glass tube as previously described (1) was mounted on a 125-ml. conical flask with a side arm. The flask was jacketed to maintain a constant temperature. The side arm was fitted with a Y-joint. One of the arms of the joint was connected to a vacuum pump and the other to a flask containing a measured amount of water. Vacuum was also applied to the top of the glass tube by means of a T-tube so as to maintain equal pressure on either side of the mounted tablet preventing any movement or damage of the tablet. Prior to the final application of vacuum, the connecting tube and stopcock bore from the water supply to the flask was completely flushed to remove the entrapped air. All connecting joints were sealed with "Apiezon" vacuum sealing material. A McLeod gauge was used to measure the pressure. A vacuum pressure of 0.9 mm. Hg was obtained before the water was allowed to flow into the sample flask. Immediately after the addition of water, the magnetic stirrer was started. The height of the tube containing the tablet had been previously adjusted to insure complete immersion of the tablet in water before the vacuum was released.

The results of the release of 5, 10, and 20% sodium salicylate tablets, obtained by the above vacuum procedure, are plotted in Fig. 8. The release rates of 20% sulfanilamide and 20% calcium benzoate tablets under similar conditions are shown in Fig. 9.

As predicted, all the release rates follow the square root of time dependence, strongly suggesting that the S-shaped curve is produced by the proposed mechanism. To further investigate this, liquid release rates of sulfanilamide and calcium benzoate tablets were carried out using procedures previously described (1, 2), and these results are plotted in Fig. 10. The quantitative evaluation of tortuosity by solid and liquid leaching procedures were made,

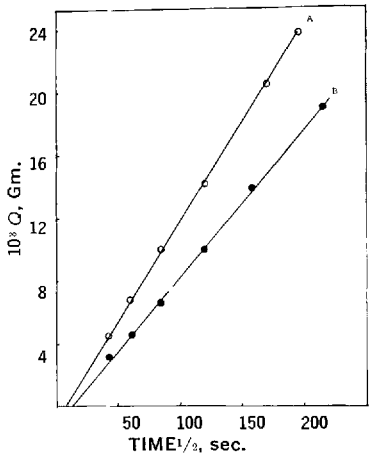

Fig. 9.—Release of 20% calcium benzoate (A) and 20% sulfanilamide (B) from PVC matrices into water, after vacuum treatment.

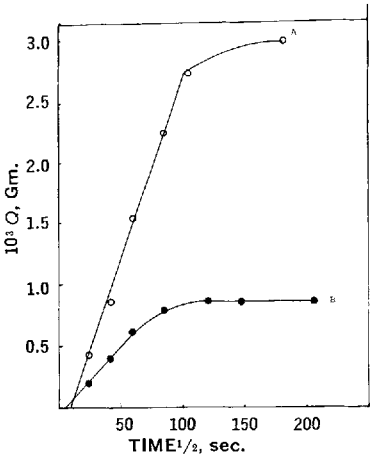

Fig. 10.—Release data from matrices saturated with drug solution. Key: A, tablet originally contained 20% calcium benzoate, which was completely leached (the matrix was equilibrated with saturated calcium benzoate solution prior to studying the liquid release); B, same as A, except sulfanilamide was used as the drug, and saturated sulfanilamide solution was used instead of calcium benzoate solution.

TABLE I.—CALCULATION OF TORTUOSITIES IN POLYVINYL CHLORIDE MATRICES CONTAINING SULFANILAMIDE AND CALCIUM BENZOATE. SOLID RELEASE STUDIED WITH VACUUM PROCEDURE

Tablet Compn.	D 10^6 cm.^{2} sec.$^{-1}$	Vol. of Tablet, ml.	I Vol. of Drug, ml.	II Vol. of Air, ml.	ϵ	III Wt. of Drug, Gm.	C_0 10^2 Gm. ml.$^{-1}$ $\frac{\text{III}}{\text{I} + \text{II}}$	Solid Release Rate $10^4 Q/t^{1/2}$	τ
5% Sodium salicylate	13.30	0.4385	0.0161	0.1093	0.286	0.025	0.200	1.79	1.7
10% Sodium salicylate	17.20	0.4294	0.0323	0.1006	0.309	0.050	0.376	4.34	1.6
20% Sodium salicylate	23.00	0.4189	0.0645	0.0908	0.371	0.100	0.644	6.55	3.8

and the results are summarized in Table I. The good agreement of the tortuosity values obtained by the two methods indicate that the total porosity is available when the vacuum procedure is followed.

The τ values were similarly calculated for the sodium salicylate systems. The calculated values for τ, however, were physically impossible as they were less than unity. Analysis of the situation revealed that when the vacuum procedure is used, the solid release equation should not be applicable. Under these conditions, the water is able to rapidly permeate all available channels. Since the dissolution rate of sodium salicylate is very rapid, the water which penetrated the matrix is rapidly saturated. If the amount of drug in the matrix, however, is not sufficient to produce a saturated solution, then all of the drug will be rapidly dissolved. As a result, a matrix containing no solid drug but only its solution will be produced. In these cases the release rates should follow the liquid release equation rather than that of the solid release.

The concentrations of the resultant solutions in the 5, 10, and 20% tablets were calculated on this basis assuming that all the volume of each tablet initially occupied by air and sodium salicylate became occupied by a solution containing all of the incorporated drug. The concentrations of the solutions in the matrix for 5, 10, and 20% tablets were calculated and found to be 0.20, 0.37, and 0.64 Gm./ml., respectively. In addition, τ values were calculated using the above solution concentrations in the liquid leaching equation and are listed in Table II. These values are in excellent agreement with those obtained from the sulfanilamide and calcium benzoate studies and provide strong support for the concepts developed here.

An interesting observation can be made by comparing the magnitude of the tortuosity values obtained for these different drugs in a PVC matrix with those that were obtained for the same drugs dispersed in a polyethylene matrix (3). It is seen that the tortuosity values obtained for the PVC matrix vary from about 1.5 to 4, whereas for the polyethylene matrix they vary from about 7 to 10. It has been shown (4) that the value of τ for a system composed of closely packed spheres is generally above 1.5 to 2.0. This indicates that the structure of a PVC matrix resembles that of a closely packed glass bead bed, and implies that PVC particles are elastic, and, therefore, they are not permanently distorted when compressed. The high τ values of the polyethylene matrix, on the other hand, indicate that its particles are plastic and are severely distorted when compressed.

APPENDIX

The equations used in the explanation of the rate process are:

$$Q = \frac{D\epsilon}{\tau}(2A - \epsilon C_s)C_s t^{1/2} \qquad \text{(Eq. 1)}$$

and

$$Q = 2\,C_0\epsilon\left(\frac{DT}{\pi\tau}\right)^{1/2} \qquad \text{(Eq. 2)}$$

where

Q = amount of drug released per unit area of the tablet surface exposed at time, t,
D = diffusion coefficient of the drug in release medium,
C_s = solubility of the drug in the release medium,
C_0 = concentration of the solution in the matrix,
ϵ = porosity of the matrix,
τ = tortuosity of the matrix.

Near-Infrared Spectroscopy of Amine Salts

By JOSEPH E. SINSHEIMER and ANNE M. KEUHNELIAN

The purpose of this investigation was to study the applicability of near-infrared spectroscopy to pharmaceutical analysis. Of particular interest was a model series of aliphatic amine hydrochlorides, and as typical pharmaceutical examples, the sympathomimetic amine salts were studied. Both solid state and chloroform solution spectra were obtained and their qualitative and quantitative applications were evaluated.

THE SPECTRAL characteristics of amines, especially aromatic amines, have been well established in the near-infrared region (1). However, while amine salts have been studied in the infrared (2–4), little has been established in the near-infrared region probably because of a lack of suitable solvents and sampling techniques.

Since the medicinal use of amines, especially as their amine salts, is extensive, it was felt that an investigation into the application of the near-infrared for the direct analysis of pharmaceutical amine salts would be of interest. This is particularly true in the case of aliphatic amine salts where the absence of ultraviolet absorption makes alternate spectral methods even more desirable. Molar absorptivity values in the near-infrared region are usually low even compared to the infrared region. However, measurements in the near-infrared can offer the advantage of the high resolution of the quartz optics employed. Use of cells and techniques more analogous to ultraviolet techniques than to those of use in the infrared also may be a potential advantage.

Objectives of the present study were the development of sampling techniques together with an investigation of the qualitative aspects, sensitivity, and conformity to Beer's law of near-infrared measurements of amine salts.

EXPERIMENTAL

Instrumental Parameters.—Beckman DK 2A: sensitivity, 50; time constant, 0.2; recording speed, 18 mμ/min.; wavelength expansion, 50 mμ/cm. Zeiss PMQ II with a M4Q III monochromator: amplification 5/1/1 and slit widths less than 0.08 mm. Both instruments were calibrated for wavelength accuracy against 1,2,4-trichlorobenzene (5).

Reagents.—Commercially available amines and sympathomimetic amine salts of production grade were used without further purification. Except where indicated as being commercially available, amine salts were prepared by adding 50 ml. of a saturated solution of HCl in anhydrous ether to 10 ml. of amine dissolved in 10 ml. of anhydrous ether. The resulting product was filtered, washed with three portions of 50 ml. of anhydrous ether, air dried, and stored in a desiccator over silica gel.

The reagent grade chloroform used as a solvent in spectrophotometric measurements was passed through a column of alumina to remove traces of water and ethanol. This process was followed by noting the absence of the strong ethanol peak at 2.90 μ. Chloroform treated in this manner was stored in a brown bottle for use within 5 days.

Solid State Spectra.—In general, from 25 to 40 mg. of amine salts taken directly from a desiccator were reduced to a powder in an agate mortar and pestle as quickly as possible to avoid the adsorption of moisture. The powders were transferred to a KBr die (Limit Corp. KB-01) and a 13-mm. disk was formed at 20,000 lb. for 5 min. Spectra were obtained on a DK-2A spectrophotometer from 2.80 to 1.05 μ or to as low a wavelength as dispersion permitted. A base line was established on the lowest absorbance range possible at 2.65 μ and with a slit width below 0.3 mm. by manual attenuation of the reference shutter.

Solution and Liquid Spectra.—(*a*) Absorption spectra of from 0.1 to 3% solutions of amine salt in chloroform were obtained on a DK-2A spectrophotometer from 2.35 to 2.10 μ. Near-infrared 1-cm. matching pair cells were used with chloroform in the reference cell.

(*b*) Absorption spectra for the parent amines were obtained from 2.65 to 1.05 μ in a 0.25-mm. short-path cell against silica as the reference.

(*c*) Percentage-transmittance spectra were obtained from 2.15 to 1.70 μ for 1% chloroform solutions of amine salts and 0.1% chloroform solution of the parent amines. In both series, spectra were obtained in 1-cm. matching pair near-infrared cells with chloroform in the reference cell. The 90 to 100% range of the DK-2A instrument was used.

(*d*) Quantitative measurements were made with the Zeiss spectrophotometer on 200 to 500 mg./10-ml. solutions of amine salts in chloroform. The major peaks of the recorded spectra were reconfirmed in the 2.33 to 2.10 μ range and the absorbance of these peaks determined. The validity of Beer's law was examined by determining the absorbances for 1 in 2, 1 in 5, and 1 in 10 dilutions of these initial solutions. Micro quantitative measurements were also made in a similar manner but with the use of the Zeiss microcell equipment (507425) with 1-cm. cylindrical MR 5 microcells of 0.2-ml. volume.

Received April 28, 1966, from the College of Pharmacy, University of Michigan, Ann Arbor.

Accepted for publication July 7, 1966.

Presented to the Drug Standards, Analysis and Control Section, A.PH.A. Academy of Pharmaceutical Sciences, Dallas meeting, April 1966.

This investigation was supported in part by research grant GM 11626-01 and fellowship award 1-F1-GM-32017-01 from the National Institute of General Medical Sciences, U. S. Public Health Service, Bethesda, Md.

[a] Solubility too limited to obtain spectra in chloroform in the 2.32 to 1.70-μ regions. [b] Partially resolved peak as a shoulder on a more intense peak. [c] Spectra influenced by the hygroscopic character of the salt. [d] There were no significant differences between the hydrochloride and hydrobromide salts.

RESULTS AND DISCUSSION

As is true in the infrared, carbon tetrachloride and carbon disulfide are also generally the most useful solvents in the near-infrared. However, neither solvent was of value in the present investigation either because of the interaction of the parent amines with these solvents (6, 7) or because of the lack of solubility of amine salts in the solvents.

Within their well-recognized limitations (3) solid state spectra appeared to be a promising approach to the authors' primary objective of the direct measurement of amine salts. Disks were prepared in the ratio of from 5 to 20 mg. of amine salt to 200 to 400 mg. of KCl. However, dispersion was great at either the high concentration or thick disks required for usable absorption. It was noted, however, that model amine salts could be pressed directly into satisfactory disks without addition of the halide salts. The spectra so obtained are summarized in Table I and a set of typical examples are shown in Fig. 1. It was also possible to form transparent disks directly with some sympathomimetic amine salts as summarized in Table II. In general, disks were formed under 10 tons force, although a few amine salts produced disks at even lower force. However, for the majority of compounds, it is reasonable to assume that a 20-ton system with a properly designed die for the efficient application of vacuum (8) would result in disks with less dispersion. In the present study, dispersion was partly compensated by the use of a KBr disk with high dispersion or by manual attenuation of the reference shutter. In either case, a slit width no greater than 0.3 mm. at 2.65 μ with a sensitivity of 50 was used. Under these parameters, there was no distortion of a test spectrum of didymium. Disks where held in the spectrophotometer in a pellet holder similar to the Beckman holder but with a threaded connection at the sample position to permit access to variable thickness disks. The crystalline form of the amine salt is important for disk formation. For example, 2-phenylethylamine hydrochloride in the form of platelets could not be compressed but in a microcrystalline form was compressible.

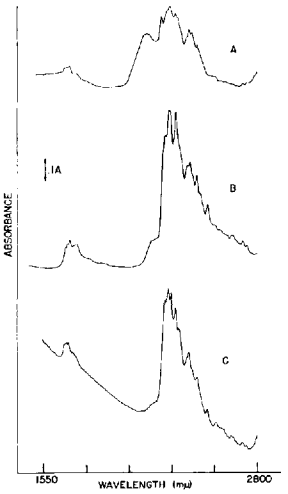

Fig. 1.—Solid state spectra. Key: A, butylamine hydrochloride; B, dibutylamine hydrochloride; C, tributylamine hydrochloride.

As can be noted in Fig. 1, the solid state spectra revealed a series of moderately strong absorbance peaks in the region from 2.55 to 2.15 μ which hold promise for quantitative measurements. Of the solvents and combination of solvents tested showing at least partial transparency (1) in the region of

interest, chloroform was found to be the most useful. That is, the hydrochloride salts of amines divorced of other polar groups exhibit sufficient solubility to permit the quantitative measurement of these salts in the chloroform transparent portion (2.32 to 2.10) of the region of interest. Indication is given in Tables I and II of the compounds which could be measured in this manner.

Quantitative dilutions of the initial 1 to 3.5% chloroform solutions used to obtain these recorded spectra indicated conformity to Beer's law. Typical compounds were further examined in this regard on a Zeiss single beam instrument and conformity to Beer's law was established. The compounds tested, together with molar absorptivity of major peaks in the 2.32 to 2.10 μ region, are listed in Table III. Thus, 1% concentrations yield absorbance values in the order of 0.1 to 0.3. The use of microcells permits from 0.4 to 0.6 mmole of compound to be measured. For example, 2 mg. of adamantanamine hydrochloride can be determined in a 1-cm. microcell if total volume of solution is limited to the 0.2-ml. volume of the cell.

Spectra of solid state amine salts, especially in the 2.70 to 2.10 μ region, are complex enough and sensitive to small changes in structure to be useful for the "fingerprint" comparison and identification of these compounds. A comparison of the spectra of closely related compounds such as *n*-propylamine hydrochloride to that of isopropylamine hydrochloride (Table I) illustrates this point. The effectiveness of a comparison of this type is also illustrated with the butylamine salt series in Fig. 1. These spectra are a useful adjunct to infrared spectra in this regard.

Although the 2.70 to 2.20 μ region was the most complex and contained the most intensive absorbance bands, it was not readily possible to assign bands due to amine salts. The suspected presence of bands in this region based upon protonated nitrogen is supported by the solid state spectra of ammonium chloride (Table I). However, overtone and combination bands due to CH stretching are also exhibited in this region (1) and tend to obscure the amine salt bands.

Just below 2.20 μ and extending to 2.12 μ, there was observed for every primary amine salt studied, a broad band of medium intensity. A band in this region does not correspond to a calculated overtone for primary amine salt absorption in the infrared (2, 3). However, this band was consistently present in primary amine salts and except for the *N*-methylamines and cyclic amines studied was absent in the secondary and tertiary amine salts. The butylamine salts in Fig. 1 are a typical illustration of this difference in the 2.20 to 2.12 μ region.

The primary amine band consistently exhibits a shift of from 10 to 50 mμ to higher wavelengths when a spectrum in chloroform is compared to the corresponding spectrum of the solid state. The band at 2.25 to 2.27 μ is not shifted in this manner while the band at 2.32–2.27 μ is usually constant but with some compounds exhibits a 15 to 20 mμ hypsochromic shift in chloroform.

To study the weak bands below 2.12 μ, per cent transmission spectra of chloroform solutions recorded on the 90 to 100% expansion scale of the DK 2-A instrument were found to be the most helpful. Chloroform in a 1-cm. cell is transparent below 2.32 μ with the exception of two brief ranges (1.86 to 1.85 μ and 1.70 to 1.67 μ) and, therefore, offered a satisfactory medium for the comparison of amine salts and their parent amines. Concentrations were chosen such that the spectral region from 2.15 to 1.70 μ could be expanded full scale on the 90 to 100% range. For the amine salts, 1% solutions were satisfactory while the parent primary amines were run as 0.05% solutions and the remaining free bases as 0.1% solutions. The results are summarized in Table IV and typical examples are shown in Fig. 2.

All spectra of both amine salts and their parent amines have a band between 1.90 and 1.87 μ. This band exhibits a bathochromic shift of 3 to 10 mμ in the salts as compared to their parent amine and is the major similarity between a given amine salt and its parent amine in this region.

There is no other significant absorption from 2.15 to 1.70 μ for primary amine salts which is in direct contrast to the very strong combination band noted in the present investigation and previously reported for the free base primary amines (1). The absence of bands by this technique in this region for primary amine salts and the presence of a band at 2.05 μ for both secondary and tertiary amine salts offer a second method of distinguishing primary amine salts. Again, the 2.05 μ band does not correspond to an overtone for reported (2, 3) NH stretching bands in the infrared.

SUMMARY

The spectra of both model amine hydrochlorides and pharmaceutical amine salts have been observed in the near-infrared. Solid state spectra and solutions of hydrochlorides in chloroform have been shown to be useful sampling techniques and have

applications for qualitative work. Bands in the 2.15 to 2.32 μ region have been shown to be useful for the quantitative measurement of amine hydrochloride salts. Primary amine salts were distinguished from secondary and tertiary amine salts on the basis of the presence of a 2.18 μ band and the absence of a band at 2.05 μ.

Applications of the Montmorillonites in Tablet Making

By KEE-NENG WAI, H. GEORGE DEKAY, and GILBERT S. BANKER

The montmorillonites were studied for their use as disintegrants, binders, and lubricants for the manufacture of compressed tablets. It was found that the clays, although traditionally believed to be inert materials, agglomerated with several macromolecules commonly used as tablet binders. When added dry to prepared granulations, magnesium aluminum silicate F was an excellent disintegrant which produced tablets disintegrating twice as fast as those containing an equal amount of cornstarch. Furthermore, the clays contained a lower moisture content and were more compressible than starch. However, the other grades of montmorillonite studied were less effective as disintegrating agents than starch, and wet granulation of the clays with the diluents substantially decreased the effectiveness of these materials as disintegrants.

MONTMORILLONITE is the name given to a clay mineral first found near Montmorillon, France. Essentially, it has the composition $Al_2O_3 \cdot 4SiO_4 \cdot H_2O \cdot xH_2O$. Many minerals of similar properties, but distinctly different chemical compositions, have since been found (1). The clay minerals frequently exhibit properties which are highly desirable for any products used as disintegrants, binders, and fillers, or viscosity imparting agents. They have a high swelling volume in water, form gels at low concentrations, are chemically inert and stable to a wide range of temperatures, and are smooth, white to off-white fine powders. This study was undertaken to investigate the extent of application and limitations of the montmorillonite type of clays in tablet making, based on and in view of selected physical properties of the clays which were previously determined (2).

Bentonite and magnesium aluminum silicate[1] have been studied by several workers as tablet disintegrating agents. Granberg and Benton (3) reported that bentonite was an effective filler and disintegrating agent in thyroid tablets. Gross and Becker (4), on the other hand, found that neither bentonite nor magnesium aluminum silicate, in concentrations up to 17%, produced any disintegrating effect in tablets. However, Firouzabadian and Huyck (5) and Ward and Trachtenberg (6), who conducted comparative studies on the effectiveness of tablet disintegrants, found that magnesium aluminum silicates were among the best disintegrants studied. Nair and Bhatia (7) in another comparative study reported that sulfathiazole tablets containing magnesium aluminum silicate as the disintegrant appeared to have the most rapid distintegration time when most of the clay product was added after granulation and only a small portion before granulation. A suspension of 20% montmorillonite clay has been used as a granulating agent with reported disintegration activity (8).

EXPERIMENTAL AND RESULTS

The three commercial montmorillonites studied in this work will be referred to as clay I, II ,and III,[2] respectively. The composition and properties of these

clays were reported in an earlier paper (2). The clays were oven dried at 50° for 24 hr. prior to use to remove nonbound moisture which may have been sorbed on storage.

Compatibility of Montmorillonite with Various Tablet Adjuncts.—The montmorillonites are frequently used in tablet matrices in combination with other tablet adjuncts with which the montmorillonites might be reactive. Such reactivity could affect tablet disintegration, drug availability, or manufacturing methods.

Two liters of a 5% dispersion of clay III were prepared in hot water. This preparation was permitted to hydrate for 24 hr. and was then divided into 100-ml. portions. To each portion, 100 ml. of another common or previously reported tablet binder was added. The change in pH and appearance of the mixed binders were observed and are summarized in Table I.

In spite of their relative chemical inertness, the montmorillonite clays were incompatible with certain common tablet adjuvants. The montmorillonites apparently interact with many macromolecules. The clays consistently increased the pH of the combined systems from 2 to 4 units. Hydrogen bonding between the clay and the polymer molecules and electrical discharge between two oppositely charged particles (or molecules) may explain the agglomeration phenomenon which frequently occurred between clay and polymer.

Disintegrating Action of Unwetted Montmorillonites.—Sixty-four batches of tablets were prepared, containing various concentrations of the three grades of clay, or starch, blended with a granulation of calcium sulfate. The relationships between the disintegration time and the concentrations of disintegrants, disintegration time and granule size, and between tablet hardness and disintegrant concentration were studied. The calcium sulfate granulation was prepared according to the following formula:

Calcium sulfate	10 Kg.
Ethylcellulose 47 cps. (5% solution in ethanol)	4 L.

The calcium sulfate was granulated in a dough mixer[3] and then passed through an oscillating granulator[3] fitted with a No. 12 screen. The granulation was air-dried. Through a series of hand sizing and screening processes, it was separated into granulations of the following size ranges:

Mesh Size	Quantity, Kg.
12–16	1
16–20	1
20–30	5
30–40	1
40–80	1

Ethyl cellulose was used in granulating the calcium sulfate to produce a granulation which did not readily disintegrate in water or simulated gastric juice. This granulation formula was used because the experiment was designed to study the efficiency of the clays as disintegrants when they were blended with prepared, insoluble, nondisintegrating granulations. Using this granulation, 100-Gm. samples of material were prepared by adding 0.5 Gm. of magnesium stearate and various concentrations (0, 0.5, 1, 2, 4, 8, 15, or 25%) of a disintegrating agent (clays I, II, III, and starch) to the granulation. These granulations were compressed into $^{5}/_{16}$-in. standard cup, 200-mg. tablets with a Colton 120 single punch machine.[4] Tablets of a hardness of about 4.5 to 5.5 Kg. were prepared when possible. Hardness was measured with a Dillon prototype tablet hardness tester[5] and is expressed as the average of 20 measurements. The average disintegration time of six tablets was determined in gastric juice U.S.P. by the official method. The results are summarized in Table II.

Figure 1 represents the relationship found between the disintegration time and the concentration of the four disintegrating agents. The straight lines were drawn with the assumption that the relationship holds when the concentration of the disintegrating agent is between 1 and 20%. The figure also illustrates that tablets containing clay II disintegrate about twice as fast as tablets containing cornstarch as a disintegrating agent in the same percentage. Starch, in turn, is a better disintegrating agent than clay III or clay I. The addition of 2% of clay II reduced the disintegration time of the tablets to below 5 min. The presence of 5% of clay II with

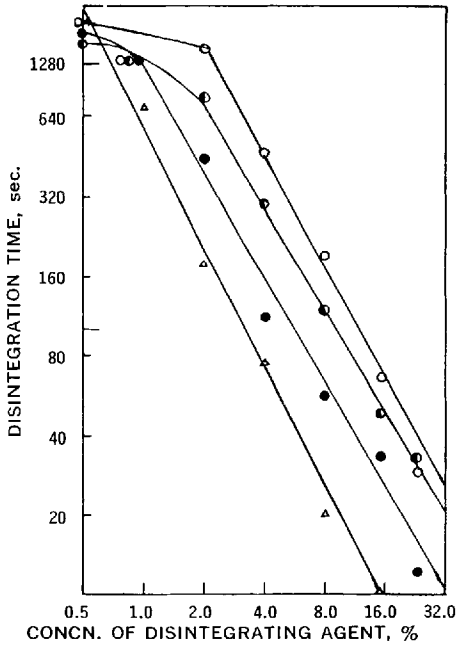

Fig. 1.—Disintegration time of $CaSO_4$–ethylcellulose tablets containing clays I, II, and III and starch as disintegrating agents (prepared from 20/30 mesh granulations). Key: ○, clay I; △, clay II; ◐, clay III; ●, starch.

the granulation reduced the disintegration time to below 1 min.

When the concentration of starch added dry with the lubricant was 8% or higher (Table II) it became very difficult to produce a tablet with a hardness above 5 Kg. Granulations containing more than 15% starch in powder form were practically incompressible, while fairly hard tablets could be produced with the concentration of clay II as high as 25%. Using clay III, in the coarser three granule sizes (Table II) a degree of tablet hardness appeared to be lost at clay concentrations of 8 to 15% or higher.

The particle-size distribution of the clay may be a factor which influences the disintegration rates of the tablets. Clay II had the smallest average particle size (completely passed a number 200 sieve) of the clays studied, and was the best disintegrant; clay I had the coarsest particles (average diameter equal to 373 μ by sieve analysis) and was the poorest disintegrant among the three clays studied (2). The ion-exchange capacity of the clays (0.601, 0.585, and 0.523 mmoles/Gm. for clays I, II, and III, respectively) and the swelling volume of the clays (21.3, 20.0, and 10.8 ml. in gastric juice) (2) showed no apparent relationship to the disintegration action of the clays.

The Disintegrating Action of Montmorillonites When Incorporated Within the Granulation.—The compatibility study (Table I) showed that the clays in this study agglomerated with many other commonly used tablet binders. It was hypothesized that this agglomeration might influence both the binding action of the binder and the disintegrating

action of the clays. Lactose and calcium sulfate were separately used as tablet fillers in this study to represent a soluble and an insoluble tablet matrix. The granulations were prepared as follows.

(*a*) A 10% suspension of clay I was prepared and was used alone, or was mixed with the other granulating agents and the mixture used to granulate the filler. The final granulations contained 1% clay by weight. If the mass was not adequately wet after adding sufficient clay suspension to provide 1% clay in the dry granulation, water was used to complete the massing operation.

(*b*) The fillers alone and with 1% clay added dry were granulated with the various syrup and gum granulating agents. These were the control samples against which the other clay-containing (clay added as granulating agent) tablets were compared. Each of the two diluents, with and without the addition of 1% clay, was also granulated with water alone.

Each batch of granulation contained 200 Gm. of lactose or 300 Gm. of calcium sulfate. The granulation masses were passed through a 12-mesh screen by hand, dried at room temperature for 48 hr., and resized through a 16-mesh screen. Magnesium stearate was added as the lubricant (0.5% for the calcium sulfate granulations and 0.25% for the lactose granulations). The tablets were compressed to a weight of 200 mg. using $^{5}/_{16}$-in. standard concave punches. A compression force was used which would yield tablets having a hardness of 2 to 3.5 Kg. for the calcium sulfate tablets and about 5 to 6 Kg. for the lactose tablets. The formula, granule hardness, disintegration time, hardness, and appearance of each batch of tablets were recorded (Table III). The dried granulations varied in per cent moisture content between 0.2 and 1.8%; most were between 0.4 and 1.2%.

According to Table III the following observations may be made.

(*a*) When the montmorillonite clays alone were used as the granulating agent-binder for calcium sulfate, soft granulations were obtained (formulas

[a] Soft granules immediately powdered on handling. Medium granules partially powdered on handling. Hard granules could be handled without appreciable powdering. [b] One per cent of clay I was added dry to $CaSO_4$ or lactose before massing. [c] All clay granulating agents were used as 10% w/v suspensions. [d] Used 10% suspension of clay I as the only granulating agent without supplemental water. [e] Simple syrup U.S.P. [f] Ten per cent starch paste. [g] Ten per cent mucilage of acacia. [h] Ten per cent methylcellulose 4000 solution. [i] Two per cent mucilage of sodium alginate.

2–5, Table III). Capping of these tablets was observed during manufacture and on handling and hard tablets could not be prepared.

(*b*) Simple syrup, starch paste, and acacia were excellent granulating agents, producing hard calcium sulfate granulations. Starch, acacia, or methylcellulose, in equal volume combination with the clay suspension generally did not affect calcium sulfate granule hardness or tablet quality, but the combination granulating materials, although incompatible (Table I), did reduce disintegration time. Sodium alginate[6] reacted with the calcium ions of the calcium sulfate and could not be used successfully as a binder for this compound. All five tablet granulating agents tested appeared to be suitable for granulating lactose.

(*c*) The disintegration times of the tablets produced from formulas 1 to 6 in Table III shows that an addition of 1% of montmorillonite clays *via* the granulating agent, to calcium sulfate reduced the disintegration time of the calcium sulfate tablets from 278 sec. (formula 1) to less than 100 sec. (formulas 2–6).

(*d*) The clays in suspension form as a granulating agent permitted satisfactory granulations and tablets to be prepared of the soluble lactose formula; but so did water (formulas 7–11). One per cent of clay, added as granulating agent, greatly increased the disintegration time of the soluble lactose tablets (formula 7 *versus* 8–11). The clay decreased the time of disintegration of the lactose tablets containing methylcellulose as the binder (formulas 33–35). The slowly hydrating methylcellulose apparently prevents the water from penetrating to the core of the soluble tablets (No. 33 and 35). The methylcellulose was dehydrated and agglomerated in the presence of the clay (No. 34), which resulted in more rapid disintegration while not adversely affecting granule hardness or tablet quality. It is interesting to note that in the insoluble calcium sulfate tablets the combination of methylcellulose and clay, even though incompatible (Table I), also produced tablets superior to those obtained when methylcellulose was used singly.

(*e*) It is obvious from Tables I and III that the combination of compatible granulating agent plus clay suspension as binder (syrup plus clay or starch paste plus clay) offered no apparent advantage. In the syrup–clay systems the combination produced the longest disintegration time with both diluents (formulas 12 and 15), while the clay–starch combination tablets (No. 19 and 22) were either not substantially better or were poorer than tablets prepared from starch paste alone. Acacia and methylcellulose agglomerated with the clay, and the disintegrating action of the combination systems were usually superior to the gum or polymer alone, while the combination systems retained adequate binding properties (formulas 24–29 and 30–35).

The clays were also studied for their use as tablet disintegrating agents when added to the granulation internally with the diluent in concentrations ranging from zero to 25%. Four granulating agents (20% glucose, 5% acacia, half strength simple syrup, 10% clay I suspension) and water and the four disintegrating agents (the three clays plus starch) were studied. Three hundred grams of calcium sulfate and disintegrating agent were mixed and moistened with 80 ml. of one of the selected granulating agents, the mass passed through a 20-mesh screen, oven dried at 100°F. for 24 hr., sized to 20 mesh, and lubricated with 1% magnesium stearate. Tablets were compressed to 200 mg. at a hardness of from 3.5 to 5.0 Kg.

Increasing the montmorillonite clay concentrations from 1–16% with each granulating agent failed to produce an equivalent consistent decrease in disintegration times, which varied inconsistently from about 10 to 30 min. *versus* 5 to 12 min. for starch. This showed that wetting the clay type disintegrating agents during the granulation process reduces the activity of the disintegrating agents. Compared to starch the clays were all relatively poor disintegrating agents when wet granulated together with the filler.

The loss of disintegration activity of the montmorillonite clays after wet granulation may be explained in two ways. First, the clays and the binder may form an adhesive gel on disintegration and thus resist falling through the screen of the disintegration tester. Although the tablets disintegrated, they remained partially suspended inside the basket and, according to U.S.P. specification, disintegration was incomplete. Second, certain granulating agents may form a film surrounding clay particles and reduce the rehydration rate of the clay.

CONCLUSIONS

Montmorillonite suspensions alone were poor granulating agents producing inadequate granule binding.

Although montmorillonite clays are relatively inert chemically, they interact with many organic macromolecules. This interaction reduces but does not destroy the binding properties of certain tablet binders while the interacted systems may produce superior tablets with more rapid disintegration than either binder alone.

The clays are not good disintegrating agents when they are added as a dry powder to the filler and are wet granulated. They are good disintegrating agents and may be superior to starch when added dry to completed granulations, in which case the disintegration time and the concentration of clay added demonstrate an inverse second-order relationship.

Mathematical Model of Sustained-Release Preparations and Its Analysis

By EKKEHARD KRUGER-THIEMER* and STUART P. ERIKSEN†

A pharmacokinetic model, involving first-order processes for drug release, absorption, and elimination, may be used for the description of the behavior of sustained-release preparations consisting of slowly and immediately available fractions. The shift of the rate-determining step, as the relative rates of absorption and release are changed, can be shown both mathematically and by analog computer simulation. These theoretical results are used for interpretation of experimental data with a new sulfa drug of low solubility, 2-sulfanilamido-5-methyl-pyrimidine, compressed tablets of which behave as a sustained-release preparation.

THE WIDESPREAD use of sustained-release and depot preparations in drug therapy has made the full understanding of their actions and properties of considerable importance. A number of publications concerned with the actions, the properties, and the importance of such a full understanding have appeared in the last decade [*viz.*, Dost (2), Lazarus and Cooper (3), Levy *et al.* (4–6), Nelson *et al.* (7–9), Parrott (10), Robinson and Swintosky (11), Sjogren and Ostholm (12), Wagner *et al.* (13), Wiegand and Taylor (14), and others].

The most useful method for the examination of the interrelationships between drug preparations and the human body has been found to be through the use of a mathematical model, first fitting it to the actual data, and then examining the model found most useful for its functional behavior. In this way the important implications of the model may be discovered and those found important checked by further laboratory experiments. Because of the complexity of the differential equations involved, direct mathematical study is not always the most useful manner of determining the implications of a mathematical model for absorption, distribution, and excretion, and it has often been found more convenient to make use of an electronic analog computor [see Fish (16), Pace (17), and Garrett *et al.* (18)].

A recent paper by Taylor and Wiegand (15) was concerned with the analog investigation of the following model, which has been found to describe suitably the behavior of sustained-release preparations from which a certain fraction, f_r, of the administered dose becomes available through a first-order process while the remaining fraction, $1-f_r$, is available immediately:

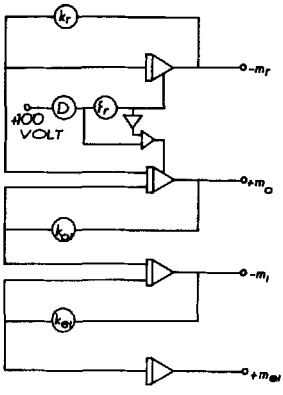

Fig. 1.—Unscaled analog computer program for the system of differential Eqs. for the model used and for initial conditions set forth in Eqs. 1, 2, and 3.

m_r the amount of undissolved drug in the gastrointestinal tract

k_r *the rate constant for the dissolution step*

m_0 the amount of dissolved drug in the gastrointestinal tract

k_{01} *the rate constant for absorption*

m_1 the amount of drug in the body (not including that in the gastrointestinal tract and the urine)

k_{e1} = *the rate constant for elimination* (the sum of the constants for renal excretion and metabolism)

$m_{e1} = m_2 + m_1{}^m$ the amount of the eliminated drug (including metabolized drug)[1]

This model involves three consecutive, irreversible first-order processes with the following initial conditions in the four compartments:

$$m_r{}^0 = Df_r,\ m_0{}^0 = D(1 - f_r),\ m_1{}^0 = 0,\ m_{e1}{}^0 = 0 \qquad \text{(Eqs. 1, 2, 3)}$$

[1] In this paper the symbols as proposed by Nelson and Kruger-Thiemer (9) are used as far as possible. The use of amounts, m, rather than concentrations, c, throughout this paper should not be construed as reflecting an "amount" driven kinetic situation, but only as a system simplification for these theoretical discussions that does not change the relative results.

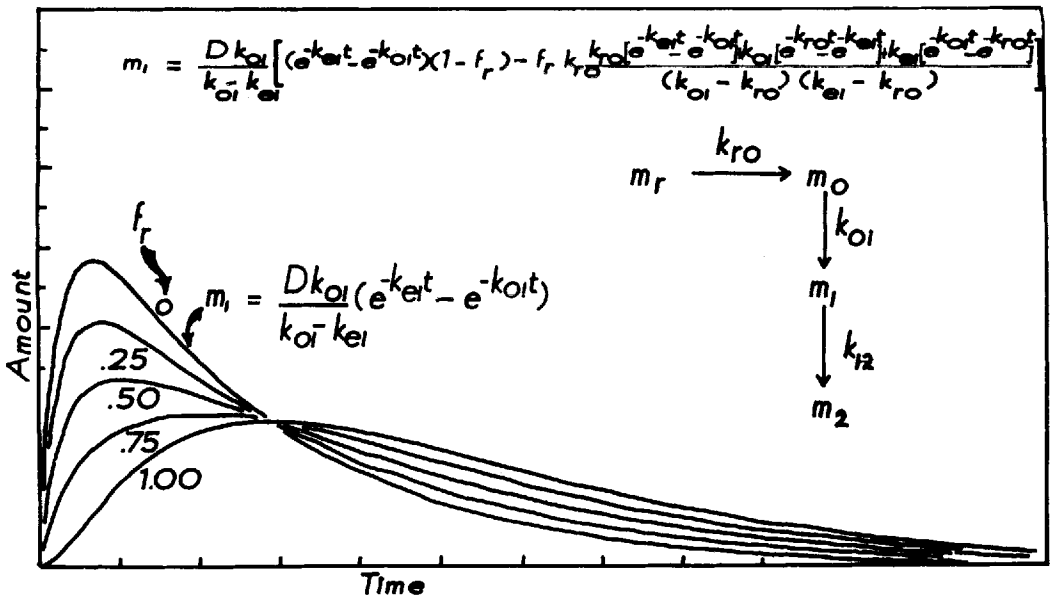

Fig. 2.—Family of computer drawn curves of m (blood amount) showing the effect of regular changes in the fraction of the total dose in sustained form (f_r).

The present paper is concerned with a more complete re-examination of this model.[2]

ADDITIVE BEHAVIOR OF TWO COMPONENTS OF SUSTAINED-RELEASE PREPARATION

Changing the sustained-release fraction, f_r, of the administered dose, D, from 0 to 1, in a stepwise fashion, a family of curves of the type shown in Fig. 2 is obtained. The most interesting feature of this figure is that this family of curves has a point of intersection that might be called the common point, which lies in the maximum point of the lowest curve corresponding to $f_r = 1$. The relationships suggested by this figure may be shown mathematically also.

Substituting $f_r = 0$ into Eq. 2 yields the well-known equation for a model consisting of two consecutive, irreversible first-order reactions, presented previously by Widmark and Tandberg (20), Teorell (19), Dost (2), and Taylor (14):

$$m_1 = \frac{D \cdot k_{01}}{k_{01} - k_{el}} \cdot (e^{-k_{el}t} - e^{-k_{01}t}) \quad \text{(Eq. 4)}$$

The substitution of $f_r = 1$ into Eq. 2 results in Eq. 5 for the model in which the total drug administered is going slowly into solution *via* a first-order process.

$$m_1 = D \cdot k_{01} \cdot k_r \times \frac{(k_{01} - k_{el})\, e^{-k_r t} + (k_{el} - k_r)\, e^{-k_{01}t} + (k_r - k_{01})\, e^{-k_{el}t}}{(k_r - k_{01}) \cdot (k_r - k_{el}) \cdot (k_{01} - k_{el})} \quad \text{(Eq. 5)}$$

[2] The computer curves shown in this work were obtained with the more standard analog programming methods (using the differential forms) rather than the less accurate and more tedious "calculation" method of Taylor and Wiegand (1). The more standard program used by the present authors is shown in Fig. 1 (derived for the Applied Dynamics PB-24 computer, Ann Arbor, Mich.).

The existence of the common point for all curves with the same k_r, k_{01}, k_{el} may be shown by calculating the point(s) of intersection of the two curves for $f_r = 0$ and $f_r = 1$. One equates m_1 from Eqs. 4 and 5 so that the following condition results for the time value, t_i, of the point of intersection:

$$k_r \cdot (k_{01} - k_{el}) \cdot e^{-k_r t_i} + k_{01} \cdot (k_{el} - k_r) \cdot e^{-k_{01} t_i} + k_{el} \cdot (k_r - k_{01}) \cdot e^{-k_{el} t_i} = 0 \quad \text{(Eq. 6)}$$

While Eq. 6 cannot be solved explicitly for t_i, one can see that it contains three solutions for t_i, two trivial ones, $t_i = 0$, $t_i = \infty$, and the intermediate solution in which we are interested. From this equation the time value, t_i, of the point of intersection for actual value of the parameters, k_r, k_{01} and k_{el}, may be calculated using the customary methods for numerical solution of transcendental equations. One obtains the same equation, Eq. 6, for the point of intersection of the curve for $f_r = 0$ (Eq. 4) and *any* other of the curves shown (*e.g.*, any arbitrary value of f_r between 0 and 1). During this calculation f_r cancels out, the mathematical indication of the independency of the point of intersection on the value of f_r; the entire family of curves intersects at a common point.

Proof that the common point is situated in the maximum of the curve for $f_r = 1$ can be verified by setting the first derivative of Eq. 5 with respect to the time equal to zero. This results in exactly the same equation, Eq. 6, as previously obtained, indicating that the time corresponding to this maximum, $t_{max.}$, and the time of the point of intersection of the family of curves, t_i, are identical.

This apparent additivity suggests a rearrangement of the equation obtained by Taylor and Wiegand (1) (our Eq. 2) into an equation representing the sum of Eqs. 4 and 5 and yields Eq. 7:

$$m_1 = \frac{D \cdot (1 - f_r) \cdot k_{01}}{k_{01} - k_{el}} \cdot (e^{-k_{el}t} - e^{-k_{01}t}) + \frac{D \cdot f_r \cdot k_{01} \cdot k_r \cdot (k_{01} - k_{el}) \cdot e^{-k_r t} + (k_{el} - k_r) \cdot e^{-k_{01}t} + (k_r - k_{01}) \cdot e^{-k_{el}t}}{(k_r - k_{01}) \cdot (k_r - k_{el}) \cdot (k_{01} - k_{el})} \quad \text{(Eq. 7)}$$

from which Eqs. 4 and 5 may still be obtained by setting $f_r = 0$ and 1 alternately.

Using the symbols F_4 and F_5 for the right-hand sides of Eqs. 4 and 5, respectively, the structure of Eq. 7 becomes apparent

$$m_1 = F_4 \cdot (1 - f_r) + F_5 \cdot f_r \quad \text{(Eq. 8)}$$

Thus, the amount in the body, m_1, (not including that in gastrointestinal tract and in urine) for any time and for any value of f_r between 0 and 1 is equal to a linear combination of the drug amounts for $f_r = 0$ and $f_r = 1$, the coefficients of which are equal to the two fractions of the dose for instantaneous $(1-f_r)$ and sustained (f_r) release. In terms of the experimental conditions this implies that both parts of the dosage form, that for instantaneous and that for sustained release, behave independently within the body, so that *the final curve of the drug amount within the body is merely the sum of the two curves that would result from separate administration of the two components of the sustained-release dosage form* (*e.g.*, this conclusion might be checked experimentally using a sustained-release preparation one of the two parts of which, either instantaneous or sustained release, is radioactively labeled). The result of this study clearly demonstrates that the functional behavior of the curves described by Eqs. 2 or 7 may be examined best by separate examination of Eqs. 4 and 5.

ASYMPTOTICAL SIMILARITY BETWEEN SLOW SUSTAINED-RELEASE AND SLOW ABSORPTION MODELS

Figure 3 shows two families of curves in which the first (Fig. 3, A) corresponds to the simplified model for $f_r = 0$, *i.e.*, Eq. 4, using values of k_{01} from 1.0 to 0.0078 hr.$^{-1}$, and the second (Fig. 3, B) corresponds to the simplified model for $f_r = 1$, *i.e.*, Eq. 5, using a constant value of $k_{01} = 1.0$ hr.$^{-1}$ and varying values of k_r from infinity to 0.0078 hr.$^{-1}$. In both cases the values of k_{el} have been set equal to 0.1 hr.$^{-1}$.

The curves with the highest maximum in Fig. 3, A and B, are identical, for $k_r = \infty$ means instantaneous release, *i.e.*, in this case Eq. 5 reduces to Eq. 4 by rearrangement of Eq. 5 before the substitution of $k_r = \infty$, or by use of L'Hospital's rule for indeterminate forms of the type ∞ / ∞.

Obviously, the lowest members of the two families of curves (Fig. 3), having identical values for k_{01} and k_r, respectively, are more similar to each other than the intermediate and the higher ones. These curves have suggested an asymptotical similarity of these two different models. The mathematical demonstration of this similarity may be found by substituting very high values of k_{01} (rising to infinity) into Eq. 5. As Eq. 5 has a symmetrical structure with respect to k_{01} and k_r, the mode of calculation is quite the same as above for $k_r = \infty$, so one finally obtains Eq. 9:

$$m_1 = \frac{D \cdot k_r}{k_r - k_{el}} \cdot (e^{-k_{el}t} - e^{-k_r t}) \quad \text{(Eq. 9)}$$

which has obviously the same structure as Eq. 4. The result is not surprising, indicating only the shift in the rate-determining step; it has already been predicted (7). The similarity of Eqs. 4 and 9 is the reason for the asympotic similarity of the lower curves in Fig. 3, A and B, because before going to $k_{01} = \infty$ all the terms in Eq. 5 that are lacking in Eq. 9 have coefficients of the type k_r/k_{01} or k_{el}/k_{01}. The smaller these two ratios, the more similar the curves in Fig. 3, B, will be to the curves in Fig. 3, A.

There is no *real* equality in Fig. 3, but only a similarity between the lower curves. The two before mentioned ratios k_r/k_{01} or k_{el}/k_{01} may become negligible either by decreasing k_r and k_{el} or by increasing k_{01}. As long as k_{01} has a finite value, the initial slopes for the curves in Fig. 3, B, will be zero, while the curves in Fig. 3, A, have initial slopes higher than zero, a fact that may be verified by differentiation of Eqs. 5 and 4 with respect to the time followed by substitution of $t = 0$.

The difference in the initial slopes of the lower curves in the Fig. 3, A and B, are easily visible from these fully drawn theoretical curves. However, it would be nearly impossible to recognize these differences in initial slope from actual experimental data, considering the usual experimental errors.

ESTIMATION OF RATE CONSTANTS OF SUSTAINED-RELEASE OR SLOW ABSORPTION PREPARATIONS

Figure 3 shows another feature of practical importance. In cases of slow absorption and/or slow sustained release a significant absorption may last much longer than anticipated so that the slope of the descending part of the concentration curve in the blood plasma (after the curve maximum) may not reflect the elimination process alone. As pointed out recently by Wagner (21), a graphical estimation or calculation of the rate constant for elimination, k_{el}, from the apparent slope of the descending part of the curve in a semilogarithmical plot may result in too low a value. Since the customary methods for the calculation of the rate constant for absorption [Dost (2), Kruger-Thiemer (22, 23), Nelson (24), Wagner (25), Schlender and Kruger-Thiemer (27)], are based on the knowledge of the rate constant for elimination, the calculated value of k_{01} will be incorrect in such cases, too. This difficulty cannot be overcome by the method of Dost and Medgyesi (26) or even by methods using digital computation (27) unless the error of the points of measurement is much lower than usual. In such cases it seems to be necessary to estimate the rate constant for elimination (and the corresponding biological half-life, $t_{50\%} = \ln 2/k_{el}$) from independent experiments with *intravenous* administration of the same drug, to the same test subject.

Tables I and II and Fig. 4 demonstrate an actual example of that kind. These experiments, the details of which will be published elsewhere (28), were performed with 2-sulfanilamido-5-methylpyrimidine, a sulfa drug on the German market

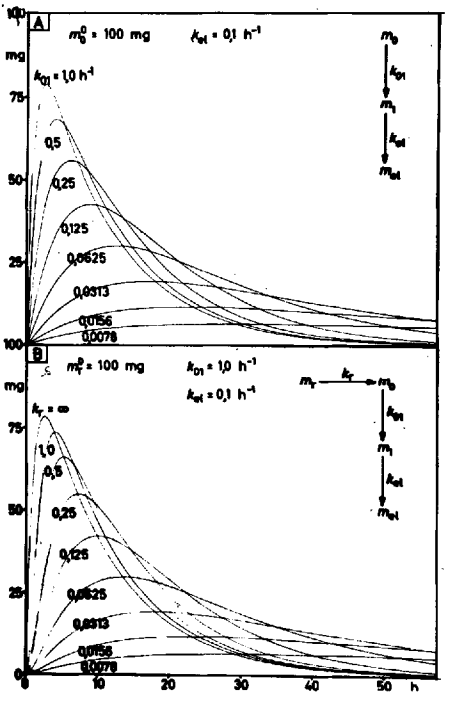

Fig. 3.—Families of computer drawn curves of m (blood amount) for the model used. Key: A, the simplified form of Eq. 4, varying k_{01}; B, the simplified form of Eq. 5, varying k_r.

TABLE I.—BLOOD PLASMA CONCENTRATION OF 2-SULFANILAMIDO-5-METHYL-PYRIMIDINE AFTER ORAL OR INTRAVENOUS ADMINISTRATION OF 2000 mg.

Time After Admin. t, (hr.)	Mode of Administration[a] (Test) Oral[b] (1) c_1' (mg./L.)	Oral[c] (2) c_1' (mg./L.)	Intravenous (3) c_1' (mg./L.)
1.0			579.8
1.33		97.9	
2.0	36.1		
4.0	74.5	149.4	473.4
6.0	88.5	144.8	445.0
8.0	100.0	120.7	412.0
24	68.4	89.6	245.4
32	80.1	68.3	153.2
48	49.9	68.8	82.0

[a] Test subject: male, 45 years, 75.0 Kg. [b] Commercial tablets. [c] Freshly precipitated suspension (neutralized solution of the sodium salt).

since 1961.[3] Table I contains the chemically measured [method of Bratton and Marshall (29)] drug concentrations in the blood plasma, c_1', after oral or intravenous administration of 2000 mg. of 2-sulfanilamido-5-methyl-pyrimidine.

The data in Table II show that the biological half-lives after oral administration are significantly higher than the biological half-life after intravenous administration. The 95% confidence limits of the latter value are much narrower than the confidence limits of the foregoing values. The same situation prevails for the apparent plasma distribution coefficient (apparent relative volume of distribution with respect to the plasma concentration). But it is unlikely that the mode of administration would influence the processes of distribution and elimination (metabolism and renal excretion) so greatly. It seems much more appropriate to assume that the apparent biological half-life and the apparent plasma distribution coefficient after oral administration should have approximately the same values as after intravenous administration. Using the assumption that the differences noted are due to a slow absorption or a slow sustained release, a provisional calculation has been made using the method of Dost and Medgyesi (26), in which the value of the rate constant for elimination after intravenous administration, $k_{el} = 0.0170$ hr.$^{-1}$, has been used (therefore, only two points of measurement, related by $t_2 = 2 \cdot t_1$, are necessary instead of three as in the original method). Using the data from $t = 4$ and 8 hr. of test *1* (Table I) produced a rate constant for absorption (or for sustained release) of k_{01} (or k_r) = 0.1775 hr.$^{-1}$ by substitution into the equation

$$e^{-k_{01}t_1} = \frac{c_1'^2}{c_1'^1} - e^{-k_{el}t_1} \qquad \text{(Eq. 10)}$$

which results from $t_2 = 2 \cdot t_1$ and Eq. 4 or Eq. 9 ($c_1'^2$ denotes the plasma concentration value at the time t_2). The corresponding value of the apparent plasma distribution coefficient, Δ', is 0.166 ml./Gm., which lies within the confidence limits of the corresponding value after intravenous administration (Table II) and supports the assumption underlying this calculation that Eqs. 4 or 9 may be used for the description of this part of the experimental curve. Using these three parameters one predicts 29.9 mg./L. as the expected value of c_1' at 48 hr. after the administration. This value is appreciably lower than the measured value of 49.9 mg./L. and might be explained by the following calculation. Repeating the foregoing calculation with the points of measurement at 24 and 48 hr. we get the rate constant for absorption, $k_{01} = 0.0437$ hr.$^{-1}$, and the apparent plasma distribution coefficient, $\Delta' = 0.149$ ml./Gm., the last of which is again rather close to the confidence limits of the corresponding value after intravenous administration. The apparent

The calculation of the data in this table was done using a digital computer program for fitting a curve to Eq. 4 (to be published) at the Calculation Center, University of Kiel (Dr. B. Schlender), Germany, with the electronic digital computer XI (Electrologica, Inc., Amsterdam, The Netherlands). [c] Freshly precipitated suspension (neutralized solution of the sodium salt). [d] By definition the entire dose is injected into the body.

rate constant for absorption (or release) for the time interval from 24 to 48 hr. is less than one-third of the value for the time interval from 4 to 8 hr. This relates well to the fact that the usual time of passage through the small intestine is approximately 8 to 12 hr., and that the rate of absorption in the large intestine is slower than in the small intestine [*cf.*, Eriksen *et al.* (30) and Diller and Bunger (31)]. Therefore, it might be necessary for a proper description of the experimental data to use the idea of a variable rate constant for absorption (or release) changing with time. Pharmacokinetic approaches of this type have been given by Wagner and Nelson (21, 32) and Stelmach *et al.* (33). In experiment *1* (Tables I and II) the rate constant for absorption (or release) in the time interval from 24 to 48 hr. is according to the calculation method of Dost and Medgyesi (26) in the same order of magnitude as the rate constant for elimination, $k_{e1} = 0.0404$ hr.$^{-1}$. From Fig. 3 and the foregoing discussion it is clear that this is one of the reasons for the apparently low slope of the curves after oral administration in Fig. 4, resulting in erroneous values for the biological half-life. The other reason is the higher value of the rate constant for absorption within the first 8 hr. Both reasons together allowed the digital computer to find a curve fitting solution according to Eq. 4, as shown in Fig. 4, which contains the erroneously high value of the biological half-life. A more detailed analysis of our experiments (Table I) is not feasible because of the low number of points of measurement.

Theoretical Formulation of Sustained-Release Dosage Forms

By J. R. ROBINSON and S. P. ERIKSEN*

The present investigation deals with the result of a mathematical and an analog computor analysis of the kinetic relationships governing the rate of release of drugs from sustained-release dosage forms. Two types of release have been considered, those described by zero-order and those that can be described by first-order kinetics. In addition, mathematical equations are derived that permit the calculation of doses and of release constants that will give a blood concentration *versus* time curve most closely approximating an "idealized" curve.

THE APPROACH most often used in the kinetic treatment of biologic data is that involving formulation of a mathematical model, the comparison of this model with *in vivo* findings, and finally the adjustment of the model and its constants to accommodate the *in vivo* results. Once a suitable model has been established, the complete interdependency of the model's parameters can be examined,[1] subject to the suitability of the model chosen. These parameters may be divided into two types, those under the control of the formulator, *i.e.*, the dosage form, release pattern, and rate, etc., and those that are imposed upon the model by the system studied, *i.e.*, the absorption, distribution, and excretion (ADE) pattern for the drug in the body. In the past, the major emphasis has been placed on the ADE parameters with relatively little attention being given to the dosage form release rate and pattern, not only because these studies are more difficult to carry out, but also because initially it was of particular concern to study the suitability of various models as simulations of the body's ADE capabilities. It seemed reasonable at that time to assume that in cases where the drug has been administered by injection or orally in some readily available form, *e.g.*, drug in solution, the effect of the dosage form release pattern might safely be neglected; for nonreadily available forms, particularly sustained-release dosage forms, this assumption cannot be made as the dosage form release pattern and its rate undoubtedly do play *major* roles in the blood concentration *versus* time curve obtained; indeed, it is the exploitation of this effect that makes sustained release possible. In addition to the rate and pattern of release from the dosage form, consideration must also be given to the effect of the relative amounts of the administered initial and maintenance dose on the resultant concentration in the blood. In the face of the recent barrage of studies supporting the suitability of the simpler kinetic models as descriptions of ADE phenomena, attention should now be paid to those aspects of the kinetic path less amenable to analysis, the dosage form release pattern and administered dose fractions. Indeed, a knowledge of the effects of these controllable parameters is essential in order to formulate sustained-release dosage forms having particular blood level characteristics.

Both Wiegand and Taylor (4, 5) and Wagner (6) have shown that the per cent released *versus* time data reported in the literature for many sustained-release preparations follow apparent first-order rate equations. Similarly, others (7, 8) have shown that some sustained-release preparations release drugs by apparent zero-order processes. From an experimental standpoint it would appear that these two mechanisms might adequately describe the rate of release for the majority of existing sustained-release dosage forms, and ADE equations involving both of these release patterns have already been described (5, 6, 9).

In order to obtain a constant blood level for some desired period of time from a sustained-release dosage form, Nelson (10) has stated that a constant (zero-order) rate of release from a dosage form is desired and has developed an approximate equation for calculating the amounts of sustained and initial drug forms required, based upon this assertion.

Utilizing essentially the same model as that of Nelson (10) but assuming first-order release, Wiegand and Taylor (1) have reported computer

[1] Testing of the effect of various parameters in a model can be carried out very effectively on an analog computer, since variables can be changed and the effect read out immediately with a subjective appraisal being made even if complete mathematical solutions are unavailable. Utilization of the analog computer for this purpose is well documented (1–3), therefore, the required computer technology will not be stressed here. The circuits used in this study are given in the *Appendix*.

drawn curves showing the effect of altering the first-order release constant at a constant rate of absorption and elimination. In addition, they have also shown the effect of variation in the elimination constant on the blood concentration curve at a constant first-order rate of release from the dosage form and a constant rate of absorption. Computer drawn curves showing the effect of the fraction of the initial and maintenance dose at a constant rate of absorption, elimination, and first-order rate of release from the dosage form excretion have also been described (2), again using the same model.

In a recent paper supporting Nelson's assertion, Rowland and Beckett (9) have further claimed that first-order release from a dosage form *cannot* give the "idealized" blood concentration-time curve.

Unfortunately, experience suggests that the majority of sustained-release formulation techniques produce formulations that release drug at roughly a first-order rather than zero-order rate. In order to adequately compare these two availability patterns as to their potential to produce suitable sustained-action forms, a complete investigation of the effects of the various parameters in the models is essential. *Part* of such a study has been done for the first-order release case (1), but to the authors' knowledge a study of the effect of design parameters for a formulation having zero-order release characteristics has not been reported.

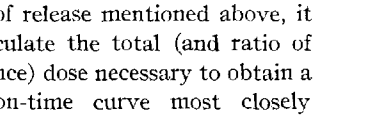
For both types of release mentioned above, it is desirable to calculate the total (and ratio of initial to maintenance) dose necessary to obtain a blood concentration-time curve most closely approximating the "idealized" case. Nelson (10) has given a method for calculating the maintenance dose of a constant rate of release dosage form, based on the biological half-life of the drug and the dose required to give the desired blood level, assuming, however, that the blood level *begins* at the concentration desired. The assumptions of these equations have been criticized recently (9), but completely corrected equations were not given. For first-order release from the dosage form, Wiegand and Taylor (4) have presented equations for calculation of the total dose remaining in a dosage form *in vitro*. These equations, while useful, cannot predict which combination of rate constant, fraction in initial form, and fraction in the maintenance form, will give a particular blood level.

In order to calculate the dosages required, methods must be available to obtain the optimum release rate constant. For zero-order release, one author (10) feels it is the product of the elimination constant and the dose required to give the desired blood level, while another (9) feels it is the product of the elimination constant and the desired blood level itself. For first-order release, there appears to be no suitable method available for obtaining the desired rate of release constant, or the fractions of initial and maintenance dose required.

In an effort to summarize the work in this area, the present investigation was designed to completely characterize the standard model for sustained-release dosage forms. In addition, it is the authors' purpose to report the analog computer, and where possible, mathematical solutions of the equations describing absorption, distribution, elimination, and availability relationships with the over-all goal of devising complete equations suitable for calculation of the doses and rate constants to give a desired blood level based on the type of release pattern employed or available. It will be apparent to the pragmatists among the readers that the ease with which a given type of release can be formulated must always be a consideration and the value of considering only those parameters within the reach of the experimenter will be appreciated.

GENERAL CONSIDERATION OF THE MODEL

In this study, the following model [after Teorell (11)] has been adopted, portions of which have been found to adequately describe actual biological processes.



(Eq. 1)

where

D = concentration of drug remaining in the dosage form,
G = concentration of drug at the sites of absorption,
B = concentration of drug in the fluids of distribution (for purposes of simplicity referred to as blood concentration),
U = concentration of drug in the urine or other permanent drug sink,
E = concentration of drug metabolized,
k_r = rate constant for release of drug from the dosage form, where the superscript 0 and 1 indicate the apparent order of release. The wavy arrow is used with k_r to indicate that the precise *form* of the release is a variable also,
k_a = rate constant for absorption,
k_e = rate constant for elimination of unchanged drug,
k_u = rate constant for elimination *via* all other routes.

For purposes of simplicity k_e and k_u have been combined into one rate constant k_d (where $k_d = k_e + k_u$).

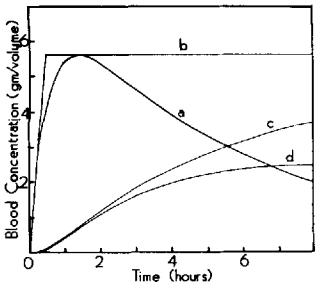


Fig. 1.—Comparable blood level *versus* time curves obtained for (a) an immediately available dose, (b) an "idealized" sustained-action formulation, (c) zero-order release maintenance from, (d) a first-order release maintenance form.

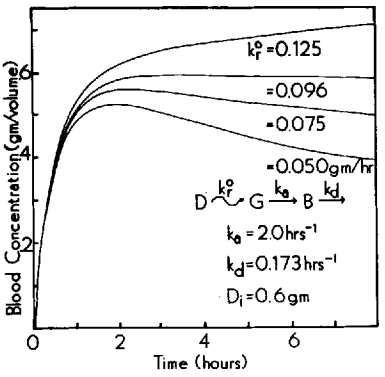

Fig. 2.—Blood level *versus* time curves showing the effect of variation in the zero-order release constant (using the ADE constants from *Reference 9*).

In using a model such as this, a problem arises in the treatment of the various components present from the standpoint of concentrations and compartments. Recent articles (9) have used amounts and concentrations interchangeably, but since the driving force in kinetic equilibria is concentration, amount can be used in its place to describe the kinetic relationships between compartments only when the volumes in each compartment are the same or when the assumption is made that the whole process takes place in the same compartment and volume. Since the one compartment–one volume idea is a useful and common, but tacit assumption, perhaps a brief explanation is necessary. The concept is more easily understood if the relationship of Eq. 1 is viewed as a chemical reaction involving four steps and taking place in a single given volume of solution, *i.e.*, a beaker. The model then becomes volume independent; the concentrations obtained have units of moles per unit volume or grams per unit volume; amounts and concentrations are interchangeable. Since the volume in each compartment of the body is different, conversion from concentrations as described by the equations, to amounts in the body compartments, then requires a knowledge of the relative compartment volumes and assumes complete uniformity within each compartment. Such a

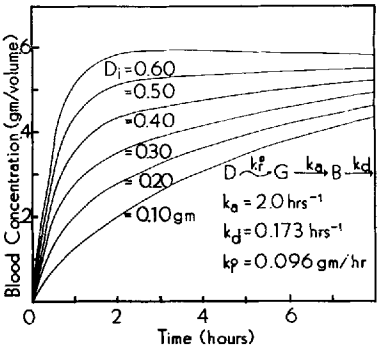

Fig. 3.—Blood level *versus* time curves showing the effect of variation in the initial dose (using ADE constants from *Reference 9*).

change is not of concern if fractions of total dose *only* are to be considered.

In this study the one volume–one compartment idea has been adopted for simplicity and thus the results are subject to the above assumptions. In addition, it is assumed that the equilibria (which must exist) for each component lie far to the right, so that reverse reactions are negligible, the drug is completely absorbed, and that after release it is immediately available.

The concentration of drug at the absorption site at time zero is the initial dose (D_i) and is equal to the fraction in the initial or in the immediately available dose (F_i) times the total dose given (W), *i.e.*, drug being in solution or in some rapidly dissolving drug form. The concentration of drug in the dosage form at time zero is the maintenance dose (D_m) and is that fraction of dose (F_m) required to maintain an optimum and as nearly as possible a constant concentration in the blood for a given length of time times the total dose given (W). It is proposed that release from the maintenance portion of the dosage form can be described by either zero- or first-order kinetics.

RESULTS AND DISCUSSION

Figure 1, curve a, illustrates the blood concentration *versus* time computer curve obtained for an immediately available dose using the model (Eq. 1), based on representative values of k_a = 2.0 hr.$^{-1}$ and k_e = 0.2 hr.$^{-1}$. Curves c and d (Fig. 1) are representative blood concentration curves for maintenance forms releasing drug by zero- and first-order kinetics, respectively.[2] Curve b (Fig. 1) illustrates the desired or "ideal" curve for a sustained-release dosage form, which includes both initial and maintenance dose. The design of a suitable sustained-action dosage form thus depends on finding the combination of a and c or a and d that produces the curve b, if such a combination exists, or as close an approximation as is possible.

The effect on the blood concentration *versus* time curve due to variation of the release rate con-

[2] The computer curves shown in this report were obtained using an Applied Dynamics AD-24-PB computer, a Moseley model 2D-2AM x-y recorder with a type F-1 photo electric curve follower, and an Electro-Instruments model 101-1518 x-y recorder.

stant as well as the effect of varying F_i and F_m are discussed under the appropriate headings for zero- and first-order release from the dosage form, and in addition, the mathematical relationships necessary to calculate both the total dosage and the required rate constant such that as close an approximation to the ideal as possible is obtained are discussed under their appropriate headings.

RELEASE BY ZERO-ORDER KINETICS

General Concepts.—From an immediately available dose, the blood concentration at any time, t, is a function of k_a, k_e, and concentration of drug in the gut (Eqs. 1 and 2),

$$B_t = \frac{D_i k_a}{k_d - k_a} (e^{-k_a t} - e^{-k_d t}) \qquad \text{(Eq. 2)}$$

where B_t is the concentration of drug in the blood at any time, and all other symbols represent quantities previously defined. The peak concentration and time to arrive at the peak are also functions of these parameters. The equation for the peak time (T_p) being:

$$T_p = \frac{2.3}{k_a - k_d} \left(\log \frac{k_a}{k_d}\right) \qquad \text{(Eq. 3)}$$

To obtain a constant blood level, one suspects, and can show mathematically, that a constant rate of availability from the dosage form is desired and once this desired rate is estimated (k_r^0), the required maintenance dose (D_m) may be found as the product of k_r^0, and the time over which sustained action is desired (h),

$$D_m = k_r^0 \times h \qquad \text{(Eq. 4)}$$

The desired rate of availability (k_r^0) can be roughly estimated, from the equations for the model, to be

$$k_r^0 = k_d \times B_d \qquad \text{(Eq. 5)}$$

where B_d is the desired blood level. The rational for this estimate can be shown by considering the differential equation for the blood level obtained from a sustained-action dosage form having both an initial and a zero-order maintenance form. From the general equations of the model in Eq. 1 one can obtain the relationship:

$$dB/d_t = k_r^0 - k_d(B_d) - e^{-k_a t}[k_r^0 - k_a(D_i)] \qquad \text{(Eq. 6)}$$

a constant blood level would require that $dB/d_t = 0$ therefore,

$$k_r^0 = k_d(B_d) - e^{-k_a t}[k_r^0 - k_a(D_i)] \qquad \text{(Eq. 7)}$$

if k_a is very large, *i.e.*, the absorption phase is not at all rate limiting

$$k_r^0 = k_d(B_d) \qquad \text{(Eq. 5)}$$

where B_d is the blood level to which the sustained action is aimed. Note that the assumption made to obtain Eq. 5 is in essence that the blood level *equals* B_d at time zero ($k_a = \infty$). This is of course not the true situation and while the use of Eq. 5 produces a reasonably flat blood level curve, it is *not the desired blood level* used in the calculation, but a somewhat higher one even if k_a is made very large. Variations in k_r^0 indicating this result are shown in Fig. 2 using the absorption and excretion constants of *Reference 9*. The k_r^0 calculated for a $B_d = 0.56$ is $k_r^0 = 0.096$

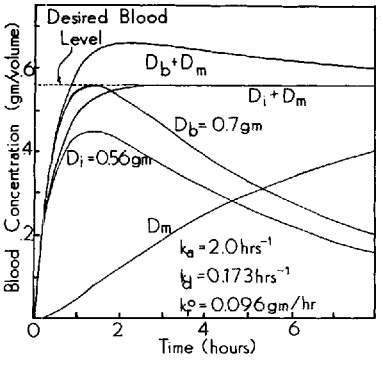

Fig. 4.—Blood level *versus* time curves showing the achievement of the desired blood level by adjustment of the initial dose provided. The blood levels that would be obtained for the initial dose required to obtain the desired level when alone (D_b), when in the presence of the maintenance dose (D_i), and those obtained with a maintenance (D_m) dose alone are also shown.

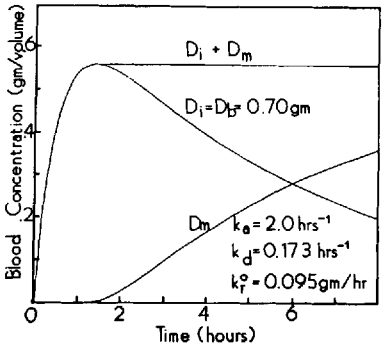

Fig. 5.—Blood level *versus* time curves showing nearly ideal sustained-action obtained by a delayed start of the maintenance dose. The blood levels that would be obtained for the initial dose (D_i) and maintenance dose (D_m) are also shown.

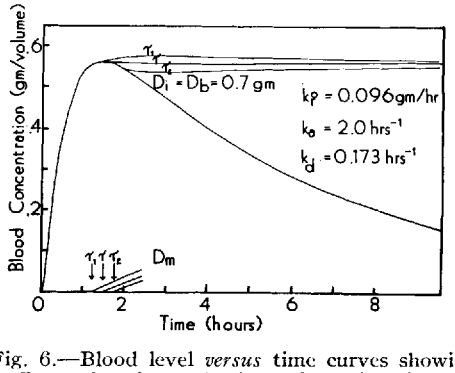

Fig. 6.—Blood level *versus* time curves showing the effects of various selections of starting time for the maintenance dose.

(the actual B_d obtained using these values can be seen to be about 0.59).

If the initial dose (D_i) is varied while a constant k_r^0 is used, a family of curves such as those in Fig. 3 are produced. It would appear that by a proper selection of D_i and k_r^0, a curve corresponding to the "idealized" one should be possible, but it is not. The "idealized" curve with a plateau slope equal to zero over the time period required cannot be obtained with a maintenance dose releasing drug in this fashion, although the slope is sufficiently close to zero to be considered "ideal." This can be seen in Figs. 2 and 3 but can more easily be demonstrated by noting that the derivative of the equation describing the blood level-time relationship (Eq. 6) *has* a real solution at $dB/dt = 0$ (Eq. 7), denoting a true maximum value for this equation (it is of course different from that of the immediately available dose), unless one is able to assume that the time to reach a *maximum* blood level was zero (and $k_a = \infty$).

The initial dose (D_i) of a sustained-release preparation cannot be assumed to be identical to that immediately available dose needed (D_b) to produce a peak equal to the desired blood level. Because the sustained portion of the dose also provides some drug for absorption over this early interval, too much drug becomes available for absorption and consequently a higher blood level is obtained than is desired. A correction on the immediately available dose is needed then such that less drug is initially available for absorption. While this does produce the desired blood level, a slightly longer time is required to reach the desired blood level; both of the above considerations are shown in Fig. 4. The correction needed should concern the time interval from time zero until absorption of the initial dose is complete, but as mathematically, absorption is never complete, for calculation purposes this may be assumed to correspond to the time to achieve the peak height, and simple subtraction of the quantity yielded by the maintenance dose in this interval produces a suitable correction. This correction is equal to $k_r^0 \times T_p$ where T_p is defined in Eq. 3,[3] so that,

$$D_i = D_b - (k_r^0 \times T_p) \qquad \text{(Eq. 8)}$$

This difficulty can be overcome more easily by using a sustained-release dosage form that begins its release of the maintenance drug *not* at time zero, but at the point where absorption of the initial dose is virtually over. This proposal is shown graphically in Fig. 5. For this type of dosage form, the initial dose and the time to reach the desired blood level remain the same, since the maintenance dose is not contributing drug over this time period [note that in the previous sample where both started together, adjustment of D_b to obtain D_i resulted in a slight delay in reaching the desired blood level (Fig. 4)]. If the maintenance form begins release of drug at times before or after the peak height time, the curve will tend to approach the desired blood level concentration at a rate which is dictated by the release constant of the maintenance form as shown in Fig. 6.

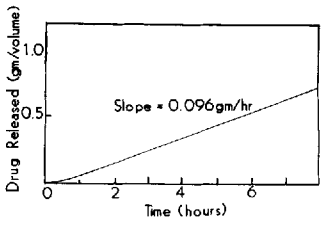

Fig. 7.—Dose release curve necessary to produce an "idealized" blood level *versus* time curve such as that shown in Fig. 5 (labeled $D_i + D_m$).

While a delayed start appears to be a difficult complication, sustained-action medication forms capable of providing it are currently available, *e.g.*, cored tablets, in which the core is commonly the maintenance dose that does not become available until some time after the initial dose has been absorbed. While not actually designed with this in mind, cored sustained-action tablets of superior action may well be assumed to owe their action to this type of behavior.

The general equations for the blood level *versus* time relationship in such a case can be solved to yield:

$$B_t = K_r^0 u(t-\tau)\left\{\frac{1}{k_d}(1 \times e^{-k_d(t-\tau)}) + \frac{1}{k_a - k_d}[e^{-k_a(t-\tau)} - e^{-k_d(t-\tau)}]\right\} + \frac{D_i k_a}{k_a - k_d}(e^{-k_d t} - e^{-k_a t}) \qquad \text{(Eq. 9)}$$

where $u(t-\tau)$ is the so-called "unit step" function whose value is 0 for all values of its argument ≤ 0 and $+1$ for all others. By making this substitution, one can see that before $t = \tau$, B_t describes the expected immediately available dose curve, while after $t = \tau$, the maintenance dose adds its effect onto whatever is left at that time. The value of such a dosage form is more apparent from the computer curves than from the equation.[4]

Calculation of the Desired Zero-Order Rate Constant.—Previous publications (10) have directed that the rate constant necessary for sustained release be set equal to k_d times the dose required to produce B_d. This has been criticized recently (9) and as found in this study the criticism is valid. The correct k_r^0 is the product of the elimination constant and the desired blood level (B_d).[5] The zero-order rate constant necessary can be obtained in another fashion also, utilizing the method of Stelmach, Robinson, and Eriksen (3), where using the desired blood concentration *versus* time curve as a computer

[3] This simple method for making the correction is of course only an approximation. The exact calculation would involve the solution of the complete equation for the blood level obtained from a zero-order sustained-action dosage formulation for the initial dose D_i, at some time after the expected peak. As no *mathematically* flat blood level *versus* time line is ever obtained using this formulation method, the equation is not soluble explicitly and the approximation given becomes the most desirable method for calculation of the correction.

[4] In the interests of complete precision, it must be pointed out that the blood level curves obtained from this type of dosage form are not mathematically straight either as absorption of D_i is mathematically "eternal." They represent major improvements on Eqs. 7 and 8 and also give complete mathematical linearity of B_d only when $k_a = \infty$, as discussed later.

[5] The use of the dose required to produce the desired blood level yields the same result as the blood level itself only if the one compartment–one volume model is used and k_a is assumed very large. In this case $B_d = W$.

input voltage, the dosage release *versus* time curve required is produced as an output. The slope of the dosage release curve can be seen to equal the zero-order rate constant required. This was tested using the plot of Fig. 5 as an input, with results shown graphically in Fig. 7.

The rate constant k_r^0 used for Fig. 5 had been set equal to 0.096 Gm./hr.; the slope of the line in Fig. 7 calculated by the computer as being required to produce the blood level curve (labeled $D_i + D_m$) in Fig. 5, was found to be equal to 0.096 Gm./hr.

The linearity of the blood concentration-time curve with a delayed start can be shown by changing the time variable in Eq. 9 to describe only times *after* the peak time of the immediately available portion, so that

$$= t - \tau$$

and

$$\text{when } \pi = 0,\ B_\pi = B \text{ peak} = B_p$$

under these conditions, Eq. 9 becomes,

$$B_\pi = k_r^0 \left\{ \frac{1}{k_d}(1 - e^{-k_d\pi}) + \frac{1}{k_a - k_d}(e^{-k_a\pi} - e^{-k_d\pi}) \right\} + \frac{D_i k_a}{k_a - k_d}[e^{-k_d(\pi + \tau)} - e^{-k_a(\pi + \tau)}] \quad \text{(Eq. 9}a\text{)}$$

setting the first derivative of B_π with respect to π equal to zero produces an expression for B_π independent of time (and thus flat), only if $e^{-k_a\pi}$ is assumed to be zero ($k_a \to \infty$) and $k_a \gg k_d$. Under those restrictions,

$$\frac{D_i k_a}{k_a - k_d} e^{-k_d\tau} = K_r^0 \left\{ \frac{1}{k_a - k_d} + \frac{1}{k_d} \right\} \quad \text{(Eq. 9}b\text{)}$$

and as the left side of Eq. 9*b* is an approximation for the desired blood level which is produced by the immediately available dose D_i (where $D_i = D_b$), one again finds,

$$k_r^0 \cong B_p k_d \cong B_d k_d \quad \text{(Eq. 5)}$$

Note that the blood concentration after the peak time (B_π) is a constant and identical to the peak blood level if and only if $k_a = \infty$, as one might expect.

Calculation of the Total Dose for Release by Zero-Order Kinetics.—As pointed out previously (10) a dosage form releasing drug at a rate equal to the rate at which drug is eliminated *will* give a very nearly constant blood level, but differentiation must be made between a dosage form releasing drug from time zero and one releasing drug at the peak height time, in the calculation of total dose.

Release from Time Zero.—For a maintenance form releasing drug from time zero, the following equations hold.

$$W = D_i + D_m \quad \text{(Eq. 10)}$$

where $D_i = D_b - (T_p \times k_r^0)$. In this equation $(T_p \times k_r^0)$ is the concentration of drug contributed by the maintenance form that represents the correction on the initial or immediately available dose, and

$$D_m = k_r^0 \times h$$

Therefore

$$W = D_b - (T_p \times k_r^0) + k_r^0 \times h \quad \text{(Eq. 11)}$$

where

- W = total dose,
- D_i = initial dose,
- D_m = maintenance dose,
- D_b = dose required to give the desired blood level, when given in an immediately available form,
- T_p = peak height time,
- k_r^0 = zero-order rate of release constant,
- h = total desired time for sustained action in hours.

Delayed Start Maintenance Dose.—When the maintenance dose begins release of drug at the peak height time, the equation for total required dose (W) becomes

$$W = D_b + k_r^0 \times (h - T_p) \quad \text{(Eq. 12)}$$

and

$$D_i = D_b$$
$$D_m = k_r^0(h - T_p)$$

where the symbols have the same significance as above.

RELEASE BY FIRST-ORDER KINETICS

General Concepts.—The relationship between the initial and maintenance dose of an absorption, distribution, and excretion model with first-order availability is shown in Fig. 8 for various values of k_a (and fractions of dose as maintenance from, F_m) at constant k_r' and k_d. As expected, k_a influences the curve very little but primarily *before* the peak height time; the intersection points remaining essentially in the same place as F_m and k_a change. The common intersection point for various fractions of dose has been recognized and reported previously by Kruger-Thiemer and Eriksen (2). Mathematically, the intersection point lies at the peak time (T_p) for the maintenance dose alone, representing a solution of the equation,

$$k_r'(k_d - k_a)e^{-k_r'T_p} = k_d(k_a - k_r')e^{-k_dT_p} + k_a(k_r' - k_d)e^{-k_aT_p} \quad \text{(Eq. 13)}$$

as has also been noted previously (2).

Figure 9 demonstrates the effect of altering k_r' at a constant k_d and k_a; this effect has also been suggested by previous workers (5). An interesting point may be noted in this family of curves, when k_a is much larger than k_r' and k_d, the intersection point is a function only of k_r' and k_d. The intersection point occurring at later times for smaller values of k_r'. The same observation can be made mathematically by letting k_a become enough larger than k_d and k_r' that its exponential term may be disregarded at an early time and then solving Eq. 13 for the intersection point of T_p

$$T_p = \frac{2.3}{k_r' - k_d} \log \frac{[k_r'(k_a - k_d)]}{[k_d(k_a - k_r')]} \quad \text{(Eq. 14)}$$

or if $k_a \gg k_d$ and k_r',

$$T_p \cong \frac{2.3}{k_r' - k_d} \log \left(\frac{k_r'}{k_d} \right) \quad \text{(Eq. 15)}$$

It becomes rapidly apparent with the computer that no combination of rate constants and/or doses will reduce a flat, constant blood level using a first-order availability model. Mathematically, this can be shown also by considering the solution for the maximum of the equation for the blood level produced by the authors' three-step model with first-order availability:

$$B_t = \frac{D_m k_a k_r'}{(k_d - k_r')(k_a - k_r')}(e^{-k_r' t} - e^{-kdt}) + \frac{D_i k_a - \frac{D_m k_a k_r'}{k_a - k_r'}}{(k_d - k_r')}(e^{-kat} - e^{-kdt}) \quad \text{(Eq. 16)}$$

[after Wiegand and Taylor (5)], and

$$\mathring{B}_t = \frac{D_m k_a k_r'}{(k_d - k_r')(k_a - k_r')}(+k_d e^{-kdt} - k_r' e^{-k_r' t}) + \frac{D_i k_a - \frac{D_m k_a k_r'}{k_a - k_r'}}{(k_d - k_r')}(k_d e^{-kdt} - k_a e^{-kat}) \quad \text{(Eq. 17)}$$

Although the actual solution for t at $\mathring{B}_t = 0$ can only be found by successive approximation, this equation obviously has three solutions, two trivial ($t = 0$ and ∞) and one real; a plot that has a maximum cannot be flat.

A sustained-release product having a *satisfactorily* flat blood level curve using a first-order release pattern can be designed, however, and that design depends upon the proper selection of both the dose fraction in each form and the maintenance dose release constant. The closest approach to the "idealized" blood level can be found by computer experimentation to require a combination of initial and maintenance does such that the intersection (T_p, Eqs. 14 and 15) occurs at a time equal to or greater than the desired sustained-action interval (h) (Fig. 10). In addition, the further past the desired time for sustained release this point lies, the more combinations of F_i and F_m are available that will give the desired type of blood concentration curve. From the intersection (T_p) equation (Eq. 14) it is observed that the smaller the value of k_d the larger the value of k_r' may be and still produce a satisfactory dosage form. For cases where k_d is large, however, the value of k_r' necessary to give an intersection point at or beyond the desired time can be very small, and, thus, the necessary dose present in the maintenance form may become quite high.

The rather remarkable improvement afforded in the zero-order release case, by delaying the start of the maintenance dose, suggests its use here also with the results shown in Fig. 11. As in the zero-order case, the blood level is obtained at a rate determined by the initial dose, and the subsequent levels by the maintenance dose. Quite opposite to the observation with first-order release started at time zero, however, the most "uniform"[6] blood levels are obtained, when the elimination rate (k_d) is high, by making k_r' high, too. The generally "sustained" shape of this curve suggests that the delayed start principle height be extremely useful for sustained release here too, especially for drugs with large elimination (k_d) constants.

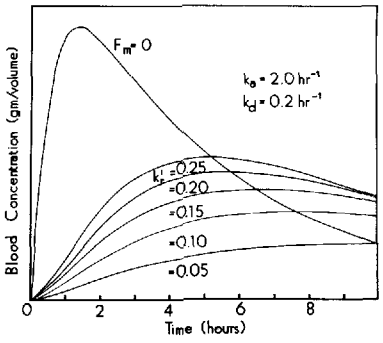

Fig. 9.—Blood level *versus* time curves showing the change in intersection point for various first-order release rate constants.

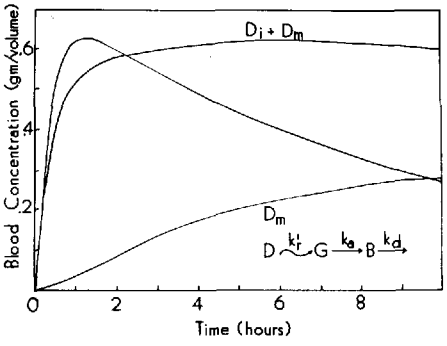

Fig. 10.—Blood level *versus* time curve showing the degree of sustained action obtainable with first-order release. The blood levels *versus* time curves obtained from the initial (D_i) and maintenance (D_m) doses are also shown. Key: $K_a = 3.0$ hr.$^{-1}$; $k_d = 0.10$ hr.$^{-1}$; $K_r' = 0.065$ hr.$^{-1}$.

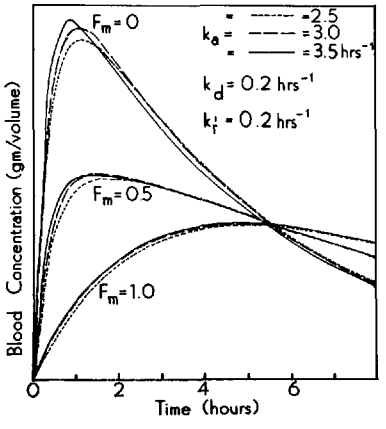

Fig. 8.—Blood level *versus* time curves showing the same intersection point despite variation in absorption rate constant (k_a) for several maintenance dose/initial dose ratios.

[6] A "uniform" or "sustained" blood level in this case represents a nonhorizontal blood level oscillating about some average value.

The general equation for the blood level *versus* time relationship when a delayed start of release and first-order kinetics is used is:

$$B_t = \frac{D_m k_r'}{(k_a - k_r)} u(t - \tau) \left\{ \frac{k_a}{(k_d - k_r')} [e^{-k_r'(t-\tau)} - e^{-k_d(t-\tau)}] + \frac{k_a}{(k_a - k_d)} [e^{-k_a(t-\tau)} - e^{-k_d(t-\tau)}] \right\} + \frac{D_i k_a}{(k_d - k_a)} \left\{ e^{-kat} - e^{-kdt} \right\} \quad \text{(Eq. 18)}$$

using the same "unit step" concept discussed before and τ the time of the delayed start. The similarity in form to Eqs. 9 and 16 are apparent.

Calculation of the First-Order Rate of Release Constant.—It was stated earlier that the intersection points of the blood level curves obtained for immediate and sustained-release forms should be equal to or longer than the desired time for sustained release (h), in order to achieve the closest approximation to the "idealized" blood concentration-time curve when a maintenance dosage beginning immediately is used. As this intersection point depends essentially on k_d and k_r', (if k_a is assumed large) and k_d is a parameter over which the formulator has no control, k_r' must be altered to move this intersection point to the desired time. With k_a and k_d given, Eq. 14 (or Eq. 15) may be used to solve for the rate constant required, to make the intersection point equal to, or greater than, the desired sustained-action time (h). Alternatively, as has been suggested for zero-order release, calculation of the necessary first-order availability constant can be carried out using the desired blood level curve and the computer method of Stelmach, Robinson, and Eriksen (3).

When a delayed start is used, two approaches to the desired k_r' are possible; the maintenance dosage form can provide drug in an approximately zero-order fashion (but *actually* first order) with an over-all rate of $k_d B_d$, or the peak of the blood level produced by a maintenance dose alone may be positioned at a point between the initial dose peak and the desired sustained-action time.

In the first case, the sustained portion should begin releasing at the T_p of the initial portion. The drug released from the dosage form in t hours may be set equal to the drug lost over the same interval assuming constant blood level,

$$D_m(1 - e^{-k_r' t}) = k_d B_d t \quad \text{(Eq. 19)}$$

and the approximation relating the release rate and the administered dose,[7]

$$k_r' D_m \cong k_d B_d = k_r^0 \quad \text{(Eq. 20)}$$

results. Using the maximum dose that the patient will swallow or that can be accommodated in the dosage form, k_r' can be estimated; for any satisfactory degree of sustained action a first-order release form will require roughly 10× the dose required for a zero-order form.

In the second case, a more rapid release rate may be used and a later time of onset tolerated producing, in general, a more practical dosage form. Experimentation on the computer suggests that for the ADE constants normally found, the point where 99% of the initial dose has been absorbed is the most suitable onset point for the maintenance dose,

$$\tau = \frac{4.6}{k_a} \quad \text{(Eq. 21)}$$

The k_r' required to obtain a maintenance dose generated peak at roughly the midpoint between the

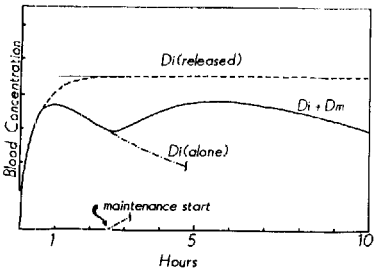

Fig. 11.—Blood level *versus* time curves showing the degree of sustained action obtained by a delayed start of a first-order release maintenance dose. Portions of the blood level *versus* time curves obtained from the initial (D_i) and maintenance (D_m) doses are also shown.

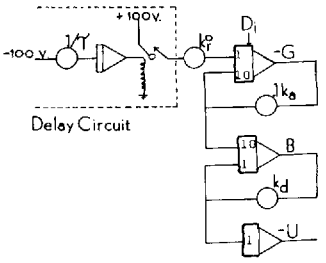

Fig. 12.—Scaled analog computer program for the system shown in Eq. 1, using a zero-order delayed start maintenance dose.

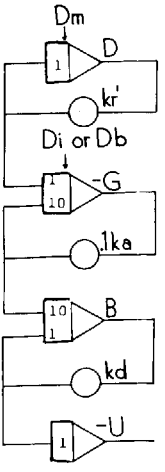

Fig. 13.—Scaled analog computer program for the system shown in Eq. 1, using a first-order immediate start maintenance dose.

[7] This is the "rate in equals rate out" equation of Nelson (10) and again implies $k_a = \infty$ and its applicability one can also verify by solving the maintenance only portion of Eq. 16 for B in the case where k_a and $k_d >> k_r'$.

initial dose blood level peak and the desired sustained-action time (h) may be estimated solving Eqs. 14 or 15 for k_r' at

$$T_p = \frac{h - \tau}{2} \qquad \text{(Eq. 21}a\text{)}$$

Calculation of the Total Dose for Release by First-Order Kinetics.—The total dose required for adequate sustained release (W) will again be described by Eq. 10 and may be approximately solved for both methods of first-order release.

Release from Time Zero.—

$$D_i = D_h - D_{correction} \qquad \text{(Eq. 22)}$$

as before, a correction ($D_{correction}$) for D_h is required which may be thought of as equal to the amount of drug contributed to the blood by the maintenance dose, during the phase controlled by the initial dose, and which can be estimated using reasoning similar to that used in deriving Eqs. 19 and 20.

$$D_{correction} = D_m(k_r'T_p) \qquad \text{(Eq. 23)}$$

Thus, Eq. 22 is found to be approximately[8]

$$D_i = D_h - D_m \times k_r' \times T_p \qquad \text{(Eq. 24)}$$

The maintenance dose required to keep the blood level at approximately the desired value can be calculated by equating the desired "rate in" (k_dB_d) with the actual "rate in"[8]

$$k'_rD_me^{-k_r't} = k_dB_d$$

$$D_m = \frac{k_dB_d}{k_r' - (k_r')^2t} \cong \frac{k_dB_d}{k_r'} \qquad \text{(Eq. 25)}$$

The approximation is sufficiently accurate for most purposes, although the first is better, the time when the desired blood level is reached being used for t.

The total dose (W) then is

$$W = D_h - D_mk_r'T_p + \frac{k_dB_d}{k_r'} \qquad \text{(Eq. 26)}$$

Delayed Start Maintenance.—The immediately available dose (D_i) completely dictates the attained blood level as described for the care of release by zero-order process; but the maintenance dose required for a satisfactorily "uniform" blood level depends on the delay time, τ, and the placing of the maintenance peak.

A precise delay time value is not critical; it may be calculated easily from Eq. 21, and k_r' calculated from Eqs. 14 or 15 as mentioned before (to place the "maintenance peak" at roughly the midpoint of the desired sustained-action time, h, Eq. 21a).

The maintenance dose required to produce a secondary blood level peak equal to the first may be calculated as the maintenance dose (alone) required to produce a peak sufficient to increase the blood level remaining from the initial dose to the desired value. At the desired time for the secondary peak T_p^*, the residual blood level is

$$B_r = \frac{D_ik_a}{k_a - k_d}\,(e^{-k_dT_p^*} - e^{-k_aT_p^*}) \qquad \text{(Eq. 27)}$$

and the peak blood level from the maintenance dose is that calculated from Eq. 16 at $t = (T_p^* - \tau)$ and $D_i = 0$. If it is assumed as before that at the time involved $e^{-k_aT_p}$ becomes negligible, both these equations can be simplified and D_m easily calculated. Under these circumstances,

$$B_r \cong \frac{D_ik_a}{k_a - k_d}\,(e^{-k_dT_p^*}) \qquad \text{(Eq. 28)}$$

Then

$$D_m = \frac{k_d}{k_r'}\,(B_d - B_r)e^{+k_r'(T_p - \tau)} \qquad \text{(Eq. 29)}$$

Figure 10 shows the computer generated blood level produced for the ADE constants used before, calculated for such a delayed first-order start. In addition, the drug delivered from the dosage form is also shown to indicate the separation of starting times.

SUMMARY AND CONCLUSIONS

The general phenomena involved in the ADE kinetics of many drugs are found to be described by rather simple "overall" expressions and these phenomena according to the descriptive equations that happen to fit, *i.e.*, absorption is described as "first order," etc.; while there is little real doubt that such a naive approach is incorrect, the fact that such simple equations *can* adequately describe the concentrations of biologic interest, should be of real use (if not importance) in the formulation of effective sustained-action dosages. As discussed in this report, however, even these "simple" equations cannot be mathematically solved to produce explicit solutions for the dosage fractions and rate constants required, but instead suitable approximations must (and can) be made that permit *useful* solutions for the single sustained-release dose case. These approximations and the assumptions upon which they have been made have not always been explicitly described when (and if) they have been published before and the present authors felt sufficient benefit would accrue from collecting them both in one place that this has been done for the two theoretical cases described before: (a) simultaneous start of initial and "zero-order" sustained dosages and (b) simultaneous start of initial and "first-order" sustained dosages. The methods for calculating the dose fractions of both the initial and the sustained portions as well as the rate constant most suitable for producing a sustained blood level are described fully.

Secondarily, but of interest in order to complete the picture, the effect of delaying the start of the sustained portion of the dosage form has been shown to produce in one case (c) the best theoretical sustained-action blood level picture available and in the other (d) a novel and perhaps not unusable blood level situation: (c) initial release followed by "zero order" sustained dosage after some delay and (d) initial release followed by "first order" sustained dosage after some delay.

The aim and the result of the analysis in this report has been to show the theoretically available blood level situations resulting from a *single* complete (sustained *and* initial) dosage form designed to produce the most constant blood level over the desired sustained-action time and but for the irksome (though real) vagaries of the human gastrointestinal tract would describe the blood level–time pictures actually observed.

[8] The approximations made here are similar to those made for the zero-order case (see *Footnote 3*). The exact solution is similarly not possible and experimentation convinces us that for practical situations, this approximation is suitable.

APPENDIX

Figures 12 and 13 show the computer circuits used in simulating the solutions shown in this work. Of prime concern and utility here is the "nonlinear delay input" by programmed relay shown in Fig. 12. The remaining programs required (immediate start, zero-order, and delayed start, first-order) have been published and discussed previously (3).

Kinetics of Deterioration of Trimethylene Bis-(4-formylpyridinium Bromide) Dioxime in Dilute Aqueous Solutions

By R. I. ELLIN, D. E. EASTERDAY, P. ZVIRBLIS, and A. A. KONDRITZER

The degradation of trimethylene bis-(4-formylpyridinium bromide) dioxime, TMB-4, occurs by two mechanisms. The first is a hydrolytic reaction of the acid form of the oxime catalyzed by hydrogen ion, and the second, a dehydration reaction. The latter may proceed by either of two pathways—a hydroxyl ion catalyzed dehydration of the acid form of the oxime, or a spontaneous dehydration of the oximate species. Velocity and various thermodynamic constants were determined for each of the mechanisms postulated. General equations were derived that relate the half-life of TMB-4 solutions to pH and temperature.

FOLLOWING THE introduction of pyridinium oximes for the management of intoxication by organophosphorus anticholinesterase compounds, an active search has taken place for more effective compounds. As a result, 1,1′-trimethylene bis-(4-formylpyridinium bromide) dioxime, referred to as TMB-4, was synthesized and shown to be a potent reactivator of phosphorylated cholinesterases (1, 2). Grob has reported (3) that TMB-4 in one-tenth to one-fifteenth the dose of 2-PAM iodide was more effective in humans against the weakening of the response of a muscle to electrical stimulation of its motor nerve. A better therapeutic index for TMB-4 has been demonstrated in laboratory animals (4), and the use of a mixture of 2-PAM and TMB-4 has been reported to be superior to any single oxime tested (5). In view of these reports the establishment of the conditions of maximal stability of TMB-4 in aqueous solution becomes important and worthwhile.

Presented to the Scientific Section, A.PH.A., New York City meeting, August 1964.
Accepted for publication July 20, 1966.

Mechanisms for the degradation of pyridinium aldoximes in aqueous solution have been postulated in previous reports (6, 7). Recent studies by Kosower (8) support the conclusion that the rate-limiting step for the degradation of pyridinium oximes in basic solution is the formation of cyanopyridinium ion. The mechanisms postulated for the breakdown of TMB-4 are presented in Scheme I. The reaction of TMB-4 in basic solution may be explained by an ElcB unimolecular elimination mechanism (9). Hydroxyl ion attack at each methine hydrogen atom results in the removal of a proton and the formation of a carbanion as the rate-controlling step. Subsequent loss of hydroxide ion from the oximino nitrogen leads to the formation of a triple bond; for TMB-4 the corresponding dinitrile would be the final product of this process. Hydroxide ion attack on the cyano group or addition to the pyridine ring forms dicarbamido and dihydroxy dipyridinium ions, respectively. The latter, on further reaction with hydroxide ion, readily lose a proton to form the corresponding dipyridone. Reaction of TMB-4 with hydrogen ion leads to various states of equilibrium involving the splitting out of hydroxylamine and the formation of

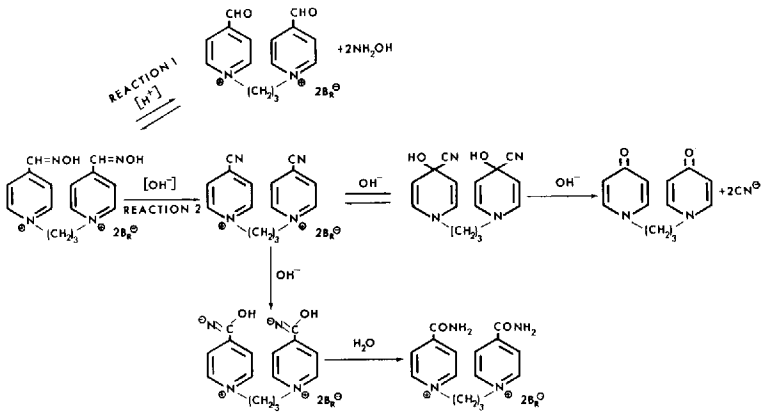
Hydroxyl ion attack at each methine hydrogen atom results in the removal of a proton and the formation of a carbanion as the rate-controlling step. Subsequent loss of hydroxide ion from the oximino nitrogen leads to the formation of a triple bond; for TMB-4 the corresponding dinitrile would be the final product of this process. Hydroxide ion attack on the cyano group or addition to the pyridine ring forms dicarbamido and dihydroxy dipyridinium ions, respectively. The latter, on further reaction with hydroxide ion, readily lose a proton to form the corresponding dipyridone. Reaction of TMB-4 with hydrogen ion leads to various states of equilibrium involving the splitting out of hydroxylamine and the formation of



Scheme I

the dialdehyde. Compounds isolated, or identified, or both, from the degradation of TMB-4 were the picrate derivative of the corresponding dipyridone, hydroxylamine, and inorganic cyanide.

The purpose of the present investigation was to determine the stability of TMB-4 in aqueous solution. Kinetic studies of the degradation of TMB-4 were made at various pH values and temperatures in order to obtain equations that would permit the prediction of the stability of the oxime at any pH and temperature.

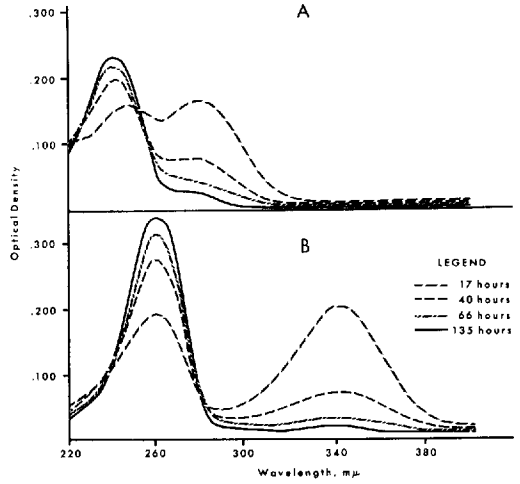


Fig. 1.—Ultraviolet absorption spectra of TMB-4 solutions undergoing degradation. Key: A, in 0.1 *N* perchloric acid, 71°; B, 0.1 *N* sodium hydroxide, 71°.

EXPERIMENTAL

The degradation of TMB-4 was carried out at five different temperatures in buffer solutions of various pH values, as well as in dilute solutions of perchloric acid and sodium hydroxide. Essentially the same buffer systems used previously (7) were employed in this study. The pH of each system was determined at the temperature at which the experiments were performed. The TMB-4 used in these experiments was recrystallized from ethyl alcohol to a melting point of 224–226° dec. (Thomas-Hoover, U.S.P. substances of class I).

Molar absorptivities of this oxime were found to be 4.82×10^4 at 345 mμ in 0.1 *N* alkaline and 3.39×10^4 at 281 mμ in 0.1 *N* acid solutions. Figure 1, B, shows that the intensity of the TMB-4 peak at 345 mμ in basic solutions diminishes with time and that simultaneously a single peak appears at 259 mμ and increases in intensity. Figure 1, A, shows a similar occurrence with TMB-4 in acid solution: the gradual diminution of the peak at 281 mμ and the corresponding appearance of a peak at 239 mμ. A solution of the breakdown products of TMB-4 gives practically no absorbance at 345 mμ in alkaline solution. Therefore, the residual TMB-4 in the

experimental solutions may be determined quantitatively by measuring the absorbance at 345 mμ in 0.1 *N* alkaline solution.

Buffered solutions were placed in a thermostatically controlled bath and were allowed to reach the temperature of the bath. A relatively small volume of a TMB-4 solution was added to obtain a final concentration of 1 mg./ml. Samples of 0.5 ml. were removed and diluted to 100 ml. with 0.1 *N* sodium hydroxide and the concentrations of the oxime were determined spectrophotometrically at 345 mμ.

RESULTS

Influence of Oxime Concentration.—The rate of disappearance of TMB-4 in both acid and alkaline solutions was found to be directly proportional to the concentration of the oxime, indicating that the degradation is of the first order with respect to the concentration of the oxime. The calculated reaction rate constants obtained at the various temperatures and hydrogen-ion concentrations are given in Table I. Typical plots of the results are shown in Figs. 2 and 3.

Temperature Dependency.—The velocity constants of the degradation of TMB-4 at 50, 59.7, and 71° in perchloric acid solutions ranging from 0.1 to 1.0 *N* (reaction 1 of Scheme I) were used to calculate the respective values for the catalytic constant, k_{H^+}, at normal hydrogen-ion concentration for each of the temperatures used. In Fig. 4 the rate constants are plotted against the reciprocal of the absolute temperature. The straight line relationships obtained indicate that the mechanism of the hydrolysis reaction is not altered by changes in temperature.

The temperature dependency of reaction 2 in Scheme I is graphically illustrated in Fig. 5 and indicates that the postulated dehydration mechanism is not affected by changes in temperature.

The effect of pH on the rate of degradation of TMB-4 at various temperatures is shown in Fig. 6. Between approximately pH 4.5 and 8, the rate is linear with hydroxyl-ion concentration; above approximately pH 8, the reaction becomes nonlinear. This phenomenon may be interpreted as representing

either spontaneous degradation of the oximate species or dehydration of the oxime catalyzed by hydroxyl ion. Either possibility would support the conclusion that above approximately pH 4.5 the mechanism of degradation can be due predominately to reaction 2 (Scheme I). On the assumption that the rate of the water reaction, *i.e.*, k_{H_2O} is negligible, and by use of the initial rate constants obtained for the reaction in acid solution and the rate constants for the reaction in alkaline solution, one obtains a general expression for the observed velocity constant of the degradation of TMB-4 (Eqs. 1 and 2).

$$\text{rate} = k_{H^+}(H^+)\frac{(H^+)}{K_a + (H^+)} + k_{OH^-}\frac{K_w}{K_a + (H^+)} \quad \text{(Eq. 1)}$$

or

$$\text{rate} = k_{II^+}(H^+)\frac{(H^+)}{K_a + (H^+)} + k_{Ox}\frac{K_a}{K_a + (H^+)} \quad \text{(Eq. 2)}$$

where k_{H^+} = catalytic constant for the hydrogen-ion catalysis, k_{OH^-} = catalytic constant for the hydroxyl ion catalysis, k_{Ox} = rate constant for degradation of oximate, and K_a = acid dissociation constant,

oxime ⇄ oximate, calculated from the equation, $-\log K_a = 3.41 + 1422/T$, which was derived from titration with alkali between 25 and 90°.

If the reaction is determined in solutions wherein the hydrogen ion is the only effective catalyst, Eqs. 1 and 2 reduce to rate = $k_{H^+}(H^+)$; at relatively high pH values, Eq. 1 reduces to rate = $K_w k_{OH^-}/K_a$ and Eq. 2 to rate = K_{Ox}.

The activation energies, E_a, were determined from the slopes of the Arrhenius-type plots in Figs. 4 and 5. The relationship between the rate constant and the equilibrium constant, ΔK^*, was used to determine the free energy of activation, ΔF^*, the frequency factor, A, and the entropy of activation, ΔS^*. The values for the latter two characteristics were calculated from Eqs. 3 and 4.

Table IV.—Predicted Stability of TMB-4 in Aqueous Solutions, $t_{1/2}$ (Half-Life)

$$k = \frac{RT}{Nh} e^{\Delta S^*/R} \cdot e^{-\Delta H^*/RT} \quad \text{(Eq. 3)}$$

and

$$A = \frac{RT}{Nh} e^{\Delta S^*/R} \quad \text{(Eq. 4)}$$

The calculated values for the thermodynamic constants are listed in Table II. By substituting the appropriate constants into Eqs. 1 and 2, the observed reaction rate can be expressed, in terms of hr.$^{-1}$, as either Eqs. 5 or 6.

$$k = 1.01 \times 10^{10} e^{-14,600/RT}(H^+) + 1.70 \times 10^{18} e^{-22,800/RT}\left[\frac{K_w}{K_a + (H^+)}\right] \quad \text{(Eq. 5)}$$

or

$$k = 1.01 \times 10^{10} e^{-14,600/RT}(H^+) + 1.13 \times 10^{14} e^{-24,200/RT}\left[\frac{K_a}{K_a + (H^+)}\right] \quad \text{(Eq. 6)}$$

Agreement of the values calculated by means of the equations with those obtained experimentally is shown in Fig. 6, where the lines are calculated and the open circles represent experimental data.

pH of Minimum Hydrolysis.—The equation for the hydrogen-ion concentration at which the rate of degradation is minimal can be derived by differentiating Eqs. 1 and 2 with respect to (H^+) and equating to zero, as described previously for 2-PAM iodide (7). It may be expressed as:

$$pH_{Min.} = {}^1/_2\left(pKa - 4.05 + \frac{2102}{T}\right)$$

Calculated values for $pH_{Min.}$ at various temperatures are given in Table III and vary inversely with temperature, ranging from 6.13 to 0° to 4.39 at 100°.

The over-all reaction rate of the decomposition of TMB-4 can be expressed as the half-life, $t_{1/2}$, of the reaction; half-lives can be calculated for any pH and temperature. Predicted stability data for pH from 3 to 13 and for temperatures from 40 to 90° are shown in Table IV.

Isolation and Identification of Degradation Product.—Three grams of TMB-4 and 300 ml. of 0.1 *N* sodium hydroxide were heated for 24 hr. in a water bath at 90°. About 3% of the original oxime remained when determined by ultraviolet analysis. To a 25-ml. aliquot, enough picric acid solution in ethanol was added to produce a definite turbidity. The mixture was heated for 15 min. on a steam bath and then was cooled. The resulting yellow precipitate was collected by filtration, dried, and recrystallized from alcohol–water and then from water. The product melted at 234–238°. The elemental analysis for the compound was: C, 43.6%; H, 3.1%; O, 37.2%. The analytical results agree with the calculated elemental content of the dipicrate of 1,1′-trimethylene bis-(4-pyridone): C, 43.6%; H, 2.9%; O, 37.2%.

DISCUSSION

The decomposition of TMB-4 proceeds both by a proton catalyzed hydrolysis mechanism and a dehydration reaction in which the cyanopyridinium intermediate is formed. The experimental data indicate that the dehydration may be explained equally well either by a hydroxyl-ion catalyzed reaction of the oxime, represented by k_{OH^-}, or by spontaneous dehydration of the oximate ion, represented by k_{Ox}.

A comparison of the thermodynamic constants for the dehydration reaction of TMB-4 with those found for the monoquaternary pyridinium aldoxime, 2-PAM (7), may lead to the conclusion that the predominant mechanisms involved differ for the two compounds. In the dehydration reaction for 2-PAM, activation energies assigned for k_{Ox} and k_{OH^-} are 28 and 17 Kcal., respectively. The activation energy for k_{Ox} is determined directly from the observed reaction rates in 0.1 *N* alkali; whereas, that for k_{OH^-} is determined from extrapolated values of observed rates at lower pH. The activation energy for the dehydration reaction of TMB-4 is about 24 Kcal. for both k_{OH^-} and k_{Ox}. The entropy of activation, ΔS^*, for the dehydration reaction of 2-PAM is more positive for k_{Ox} than for k_{OH^-}. In the case of TMB-4 the opposite is true; ΔS^* for k_{OH^-} has the more positive value. If it is assumed that the least sterically hindered mechanism would occur more readily, a base-catalyzed mechanism could be assigned to the degradation of TMB-4 and a spontaneous degradation mechanism to 2-PAM.

The data in this study, with that given in the investigation of 2-PAM (7), provide a means for optimizing conditions for long-term storage of a mixture of the two compounds in solution. The pH-rate profiles of the two aldoximes are similar but not congruent. TMB-4 is the more stable of the two with respect to the dehydration reaction; whereas, 2-PAM is the more stable with respect to the proton catalyzed hydrolysis mechanism. The pH of maximum stability for the two compounds differs by about 1.2 pH units. A pH of 4.5 to 5.0 would be practical for the prolonged storage of mixtures of the two oximes in solution, provided storage temperatures were below 30°. At temperatures appreciably higher than 30°, the stabilities of both oximes in solution decrease to such an extent that long-term storage becomes impractical. If storage temperatures above 30° are anticipated, then the mixture should be packaged as a dry powder; provisions and directions for preparing solutions extemporaneously should be supplied.

Effects of Aging and Surfactant Concentration on the Rheology and Droplet Size Distribution of a Nonaqueous Emulsion

By RICHARD D. HAMILL* and ROBERT V. PETERSEN

Six olive oil-in-glycerin emulsions were prepared wherein ammonia and 2-amino-2-methyl-1,3-propanediol (AMP), in various concentrations, served as saponifying agents. Six-tenths, 2, and 6 mg. ammonia/100 ml. and 2, 6, and 20 mg. AMP/100 ml. were used in making the emulsions. The emulsions were stored at room temperature (25°), and droplet size, rheology, and emulsion stability studied on days 1, 2, 4, 7, 14, 30, and 60. Droplet size, as measured from photographs taken by phase contrast photomicrography, were inversely related to amine concentration. Growth in droplet size over the period of study was more striking in AMP emulsions than in ammonia emulsions. Rheology studies with the Brookfield LVT viscometer revealed the existence of non-Newtonian pseudoviscous flow. The emulsions were very stable, as indicated by logarithmic graphs of viscosity and time. It is suggested that the data may be extrapolated to predict viscosity over longer time periods.

WHEN AN EMULSION is aged there is usually a distinct growth in droplet size before the dispersed phase separates in bulk (1). This growth can be attributed to coalescence between neighboring droplets and has been characterized as following first-order kinetics (2, 3).

Some of the factors which have an effect on droplet size in an emulsion are the method of preparation, phase–volume ratio, temperature during mixing, viscosity (4–8), and surfactant type and concentration (9). Conversely, the effects that droplet size and droplet size distribution have on emulsion viscosity have been explored. For example, the effects of homodispersity (10–14), flocculation (15–21), surfactant properties and concentration (22), and phase–volume relative to surfactant concentration (23, 24) on viscosity in oil–water emulsions have been studied and reported.

Previous reports (25, 26) have described the emulsifying effects of several ionic and nonionic surfactants on the nonaqueous, binary, immiscible system, glycerin and olive oil. More recently (27) this system was studied with regard to the effect of surfactant concentration on the effective size of two anionic amine surfactants formed *in situ* by the combination of either ammonia or 2-amino-2-methyl-1,3-propanediol (AMP) with the free fatty acids of olive oil. The present study was designed to learn more about the stability of this emulsion system by examining the effects of aging and amine concentration on both rheology and droplet size distribution.

Received April 20, 1966, from the College of Pharmacy, University of Utah, Salt Lake City 84112.

Accepted for publication August 26, 1966.

Presented to the Basic Pharmaceutics Section, A.PH.A. Academy of Pharmaceutical Sciences, Dallas meeting, April 1966.

Abstracted in part from a thesis submitted by Richard D. Hamill to the Graduate School, University of Utah, Salt Lake City, in partial fulfillment of Doctor of Philosophy degree requirements.

This investigation was supported in part by a grant from the University of Utah Research Fund.

EXPERIMENTAL

Six olive oil–glycerin emulsions were prepared with varying concentrations of amine. Samples 1, 2, and 3 contained 0.6, 2, and 6 mg. of ammonia/100 ml. of emulsion, respectively; whereas samples 4, 5, and 6 contained 2, 6, and 20 mg. of AMP/100 ml. of emulsion, respectively. These concentrations were chosen because 0.6 mg. of ammonia/100 ml. and 2 mg. AMP/100 ml. correspond to the minimum amine concentrations needed for stable emulsifications at phase volumes of 0.40 as previously reported (27). Concentrations of 6 mg. of ammonia/100 ml. and 20 mg. AMP/100 ml. represent a tenfold increase above these minima. The two remaining samples contained concentrations intermediate between the minimum concentrations and the tenfold increase. The olive oil and glycerin used in making the emulsions and the order of mixing were the same as those previously described (25–27). All emulsions were made with phase volumes of 0.40. Emulsion type was confirmed by the phase dilution method.

The emulsions were stored at room temperature (25 ± 2°) for 2 months. A testing schedule was established wherein the six samples were tested at days 1, 2, 4, 7, 14, 30, and 60. Day 1 corresponds with the day the emulsions were made.

Photographs were taken by means of phase contrast photomicrography on the days chosen in the testing schedule. A Wild phase contrast microscope providing 480× magnification and equipped with a Polaroid camera was used. The wavelength of the light source was 475 mμ.

A glass microscope slide was prepared by placing a drop of emulsion on the slide after which a cover glass was gently rested on the emulsion. Care was taken not to apply any pressure on the sample other than that exerted by the weight of the cover

glass. Pressure on the cover glass could cause distortions or force some droplets to coalesce in the emulsion, thus altering the droplet diameter results. The prepared slide was set aside for 1 hr. This time period was required to allow movement in the sample virtually to stop so that a clear photomicrograph could be obtained. The low intensity of the light source used in this type of microscopy required a several-second exposure time. Photographic prints were obtained using Polaroid Polapan 200 film. The photograph taken was immediately available for inspection to insure a picture of best possible clarity.

Two or three 1-in. squares were arbitrarily selected from each photomicrograph and the diameters of 200 to 300 droplets were classified within these areas. The average droplet diameter (D_m) was calculated using Eq. 1 (22).

$$D_m = \sqrt[3]{\frac{\Sigma n D^3}{\Sigma n}} \qquad \text{(Eq. 1)}$$

where n is the number of droplets with a diameter of D.

The rheology of each emulsion was studied on the test days using a Brookfield LVT viscometer. Day 120 also was included in the rheology testing schedule. Each sample was poured into the test container which was then placed into a constant-temperature water bath, maintained at 25 ± 0.2°, and allowed to equilibrate for 45 min. Spindle No. 2 provided with the Brookfield viscometer was chosen for testing the emulsions because it allowed the widest range of scale readings over a large number of r.p.m. (shear rate). Dial readings (shear stress) at spindle speeds of 0.6, 1.5, 3, and 6 r.p.m. were recorded for each sample. A test was conducted to determine the presence of thixotropy by running the viscometer at 60 r.p.m. for 10 min. after having measured speeds from 0.6 up to 6 r.p.m. After this period of time the dial readings were again recorded, but this time from 6 down to 0.6 r.p.m. In samples where thixotropy was present, the amount of standing time required before the "up" readings could be duplicated was noted.

To utilize effectively the Brookfield viscometer on non-Newtonian materials, various methods of calculation have been proposed (28, 29). The method described by Runikis *et al.* (29) takes into account the entire flow data obtainable with the Brookfield instrument. Their "n value" method utilizes Eq. 2 which they derive and explain.

$$\text{viscosity} = \frac{(K_B)\,(n)\,(\text{scale reading})}{(\text{r.p.m.})} \qquad \text{(Eq. 2)}$$

Since $K_B = 300$ when spindle No. 2 is used with the Brookfield LVT viscometer, Eq. 2 becomes

$$\text{viscosity} = \frac{300\,(n)\,(\text{scale reading})}{(\text{r.p.m.})} \qquad \text{(Eq. 3)}$$

A logarithmic plot of r.p.m. *versus* scale reading is a convenient method of calculating n since the reciprocal of the slope of the line formed in such a plot equals n.

All viscosity data reported in this study have been calculated from Brookfield data using Eq. 3 and recorded in centipoise (cps.).

A brief definition of some rheology terms which will appear in subsequent parts of this paper is necessary to avoid confusion later. Non-Newtonian flow can be classified according to the presence or absence of a yield value. A yield value represents that amount of force necessary before a liquid begins to flow. If a material does not exhibit a yield value, it is referred to as viscous flow and if it does, it is called plastic flow (30, 31). This division of flow type is rarely referred to in pharmaceutical literature, but it represents more precisely the fundamental types of flow with less ambiguity. According to this definition, a material which thins out or becomes less viscous as the rate of shear is increased is referred to as pseudoviscous rather than pseudoplastic, a term more commonly employed. The term pseudoplastic is reserved for that type of flow which becomes less viscous upon an increase in shear rate, but in addition, also exhibits a yield value. Dilatant materials, which become more viscous upon an increase in shear rate, must be identified further as dilatant-viscous or dilatant-plastic.

RESULTS

The effects of shear rate and age on the viscosity of the ammonia samples are shown in Table I. In sample 1 (0.6 mg. ammonia/100 ml.) the viscosity on day 1 at 0.6 r.p.m. was 3700 cps.; however, as the rate increased to 6 r.p.m. the viscosity dropped to 3630 cps. The influence of shear rate on viscosity became more marked in samples 2 (2 mg. ammonia/100 ml.) and 3 (6 mg. ammonia/100 ml.). Sample 2 decreased 220 cps. going from 3860 cps. at 0.6 r.p.m. to 3640 cps. and 6 r.p.m. Sample 3 exhibited a decline of 530 cps. as the rate was increased over the same interval. There were individual variations in each sample over the period of study, but no meaningful pattern could be defined.

Table I also shows that thixotropy appears to have developed by day 14 in sample 1. Although it could not be demonstrated on day 30, it appeared again on days 60 and 120. Samples 2 and 3 did not appear to display thixotropy until day 60, but after it developed it appeared to remain throughout the duration of the study.

The effect of shear rate on viscosity is further illustrated in Table II. The decrease in viscosity when the shear rate was increased from 0.6 to 6 r.p.m. is listed for each sample according to the day on which it was determined. The last column represents the mean decrease in viscosity for each sample. As shown in the table, the mean decrease in viscosity of sample 1 was 210 cps., whereas that for sample 3 was 590 cps. As was expected, the mean decrease in viscosity of sample 2 was intermediate to these values (340 cps.). Thus, there appears to be an inverse relation between amine concentration and susceptibility of the emulsions to shear rate.

Table III shows the effects of shear rate and age on the viscosities of the AMP emulsions. Pseudoviscous flow was also displayed by these emulsions. The influence of shear rate on the viscosities of samples 4, 5, and 6 (corresponding to 2, 6, and 20 mg. AMP/100 ml., respectively) is demonstrated in the same manner as for samples 1, 2, and 3. Sample 4 decreased in viscosity 130 cps. (from 3720 to 3590 cps.) as the shear rate was increased from 0.6 to 6 r.p.m. The effect of shear rate on viscosity

TABLE I.—EFFECT OF SHEAR RATE AND AGE ON THE VISCOSITY OF AMMONIA[a] EMULSIONS

Sample	Shear Rate (Spindle Speed, r.p.m.)	Viscosity, cps.[b] Day 1	Day 2	Day 4	Day 7	Day 14	Day 30	Day 60	Day 120
1	0.6	3700	4070	4060	4000	4000[c] / 3560	3960	3950 / 3320	4090 / 3790
	1.5	3680	3920	3920	3910	3850 / 3450	3810 / 3790	3810 / 3270	4030 / 3850
	3	3670	3860	3880	3840	3780 / 3400	3750 / 3730	3770 / 3200	3930 / 3800
	6	3630	3820	3840	3810	3730 / 3430	3720 / 3690	3740 / 3230	3890 / 3790

	1.5	3750	3850	4060	4040	3850	3770	3770 / 3710	3830 / 3440
	3	3660	3750	3990	3980	3750	3710	3700 / 3640	3790 / 3360
	6	3640	3660	3920	3920	3710	3650	3650 / 3590	3720 / 3300
3	0.6	4250	4320	4530	4470	4320	4320	4230 / 4020	4470 / 4340
	1.5	3940	4000	4200	4160	3990	3950	3880 / 3650	4190 / 4000
	3	3810	3850	4020	4020	3830	3810	3670 / 3460	4020 / 3840
	6	3720	3750	3920	3910	3720	3700	3530 / 3350	3930 / 3730

[a] Samples 1, 2, and 3 contain 0.6, 2, and 6 mg./100 ml., respectively. [b] Viscosity measured with the Brookfield viscometer is reproducible to ±1%. [c] Thixotropy is represented by two figures for the same day and spindle speed. The upper figure represents the "up" viscosity determined when the spindle speed was increased from 0.6 to 6 r.p.m. The lower figure represents the "down" viscosity determined when the spindle speed was decreased from 6 to 0.6 r.p.m.

TABLE II.—VISCOSITY DECREASE IN AMMONIA[a] EMULSIONS RESULTING FROM SHEAR RATE INCREASE FROM 0.6 TO 6 r.p.m.

Sample	Day Examined 1	2	4	7	14	30	60	120	Mean Decrease
1	70	250	240	190	270	240	210	200	210
2	220	490	350	330	350	360	360	290	340
3	530	570	610	560	600	620	700	540	590

[a] Samples 1, 2, and 3 contain 0.6, 2, and 6 mg./100 ml., respectively.

was not as apparent in samples 4 and 5 as it was in samples 1 and 2; however, sample 6 showed a marked effect when compared with sample 4. Over the same shear rate interval sample 6 decreased 470 cps. The effect of shear rate on viscosity also varied with age. These variations did not follow a meaningful pattern, however.

Thixotropy appeared on day 14 in all AMP emulsions and continued through day 120 in sample 4 but could not be demonstrated in sample 5 on day 30 nor in sample 6 on day 120. In each case where thixotropy was present, the emulsion showed complete structural recovery within 2 hr. after the test.

Table IV, constructed like Table II, illustrates the net effect of viscosity decrease with shear rate for each AMP sample according to age. Sample 4 showed a mean decrease of 240 cps. There was no change in the mean viscosity decrease between samples 4 and 5. Sample 6 does show greater mean decrease in viscosity than shown for samples 4 and 5. These data are consistent with those of the ammonia emulsions.

The effect of age on the droplet size in each emulsion studied is shown in Table V. The figures listed show the droplet size as per cent within a size class on the day examined for each sample studied. Upon inspection of the data for sample 1 it is easily seen that the per cent of droplets less than 0.5 μ decreased from 2.5 on day 1 to 0.6 on day 60, whereas the per cent of droplets 1.0 μ increased from 94.3 on day 1 to 96.0 on day 60. There was no significant change in the per cent of droplets with a diameter of 2.0 μ. Sample 2 shows the same pattern but to a lesser extent. Since the magnification in the photomicrographs was 480×,

TABLE III.—EFFECT OF SHEAR RATE AND AGE ON THE VISCOSITY OF AMP[a] EMULSIONS

Sample	Shear Rate (Spindle Speed, r.p.m.)	Viscosity, cps.[b] Day 1	Day 2	Day 4	Day 7	Day 14	Day 30	Day 60	Day 120
4	0.6	3720	3720	4140	4090	4000[c] / 3820	4140 / 3960	4110 / 3950	3980 / 3840

	6	3600	3520	3890	3890	3830 / 3670	3880 / 3820	3830 / 3580	3880

[a] Samples 4, 5, and 6 contain 2, 6, and 20 mg./100 ml., respectively. [b] Viscosity measured with the Brookfield viscometer is reproducible to ±1%. [c] Thixotropy is represented by two figures for the same day and spindle speed. The upper figure represents the "up" viscosity determined when the spindle speed was increased from 0.6 to 6 r.p.m. The lower figure represents the "down" viscosity determined when the spindle speed was decreased from 6 to 0.6 r.p.m.

TABLE IV.—VISCOSITY DECREASE IN AMP[a] EMULSIONS RESULTING FROM SHEAR RATE INCREASE FROM 0.6 TO 6 r.p.m.

Sample	Day Examined 1	2	4	7	14	30	60	120	Mean Decrease
4	130	120	240	180	220	240	290	510	240
5	140	160	260	180	420	230	260	250	240
6	470	200	450	400	560	510	430	510	440

[a] Samples 4, 5, and 6 contain 2, 6, and 20 mg./100 ml., respectively.

1 mm. was equivalent to 1.92 μ. The droplets in sample 3 were so small (in the range of 0.25 mm.) that they were impossible to measure; consequently, droplet size could not be obtained. It can be stated, however, that the droplets in this sample were less than 0.5 μ.

The emulsion having the lowest concentration of AMP is sample 4. As aging occurs, droplet size distribution appears as a decrease in per cent of droplets in smaller sizes and as an increase of larger sizes. The droplet size range narrows in sample 5; in sample 6 the droplet size became so small (as it did in sample 3) that a count could not be made. The droplet size range in sample 6 fell entirely below 0.5 μ.

The mean droplet size is reported in Table VI for each sample on the day it was determined. This table shows that even though a significant rise in droplet size with age cannot be demonstrated, the increase in mean droplet size with increased amine concentration is readily apparent.

DISCUSSION

It has been said that, with very few exceptions, all emulsion systems display some type of non-Newtonian flow characteristics especially when the phase volume exceeds 0.4 to 0.5 (23). The emulsions examined in this study proved no exception to this statement. A pronounced pseudoviscous type flow with the appearance of thixotropy was seen during the study. Thixotropy has been attributed to the formation of extended flocculated networks capable of giving the emulsion necessary structural properties before thixotropy can be seen (15, 16). Since flocculation is an important factor (15-21), its effects are seen to some extent in most

emulsions. Thus, it was not unexpected to see thixotropy displayed in all of the emulsions used in this study.

The increased influence of shear rate on viscosity as the rate was increased, as shown in both the ammonia and AMP emulsions, can undoubtedly also be explained on the basis of increased interaction between droplets or between the droplets and the dispersion medium.

The over-all increase in viscosity as the concentration of amine was increased agrees with previously cited work by Sherman (22). He concluded that the emulsifier can influence emulsion viscosity in several ways depending on its solubility in the two liquid phases, its chemical composition, the concentration used, and the physical properties of the film adsorbed around the droplets. The latter property has been studied on nonaqueous systems and will be described in a separate publication.

The effects of droplet size are also important here. A decreased mean droplet size corresponds to an increased total interfacial area. Both a decreased mean droplet size and an increased homodispersity was seen in the ammonia emulsions and also in the AMP emulsions. The effect of this on viscosity has been explained on the basis of a more uniform droplet size offering more resistance to flow, thus increasing viscosity (10), and by an increased interaction among droplets due to an increased interfacial area (12) with the effect being more pronounced when droplet dispersity becomes more uniform (13, 14).

Levius and Drummond (32) found that droplet size frequency analysis yielded more complete and reliable information about the internal state of the emulsion than was obtained from mean droplet size data only. This is in agreement with the results presented in Tables V and VI. The mean droplet size of each sample listed in Table VI gives the impression that little growth occurs between days 1 and 60. Table V reveals that droplet growth did continue through the entire period of study.

TABLE V.—EFFECT OF AGE ON DROPLET SIZE[a]

Diam., μ	Day Examined: 1	2	4	7	14	30	60
Sample 1, 0.6 mg. NH_3/100 ml.

TABLE VI.—EFFECT OF CONCENTRATION ON MEAN DROPLET SIZE[a]

Sample[b]	Day Examined: 1	2	4	7	14	30	60
1	2.04	2.04	2.04	2.05	2.04	2.05	2.05
2	0.80	0.80	0.81	0.84	0.84	0.84	0.84
3				Less than 0.5			
4	3.36	3.53	3.65	3.74	3.73	3.74	3.73
5	1.61	1.62	1.70	1.77	1.77	1.80	1.79
6				Less than 0.5			

[a] Numbers represent droplet diameters calculated in microns using Eq. 1. [b] Samples 1, 2, and 3 contain 0.6, 2, and 6 mg. NH_3/100 ml., respectively. Samples 4, 5, and 6 contain 2, 6, and 20 mg. AMP/100 ml., respectively.

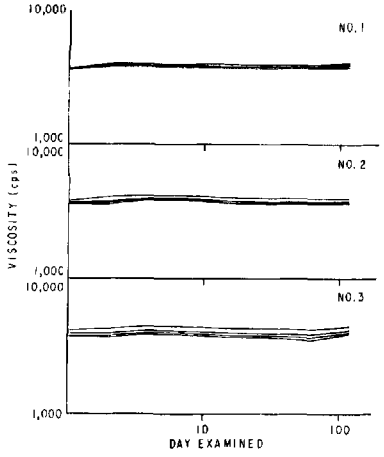

Fig. 1.—The effects of age on the viscosities of ammonia emulsions (logarithmic scale). Samples 1, 2, and 3 represent ammonia concentrations of 0.6, 2, and 6 mg./100 ml., respectively.

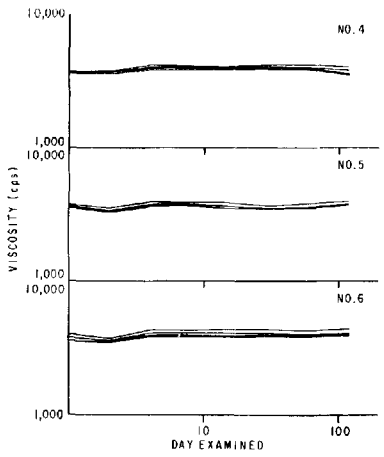

Fig. 2.—The effects of age on the viscosities of AMP emulsions (logarithmic scale). Samples 4, 5, and 6 represent AMP concentrations of 2, 6, and 20 mg./100 ml., respectively.

The fact that samples 2 and 5 both showed a smaller mean droplet size and droplet distribution than was seen with samples 1 and 4, respectively, infers a greater degree of stability between the emulsions as the amine concentration was increased. Even though a droplet size could not be calculated in either sample 3 or 6, the fact that both samples had sizes completely below 0.5 μ can have significant implications as to their stability.

Several published reports have shown the importance and usefulness of time plots on a logarithmic scale (33–36) in stability studies on dispersed systems. These studies demonstrated that linear relations existed when the logarithm of some property to be followed in the system was graphed with the logarithm of time. For example, Wood and Catacalos (36) applied this concept to studies on viscosity and concluded that changes in viscosity expected to occur after 1 year can be predicted from data on only 100 days.

In order to perform a similar evaluation of the data obtained in this study, logarithm time plots of viscosity and age for the various ammonia emulsions and AMP emulsions were prepared and are represented in Figs. 1 and 2, respectively. Figure 1 shows a fairly linear relation for each sample. Sample 3 takes a slight rise between day 60 and day 120. However, this increase, if continued, would not result in an appreciable rise after 1 year. Figure 2 also shows fairly good linearity. Therefore, no appreciable viscosity change should be seen after 1 year.

SUMMARY

Six olive oil-in-glycerin emulsions were prepared wherein ammonia and 2-amino-2-methyl-1,3-propanediol (AMP), in various concentrations, served as saponifying agents. Six-tenths, 2, and 6 mg. ammonia/100 ml. and 2, 6, and 20 mg. AMP/100 ml. were used in making the emulsions. The emulsions were stored at room temperature (25°) and droplet size, rheology, and emulsion stability studied on days 1, 2, 4, 7, 14, 30, and 60. Day 1 corresponded to the day the emulsions were prepared.

Droplet size, as measured from photographs taken by phase contrast photomicrography, was inversely related to amine concentration. This work also demonstrated that a droplet size frequency analysis was much more meaningful to a stability study than was mean droplet size data alone.

Rheology was studied on the respective test days with a Brookfield LVT viscometer. Viscosity was calculated from Brookfield data using the "*n* value" method described by Runikis and coworkers. These studies revealed the existence of non-Newtonian pseudoviscous flow with occasional thixotropy.

Logarithmic graphs of viscosity and time illustrate stability in the emulsion systems. These graphs also suggest that no significant changes in viscosity would be expected over longer time periods.

Effect of Surfactant Concentration on the Interfacial Viscosity of a Nonaqueous System

By RICHARD D. HAMILL* and ROBERT V. PETERSEN

The interfacial viscosities of the glycerin–olive oil interface after either ammonia or 2-amino-2-methyl-1,3-propanediol (AMP) had been added were studied by means of a viscous traction interfacial viscometer. The amine concentrations used were 0.6, 2, and 6 mg. ammonia/100 ml., and 2, 6, and 20 mg. AMP/100 ml. The results indicate that more rigid films were produced at the interface as amine concentrations were increased. The original viscosities and the increased viscosities resulting from increased amine concentrations were as would be predicted from fatty acid films. However, viscosities were not so high as thought to be necessary for stability against coalescence in emulsions.

PREVIOUS STUDIES from this laboratory have demonstrated that nonaqueous emulsions of glycerin and olive oil can be prepared by means of anionic, cationic, or nonionic surfactants (1, 2). It has further been pointed out that a high degree of emulsion stability can be achieved with extremely low concentrations of saponifying amines such as ammonia or 2-amino-2-methyl-1,3-propanediol (AMP). Indeed, concentrations barely sufficient to produce monomolecular films of the amine soap at the interface produced stable emulsions (3).

The effect on emulsion stability of a rigid interfacial film as a mechanical barrier to coalescence has been studied by several investigators. In 1941, King (5) proposed that the strength and compactness of the interfacial film in an emulsion were the most important factors favoring stability. A year earlier, Schulman and Cockbain (6, 7) implied the necessity of high interfacial viscosity for emulsion stability by stating several conditions essential for optimum stability including the need for a "condensed" interfacial film. Becher (8) has also suggested that the formation of a rigid interfacial film is a mechanism in stabilizing emulsions. Sumner (10) supports this concept by suggesting that the mechanical strength of the film of emulsifying agent around the droplets is important. Blakey and Lawrence (11) found a partial correlation between emulsion stability and surface viscosity at the solution–air surface. More recently, the mechanical resistance of the film and emulsion stability have been related (12, 13).

Because of the remarkable stabilizing effect of ammonia and AMP and because it has been repeatedly suggested that a relation exists between emulsion stability and the interfacial viscosity and mechanical strength of the film in oil–water systems (4–13), it seemed important to study the interfacial viscosities of the glycerin–olive oil system containing varying concentrations of amine to determine if a similar relation exists which could help to explain the unusual stability of emulsions of these components.

EXPERIMENTAL

The term interfacial viscosity, as used throughout this study, is defined as the shear viscosity of a monolayer spread or adsorbed at the interface

Effect of Surfactant Concentration on the Interfacial Viscosity of a Nonaqueous System

By RICHARD D. HAMILL* and ROBERT V. PETERSEN

The interfacial viscosities of the glycerin–olive oil interface after either ammonia or 2-amino-2-methyl-1,3-propanediol (AMP) had been added were studied by means of a viscous traction interfacial viscometer. The amine concentrations used were 0.6, 2, and 6 mg. ammonia/100 ml., and 2, 6, and 20 mg. AMP/100 ml. The results indicate that more rigid films were produced at the interface as amine concentrations were increased. The original viscosities and the increased viscosities resulting from increased amine concentrations were as would be predicted from fatty acid films. However, viscosities were not so high as thought to be necessary for stability against coalescence in emulsions.

PREVIOUS STUDIES from this laboratory have demonstrated that nonaqueous emulsions of glycerin and olive oil can be prepared by means of anionic, cationic, or nonionic surfactants (1, 2). It has further been pointed out that a high degree of emulsion stability can be achieved with extremely low concentrations of saponifying amines such as ammonia or 2-amino-2-methyl-1,3-propanediol (AMP). Indeed, concentrations barely sufficient to produce monomolecular films of the amine soap at the interface produced stable emulsions (3).

The effect on emulsion stability of a rigid interfacial film as a mechanical barrier to coalescence has been studied by several investigators. In 1941, King (5) proposed that the strength and compactness of the interfacial film in an emulsion were the most important factors favoring stability. A year earlier, Schulman and Cockbain (6, 7) implied the necessity of high interfacial viscosity for emulsion stability by stating several conditions essential for optimum stability including the need for a "condensed" interfacial film. Becher (8) has also suggested that the formation of a rigid interfacial film is a mechanism in stabilizing emulsions. Sumner (10) supports this concept by suggesting that the mechanical strength of the film of emulsifying agent around the droplets is important. Blakey and Lawrence (11) found a partial correlation between emulsion stability and surface viscosity at the solution–air surface. More recently, the mechanical resistance of the film and emulsion stability have been related (12, 13).

Because of the remarkable stabilizing effect of ammonia and AMP and because it has been repeatedly suggested that a relation exists between emulsion stability and the interfacial viscosity and mechanical strength of the film in oil–water systems (4–13), it seemed important to study the interfacial viscosities of the glycerin–olive oil system containing varying concentrations of amine to determine if a similar relation exists which could help to explain the unusual stability of emulsions of these components.

EXPERIMENTAL

The term interfacial viscosity, as used throughout this study, is defined as the shear viscosity of a monolayer spread or adsorbed at the interface

Received April 20, 1966, from the College of Pharmacy, University of Utah, Salt Lake City, 84112.

between two liquids. The term surface viscosity, on the other hand, is the shear viscosity of a monolayer spread or adsorbed at the surface of a liquid (14). Both interfacial and surface viscosities have the dimensions MT^{-1}, instead of $ML^{-1}T^{-1}$ as for bulk viscosity (where M, L, and T represent mass, in Gm., distance, in cm., and time, in sec., respectively), and are measured in units of Gm. sec.$^{-1}$ called "surface poise" (s.p.).

Interfacial viscosity was measured by means of the instrument shown in Fig. 1. Except for the diameter of the wire (0.078 cm. instead of 0.064 cm.) used to form the concentric rings and the driving mechanism (Bodine speed reduction motor and appropriate pulley arrangement), this instrument was constructed according to the specifications of the modified viscous traction interfacial viscometer of Davies and Mayers (15). The specifications of the instrument will be mentioned briefly. The two concentric stainless steel wire rings were held in place by the larger support rods

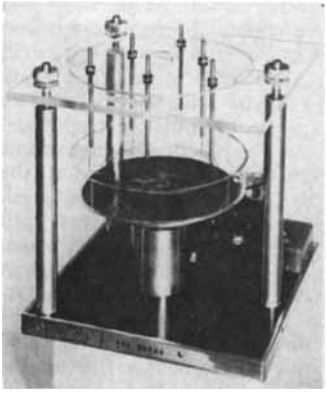

Fig. 1.—Interfacial viscometer.

attached to the upper plastic platform. Three wires of the same diameter as used for the rings were soldered to each ring and made to lie in the plane of the rings for a short distance (about 1.5 cm.) before they were bent upward and soldered to the support rods. The diameters of the outer and inner rings were 12.5 and 11.6 cm., respectively. A Pyrex dish, 18.5 cm. in diameter and 4 cm. high, was centered on the turntable and held the liquids which formed the interface to be studied. The turntable rotated at 1 rev. in 38 sec. The wire rings were held stationary by both the support rods and the upper platform, but the platform could be adjusted, thereby raising and lowering the rings to the desired position.

The methods employed in the use of the instrument were also patterned after those described by Davies and Mayers (15). The results obtained are dependent upon the amount of retardation of the film flowing in the canal when the interface is clean and when an additive is present. To measure retardation, talc particles were placed at the interface and the time for 1 rev. was measured. The rings were raised slightly above the interface producing a meniscus, which acted as a trough to insure that the talc particles remained in the canal.

In order to determine if the difference in wire diameter modified the calibration curve used by Davies and Mayers when applied to this instrument, three experiments were performed. First, the two interfaces (benzene/water and ethyl acetate/water) utilized by the original investigators when calibrating their instrument at the oil–water interface were formed and duplicate results were obtained. Second, Davies and Mayers reported interfacial viscosities of monolayers adsorbed from 4×10^{-3} M sodium lauryl sulfate solutions at the benzene–water interface as 1.5×10^{-4} s.p. at 20° and as 1×10^{-4} s.p. at 22°. The viscometer constructed for this study gave an interfacial viscosity of 1.2×10^{-4} s.p. at 21°. Third, Davies (4) reported the surface viscosity of stearic acid on 0.01 N HCl as 6.25×10^{-4} s.p. at 20.1 Å.^{2}. A similar film was used to verify this value with the present instrument. A benzene solution of stearic acid was applied to the surface of 0.01 N HCl using a micrometer syringe. Surface area calculations were corrected for the small area occupied by the wire rings. A surface viscosity of 6.5×10^{-4} s.p. was obtained when measuring this film. These data suggest that the results obtained with this instrument are remarkably similar to those obtained by Davies and Mayers and that their calibration curve can be used within the range of duplicate results.

Six solutions of amine in glycerin were prepared to correspond with the concentrations of ammonia (0.6, 2, and 6 mg./100 ml.) and 2-amino-2-methyl-1,3-propanediol (AMP) (2, 6, and 20 mg./100 ml.) used in emulsions studied and reported in a separate publication (16). These concentrations were based on the total amount of olive oil and glycerin contained in the dish. The ratio of glycerin to olive oil was 60:40 analogous to a phase volume of 0.40 used in the olive oil-in-glycerin emulsions previously studied (16).

The mean time of 1 rev. at the clean glycerin–olive oil interface was determined. Following this, mean revolution times were measured at the glycerin–olive oil interface after varying amounts of ammonia or AMP had been added. All determinations were made at 20°.

Each interface was measured within a few minutes after it was formed and at intervals over the next 2 hr. Several revolutions were timed and averaged to obtain the mean time of 1 rev. The mean time of the clean glycerin–olive oil interface was subtracted from the mean time of each sample to determine the amount of retardation. The calibration curve (Fig. 2) was then used to obtain the interfacial viscosity in s.p.

RESULTS

Table I lists the results of the interfacial viscosity studies at the glycerin–olive oil interface.

When the interface was clean (no amine added) the mean time of 1 rev. was 171 sec., corresponding to no retardation and therefore, no interfacial viscosity. Upon the addition of 0.6 mg. ammonia/100 ml. to the glycerin phase, the mean time of 1 rev. at the interface was 185 sec. representing a 14-sec. retardation. This was equivalent to an interfacial viscosity of 1.2×10^{-4} s.p. The mean revolution time rose to 204 sec. with the addition of 2 mg. ammonia/100 ml. to the glycerin phase. This represented a retardation of 33 sec. and a

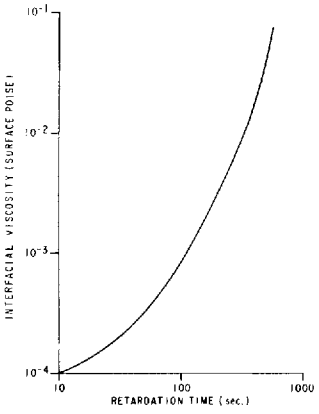

Fig. 2.—Calibration curve for the interfacial viscometer. [After Davies and Mayers (15).]

viscosity of 2.2×10^{-4} s.p. A 52-sec. retardation time was shown when 6 mg. ammonia/100 ml. was added to glycerin. This corresponded to a mean revolution time of 223 sec. and an interfacial viscosity of 3.4×10^{-4} s.p.

Upon the addition of 2, 6, and 20 mg. AMP/100 ml. to the glycerin phase, mean revolution times of 206, 217, and 225 sec., respectively, were obtained; these represent retardation times of 35, 46, and 54 sec., and interfacial viscosities of 2.3×10^{-4}, 3.0×10^{-4}, and 3.6×10^{-4}, respectively.

All interfaces formed with either ammonia or AMP in the glycerin phase showed constant mean revolution times within 30 min.

DISCUSSION

This study was undertaken to measure the effects of various concentrations of ammonia or AMP upon the interfacial viscosities of the glycerin–olive oil interface.

The existence of surface viscosity was first observed by Plateau in 1869 (14). Plateau observed that a fluid surface exhibited resistance to deformation or flow from the difference in damping rates of a compass needle oscillating on the surface and in the interior of a liquid. Since that time several methods for the measurement of surface and interfacial viscosities have been developed (4, 15, 17–22). However, the modified "flow through a canal" method of Davies and Mayers was selected for this study because of several inherent advantages. Ewers and Sack (21) have discussed the validity of the "flow through a canal" technique with soluble layers. They pointed out that where surface pressure is applied to soluble layers, part of the adsorbed film merely dissolves in the interior of the liquid instead of passing through the canal. The "viscous traction" modification of Davies (4) and Davies and Mayers (15) overcomes this disadvantage by allowing the liquid substrate to cause the film to move. Another advantage in the use of this modification is that the width of the canal can be varied and made as narrow as required to increase the sensitivity when working with monolayers of very low viscosity. Joly (14) states that this method is considered best for measuring films of low Newtonian viscosity. The existence of both Newtonian viscosity and viscosity of a low magnitude (10^{-4} s.p.) can easily be established for the glycerin–olive oil system. The very presence of olive oil with its free fatty acid content makes it reasonable to hypothesize that the surfactant found at the interface is a fatty acid type. Furthermore, Joly (23) states that practically all monolayers of fatty acids and triglycerides are Newtonian and are of a low order of magnitude.

The disadvantage in the use of this instrument involves the mathematical interpretation of the hydrodynamics of the process. Since this is extremely complicated, Davies and Mayers calibrated their instruments using films of known surface viscosities. After calibrating the instrument at the air–water surface, they applied it to the oil–water interface. In the first instance, a benzene water interface was measured and flow in the canal was found to take only 10 sec. longer than at the clean air–water surface. When ethyl acetate was used in place of benzene, 1 rev. took only 5 sec. longer. Because of this approximate equality, they concluded that the viscous drag, which the rotating oil exerts on the talc in the canal, balances the extra drag on the interface by the stationary canal walls *via* the adjacent oil. Therefore, the same calibration curve which was determined at the air–water surface was used at the oil–water interface. Davies

Table I.—Interfacial Viscosity of Glycerin–Olive Oil Interface After the Addition of Either Ammonia or AMP

Additive	Mean Time of 1 rev., sec.	Retardation, sec.	Interfacial Viscosity, $\times 10^{-4}$ s.p.
No additive	171 (170–175)[a]	0	0
0.6 mg. NH_3/100 ml.	185 (182–187)	14	1.2
2 mg. NH_3/100 ml.	204 (203–205)	33	2.2
6 mg. NH_3/100 ml.	223 (221–223)	52	3.4
2 mg. AMP/100 ml.	206 (202–209)	35	2.3
6 mg. AMP/100 ml.	217 (215–219)	46	3.0
20 mg. AMP/100 ml.	225 (223–229)	54	3.6

[a] Numbers in parentheses indicate the range of observed revolution times from which mean time was calculated.

and Mayers claim that their instrument can be used to study interfacial viscosities from 10^{-4} to 10^{-1} s.p. The only portion of the curve utilized in this study was between 10^{-4} and 10^{-3} s.p., which was essentially within the range where duplicate results were obtained with known films.

The results obtained demonstrate that there is a measurable increase in viscosity when the concentration of ammonia is raised from 0.6 mg./100 ml. to 6 mg./100 ml. At 0.6 mg./100 ml. the interfacial viscosity was 1.2×10^{-4} s.p. This increased to 2.2×10^{-4} s.p. at 2 mg./100 ml. and rose again at 6 mg./100 ml. to 3.4×10^{-4} s.p.

The addition of AMP to the glycerin phase showed a similar increase in interfacial viscosity. At 2 mg./100 ml., the interfacial viscosity was 2.3×10^{-4} s.p. The interfacial viscosity rose to 3.0×10^{-4} at 6 mg./100 ml. and to 3.6×10^{-4} s.p. at 20 mg./100 ml.

Davies and Rideal (24) state that monolayers of fatty acid esters which give "gaseous" films of great areas are characterized by Newtonian flow and low viscosities (10^{-5} to 10^{-4} s.p.). Monolayers of higher fatty acid esters and of oleic acid also show Newtonian flow and viscosities of this order, but show an increase in viscosity as the concentration is increased and the available surface area decreased producing a more "condensed" film.

Davies (25) reports that an interfacial viscosity of at least 10^{-2} s.p. *seems* to be required if the interfacial film is not to allow coalescence during the close approach of two droplets. The results of this study indicate that a more rigid film is produced at the interface as the amine concentration is increased. The results also indicate that the orders of magnitude of the viscosities and their increases over the concentrations studied were similar to viscosities predictable from Newtonian fatty acid films, but that they were not so large as Davies suggests is needed for coalescence inhibition.

The knowledge that a more viscous interfacial film is present in the glycerin–olive oil system is not meaningful in itself, but when correlated with published work on the stability of glycerin–olive oil emulsions (16), a significant relation can be hypothesized. When either ammonia or AMP was employed in the emulsion system, stability as seen by droplet size distribution data, increased as the added amine was increased. This study then has demonstrated that stability can be achieved in these emulsions with interfacial viscosities which are on the order of 100 times lower than that considered necessary.

SUMMARY

A viscous traction interfacial viscometer, patterned after the one described by Davies and Mayers, was used to measure interfacial viscosity at the glycerin–olive oil interface after either ammonia or 2-amino-2-methyl-1,3-propanediol (AMP) had been added. The concentrations of amine employed corresponded with those used in an olive oil-in-glycerin emulsion stability study.

The results indicate that a more rigid film was produced at the interface as the amine concentration was increased. The interfacial viscosity increased from 1.2×10^{-4} s.p. at 0.6 mg. ammonia/100 ml. to 3.4×10^{-4} s.p. at 6 mg./100 ml. The interfacial viscosity of the AMP film increased similarly. At 2 mg. AMP/100 ml., the interfacial viscosity was 2.3×10^{-4} s.p. This rose to 3.6×10^{-4} s.p. at 20 mg./100 ml.

The viscosities measured and the increases seen are as would be predicted from known fatty acid films. However, the viscosities were on the order of 100 times smaller than that thought necessary for stability against coalescence in emulsions.

Determination of 7-Bromo-1,3-dihydro-5-(2-pyridyl)-2H-1,4-benzodiazepin-2-one (Ro 5-3350) in Blood by Gas–Liquid Chromatography

By J. ARTHUR F. DE SILVA and J. KAPLAN

A method for the determination of Ro 5-335 0 [7-bromo-1,3-dihydro-5-(2-pyridyl)-2H-1,4-benzodiazepin-2-one] in whole blood of humans is described involving selective extraction into ether, acid hydrolysis, and analysis by gas–liquid chromatography. The method has good sensitivity (0.07 to 0.10 mcg./ml., blood), is specific for Ro 5-3350 after it is hydrolyzed to 2-amino-5-bromo-benzoylpyridine, and has an acceptable recovery of the order of 61.0 ± 3.0 per cent. The method has been successfully applied to the determination of Ro 5-3350 in samples obtained from a blood level fall-off study.

Ro 5-3350 [7-BROMO-1,3-DIHYDRO-5-(2-PYRIDYL)-2H-1,4-BENZODIAZEPIN-2-ONE] (1) is a new psychotherapeutic drug of the 1,4-benzodiazepine class of compounds (2, 3). It is undergoing clinical evaluation as a psychotropic drug in the control of ambulatory schizophrenics.

The compound is chemically related to chlordiazepoxide[1] and diazepam.[2] Ro 5-3350 undergoes strong acid hydrolysis to an aromatic primary amine which can be measured by a Bratton-Marshall procedure as is chlordiazepoxide (4) (Scheme I).

Studies of Schwartz and Baukema (5) with ^{14}C-labeled Ro 5-3350 (labeled in the benzodiazepine ring at $\diagdown C{=}O$, Scheme I) conducted in dogs revealed that the maximum concentration of the compound in blood after a 3.5-mg./Kg. oral dose totaling 36 mg. was 0.90 mcg./ml. 4 hr. after administration of the drug. This indicated the need for an assay capable of detection in the submicrogram range and suggested the use of gas–liquid chromatography (GLC).

Preliminary work showed that intact Ro 5-3350 could not be determined by GLC because of thermal decomposition at the high flash temperatures required for volatilization. However, strong acid hydrolysis of the compound to 2-amino-5-bromo-benzoylpyridine (ABBP), Scheme I, reaction 3, gave a good response to electron-capture detection when chromatographed on a 2-ft. column of 2% Carbowax 20M-TPA (6). The method finally adopted utilized the electron-capture detector response to ABBP for the determination of the parent compound. Ro 5-3350 in blood or plasma was extracted at pH 9.0 into diethyl ether and then re-extracted from ether into 6 N H_2SO_4. The Ro 5-3350 in this acid medium was hydrolyzed to 2-amino-5-bromo-benzoylpyridine (ABBP) and glycine, after which the acid phase was neutralized, and the ABBP was extracted into diethyl ether. The residue after the evaporation of ether was taken up in a known volume of n-hexane, an aliquot of which was analyzed by GLC. The area of the ABBP peak was used to determine the concentration of Ro 5-3350 in the sample.

EXPERIMENTAL

Operational Parameters.—Instrument: Jarrell-Ash chromatograph, Universal model 28-700 with a 100 mc. titanium tritide electron-capture detector (No. 28-750). Column: a 2-ft. column of 2% Carbowax 20M–TPA on silanized Gas Chrom P 100–120 mesh contained in stainless steel 1/4-in. tubing. Carrier gas: nitrogen passed through a molecular sieve before entering the column and adjusted to a flow rate of 250–300 ml./min. Column head pressure: 25–27 psig on a second stage of gas regulator. Conditions of column head pressure and flow rate may be varied so as to obtain a retention time for ABBP between 6 and 7 min. for effective separation from adjacent peaks. Temperature of oven: 220 ± 2° (isothermal). Temperature of injection port: 250 ± 2°. Temperature of detector: 210 ± 2°. Amplifier range: 1.0×10^{-9} amp. full-scale deflection. Optimum detector voltage for ABBP: 20–30 v. d.c. Output on recorder: 1.0 mv. (Brown-Honeywell.) Chart speed: 1.25 cm./min. = 30 in./hr. Time constant: 1 sec. Minimum detectable amount of ABBP = 5.0×10^{-9} Gm. (5.0 ng.). Retention time (R_t) of ABBP = 6–7 min.

Preparation of Column Substrate.—The inert support Gas Chrom P 100/120 mesh (Applied Science Labs, State College, Pa.) was silanized, and coated with Carbowax 20M-TPA (Wilkens Instrument and Research, Inc.) to give a 2% loading on a weight–weight basis (7).

Packing and Conditioning the Chromatographic Column.—A 2-ft. piece of stainless steel tubing was

Chemical Reactions of Chlordiazepoxide, Diazepam, and Ro 5-3350.

packed with the prepared substrate and conditioned for 24–48 hr. at 240° (7). A properly conditioned and sensitized column had a useful life-span of about 6 months of continuous use.

Determination of Standard Curve of ABBP

2-Amino-5-bromo-benzoylpyridine synthesized by Fryer *et al.* (1) of >98% purity was dissolved in hexane to yield a stock standard solution of 1 mg./ml. From this solution suitable dilutions were made with *n*-hexane to yield final standard solutions covering the range of 5 ng./10 μl. to 30 ng./10 μl. Three 10-μl. aliquots of each of the final solutions were injected and from their average peak areas a standard curve of peak area (cm.²) *versus* nanograms of ABBP was drawn as shown in Fig. 1. A standard curve should be determined for each day of analysis because column performance and detector response to ABBP changes with time.

Procedure

Reagents.—All reagents must be of reagent grade purity (>98%) and all inorganic reagents were made up in triple-distilled water. 6 *N* H_2SO_4 in triple-distilled water. 6 *N* NaOH in triple-distilled water.

1 M H_3BO_3–Na_2CO_3–KCl Buffer.—Dissolve 62.8 Gm. of boric acid (H_3BO_3) and 74.6 Gm. of KCl/L. of triple-distilled water. Dissolve 106.0 Gm. Na_2CO_3/L. of triple-distilled water. To 630 ml. of the boric acid–KCl solution add 370 ml. of the Na_2CO_3 solution to make a liter of buffer solution. Shake well and check pH, buffer it up to pH 9.0 if necessary with the Na_2CO_3 solution. This solution is 1 *M* with respect to H_3BO_3–Na_2CO_3–KCl. The solution should be stored at about 35–37° to prevent crystallization of the salts out of the solution.

Diethyl Ether.—Analytical reagent grade ether (absolute) containing not more than 0.0005% residue after evaporation and peroxide content not more than 0.00005% (Mallinckrodt) must be used from a freshly opened can on the day of use or up to 3 days after opening.

n-Hexane.—Reagent grade "spectranalyzed" hexane (Fisher) containing not more than 0.0003% residue after evaporation must be used.

Into a 40-ml. glass-stoppered centrifuge tube, add 1 ml. of sample of blood containing Ro 5-3350, 2 ml. of triple-distilled H_2O, and 5 ml. of pH 9.0 1 *M* borate buffer, and mix well by tapping.

Add 15 ml. of ether, seal stopper with triple-distilled water, and shake on a reciprocating shaker for 10 min. Centrifuge at 0–5° (refrigerated centrifuge) for 5 min. at 2100 r.p.m. to separate the layers and transfer ether phase into another 40-ml. glass-stoppered tube.

Re-extract the blood with another 10 ml. of ether and combine the ether extracts.

Add 5 ml. of 6 *N* H_2SO_4 to the combined ether extract, shake for 10 min., and centrifuge for 5 min. to effect a quantitative separation of the ether and acid phases. Remove the ether layer by aspiration with a capillary pipet.

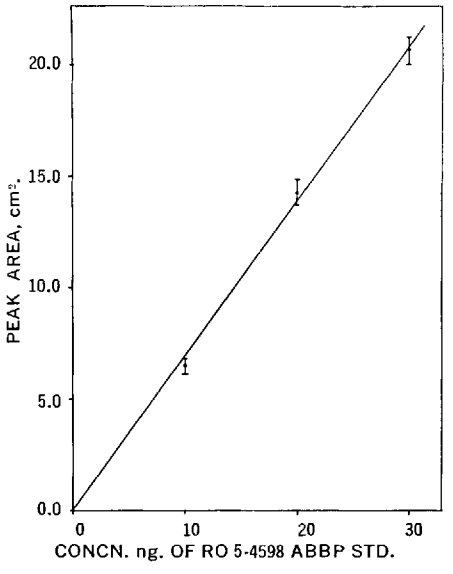

Fig. 1.—Linear response of ABBP standards on a 2-ft. column of 2% Carbowax 20M-TPA on silanized Gas Chrom P.

Extract the acid phase once by shaking with 10 ml. of ether for 10 min., followed by a second extraction with 10 ml. of ether for 5 min. After each extraction centrifuge for 5 min. to separate the phases and remove the respective ether layers by aspiration with a capillary pipet.

Place the tube containing the ether-washed H_2SO_4 extract (unstoppered) in a hot water bath (80–90°) for 10 min. to drive off all the remaining ether. Then stopper the tube (seal with triple-distilled water) and place it in a boiling water bath for 2.5 hr. to hydrolyze the Ro 5-3350 to ABBP.

After hydrolysis, cool the sample in ice, and add 1 drop of bromthymol blue indicator (0.1% in 50% alcohol). Neutralize the cooled H_2SO_4 extract in ice with 6 *N* NaOH to a blue color.

Add 10 ml. of ether to the neutralized sample, seal the stopper with triple-distilled water, and shake for 10 min. on a reciprocating shaker. Centrifuge for 5 min. to separate the phases and transfer the ether layer into a 15-ml. glass-stoppered conical centrifuge tube, and evaporate the ether down to a volume of about 1 ml.

Re-extract the sample with another 10 ml. of ether and combine the ether extracts in the 15-ml. centrifuge tube.

Centrifuge the combined ether extracts for 5 min. and carefully remove any aqueous layer present using a hypodermic syringe fitted with a cannula (BD-20, 15 cm. in length).

Evaporate the combined ether extracts to dryness in a hot water bath and dry the residue in a vacuum desiccator for 30 min. The samples must not be maintained under vacuum for more than 1 hr. or loss of ABBP is incurred.

Dissolve the residue in 100 μl. of *n*-hexane and ensure uniform distribution and solution of the material by tapping the tube for 60 sec.

A suitable-sized aliquot, 1–10 μl., of the final 100 μl. of *n*-hexane extract of the sample residue is chromatographed and the ABBP peak is identified by its retention time.

The area of this peak is determined and the nanogram amount of ABBP present is obtained from a standard curve. The nanogram amount of Ro 5-3350/ml. of blood or plasma is determined from the total nanograms of ABBP × 1.142 [conversion factor, based on the molecular weights of Ro 5-3350 (316.16) and ABBP (276.9), respectively]. The amount of compound present in the samples should be corrected for the per cent recovery of internal standards run concurrently.

RESULTS AND DISCUSSION

Preparation of the Sample for GLC.—Two problems were encountered in this phase of the study. The first one was to effect a quantitative extraction of Ro 5-3350 from blood and back into 6 *N* H_2SO_4, the second was the complete hydrolysis to ABBP and the extraction of this compound into ether. Because of the basic nature of the compound it was found that Ro 5-3350 was quantitatively extracted (97–99%) into diethyl ether from blood buffered to pH 9.0 and back into 2 *N* HCl as determined by its U.V. absorbance values in 2 *N* HCl, $A_{240}^{\text{max.}} = 0.057$/mcg. The recovery from blood into ether was also determined to be 98–99% of added Ro 5-3350 using ^{14}C-labeled material determined by radioisotope scintillometry (Table I). When the ether phase was extracted with 6 *N* H_2SO_4, all the radioactivity (dpm) was quantitatively removed into the acid.

The next step, conversion of Ro 5-3350 to ABBP by acid hydrolysis in 6 *N* H_2SO_4 and the extraction of ABBP into ether was studied, and was followed by thin-layer chromatography (TLC) on Silica

Gel G (Stahl) with a fluorescent indicator in two solvent systems: *n*-heptane–chloroform–ethanol (10:10:1) and in ethyl acetate. By running separate standards of Ro 5-3350 and ABBP alongside the hydrolysate extract and by viewing the developed plate under shortwave U.V. light, the position of each compound was made visible so that the segments of Silica Gel G containing them could be scraped off the plate and either counted by radioisotope scintillometry or analyzed by GLC. Using ^{14}C-labeled Ro 5-3350 extracted from blood into ether and back in 6 *N* H_2SO_4, and also added directly to 6 *N* H_2SO_4 and hydrolyzed for 2.5 hr. at 100°, no significant radioactivity was measurable in the Ro 5-3350 area on TLC. This indicated that the compound was quantitatively converted. The area on the TLC plate having the same R_f as the ABBP standard showed an intense yellow band which was scraped off, extracted into ether, and analyzed by GLC. This compound had the same retention time as the ABBP standards and was quantized from a standard curve of ABBP.

Studies on the kinetics of the hydrolysis of Ro 5-3350 to ABBP showed that 6 *N* H_2SO_4 produced the more reproducible and optimal yield of the compound when compared with 6 *N* HCl. The average recovery of Ro 5-3350 after hydrolysis for 2.5 hr. at 100° (boiling water bath) was determined by GLC and was found to be of the order of 77% ± 3% of initially added compound (Table II). This yield could not be improved, and it is suspected that a loss of ABBP under the hydrolysis conditions to *p*-bromoaniline and nicotinic acids (Scheme I, reaction 3) occurs with the resultant loss in yields of ABBP. The conversion of Ro 5-3350 to ABBP is quantitative as there was no measurable amount of residual Ro 5-3350-^{14}C left after hydrolysis, as determined by TLC and radioisotope scintillometry. The amount of ABBP recovered after hydrolysis was determined by GLC. The possible interference of *p*-bromoaniline with the GLC determination of ABBP was investigated. The compound does not interfere with the quantization of ABBP. The use of 6 *N* H_2SO_4 over 6 *N* HCl also gave cleaner chromatograms for control blood after a 2.5-hr. hydrolysis (Fig. 2, curve A).

During the investigation of suitable clean-up methods for the purpose of eliminating interfering peaks, it was found that centrifuging at each extraction gave clean separation of ether and aqueous phases resulting in a minimal contamination of the ether extracts with water-soluble material. Washing the H_2SO_4 with ether, centrifuging the final ether extract, and careful removal of any droplets of water and alkali carried over in the transfer operation very effectively cleaned up the extract and gave a very clean chromatogram in the area of the ABBP peak.

Parameters for Gas Chromatography

The development of GLC parameters for the determination of ABBP involved the investigation of several phases of which Carbowax 20M (CBW 20M) and ethylene glycol adipate (EGA) proved to be the most satisfactory. Using 2-ft. columns of 2% CBW 20M or 2% EGA on silanized Gas Chrom P 100/120 mesh, the minimum detectable amounts of ABBP were in the order of 50 to 100 ng. by electron capture. This level was not sensitive enough since the blood levels from the dog experiments (5) indicated the need for an assay in the 10–20 ng. order of sensitivity for ABBP.

The compound ABBP has an aromatic amine group and the pyridyl-*N* moiety, both of which are electrophilic groups, and thus would tend to reduce the electronegativity of the Br and carbonyl groups. This would tend to reduce the response of ABBP to electron-capture detection (ECD) by GLC. The formation of a derivative (8) which would reduce or eliminate such effects was attempted (Scheme I, reaction 4) but was unsuccessful in the submicrogram range. A few grams of the "fluorenone" derivative was synthesized (9) for use as an analytical standard. It showed excellent response to ECD with a minimum detectable range of 5–10 ng.

The use of lightly loaded columns of 2-ft. 0.20–0.25% Carbowax 20M on micro glass beads 100–120 mesh gave better results on GLC and enabled the determination of 10–20 ng. of ABBP as minimum detectable amounts. The major disadvantage with this preparation was a marked tailing of the ABBP peak and short column life of 4–6 weeks after which the entire column had to be discarded. Finally the use of 2% Carbowax 20M-TPA as the

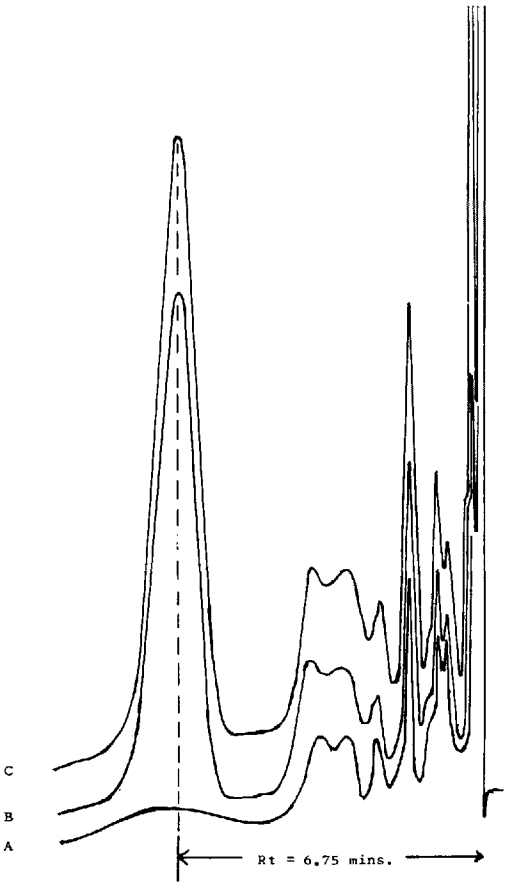

Fig. 2.—Chromatogram of control blood (A) and control blood containing 400 ng. (B) and 500 ng. (C) of added Ro 5-3350 recovered as the ABBP compound (10/100 μl.).

[a] Total ng. ABBP × 1.142 = Ro 5-3350 equivalent.

liquid phase gave the best results, with well-resolved symmetrical peaks, and a minimum detectable limit of 5–10 ng. of ABBP. It is believed that the terminal TPA moiety of this polyester phase inactivates adsorbent sites still remaining exposed after silanizing and produces a very thin uniform coating which enhances resolution and sensitivity by minimizing losses on the column due to adsorption.

Gas Liquid Chromatography of Sample Extracts.—The response of the electron capture detector to ABBP standards of concentrations ranging from 10.0–30.0 ng. was found to be linear when chromatographed on a properly conditioned column of 2% Carbowax 20M-TPA, as is demonstrated by the standard curve (Fig. 1). Using a constant-injection volume of 10 μl. it was possible to reproduce repeated injections of the same standard within very close limits. Since the response of the detector changes with time possibly due to contamination of the foil with a resultant change in standing current, it was necessary to plot a standard curve for each day of use. A properly conditioned and sensitized column has an average useful life span of about 6 months of continuous use, after which it begins to show signs of deterioration. When the peak response of the column to any given ABBP standard has dropped by 10% or more of its previously determined peak value it is advisable to discharge the column and repack it with fresh substrate and repeat the conditioning operation.

Recovery Experiments

The over-all recovery of known amounts of Ro 5-3350 added to blood and taken through the entire procedure was determined by gas chromatography as the ABBP compound, Fig. 2, curves B and C. The average over-all recovery of 200–500 ng. of Ro 5-3350 added to 1 ml. of blood was in the order of 61% ± 3.0% (Table III). This represents the product of a 98–99% recovery of Ro 5-3350 from blood into 6 *N* H_2SO_4, and an average hydrolysis and recovery of the compound as ABBP of 77%. This represents a theoretical over-all recovery of 75–76%, but in actuality only a 61% recovery is obtained. The discrepancy of 15% recovery has not been satisfactorily accounted for as yet. However, the practical recovery obtained is very reproducible. The minimum detectable amount of ABBP is 5–10 ng./10 μl., and the sensitivity limit of the method is of the order of 0.07–0.10 mcg./ml. of blood or plasma. Blood specimens from a patient who had received a single 15-mg. oral dose of the compound were pooled and extracted into ether using 1 *M* pH 9.0 buffer. The extract was analyzed by thin-layer chromatography (TLC) in two solvent systems: ethyl acetate–NH_4OH–(97:3, v/v) and chloroform–heptane–ethanol (10:10:5, v/v) and showed the presence of Ro 5-3350 which yielded ABBP on strong acid hydrolysis and GLC analysis. This demonstrates the specificity of the extraction procedure and GLC assay for Ro 5-3350 (Fig. 3).

Application of the GLC Method to Biological Samples

Blood Level Fall-Off Curves of Ro 5-3350 Following the Administration of a Single 15-mg. Oral Dose in Man.—Three patients were each given a

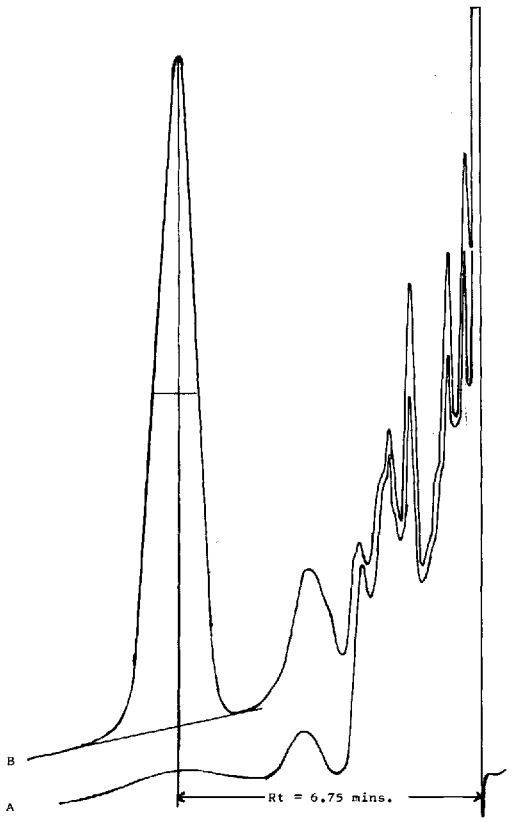

Fig. 3.—Chromatogram of blood extracts from a patient (E.M.) prior to medication, control blood (A), and 4 hr. after a single 15-mg. oral dose of Ro 5-3350; B, recovered as the ABBP compound (10/100 μl.).

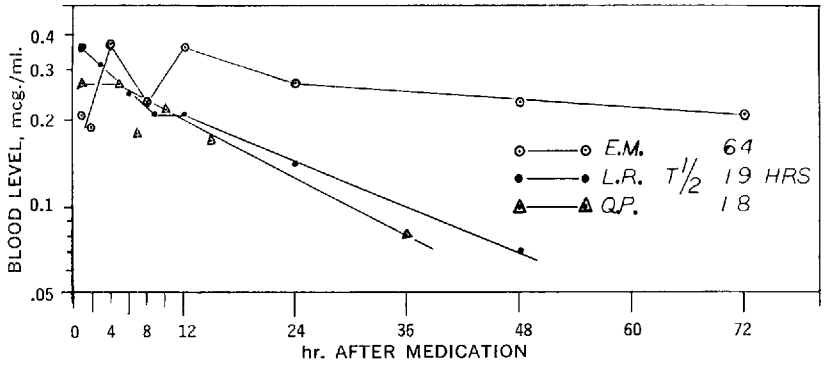

Fig. 4. — Blood level fall-off curves in three humans following the administration of a single 15-mg. oral dose of Ro 5-3350.

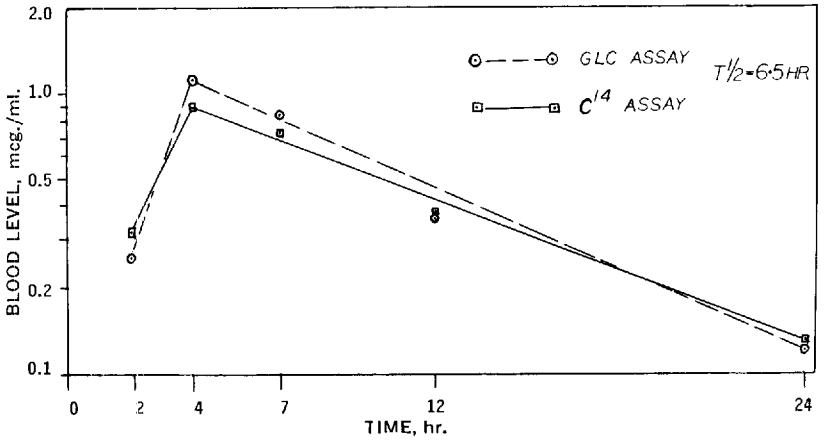

Fig. 5. — Blood level fall-off curve in a dog given a single oral dose (3.5 mg./Kg.) 36 mg. of Ro 5-3350-^{14}C determined by liquid scintillation counting and by GLC.

single oral 15-mg. dose of Ro 5-3350 and specimens of whole blood collected prior to medication (control), and thereafter at suitable intervals of time covering a period of 72 hr. (3 days) from which blood level fall-off curves could be constructed (Fig. 4). In two out of three patients blood level maxima were obtained 1 hr. after dosage of 0.27 (Q. P.) and 0.36 mcg./ml. (L.R.) after which a progressive decline with time was seen with half-lives of 18 hr. and 19 hr., respectively. One patient (E.M.), showed a level of 0.21 mcg./ml. at 1 hr. which rose to 0.37 mcg./ml. at 4 hr., which declined to 0.23 mcg./ml. at 8 hr., rose to 0.36 mcg./ml. at 12 hr., after which a very gradual decline was seen with a half-life of about 64 hr. This erratic behavior may be due to a metabolic factor inherent in this patient.

Blood Level Fall-Off of Ro 5-3350 in the Dog.— The blood level fall-off pattern of Ro 5-3350 was determined in a dog given a single oral dose of 3.5 mg./Kg. totaling 36 mg. of Ro 5-3350-^{14}C. Specimens of whole blood were taken prior to medication and thereafter at 1, 2, 4, 7, 12, and 24 hr. after medication (5) and analyzed for intact Ro 5-3350 by (*a*) liquid scintillation counting and (*b*) GLC. The fall-off curves are shown in Fig. 5 and demonstrate the close reproducibility of the two methods. A blood level maximum of 1.11 mcg./ml. (GLC) and 0.90 mcg./ml. (scintillometry) was obtained 4 hr. after dosage, which declined with a half-life of 6 hr. (GLC) and 7 hr. (scintillometry), indicating an average half-life of about 6.5 hr. in blood.

SUMMARY

The GLC method for the determination of Ro 5-3350 in blood was developed and involves the selective extraction of the compound from blood with pH 9.0 1 *M* borate–Na_2CO_3–KCl buffer using ether as the solvent, followed by extraction of the ether with 6 *N* H_2SO_4. The compound was hydrolyzed in 6 *N* H_2SO_4 for 2.5 hr. at 100° (boiling water bath) to convert it into 2-amino-5-bromobenzoylpyridine (ABBP) which was quantized by GLC.

The average over-all recovery of 200 to 500 ng. of Ro 5-3350 added per milliliter of blood was in the order of 61 ± 3.0%. The minimal detectable amount of ABBP by electron capture was 5–10 ng.

The method was applied to the determination of blood levels in a dog and in man following single oral doses of Ro 5-3350.

Changes in Ergoline Alkaloids in Seeds During Ontogeny of *Ipomoea violacea*

By K. GENEST

Ipomoea violacea L. (*Convolvulaceae*) (heavenly blue) plants were grown under greenhouse conditions. Seed samples were taken following the tenth day of fertilization until maturity was reached. Their content of total alkaloids, lysergic acid amide, isolysergic acid amide, and clavine alkaloids was determined. The alkaloid values were highest (about 0.1 per cent of dry seed) during the early stages of seed development. Chanoclavine was the most abundant alkaloid in the immature seed. With increasing maturity the lysergic acid amide/chanoclavine ratio increased. Experimental findings are discussed to illustrate biogenetic interrelationships between ergoline alkaloids in *I. violacea* in the light of earlier studies on ergot alkaloids.

THE FORMATION of alkaloids during various stages of plant growth has been investigated in several species of medicinal importance, notably in *Solanaceae* (1, 2). Our interest in the ontogeny of alkaloids in seeds of *Ipomoea violacea* stems from earlier work which dealt with the examination of various commercial samples of morning glory seeds for alkaloids, the toxicity of crude seed extracts, and the composition of the lipid fraction of these seeds (3–6). The active principles of *I. violacea* can be classified as ergoline derivatives, most of which occur also in ergot. Extensive biogenetic work elucidated the origin of the ergoline ring in ergot alkaloids (7, 8). Biogenetic interrelationships between these alkaloids have also been investigated (9–11). Gröger *et al.* (12) reported on the biogenesis of ergoline derivatives in *I. rubro-caerulea* Hook, which is considered to be synonymous with *I. violacea*, and found that in young excised plants L-tryptophan and mevalonic acid can be considered precursors of the ergolines, a pathway proposed earlier for the biogenesis of ergot alkaloids. Taber and Heacock (13) reported that in the seeds of *Rivea corymbosa*, another species of the *Convolvulaceae*, ergoline alkaloids are concentrated in the embryo. The alkaloids were also found in vegetative tissues of mature plants of *R. corymbosa* (14) and *I. violacea* (15) but in lower concentrations than in the seeds. The morphology of the seed development of *I. rubro-caerulea* and *I. violacea* has been described (16, 17), but no chemical studies during ontogeny can be found in the literature. Investigation of the seeds is of importance because frequently their misuse, stimulated by accounts of the alleged psychotomimetic action of the active principles, has been reported (18–20). A recent study by Isbell and Gorodetzky (21) with former morphine addicts indicates that the ergolines in *I. violacea* have predominantly sedative properties. It is the purpose of this paper to report on changes of the alkaloid content in the seeds of *I. violacea* which occur during ontogeny of the plant.

Received June 2, 1966, from the Research Laboratories, Food and Drug Directorate, Department of National Health and Welfare, Ottawa, Ontario, Canada.

Accepted for publication July 20, 1966.

The author thanks Dr. Leo Levi for valuable discussions and for encouragement, Dr. A. P. Chan for permission to use greenhouse facilities, Professor F. Arcamone for a generous gift of lysergic acid methyl carbinolamide, and Mr. G. Belec for technical assistance.

EXPERIMENTAL

Procedure.—Plants employed in this study were grown under greenhouse conditions. Seeds from a commercial source of *I. violacea* L. (heavenly blue) were germinated in culture flats (March 10, 1965). After 10 days the plants were transplanted into clay pots containing sandy loam and then fed with 20-20-20 fertilizer at regular intervals. Three plants (*A*, *B*, and *C*) were selected for this study. Seed collections were made for each plant separately. Greenhouse temperatures were as follows: sunny days, 70° F.; cloudy days, 65° F.; nights, 60° F. No artificial light was employed. The first flowers appeared on June 10, 1965. From then on pollination was carried out daily by hand during the time of maximal opening of the corolla (10 a.m. to 12 p.m., depending on daylight conditions). The pollinated flowers were marked. Plants yielded from 1 to 22 flowers daily. Collection of fruit capsules was begun 10 days after fertilization and continued at 10-day intervals for 57–62 days when maturity was reached. Seeds were freed from locules of the fruiting body, and placed in a deep freeze refrigerator (−25°) under nitrogen within 1 hr. after collection. One to seven days after harvesting, the seeds were freeze-dried to constant weight and stored under nitrogen at −25° until used for analysis. There were 36 to 305 seeds per plant harvested at each stage of collection.

Alkaloid Analysis.—The dry seeds were ground in a Wiley laboratory mill to pass a 0.037-in. screen and defatted with petroleum ether (b.p. 30–60°). Analyses for total alkaloids, lysergic acid amide (LAA), isolysergic acid amide (isoLAA), and clavines, and examinations of alkaloidal patterns obtained by thin-layer chromatography (TLC) were carried out by methods described previously (3, 6). Samples (0.25–1 Gm.) of dried seeds were analyzed in duplicate for total alkaloids. Values for LAA, isoLAA, and clavines were obtained by averaging

results from densitometric scannings of 2–4 thin-layer plates per sample, each containing nine spots of test material. TLC systems used were: sytem *1* (alumina G and $CHCl_3$–EtOH, 96:4), system *2* (Silica Gel G and acetone–piperidine, 9:1) for densitometric method; system *3* (Silica Gel G and acetone–ethylpiperidine, 9:1); system *4* (alumina G and acetone–ethylpiperidine, 9:1); system *5* (Silica Gel G and acetone–ethyl acetate–dimethylformamide, 5:5:1).

RESULTS

Flower and Seed Production.—The pattern of flower and seed production was very similar in all three plants. While the first flowers appeared during the 13th week after sowing, the first peak of flower production was reached within 3 weeks after flowering had begun. At that stage approximately 100 flowers per plant were produced each week. Until the end of July when flower production had subsided the plants had produced 284, 278, and 291 flowers, respectively. During this period they produced 230, 238, and 228 fruit capsules. Seed samples derived from flowers fertilized from June 6 to July 31 are referred to as first crop. After the first a second, smaller, flowering peak developed. Seed samples derived from flowers fertilized from August 11 to September 23 are referred to as second crop. Since the second crop was only 12.5% of the first, the mature seeds in this group only were collected. Fresh and dry weights of the maturing seeds are plotted in Fig. 1. The fresh weight increased rapidly after fertilization, reached a plateau after 20 days, and fell rapidly during the latter stage of maturity, while the dry substance rose gradually until the 50th day after fertilization, leveling off during the last 10 days of the maturation process.

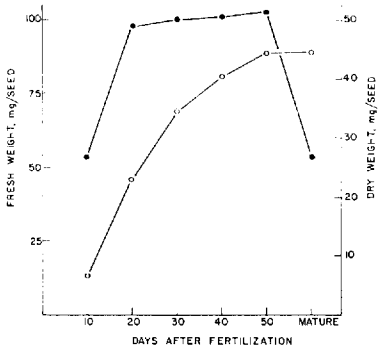

Fig. 1.—Fresh and dry weight of average seed of *I. violacea* L. (heavenly blue) during increasing maturity. Average from three plants. Key: ●, fresh weight, mg.; O, dry weight, mg.

Total Alkaloids.—The total ergoline alkaloids in seeds with increasing maturity are represented in Fig. 2. Their concentrations are highest during the early stage of seed development. From the 30th day after fertilization until full maturity was reached the alkaloid content in the dry seed substance decreased slowly. If calculated on a per seed basis (Fig. 3), the total ergoline alkaloids increased rapidly from the 10- to the 40-day samples and then dropped slowly again as maturity increased. Values for the second crop were always higher than those for the first crop.

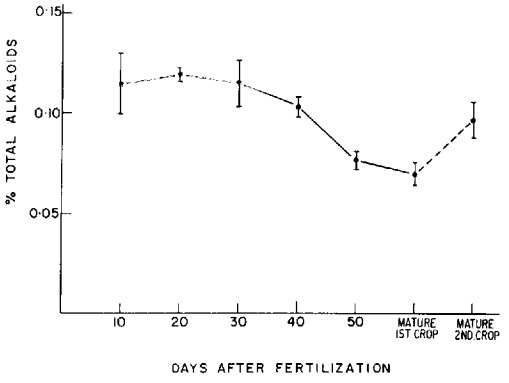

Fig. 2.—Total ergoline alkaloids as per cent of dry seeds during increasing maturity. Average value from three plants and standard deviation are indicated schematically.

Individual Alkaloids.—Results of the determination of LAA, clavines, and isoLAA in seeds collected during increasing maturity are given in Table I and Fig. 4.

As shown in Table I all three alkaloidal components were present from the first sampling date until maturity of the seed was reached. Their relative composition, however, changed. In the early stages after fertilization the clavines were most abundant. Between the 20th and 30th day after fertilization LAA became the predominant constituent which it remained until full seed maturity was reached. The steady decrease of clavine alkaloids after the 20-day sampling can been seen in Fig. 4. LAA reached its maximum concentration at about the 40th day after fertilization, and

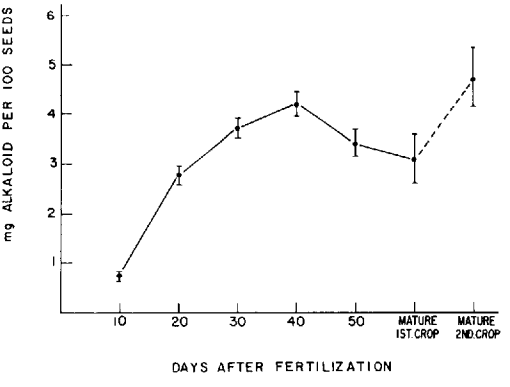

Fig. 3.—Total ergoline alkaloids (mg.) in 100 dry seeds during increasing maturity. Average value from three plants and standard deviation are indicated schematically.

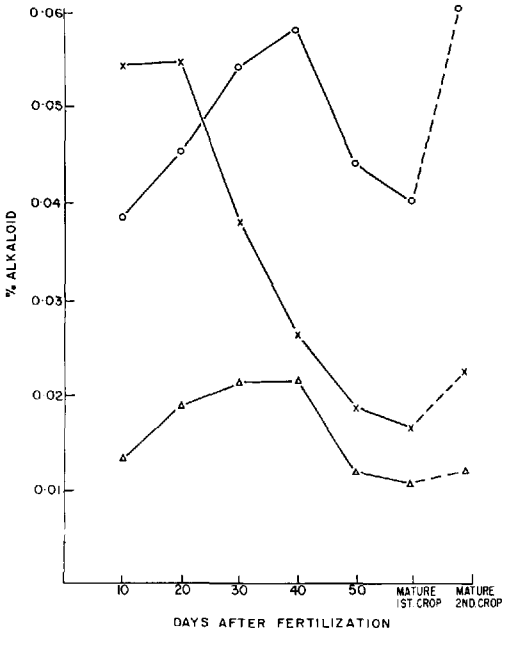

Fig. 4.—Content of lysergic acid amide (LAA), clavines and isolysergic acid amide (isoLAA) in maturing seeds expressed in per cent alkaloid in dry seeds. Averages from three plants are plotted. Key: O, LAA; ×, clavines; △, isoLAA.

its concentration decreased in the later stages of maturity. The change in concentration of isoLAA was similar to that of LAA during increasing maturity but on a lower level. IsoLAA was always the smallest component of the three groups investigated. It too reached its maximum concentration about halfway through maturity. Ergometrine included in the values for clavines, was also present during all stages of seed development. In some cases it was measured separately from the clavine alkaloids. Thus, in seed samples of plant *C* obtained 30 days after fertilization and in the mature seed of plant *B*, 33.0 and 39.4%, respectively, of the clavine fraction consisted of ergometrine. For plant *A* a complete set of ergometrine analyses was carried out. Comparison of results shown in Table II with those recorded in Fig. 2 demonstrates that the decrease of the percentage of ergometrine in the dry seeds was accompanied by a decrease of total alkaloids during seed development. On a per seed basis the ergometrine content is rather constant following the 20th day of fertilization. The ergometrine concentration in the clavine fraction is, however, higher in the more mature samples as compared to the samples closer to the fertilization stage.

The increase in alkaloids in the second crop samples is due to higher values in all three alkaloidal groups as can be seen in Table I and Fig. 4.

Qualitative TLC Patterns.—More information on the clavine alkaloids, which in the densitometric method were estimated as one group, could be

TABLE II.—ERGOMETRINE CONTENT IN SEEDS OF PLANT *A* DURING INCREASING MATURITY

Age of Seeds, Days	10	20	30	40	50	Mature
Ergometrine in dry seeds, %	0.0108	0.0132	0.0107	0.0078	0.0064	0.0061
Ergometrine in 100 dry seeds, mg.	0.06	0.29	0.36	0.31	0.28	0.27
Ergometrine in clavine fraction, %	17.4	23.8	35.7	33.0	32.2	32.0

obtained by chromatography in other TLC systems. Chromatography of the extracts of seeds in various stages of maturity indicated that the changes observed in the clavine group were mainly due to a decrease of the chanoclavine content (Fig. 5) with increasing seed age. This was also observed in systems *1* and *4*. The sum of lysergol, elymoclavine, and penniclavine, which compounds were present in trace amounts only, was lower than the content of ergometrine in all stages of seed development. Lysergic acid methyl carbinolamide, if present, would also be included with the clavine group in the TLC system used for densitometry. R_f values obtained in five systems for this carbinol are shown in Table III. The carbinol can be separated from the other known alkaloidal constituents of *I. violacea* using systems *3* or *5* after rechromatography to separate it completely from penniclavine. As indicated in Fig. 5, no appreciable amounts of the carbinol could be detected at any stage of seed maturity. In addition to the known ergoline alkaloids, at least three spots were observed having higher R_f values than any other alkaloid (R_f system *5*: 0.63, 0.75, 0.79). All these spots showed blue fluorescence under U.V. light and the characteristic blue color given by ergot alkaloids following treatment with dimethylaminobenzaldehyde. Although none of them were identical with agroclavine, there were very faint spots in the agroclavine area when using systems *1*, *3*, *4*, or *5* for the analysis of some seed extracts. In the area where penniclavine is expected, only weak greyish-bluish spots developed 30 min. after spraying.

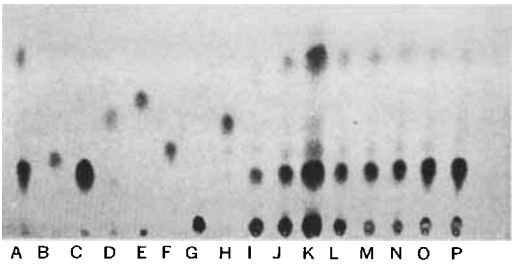

Fig. 5.—Thin-layer chromatogram of ergoline alkaloids and seed extracts of *I. violacea* in system *5*. Key: the spots from left to right are: A, LAA + isoLAA; B, lysergol; C, elymoclavine; D, penniclavine; E, agroclavine; F, ergometrine; G, chanoclavine; H, lysergic acid methylcarbinolamide (with some impurities of ergometrine and LAA). Seed extracts: I, 10; J, 20; K, 20 (3× concentration); L, 30; M, 40; and N, 50 days after fertilization; O, mature seeds (1st crop); P, mature seeds (2nd crop).

TABLE III.—R_f VALUES OF LYSERGIC ACID METHYL CARBINOLAMIDE IN FIVE TLC SYSTEMS

System	*1*	*2*	*3*	*4*	*5*
R_f value	0.30	0.36	0.55	0.23	0.38

DISCUSSION

Many investigations have been carried out on the biogenesis of ergoline alkaloids in parasitic and saprophytic cultures of various ergots or strains of *Claviceps*. The origin of the ergoline nucleus has been attributed to L-tryptophan and mevalonic acid. Several possible biogenetic interrelationships have been discussed. While Abe (22) suggested that all ergot alkaloids derive from a common precursor, a hypothetical lysergic acid aldehyde, which then would be oxidized to lysergic acid or reduced to elymoclavine, agroclavine, and chanoclavine, Rochelmeyer postulated (23, 24) that penniclavine and chanoclavine were possible precursors. The partial pathway, agroclavine → elymoclavine → penniclavine, was established by Agurell and Ramstad (10) in tracer experiments with an ergot strain isolated from *Pennisetum typhoideum*. This observation eliminated the possibility of clavine formation *via* reduction. According to Voigt (11) chanoclavine plays a key role in the development of biogenetic alkaloidal patterns as shown by experiments with rye ergot in various stages of maturation. Further contributions to the biogenetic interrelationships between various clavine alkaloids were made by Abou-Chaar *et al.* (25), Baxter *et al.* (26–28), and Agurell and Ramstad (29). The conversion of clavine alkaloids into lysergic acid alkaloids was proven in experiments with parasitic and saprophytic cultures of *Claviceps* (30, 31). The various findings in this field could partially be explained by the use of different nutrients for saprophytic cultures of fungi (32), but differences in strains producing different alkaloidal patterns have to be considered. The occurrence of alkaloids in varying concentrations during different stages of seed development in *I. violacea* could also be due to transformations of alkaloids into one another. Problems on possible transformation paths are complicated because all alkaloids occur simultaneously in all phases of seed development, and little information has yet been gained on the movement of the alkaloids in the plant. Although only limited conclusions in relation to the biogenesis of ergoline alkaloids are possible from our experimental data, findings in the much more thoroughly investigated field of ergot alkaloids could have some bearing on the elucidation of a biogenetic pathway for lysergic acid derivatives in *I. violacea*. The relatively high concentration of alkaloids and their pattern during the early stages of seed development could indicate that preformed alkaloids are predominantly deposited in the seeds, and that the seed is not necessarily the original site of alkaloid synthesis. Gröger *et al.* (12) reported in tracer experiments that while L-tryptophan and mevalonic acid were incorporated into excised *I. rubro-caerulea* plants to form ergoline alkaloids, their specific rate of incorporation into alkaloids isolated from seeds was much smaller than that into alkaloids isolated from stems. Also radioactive elymoclavine could be converted into penniclavine by detached stems of the same plant (33). Comprehensive tracer studies proving to what degree, if at all, seeds in *I. violacea* can synthesize ergoline alkaloids remain to be carried out and are not only important for finding the site of alkaloid synthesis but also for the elucidation of biogenetic interrelationships between alkaloids in this plant. Indications that chanoclavine may be the precursor of LAA and its epimer are seen in our results on individual alkaloids (Figs. 4 and 5). Ergo-

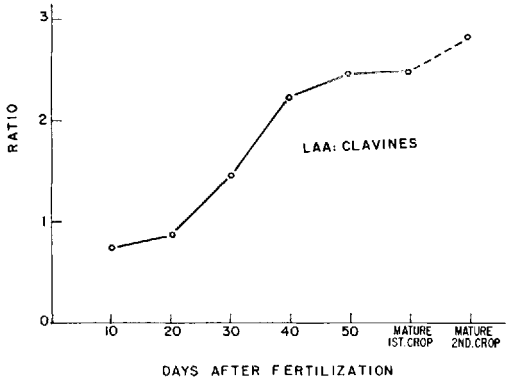

Fig. 6.—Ratio of lysergic acid amide/clavine alkaloids during increasing maturity of seeds.

metrine, on the other hand, seems to appear preferably in the middle and later period of seed development. The change of the LAA/clavine ratio (Fig. 6) would indicate a transformation of clavines (chanoclavine) into LAA during the course of increasing seed maturity. Thus, a biogenetic pathway for ergoline alkaloids in *I. violacea* analogous to that of the ergot alkaloids may be postulated: chanoclavine → (agroclavine) → (elymoclavine) → (penniclavine) → LAA; isoLAA → ergometrine → (lysergic acid methyl carbinolamide). The alkaloids shown in parentheses were found in the seeds in traces only or, in some cases, not even detected. They could, possibly, occur in greater abundance at the original site of alkaloid synthesis in the plant. The presence of mere trace amounts of lysergic acid methyl carbinolamide, which (alkaloid) was reported as one of the major components in *I. rubro - caerulea* (15) could indicate a genetic difference between this plant and *I. violacea* even though both plants are considered to be synonymous botanically. This interpretation, however, has to be used with caution since blank experiments with small amounts of carbinol showed that, under our experimental conditions, some of the applied carbinol is being decomposed.

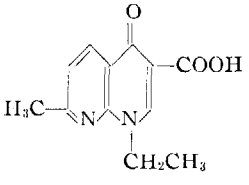
Qualitative and Quantitative Tests for Nalidixic Acid

By EDWARD F. SALIM* and IRWIN S. SHUPE†

Provisional, unofficial monographs are developed by the Drug Standards Laboratory, in cooperation with the manufacturers of the drug concerned, for publication in the *Journal of Pharmaceutical Sciences*. The ready availability of this information affords discriminating medical and pharmaceutical practitioners with an added basis for confidence in the quality of new drug products generally, and of those covered by the monographs particularly. Such monographs will appear on drugs representing new chemical entities for which suitable identity tests and assay procedures are not available in the published literature. The purity and assay limits reported for the drugs and their dosage forms are based on observations made on samples representative of commercial production and are considered to be reasonable within expected analytical and manufacturing variation.

1-ETHYL-7-METHYL-1,8-NAPHTHYRIDIN-4-ONE-3-CARBOXYLIC ACID; $C_{12}H_{12}N_2O_3$; mol. wt. 232.24. The structural formula of nalidixic acid may be represented as:



Physical Properties.—Nalidixic acid occurs as a white to slightly yellow crystalline, odorless powder, m.p. 225–231°, U.S.P. class *Ia*. It is practically insoluble in water, slightly soluble in alcohol, soluble in chloroform, and very slightly soluble in ether. It is soluble in solutions of fixed alkali hydroxides and carbonates.

Identity Tests.—A 1 in 200,000 solution of nalidixic acid in 0.1 *N* sodium hydroxide exhibits ultraviolet absorbance maxima at about 332 and 258 mμ [absorptivity (*a*) about 111] and minima at about 276 and 236 mμ. The spectrum is shown in Fig. 1.

The infrared spectrum of a 0.5% dispersion of nalidixic acid in potassium bromide, in a disk of about 0.82 mm. thickness, is shown in Fig. 2.

Purity Tests.—Dry about 1 Gm. of nalidixic acid, accurately weighed, at 105° for 2 hr.: it loses not more than 0.5% of its weight.

Char about 1 Gm. of nalidixic acid, accurately weighed, cool the residue, add 1 ml. of sulfuric acid, heat cautiously until evolution of sulfur trioxide ceases, ignite, cool, and weigh: the residue does not exceed 0.2%. Retain the residue for the heavy metals test.

Dissolve the sulfated ash obtained from 1 Gm. of nalidixic acid in a small volume of hot nitric acid and evaporate to dryness on a steam bath. Dissolve the residue in 2 ml. of diluted acetic acid, dilute to 25 ml. with water, and determine the heavy metals content of this solution by the U.S.P. heavy metals test, method I: the heavy metals limit for nalidixic acid is 20 p.p.m.

Determine the nitrogen content of nalidixic acid by the U.S.P. nitrogen determination, method II: not less than 11.77% and not more than 12.37% of nitrogen (N) is found.

Assay.—Transfer about 250 mg. of nalidixic acid, accurately weighed, to a 125-ml. conical flask, and dissolve in 30 ml. of dimethylformamide which has been previously neutralized to thymolphthalein T.S. Titrate with 0.1 *N* lithium methoxide, using a magnetic stirrer and taking precautions against the absorption of atmospheric carbon dioxide. Each milliliter of 0.1 *N* lithium methoxide is equivalent to 23.22 mg. of $C_{12}H_{12}N_2O_3$. The amount of nalidixic acid found is not less than 98% and not more than 102% of the weight of the sample taken.

DOSAGE FORMS OF NALIDIXIC ACID

Nalidixic Acid Tablets

Identity Tests.—The ultraviolet absorption spectrum of the sample solution obtained in the *Assay* exhibits maxima and minima at the same wavelengths as that of the *Standard Preparation*.

Transfer a sample of finely powdered tablets, equivalent to about 100 mg. of nalidixic acid to a glass-stoppered conical flask. Add 50 ml. of chloroform and shake for 15 min. Filter through paper and evaporate the chloroform solution on a steam bath to dryness. Dry the residue at 105° to constant weight: the resulting residue of nalidixic acid melts between 225° and 231°.

Assay.—*Standard Preparation.*—Dissolve about 100 mg. of nalidixic acid, accurately weighed, in 200.0 ml. of chloroform. Transfer 2.0 ml. of this solution to a 200-ml. volumetric flask, dilute to volume with chloroform, and mix.

Procedure.—Weigh and finely powder not less than 20 nalidixic acid tablets. Transfer an accurately weighed portion of the powder, equivalent to about 100 mg. of nalidixic acid, to a 125-ml.

Received May 11, 1966, from the * Drug Standards Laboratory, American Pharmaceutical Association Foundation, Washington, D.C. 20037.

Accepted for publication July 26, 1966.

† Winthrop Laboratories, New York, N. Y. Winthrop Laboratories has cooperated by furnishing samples and data to aid in the development and preparation of this monograph.

The Drug Standards Laboratory gratefully acknowledges the assistance of Miss Hannah Klein.

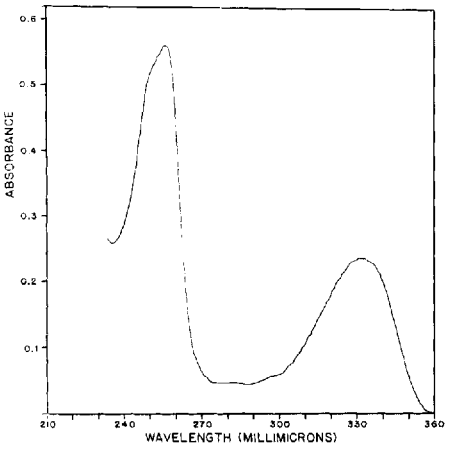


Fig. 1.—Ultraviolet absorption spectrum of nalidixic acid in 0.1 *N* sodium hydroxide (5 mcg./ml.); Beckman model DK-2A spectrophotometer.

separator containing 10 ml. of water. Completely extract the nalidixic acid with four 25-ml. portions of chloroform, filtering each portion into a 200-ml. volumetric flask, dilute to volume with chloroform, and mix. Pipet 2 ml. of this solution into a second 200-ml. volumetric flask, dilute to volume with chloroform, and mix. Concomitantly determine the absorbance of this solution and that of the *Standard Preparation* in 1-cm. cells at the wavelength of maximum absorbance at about 258 mμ with a suitable spectrophotometer, using chloroform as the blank. Calculate the quantity, in mg., of $C_{12}H_{12}N_2O_3$ in the portion of tablets taken by the formula $20\,C(A_u/A_s)$ in which C is the exact concentration, in mcg./ml., of nalidixic acid in the *Standard Preparation*, A_u is the absorbance of the solution from the tablets, and A_u is the absorbance of the solution from the tablets, and A_s is the absorbance of the *Standard Preparation*. The amount of nalidixic acid found is not less than 93% and not more than 107% of the labeled amount.

DISCUSSION

U.S.P. and N.F. terminology for solubility, melting range, reagents, etc., has been used wherever feasible.

Nalidixic acid,[1] synthesized by Lesher and Gruett (1), is a systemic antibacterial agent which is highly effective against many Gram-negative bacteria and some Gram-positive organisms. It is particularly useful in genitourinary tract infections and can be used in other infections in which the causative agent is susceptible to the drug.

Quantitative Methods.—The nonaqueous titration of nalidixic acid with lithium methoxide using thymolphthalein T.S. gave an average value of 100.7 ± 0.1%.[2] The titration can be conducted using 0.1 *N* sodium methoxide with comparable results and thymol blue T.S. can be conveniently substituted as the visual indicator for either titrant.

[1] Marketed as NegGram by Winthrop Laboratories, New York, N. Y.

[2] Maximum deviation from the mean value.

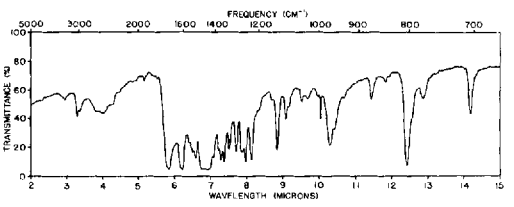

Fig. 2.—Infrared spectrum of nalidixic acid in potassium bromide disk (0.5%); Perkin-Elmer model 21 spectrophotometer, sodium chloride prism.

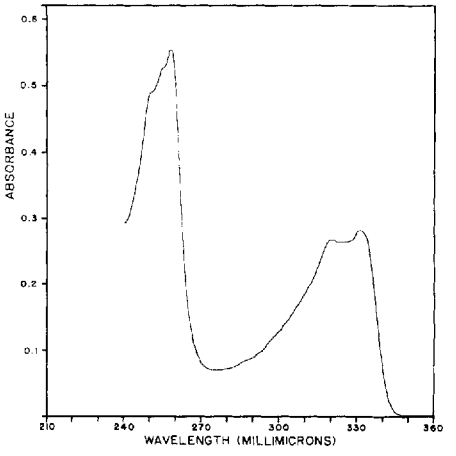

Fig. 3.—Ultraviolet absorption spectrum of nalidixic acid in chloroform (5 mcg./ml.); Beckman model DK-2A spectrophotometer.

The spectrophotometric assay for nalidixic acid tablets was designed to isolate the active ingredient prior to ultraviolet measurement. The extracted nalidixic acid is conveniently determined in chloroform solution at the absorbance maximum at either 258 or 332 mμ. The ultraviolet absorption spectrum of the *Standard Preparation* is shown in Fig. 3. Spectrophotometric analysis of commercial tablets gave an average value of 98.5 ± 0.5%[2] of the labeled amount.

An alternative method of analysis for the tablet formulations has been demonstrated by nonaqueous titration subsequent to chloroform extraction and evaporation to dryness. The residue representing about 250 mg. of nalidixic acid is dissolved in 30 ml. of dimethylformamide, previously neutralized to thymolphthalein T.S., and titrated with 0.1 *N* lithium methoxide in the manner noted for bulk nalidixic acid. An average recovery of 99.0 ± 0.4%[2] was obtained for the tablets by this procedure.

Powder Flow Studies II

Effect of Glidants on Flow Rate and Angle of Repose

By GERALD GOLD, RONALD N. DUVALL, BLAZE T. PALERMO, and JAMES G. SLATER

Glidants have often been selected by subjective or indirect methods such as measurement of the angle of repose. As a result, several materials have been empirically classified as glidants. The recording powder flowometer described in Part I of this series was utilized to evaluate various glidants. A comparison was made between the results obtained with this instrument and those by measurement of the angle of repose. The commonly used glidants, fumed silicon dioxide, magnesium stearate, starch, and talc were studied in combination with selected materials. Many of the more widely used glidants actually decreased the flow rate. Glidants which lowered the angle of repose did not necessarily increase the flow rate and marked changes in flow rate were not always detectable by angle of repose measurement. In addition, a comparison of the angle of repose and the flow rate of various commonly used raw materials indicated that the angle of repose was not a reliable method for evaluating the flow of these materials.

THE FLOW properties of powders vary considerably from those of formulations which flow freely and continuously through a small orifice to those which are evident of noncontinuous flow under any circumstance. Poorly flowing powders or granulations present many difficulties in the pharmaceutical industry, especially in compressed tablet manufacturing, and considerable effort, therefore, has been directed toward overcoming flow problems. The most commonly used technique involves the addition of materials known as glidants in an attempt to improve the flow characteristics of the formulation. Selection of the glidant and the concentration thereof is often empirical since there is no generally accepted method for evaluating the effectiveness. As a result, glidant usage is often ascertained on a trial and error basis *via* subjective information.

One of the more objective methods, probably the most widely used, involves the measurement of the angle of repose. The powdered or granular material is allowed to fall freely through an orifice onto a flat surface to form a conical pile of the deposited material. The angle between the surface of the cone and the horizontal plane is known as the angle of repose. This numerical value is reproducible provided the conditions remain constant. Train (1), in a critical examination of four methods of determining the angle of repose with glass balls, lead shot, and silver sand, concluded that the type of method influenced the results, but that most methods of measurement would provide suitable data for comparison between samples during routine quality control tests. He did not mention relationship to flow. Although it is not clear to what physical property the angle of repose corresponds, it has often been assumed (2–4) that it relates to the flow properties of the material. A high angle reputedly indicates a poorly flowing material, while conversely a low angle indicates good flow. The magnitude of this angle is dependent on the conditions of measurement and the numerous methods by which this angle has been measured have added to the confusion. Pilpel (4), in summarizing the work of others, indicated that the value of the angle of repose depends not only on the way in which the cone is produced, but also on the nature of the powder, its preparation, particle size, and particle size distribution. In an attempt to study the problem of granulation flow in tableting as it is related to interparticle friction, Nelson (5) measured the angle of repose of a sulfathiazole granulation as a function of average particle size, the presence of lubricants, and admixed fines, but carefully avoided direct correlation with flow properties. Craik applied the supposed relation of flow to the angle of repose in an

investigation of the flow properties of starch powders under laboratory conditions (2) and of three very different powders under humid conditions (3).

Timed delivery through an orifice is also of value in appraising the flow of materials. A stop watch is usually used to either time a certain weight of powder flowing through the orifice or to close the orifice after a given time so that the powder flowing through in that time period can be weighed. With this method, Hammerness and Thompson (6) showed that the addition of fines increased the rate of flow to an optimum level, after which the rate began to decrease. The addition of lubricant beyond 2% did not substantially improve the flow rate. Gunsel and Lachman (7) comparatively evaluated tablet formulations by the timed delivery technique and used the angle of repose measurement to substantiate similarities in flow rates. However, their data show nearly identical flow rates for two formulations having differences in angles of repose and a marked difference in flow rate for two materials having identical angles. Munzel (8), using a modified Emix powder dispenser and weighing the amount of material discharged in 10 sec. by manually opening and closing the flap, studied the influence of glidants on the flow properties of granules. He apparently was the first to employ the term "glidant" to designate agents which added in small amounts improve flow characteristics of granulations. Flow regulators and solid flow conditioners are two other terms used synonymously with flow glidants. The report of Munzel is the source of the Remington (9) differentiation of lubricants into three groups based on their ability to carry out respective functions: glidants, antiadhesives, or antisticking agents and lubricants.

Recently, Augsburger and Shangraw (10) rated some silica-type glidants in two microcrystalline cellulose systems based on tablet weight variation data. However, this method is tedious, time consuming, and not practical at the preliminary product development stage.

In the previous report from this laboratory (11), a recording powder flowometer was described and represented a new approach to the study of powder flow. The authors believe that this technique more closely simulated and recorded flow as it occurs in a tableting operation. Although the angle of repose is controversial in the area of flow measurement, it has been widely used, and one objective of this study was to investigate the relationship between this angle and the flow rate with the recording powder flowometer. Numerous materials were evaluated in an effort to ascertain correlation, if any, between the two techniques. A second aspect of this work was to study the effect of materials generally known as glidants when added to selected powdered, crystalline, and granulated materials. The glidants used were fumed silicon

dioxide, magnesium stearate, cornstarch, and talc. Varying concentrations of these were evaluated for their effects on the angle of repose and flow rate of aspirin crystals, calcium sulfate granules, and spray-dried lactose. The numerous comparisons obtained from this study should help to clarify the status of angle of repose measurement as a measure of flowability.

EXPERIMENTAL

Materials.—The spray-dried lactose, crystalline aspirin, magnesium stearate, talc, fumed silicon dioxide,[1] and cornstarch were either U.S.P. or pharmaceutical grade materials. The calcium sulfate granulation was prepared by adding 5% gelatin solution to calcium sulfate dihydrate in a Blakeslee kitchen mixer and wet sizing through a No. 6 screen on an oscillating granulator. It was dried for 8 hr. at 140° F., and the dried granules were sized with an oscillating granulator and a No. 16 screen. Mesh analyses of the aspirin, spray-dried lactose, and calcium sulfate granulation used in the glidant studies

[1] Marketed as Cab-O-Sil by the Cabot Corp., Boston, Mass.

are shown in Table I. The cornstarch was dried at 140° F. for 24 hr., and all glidants were passed through a No. 40 hand screen prior to using. Glidants were used at concentration levels as indicated in Table II.

The materials used for the flow rate and angle of repose correlation study are listed in Table III and characterized according to the U.S.P. powder fineness classification for chemicals following particle size analysis.

Particle Size Analysis.—Particle size was determined with a Ro-Tap testing sieve shaker, using U. S. standard sieves in series 20, 40, 60, 80, 120, and 200 mesh sizes. A 100-Gm. sample was tested in the shaker for 5 min.

Flow Rate Determinations.—Flow rates, expressed in Gm./sec., were determined with the flowometer on 500-Gm. samples and with a conical stainless steel hopper measuring 20 cm. top diameter by 30 cm. in length and 10 mm. orifice diameter. Each value represents the average of nine measurements. To minimize variations in ambient conditions, three measurements were made on 3 different days. The average standard deviation was 0.47 Gm./sec.

Angle of Repose Measurements.—Repose angles were measured by the fixed funnel and free standing cone procedure described by Train (1). The fixed height of the funnel orifice was 2.54 cm., and the orifice diameter was 5.0 mm. The reported repose angles represent the average of five determinations. In no case was the standard deviation greater than 0.81°, which compares favorably with the average standard deviation of 0.74° reported by Fonner *et al.* (12).

RESULTS AND DISCUSSION

The effects of varying concentrations of glidants on the flow rate and angle of repose of aspirin crystals, calcium sulfate granules, and spray-dried (S.D.) lactose are shown in Table II. The concentrations of specific glidants included those recommended or generally used. Since S.D. lactose had the slowest flow rate, it might be assumed to respond more favorably to the addition of a glidant. However, with the exception of the lowest levels of magnesium stearate and fumed silicon dioxide, the flow rate was decreased substantially. Munzel (8) reported that the flow rate of sodium chloride was reduced by the addition of glidants, and attributed this to the fact that sodium chloride itself is an excellent glidant and that its flow properties were impaired by poorer glidants. This does not apply to S.D. lactose and suggests that other factors are involved. The S.D. lactose had a particle size distribution (Table I) much finer than the other two sample materials, a factor which may influence the effectiveness of glidants. Magnesium stearate and fumed silicon dioxide at their usual concentration ranges did increase the flow rate of both calcium sulfate granules and aspirin crystals. Cornstarch, at low levels, increased the flow rate of the same two materials but decreased the flow rate at concentrations normally employed. Talc appears to be a poor glidant for these sample materials since it decreased the flow rate at all concentration levels. The talc used in this study was designated as having "good slip," a designation determined subjectively by rubbing the material between the thumb and fingers. It is evident that a glidant which is effective with a given material may prove otherwise when used with a different material. The flowometer appears to be a convenient tool to determine the best glidant for specific material more objectively. This technique also appears to be valuable to ascertain the optimum concentration of a particular glidant. In those instances where the glidant increased the flow rate, the lower concentration was usually more effective. Two exceptions were magnesium stearate with calcium sulfate granules and silicon dioxide with aspirin crystals. The indiscriminate use of glidants should be avoided since beyond their optimum concentration they usually cause a marked decrease in flow rate.

In evaluating the effect of glidants by angle of repose measurement, an increase in magnitude of the angle should be associated with a decrease in flow rate and conversely, a decrease in the angle should result in an increased flow rate. This relationship seems to exist within the three talc-containing systems which were studied, as illustrated in Fig. 1. However, the angles of repose for both the calcium sulfate and aspirin series with talc were much higher than those for the S.D. lactose–talc series, yet the former two series had much faster flow rates. Figure 2 illustrates the relationship in the three systems containing magnesium stearate. The angle of repose did correlate generally with flow rate within these systems, although again no correlation between the three series was evident, and a marked drop in flow rate for aspirin–magnesium stearate was accompanied only by a negligible change in angle of repose. Figures 3 and 4, illustrating the three systems with silicon dioxide and cornstarch, respectively, indicate many exceptions to the angle of repose-flow rate theory. In many instances a decrease in the angle of repose was not associated with an increased flow rate, and marked changes in

the flow rate were not detectable by changes in the angle of repose.

Measurement of the angle of repose of a powder has been reported to yield information on flowability in comparison to that of other powders (2-4). Since this current work concerning the addition of various glidants to the three systems had cast considerable doubt on this relationship, the flow rate and angle of repose of 15 selected raw materials were determined. The results are shown in Table III. The materials represent wide ranges in angles of repose and flow rates. The coefficient of correlation (13) has been used to statistically measure the extent of the linear relationship between angle of repose and flow rate. A correlation coefficient close to 0 indicates a weak or nonexistent relationship, whereas a value close to +1 or −1 indicates a close relationship between the two variables. The per cent dependence (14), a measure of the percentage of the variation in flow rate related to variation in the angle of repose, has also been calculated. These statistics were used to evaluate the angle of repose–flow rate relationship for the aspirin, calcium sulfate, and S.D. lactose glidant series. Results are given in Table IV. Coefficients of correlation for the calcium sulfate and S.D. lactose systems are significant or high enough to assume some correlation between the two variables. However, the per cent dependence of these two systems are not sufficient to have high or reliable correlation. Correlation between the selected raw materials was poor. This is illustrated in Fig. 5. The difference in regression lines is indicative of the weak relationship between angle of repose and flow rate (r = −0.32). Although still not high, correlation was better within a given system. The over-all low correlation coefficients and corresponding per cent dependence values indicate that the angle of repose is not a reliable method to evaluate flow of materials.

SUMMARY

1. The effects of varying concentrations of the glidants, magnesium stearate, fumed silicon dioxide, cornstarch, and talc, on the flow rate of aspirin crystals, calcium sulfate granules, and S.D. lactose have been investigated with a recording powder flowometer. The angle of repose measurement was also used in a further attempt to evaluate flow and to investigate the relationship between this angle and flow rate.

2. The flowometer appears to be a valuable instrument to select the best glidant for a given material or granulation and to determine the optimum concentration of a particular glidant in a given system.

3. Magnesium stearate, fumed silicon dioxide, and cornstarch in low concentrations increased the flow rates of aspirin and calcium sulfate. However, effectiveness of the glidants with S.D. lactose was negligible. Talc appears to be a poor glidant for these materials since it decreased the flow rate at all concentration levels.

4. Optimum concentrations of glidants were 1% or lower. Excess of glidants should be avoided since beyond their optimum concentration they usually caused a marked decrease in flow rate.

5. Statistical tests were used to determine the relationship between angle of repose and flow rate. Low correlation was obtained within a specific system, whereas no correlation was found for selected raw materials. Consequently, angle of repose measurement does not appear to be a reliable method to evaluate flow of materials.

Evaluation of Automatic Potentiometric Titrator in Nonaqueous Titrations

By THOMAS MEDWICK and ELY KIRSCHNER

A procedure is reported for the evaluation of the behavior of an automatic recording titrator in nonaqueous titrations and is applied to an instrument composed of commercially available units. First, the behavior of the purely instrumental features was determined and the experimental errors were compared with calculated maximum anticipated relative values. The instrument's function in this case was within expectation. Then, the response of the titrator was evaluated from titration curve properties of two compounds in acetic acid and two other compounds in isopropanol. The following maximum relative errors, with instrumental errors discounted, were observed: range, 1.5 per cent; end point potential, 4.4 per cent; analytical results, 1.0 per cent; slope of the rapidly rising portion, 11.4 per cent. On the basis of satisfactory instrumental response and reasonable titration curve errors, the relatively inexpensive unit used here is found reliable for general laboratory use. The procedure described is recommended for use in evaluating any automatic potentiometric recorder.

TITRIMETRIC analysis in various nonaqueous media enjoys success and acceptance. The biannual reviews of the literature pertaining to this work attest to this fact (1). Inspection of the official compendia (2, 3) indicates that this type of determination is useful in pharmaceutical analysis. If potentiometric end point detection is required, the use of a dependable automatic recording titrator permits convenient and rapid analyses. It is possible to build a titrator from published schematics, but this involves expense and considerable labor. Several varieties of commercial automatic recording titrators are available or, if cost is a consideration, commercial components may be simply assembled. If not already available in the laboratory, the required components are a potentiometric recorder, a suitable automatic buret, and a pH meter. No matter which of these instruments is chosen, proper evaluation of the automatic recording titrator setup should be carried out to determine performance under the specific conditions to be imposed during use.

This paper reports on a detailed evaluation procedure which examines titrimetric performance in nonaqueous media where high solution resistance makes potential measurements difficult; the titrimetric behavior of two compounds in glacial acetic acid solvent and two other compounds in isopropanol is studied. Since titration behavior yields useful acid-base information as well as purely analytical data, various features of the resultant curves are measured. In addition, the known determinate errors inherent in the various measurements are estimated in an attempt to evaluate the ability of the described instrumentation to present data reproducibly. The automatic recording potentiometric titrator used is composed of commercially available components. Wilson and Munk (4) have written about a similar titrator but did not carry out an evaluation of its performance.

Received June 13, 1966, from the College of Pharmacy, Rutgers—The State University, Newark, N. J. 07104.

Accepted for publication August 1, 1966.

The authors are grateful to Miss Barbara Ann Nemeth for technical assistance. Discussions with Mr. Leonard Bailey, Mr. Stephen Baron, and Mr. Gerald Kaplan proved very useful.

This work is supported in part by a grant from the Research Council of Rutgers—The State University.

EXPERIMENTAL

Chemicals and Solutions.—All chemicals not otherwise described were reagent grade. 1,2,3-Triphenylguanidine (Eastman yellow label) was recrystallized from 95% aqueous ethanol, m.p. 145–147° uncorrected. *m*-Nitrobenzhydrazide (Eastman white label) was recrystallized from water, m.p. 152–155° uncorrected.

Benzoic acid, primary standard (J. T. Baker) 99.99% assay. *p*-Hydroxybenzoic acid (Eastman white label). Hexadecyltrimethylammonium bromide (Eastman blue label). Acetous perchloric acid, about 0.1 *N*, was prepared according to Fritz (5).

Hexadecyltrimethylammonium hydroxide, about 0.1 *M*, was prepared according to the method described by Cundiff and Markunas (6) with the exception that isopropanol was the only organic solvent used.

Apparatus.—Sargent model SR recorder, 125 mv. full scale, equipped with a 5.0-mv. range plug, a 1 in./min. chart drive motor, and wired with a switching arrangement such that it may be turned on synchronously with the constant rate buret.

Leeds and Northrup pH indicator, model 7401, equipped with a 10 or 20-ohm precision resistor (±0.05%).

Sargent model C constant-rate buret, delivering 10 ml., equipped with a Teflon stopcock and a Teflon sleeve-covered ground-glass connection, and connected to a 2-L. titrant reservoir *via* ball socket joints and glass tubing.

Magnetic stirrer, used with Teflon-coated magnetic stirring bars.

Titration vessel, for titrations requiring protection from the atmosphere, consisting of a beaker 7 cm. in height, 7.1 cm. in diameter, with a female

71/15 ground-glass joint, and a cover with a male 71/15 joint, and with four openings to admit the reference electrode, the indicating electrode, the buret tip, and a nitrogen gas tube.

For titrations in both acetic acid and isopropanol solvents, a Beckman glass electrode (40498) was used as the indicating electrode. The reference electrode used for acetic acid was a Beckman inverted sleeve calomel electrode (43462), the saturated aqueous KCl solution being replaced by 0.1 *M* acetous LiCl; for isopropanol, the same type of calomel electrode was employed but with 0.1 *M* hexadecyltrimethylammonium bromide in isopropanol replacing the saturated aqueous KCl.

Procedure.—A sample of the compound to be titrated, listed in Table I, column 1, was accurately weighed (column 2) and dissolved in 50 ml. of the proper solvent (column 3). When acetic acid solvent was used, a 400-ml. beaker was used as the titration vessel. However, when isopropanol was to be the solvent, the titration vessel was the cell previously described which provided for the use of nitrogen as an inert atmosphere. After the proper electrodes were immersed and the stirrer turned on, the solution was automatically titrated with the specified titrant (column 4) until the total volume of about 10 ml. was delivered by the buret.

The following electrical grounding arrangement was used. The negative input terminal of the recorder was grounded to its chassis and was also connected to the "ground" terminal of the pH meter. The "ground" terminal of the pH meter, the automatic constant-rate buret chassis, and the magnetic stirrer chassis were all connected to a common water pipe ground. No titration solution ground was used.

Measurement of Titration Curve Parameter.—The recorded titration curves are plots of millivoltage (ordinate) as a function of titrant volume (abscissa). For each titration curve, the following measurements as shown in Fig. 1 were made using a metric ruler: the length of chart representing the complete titration, distance X; the voltage represented by a centimeter of abscissa distance in terms of the voltage equivalent to distance Y divided by distance Y; the range, in millivolts, or distance AB; the potential at the end point, point C; the slope of the rapidly rising linear portion or the tangent of angle ADE; the end point according to the method described by Blaedel and Meloche (7). In addition, determinate errors involved in the measurement of graphical features and found in the instrumental specifications were treated according to the usual concepts of error propagation (8).

RESULTS AND DISCUSSION

An automatic recording titrator setup may be conveniently divided into two parts: (*a*) the instrumental portion composed of the automatic buret, the pH meter, and the potentiometric recorder; and (*b*) the titration cell portion containing the sample solution together with the electrodes. If the instrumental portion is found to be functioning correctly and reproducibly, then it can properly receive and represent the signal being produced by the titration cell portion. On this basis, the two sections which follow deal first with the instrumental operation and behavior, and second, discuss the entire instrument, including, of course, the titration cell portion.

Instrumental Operation and Behavior.—The components of this titrator were chosen with the aim of achieving flexibility. The recorder is one with a large chart (25 cm.), variable ranges, and variable chart speeds. However, any good potentiometric recorder may be adapted. Similarly, any good pH meter, with a recorder output, may be used. The pH meter chosen presented such advantages as stability, ease of variation of the output signal *via* precision resistors (9), and adjustability of the "zero" millivolts position. This latter advantage is extremely important when titrations are to be carried out using various solvents and different strength acidic and basic samples. The last and only component which need be obtained specifically for this titrator is the automatic constant-rate buret. The one used here was chosen since it could be cleaned easily and was adaptable to an all glass titrant delivery system.

A factor which is extremely important in obtaining instrumental stability, particularly in the titrations involving solvents of low dielectric constant, *e.g.*, acetic acid, is that of electrical grounding. If grounding is not proper then any extraneous signals will be superimposed on the desired response resulting in unsatisfactory, erratic titration curves.

Since the magnitude of a potentiometric "break" is a function of the acid or base strength of the compound being titrated, certain compounds will give rise to a smaller potentiometric break than others. In order to make the recorded titration curves as large as possible and thereby take advantage of the large recorder chart, the sensitivity of the instrument was varied. In all instances, the recorder range was kept at 5.0 mv. and the pH meter operated in the 0–1400 mv. range. However, the pH meter output was varied by using different output resistors (9). Table II, column 2, is a listing of the resistors used in each case while columns 3 and 4 show the anticipated effect of the resistor on the recorder response and instrument sensitivity. It is seen that in the study of *m*-nitrobenzhydrazide, a relatively weak base, the highest instrument sensitivity was used. The sensitivity was not increased when *p*-hydroxybenzoic acid was titrated, in spite of the weakly acidic phenol which is present, in order to titrate both acidic groups within the potential range represented by a single width of recorder chart.

It was desirable to test the reliability of the instrumental performance for every titration. The chart abscissa, in terms of centimeters of chart travelled for a complete titration, is an index of how well the automatic buret motor, the recorder chart drive motor, and the synchronous switch operate. The abscissa mean values and their standard deviation, listed in Table II, column 7, show a maximum relative standard deviation of about 0.2%. The determinate portion of this uncertainty may be ascribed to two sources. The first source, the instrumental error, arises from the automatic constant rate buret motor whose specifications list an accuracy of 0.1% in delivering the total volume (10). The recorder chart motor is not expected to contribute to the determinate error since it is activated *via* a synchronous switch and shuts off

[a] $HDTMA^+OH^-$ is the abbreviation of hexadecyltrimethylammonium hydroxide. [b] In each instance, S indicates the standard deviation. [c] The figures in the parentheses are relative standard deviations.

automatically when the complete titrant volume is delivered (11). The second source of error stems from the chart measurements using a metric ruler. Distance measurements made with a metric ruler are no more accurate than about 0.02 cm. which in a distance of about 26 cm. represents 0.1% relative uncertainty. Thus, from these two sources, 0.2% total relative determinate uncertainty are calculated. This is in good agreement with the 0.2% observed uncertainty.

A second criterion for instrumental performance is the reproducibility of the ordinate, in terms of mv./cm. of chart. This axis is influenced by the reliability of the meter needle (since points on the chart are marked to indicate a particular voltage reading) as well as the ability of the recorder to reproduce the same reading. The uncertainty of the entire meter scale reading is given as 10 mv. and the visual reading error is ±2 mv. (12). Thus, in the situation where the entire scale is equivalent to 700 mv., a maximum error of ±12 mv. in 700 mv. or 1.7% relative uncertainty could be recognized. The recorder is accurate to 0.25% (13) which is added to the meter relative uncertainty to yield a total of 1.95%. Finally, the metric ruler uncertainty of 0.02 cm. in a distance of approximately 25 cm. would introduce a variation of about 0.1%. Since the ordinate is expressed as a quotient, the anticipated relative determinate error is calculated to be about 1.85%. The values presented in Table II, column 6, are seen to have a maximum relative standard deviation of about 1%. This is within the calculated maximum anticipated determinate uncertainty. It should also be mentioned that the values in column 6 are all in agreement within experimental error with the anticipated values for the instrument sensitivity noted in column 4.

Titration Behavior.—In this section the ability of the entire system to sense, transmit, and reproducibly record the course of a titration in two nonaqueous media is treated. The determinate errors attributable to instrumental and measurement factors are estimated. No determinate error is assigned to the titration cell function. The four characteristics of the titration curves are listed in Table I, columns 6–9. Some variation in the concentration dependent measurements should be expected since the sample weights (column 2) are not exactly constant. Since the dilution during titration is the same for each case, no corrections are carried out.

The range values listed in Table I, column 6, are reproducible with a maximum relative standard deviation of 3%. This value is calculated from the curve by multiplying a distance (absolute uncertainty 0.02 cm.) by the proper instrument sensitivity value, Table II, column 6. For a small distance, *e.g.*, 5 cm., a relative measurement error of 0.4% may be added to a maximum sensitivity error of 1.1% to yield a total determinate relative error of 1.5%. When the individual values presented in Table I, column 6, are examined, it is noted that three of the values are within the maximum anticipated error limits, whereas one of the remaining two is 0.3% and the second is 1.5% higher than the calculated limit. It should be noted that in the last-named case the sample size varies about 1.6%. This variation would be expected to have an effect

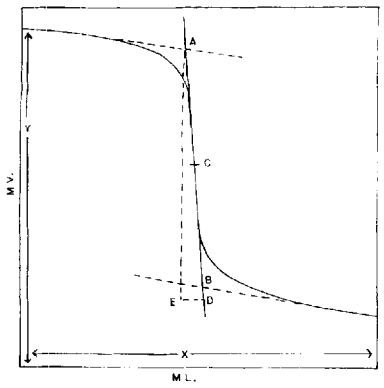

Fig. 1.—Titration curve features. Key: X, milliliters; Y, millivolts; AB, range; C, end point potential; tangent of ADE, slope.

on the range values. However, on the basis of the observed results, the titrator is able to reproduce the range value with a maximum anticipated uncertainty of 1.5% when the measurement and instrumental errors have been discounted.

The calculation of the value for the end point potential is carried out by measuring a linear distance, multiplying this distance by the recorder sensitivity, and adding the product to a reference potential on the chart. The maximum anticipated determinate error is about the same as that calculated for the range values, *viz.*, 1.5%. However, the use of a reference potential on the chart introduces an absolute uncertainty of 2 mv. in values based on this potential. In order to account for this factor, 2 mv. have been subtracted from each standard deviation (S) value reported in Table I, column 7, before the relative standard deviation is calculated. Of the 5 values reported in Table I, column 7, those for acetic acid solution are most reliable since the hydrogen-ion concentration and presumably the electrochemical potential at the end point when bases are titrated in acetic acid has been found to be independent of concentration (14). The values for 1,2,3-triphenylguanidine and *m*-nitrobenzhydrazide in acetic acid solution indicate that these potentials are reproducible within expected limits. The relative errors of the values determined in isopropanol solution are higher than the calculated limit. On the basis of the observed values, the titrator reproduces the end point potential with a maximum uncertainty of 4.4% when the measurement and instrumental errors have been discounted.

Another indication of the ability of this system to reproduce results is the analytical data which are presented in Table I, column 9. It is noted that both titrants have been standardized to values precise to about 0.3%. This is within expectations for a volumetric method. The recoveries as listed in column 9 of the other two compounds have a maximum standard deviation of 1.0%. This demonstrates that the instrument is able to yield analytical data and 1.0% maximum uncertainty.

The last criterion chosen to evaluate the behavior of the system is the slope of the rapidly rising portion of the curve. This property is also known as the sharpness index (15). The values presented in Table I, column 8, were obtained by measuring the tangent of angle ADE, Fig. 1. The calculations are carried out according to the following equation:

$$\text{tan. ADE} = \frac{(\text{AE})\ (\text{sensitivity})}{(\text{DE})}$$

The estimate of the relative errors transmitted to the final slope value was found to be a maximum of 3.6% in the case of benzoic acid. The observed relative standard deviations are larger than the estimated relative errors. On the basis of these data, the slope is reproduced with a maximum uncertainty of 11.4% (15.0–3.6) when the measurement and instrumental errors have been discounted.

The value of 11.4% which has been calculated to be the maximum uncertainty of the slope may be composed of unknown determinate as well as random errors. Blaedel and Meloche (16) discuss end point errors and particularly the random error involved in selecting the inflection point. These authors make the following statements: "In locating the inflection point, the standard error appears to be about 10% of the volume interval covered by the straight-line portion of the experimental titration curve. This figure of 10% is a rough estimate based on experience, and has no theoretical basis." The "volume interval covered by the straight-line portion" mentioned corresponds to the line DE of Fig. 1. Since DE is used in the slope calculation, its random error will be propagated according to usual concepts which dictate that the squares of the relative standard deviations

[a] In each instance, S indicates the standard deviation. [b] The figures in the parentheses are relative standard deviations.

of the elements in a quotient are summed and the square root is extracted to yield the relative standard deviation of the quotient (8). When this is done with the 10% uncertainty mentioned previously, a relative random error of at least 10% is expected in the result. On this basis, only 1.4% of the original 11.4% remains unexplained. This percentage may very well be random error in AE for which no estimate is available.

During the rapidly rising portion of the curve, the sensing and recording of potentials is most difficult since the potential is changing very rapidly. Factors such as speed of recorder response, efficiency of stirring, and rate of titrant addition are all involved in this measurement. It is possible to obtain an electronic setup whereby the rate of titrant addition is slowed as a function of the rate of change of potential. This may improve the reproducibility of the slope. However, this feedback mechanism substantially increases the cost of the instrument. Commercial titrators offer this advantageous feature.

SUMMARY

1. A procedure for evaluating titration behavior of an automatic potentiometric titrator is reported.

2. The procedure consists of an instrument evaluation followed by an examination of titration curve properties. The range, end point potential, analytical results, and the slope of the rapidly rising portion of each curve are determined.

3. The maximum anticipated relative errors are calculated and compared with experimental results obtained from a relatively inexpensive titrator composed of commercially available units.

4. On the basis of satisfactory instrumental response and of reasonable titration curve errors, the titrator used here is found to be reliable for general laboratory use.

Isolation of Aurantiacin from *Hydnellum caeruleum*

By M. L. MONTFORT*, V. E. TYLER, JR., and L. R. BRADY

Two procedures were employed for the isolation of aurantiacin from an ether extract of the basidiomycete *Hydnellum caeruleum*. Identification of the compound was based on its melting point, spectral properties (infrared, visible, and ultraviolet), and alkaline degradation to atromentin and benzoic acid.

POLYPORIC ACID (2,5-dihydroxy-3,6-diphenyl-1,4-benzoquinone) was shown by Burton and Cain to be the constituent responsible for the antitumor properties of the lichen *Sticta orygmaea* Ach. (*S. coronata* Müll. Arg.) (1). Subsequently, the antitumor activity of some related synthetic diaryldihydroxyquinones (2, 3) has been recorded. Recently, atromentin [2,5-dihydroxy-3,6-bis(4′-hydroxyphenyl)-1,4-benzoquinone] was identified as the anticoagulant principle in *Hydnellum diabolus* Banker (4, 5). Thus, compounds of this type have therapeutic potential, and their occurrence in nature has medicinal interest.

No diphenylbenzoquinone compound is known to occur in spermatophytes, but aurantiacin (atromentin-2,5-dibenzoate) (6), leucomelone (3′-hydroxyatromentin) (7), muscarufin [2,5-di(2′-carboxyphenyl) - 3 - hydroxy - 6 - (4′ - carboxy - 1,3 - buta-

dienyl)-1,4-benzoquinone] (8), thelephoric acid [2,3,8,9-tetrahydroxybenzobis(1,2-*b*, 4, 5-*b'*)-benzofuran-6,12-quinone] (9–14), and polyporic acid (15–21), in addition to atromentin (4, 22, 23), have been isolated from certain basidiomycetes belonging to the genera *Amanita, Cantharellus, Hydnellum, Hydnum, Lopharia, Paxillus, Polyporus,* and *Thelephora.* The *Hydnaceae* appear to be a particularly rich source of the diphenylbenzoquinone compounds with *Hydnellum, Hydnum,* and *Lopharia* species yielding atromentin, aurantiacin, polyporic acid, and thelephoric acid. *Hydnellum caeruleum* (Pers.) Karst. is known to lack anticoagulant properties (5), but the species has never been investigated chemically. When a quantity of this species became available, it was considered desirable to examine the fungus for diphenylbenzoquinone constituents.

EXPERIMENTAL AND RESULTS

Material and Extraction Procedure.—Carpophores of *H. caeruleum* were collected, cleaned, and dried in a forced-air drying oven at 48° for a minimum of 72 hr. Ninety-three grams of a 40-mesh powder of the whole mushroom was extracted exhaustively with successive portions of petroleum ether, diethyl ether, chloroform, and 95% ethanol in a Soxhlet apparatus. An orange-red crystalline precipitate (6.33 Gm.) separated from the ether solution during extraction and was removed by filtration prior to evaporation of the solvent. Gripenberg (6) had isolated aurantiacin from a similar precipitate obtained upon ether extraction of *Hydnellum aurantiacum* (Fr.) Karst. (*Hydnum aurantiacum* Batsch); consequently, this precipitate was selected as the first fraction to be examined.

Chromatographic Evaluation of the Crude Precipitate.—Chromatography was potentially the most convenient way to obtain a preliminary evaluation of the various extracts, but no chromatographic procedures have been reported for the separation of diphenylbenzoquinone compounds. Thus, a solution of the precipitate from the ether extract was examined using a variety of adsorbents and solvent systems to determine if it could be resolved readily. Maximum resolution of the components in the crude precipitate was obtained on a layer of Silica Gel G with a benzene–ethyl acetate–glacial acetic acid (75:24:1) solvent system. A mixture of 20 Gm. of Silica Gel G and 40 ml. of distilled water was shaken for 1 min. and spread on 20 × 20 cm. glass plates in a uniform 250-μ layer. The plates were allowed to stand for 10 min., heated at 105–110° for 30 min., and cooled. The crude material was applied to the chromatograms, and they were formed ascendingly using the solvent mixture. Some material remained at the point of origin; the other components separate into five chromatographic zones, two of which developed latent colors upon standing at room temperature for 24–48 hr. The actual migration of the zones on the chromatographic layers was observed to vary slightly with the quantity of material spotted and with different batches of chromatographic plates. However, the relative position of the zones was always the same, and representative R_f values are as follows: 0.33, yellow-orange; 0.24, latent lavender-brown; 0.17, yellow-brown; 0.13, latent gray; 0.10, slate gray. The ether filtrate which remained after separation of the precipitate exhibited the same qualitative composition upon chromatography. Examination of available diphenylbenzoquinones revealed that atromentin and polyporic acid remained at the point of origin under these chromatographic conditions, whereas 2,5-diphenyl-1,4-benzoquinone had an R_f value of 0.63.

Isolation of the Major Component of the Crude Precipitate.—Gripenberg (6) utilized a column of acid-washed alumina in his isolation of aurantiacin, but the results obtained with thin-layer chromatography and with preliminary columns suggested that the use of silica gel permitted more effective separation of the components of *H. caeruleum.* A mixture of silica gel (100–200 mesh) and flux calcined diatomaceous silica[1] (75:1) was suspended in benzene and transferred to an 18-mm. diameter extrusion-type chromatographic column to give a 30.5-cm. column of adsorbent. A sample of the crude precipitate (1.3 Gm.) was dissolved in a minimum volume of dioxane and adsorbed on a small quantity of the silica gel–flux calcined diatomaceous silica[1] mixture. The dioxane was evaporated at 50°, and the adsorbed material was added to the top of the chromatographic column. The column was washed successively with approximately 2000 ml. of benzene–ethyl acetate (9:1), 1850 ml. of benzene–ethyl acetate (1:1), 150 ml. of ethyl acetate, and 400 ml. of ethyl acetate–glacial acetic acid (20:1). The eluate was collected in approximately 50-ml. fractions, and 25–50-μl. portions of each fraction were examined using the thin-layer chromatographic procedure. The first 200 ml. of eluate contained no pigmented compounds, and the next 900 ml. were chromatographically homogeneous (R_f 0.33). Thin-layer chromatography revealed that the compound with R_f 0.33 was the major component of the crude precipitate; it was detected in all subsequent fractions of the eluate. The eluates containing only the one compound (R_f 0.33) were combined, the solvent was evaporated in a stream of air at room temperature, and the residue was recrystallized 3 times from dioxane. The solvent of crystallization was removed by heating in a drying pistol over phosphorus pentoxide at 146° *in vacuo* for 120 hr.

Isolation of the orange-red crystalline material using the column chromatographic procedure was tedious and relatively inefficient. Consequently, an alternate procedure which employed selective solubilization of the accompanying impurities was developed. A sample of the crude precipitate (2.5 Gm.) was stirred with successive 50-ml. portions of methanol, and the supernatant solutions were examined using thin-layer chromatography. After washing the crude precipitate with 5 portions of methanol, the remaining residue was chromatographically homogeneous (R_f 0.33). When this material was recrystallized from dioxane and dried, it was indistinguishable from the crystalline substance obtained by column chromatography.

Preliminary Identification of the Isolated Material.—Qualitative elemental analysis following sodium fusion revealed the absence of nitrogen, sulfur, and halogens in the molecule. The infrared spectrum of the compound in a potassium bromide pellet using a Beckman infrared spectrophotometer, model IR5A, strongly suggested the presence of an

[1] Marketed as Hyflo Super Cel by the Johns-Manville Corp.

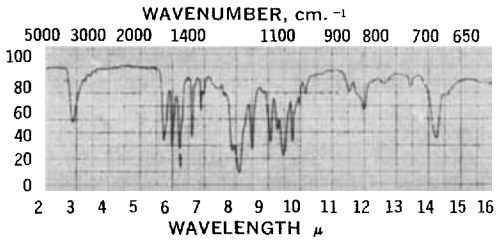

Fig. 1.—Infrared spectrum of isolated aurantiacin.

ester carbonyl group (1748 cm.$^{-1}$) and a quinone carbonyl function (1665 cm.$^{-1}$). The balance of the infrared spectrum (Fig. 1) was consistent with that anticipated for a substituted diphenylbenzoquinone compound (24), and the micro m.p., K., of 285–295°, agreed with the melting point reported for aurantiacin (6).

Visible and ultraviolet absorption spectra are useful in distinguishing some diphenylbenzoquinones (25). Such spectra were obtained by dissolving 2.0 mg. of the recrystallized compound in 10 ml. of dioxane, diluting the solution 25-fold, and recording the absorption with a Beckman spectrophotometer, model DB. The absorption maxima obtained at 240 mμ (log ϵ = 4.71) and 405 mμ (log ϵ = 3.94) were in agreement with the values 240 mμ (log ϵ = 4.63) and 405 mμ (log ϵ = 3.82) reported for aurantiacin.

Degradation of the Isolated Material.—Preliminary data suggested that the isolated material was aurantiacin, a compound which can be decomposed to atromentin and benzoic acid (6). A small sample of the crystals (100 mg.) was dissolved in 50 ml. of 2 *N* sodium hydroxide solution. The alkaline solution was acidified with concentrated hydrochloric acid and partitioned with three successive 50-ml. portions of ether. The ether solution was extracted with three 50-ml. portions of saturated sodium bicarbonate solution. Acidification of the bicarbonate solution gave a brown precipitate which was separated by filtration and washed with benzene. The mother liquor from the filtration was extracted with ether, the ether was removed by evaporation, and the residue was washed with benzene. The corresponding benzene-soluble and insoluble portions of the precipitate and residue were combined.

The benzene solution was evaporated to dryness, and the residue was sublimed under reduced pressure. Micro m.p., K., of the sublimate was 120–121°. An admixture with authentic benzoic acid showed no depression in melting point.

The benzene–insoluble material was recrystallized from methanol and dried *in vacuo* over phosphorus pentoxide at 146° for 120 hr. It decomposed without melting at about 303–305°. A dioxane solution of the material (1 mg. dissolved in 10 ml., then diluted 25-fold) had absorption maxima at 268 mμ (log ϵ = 4.51) and 384 mμ (log ϵ = 3.73); these results agreed with the values 268 mμ (log ϵ = 4.55) and 385 mμ (log ϵ = 3.66) reported for atromentin (25).

DISCUSSION AND CONCLUSIONS

Extraction and fractionation procedures were utilized to investigate the occurrence of diphenylbenzoquinone compounds in carpophores of *H. caerulum*. An orange-red crystalline compound was isolated from a precipitate that separated from the ether extract. The melting point and spectral properties (infrared, visible, and ultraviolet) of the isolated compound corresponded to those of aurantiacin. This identification was confirmed by alkaline degradation of the material to atromentin and benzoic acid.

The isolation of aurantiacin from *H. caeruleum* marks the second reported occurrence of this compound in nature and the first since its original isolation from *H. aurantiacum* (6). The genus *Hydnellum* is a reasonably well-defined taxon which is characterized by a tough fibrous or leathery context (26). Major morphologic criteria for the separation of species within the genus are the presence or absence of clamp connections in the hyphae of the pileal trama and the presence or absence of incrusting granules in the tramal hyphae. *H. aurantiacum* has incrusting granules and no clamp connections; *H. caeruleum*, the antipode, has clamp connections and no granules. Thus, morphologic considerations suggest that the two species are not as closely related as could be predicted on the basis of aurantiacin accumulation. However, there is no available evidence which permits the assignment of a greater or less phylogenetic significance to chemotaxonomic indicators than to morphologic relationships.

Effect of Antitumor Antibiotics and Antimetabolites on Rat Diaphragm Carbohydrate Metabolism

By LEON L. GERSHBEIN

Rat hemidiaphragms have been incubated with antitumor antibiotics and antimetabolites in a phosphate–saline medium containing 120 mg. per cent glucose and the changes in oxygen uptake, hexose utilization, and glycogen turnover ascertained. Aminopterin (0.40 mg.), triethylenemelamine (0.40 mg.), and 2-*n*-heptyl-4-hydroxyquinoline-*N*-oxide (50 mcg.) caused a decrease in glycogen content; the latter two as well as chlorambucil and 8-azaguanine, both screened down to 10 mcg., depressed glucose utilization. Of the antibiotics, glycogenolysis occurred in the presence of tubercidin (0.50 mg.), antimycin D (0.75 mg.), streptonigrin (50 mcg.), and antimycin A (0.25 mg., suspension). Muscle glucose uptake was depressed in the presence of more physiologically significant levels of puromycin, tubercidin, streptonigrin, duazomycins A and B, and actinogan and with antimycin A (0.25 mg.); tylosin was effective in this regard at 1.00 mg. Diaphragm Q_{O_2} was depressed by 2-*n*-heptyl-4-hydroxyquinoline-*N*-oxide (50 mcg.), 8-azaadenine (0.25 mg.), and 0.50 mg. each of streptonigrin, E73 base, glutinosin, psicofuranine, and actinogan and was elevated by porfiromycin (0.50 mg.).

IN RECENT studies by this laboratory, the effect of a variety of antibiotics was ascertained on the isolated rat diaphragm (1). Of these, albamycin decreased both glucose uptake and glycogen content at concentrations to 30 mcg. and at even lower levels, hexose utilization was depressed, as was also the case with chloramphenicol and kanamycin. In the present investigation, these criteria were applied to antitumor antimetabolites and antibiotics. The agents, tylosin and capreomycin, were also included as well as a cytotoxic sterol, kethoxal-bis(thiosemicarbazone), and 2-*n*-heptyl-4-hydroxyquinoline-*N*-oxide. The last compound is a streptomycin antagonist, inhibiting NADH and succinate oxidation by mitochondria (2–4).

EXPERIMENTAL

Antitumor antibiotics were generously supplied by several companies, the sources and code designations of which appear in Table I. The antimetabolites of high purity originated from commercial sources.[1] The agents were dissolved in 0.85% saline and for acids and water-insoluble aza-derivatives, solution was first effected with aqueous NaOH and then further diluted to the desired concentration with saline; all mixtures were prepared fresh prior to use. For the incubation of the hemidiaphragms, the medium of Stadie and Zapp (11) was used double strength (final concentration: 0.04 *M* Na_2HPO_4, 0.005 *M* $MgCl_2.5H_2O$, and 0.08 *M* NaCl, pH 6.8–7.0; the glucose level was 120 mg. %).

The removal of hemidiaphragms from male Holtzman rats weighing 135–165 Gm., starved for 24 hr., and their processing as well as the incubation and analytical procedures were identical with those described in previous reports (12–14). By the method of paired hemidiaphragms, one tissue was incubated with 1 ml. double strength medium + 1 ml. saline–drug solution, and the other hemidiaphragm, with 1 ml. medium + 1.0 ml. saline (control); the requisite flasks without muscle were also employed in each run. Incubation was carried out under oxygen in a Warburg apparatus at 37° for 1 hr., after which time the rinsed hemidiaphragms were hydrolyzed with 30% KOH and analyzed for glycogen (15–17); glucose in the incubation fluids was determined following dilution and deproteinization (18, 19).

RESULTS AND DISCUSSION

Average differences in Q_{O_2}, glucose uptake, and glycogen content for hemidiaphragms incubated with antimetabolites and antibiotics together with the standard errors and the Fisher *t* values in the comparisons appear in Table I. Since no experimental design was followed, a statistical method was applied to the bulk data; differences in excess of $\bar{R} \pm 2.5\ \bar{R}$, $\bar{R}$ being the average range, were discarded (20). As small to slight amounts of glutinosin (0.50 mg.), porfiromycin (0.50 mg.), streptimidone (0.50 mg.), and actinomycin D (0.75 mg.) and even larger portions of chlorambucil (0.50 mg.), tubercidin, antimycin A, and 2-*n*-heptyl-4-hydroxyquinoline-*N*-oxide (0.050 mg.) remained undissolved, fine suspensions were used in each instance.

The mean differences were not statistically significant for the following, the values in parentheses denoting the highest levels (mg.) screened: methotrexate (0.40), thio-tepa (0.40), 6-mercaptopurine (0.25), cyclophosphamide (0.40), 5-fluorouracil (1.00), 8-azaxanthine (0.25), 6-azathymine (0.25), 6-azauracil (0.25), 7-azatryptophan (0.050), 4-azaleucine·2HCl (1.00), cycloleucine (2.00), carzinophilin (400 u.), cycloserine (1.00), mitomycin C (0.10), kethoxal-bis(thiosemicarbazone) (0.50), the cytotoxic steroid (0.050), capreomycin disulfate (1.00), actino-

Accepted for publication July 27, 1966.

[1] Thio-tepa, triethylenemelamine (trademark, TEM), aminopterin, and methotrexate were obtained from Lederle Laboratories; the antiviral and antitumor agent, kethoxal-bis(thiosemicarbazone) [(5); derivative of β-ethoxy-α-ketobutraldehyde], the cytotoxic sterol, γ-lactone of 16-β-hydroxy-3,11-dioxopregna-4,17(20)-dien-21-oic acid (6) from the Upjohn Co.; cyclophosphamide (trademark, Cytoxan) from Mead Johnson Laboratories; capreomycin disulfate (750 mcg./mg. solids) and tylosin from Eli Lilly & Co.; chlorambucil (trademark, Leukeran) from Burroughs Wellcome & Co.; 2-*n*-heptyl-4-hydroxyquinoline-*N*-oxide, 8-azaadenine, and 8-azaguanine in addition to the antibiotic, antimycin A, from Sigma Chemical Co.; 5-fluorouracil from Roche Laboratories and 6-mercaptopurine, 6-azathymine, 6-azauracil, 7-azatryptophan, cycloserine (D-4-amino-3-isoxazolidone), the antitumor agent and methionine antagonist, cycloleucine [1-aminocyclopentanecarboxylic acid; (7–9)]; and a competitive antagonist of leucine utilization in some bacteria, 4-azaleucine hydrochloride [2-amino-3-dimethylaminopropanoic acid · 2HCl; (10)] from Nutritional Biochemicals Corp. The latter was also the source of the antibiotics, puromycin hydrochloride, carzinophilin, and mitomycin C.

[a] The means (±S.E.) are deduced on the basis of the specified number of paired hemidiaphragms given in the parentheses. [b] A positive mean difference indicates a decrease in response in the presence of the antimetabolite or antibiotic. [c] mg. of agent per Warburg flask in a fluid volume of 2.0 ml. [d] In the codings, BL, EL, MSD, PD, PF, and U refer to Bristol Laboratories, Eli Lilly & Co., Merck Sharp & Dohme, Parke, Davis & Co., Chas. Pfizer & Co. and the Upjohn Co., respectively. [e] The extent of glucose utilization was based on the final concentration of the respective media incubated without diaphragm. [f] $p < 0.05$. [g] $p < 0.01$. [h] $p < 0.02$.

bolin sulfate (0.50, Parke Davis), streptimidone (0.50, Parke Davis), 6-diazo-5-oxo-L-norleucine (0.50, Parke Davis), azaserine (1.00, Parke Davis), pactomycin (0.50, Upjohn), streptovitacin A (0.50, Upjohn), decoyinine (0.50, Upjohn), cycloheximide (0.50, Upjohn), actinomycin P_2 (0.050, Pfizer), roseolic acid (0.50, Pfizer), and netropsin sulfate (0.50, Pfizer).

Of the tumor antimetabolites, decreases in glycogen content occurred only with aminopterin (0.40 mg.), triethylenemelamine (0.40 mg.), and even more pronounced, with 2-*n*-heptyl-4-hydroxyquinoline-*N*-oxide (0.050 mg.). The last two agents also caused depressions in glucose uptake as was also noted with chlorambucil (0.010 and 0.10 mg.) and 8-azaguanine screened down to levels of 10 mcg.; the streptomycin antagonist also markedly depressed oxygen uptake. In this regard, similar runs conducted with 8-azaxanthine, 8-azaadenine, and 6-azauracil, each at 0.25 mg., showed them to be essentially without effect, except for a minor decrease in Q_{O_2} with 8-azaadenine. At this dosage, 7-azatryptophan, an agent which can be incorporated into protein (21, 22), lowered glucose utilization, an effect which did not extend to 0.050 mg.

With the antibiotics, puromycin (0.020 and 0.25 mg.) and tubercidin (0.050 and 0.50 mg.), representing the nucleoside types, diminished glucose uptake and at the higher level of tubercidin (7-deaza-adenosine), the glycogen content underwent a definite decrease. In fact, of the antibiotics, a fall in glycogen content, in addition to tubercidin, was noted with the high dosage of actinomycin D (0.75 mg.), streptonigrin (0.050 and 0.50 mg.; almost borderline significance with 0.10 mg.), and antimycin A (0.25 mg. suspension). Glucose utilization was decreased in the presence of the last agent and streptonigrin at 0.50 mg., a level which also inhibited diaphragm respiration. It is of interest that the glutarimides, cycloheximide, streptovitacin A, and the related E73 base were without effect except that the decrease in Q_{O_2} was significant only with E73 (0.50 mg., $p < 0.05$). Respiration was also depressed with glutinosin (0.50 mg.) and psicofuranine (0.50 mg.) but was elevated at the 2% level of probability with porfiromycin (0.50 mg.). Tylosin proved a depressant of glucose uptake solely at the higher dosage (1.00 mg.).

The antitumor glycoprotein, actinogan (23), markedly depressed glucose utilization by rat diaphragm even at a level of 0.50 mcg. and with 0.50 mg., the Q_{O_2} difference was decreased at the 5% level of probability but the diminution in glycogen content was just short of statistical significance. The findings were somewhat similar with mithramycin and duazomycins A and B, each screened down to levels of 10, 10, and 50 mcg., respectively. However, Q_{O_2} and glycogen content differences were not affected at the highest dosage of each (0.50 mg.). It would be of interest to compare the effect of actinogan with peptinogan, a polypeptide fraction obtained from this antibiotic and which also possesses antitumor action (24), an experiment not included in this series.

Attempts at Induced Agranulocytosis in Rats Using Dipyrone

By N. M. FERGUSON and ARTHUR F. NOVAK*

Dipyrone administered orally to rats at the rate of 50 and 100 mg. per day over a period of 8 weeks did not produce any abnormalities in the blood picture. In addition no visible differences could be observed in the rats receiving the drug over those of the control group. No sensitivity to the drug was observed.

AGRANULOCYTOSIS is a disease characterized by a marked change in the blood picture, particularly that of a reduction in the polynuclear leukocyte count. A great many substances have been suspected of causing agranulocytosis (1). Included in this list are industrial solvents, *e.g.*, benzene, toluene, naphtha, paints and paint removers, and heavy metals such as gold and lead and their salts. By far the greater number, however, consist of drugs. This list includes practically all of the different classes of drugs such as anti-infectives, sedatives, tranquilizers, cardiotonics, and analgesics. Since some analgesic drugs are used in large quantities for fever as well as for pain, the total number of doses prescribed annually is very great. As a result of the widespread use of these drugs even a very low incidence of agranulocytosis appears to be alarming (1).

Attempts at controlling the distribution of these drugs have resulted in their being limited to prescription use only. Since most of them are very effective in relieving pain and some in reducing fever, they often constitute the only means of producing these desired therapeutic effects.

One of the most effective analgesic drugs which is equally effective in reducing fever is dipyrone, a derivative of antipyrine. This substance has been suspected of being a causative agent in agranulocytosis (1). This tabulation indicates that prior to June 1963, eight cases of agranulocytosis were reported to the panel and an additional nine cases were cited in the literature where dipyrone was the only drug given in the 6-month period prior to the onset of the disease. Six other cases, four from direct reports and two from the literature, occurred in which dipyrone was given in conjunction with other drugs which are believed not to be associated with agranulocytosis. During the same period other cases were brought to light where dipyrone was given along with additional medication which in turn is not known to be innocent or in many cases is actually known to precipitate agranulocytosis. From July 1963 to July 1964, only two cases are reported where the only drug given during the previous 6-month period prior to the onset of the disease was dipyrone, whereas, four cases have been recorded during the same period where other drugs not known to be innocent of this reaction and four cases where drugs known to be toxic were administered. During these same periods, however, many other drug substances have been reported as being responsible for or associated with agranulocytosis and many of these in much higher incidence than dipyrone (1).

TABLE I.—EXPERIMENTAL CONDITIONS

Group No.	Drug Received	Daily Dose, ml.	Days
1	None	0	30
2	Dipyrone[a]	0.5 (50 mg. dipyrone)	30
3	Dipyrone	1.0 (100 mg. dipyrone)	30

[a] The authors thank Savage Laboratories, Inc., Houston, Tex., for supplying dipyrone as Pyralgin Liquid used in this study.

Many attempts have been made to learn the exact mechanism of drug induced agranulocytosis. Kracke (2) found that clinical agranulocytosis could be produced in rabbits by subcutaneous injections of benzene. Lu *et al.* (3) reported that there was no reduction of blood cell count and hypoplasia of bone marrow was not observed in rabbits receiving daily administration of aminopyrine for 4 to 6 weeks even in the presence of a sensitizing agent such as busulfan.[1]

In view of the fact that dipyrone is prescribed widely for the relief of fever and pain and has been associated with the reported incidence of agranulocytosis, it was felt that further studies should be conducted with this substance. The present study, the first in a series, concerns attempts to induce agranulocytosis in rats with dipyrone.

EXPERIMENTAL

A series of 120 white rats, approximately 6 weeks old, having an average weight of 250-Gm., and equally divided as to sex, were selected for these experiments. The experimental design was planned so that the results could be analyzed statistically if this was necessary to interpret the results.

All of the rats were maintained since birth, and during the course of the entire experiment on Purina rat chow, which is a highly standardized commercial feed, fulfilling all of the nutritional requirements of rats for normal growth. Feed and water were available to the animals continuously.

The experiments were performed in an air-conditioned laboratory maintained at 72–74° F. Feed was added as required by replacing the used feed containers with clean filled containers of feed. Clean water was replaced daily. Records of feed consumption and body weight were kept for each animal.

At the outset of this investigation, the rats were separated into three groups of 20 males and 20 females each. Table I lists the experimental conditions.

Group *1* served as the control, while groups *2*

and *3* were administered daily doses of dipyrone according to the quantities listed in the above table.

Blood counts were made initially, and after every 2 weeks during the course of the experiment. Body weights were recorded and visual observations were made on each rat. None of the rats died during the course of the experiment.

PROCEDURES

Administration of Dipyrone.—The drug was administered orally each morning by employing a 1-ml. graduated pipet, and allowing the animal to drink the fluid as it was released slowly from the tip. No problems were encountered with this technique.

Blood Counts.—Since the tail is free from local circulatory change, it was used as the site of puncture. The tail was cleaned with ethanol and dried, and the tip of the tail was cut off with sterile surgical scissors. After the first few drops of blood were wiped away, the subsequent drops were obtained for red cell count, white cell count, and a blood smear for a differential count. Standard methods were employed for the counts.

RESULTS

All of the results obtained are presented in Tables II–IV. The total number of red and white blood cells are the average values. The individual variations in the population within the groups were too insignificant to have any biological importance.

DISCUSSION

The statistical treatment of the data was by the method of analyses of variance by the *F* test method. The variance of the average values of rats with dipyrone from an initial period to a period of 8 weeks was compared to that of initial averages of controls for the same period. Table IV shows the range of results for 20 rats in each series. It is to be noted that the highest and lowest values are within the normal ranges for each type of blood cell counted.

The weights and feed intake were the same for the control group as well as for the groups receiving the drug. No visual differences could be observed in the rats receiving the drug over those in the control group. Furthermore, the rats showed no sensitivity to the drug.

Four rats out of each series (*i.e.*, two males and two females) were checked at the end of 8 weeks and no abnormalities were found with respect to blood glucose, cholesterol, phospholipids, and urea nitrogen suggesting that no chemical changes resulted from the use of the drug.

SUMMARY AND CONCLUSIONS

In carefully controlled studies carried out over a period of 8 weeks, involving 120 rats, no statistically significant changes occurred in the blood picture with respect to red cell, white cell, and differential counts when varying amounts of dipyrone were administered orally.

No visual differences could be observed in the rats receiving the drug over those in the control group.

No rats died as the result of taking the drug.

No abnormalities were found with respect to blood glucose, cholesterol, phospholipids, and urea nitrogen on examining animals from each group suggesting that no chemical changes resulted from the use of the drug.

In this study using massive doses of dipyrone no indications of agranulocytosis were produced.

Phytochemical Investigation of *Abies concolor*

By AYHAN ULUBELEN*, MARY E. CALDWELL, and JACK R. COLE

Extracts of the bark of *Abies concolor* have shown antitumor activity against the adenocarcinoma of the duodenum test system of the Cancer Chemotherapy National Service Center. One of the active materials appears to be a complex tannin. The isolation of the active fractions has been reported utilizing solvent extraction, column, paper, and thin-layer chromatography.

In a routine screen of Arizona and Mexico plants for antitumor activity, it was found that extracts of the bark of *Abies concolor* (Gordon and Glendinning) Hoopes were shown to have activity against the adenocarcinoma of the duodenum (7D1) test system of the Cancer Chemotherapy National Service Center, Bethesda, Md. The plant, also known as white fir, is a soft-wooded, resinous evergreen monoccious tree, 100–200 ft. tall, 3–6 ft. in trunk diameter. It is distributed from Wyoming west to Oregon and south into Baja California, Arizona, New Mexico, and Sonora, at elevations of 3000–10,000 ft.

The collection used in this study was obtained from upper Sabino Creek, 8000 ft. elevation, Santa-Catalina Mountains, Pima County, Ariz.[1]

EXPERIMENTAL

Preliminary Extraction.—The bark (3.5 Kg.) of *A. concolor* was extracted with chloroform–ethanol (1:1) in a Lloyd extractor for 2 days. After evaporation, this crude extract was submitted to the adenocarcinoma of the duodenum test system (7D1). The crude material showed a decrease in tumor size of approximately 86 and 84% at a dose of 400 and 200 mg./Kg., respectively (Table I).

Table I.—*In Vivo* Tumor Inhibition

	Dose, mg./Kg.	% T/C[a]
n-Hexane extract	175	32
	200	32
Brown powder	100	26
	200	11

[a] The criteria for activity is defined as being a % T/C (test/control) value of less than 42 in a satisfactory dose response test (1).

One kilogram of the crude material was extracted with 2000 ml. of *n*-hexane in a Soxhlet for 72 hr. The green *n*-hexane extract upon evaporation yielded 200 Gm. of gummy material. A brown powder was obtained in the Soxhlet. Both of the materials were active against the test system.

n-Hexane Extraction

Twenty-five grams of the green material obtained from the *n*-hexane extraction was extracted with 10 × 100 ml. of petroleum ether (36–60°). The petroleum ether was evaporated to dryness in a Rinco evaporator under reduced pressure. A light green residue (10 Gm.) was obtained.

Part A.—Five grams of this residue was chromatographed on a neutral alumina column (30 × 3 cm.) (Fisher certified reagent catalog No. A-950 Brockman, activity I, 80–200 mesh). The column

was successively washed with the following solvents until extinction: (*a*) benzene, (*b*) chloroform, (*c*) ether.

(*a*) The benzene fraction was evaporated to a small volume. A white substance was separated (45 mg.). This substance was purified by preparative thin-layer chromatography using 20 × 20 cm. plates covered with a slurry of Silica Gel G (35 Gm. in 50 ml. of water), and activated in an oven at 110° for about 2 hr. Benzene–petroleum ether (3:7) was used as the developing solvent. The compound obtained from the plates was crystallized from ethanol and had a melting point of 82–83°. The I.R. curve showed that it was a simple long chain ketone. The semicarbazone derivative was oily. The oxime was prepared. It had a melting point of 59°. The compound was identified as palmiton by comparing the melting point of the compounds and oxime derivative (2) and I.R. curves. The remaining part of the benzene fraction was evaporated to dryness. An oily compound (2.0378 Gm.) was obtained. Preparative thin-layer chromatography indicated a series of materials. These appear to be small molecular weight terpenes. Since a thorough work has been performed by Carlberg (3), and since this part had no activity, no further work has been done.

(*b*) The chloroform fraction was evaporated to dryness and yielded 2.2 Gm. of material. Again by means of the preparative thin-layer chromatography, using chloroform–petroleum ether (7:3) as the developing solvent, two main spots and a series of minor compounds were obtained. Since the two main compounds were close to each other, they were extracted from the plates with chloroform and rechromatographed with petroleum ether–ether (1:1) as the developing solvent. A better separation was achieved. The yields of the compounds were 430 mg. for compound I with an R_f value 0.5, and 700 mg. of compound II with an R_f value of 0.7. Compound I was recrystallized from methanol and had a melting point of 136–137°. The I.R. spectrophotometry and mixed melting points indicated that the compound was *p*-menthandiol-(1,4). Compound II was recrystallized from acetone and had a melting point of 70–71°. The I.R. spectrophotometry and mixed melting points indicated the compound to be docosonol-1.

(*c*) The ether fraction, when evaporated, yielded 0.5318 Gm. of material. Preparative thin-layer chromatography with chloroform–ether (99:1) as developing solvent showed four spots (R_f values were 0.2, 0.27, 0.5, 0.95). The yields were 54.2 mg., 66.8 mg., 53.4 mg., and 203.8 mg., respectively. The first spot had a melting point of 88–89°. The I.R. curve has bands at 3509, 2941, 2874, 1718, 1626, 1595, 1508, 1464, 1422, 1266, 1156, 1022, 975, 845, 808, and 720 cm.$^{-1}$. The U.V. curve has a maximum at 321, 243, and a minimum at 263 mμ. The other three compounds were simple ketones and alcohols. No further investigation of the above materials was carried on since they were inactive.

Part B.—The remaining material after the petroleum extraction (13 Gm.) was diluted to 10 times its weight with 50% aqueous potassium hydroxide (4). The mixture was left to cool and 4 times the volume of ethanol was added. The mixture was then refluxed under nitrogen atmosphere for 3 hr. At 30-min. intervals a small amount of the mixture was subjected to thin-layer chromatography using petroleum ether–ether–acetic acid (70:30:2) solvent system. This was done in order to see if the hydrolysis was completed. After the 3-hr. refluxing period the volume was increased 3 times with water. The solution was extracted with ether (10 × 100 ml.), the ether was washed with water, and dried over anhydrous sodium sulfate. The yield of the nonsaponifiable portion was 9 Gm. One gram of this material was applied to a preparative thin layer of silica gel, and chloroform–benzene–ether (6:2:3) was used as the developing solvent system. Three spots were obtained with R_f values of 0.97, 0.6, and 0.4. The material at 0.97 R_f was oily and in minimal concentration. The middle spot yielded 395 mg., which was recrystallized from alcohol and then from acetone. It had a melting point of 76–77°. Comparison of the I.R. curves and mixed melting points showed that it was lignoceryl alcohol. The third compound (117.6 mg.) was recrystallized from alcohol. It had a melting point of 138–139°. The I.R. curve comparison and mixed melting point showed that it was β-sitosterol.

After the extraction of the nonsaponifiable part with ether, the aqueous solution was acidified and extracted with ether (10 × 100 ml.). Upon evaporation 6.5 Gm. of brown material was obtained. A portion of this material (2.5 Gm.) was separated using preparative thin layers with petroleum ether–ether–acetic acid (90:10:1) as the developing system. Four fractions were obtained. R_f values were 0, 0.01, 0.04, and 0.2, and the amounts 550 mg., 1.200 Gm., 200 mg., and 280 mg., respectively. All of these fractions were subjected to further separation using reverse phase paper and thin-layer chromatography. Papers were covered with 7 and 12% of paraffin in benzene and the developing solvent was 85% aqueous methanol. Fraction 4 gave a yellow spot on a blue background when sprayed with bromophenol blue. Methyl derivatives were prepared and only one spot was obtained in the case of fraction 4 when sprayed with Sudan IV solution (5). A dimethyl polysiloxane,[2] 5% in ether, was used to impregnate the silica gel plates for the reverse phase thinlayer chromatography. Acetic acid–formic acid–water (40:40:20) was used as the mobile phase. Again fraction 4 revealed one single spot. This fraction (280 mg.) was recrystallized from alcohol. It had a melting point of 79–80°. The I.R. curve comparison and the mixed melting points revealed that it was lignoceric acid. The compounds thus far isolated from the *n*-hexane extracts do not exhibit antitumor activity in the 7D1 test system.

Alcohol Soluble Part

The material remaining after the *n*-hexane extraction was an amorphous red-brown powder which charred above 250°. Elementary analysis showed 16.9% inorganic residue and the absence of nitrogen, sulfur, and halogens. Magnesium and hydrochloric acid (6), ferric chloride (6), gelatin test (7), and Wilson's boric acid test (8) suggested that this material was a mixture of complex tannin and flavonoid substances. Attempts to purify this crude material were made using the following chromatographic substrates: silica gel, aluminum oxide (neutral),

[2] Marketed as Dow Corning 200 fluid by the Dow Corning Corp., Midland, Mich.

TABLE II.—R_f VALUES OF DELPHINIDIN AND CYANIDIN IN DIFFERENT SOLVENT SYSTEMS

No.	Solvent System	Known		Unknown	
		Cyanidin	Delphinidin		
1	H_2O–HCl–Acetic acid (10:3:30)	0.52	0.31	0.52	0.30
2	*n*-Butanol–acetic acid–H_2O (4:1:5) (upper phase)	0.91	...	0.93	...
3	Formic acid (88%)–3 *N* HCl (1:1)	0.23	0.12	0.23	0.12
4	*n*-Butanol–2 *N* HCl (1:1) (upper phase)	0.62	...	0.62	...

magnesium trisilicate, and polycaprolactam pulver "S".[3]

The first three columns adsorbed the material. When polycaprolactam pulver "S" is mixed with the same amount of diatomaceous earth[4] and packed into a 35 × 3 cm. column, a yellow substance was obtained from ethanol elutions. This was a flavonoid substance. Column chromatography with polycaprolactam powder utilizing preparative thin-layer chromatography yielded the same material, but no antitumor activity was demonstrated by this material. Solvent purification was then employed. Fifty grams of the crude material was dissolved in alcohol and upon the addition of water a precipitate appeared (6.5 Gm.). This precipitate was washed with ether. One gram of a yellow flavonoid substance was obtained. The U.V. spectrum of the flavonoid showed maxima at 285 and 206 mμ and a minimum at 260 mμ. The ether and water-insoluble portion was active against adenocarcinoma of the duodenum test system (7D1), 11% T/C at 200 mg./Kg., 26% T/C at 100-mg. doses. This part gave long streaking blue spots when applied on paper with solvent systems such as (*a*) *n*-butanol–acetic acid–water (4:1:5), (*b*) 50% acetic acid, and (*c*) 2% acetic acid and when sprayed with ferric–ferricyanide, a long pink spot with *p*-toluene sulfonic acid, two violet-pink spots with vanillin-HCl, and no sugar spots with aniline phthalate. The I.R. curve revealed a large hydroxyl band at 3400, and phenyl group at 1595, 1505, and 855 $cm.^{-1}$. The U.V. spectra showed adsorption maxima at 280 and 206 mμ and a minimum at 260 mμ. This compound, when boiled with hydrochloric acid, caused the solution to turn a light pink color and had only 2.5% inorganic material. The compound was water and ether insoluble, nonhydrolyzable, and the classification tests indicated the presence of a phlobaphene. Further purification was accomplished by dissolving the material in alcohol and precipitation by the addition of ether. Column chromatographic separation or hydrolysis with HCl resulted in a loss of activity. The water-soluble portion was extracted with isoamyl alcohol. A slightly brown-red solution was obtained. This also gave streaking spots with the same solvent systems that were used on the phlobaphenes, and the same results were obtained when sprayed with the reagents as indicated above. This compound had less activity, 49% T/C at a dose of 100 mg./Kg. No residue was obtained upon burning. The I.R. curve was very similar to that of the phlobaphene. The U.V. curve gave maxima at 281 and 206 mμ and a minimum at 260 mμ. Being water soluble and ether insoluble, the differential classification reactions indicated above showed that this was a complex tannin. In the three compounds separated the U.V. curve did not show any shift when 1.2 ml. of a 1% $AlCl_3$ in alcohol solution was added, which shows the absence of 3-hydroxy flavones or flavonones with *o*-hydroxy carbonyl groups. When the alcoholic solution was made 0.006 *N* alkaline with KOH, the flavonoid spectra had a bathochromic shift of 20 mμ, phlobaphenes 22 mμ, and the complex tannin 14 mμ. The maximum 280–281 mμ indicated a flavan nucleus, and this is corroborated by the absence of a shift in the spectra with $AlCl_3$ and a definite shift in the spectra of the alkaline solution.

Boiling the complex tannin with hydrochloric acid for approximately 2 hr. changed the color to a bright red. Paper chromatography of this hydrolyzed compound using several solvent systems indicated the presence of cyanidin and delphinidin (Table II).

After hydrolysis, the compound did not yield any sugar spots on paper. Drastic hydrolysis of anthocyanidins isolated using the same method as reported previously (9) yielded protocatechuic acid, phloroglucinol, and gallic acid.

SUMMARY

A. concolor has been investigated to determine the chemical agents responsible for its activity against adenocarcinoma of the duodenum. A complex tannin and phlobaphene fractions appear to be the active compounds in the plant. In addition to the above, palmiton, *p*-menthandiol-(1,4), docosonol-1, lignoceryl alcohol, β-sitosterol, and lignoceric acid were separated and identified by using column and paper chromatographic techniques.

Evaluation of Oral Dilution as a First Aid Measure in Poisoning

By METTA LOU HENDERSON, ALBERT L. PICCHIONI, and LINCOLN CHIN

Dilution with large volumes of water is a widely recommended first aid measure for the treatment of poisoning from ingested chemical agents. In view of the lack of experimental work to support its clinical application and of possible adverse effects that may attend its use, further investigation was undertaken to determine the influence of oral dilution on blood levels of sodium pentobarbital, quinine hydrochloride, and aspirin. The results indicate that oral dilution with large volumes of water increases the rate and degree of gastrointestinal absorption of pentobarbital and quinine, although it has no significant effect on the absorption of aspirin. In view of the possibility of enhanced gastrointestinal absorption of certain chemicals caused by oral dilution, it is suggested that this procedure not be employed as a first aid treatment for ingested systemic poisons.

DILUTION with large volumes of water or other fluids is a widely recommended first aid measure for the treatment of poisoning from ingested chemical agents (1–4). This procedure is based on the belief that dilution will slow absorption of a chemical from the gastrointestinal tract by increasing the amount of fluid that must be absorbed for a given amount of poison (4). However, no experimental evidence has been presented to support this view. Indeed, a study by Ferguson (5) showed that oral median lethal doses (LD_{50}s) of a number of drugs in rats vary inversely with the volume of water in which a drug is administered. In contrast to the above view, the observations of Ferguson would seem to imply that dilution of an ingested chemical may enhance rather than retard its absorption from the gastrointestinal tract.

In view of the lack of experimental work to justify the use of oral dilution in poisoning, and of the possible adverse effects that may attend its use, further investigation of this recommended procedure seems warranted.

The present investigation was designed to determine the influence of oral dilution with water on blood levels of certain chemicals, since the blood concentration of a chemical compound is related to its rate of absorption from the gastrointestinal tract. Sodium pentobarbital, quinine hydrochloride, and aspirin were selected as representative chemical compounds for this project. Barbiturates, in general, are absorbed from the stomach (6, 7) and small intestine (6–9). Quinine is predominantly absorbed from the small intestine (10, 11). Aspirin is considered to be readily absorbed from both the stomach and small intestine (7, 12, 13). The results obtained constitute the basis of this report.

EXPERIMENTAL

Female Sprague-Dawley rats weighing 170–295 Gm. were fasted for 24 hr. and divided into control and test groups of five to nine animals. They were allowed free access to water except during the last hour prior to testing. All drugs were given by oral intubation in a volume of 2 ml./Kg.; 1 min. later the control animals were administered a small volume of water (1 ml./Kg.) by gavage and the test animals were administered a large volume of water (20 ml./Kg.). At each time period after drug treatment, as indicated below, a control group and a test group of animals were anesthetized with ether and blood samples collected from the abdominal aorta for analyses. The difference in the concentrations of each drug in the blood of test and control animals at each time period was statistically compared by means of Student's t test (14).

Pentobarbital.—Control and test animals were administered sodium pentobarbital,[1] 25 mg./Kg., calculated as the base. Blood samples were collected 10, 20, 40, 80, 160, and 320 min. after drug treatment and extracted and analyzed for pentobarbital by the method of Goldbaum (15) as modified in this laboratory (16).

Quinine.—Control and test animals were administered quinine hydrochloride, 100 mg./Kg., calculated as the base. Plasma samples were collected 15, 60, and 120 min. after drug treatment and extracted and analyzed for quinine by the fluorimetric procedure described by Brodie and Udenfriend (17); measurements of fluorescence were made with an Aminco-Bowman spectrophotofluorometer.

Aspirin.—Control and test animals were administered aspirin, 200 mg./Kg., as an aqueous suspension.[2] Plasma samples were collected 5, 15, and 60 min. after drug treatment and analyzed for salicylate by the method of Trinder (19). At the 5-min. time period, the plasma samples were incubated in a water bath at 37° for 2 hr. to ensure that all of the aspirin was hydrolyzed to salicylic acid (20).[3]

RESULTS

Pentobarbital.—The results of the pentobarbital study are presented in Fig. 1. Ten minutes after the administration of pentobarbital the blood concentration of the drug in test animals was 33% higher than in control animals, but the difference is not statistically significant ($p > 0.05$). At the 20- and 40-min. time periods, the pentobarbital levels of test animals were 90 and 78% greater than those of corresponding control animals, respectively. These elevated blood levels of pentobarbital are significantly higher than the control levels ($p < 0.01$). By the 80-, 160-, and 320-min. time periods

Received April 25, 1966, from the Division of Pharmacology and the Arizona Poisoning Control Information Center, College of Pharmacy, University of Arizona, Tucson 85721.

Accepted for publication July 27, 1966.

Presented to the Pharmacology and Biochemistry Section, A.PH.A. Academy of Pharmaceutical Sciences, Dallas meeting, April 1966.

[1] Sodium pentobarbital was supplied through the courtesy of Abbott Laboratories, Chicago, Ill.

[2] The aspirin was triturated in a mortar and sifted through a 100-mesh sieve in order to provide a more uniform suspension and to reduce variability in absorption (18).

[3] Preliminary studies in this laboratory demonstrated that aspirin was completely hydrolyzed to salicylic acid in plasma collected 15 and 60 min. after drug treatment; hence, plasma was not incubated at these two time periods.

the blood pentobarbital concentrations of the test animals were similar to those of the corresponding control animals ($p > 0.05$).

Quinine.—The results of the quinine study are presented in Fig. 2. At the 15-, 60-, and 120-min. time periods the plasma concentrations of quinine in the test animals were 138, 72, and 62.5% higher than those of the corresponding control animals. These values are statistically significant ($p < 0.05$).

Aspirin.—The results of the aspirin study are presented in Fig. 3. The plasma levels of aspirin in test animals did not differ significantly from those of the corresponding control animals during the 5-, 15-, and 60-min. time periods ($p > 0.05$).

DISCUSSION

The results of the present study indicate that oral dilution with large volumes of water increases the rate and degree of gastrointestinal absorption of pentobarbital and quinine, although it has no significant effect on the absorption of aspirin.

Some factors which influence the absorption of drugs from the gastrointestinal tract include: (*a*) degree of ionization of the drug, (*b*) lipoid solubility of the nonionized form of the drug, (*c*) gastric emptying time, (*d*) concentration of the drug in the digestive system, (*e*) solubility of the drug in the digestive system, and (*f*) size of the area over which the drug is spread (6–10, 21–24). Oral dilution with a large volume of water would affect factors (*c*), (*d*), and (*f*).

Since barbiturates are absorbed from the intestine (6–9) as well as from the stomach (6, 7) by nonionized diffusion (8), gastric emptying time probably has only a slight influence on the absorption rate of pentobarbital. The large volume of water administered to the test rats would decrease the concentration of pentobarbital in the gastrointestinal tract and tend to reduce the rate of absorption. However, oral dilution causes a marked increase in surface area over which absorption may take place; this factor undoubtedly exerts a more significant effect on gastrointestinal absorption of pentobarbital than does the factor of concentration of the drug in the digestive system.

Quinine is poorly absorbed from the stomach (7, 10), but it is readily absorbed from the small intestine (10, 11). Hence, hastening the passage of the drug from the stomach into the intestine by oral dilution would tend to allow intestinal absorption to start sooner in the test animals than in the control animals. However, the higher plasma quinine levels in the test animals are most likely due to the increase in surface area for absorption in the intestine.

Aspirin is readily absorbed from the stomach and small intestine (7, 12, 13). Martin (12) states that gastrointestinal absorption is very rapid and complete. In the present study, since the plasma salicylate concentration of the test rats is no higher than that of the control rats, it could be postulated that aspirin is absorbed so rapidly and completely that oral dilution has no significant effect on gastrointestinal absorption of this drug.

Dreisbach (4), who has recommended oral dilution as a first aid treatment in poisoning, warns that the volume of fluid given should not exceed the capacity of the stomach, otherwise the noxious material may be forced into the intestine and absorption would be increased. However, due to the increased surface area for absorption in the stomach following oral dilution, absorption is likely to be enhanced even in the absence of gastric emptying.

Although the present investigation involves only three chemical agents, it appears logical to conclude that oral dilution would generally be ineffective in retarding the gastrointestinal absorption of ingested chemicals. The act of dilution with water cannot occur without a concomitant increase in volume and a consequent increase in surface area from which absorption of a chemical can take place. In view of the possibility that oral dilution may enhance gastrointestinal absorption of chemicals, it is suggested that this procedure not be employed as a first aid treatment for ingested systemic poisons.

Quantitative Determination by Thin-Layer Chromatography of Anhydrotetracyclines in Degraded Tetracycline Tablets

By D. L. SIMMONS, H. S. L. WOO, C. M. KOORENGEVEL, and P. SEERS

A two-dimensional thin-layer chromatography (TLC) procedure on microcrystalline cellulose is presented for the quantitative determination of anhydrotetracycline and epianhydrotetracycline in degraded tetracycline tablets. Initial development is performed with 0.1 *M* EDTA–0.1 per cent ammonium chloride solution to separate the anhydrotetracyclines (R_f 0.34–0.38) from the tetracycline (R_f 0.72) and methanol-soluble excipients. Anhydrotetracycline (R_f 1.0) and epianhydrotetracycline (R_f 0.52) are then resolved by developing the chromatogram with chloroform which has been saturated with the same EDTA–ammonium chloride solution. A complete assay for these anhydro compounds can be performed in less than 2 hr.

POOR RESOLUTION and/or excessive development time has characterized previous chromatographic attempts to separate tetracycline (TC) and its major degradation products, anhydrotetracycline (ATC) and 4-epianhydrotetracycline (EATC). The latter was recently incriminated in the reversible renal dysfunction (Fanconi-type syndrome) caused by the ingestion of degraded TC products (1–7).

In a qualitative examination of TC and its anhydro derivatives by radial chromatography, using water-saturated butanol on silica gel, Rustici and Ferappi (8) obtained the following similar R_f values after 2 hr. of development: TC (0.36), ATC (0.50), and EATC (0.40). When Kelly and Buyske (9) employed paper which had been impregnated with 0.1 *M* EDTA solution and the solvent system *n*-butanol–ammonium hydroxide–water (4:1:5), they obtained the following 16 hr. R_f values: TC (0.39), ATC (0.62), and EATC (0.40). In a recent paper (10) the authors reported the quantitative analysis of ATC from TC test mixtures by TLC on microcrystalline cellulose. This method required only 20 min. development with 0.1% ammonium chloride solution to give R_f values of 0.38 and 0.72 for the ATC and TC, respectively. Subsequent experiments revealed that mixtures of EATC, ATC, and TC are partially resolved by the same chromatographic system, but overlapping of the ATC (0.38) and EATC (0.34) occurred. In order to completely resolve the two anhydro-compounds, two-dimensional chromatography was attempted. The findings of Kelly (11) that ATC and EATC can be separated by partition chromatography employing buffered 0.1 *M* EDTA solution (pH 7.8) as stationary phase and buffer saturated chloroform as moving phase, prompted the authors to utilize these findings in their search for a suitable second solvent system. By developing the chromatogram with 0.1 *M* EDTA (disodium salt)–0.1% ammonium chloride solution (pH 4.5), followed by chloroform which had been saturated with the same EDTA–ammonium chloride solution, complete resolution of the ATC (1.0) and EATC (0.52) occurred. On altering the pH of the aqueous phase between 3.5 and 8.0, R_f values for ATC (1.0) and TC (0.17) were observed to remain constant in the second development;

5.0	6.09 ± 0.10	100.2	5.0	5.16 ± 0.12	97.8	0.1	10
10.0	10.95 ± 0.08	98.8	10.0	10.32 ± 0.24	100.4	0.05	10

[a] ± = standard deviation. The average of five determinations. The blank value for EATC (0.23 mg.) was obtained from the difference between total anhydro content and ATC only.

on the other hand, the R_f value for EATC varied between 0.60 and 0.30. In contrast to Kelly's procedure (11) the results demonstrate that precise pH requirements are not necessary for the system to be operative. Such a large difference between the R_f values for ATC and EATC led to their easy isolation and determination.

EXPERIMENTAL

Preparation of Anhydrotetracycline Hydrochloride.—A modified procedure of McCormick *et al.* (12) was used. Tetracycline hydrochloride was heated in methanol–concentrated hydrochloric acid (1:4) on a steam bath for 30 min. The solution was cooled and diluted with ice water; the resulting precipitate was collected by filtration. Purification was achieved by dissolving the precipitate in hot methanol–concentrated hydrochloric acid (30:1), treating the solution with charcoal, and filtering it through Celite. Crystallization occurred when the filtrate was cooled, and a small amount of concentrated hydrochloric acid was added. By repeating this procedure 6 times, a product was obtained with the melting point and ultraviolet absorption spectrum (0.1 *N* sodium hydroxide solution) of pure anhydrotetracycline hydrochloride.

Preparation of Epianhydrotetracycline Hydrochloride.—By employing the ammonium salt of epi-tetracycline (12) in the foregoing procedure instead of tetracycline, a pure sample of epianhydrotetracycline hydrochloride was prepared.

Preparation of Standards.—Standard solutions (2 mg./ml.) of ATC and EATC in methanol were prepared and aliquots (5, 10, . . . 25 μl.) were removed and diluted to volume with methanol in 10-ml. volumetric flasks. Dilution absorbances were determined at 428 mμ on a Beckman DU spectrophotometer. The results are illustrated in Figs. 1 and 2.

Identical aliquots of the two foregoing standard solutions were subjected to the two-dimensional chromatographic procedures described below for TC tablet test mixtures. The methanolic TLC extracts were diluted to volume with 10 ml. of methanol and dilution absorbances were determined spectrophotometrically at 428 mμ. Standard

TABLE II.—ANALYSIS[a] OF DEGRADED TETRACYCLINE TABLETS

Sample	Spot Load, Vol., ml.	ATC, mg./Tablet	EATC, mg./Tablet
A	0.02	16.23 ± 0.48	15.28 ± 0.66
B	0.04	8.10 ± 0.29	5.89 ± 0.37

[a] ± standard deviation. The average of five determinations.

curves, comparing dilutions after TLC with direct dilutions, are illustrated for ATC and EATC in Figs. 1 and 2, respectively.

Procedure.—*TC Tablet Test Mixtures.*—TC tablets[1] each containing 250 mg. of tetracycline hydrochloride were crushed by mortar and pestle. The resulting powder was deliberately contaminated with known quantities of ATC and EATC. Powder equivalent to one tablet was transferred to a 3-ml. sintered-glass funnel and vacuum extracted with approximately 20 ml. of hot methanol. The extract volumes were adjusted to 25 ml. in volumetric flasks and appropriate aliquots spotted for two-dimensional chromatography (13) on microcrystalline cellulose plates (10). The chromatograms were developed for 20 min. in a chamber containing 0.1 *M* EDTA—0.1% ammonium chloride solution (pH 4.5). Development was followed by drying the plates under ambient conditions for 25 min. The plates were then placed for two-dimensional chromatography in a second chamber which contained chloroform saturated with the EDTA–ammonium chloride solution as used previously. Development for 20 min. was then permitted. R_f values of 1.0 and 0.60 were obtained for ATC and EATC, respectively. After removing and thoroughly drying the plates, the visible spots were scraped into 3-ml. sintered-glass funnels and vacuum extracted with hot methanol. Care was taken to ensure that complete drying of the microcrystalline cellulose occurred prior to extraction with methanol. When the adsorbent was too wet, EDTA was found to be extracted and caused characteristic increases (0.008) in absorbance at 428 mμ. These results were confirmed by deliberate addition of EDTA solution to test samples. A drying period of not less than 5 min. under a gentle stream of air[2] proved to be satisfactory.

[1] Marketed as Tetrosol Tablets by Frank W. Horner Ltd., Montreal, Quebec, Canada (July 1965).

[2] Oster "airjet" hair dryer, John Oster Manufacturing Co., Milwaukee, Wis.

As previously described by the authors (10), quantitative isolation and determination of anhydrotetracycline from microcrystalline cellulose is only possible in the 10–40 mcg./spot range. To keep within this range when working with samples containing unknown quantities of anhydro- compounds, the authors used the separation of the initial plate load as an indication of the quantities involved in the analysis. Suitable absorbance readings for ATC and EATC solutions were obtained by diluting the extracts of the plate scrapings with appropriate quantities of methanol. The spot load volumes and TLC extract dilutions which were used experimentally are indicated in Table I for easy reference.

Degraded Tetracycline Tablets.—Having established the validity of the foregoing procedures in the analysis of TC samples to which anhydrotetracyclines had been added, the authors applied the procedure to the analysis of degraded TC tablets. Sample *A* had been subjected to a 6-week thermal degradation study at 70° (14) followed by a storage period of 4 years at room temperature in screw-cap vials. Sample *B* had been stored in plug-cap glass vials, under tropical conditions for 4 years. The results are given in Table II.

DISCUSSION

A simple, rapid, and quantitative analysis for ATC and EATC has been performed by two-dimensional TLC on microcrystalline cellulose. The procedure is not affected by tablet excipients, and permits easy separation and quantitative recovery of minute (0.5 mg.) quantities of the harmful impurity, EATC. The method can be adopted for routine control quantitative or qualitative analysis of TC raw materials and solid dosage forms.

New Synthesis of Thiphenamil Hydrochloride

By A. GARNETT RICHARDSON

A new synthesis of thiphenamil hydrochloride, 2-(diethylaminoethyl)diphenylthioacetate hydrochloride, a direct-acting smooth muscle antispasmodic with no appreciable anticholinergic or muscarinic activity, is described. The synthesis is carried out under mild conditions and is much simpler than any other known method of preparing this drug.

THIPHENAMIL HYDROCHLORIDE [2-(diethylaminoethyl)diphenylthioacetate hydrochloride][1] was prepared in two steps from diphenylacetyl chloride by reacting the latter with ethylene sulfide, followed by treatment of the resulting 2-(chloroethyl)diphenylthioacetate with diethylamine. Ethylene sulfide is not commercially available, but it can be prepared easily from ethylene carbonate and potassium thiocyanate by the method of Searles and Lutz (1). Ethylene sulfide polymerizes readily, so it is advisable to prepare it immediately before use.

EXPERIMENTAL

2-(Chloroethyl)diphenylthioacetate.—A solution of 231 Gm. (1 mole) of diphenylacetyl chloride in 225 ml. of benzene was mixed with 63 Gm. (1.05 moles) of ethylene sulfide in a suitable vessel fitted with an air-tight closure. The air above the surface of the liquid was swept out with nitrogen, the vessel sealed, and the mixture allowed to stand at room temperature for 7 days. At the end of this period the liquid was filtered with decolorizing carbon and the solvent evaporated from the filtrate under reduced pressure below 40°. The yield of white, crystalline product was 270 Gm. (93%) melting at 45°–47°. 2-(Chloroethyl)diphenylthioacetate was originally prepared by this author (2) from potassium diphenylthioacetate and ethylene chlorobromide.

2-(Diethylaminoethyl)diphenylthioacetate Hydrochloride.—The 2-(chloroethyl)diphenylthioacetate from the preceding reaction was dissolved in 146 Gm. (2 moles) of diethylamine, and the mixture was allowed to stand in a sealed vessel at room temperature for 7 days. At the end of this period the unreacted diethylamine was removed by evaporation under reduced pressure below 30°. The residual material was stirred with 600 Gm. of cracked ice and water in which 30 Gm. of sodium carbonate had been dissolved. The basic ester precipitated as a white, waxy solid. This was collected on a filter and washed thoroughly with cold water. The pure basic ester melts at 35°, but in this case the product was not purified.

The crude material was suspended in approximately twice its volume of water containing the calculated quantity of hydrogen chloride (77 ml. of hydrochloric acid, sp. gr. 1.19 in 600 ml. of water for 0.93 mole). When all of the base had dissolved the pH of the solution was adjusted to 5.0 with additional hydrochloric acid, or with sodium hydroxide. Five grams of decolorizing carbon was added and the mixture filtered with suction at 60°. The product crystallized as the monohydrate when the filtrate was slowly cooled. The cooling was carried almost to the freezing point and the crystals collected on a filter. The anhydrous salt was obtained by placing the monohydrate in a hot-air drier at 60° and raising the temperature at the rate of 5°/hr. to 105°. The yield of fine, white powder was 244 Gm. (72%) melting at 127°–129°.

DISCUSSION

This synthesis of thiphenamil hydrochloride precludes the use of high reaction temperatures and to a great extent the use of flammable solvents as well. These are advantages in a manufacturing process. In addition, this procedure offers a considerable saving in labor and materials compared to other known methods for the preparation of this compound.

Effect of Chronic Nortriptyline Pretreatment on the Acute Toxicity of Various Medicinal Agents in Rats

By D. B. MEYERS, D. O. KANYUCK, and R. C. ANDERSON

A method using rats that can be of value in predicting the effects of chronic treatment with psychotherapeutics on the acute toxicity of other medicinal agents is described. Results obtained by this method showed that nortriptyline, like amitriptyline, enhanced the toxicity of most cerebral depressants in an additive manner. Both of the antidepressive compounds were shown to markedly potentiate the toxicity of physostigmine and to a lesser degree pilocarpine. Ephedrine toxicity was significantly antagonized by thymoleptic pretreatment. The test failed to verify reports that the tricyclic antidepressives dangerously potentiate the toxicity of alcohol or monoamine oxidase inhibitors. Results indicated that a variety of medicinal agents can be used in the nortriptyline treated patient without any problem of significant drug interaction.

NUMEROUS but sometimes contradictory reports of clinical problems resulting from the interaction of antidepressive agents with various other drugs have appeared in recent months. The potentiation of toxicity of thymoleptics by ethyl alcohol has been reported by some workers but not confirmed by others (1, 2). Various articles have cited the hazards of concurrent use of the tricyclic antidepressives and monoamine oxidase inhibitors while others have minimized the danger and cited evidence of the value of such combinations (3–8). More isolated cases in which a thymoleptic agent has been suspected of potentiating the toxicity of barbiturates, chlordiazepoxide, amphetamine, digitoxin, meperidine, or isopropylarterenol have been reported.

In view of the controversial nature of many of these observations this study was designed to evaluate the effect of chronic pretreatment of rats with nortriptyline HCl upon the acute toxicity of a variety of medicinal agents. It was felt that information gained from a systematic animal study might be of value in predicting the safety or hazards of administering other drugs to patients receiving thymoleptic treatment.

Lethality rather than more subtle pharmacological effects was chosen as the criterion for measuring interaction as it clearly predicts the actual hazard of drug therapy. It also provided a well-defined end point free of operator bias.

EXPERIMENTAL

Materials.—The rats used in this study were Harlan strain males weighing about 250 Gm. Animals of this size were 100–120 days of age and were considered sexually mature.

The nortriptyline HCl and amitriptyline HCl used to pretreat the rats were medicinal grade compounds obtained from the manufacturers. Both were incorporated as the dry powder into the standard rat diet by means of a Hobart mixer.

All of the neuro-pharmacologic agents used to challenge the pretreated rats were standard medicinal preparations. Most of them were soluble enough so that they could be injected intraperitoneally in aqueous solutions of suitable concentration. Acetylsalicylic acid, meprobamate, and isocarboxazid were given by the same route suspended in a 3% acacia vehicle.

Received April 25, 1966, from the Lilly Toxicology Laboratories, Eli Lilly and Co., Greenfield, Ind.
Accepted for publication July 20, 1966.
Presented to the Pharmacology and Biochemistry Section, A.Ph.A. Academy of Pharmaceutical Sciences, Dallas meeting, April 1966.

Method.—Rats were divided into groups so that one group received a standard control diet and a second group the same diet containing 0.04% nortriptyline HCl. For comparison purposes a third group was placed on a diet containing 0.04% amitriptyline HCl. The 0.04% drug concentration was great enough to produce overt signs of thymoleptic activity without undue debilitation of the animals. The rats were caged separately with food and water available *ad libitum*. After remaining on their respective diets for 11–15 days, five animals from each group were used for each interaction test. The compounds used to challenge the thymoleptic pretreated animal for a test of interaction included a variety of neuro-pharmacological agents with established clinical uses. In each interaction test predetermined doses of the challenging agent were given intraperitoneally every 30 min. to the control and thymoleptic pretreated rats until death ensued. A cumulative lethal dose (CLD) for the challenging agent was computed for the individual animals by multiplying the amount of drug per dose (mg./Kg.) by the number of doses required to produce death. An index of interaction (I.I.) was then established by dividing the geometric mean of the CLD values for the control animals by the geometric mean of the CLD's in each of the thymoleptic pretreated groups. Thus, an I.I. significantly larger than 1.00 indicated a synergistic interaction, while an index significantly less than 1.00 was considered evidence of antagonism.

RESULTS AND DISCUSSION

Table I shows the effects of pretreatment of rats with nortriptyline HCl and amitriptyline HCl on the acute toxicity of several compounds that have primary cerebral depressant activity.

Thymoleptic pretreatment augmented the lethal action of most of the cerebral depressants in rats. This observation was in accord with previous findings that many depressants increase nortriptyline toxicity in mice, and lends support to the statement that the newer antidepressives increase barbiturate toxicity in man (5). The increase in depressant toxicity may be explained in part by the fact that the tricyclic antidepressives possess a measurable CNS depressant component of activity (9). Contrary to some reports, this study failed to reveal any significant effect on ethyl alcohol toxicity by either amitriptyline or nortriptyline.

Table II illustrates the influence of nortriptyline and amitriptyline on the toxicity of various types of CNS stimulants.

TABLE I.—EFFECT OF THYMOLEPTIC PRETREATMENT ON THE ACUTE TOXICITY OF CEREBRAL DEPRESSANTS IN RATS

Dextropropoxyphene HCl	0.82	0.68[a]
Acetylsalicylic acid	1.05	1.01
Chlorpromazine HCl	0.96	1.07
Scopolamine HBr	1.00	0.87
Nortriptyline HCl	1.15	...
Quinidine sulfate	0.92	0.95

[a] $p = 0.1$.

Although the intensity of the stimulant-induced convulsions was somewhat moderated in the pretreated animals, there was no significant interaction between the thymoleptics and any of the stimulants tested. Neither type of monoamine oxidase inhibitor, isocarboxazid or tranylcypromine, proved to be significantly more toxic in the pretreated animals.

The influence of pretreatment with the thymoleptics on the toxicity of various types of agents that actively affect the autonomic nervous system is shown in Table III.

Marked influences of the antidepressive pretreatment on the toxicity of some of the drugs which act upon the autonomic system were apparent. In general the toxicity of the adrenergic stimulants and cholinergic blockers was reduced. The most significant reductions occurred with ephedrine and atropine, both of which possess a measurable component of central stimulation. The most dramatic potentiation of toxicity was seen with physostigmine which killed the thymoleptic pretreated rats with intraperitoneal cumulative doses as low as 0.9 mg./Kg. Evidence that this potentiation of toxicity might be applicable to human medicine was found in a medical report which described an abnormal response to neostigmine in a patient who was concurrently receiving therapeutic doses of nortriptyline HCl (10). Pilocarpine toxicity was also increased in the pretreated animals but not in the same magnitude as was physostigmine.

The effect of the cyclazid antidepressives on the acute toxicity of other drugs with neuro-pharmacological properties is shown in Table IV.

The only compound in this group to show an interaction was dextropropoxyphene HCl. The significant reduction in toxicity can be accounted for by the fact that dextropropoxyphene when administered intraperitoneally or intravenously exhibits a stimulating action in rodents which contributes greatly to its lethality. It is probable that this component of action was antagonized by the thymoleptics. The result obtained with nortriptyline HCl indicated that neither tolerance nor sensitivity to the compound itself developed during the pretreatment period.

CONCLUSION

The data collected by the method described show that nortriptyline, like amitriptyline pretreatment, enhances the toxicity of most cerebral depressants in rats. Quantitatively, the results indicate that the increase is probably in the order of an additive effect.

The test confirmed that the concurrent use of physostigmine and the cyclazid antidepressives may produce dangerous results. The data indicate that the physostigmine–thymoleptic interaction should be described as marked potentiation. The increase in pilocarpine toxicity may also be regarded as potentiation but of a much milder degree.

The test failed to supply confirming evidence to clinical reports of the potentiation of the toxicity of alcohol by the antidepressive compounds. Nor did it substantiate the validity of the controversial warning that the concurrent use of thymoleptics and monoamine oxidase inhibitors should be strictly avoided.

The experimental results indicated that a wide variety of medicinal agents could be used following thymoleptic pretreatment without danger of drug interaction.

Absorption, Metabolism, and Excretion of Salicylic Phenolic Glucuronide in Rats

By GERHARD LEVY, LEONARD WEINTRAUB*, TAI MATSUZAWA, and STANLEY R. OLES*

Salicylic phenolic glucuronide is excreted rapidly by apparent first-order kinetics ($t_{1/2}$ about 0.7 hr.) after intravenous administration to adult rats. Only a small fraction of an injected dose is hydrolyzed *in vivo* to salicylic acid. The glucuronide is apparently not absorbed significantly as such from the gastrointestinal tract. Part of an orally administered dose is absorbed apparently from the lower region of the intestinal tract after hydrolysis to salicylic acid.

THE PHARMACOKINETICS of elimination of salicylic acid and its major metabolite, salicyluric acid, have been studied in some detail in man and rats (1–4). Much less is known about the kinetics of elimination of salicylic phenolic glucuronide, another important metabolite of salicylic acid.[1] This glucuronide has been prepared in pure form and (since technical problems did not permit its intravenous administration to man) its absorption, metabolism, and excretion have been studied in rats. A previous study has shown that the pharmacokinetics of salicylate elimination in man and rats are quite similar (4).

EXPERIMENTAL

Synthesis of Salicylic Phenolic Glucuronide.—Methyl (tri-*O*-acetyl-α-D-glucopyranosyl bromide) uronate was prepared from glucuronolactone by the procedure of Bollenback *et al.* (6). From it, *o*-carboxyphenyl-β-D-glucopyranosiduronic acid (salicylic phenolic glucuronide) was obtained by methods described by Lunsford and Murphey (7), m.p. 144.5–146°. (Lit. 145–146°.) $[\alpha]_D^{27} = -70.8°$ (C, 6,H_2O). [Lit. $[\alpha]_D^{23} = -75.9°$ (C,6,H_2O).]

Anal.—Calcd. for $C_{13}H_{14}O_9$: C, 49.69; H, 4.49. Found: C, 49.64, 49.73; H, 4.87, 4.72.

No free salicylic acid was detected by a thin-layer chromatographic method capable of detecting 0.5% of this compound in the glucuronide.

Animal Study.—Male Sprague-Dawley rats, weighing 250–400 Gm., were fasted for 24 hr. prior to drug administration but had unrestricted access to drinking water at all times. The drug was dissolved in 1.5 ml. distilled water and injected intravenously into the femoral vein, or administered orally by stomach tube as 5 ml. aqueous solution. The rats were confined in plastic animal holders for the first 24 hr. in order to permit frequent urine and feces collections. The animals were then transferred to individual metabolic cages for another 24 hr. Food and water were freely available to the rats throughout the 48-hr. period of urine and feces collection.

Assay Methods.—Salicylic acid and its metabolites were determined in the urine by a modification of the methods of Smith *et al.* (8). Feces was homogenized with distilled water and assayed similarly.

RESULTS

The urinary excretion kinetics of salicylic phenolic glucuronide (SPG) as a function of time after intravenous injection are shown in Fig. 1. Excretion followed apparent first-order kinetics, with a half-life of about 0.7 hr. The slow initial excretion of SPG in one of the animals appears to be due to accidental extravascular injection of part of the dose. About 82% of the injected amount was recovered in the urine; of this, about 85% was excreted as SPG (Table I). A much smaller fraction of the dose (about 36%) was recovered in the urine after oral administration and the fraction of urinary salicylate excreted as SPG was also much smaller than after intravenous injection (Table I). No measurable amounts of salicylic acid or its metabolites were present in the feces after intravenous administration of SPG. The time course of urinary excretion of total salicylate after oral administration of SPG indicates an appreciable delay in absorption (Table II).

DISCUSSION

Man excretes SPG relatively rapidly by a combination of glomerular filtration and tubular secretion (9). The rapid excretion of intravenously administered SPG by rats is consistent with these observations.[2] The renal excretion kinetics of SPG are not affected by urine pH and urine flow rate (9); this probably accounts for the lack of significant variation between animals in the excretion half-life of SPG. The excretion of SPG mainly as such after intravenous administration suggests that β-glucuronidase mediated hydrolysis in the tissues is too slow to reduce appreciably the net formation rate of SPG after salicylic acid administration. Inhibitors of β-glucuronidase, such as glucuronolactone, are therefore unlikely to enhance salicylate elimination. This conclusion is consistent with the results of a recent study (4). The lack of biliary excretion of SPG, suggested by the absence of detectable amounts of salicylates in the feces and by the absence of secondary maxima in the excretion rate *versus* time curve after intravenous injection of SPG, is in agreement with the observations of Williams *et al.* (10). These workers recovered just

Accepted for publication August 18, 1966.

The authors thank Mr. N. Angelino for technical assistance in the animal work, Mr. H. M. Ederma for the thin-layer chromatography, and Dr. David Goldhamer and Dr. Armin Wilson for helpful discussions.

[1] Only a small fraction of salicylic acid is biotransformed to salicylic acyl glucuronide in man (5).

[2] The rapid excretion of SPG after intravenous injection indicates also that the SPG found in the urine is not the product of conjugation of free salicylic acid derived from the *in vivo* hydrolysis of injected SPG. Excretion of SPG by the latter mechanism is rate-limited by the formation process and would proceed at a considerably lower rate (4).

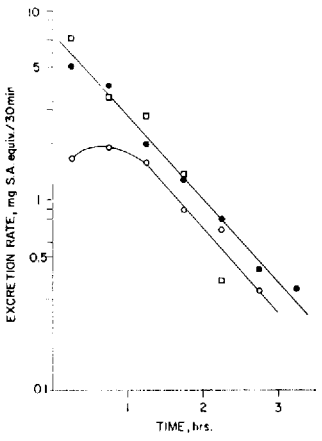

Fig. 1.—Urinary excretion rate of salicylic phenolic glucuronide in three rats as a function of time after intravenous injection of 120 mg./Kg. body weight. The slow initial excretion of SPG in one of the animals (○) appears to be due to accidental extravascular injection of part of the dose.

TABLE I.—URINARY RECOVERY OF SALICYLATE AFTER INTRAVENOUS AND ORAL ADMINISTRATION OF SALICYLIC PHENOLIC GLUCURONIDE TO RATS

Rt.	Animal	Dose, mg./Kg.	Total Urinary Recovery, % of Dose	% of Recovered Drug Excreted as Glucuronide
i.v.	*1*	120	86	86
i.v.	*2*	120	75	79
i.v.	*3*	120	84	89
Oral	*4*	600	41	22
Oral	*5*	600	28	6
Oral	*6*	600	39	29

1.5% of the dose (and only in the form of free salicylic acid) in the bile of rats within 24 hr. after i.p. injection of 50 mg. salicylic acid/Kg. body weight.

Vogt *et al.* (11) have shown that appreciable β-glucuronidase activity is located in the large intestine of the rat, but that no significant activity is present in the small intestine. They observed that desacetylbisacodyl, when administered as the glucuronide, is absorbed only in the large intestine, after enzymic hydrolysis. There is strong evidence

TABLE II.—TIME COURSE OF URINARY EXCRETION OF TOTAL SALICYLATE AFTER ORAL ADMINISTRATION OF SALICYLIC PHENOLIC GLUCURONIDE TO RATS[a]

Time, hr.	Amt. Excreted, mg. Salicylic Acid Equiv. Rat *4*	Rat *5*	Rat *6*
0–3	5.8	1.9	24.1[b]
3–5	2.0	1.2	
5–24	21.8	15.4	
24–48	2.8	4.9	12.1

[a] The administered amounts of SPG, expressed as mg. salicylic acid equivalent, were: rat *4*, 79.16 mg.; rat *5*, 83.55 mg.; rat *6*, 92.35 mg. [b] Only a single urine collection was made in rat *6* during the first 24 hr.

that other glucuronides also are not absorbed as such (10, 11). The approximately 4-hr. delay in absorption observed by Vogt *et al.* is similar to the delay in salicylate absorption after oral administration of SPG as judged by the time course of urinary excretion of total salicylates (Table II). The composition of urinary metabolites after oral administration of SPG (Table I) is similar to that which would be expected after administration of free salicylate (4). The very small SPG fraction in rat *5* appears to be due to the particularly slow absorption of salicylate in this animal and the resulting lack of saturation of the salicylurate formation process (4). The delayed and incomplete absorption of salicylate after oral administration of SPG, and the difference in the composition of urinary metabolites of SPG after oral and intravenous administration, respectively, suggest strongly that SPG is absorbed from the gastrointestinal tract of the rat only after hydrolysis to salicylic acid.

Determination of Acetyl Values

Sir:

The determination of acetyl values of acetylated fatty acids as described in the "National Formulary," 12th ed. (1), was adapted from the derivation by Cook (2). This procedure is also very useful where hydroxyl groups exist together with esters. Cook's derivation provides a mathematical correction for the molecular weight difference between an original fatty material and the acetylated product and requires the determination of the saponification values of both materials.

The equation employed by the N.F. substitutes the acid value of the unacetylated free fatty acid for the saponification value of the original fatty substance in the Cook formula. The acid value of a free fatty acid is equivalent to its saponification value since there are no esters present. The N.F. equation, however, is incorrect in the denominator term. Since the correct denominator is a function of the saponification value *of the original fatty substance* (not the acetylated product), the proper denominator should be based on the acid value of the free fatty acids. The correct equation is

$$A = S - F/1 - 0.00075\ F$$

where A is the acetyl value of the acetylated fatty acids, S is the saponification value of the acetylated fatty acids, and F is the acid value of the original fatty acids. The existing official formula gives values which are 10 to 15% high for usual monohydroxylated fatty acids. Di- and trihydroxylated fatty acids show progressively higher deviations. The corrected formula above is in exact agreement with theoretical values in all cases. The term "A" is incorrectly defined in the monograph as the acetyl value of the *free* acid. This term must be the acetyl value of the *acetylated* fatty acid which would be in agreement with the N.F. definition of acetyl value and with the Cook formula derivation.

In the specific case of fatty acids, it is also possible to further simplify the calculations and the analytical procedure since all saponifiable groups are hydrolyzed prior to acetylation. The absence of interfering mixed anhydrides referred to by Warth (3) is assured since the acetylated product is purified by twice boiling in water. After saponification of the fatty material and acetylation of the fatty acids, it is only necessary to determine the ester value of the acetylated product as described in the N.F. In this case, ester value and acetyl value are identical. If acetylated fats, oils, waxes, or similar substances containing ester groups other than acetyl are used, the official methodology must be employed.

Results obtained using the official procedure and ester value determinations are compared to theoretical acetyl values in Table I for acetylricinoleic acid and cholesterol acetate.

TABLE I.—ACETYL VALUES

Compd.	Theoretical	Official Method[a]	As Ester Value
Acetylricinoleic acid	164.76	163.13	162.41
Cholesterol acetate	130.86	136.26	123.65

[a] Corrected formula.

Since the procedure described in the N.F. is very reliable and applicable to a wide variety of fatty materials, the scope of the monograph could be expanded to include these substances. The formula for calculation of results and the definition of the term "A" should be corrected as indicated.

Apparent Renal Tubular Secretion of Riboflavin in Man

Sir:

The authors recently have shown that riboflavin is absorbed from the gastrointestinal tract of man by a specialized transport process rather than by passive diffusion (1). Data have now become available from the study of Stripp (2) which permit determination of the mechanism of renal excretion of this vitamin. Figure 1 is a plot of riboflavin excretion rate *versus* time during and after administration of 84 mg. riboflavin to a human by slow intravenous infusion. The data were obtained from a photographic enlargement of Fig. 6 of Stripp's paper (2). The postinfusion excretion rate declined exponentially as a function of time, with a half-life of 1.2 hr. This value is in excellent agreement with the 1.1 hr. average value observed after oral administration of riboflavin (1).

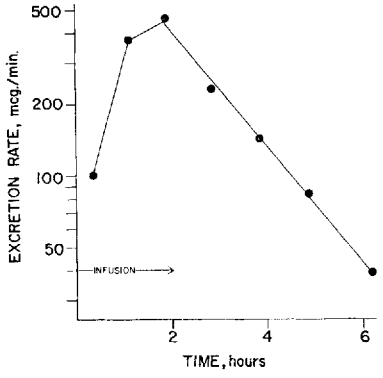

Fig. 1.—Excretion rate of riboflavin as a function of time during and after intravenous infusion of 84 mg. of riboflavin (data from Fig. 6 of *Reference 2*).

Apparent volumes of distribution for riboflavin have been calculated from Stripp's urinary excretion and blood level data (2) by three standard pharmacokinetic methods (see *References 3* and *4*) and are listed in Table I. There was good agreement between the results obtained by these different procedures. Renal clearance values were also calculated by three different methods and are listed in Table II. The calculations are based on riboflavin plasma concentrations which have not been corrected for protein binding (5) and are therefore minimum values which, had the extent of protein binding been known and taken into account, would have been even higher. However, even these minimum values are about twice as large as the glomerular filtration rate of 131 ± 22 ml./min. in normal man (6). This indicates that the renal excretion of riboflavin involves not only glomerular filtration but also renal tubular secretion. It is of interest that at least two other B vitamins, thiamine and pantothenic acid, are actively secreted by the renal tubules (7, 8).

TABLE I.—ESTIMATION OF THE APPARENT VOLUME OF DISTRIBUTION OF RIBOFLAVIN

Method of Calculation[a]	Determinations, No.	Vol. of Distribution, L. Mean	Range
$\frac{A}{C}$	5	31	29–33
$\frac{dU/dt}{kfC}$	6	26	23–30
$\frac{D}{k \text{ area}}$	1	26	...

[a] A = amount in the body; C = plasma concentration; dU/dt = urinary excretion rate; k = apparent first-order elimination rate constant; f = fraction excreted unchanged; D = dose; area = area under the plasma level *vs.* time curve.

TABLE II.—ESTIMATION OF THE MINIMUM RENAL CLEARANCE OF RIBOFLAVIN

Method of Calculation[a]	Determinations, No.	Min. Renal Clearance,[b] ml./min. Mean	Range
$\frac{Akf}{C}$	5	290	270–310
$\frac{dU/dt}{C}$	6	240	220–280
$\frac{Df}{\text{area}}$	1	240	...

[a] Abbreviations as in Table I. [b] Not corrected for plasma protein binding.

New Method of Solid-State Dispersion for Increasing Dissolution Rates

Sir:

The authors have recently reported on the potential value of solid-state dispersion, *viz.*, solid solutions, in enhancing the dissolution rate and gastrointestinal absorption of drugs (1–4). Although this approach has been quite successful in modifying the dissolution characteristics of griseofulvin (3) and chloramphenicol (4), the application of solid solutions formed by fusion technique, for enhancing dissolution, is somewhat limited. The method has been found inapplicable to a number of drugs which are unstable at or near their melting points, or which fail to crystallize from the mixed melt.

Therefore, other methods have been sought to obtain solid-state dispersions of insoluble drugs in water-soluble matrices. In 1965, Tachibana and Nakamura (5) reported a method for preparing aqueous dispersions of β-carotene by using water-soluble polymers.

An earlier report by Stone (6) described a similar technique for the preparation of water dispersible antibiotics. This preliminary communication concerns the use of the dispersion method to obtain physically modified forms of a drug, which are much more rapidly soluble than the pure compound. Although the mechanism of the dispersion has not yet been rigorously established, the striking findings and the apparent general applicability of the method warrant consideration.

The authors' initial studies were concerned with dispersions of griseofulvin in polyvinylpyrrolidone (PVP). The drug was crystallized from a 1% solution in chloroform containing 0, 5, 10, and 20% PVP. In each case the solvent was evaporated at 37° until a clear film, essentially free of solvent, remained. The film was further dried to constant weight, and the material was then sized using a Syntron shaker. The 40–50 mesh particles were collected for dissolution rate studies.

Sekiguchi *et al.* (7) have reported that griseofulvin forms a 1:1 solvate with chloroform. In the present work, the existence of the solvate was confirmed; but it was found to be quite unstable and decomposed rapidly under our drying condition. In order to determine the dissolution rate of the solvate, a sample was carefully prepared. Analysis of the material immediately before dissolution rate studies indicated that it contained about 23% chloroform corresponding to a 1:1 solvate.

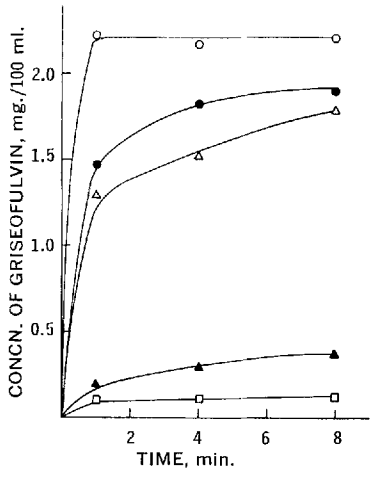

Fig. 1.—Dissolution rate of micronized griseofulvin (▲); griseofulvin chloroformate (□); griseofulvin–PVP, 1:5 (△); griseofulvin–PVP, 1:10 (●); and griseofulvin–PVP, 1:20 (○).

TABLE I.—DISSOLUTION STUDIES OF GRISEOFULVIN

Sample	Relative Dissolution Rate 1 min.	4 min.
Micronized griseofulvin	1.0	1.0
Griseofulvin–chloroform solvate	0.5	0.4
Griseofulvin–PVP (1:5)	6.1	5.1
Griseofulvin–PVP (1:10)	7.2	6.1
Griseofulvin–PVP (1:20)	11.0	7.3

Particulate dissolution rate was determined in the following manner. Each sample, containing 10 mg. of griseofulvin, was added to a 600-ml. beaker containing 300 ml. of distilled water at 37°. Stirring was provided by an overhead stirrer operating at 150 r.p.m. In order to overcome the "nonwetting" character of the micronized griseofulvin[1] (included in the study to provide a basis of comparison) the dissolution medium contained 0.02% polysorbate 80. The wetting agent was used in each dissolution study, although it proved inconsequential with the PVP–griseofulvin samples. After the addition of the drug, 5-ml. samples of the dissolution medium were taken periodically, rapidly filtered through a Millipore filter (0.45 μ), and assayed for griseofulvin using a Beckman DB recording spectrophotometer.

The results of this investigation are shown in Fig. 1. Table I provides a comparison of the dis-

[1] The griseofulvin used in this investigation was generously supplied by the Schering Corp.

solution rate of the various samples with the dissolution rate of micronized griseofulvin. The solid-state dispersion of griseofulvin in PVP results in a five- to tenfold increase in the dissolution rate of the drug. In the absence of wetting agent in the dissolution medium the enhancement is still greater.

Although some complexation seems to exist between griseofulvin and PVP (on the basis of preliminary solubility studies), the authors do not believe that this imposes a restriction on the utility of this dispersion technique for a large number of water-insoluble drugs. Based on our initial observations, it is suggested that griseofulvin is dispersed molecularly in the polymer film and forms a solid solution with PVP in the film. It is believed that this approach to the modification of drug properties may be of broad import in the area of biopharmaceutics and may find significant therapeutic application.

Books

REVIEW

Drug Identification. Edited by C. A. JOHNSON and A. D. THORNTON-JONES. The Pharmaceutical Press, 17 Bloomsbury Square, London, W. C. 1, England, 1966. ix + 133 pp. 14 × 22 cm. Price $4.90.

This book subtitled "a scheme for the identification of organic chemicals used in medicine and pharmacy" is an extension of the techniques first introduced in 1904 by Mulliken in his publication *The Identification of Pure Organic Compounds.* Within the past twenty-five years, numerous investigators have authored reference works based on accumulated data for characterization analysis. In general, a compound is subjected to preliminary tests including solubility in selected solvents, reaction with acidic and basic solutions, melting point, etc., as well as an elemental analysis. Additional tests may be performed to identify functional groups present in the compound. Based on the assigned presence of C, H, O, N, S, F, Br, Cl, I, and metals in the test sample, the analyst refers to tables which subdivide the book into combinations of elements as they frequently occur in drug substances. Compounds listed in each table are arranged in order of increasing boiling or melting points. The schematic approach ends here, and the individual is confronted with final identification by conducting the tests (e.g. colorimetric, precipitation, light-absorption, preparation, or derivatives, etc.) included for compounds which fit the general information obtained to this point.

The data contained in this volume are a creditable compilation but should be augmented for extensive and accurate identification. Improvement, is required in the form of definitive identification tests for many substances, and wherever feasible the tables should be expanded to include entries for nonofficial drugs. A worthwhile addition would be classical tabulations by functional groups which could be used in conjunction with accrued preliminary data for rapid identification of many compounds.

Powders: Particle–Particle Interactions

By EVERETT N. HIESTAND

BECAUSE nearly all medicaments exist as powders at some stage in their manufacture, it is not considered necessary to justify an interest in powders.

Many difficulties are associated with the study of the powdered state of solids. Even today technological advances have not produced satisfactory quantitative methods for describing their properties. However, it is possible to define more precisely the problems associated with characterizing powders and to discuss in a qualitative manner the factors that determine their physical properties. Because much of the work pertinent to the subject is scattered throughout the literature and has been done outside of the pharmaceutical field, it seems worthwhile to attempt to organize this material into a review article.

The emphasis of this discussion will be on the properties of solids that determine the magnitude of the forces acting between the particles when they are in contact. These are predominately surface properties. If the particles have been compressed enough to produce plastic deformation or crushing of the particle, the mechanical properties become very important also. Since compressed tablets compose the largest volume of pharmaceutical products sold, it is tempting to extend the discussion to include the compression of particles into aggregates. However, in the interest of brevity, the scope of this review will be limited to particulate solids under compression forces of a much smaller nature than used in tableting. For example, forces such as might be exerted by the weight of the powder bed on the particles at the bottom of the bed or the forces imposed by an auger in moving the material. The theoretical discussion will describe the properties of solid surfaces. The discussion of experimental methods will emphasize methods of measuring the cohesion and adhesion of powder particles.

Definition of the Problem.—The bulk density of a powder bed is not uniform. Therefore, the physical properties of the bed are not uniform either. The properties of a powder bed depend on the cumulative effect of the previous history of all the portions of the bulk being considered. Isolated regions of shear, vibration, or compaction may have produced high bulk density regions. These may remain intact in subsequent flow of the powder or may fragment into macroscopic regions mixed throughout the less dense bed. The forces acting on the top of a bed may be quite different from those at the bottom of the bed. Therefore, a thermodynamic treatment of a powder bed as a homogeneous mass is not possible. This discussion will try to develop, qualitatively, the factors that contribute to the interaction of solids. The following are considered the main topics of interest.

(*a*) The interaction between two particles is

Received from the Pharmacy Research Unit, The Upjohn Co., Kalamazoo, Mich.

dependent upon the surface to interfacial energy change that occurs when the solids come into contact. The surface energy of a solid rarely is homogeneous. Therefore, the energy change at the true areas of contact will not be a single function of the true area of contact but will vary with the nature of the exact portions of the two solid surfaces in contact.

(*b*) The area of true contact between individual particles is dependent on the particle shape, size distribution, roughness, the compressive force at the interface, the shear to which the sample has been subjected, and the mechanical properties of the particles. Also, the number of nearest neighbors, *i.e.*, the coordination number, will be a function of these same factors.

(*c*) Most organic solids are insulators. Unless their surface is made conducting by contaminants such as surfactants or water (especially under high humidity conditions), the solids will charge on contact. The resulting electrostatic attraction may be large.

GENERAL BULK PROPERTIES OF SOLIDS

When the forces acting between molecules are strong enough to overcome the translational motion of the molecules and to compensate for necessary entropy changes, the molecules associate as a solid mass. If the association is in a predominately orderly manner, the solid is said to be crystalline. The crystalline solid is not necessarily the permanent, fixed arrangement often implied in elementary texts. Entropy *versus* temperature curves may provide evidence of nonisothermal changes in addition to the isothermal changes that occur when there is a change in crystal structure (1). Globular solids are said to be the antipode of liquid crystals (2). In globular solids, rotational freedom apparently occurs at lower temperature than the translational freedom of the molecules, whereas in liquid crystals, translational motion occurs prior to rotational freedom. These phenomena suggest that the properties of all crystalline solids are not the same and that the physical properties are not a single entity for a given solid substance but may be strongly temperature-dependent.

The order within the crystal always is much less than perfect. Solids often consist of numerous intimately associated grains. Crystal lattice continuity does not exist across these grain boundaries. Within the grains, numerous crystal dislocations, both screw and edge type, exist (3). The mechanical properties of solids are determined by the freedom of these dislocations to move. If they move readily, the solid will be plastic. If they cannot move, the solid will be brittle (4). The mechanical strength of brittle solids will vary with the presence or absence of surface cracks (5). Also, the mechanical properties are influenced by the surface energy. The mechanical properties of solids are a principal factor in determining the true area of contact between solid materials under pressure.

The mechanical properties of organic solids have had only limited attention and our knowledge of the role of dislocations must, for the most part, be extrapolated from the studies on metals, semiconductors, and a few inorganic materials. However, dislocations in organic crystals do exist (6).

Some grain boundaries and dislocations extend to the surface of crystals and provide one source of heterogeneity on the surface. Adsorption of impurities result in additional sources of surface heterogeneity.

Because our primary interest is the forces of interaction between two surfaces brought into contact, the bulk properties will not be discussed in greater detail. However, it is necessary that one recognize that both the bulk and surface properties of a given substance may vary significantly and particle–particle interactions may be influenced by these variations. Furthermore, plastic flow is known to occur in many organic solids. Globular solids are sometimes called "plastic crystals." Some nonglobular solids may be tableted directly. This would not be possible unless plastic flow occurred to relieve elastic stresses.

THE "ADSORPTION" THEORY OF PARTICLE–PARTICLE INTERACTIONS

The Minimum Work of Fracture.—The minimum work required for the separation of two surfaces and, therefore, the energy bonding them together is equal to the difference in free energy after separation and the free energy before separation, *i.e.*, for materials C and D, the work of adhesion, W_a, is given by:

$$W_a = A\ (\gamma_C + \gamma_D - \gamma_{CD})$$

where

A = the area produced by the separation,
γ_C = the free energy of the surface per unit area of the solid C in air,
γ_D = the free energy of the surface per unit area of the solid D in air, and
γ_{CD} = the free energy of the C–D interface per unit area.

Similarly, for the fracture of a single material, for

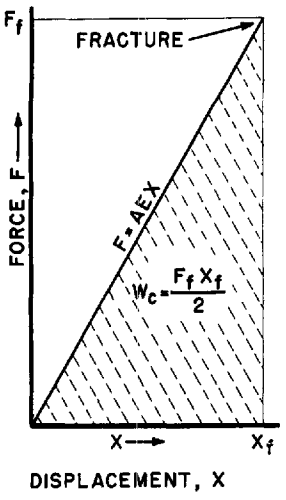

Fig. 1.—The minimum work of fracture of an ideal elastic body.

example, substance C, the work of cohesion, W_c, is given by:

$$W_c = 2A\ \gamma_C$$

If substance C obeys Hooke's law until it fractures, then the stress-strain diagram is as shown in Fig. 1. The equation for the line is $F = AEX$, where E is Young's modulus, F is the tensile force, and X is the displacement. The minimum work done in fracturing the solid, *i.e.*, the work of cohesion, is the area under the line, $W_c = F_f X_f/2$; where F_f is F at fracture and X_f is the displacement at fracture.

Eliminating X_f from the work equation gives $W_c = F_f^2/2AE$. Replacing W_c with the surface energy from our earlier equation, one obtains on rearrangement:[1]

$$F_f = 2A\ \sqrt{\gamma_C E}$$

The analogous equation for W_a is:

$$F_f = 2A\ \sqrt{\frac{E_C + E_D}{E_C E_D}\ (\gamma_C + \gamma_D - \gamma_{CD})}$$

The notion that the cohesion of solids is related to the surface energy is not new. Bradley (8), in 1932, discussed the role of dispersion forces in surface energy and in the cohesion of solids. Morgan (9) and Rumpf (10) have considered the strength of attraction between solids in a similar way. Recently Krupp and Sperling (11) have developed a model for the interaction of powder particles that involves the surface energy.

[1] Note the similarity of this equation to the fundamental equation of the Griffith crack theory of the strength of brittle solids (5, 7) which is:

$$F = K\sqrt{\frac{\gamma E}{C}}$$

where K is a proportionality constant and $2C$ is the crack length.

The Surface Energy of a Solid.—The argument in the preceding paragraphs has demonstrated that the surface energy of a solid is an important term in the strength of attraction between two substances. Therefore, the factors contributing to surface energy must be explored if even a qualitative concept is to be obtained. Part of the information may be inferred from our knowledge of liquids. First, let us consider the differences between solid surfaces and liquid surfaces.

Obviously, the relative immobility at room temperatures of the molecules of a solid account for the differences between the solid and liquid. For example, the chemical potential is the same in both the surface and bulk of a liquid phase, even when more than one component is present. However, for the solid, the surface usually is impure and the surface layer cannot equilibrate with the bulk in any reasonable length of time. Therefore, the chemical potential of a component on the surface may be quite different from that in the bulk.

The surface layer of a liquid has a lower density of molecules than the bulk. Since these molecules are free to move in the surface plane, they tend to undergo a two-dimensional "condensation," which results in a tension force in the surface plane. Because of random fluctuations, this process is never completed; the "condensed" molecules disappear into the bulk and are replaced randomly by other molecules. Gurney (12) discusses the thermodynamics of surfaces and concludes that equilibrium can exist only when the surface molecules are under a tension stress.

The tension component in the surface of liquids depends on the mobility of the surface layer. A solid surface cannot produce a tension component unless its surface molecules are mobile also. However, the unbalance of forces acting at the surface does result in a significant surface energy. Often the terms surface tension and specific surface free energy of a solid are carefully defined mathematically but the molecular model is not discussed. A recent review of the surface tension of solids (13) is of interest and illustrates this point. In this review, reference will be made only to the specific free energy of solids.

Attraction Forces Between Molecules at Interfaces.—There is an oft-stated observation that oil repels water. This useful though inexact statement could induce careless thinking. Only differences in magnitude of attraction are involved, not repulsion. All electrically neutral materials attract one another by dispersion

forces except when the spacing between them is so small that electron orbitals overlap. Attraction forces of greater magnitude than the dispersion forces often exist. The only repulsion force known that acts over a long distance is the electrostatic repulsion of like charges. Water is attracted to paraffin. A small droplet of water will cling to the underside of a paraffin surface. However, when the size of the drop is increased, enough gravitational force exists to overcome the attraction of the water for the paraffin and it falls off. Each water molecule has greater attraction for the other water molecules than for the paraffin; therefore, the entire drop falls away.

The origin of the attractive forces between two different solids in contact should not be a mystery to anyone since they are the same forces that act to hold all solids together. The one whose magnitude is most commonly underestimated is the London–van der Waals' force or the dispersion forces. Too often, the dispersion forces are described as "those weak interactions such as between hydrogen molecules, which explains it being a gas." However, these same forces cause many materials to be a solid at room temperature, *e.g.*, the longer chain aliphaptic hydrocarbons. Unfortunately, theoretical treatments such as those given by Rowlinson (14), Debye (15), and de Boer (16) often do not leave the reader with an intuitive feel for their magnitude. Consequently, we shall look at some experimental evidence that indicates the relative importance of various forces.

Solubility Parameters.—The development of the solubility parameter concept provided considerable insight into the interactions between unlike molecules. However, the primary reason for including the solubility parameter in this discussion is to show the relationship of surface tension to the cohesion energy density. The term "cohesive energy density" is the square of the solubility parameter δ. Solubility parameters are intended only for "regular solutions" (17–20), *i.e.*, nonpolar substances. This parameter has been identified with the heat of vaporization:

$$\delta = \left(\frac{\Delta E}{V}\right)^{1/2}$$

where ΔE is the energy of vaporization to a gas at zero pressure and V is the molal volume of the liquid. Also, $\delta \simeq 1.2\, a^{1/2}/V$, where a is van der Waals' gas constant.

Note that all the above mathematical relations are measures of the cohesion of the individual liquids. Hildebrand gives for mixing components 1 and 2:

$$\frac{\Delta H_m}{V_m \phi_1 \phi_2} = (\delta_1 - \delta_2)^2$$

where ΔH_m is the heat of mixing, V_m is the total volume of the mixture, ϕ_1 and ϕ_2 are the volume fractions of the respective component in the mixture.

Thus, the square of the differences in the square roots of the cohesion energy densities gives the heat of mixing if corrected for volume effects. Solubility results when the difference $\delta_1 - \delta_2$ is small, *i.e.*, the heat of mixing does not dominate the entropy contribution to the free energy change of the solution process.

Another interesting relationship is $\delta = 4.1\,(\gamma/V^{1/3})^{0.43}$,[2] where γ is the surface tension. The experimental verification of this relationship is evidence that the surface tension results from the attraction between molecules. Each of these equations express the interaction of molecules with each other.

Interfacial Tension Method of Evaluating Interactions.—A more recent approach to describing the forces between unlike molecules is given by Fowkes (21–23). He has obtained, by a systematic use of interfacial tension values, a measure of the contribution made by dispersion forces and the other types of forces acting at interfaces. His model makes use of the fact that the surface tension in air is a measure of the attraction due to all intermolecular forces in the liquid. Also, he assumes that the dispersion forces at the interface between two substances produce an interaction between unlike molecules. The interaction from dispersion forces is equal to the square root of the product of the dispersion component for each. He writes two equations—one for the contribution of each material to the interfacial tension. Since each equation describes only one liquid at the interface, let us call it the 1/2-interface equation. If the surface tension of C in air is γ_C and of D is γ_D, and provided only dispersion forces produce an interaction between C and D, the 1/2-interface equation for component C is:

$$\gamma_{C^{1/2}} = \gamma_C - \sqrt{\gamma_C{}^d \gamma_D{}^d}$$

where $\gamma_D{}^d$ and $\gamma_D{}^d$ are the respective contributions to surface tension produced by the dispersion forces.

For component D the 1/2-interface equation is:

$$\gamma_{D^{1/2}} = \gamma_D - \sqrt{\gamma_C{}^d \gamma_D{}^d}$$

The sum of the two yield the interfacial tension between C and D:

[2] This is an empirical relationship that gives more accurate results than the dimensionally homogeneous form $\delta \propto (\gamma/V^{1/3})^{0.5}$.

$$\gamma_{CD} = \gamma_C + \gamma_D - 2\sqrt{\gamma_C{}^d\gamma_D{}^d}$$

Since γ_{CD}, γ_C, and γ_D each can be determined by an independent experiment, it is necessary to know only either $\gamma_C{}^d$ or $\gamma_D{}^d$ before the other can be calculated. In the special case of a liquid such as an aliphatic hydrocarbon whose molecular interactions are due only to dispersion forces, $\gamma = \gamma^d$. For example, the surface tension of benzene is about 29 dynes/cm. and is due entirely to dispersion forces. Furthermore, in contact with mercury, only dispersion forces act between benzene and mercury. If benzene is called C, then $\gamma_C = \gamma_C{}^d = 28.85$ dynes/cm. Mercury is liquid D, so $\gamma_D = 484$ dynes/cm. γ_{CD} is measured and is 363 dynes/cm. Substituting into the equation and calculating $\gamma_D{}^d$, one obtains $\gamma_D{}^d = 194$ dynes/cm. Then one may calculate $\gamma_{C1/2}$ which turns out to be about -47 dynes/cm. The negative sign results because the mercury attracts the benzene stronger than the benzene attracts itself. Similarly, $\gamma_{D1/2} = 408$. Fowkes finds as average values for the mercury–air interface about 284 dynes/cm. is due to the metallic bond and 200 dynes/cm. from the dispersion forces of the mercury.

Similarly, Fowkes shows that the dispersion forces for water account for 21.8 dynes/cm. of its 72.8 dynes/cm. total surface tension. This value comes from interfacial tension data taken at a water–straight chain hydrocarbon interface. However, for the water–benzene case the assumption of only dispersion force interactions between water and benzene is not valid. About 13–16 dynes/cm. come from other forces (perhaps π bonds).

The metallic bond of mercury and the hydrogen bond in water should not interact at the water–mercury interface. However, it was questioned whether the permanent dipole of water might induce an image dipole in the mercury to produce a net attraction. Theory predicts this to be negligible and the measurements made by Fowkes confirm the prediction.

Fowkes has extended his studies to solid–liquid interfaces. Table I lists a few values for the dispersion forces of solids.

TABLE I.—γ^d VALUES FOR SOLIDS[a]

Solid	γ^d(ergs/cm.^{2})
Paraffin wax	25.5
Polytetrafluoroethylene	19.5
Polyethylene	35.0
Graphite	120–132
Copper	60.0
Lead	99.0
Silica	78.0

[a] Data from *Reference 22.*

TABLE II.—γ_c VALUES FOR POLYMERIC SOLIDS[a]

Solid	γ_c(dynes/Cm.)
Polyhexafluoropropylene	16.2
Polytrifluoroethylene	22.0
Polyethylene	31.0
Polymethyl methacrylate	39.0
Polyhexamethylene adipamide	46.0

[a] Data from *Reference 25.*

Critical Surface Tension.—Zisman and coworkers (24–26) have used the equilibrium contact angle method to assign an average surface energy value to the solid surface. A homologous series of liquids is placed on the surface of the solid and their respective contact angles are observed. A plot is made of cos θ *versus* γ_{lv} where γ_{lv} is the liquid surface tension of liquid in equilibrium with its saturated vapor in air. This plot is extrapolated to zero contact angle, and the value of the surface tension at this point noted. This surface tension at zero contact angle is called the critical surface tension, γ_c. The critical surface tension is assumed equal to the specific surface energy of the solid (23).

The technique sounds easy, but only when homologous liquids are used does one obtain a straight line. Otherwise, scatter and/or curvature exists. The experimental problems are many because of the difference between advancing and receding contact angles that often are observed. Also, contamination and roughness of the surfaces may vary and influence the results. Nevertheless, the critical surface tension has been identified within a narrow range on some solids. The γ_c values of some of these are given in Table II.

Friction and Adhesion.—In this discussion, the consideration of the forces between molecules has progressed from studies of liquid–liquid to solid–liquid interfaces. Studies of friction and adhesion of solids focuses the attention directly on the solid–solid interface. Here, for the first time, one must consider the important problem of determining the area of true contact. Since the true contact area is unknown in nearly all cases, it is most difficult to evaluate solid–solid interactions on a quantitative basis.

Friction sometimes is defined as the shear force required to break the adhesion "bonds" that form when solids are in contact, and the adhesional force is the tensile strength of the same bonds. This is the position taken in the classic work of Bowden and Tabor (27–30). They claim that the friction manifestation of adhesion is readily observed with large objects because all the "bonds" are sheared simultaneously in a friction measurement. However,

the tensile strength manifestation of adhesion usually is not observed because the elastic energy stored in the touching asperities is released gradually on separation, *i.e.*, the asperities have different lengths so that the separation does not occur simultaneously.

The classical, empirical laws of friction state that the frictional resistance to movement is independent of the apparent geometrical area of contact. It depends directly on the normal load. In the modern concept, if all unit areas of true contact have equal shear strength, then the true area of contact must be identical for a given normal load independent of the apparent geometrical contact area. Actually, exceptions to this law are readily found. However, the rarity of exceptions to the classical laws is remarkable when one considers the vast variety of surfaces that may be in contact.

The importance of the true area of contact has led to a study of adhesion and friction under very special conditions. Some of these illustrate the importance of the mechanical properties of solids and account for the author's brief treatment of the mechanical properties in an earlier part of the discussion.

A steel ball pressed into freshly scraped indium exhibits very large adhesive forces. When removed, the steel surface is covered with indium showing adhesion to be stronger than the cohesion of the indium (27). Obviously, the choice of indium is because of the low yield value that must be overcome to produce plastic flow. In plastic flow the elastic energy is reduced to a very small value, and the area of intimate contact becomes very large. Hence, the mechanical properties of indium make it possible to observe the adhesional force in a tension measurement.

The importance of a clean metallic surface, as in the freshly scraped indium above, is demonstrated in another experiment. Two clean iron surfaces, cleaned by outgassing under vacuum at high temperature, were pressed together with an initial load of only a few grams. Yet, over 500 Gm. was required to pull them apart. The metallic junction area was estimated and found to have the bulk strength of iron (29). Stepwise addition of traces of oxygen reduced the cohesion stepwise. Even H_2 and He will prevent gross seizure. The surface contamination apparently prevents the cold welding of the metals. Metallic bonding is much stronger than dispersion forces and the adsorbed contaminants prevent the stronger metallic bond from forming. The contaminants, thereby, reduce the energy of interaction.

The influence of a monolayer of lauric acid on the adhesion between two metallic surfaces has been measured (28). The monolayer was spread on the plastic surface of indium. The indentation produced by the steel ball pressed into the indium surface caused an increase of surface area so that some uncoated area of indium was formed at the indium–steel interface. The direct contact of metallic surfaces at the uncoated areas permitted metallic bonding to occur and produced high adhesion, in proportion to the area of metal–metal contact area.

Friction studies have not been limited to metals. Bowden (30) has reviewed adhesion and friction for various materials. Polymers represent a plastic material that deforms readily under load. He concludes that organic polymers under light loads exhibit friction forces that follow the same variation with load as the area of contact. Also, it appears that many polymers adhere strongly to metals and the shearing plane is in the polymer and not at the interface. Thus, transfer or wear occurs. With polytetrafluoroethylene (Teflon), the adhesion is small, slip occurs at the interface, and wear is minimal.

Also, it is of interest to consider elastic materials. Bowden (30) discusses the friction of diamond on diamond. Because diamond is a highly elastic material, the real area of contact is not expected to be proportional to the load but to the load to the 2/3 power. As expected, the friction coefficient decreases as the load increases. Removing gas films from diamond causes the friction coefficient to increase markedly, apparently due to the stronger forces of interaction at uncontaminated diamond interfaces. Estimates of the true area of contact indicate that for clean diamond sliding over clean diamond *in vacuo*, the effective shear strength of the regions of true contact is comparable to the bulk strength of diamond.

Another interesting series of studies on the interaction between solid surfaces involve molecularly flat surfaces of mica. Freshly cleaved but uncontaminated mica surfaces can be put back together with very little loss in strength. However, if the sheets are separated and coated with a monomolecular layer of a fluorinated fatty acid and then placed together, the work required to separate them is reduced. The reduction is believed to be in proportion to the surface energy, *i.e.*, to the work necessary to create the new area of solid–air interface. The shear strength of freshly cleaved mica surfaces in contact was very high and the surface damage from sliding was great. However, monomolecular layers of cal-

cium stearate placed on the sheets reduced the shear strength markedly and left the surface undamaged by the shearing process. Obviously, the shearing plane remained in the interface when contaminants reduced the energy of interaction. These studies are mentioned by Bowden (30). Much of the work is that of Bailey, some of which is reported in *References 31* and *32*.

In a later section of this review, it will become evident that much of the experimental effort to study powders has been by friction measurements. Hence, the above information from some of the general studies of friction will be useful later. Furthermore, it is one of the few fields of study in which an extensive literature of solid–solid adhesion exists. Of course, adhesives, soldering, and welding also contribute some pertinent experimental observations.

All of these studies show the significance of the surface energy and the importance of the kinds of bonds that act across the interface. Obviously, the metal–metal bond is much stronger than the van der Waals' forces for the organic monomolecular layers. Similarly, the carbon–carbon bond in diamond is much stronger than between the contaminants. The mica experiments produce similar results.

Adhesives.—Adhesion in relation to friction has been discussed. Studies in the field of adhesives confirm all of the observations that have been discussed, but also point out one additional factor that has not been considered—*viz.*, the electrostatic term due to charge transfer at an interface.

There are said to be three theories of adhesives, *viz.*, the adsorption theory (33), the electrostatic theory (34, 35), and the diffusion theory (36). All of these have two factors in common: (*a*) a very large area of true contact must be established between the adhesive and the solid; and (*b*) to assure that the air is displaced from the interface, a low contact angle is needed. The differences among the theories are in the emphasis placed on the origin of the bond strength. The adsorption theory considers the bond strength to be determined by the changes in interfacial energy necessary to remove the adhesive from the solid (provided the adhesive itself is not split at an even lower energy). The electrostatic theory assumes that an electric double layer is established in the fluid adhesive and removal requires doing work to separate this double layer. The diffusional theory assumes that the macromolecules of the adhesive diffuse into the solid surface sufficiently to add an entanglement factor to the strength of the bond. Probably all three factors are, at least in some cases, important. However, the diffusional aspect could be important for solid–solid interfaces only when contact exists for extended periods or when a solid has a very mobile surface layer.

Usually, adhesives are applied as a liquid phase in order to develop the high true area of contact. The solid–solid interactions exist after the adhesive "sets." This may be a drying by evaporational or diffusional loss of "solvent" or a chemical change such as occurs in the epoxy resins. A strong bond remains only when the setting occurs without excessive loss of true area of contact and without the development of significant elastic stresses resulting from dimensional changes of the adhesive. Again the important roles of a high true area of contact and of the mechanical properties are demonstrated.

Wear.—The process of wear has been studied in some detail (37). Although there are several classifications of types of wear, only the adhesional wear process is considered pertinent to this discussion. Adhesional wear occurs when surfaces slide over each other, and adhesion of small regions develop because of intimate contact. The adhesion is strong enough to pull fragments out from one of the solids. The size of wear particles is found to be remarkably uniform. Archard (38) has described a model for wear for which corresponding equations have been derived. Rabinowicz (39) gives the following equation for the condition of loose particle formation:

$$d = 60 \times 10^3 \frac{W_{ab}}{p}$$

where d is the diameter of the particle, W_{ab} is the work of adhesion, and p is the hardness of the surface yielding the particle. Note this is not a rate equation but only relates the size of the particles to the properties of the solid when wear occurs. Nonmetals and metals have been studied and reasonable correlation exists. One very important difference between wear and friction arises because only a few of the adhesional bonds produce wear, but all adhesional bonds contribute to friction.

Since W_{ab} appears in this equation, there is additional evidence that the surface energy is the important property determining solid–solid interactions. Although an oversimplification, boundary lubrication may be considered the technology of reducing wear by reducing W_{ab} to such a small magnitude that the wear rate is reduced to a negligible or very small value.

The "adsorption" theory of the particle–particle interaction of powders is only an ex-

tension of the "adsorption or adhesion" theories of friction, wear, and adhesives. Our interest in the forces of interaction between molecules at surfaces has been shown to be germane to a study of solid particles in contact.

Adsorption and Heats of Immersion.—Now let us look at evidence that suggests a nearly universal, heterogeneous nature for solid surfaces. We have learned already that grain boundaries and dislocations extend to the surface so that some heterogeneity results from these high energy regions. The best available evidence for the heterogeneity of a surface is found as before in reactions involving the interaction of the solid with individual molecules either from the gaseous or the liquid state. Adsorption and the related catalysis studies are of much interest.

Champion and Halsey (40) have shown that the formation of multilayers on a *homogeneous surface* must give rise to "stepped" adsorption isotherms. Apparently, the steps correspond to the formation of a new layer, each 1 molecule thick. However, the adsorption isotherms usually observed are not stepped; instead, they start off at high slope and gradually, but in a continuous manner, change to a curve of low slope. This suggests that most solid surfaces are heterogeneous, as expected. Classically, adsorption isotherms have been considered as belonging to one of five types (41). All of these show the gradual curvature characteristic of a heterogeneous surface.

Zettlemoyer and co-workers (42, 43) have used differential heats of immersion studies to characterize the heterogeneity of surfaces of solids. The derivative of the heat of immersion curve provides a differential heat curve, and the differential of the latter curve yields, when inverted, an approximate site energy distribution (43, 44). These workers have shown that the van der Waals' interaction energy between a polar adsorbent and a polar adsorbate consists of three parts, *viz.*, a nonpolar dispersion force, E_D; the force of interaction of the electrostatic field of the surface and the dipole moment of the adsorbate molecules, E_0; and a force term arising from the polarization of the adsorbate by the surface, E_I. For alcohol on rutile, the distribution is about 68% E_0, 6% E_I, and 26% E_D; for hydrocarbons on the same surface, it is 67% E_D and 33% E_I, and for polar or nonpolar liquids on graphon, it is 100% E_D (45). These results predate the data of Fowkes. Both show the importance of the dispersion forces.

Studies of catalysts have led to a more detailed understanding of chemisorption. A brief review of this type of reaction has been given by Dowden (46). Another interesting review is by Emmett (47). Both articles discuss the formation of bonds with surface atoms. Some may be electron donors and others electron acceptors. Active centers of catalysts often are classified as acid or basic. Apparently it is not clear whether a proton switching or an electron-pair switching mechanism is involved, *i.e.*, the Brönsted or the Lewis mechanisms.

Chemical interactions between particulate solids have been studied also. Specific solid–solid surface interactions of pharmaceuticals have been reported by Lach and co-workers (48).

Electrostatic Attraction.—It appears that solids are rarely separated without also separating a charge. The charge transfer becomes evident at separation of the surfaces. Richards (49) reports that by wringing together optically flat pieces of glass a charge is developed that is independent of the amount of frictional work but is proportional to the area of contact. As long as the plates remained in contact, an X-ray beam would not diminish the charge. Jefimenko (50) demonstrated that only contact and not friction is essential to electrification. A glass rod dipped into mercury or a paraffin rod dipped into water produced the same characteristic charge for the respective couple independent of the amount of work done. The kinetics of charging are not a factor in the last case because high true area of contact exists between a liquid and a solid. These experiments have established that charge transfer may result at areas of true contact between solids. Work must be done to separate the transferred charge and this is a part of the energy causing solid surfaces to attract. The amount of the charge and the direction of charge transfer will depend on the specific properties of the surfaces in contact.

Kunkel (51) dispersed dusts of homogeneous composition from containers lined with the same material. In all such cases, the total dust cloud was essentially neutral but practically all the particles were charged. If homogeneous clouds are blown so that they make and break contact with a different solid surface, the separation of the heterogeneous interface may impose an asymmetry on the relative members of positive and negative particles. The average charge increases somewhat more slowly than the surface of the particles, so particle size is important.

Nash *et al.* (52) observed the charges on powders after they passed through a copper funnel. They observed that the fraction of the sample that was charged could be altered by treating them with different surface-active agents. However, they did not distinguish between ag-

glomerates that were composed of equal numbers of oppositely charged particles and truly neutral particles or agglomerates.

Kordecki *et al.* (53) used centrifugal force to expel particles from solid surfaces. They found that glass spheres were much more difficult to remove from a Teflon surface when in a very dry atmosphere than when in a 50% relative humidity atmosphere even in the presence of a weak α-emitting radioactive source. However, the radiation from radium-D, a more powerful source, reduced the measured adhesion in a 10% relative humidity environment. They do not claim that the electrostatic component was completely removed from the adhesion by the ionization of the atmosphere. Richards' (49) work would suggest that it would not be completely removed.

Deryagin and Zimon (54) have observed the charges on individual particles torn from a flat surface. They found that both the adhesion and charge increased with residence time on the surface. [Deryagin has contributed, also, to the electrostatic theory of adhesives (55, 56).] These experiments demonstrate the importance of the electrostatic effect in the attraction between solids.

To discuss the kinetics of charging one really discusses the accumulation of charge by repeated contacts of one solid with another. This is the common way of observing friction and accounts for the term "frictional electricity." If one of the solids is a metal grounded to earth, the charge on the metal may be neutralized as soon as the separation reduces the inductive effect. Ciborowski and Wlodarski (57) observed the effect of grounding a conductor by repeatedly passing particles of a fluidized bed over a surface. They observed the charge on the powder by placing in the fluidized powder a small metal electrode connected to an electrometer. They state, "The highest electrode potentials, of a range of several thousand volts, were observed in equipment (a) when, apart from the electrode, other metal elements were also introduced into the fluidized bed and connected to earth. If there were no such elements, or else when they were not connected to earth, the electrode potential was generally considerably lower, of a range of a hundred volts at the utmost." Their equipment (a) used a glass tube to contain the fluidized bed. The grounded metal behaved as a very large body that did not change charge. All the difference in charge resulted from charge changes on the particles. Because of the grounded metal probe, the charge transfer could continue until all the powder particles were highly charged. Also, agglomeration of insulating particles was observed. This suggested that the particles were not all highly charged with the same sign. Many particles stuck to the metal probes and to the walls of the container. Furthermore, a lowering of electrode potential was produced by applying a grounded conductor to the glass wall of the equipment.

Another interesting experiment with powders was reported by Gill and Alfrey (58). Cubes of ebonite or a volume of sand slid down a grounded metal plate into a cup connected to an electrometer. Approximately 1 cm. above this plane, an insulated, parallel metal plate was positioned, and a source of potential was placed between the two plates. When the top plate had no charge, the particles became negative as they slid over the plate. When the top plate was positive the magnitude of the negative charge on the particle increased. When the top plate was negative the charge on the particles decreased; if sufficiently negative, the particles had a reversed sign of charge. The following equation fits their data:

$$Q = AX - Q_0$$

where

Q = the charge for a potential on the plate of X volts,
Q_0 = the charge when sliding in zero field,
A = a constant, and
X = taken as positive when the upper plate is at positive potential with respect to the lower one.

This experiment suggests that the charge transfer will occur until some definite potential difference exists between the particles and the surface. Perhaps most important is the observation that the particles could be made to have zero charge with respect to ground when the potential difference between the plates was chosen correctly.

The mechanism of charging of metals and semiconductors is adequately treated by the band theory of solids. Perfect insulators would not charge in this manner. However, it is not clear to what extent the charging of insulators is dependent on the electrons associated with surface states. Harper (59, 60) states that the actual transfer of ions may account for the charging of insulators. For additional discussion of the mechanism of charging, several articles about static electrification may be consulted: Montgomery (61), Loeb (62), Rose and Ward (63). Skinner (64) has treated the case of insulators from the thermodynamic viewpoint.

By now it should be clear that when a solid is in contact with another solid a difference in charge

will develop. The only sure cure for the accumulation of charge is to make the nonconductor a conductor. High humidity often provides enough surface conductivity to reduce the accumulation of charge significantly. Also, antistatic agents may be used on the surface. These function by increasing the surface conductivity. Surfactants (detergents) are commonly used for this purpose. Several patents have been obtained on combinations involving zinc soaps (65). Another approach has been demonstrated by the work of Gill and Alfrey (58) discussed earlier. This requires the presence of a highly charged surface and could result in some hazardous conditions if used indiscriminately.

Grinding and Agglomeration.—*Agglomeration During Grinding.*—Ball mills of either the rotating or vibrating type seem to be superior to air mills for producing very fine particles. Also, they produce, at least in some cases, an interesting reversal of grinding, *i.e.*, they produce compact aggregates. Khodakov and Rebinder (66) have studied the disintegration of quartz in various media. They describe their mill as a laboratory eccentric vibromill but do not elaborate further. However, in a separate study they describe a vibromill operating at 50 c.p.s. with amplitudes of 3 to 5 mm., and mention steel balls in the grinding. Perhaps it is the same mill. They found that quartz ground in air did not show the very large specific surface area of quartz ground in water (determined by nitrogen adsorption). In air the surface area reached a maximum and further grinding produced agglomeration. The agglomerates were so compact that the bonding between particles reduced the surface available to nitrogen gas. After 16 min. of grinding the specific surface was 6.5 $M.^2/Gm.$ and had decreased to 5.9 $M.^2/Gm.$ after 32 min. of grinding. When ground in water, the specific surface was 42 $M.^2/Gm.$ after 16 min. and 73 $M.^2/Gm.$ after 32 min. Evidence that grinding in air produced a high degree of agglomeration was obtained when water was added to the quartz ground in air. A very sharp increase of specific area was obtained with only 40 sec. of additional grinding after adding water. Furthermore, powder obtained by grinding in water when dried and then reground in air produced a decrease in specific surface during the air grinding.

Another interesting case, described by Gregg (67), shows the change with grinding time of specific surface (by N_2 adsorption) and the change in dissolution rate of kaolin in acid solution. The dissolution rate continues to increase even when the specific surface is decreasing by agglomeration. Apparently a high energy kaolin is produced. The evidence that a new state of kaolin is produced by grinding is obtained by thermogravimetric analysis. After many hours of grinding, most of the solid has changed to a new form, the form that dissolves more rapidly.

In Khodakov and Rebinder's work with quartz, other liquids, such as benzene, acetone, and alcohol, influenced the grinding, but only a slight improvement over air grinding was observed. This is somewhat surprising since the heats of wetting for all the liquids are similar to that for water. (If the Rebinder effect, adsorptional-strength-lowering, were the only determining factor, the specific surface values for grinding in these media should be nearly the same.) The product of grinding in these liquids was similar to the air-ground material, *i.e.*, very short periods of additional grinding in water yielded higher specific surfaces. Dried, water-ground materials, reground in the other liquids, agglomerated to give decreased surface areas. Only small amounts of liquids were required to produce significant effects on the amount of "amorphous" material produced. These authors studied, in addition to quartz, calcite, corundum, talc, rutile, alumina, silicate glass, quartz glass, and cement. In most cases the results were similar. Of course, the effects of hydration of cement prevented a complete study of it.

The influence of the grinding medium on the agglomeration process demonstrates that the bonding of solid particles involves a surface phenomenon. The unavailability of the "internal" surface of the agglomerates to nitrogen is evidence that the bonding involves a high true area of contact between the individual particles of the agglomerate.

Disturbed Surface Layers Produced Mechanically.—In the preceding paragraphs, the surface material produced by grinding has been referred to as high energy material and "amorphous" material. Khodakov (68) has reviewed the influence of fine grinding on the properties of solids. Rieck and Koopmans (69) have investigated wet ground quartz particles of 3 μM. diameter.[3] They have concluded that the quartz particles are coated by a disturbed layer that is about 0.4-μM. in thickness.

Bacon (70) used line width of X-ray data to follow the change in crystallinity of graphite during grinding in a mill for a period exceeding 60 hr. The deterioration of crystallinity continued throughout this period. Gundermann (71) reports that materials, such as sugar and

[3] 1 μM. = 1×10^{-6} M.

cellulose, also exhibit amorphization of the surface on prolonged grinding. He reports that the heat of solution of sugar appears to be increased by grinding; in fact, it changed from negative to positive.

The above evidence suggests that powder surfaces may have unusual properties because of a disturbed layer. Consequently, the electrostatic properties, the surface energy, and the mechanical properties may be different from the bulk properties of the same material.

Capillary Condensation Between Particles.—Moisture may influence the force of interaction between solid particles in at least three ways—namely, (*a*) it may adsorb on the surface and influence the surface energy, (*b*) it may alter the surface conductivity and, therefore, the electrostatic charging of the particles, and (*c*) it may condense in the capillary regions contiguous to the true areas of contact. Previous sections of this paper have discussed the first two. Now, we shall consider the third.

Capillary condensation occurs at high relative humidities, usually in excess of 60%. Only small amounts of water need be involved. The phenomenon of adhesion produced by capillary condensation is the same as wet granulation using very small amounts of water. Small liquid bridges are formed between particles. The case of the wet granule has been treated quantitatively and will be used here to describe the attraction between powder particles produced by capillary condensation.

Rumpf (10, 72) considers three classes of wet granules. They are: (*a*) the case where the hollow spaces between particles are only partially filled with liquid, the liquid being held by capillary forces as "lens" at the point of particle–particle contact; (*b*) the internal voids are completely filled with liquid but the external or surface layer voids of the granule are not completely filled; and (*c*) the liquid completely envelopes the solid, and only the surface tension of the drop holds the particle together (this is really a drop of a suspension, not a granule). Newitt and Conway-Jones (73) also use three classifications. Corresponding to class (*a*) according to Rumpf is a state Newitt and Conway-Jones call the *pendular* state. When the moisture content is high enough that the liquid forms a continuous network throughout the internal surface of the granule, but air spaces still exist inside the granule, these authors call it the *funicular* state. It is a condition intermediate between the (*a*) and (*b*) classes of Rumpf. The third state, according to Newitt and Conway-Jones, is called the *capillary* state. This corresponds to Rumpf's class (*b*).

The strength of a wet granule depends on the surface tension of the liquid phase and the contact angle of the liquid with the solid. The following is essentially the Newitt–Conway-Jones treatment. Consider an ideal case of two hard identical spheres of radius r in contact. About the point of contact, a small droplet of liquid would form, in the plane tangent to the two spheres, a circle of radius b. The case is simplified further by neglecting the force of gravity and by assuming the contact angle of the liquid on the solid is zero. For a small amount of liquid between the two spheres, the liquid would form a concave surface approximating the arc of a circle of radius c if viewed in a plane passing through the centers of the two spheres. The tensile force, f_1, of attraction between the two spheres produced by the surface tension at this concave surface would be:

$$f_1 = 2 \pi b \gamma$$

where γ is the surface tension. Also, the surface tension is causing the pressure inside the liquid phase to be reduced so that there is a hydrostatic "suction" pressure holding the particles together. This is given by the Laplace equation for two curvature capillary pressure and is:

$$f_2 = \pi b^2 \gamma \left(\frac{1}{c} - \frac{1}{b}\right)$$

The total force holding the particles together is:

$$f_1 + f_2 = 2 \pi b \gamma + \pi b^2 \gamma \left(\frac{1}{c} - \frac{1}{b}\right)$$

To obtain the strength of a granule it is necessary to correct this for the number of particle–particle contacts, *i.e.*, the packing. However, the above will suffice to explain the origin of the granule strength under a static condition. In powder beds, it explains the attraction produced by capillary condensation between each pair of particles. Mason and Clark (74) have eliminated the influence of gravity by studying liquid bridges between particles dispersed in liquid vehicles. They report that the maximum values agree with the calculations of Fisher (75).

A dynamic term may be added to f_2. If the liquid between the particles has a high viscosity, separation of the particles must overcome the resistance to deformation of the viscous liquid. This produces a change of the "suction" pressure that increases with the rate of particle separation. Consequently, viscous liquids add a shock resistance to the strength of the liquid "bond."

Among the classes of granules discussed by Rumpf and by Newitt *et al.*, the capillary state is the strongest. However, the amount of water condensed into the capillary regions surrounding the contact regions of powders usually would be

much less than that required to produce a high-strength granule.

Even small amounts of water deposited from the atmosphere by capillary condensation may increase the adhesion throughout the bed. If some solubility of the powder occurs in the liquid, caking may result, especially when alternating high–low humidity cycles exist. Ettle (76) used a penetrometer to detect caking in stored fertilizer. Whynes and Dee (77) have used a procedure adapted from the study of soil stability. It measures the crushing strength of a cylinder of the preconditioned powder held in a rubber sleeve.

As the liquid evaporates from the capillary region, any dissolved materials deposit at the points of particle–particle contact. If no material were dissolved in the liquid phase there would be no increase in dry strength produced by the wet–dry cycle. Newitt *et al.* report that solutions of ammonium sulfate were used to granulate fine sand. They state, "... as total dryness is approached, the strength may exceed some fifty times the original moist strength."

THE TRUE AREA OF CONTACT BETWEEN SOLIDS

This section will be limited to a discussion of the areas of true contact established between macroscopic solid objects because the author is unaware of any work done to measure the true area of contact between small particles. Worthwhile perspective on the problem is gained by considering the evidence available for the macroscopic case.

The importance of the true area of contact is obvious from the previous discussion. The surface interactions are nearly all from short-range forces. Electrostatic charging occurs at actual contact points and elastic and plastic displacement require true contact. All of these are important factors in determining the tensile strength between particles in contact.

Again the source of much of the information is from the studies of friction and wear. Earlier in this review mention has been made of the extensive contributions of Bowden and Tabor (27–29). In addition to their work, some recent reviews of studies of the true areas of contact between solids (78, 79) have been translated from the Russian language. None of the experimental methods used are free from error. However, many of the results are worthy of consideration. Among the methods used are (*a*) changes in electrical conductivity with pressure, (*b*) transfer of very thin layers of paint (both luminous phosphors and radioactive isotopes have been used with this method), and (*c*) optical methods, suitable for use only when one or both solids are transparent. These depend on light reflection or transmission, respectively, at points of contact and light scattering at regions of no contact. The optical method permits contact area measurements to be made during sliding. Theoretical calculations based on specific models have been made. These models include: (*a*) elastic contact involving hemispherical asperities in contact with a plane, (*b*) elastic contact of two surfaces involving an assembly of rods, (*c*) contacts between surfaces with randomly distributed asperities, and (*d*) elastic-plastic contacts of asperities with a rigid plane and without work hardening of the solid.

The following general conclusions are based on a large amount of experimental data and are taken from *Reference 79*.

(*a*) "The actual contact area is determined to a large degree by the original microgeometry of the compressible bodies."

(*b*) "The microgeometric shape of the surface varies during compression."

(*c*) "The contact area is directly proportional to a power smaller than one of the applied load."

(*d*) "The contact area depends on the physicomechanical properties of the surface layer of the compressed body."

(*e*) "The area of a single contact zone is almost completely independent of the applied load."

(*f*) "The deformation of a compressed surface is elastic."

A series of plots of the real area of contact *versus* the applied pressure is given in *Reference 78* for different metals. Only a slight curvature is apparent in most of the plots. Therefore, the deviation from linearity, referred to in (*c*) above, is not large for these specific materials. From simultaneous measurements of both the static frictional force and the true area of contact, the real specific frictional force in Kg./cm.^{2} and the real pressure in Kg./cm.^{2} were obtained. The results for polymethyl methacrylate and for silver chloride (apparently against a very smooth glass surface) are given. The specific frictional force was not constant. For both cases, the force appeared to increase with increase in pressure. The increase was more rapid with polymethyl methacrylate than with silver chloride. The author states that this is consistent with the known property of work hardening of this polymeric solid.

If true areas of contact are established through strong asperities, then plastic flow may occur in the bulk of the solid below the asperities. This would not lead to establishing high areas of true contact; but it would result in the storage of

some energy in the elastic displacement of the asperities. This would be necessary to exceed the yield value and produce plastic flow. Consequently, the cohesion of such a solid would be very small.

Bowden and Tabor (83) have discussed the persistence of work-hardened asperities. They have made gross indentations in bulk copper without producing extensive deformation of preformed microscopic work-hardened ridges. Herring and Galt (81) have pointed out that whiskers (growth around a single screw dislocation) of tin are many times stronger than the bulk metal. Beams *et al.* (82) have demonstrated the very large strength of thin films. The explanation is believed to be that plastic flow does not occur where sections are so small that crystal dislocations are either not present or where they cannot move to generate new dislocations.

Since none of the reported studies involve typical pharmaceutical, organic solids, it is possible only to speculate on whether these results are applicable. Probably the mechanisms are the same, but the relative occurrence or importance of various mechanisms may be different. There are important unknowns concerning the true nature of the surface regions of an organic solid. How rough is the surface of a powder particle? What is the distribution of asperities? Are the asperities whiskers? How readily do dislocations move in complex organic crystalline solids? Only further study will resolve these problems.

It is common knowledge that many powders become "sticky," *i.e.*, exhibit high cohesional forces, when the size range includes many particles of less than 10 μ diameter. However, other materials may not become "sticky" even when in a much smaller size range. Possibly the structure of the surface varies; those powders with smooth enough surfaces to readily produce high true areas of contact, even at low contact pressure, would be expected to be sticky. Those with a very rough surface and a low true contact area would be less sticky. Electron photomicrographs such as those made of polyethylene glycol 6000[4] by Nash *et al.* (52, 80) suggest that some solids may have relatively flat surfaces. Nevertheless, the resolution of these photomicrographs is not sufficient to provide evidence of the degree of roughness at molecular levels.

EXPERIMENTAL EVALUATION OF COHESION AND ADHESION OF POWDER PARTICLES

Numerous other reviews have been written that discuss both the methods and the results of measuring cohesion and adhesion of powders. Therefore, the author has chosen to treat this section relatively briefly and leave it to the reader to consult some of the other reviews or the original articles for more details. Other reports summarizing some of the studies are Böhme *et al.* (84), Lowes (85), Morgan (9), Patat and Schmid (86), and Brown (87).

Angle of Repose and the Angle of Internal Friction.—The earlier discussion of friction has indicated the significance of friction measurements in relation to particle–particle interactions. Numerous methods have been employed to obtain friction values. The simplest of these is the angle of repose. Train (88) has compared the results from four different methods and reports that the value obtained depends on the method used. The four methods he compared are: (*a*) fixed funnel, free standing cone, (*b*) fixed bed cone, (*c*) tilting box, and (*d*) revolving cylinder. Zenz and Othmer (89, 90) conclude that there are two different types of angles of repose. One is obtained when a pile is formed and the other when a hollow cone is formed by draining through an orifice. (These authors define other related angular properties of solids, *viz.*, angle of internal friction, angle of wall friction, angle of rupture, and angle of slide.) Taylor (91) points out that the angle of repose represents, at best, a crude approximation to the angle of internal friction. The angle of repose differs from the angle of internal friction because it is determined by the least stable particles. The particles on the surface can be stable only when the least stable grains are in equilibrium. The internal friction depends on the average condition for all grains. Perhaps internal friction would correlate more closely with flow properties. Dalla Valle (92) equates the tangent of the angle of repose to the coefficient of friction. However, general application of this formula may lead to serious error because the derivation assumes no cohesion between particles. When cohesion is present the normal force, σ, on a pile would be:

$$\sigma = mg \cos \theta + C$$

where m is mass, g is gravitational constant, θ is the angle of repose, and C is the cohesion force. The tangential force, τ, is:

$$\tau = mg \sin \theta$$

and the friction equation is:

$$\tau = \mu\sigma$$

or

$$mg \sin \theta = \mu (mg \cos \theta + C)$$

In this equation, μ and C are both unknowns

[4] Marketed as Carbowax 6000 by Union Carbide Corp., New York, N. Y.

and cannot be evaluated from an angle of repose measurement. Usually, C is ignored, and μ is calculated as if C equals zero.

In this laboratory, the arbitrary assignment of $C = 0$ has been overcome by adding a centrifugal component to the pile. This is accomplished by forming the pile on a rotating horizontal disk. It is called the "spinning disk" technique. The corresponding equations are:

$$\sigma = mg \cos \phi_r + C - mr\omega^2 \sin \phi_r$$
$$\tau = mg \sin \phi_r + mr\omega^2 \cos \phi_r$$

and the friction equation is:

$$g \sin \phi_r + r\omega^2 \cos \phi_r = \mu \left(g \cos \phi_r + \frac{C}{m} - r\omega^2 \sin \phi_r\right)$$

where ϕ_r is the slope of the profile of the pile at radius, r, *i.e.*, the angle between the horizontal and a tangent to the surface of the pile at radius, r, $\omega = 2\pi$ (rev./sec.).

Values of ϕ_r for various r values are obtained by sifting as much powder as possible onto an 11-cm. diameter disk covered with sandpaper. A small lip on the edge of the disk helps during the starting of the pile. The completed pile is photographed on transparency film and then projected. From the projected profile of the pile, corresponding values of r and ϕ_r are obtained by drawing tangents to the surface of the pile. By plotting the corresponding values of τ/m *versus* $\frac{\sigma}{m} - \frac{C}{m}$ and then calculating the least squares line, it is determined whether $C = 0$, *i.e.*, it is determined whether the plot goes through the origin. The slope of the line is μ. Often the plot is not linear when $C > 0$; and the method fails. Attempts to use this method to obtain both μ and C/m when $C > 0$ usually have been unsuccessful. However, the fact that one obtains an indication whether C is or is not zero is an important improvement over a simple angle of repose measurement. The accuracy and precision of a value obtained from a least squares line was found far superior to the single point method of an oridinary angle of repose pile. Of course, constant humidity conditions are essential for precision of any method.

Figure 2 shows the apparatus and Fig. 3 dramatically shows the cohesion existing in a pile of sticky powder.[5] To form this pile the powder was sifted gently onto the disk, no compaction was used to make the pile stick. The relative humidity was 50%. The surface of the pile was

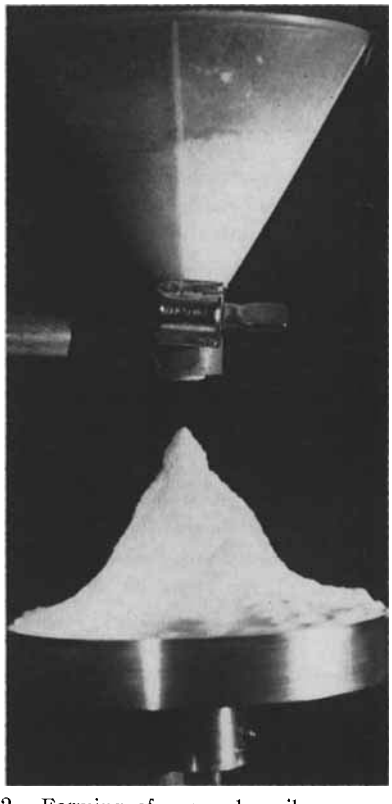

Fig. 2.—Forming of a powder pile on a spinning disk. Powder is lidocaine base.

exposed to radiation from a polonium source to remove the accumulated charge. (Of course, this did not remove the electrostatic component of adhesion at points of true contact.) The pile was inverted immediately after forming; only the tip fell off.

Variations of the angle of repose method have been used to obtain cohesion values. This is useful only when the powder bed behaves as a plastic body. A preformed bed may be tilted very slowly until a shear plane develops and a mass of the powder slides off. The angle of

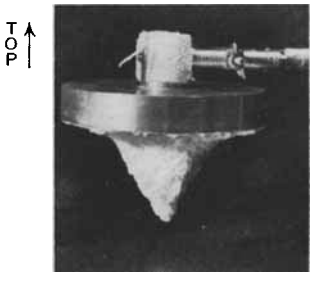

Fig. 3.—Lidocaine base pile formed in 50% R.H. air has sufficient cohesion and adhesion to remain intact when inverted.

[5] Lidocaine. Marketed as Xylocaine Base by Astra Pharmaceutical Products, Inc., Worcester, Mass.

slide observed is assumed to be the angle of internal friction. Hayashi and Minami (93) varied the length of a tilted box filled with powder to obtain variable forces and angles so that the cohesion could be calculated. Lowes (85) and Lowes and Perry (94) describe a similar method based on the tilting of a preformed cone until a shear plane develops.

Studies in which the cohesion was not evaluated are very numerous. Possibly the angle of repose is the most common method of obtaining an index of flow, in spite of its limitations. A few of these reports will be mentioned here to provide a starting point for the reader interested in pursuing the subject further. A complete list is prohibitively long.

Studies of the influence of particle size and size distribution on the angle of repose have been reported by Krishna and Rao (95), Train (88), Nelson (96), Pilpel (97), and Nakajima *et al.* (98). The influence of additives has been studied by Craik (99), Nelson (96), Awada *et al.* (100), and Nash *et al.* (52, 80). Awada *et al.* report the use of glass beads as a diluent to sticky powders. They estimate the angle of repose for the pure powder by varying the composition and extrapolating to 100%. The influence of moisture content has been reported by Fowler and Wyatt (101), Lowes and Perry (94), and Craik and Miller (102). Fonner *et al.* (103) attribute to surface roughness of granules a strong influence on the angle of repose. Other reports and discussions of interest are those of Dawes (104) and Carr (105). In general, these studies indicate that the presence of fines increase the angle of repose. Diluents alter the flow properties; diluents that are themselves free flowing usually decrease the angle of repose and vice versa of the mixture. It is clear that the angle of repose increases at high relative humidities, presumably as a result of capillary condensation in the regions of true contact.

Tilted Plane Method.—If small amounts of powder are placed on a flat surface and then the surface is tilted at an ever-increasing angle until the powder slides off, the process may be described by the same equations as before. The friction equation used is:

$$mg \sin \theta = \mu (mg \cos \theta + A)$$

A is the adhesion of the powder to the plate when the shear plane is between the powder and the plate, *i.e.*, the powder slides off as a single clump. Cremer *et al.* (106) obtained plots of τ *versus* σ by varying the size of the powder layer to change the mass. She used the equation in the form:

$$mg \sin \theta = \mu\, mg \cos \theta + H$$

Her H values correspond to μA above. Böhme *et al.* (84) discusses the work of Patat and Schmid (86) in which they concluded that the complicated nature of the sliding process prevents this from being a satisfactory method. For example, it sometimes produced negative values for H. (The same complication was observed by the author with sticky powders when using the spinning disk.) Zimon (107) reports good results with the method but points out that it is not a true measure of adhesion of individual particles because of the mechanism of sliding. Many others have used it, *viz.*, Pecht (108), Batel (109), Krishna and Rao (95), and Hayashi and Minami (93). Pecht, Batel, and Patat and Schmid used a vacuum arrangement so that the influence of different atmospheric conditions could be explored. Pecht studied relatively narrow size distributions and found that sometimes the adhesion decreased with increase in size distribution.

The above method is designed to measure friction and adhesion to the surface. However, it is not always possible to maintain the shear plane at the powder–substrate interface. Sometimes the particles may adhere to the substrate and the shear plane develops in the powder bed. Also, the particles may move as individuals. In either case the method fails.

The Shear Cell Method.—The intentional development of a shear plane in a powder bed provides another method of using the friction equations to measure cohesion. Dawes (104) used two types of shear cells. One of these assured that the shear plane was in the powder by having vertical vanes on both the upper and lower plate. The powder bed was just thick enough to prevent the vanes from striking each other. His alternate cell used only sandpaper on the bottom of the top plate. He compared the values of σ and τ for both methods; and he found, for a given powder, that the values obtained in the two cells were slightly different. In his study both μ and C were somewhat lower when the sandpaper-covered plate was used.

Jenike (110, 111) has used a shear cell that is packed with powder. The cell is split so that the shear plane is in the powder. Since the powder is packed into the cell, the true area of contact between powder particles and the test results may be influenced by the packing. Jenike has used data from his apparatus to design hoppers. Ashton *et al.* (112) have attempted to control the bulk density in a Jenike-type cell and have obtained a series of isodensity curves for various powders. These authors find that the equation $(\tau/C')^n = \frac{\sigma}{T} + 1$ describes the "yield loci" at

constant bulk density of many powders; n is a constant for a given powder of a given particle size and size distribution. It is independent of bulk density and usually is between 1 and 2. C' is equivalent to μC in the earlier equations. T is the tensile strength of the powder measured in a special apparatus described by Ashton *et al.* (113); it is a modification of an apparatus described by Dawes (114). The cohesion apparatus will be discussed under *Tensile Strength of Powder Beds*. Apparently the tensile strength measured in this manner is always less than the value of C obtained by extrapolation of the shear cell data, *i.e.*, the τ *versus* $\sigma - C$ plots.

The results of Ashton *et al.* show the effect of the bulk density changes. These results confirm many of the general conclusions stated in the sections dealing with the theoretical considerations.

The Jenike method of describing powder flow and of hopper design using the shear cell data is discussed by Williams (115). Additional discussion of the shear cell and its uses can be found in several papers in a single issue of *Rheologica Acta* (116).

Other workers have used a shear cell method in evaluating powders. Taneya (117)[6] has compared the results of the shear cell technique with another based on a modified Couette viscometer (discussed below). The two methods do not always produce the same results. Okada and Abe (118) report results using an apparatus they attribute to Deryagin and Lasarev (119).

A simplified apparatus is described by Nash *et al.* (52, 80). This simple shear cell has been used in these laboratories. The force required to shear a thin layer of powder between two emery paper-coated surfaces is observed. The author has modified the apparatus to permit the top plate to be suspended on a long thread from a balance so that normal loads less than the weight of the top element may be applied. A laboratory jack is used to raise the powder bed gently up and under the top plate, stopping at the null point of the balance. Because of the simplicity of the apparatus, it is readily used inside a constant humidity chamber.

It is difficult to assess the merits of the various shear cell designs and methods of using them. However, the choice of the simple cell described by Nash *et al.* is not determined only by its convenience in use. Because it uses a very thin layer of powder, it was felt that the sample density will be more uniform throughout; also, that its bulk density will be determined by the load applied instead of by the method of prepacking of the cell. Tests indicate that the bed thickness used, $^1/_8$ in., is sufficient that the magnitude of τ is not affected by changes in thickness. The powder bed is formed by gentle sifting to minimize the packing. However, the screen size through which the powder passes and previous handling may determine the agglomerate size and influence the density of beds of a cohesive powder. Certainly these factors can influence the results.

Certain powders do not yield straight line plots of τ *versus* $\sigma - C$. Often these same powders form nearly spherical compact aggregates when handled, often called pilling. The author's experience has been that these are very cohesive powders of fine particle size. Also, qualitatively a low plastic yield value for beds of these powders has been observed. Under the heavier loads, *e.g.*, about 20 Gm./cm.^{2}, they form a sufficiently strong wafer that it must be peeled off the sandpaper. Also, a few cohesive powders yield negative values of C. Hence, the assumed model on which the simple friction law is based is not sufficient to describe all powders.

Several investigators have used coaxial cylinders in an arrangement similar to a Couette viscometer to measure the friction coefficient and the cohesion. Matheson *et al.* (120) used a Stormer type viscometer with a flat paddle as the moving element. It was suspended in a fluidized bed. They classified the flow into three types, *viz.*, (*a*) cohesive, (*b*) aggregative with good fluidization, and (*c*) slugging. Type (*a*) was observed with small particles, usually less than 40 μ diameter. Slugging occurred with high air velocities. Meaningful results were obtained only with type (*b*) flow. Quantitative values for the cohesion are not possible with this arrangement. Benarie (121), Taneya (122), and Kuno and Kurihara (123) have used the "viscometer" arrangement to produce a cylindrical shear region in a powder bed. This permits calculation of μ and C if the radius of the effective cylinder can be determined. It was found that this experimental approach is limited to relatively noncohesive powders. The powders must flow freely into any voids formed by the motion in the shear plane. Cohesive powders that have a low bulk density first undergo forced packing in the vicinity of the shear plane and then form a cylindrical void region. The shear region becomes an air gap and no measurement is obtained. Taneya and also Benarie report surprisingly large cohesion values for the coarse particles they studied. Possibly this technique is a more sensitive method than the direct tensile strength test procedure to be described next.

[6] Refers to description of apparatus in Taneya, S., and Sone, T., *Oyo Butsuri*, 31, 286(1962).

Tensile Strength of Powder Beds.—Reference has been made previously to the Tideswell-Tallyfield apparatus described by Dawes (114). An improved model is described by Thouzeau and Taylor (124); also, a similar apparatus used by Ashton *et al.* (113) already has been mentioned. These apparatus are split containers with one-half fixed and the other movable. They are arranged so that the powder bed breaks into two halves either by tilting the apparatus so the movable half moves away (104) or by using the apparatus in a horizontal position and applying a force on the movable half of the cell (113) to pull it away and break the powder bed. Obviously, this method cannot be used unless the powder is cohesive enough to provide a clean break. Otherwise, the powder would slide into the space between the two halves of the cell as they separate.

The true area of the break plane is not easily calculated since the fracture results in an irregular surface. Furthermore, the concentration of stresses at local regions usually cause tensile strength tests of brittle solids to measure a low cohesion value. It seems reasonable to assume that in this test the powders would behave similar to a brittle solid. However, McKee (125) has measured very weak, sintered compacts in a modified Tideswell apparatus, and he claims that the Griffith crack mechanism is not a significant factor in the breaking mechanism of these compacts.

Farley and Valentin (126) have combined data from the equipment described by Ashton *et al.* with data from a Jenike-type shear cell. The observed cohesion is less than the intercept value, C, from the shear cell data. Eisner *et al.* (127) have studied the increase in tensile strength of powder beds on exposure to humid air. Increases continued for up to 8 hr. Thouzeau and Taylor (124) observed differences in raw materials supposedly supplied from the same source. In both studies (124, 127), a decreased cohesion value was observed after the powder had been "waterproofed," *i.e.*, coated to alter its surface energy. Shotton and Harb (128) studied various starches and observed various patterns of change in cohesion with changes in moisture content of the powder.

Another device for evaluating the cohesion of powders has been described by Nash *et al.* (52, 80). Two coaxial cylinders of the same diameter are placed end to end. Powder is placed in the cylinders; and it is compressed at low load. The force required to separate the cylinders and to fracture the powder bed is observed. For a given compression load, the bulk tensile strength is an exponential function of the length of the column in the cylinders. By using different amounts of powder to change the column length and then plotting the observed cohesion values on semilog paper, an extrapolation to zero column height may be made. This zero height value varies with compression load. A plot of zero column length cohesion values *versus* the respective compressive loads yields an approximately linear relationship over the range studied by these investigators.

So far the methods considered for evaluating powders have been concerned only with a powder bed, not the individual particles. Another very interesting body of experimental data has been obtained on individual particles. The normal force required to pull a particle off a surface is a tensile strength test of the individual particle "bond" to the surface. These studies are most interesting. They reveal a very broad range of forces for similar particles and the maximum force between a particle and a solid surface is surprisingly large.

The Centrifugal Method.—Kordecki *et al.* (53, 129) used a centrifuge in studies of the adhesion of particles to a flat surface. Determinations were made of the size distribution of the particles initially sprinkled on a slide and of the size distributions of those remaining after subjection in discrete steps to successively higher fields of force. The maximum acceleration applied was in excess of 8 g. At maximum acceleration, nearly all of the largest particles and a significant fraction of the smallest particles were removed.

Böhme *et al.* (84, 130–132) also have used the ultracentrifuge, one of them capable of producing forces in excess of 10^6 g. Because they used a very narrow size range of particles, they plotted their results differently. They compared the per cent of particles adhering *versus* the applied force (dynes) and found that the variation of force with particle size was small. Apparently the larger acceleration required for small particles is a consequence of their small mass. Also, these authors have gathered some data on the influence of surface composition and texture on the adhesion of particles to the surface. Their results are consistent with the concepts developed in the early paragraphs of this review. Krupp and Sperling (11) have developed a theory of the adhesion of small particles using the concepts of deformability of solids, surface roughness, and surface energy.

Zimon and Volkova (133) have used the centrifuge method to study the effect of surface roughness. Their conclusions are in agreement

with others, *i.e.*, the adhesion is highest on very smooth surfaces. Zimon (134) has studied the influence of capillary condensation on the adhesion of individual particles. The observed adhesion force was smaller than his calculated values.

Deryagin *et al.* (135) have used centrifugal fields providing up to 300,000 g. They did not succeed in removing all 5-μ diameter glass particles from a polished steel rotor. They used, also, an impact method but give no details. They state that they completely removed glass particles using an impact. The experiments were performed at relatively high velocities of the bullet.

The Vibrating Plate Method.—Deryagin and Zimon (54) used ultrasonic vibration of a metal support surface to measure the force required to remove particles from the metal. Accelerations up to 24,000 g were possible with this unit. Because the forces required to hold individual mono-sized particles covers such a broad range, the representative force used in making comparisons was chosen as the force required to remove 50% of the particles. They found that to remove small particles a larger force was required than for large particles. In this paper, these authors report also the electrical charge observed on particles being blown off the surface of a solid. A broad range of charges was observed. The charge on the particles increased with time in a manner similar to the rate of the increase in adhesional force with time. Consequently, these authors propose that the electrostatic charging process makes an important contribution to the adhesional force.

Impingement and/or Dispersibility of Powders in an Air Stream.—Both the dispersibility in an air stream and the adhesion on impingement of powder in an air stream are used to evaluate the stickiness of powder. Dawes *et al.* (104, 136, 137) have studied the dispersibility of a powder bed in an air blast. In general, two types of behavior are observed. Noncohesive powders allow a gradual erosion process to occur. Cohesive powders denude suddenly by the tearing away of large chunks.

Pecht (138) measured the loss in an air stream of powder from the surface of a granular substrate. From this he developed a relative stickiness factor. Jordan (139) used the air velocities required to remove various percentages of the particles from a plate for making comparisons. Larsen (140) and Corn and Silverman (141) have studied removal by air streams of solid particles from filters. The relationship between adhesion and adherence on impingement has been discussed by Jordan (139). Adherence on impingement has been studied both in connection with the air filtration problem and in connection with the impactor as a sampler of dust in air.

The cascade-impactor is used in the particle size analysis of aerosols. It depends on the size selective impingement (with adhesion) of particles from successively higher velocity air streams. Several factors that influence collection efficiency in impactors have been discussed by Stern *et al.* (142). Aerosol sampling has been reviewed briefly by Whitby and Liu (143).

In addition to the relatively sophisticated approaches, some very empirical methods have been used to provide indexes of dispersibility. Drop tests have been described by Neumann (144) and by Carr (105).

The Weight Method.—Böhme *et al.* (84) reviewed the older efforts to measure directly by weighing the adhesion of relatively large particles or fibers. A more recent study is reported by Corn (145) in which the adhesional force of micron-sized particles to solid surfaces were measured using a microbalance. The pendulum technique was used by Howe *et al.* (146) for measuring adhesion of a large bead (0.5 mm. or larger) to a surface measures adhesion directly but is not suitable for very small particles.

SUMMARY

It would be encouraging if from all of the studies considered in this review one could summarize the results in a simple quantitative manner. However, the only generalizations possible seem to be statements of the variations observed. The observed cohesion varies with the experimental method used to measure it. Some powder beds seem to exhibit negligible cohesion. Yet, individual particles may require accelerations approaching 1,000,000 g to remove them. At low humidities, the electrostatic component may be large. Theoretical considerations of the electrostatic charging of insulators is not sufficiently developed to be of any help in predicting the behavior of most organic powders. Surface energy and topography are seldom known. Mechanical properties of individual particles vary and have been explored insufficiently to permit any quantitative consideration.

In this review the author has attempted to discuss experimental evidence that indicates the types of forces that act between solids in contact. That powder particles attract is not surprising. Also, the relationship of the mechanical properties and topography to the areas of true con-

tact have been considered. The final section reviewed the methods used by various investigators to obtain either numerical values or rank order classifications of the forces of attraction between solids, powders, and/or particles. The complexity of the problem of developing a quantitative, universal theory for the interaction of powder particles with solids makes such a result appear to be remote indeed. However, from a qualitative understanding, it often is possible to determine a systematic approach to our formulation problems; some call it guided empiricism.

Factors Influencing the Surface Activity of Chlorpromazine at the Air–Solution Interface

Effect of Inorganic and Organic Electrolytes

By RASHMIKANT M. PATEL and GEORGE ZOGRAFI

In a previous study it was observed that adsorption of chlorpromazine at the air-solution interface is influenced significantly by anionic buffer components. In view of this, the effect of a large number of inorganic and organic ions has been considered. Marked inhibitory effects were noted in the presence of organic cations *e.g.*, the tetraalkylammonium ions; the greater the chain length, the greater the inhibition. Inhibition was also noted in the presence of sodium methanesulfonate. On the other hand, bromide, iodide, propanesulfonate, benzenesulfonate, and naphthalenesulfonate ions all produced increased surface activity when compared to the system containing NaCl. The inhibitory effects appear related to factors influencing the structure of water, while the effect of anions appears due to interfacial ion-pair formation.

RECENT studies in this laboratory have been concerned with the possible relationship between surface activity at various interfaces and pharmacological activity of the phenothiazine drugs (1–3). The rationale for such studies is based upon many reports of phenothiazine involvement in metabolic processes controlled by the presence of biological membrane interfaces (4).

In a recent study (3) the surface activity of various phenothiazine derivatives was compared at the air–solution interface and found to reflect the relative nonpolarity and pharmacological activity of each compound. In addition, a significant effect due to the presence of buffer ingredients was noted at pH 5.0 and ionic strength 0.1. Phthalate, citrate, and succinate buffers markedly increased surface activity, while an acetate buffer decreased the tendency for surface pressure development. In contrast to acetate, studies with a phenylacetate buffer also showed a marked increase in surface activity (5). Dilution of all buffers, while maintaining pH and ionic strength constant, tended to restore surface activity to the value expected of the protonated form.[1]

It was suggested at that time (3) that increases in surface activity in the presence of the various buffer ingredients were due to specific interactions between the cationic drugs and the anionic buffer ingredients. The decrease in surface activity due to the acetate–acetic acid system suggested the possibility that the thermodynamic activity of these drugs was decreased by some change in water structure (18) or by a competing process at the interface. Since such factors could play an important role in determining the properties of these drugs at biological interfaces, the authors decided to examine more closely those factors influencing the surface. This first study is concerned with the influence of some inorganic and organic ions. The latter are comparable to the buffer ingredients utilized in the authors' earlier study; but, in addition, they are completely ionized at all pH values.

EXPERIMENTAL

Materials.—The hydrochloride, hydrobromide, and hydroiodide salts of chlorpromazine were obtained from the Smith Kline & French Laboratories, Philadelphia, Pa. They were all recrystallized twice from reagent grade isopropyl alcohol. All inorganic salts were reagent grade and, with the exception of NH_4Cl, were dried before use by heating to 200°. The various tetraalkylammonium chlorides were obtained from Eastman Chemicals. The tetramethyl derivative was recrystallized from isopropyl alcohol, the tetraethyl and tetrapropyl derivatives from acetone, and the tetrabutyl derivative from benzene. Sodium-1-propanesulfonate, sodium benzenesulfonate, and sodium-2-naphthalenesulfonate were obtained from Eastman and recrystallized from absolute methanol. Sodium methanesulfonate was pre-

[1] Since the pKa values of all drugs studied are above 9.0 (6, 7), it is assumed that the drug is essentially 100% dissociated at pH 5.0. Therefore, the point of comparison for the protonated form, uninfluenced by buffer, is a solution of the hydrochloride brought to pH 2.0 and ionic strength 0.1 with HCl and NaCl.

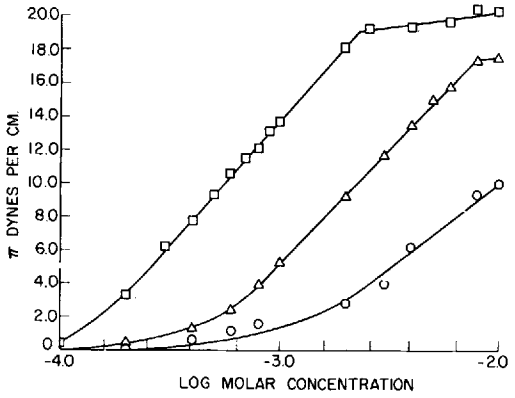

Fig. 1.—Plot of surface pressure, π, *vs.* log molar concentration for chlorpromazine at pH 5.0 and 25°. Key: O, no salt; ▽, 0.1 *M* NaCl; □, 0.5 *M* NaCl.

pared by adding an equivalent amount of a sodium hydroxide solution to methanesulfonic acid (Eastman). The reaction mixture was treated with activated charcoal. All recrystallized materials were powdered and dried under vacuum at 60°.

Methods.—Surface tension measurements of all solutions were made at 25° utilizing the drop-volume apparatus, described previously (3, 8). Details for measuring the volume of drops and for calculating surface tension have been reported earlier (8). Values reported here are generally accurate to ±0.3 dyne/cm. Due to the possibility of chlorpromazine photodecomposition, all solutions were prepared just prior to measurement and were kept from any contact with light. The buffer utilized to maintain pH 5.0 was a 0.01 *M* acetate–acetic acid system, which did not exhibit any surface pressure beyond that of a blank solution and did not have any effect on the expected surface activity of the protonated drug. Unless otherwise stated, in all studies chlorpromazine hydrochloride was used as the drug. All pH measurements were made with a Beckman research pH meter.

RESULTS

In general, two criteria may be used to evaluate surface activity. The first, and perhaps the most important, is the concentration of drug required to achieve measurable surface pressures. The second involves estimating the surface excess or surface concentration at various bulk solution activities. This value requires measuring the change in surface pressure with changing solution activity and applying the appropriate form of the Gibbs adsorption equation (9). Unfortunately, in systems under study here bulk solution concentration cannot be easily equated or related quantitatively to solution activity. However, for the present, plots of surface pressure, π *versus* log *C*, will be given for the various systems studied, and it will be assumed that a greater slope at a given concentration *reflects* greater surface concentration.

Figure 1 indicates the relative tendency of chlorpromazine (CPZ) to develop surface pressure in the presence of buffer alone, and buffer plus 0.1 *M* and 0.5 *M* NaCl. The reduction in required concentration, the general increases in slope, and the appearance of an apparent critical micelle concentration (CMC) clearly indicate the strong tendency of chlorpromazine to exhibit marked surface activity once the apparent repulsive forces of the ionized polar group are reduced. The effect of different inorganic cations, as seen in Fig. 2, is relatively nonspecific except for small differences, particularly above the apparent CMC. At these higher drug concentrations, differences in hydration energies and ionic size may be accentuated.

Figures 3 and 4 demonstrate the inhibition of surface activity due to the presence of various tetraalkylammonium salts. It is interesting to note that 0.1 *M* tetramethylammonium ion acted exactly as an inorganic cation, while the 0.5 *M* solution offset the expected ionic strength effect by reducing surface activity. The surface pressure developed by these substances in the absence of drug was no greater than 1.0 dyne/cm. As can be seen, increasing the chain length of the four alkyl groups beyond one carbon greatly inhibits the surface activity, par-

ticularly 0.1 *M* tetrapropyl and tetrabutyl. The tetraethyl, tetrapropyl, tetrabutyl derivatives, at 0.1 *M* concentration without drug, exhibited surface pressures of 1.0, 5.0, and 10.0 dynes/cm., respectively. The 0.5 *M* solution of tetraethylammonium chloride exhibited a surface pressure of 2.0 dynes/cm. in the absence of drug.

A most interesting and revealing series of observations were made when the influence of various anions on surface activity was measured. Figure 5 illustrates the results with chlorpromazine hydrochloride plus 0.1 *M* NaCl, NaBr, and NaI. One can see that compared to NaCl a marked increase in surface activity occurs with a change in counter-ion. The iodide ion seems to exert the greatest effect and the bromide next. Note in particular the complete loss of curvature in the presence of iodide ion so that the plot of surface pressure *versus* log concentration is linear down to zero π. Under the conditions of this particular experiment, chlorpromazine hydrochloride was quite soluble (up to $10^{-2}M$) in the presence of excess bromide and chloride ion but separated as an oil at about $9 \times 10^{-3}M$ CPZ in the presence of iodide ion. The oil, upon standing, turned into a solid which, when collected and recrystallized from isopropyl alcohol, was identified as chlorpromazine hydroiodide by comparison with a sample on hand.

Since both the hydrobromide and the hydroiodide of CPZ were available, a solution of each salt was prepared in a 0.1 *M* solution of NaCl and in 0.1 *M* of its own sodium halide salt. These were compared with the previous experiments and the results are given in Fig. 6. It is interesting to note that each salt of CPZ in the presence of 0.1 *M* NaCl exerts a small but significant effect as compared to CPZ–HCl. The rapidly rising curve for CPZ–HI appears particularly significant and suggests that the iodide ion is strongly interacted with CPZ. A comparison of CPZ–HCl and CPZ–HBr in 0.1 *M* NaBr indicates no significant difference except as one approaches upper limits of surface pressure. This would indicate that bromide ion can essentially replace Cl^-, so that the system is behaving as CPZ–HBr. An exaggerated example of Cl^- displacement was apparently seen with CPZ–HCl and 0.1 *M* NaI (Fig. 5), since marked surface activity occurred at much lower concentrations of CPZ. The results of experiments with the hydroiodide salt of CPZ in 0.1 *M* NaI were most interesting since no significant concentration of CPZ could be dissolved. Reduction of the concentration of the common ion (iodide) resulted in higher solubilities, but no concentrations approaching that of the hydrochloride in 0.1 *M* NaI could be reached. Apparently in the former case the oil produced *in situ* is more soluble than the crystalline salt. Such oil formation was also observed in the presence of the phthalate buffer in a previous study (3).

Since the buffer effects noted in a previous study appeared in the presence of organic anions, the authors chose to study a series of sulfonates which are completely dissociated over a wide range of pH values. Figure 7 shows the effect of adding 0.1 *M* solutions of sodium methane-, propane-, and benzenesulfonate. Compared to the hydrochloride, note the apparent increase in surface activity due to the latter two, while a significant decrease results in the presence of methanesulfonate ion. It is interesting that these results appear to parallel those seen

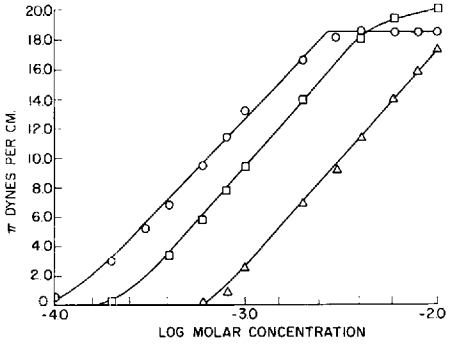

Fig. 4.—Plot of surface pressure, π, *vs.* log molar concentration for chlorpromazine at pH 5.0 and 25° in the presence of 0.5 *M* NH_4Cl, tetramethylammonium chloride, and tetraethylammonium chloride. Key: ○, 0.5 *M* NH_4Cl; □, 0.5 *M* $(CH_3)_4 N^+ Cl$; △, 0.5 *M* $(C_2H_5)_4 N^+ Cl$.

earlier with the buffers, in that the greatest increase in surface activity was seen with the aryl derivatives and an actual decrease was observed for the short chain species (3, 5). It may also be noted that, as in the case of iodide ion, there is complete loss of curvature for propane- and benzenesulfonate.

Figure 8 compares the same three sulfonates along with sodium-2-naphthalenesulfonate at a concentration of 0.01 plus 0.09 *M* NaCl. Here the marked surface activity due to the presence of the higher molecular weight anions may be noted. One can also observe that curvature is restored to the dilute propanesulfonate system and that there is no effect due to the methanesulfonate ion as compared to 0.1 *M* NaCl. As with the iodide system, oils were produced by the arylsulfonate system in the presence of CPZ but not by the aliphatics, but so far these oils have proved difficult to crystallize. Figure 9 indicates the effect of changing the benzenesulfonate concentration from 0.001 *M* to 0.1 *M* while maintaining an ionic strength of 0.1 with NaCl. Note the progressive reduction in concentration required for surface pressure development, the loss in curvature at higher concentrations of benzenesulfonate, and the fairly parallel slopes for all of the plots. Oil formation occurred at sulfonate concentrations of 0.01 *M* and higher.

DISCUSSION

Factors Enhancing Surface Activity.—In general, it would appear that increases in surface activity in the presence of the various anions are due to some type of interaction with the CPZ cation. These interactions appear to be above and beyond the usual effects of electrolytes seen in Figs. 1 and 2. There, as seen with most ionic surfactants, the effect of increasing electrolyte concentration apparently produces penetration of the counterions between film molecules with a resulting increase in surface pressure (10). Additional electrolyte effects have been related to the hydration energies of the counterions (11) or, as the authors suspect with the anions considered here, to actual ion-pair formation of some type (12). Such interaction should produce a species which is more hydrophobic than the cation or anion alone. It is more than likely that the interactions involve secondary forces in addition to electrostatic forces since the increased hydrophobic nature and polarizability of the counterions appear to promote the effects we are seeing at the interface.

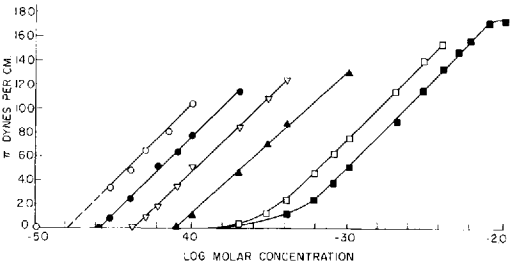

Fig. 9.—Plot of surface pressure, π, *vs.* log molar concentration for chlorpromazine at pH 5.0 and 25° in the presence of various concentrations of benzenesulfonate. Key: ○, 0.1 *M* $C_6H_5SO_3Na$; ●, 0.05 *M* $C_6H_5SO_3Na$; △, 0.025 *M* $C_6H_5SO_3Na$; ▲, 0.01 *M* $C_6H_5SO_3Na$; □, 0.001 *M* $C_6H_5SO_3Na$; ■, 0.1 *M* NaCl.

In all cases where marked increases in surface activity were noted the π *versus* log *C* curves appeared linear over the entire portion of the plot. Reduction of excess counterion concentration, while maintaining ionic strength, eventually restored curvature to the plots (Fig. 9, for instance) so that the degree of curvature seems related to the bulk solution state of the CPZ–anion pair. The linearity of such plots at concentrations just below the CMC has been reported for most common surfactants (13) but not over the entire plot. Such linearity implies a constant surface concentration, as seen when the Gibbs equation is applied, and it has been proposed that this is due to a hydration layer around the polar groups which prevents further increases in surface concentration (13). Elworthy and Mysels (14), however, have recently reported that constant surface concentration below the CMC, although thermodynamically possible, does not seem likely and does not occur as has been thought with sodium lauryl sulfate in water. Linear plots are believed to occur primarily because slight curvature is not easily detected and/or because corrections for activity coefficients and other bulk solution activity

effects are not included. In either case, therefore, in this region the linearity probably indicates that the change in surface concentration, if there is any, is very small and that the degree of surface coverage is very high. Fairly high surface coverage might be expected for the CPZ–anion systems since the anions probably produce fairly hydrophobic ion-pairs of rather large size; but, in order to prove this, radiotracer techniques (15) will be needed to directly measure surface concentration.

On the basis of the authors' experience with these systems, it is apparent that any situation producing a more hydrophobic form of chlorpromazine eventually produces an oil which appears to be more soluble than the crystalline form, at least in those cases where crystals have been isolated. This was seen also with the pure base as well as with the phthalate buffer in our earlier study (3). In addition, the solutions preceding the appearance of oil are quite surface active and yield the linear plots. In a sense, therefore, the solutions exhibiting linearity are in a supersaturated state which explains the apparent marked increase in thermodynamic activity. However, the exact state or degree of aggregation of the CPZ systems in this region remains unclear and is presently under study.

Factors Inhibiting Surface Activity.—The inhibition of surface activity by the quaternary ammonium salts and sodium methanesulfonate has raised many questions requiring more study. However, some clues related to the original observation of inhibition by the acetate buffer have been uncovered. If one only considers the effects of various quaternary ammonium ions, two major reasons for inhibition appear possible. Since they are cationic, as is CPZ, one might expect some competition at the air–solution interface. This could be a factor for the 0.1 *M* solutions of tetrapropyl and tetrabutyl derivatives since, in the absence of drug, they exhibited significant surface activity. However, the tetramethyl and tetraethyl derivatives are hardly surface active even at 0.5 *M* concentrations. Steigman *et al.* (16) have measured the effects of these quaternary ammonium ions on the CMC of hexadecyltrimethylammonium bromide with results similar to those reported here. Although some contribution was attributed to the surface activity of the short-chain compounds, the effects noted with the tetramethyl and tetraethyl derivatives caused them to consider an additional factor. This factor is the entropy change associated with the disorganization of water when molecules go to a surface or to a micelle. The authors feel that the presence of other alkyl groups tends to organize water structure in such a way as to reduce the tendency for nonpolar groups to leave an aqueous environment. Since alkyl anions such as methanesulfonate and acetate inhibit surface activity and yet cannot compete with CPZ, this mechanism seems quite plausible in the present case. Apparently beyond an anion molecular size involving one or two carbons the interaction of the anion with CPZ offsets this tendency to cause inhibition. A stronger insight into this picture is seen with some preliminary data which indicate that urea, methyl urea, and 1,3-dimethyl urea, in increasing order, inhibit surface activity and CMC (5). The influence of urea and its derivatives on CMC and protein denaturation has been discussed (17); and, although a number of theories are proposed, they all evolve around alteration of water structure.

SUMMARY AND CONCLUSION

The surface activity of chlorpromazine at pH 5.0 at the air–solution interface was studied in the presence of a variety of inorganic and organic ions.

In addition to expected increases in surface activity due to increases in ionic strength, marked effects, apparently due to some type of interaction, were noted with bromide, iodide, propanesulfonate, benzenesulfonate, and naphthalenesulfonate ions. These results appear related to buffer effects observed previously.

Significant decreases in surface activity were observed in the presence of short chain quaternary ammonium ions and methanesulfonate ion. This strongly suggests the marked dependence of CPZ surface activity on the structure of water and the ability of environmental factors to influence the thermodynamic activity of this drug without necessarily interacting with it. This and other possible mechanisms will be the subject of future work.

Mono-*O*-isopropylidine Derivatives of Digitoxin, Digoxin, and Ouabain

By OLE GISVOLD

The mono-*O*-isopropylidene derivatives of digitoxin, digoxin, and ouabain have been prepared. In the case of digoxin, this derivative was more lipid soluble than the parent compound and more water soluble than digitoxin or acetyldigitoxin. All derivatives were less active than the parent glycosides when they were assayed intravenously in cats. Mono-*O*-isopropylidene digoxin was 50 per cent absorbed when administered orally.

IT IS WELL KNOWN that digitoxin taken orally is completely absorbed (1), whereas this is not the case with digoxin. Gitoxin and ouabain are very poorly absorbed if at all. Acetyldigoxin is better absorbed than is digoxin when orally administered to cats (2). Evidence in the literature to date strongly supports the concept that the lipophilic properties of the cardiac glycosides (3) are an important factor in the degree to which they are absorbed orally.

Although digitoxin is well absorbed orally, its prolonged duration of action and cumulative properties sometimes are not desirable. Digoxin's duration of action and cumulative properties are more favorable; however, its oral absorption is less dependable as measured by its oral dose *versus* its LD_{50} in intravenous assays in cats. MLD is 230 ± 10 mcg./Kg. for digoxin in cat assays and an average oral dose for humans is 0.5 mg. *versus* MLD 330 ± 8 mcg./Kg. for digitoxin in cat assays and an average oral dose for humans is 0.1 mg. Therefore, it seemed of interest to explore the possibilities of preparing a derivative of digoxin whose lipophilic properties would be enhanced with the retention of effective hydrophilic properties. Dioxolanes and dioxanes enhance the lipophilic properties of the parent compound together with the retention of some hydrophilic properties *via* hydrogen bonding to the two ether oxygens.

DISCUSSION

The cardiac glycosides digoxin and digitoxin have two free adjacent *cis* hydroxyl groups on the terminal digitoxose residue that should yield monodioxolanes upon proper treatment. The isopropylidene derivatives are the most readily prepared dioxolanes under mild conditions that should preclude any undesirable changes in the structures essential for cardiac activity. The sugar residue of ouabain also should lend itself to the preparation of a mono-*O*-isopropylidene derivative. The method that yielded the best results utilized anhydrous copper sulfate, anhydrous acetone, room temperature, and continuous shaking. The course of the reaction was followed by paper chromatography. In the case of digoxin, the mono-*O*-isopropylidene derivative was mobile on formamide-impregnated paper, whereas digoxin remained at the starting line when formamide-saturated benzene was used as the mobile phase (Fig. 1). The use of this simple system led to erroneous results because no amount of time and anhydrous copper sulfate would eliminate some material at the starting line. The use of solvent system II (4) demonstrated that after the most effective reaction conditions, the substance at the starting line (with benzene as the mobile phase) moved faster than digoxin (Fig. 2). This product was very minor in amount and as yet has not been characterized. All attempts at fractional crystallization failed to yield a homogeneous mono-*O*-isopropylidene product even though in the case of digoxin and digitoxin this derivative was quite soluble in anhydrous ether. Separation of the minor by-product was effected by the use of a formamide-impregnated microcrystalline cellulose[1] column and benzene saturated with formamide as the eluant or by Whatman No. 31 paper and preparative paper chromatography methods.

All the mono-*O*-isopropylidene derivatives showed greater lipid solubility properties when compared to the parent glycosides as measured by their pronounced solubility in ether and their movement on formamide-impregnated paper with solvent system II (Figs. 2 and 3). This increase in lipid solubility was greatest with digoxin and was about midway between digitoxin and acetyldigitoxin. When examined by a reverse phase paper chromatographic system (5), digoxin showed greater water solubility than mono-*O*-isopropylidene digitoxin or acetyldigitoxin (Fig. 4). Mono-*O*-isopropylidene ouabain still exhibited the greatest water solubility (Fig. 5). All these derivatives gave a positive Raymond reaction which suggests that the α,β-unsaturated lactone ring was still intact. These changes in water and liposolubilities would suggest that mono-*O*-isopropylidene digoxin probably has the more favorable lipophilic–hydrophilic balance for good oral absorption.

A preliminary screening for cardiac activity was carried out in pigeons and activity still was present although of a lower order. Intravenous assays

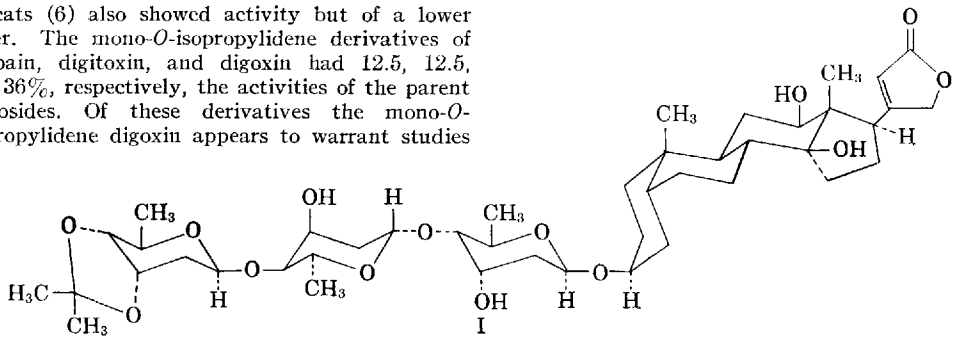
[1] Marketed as Avicel by American Viscose Co., Marcus Hook, Pa.

in cats (6) also showed activity but of a lower order. The mono-*O*-isopropylidene derivatives of ouabain, digitoxin, and digoxin had 12.5, 12.5, and 36%, respectively, the activities of the parent glycosides. Of these derivatives the mono-*O*-isopropylidene digoxin appears to warrant studies



3‴,4‴-*O*-Isopropylidene Digoxin

on its oral absorption because of its physical properties. Although it has 36% of the activity of digoxin, its degree and reliability of absorption might more than offset the reduction in activity. Its toxicity and duration of action also would have to be considered. These might be modified in view of the fact that some cyclic ketals are stable *in vivo* and also might be true of this compound. Thus, the rate of hydrolysis *in vivo* of the sugar residues and other *in vivo* transformations might be altered to provide favorable or unfavorable biological effects.

EXPERIMENTAL

The details of some of the paper chromatographic techniques used in these studies have been described previously (4). Solvent system II was used to very good advantage for the development of some of the paper chromatograms. The original glycosides as well as the reaction products separated effectively by this mobile system. Benzene saturated with formamide provided a simple and rapid mobile system to detect the extent of isopropylidene formation on Whatman No. 1 paper treated with 30% formamide in acetone. It also was used as a very fast moving system for preparative paper and powdered cellulose column studies. A descending reverse system described by Tschesche *et al.* (5) was used to compare the relative hydrophobic properties of the parent glycosides and their

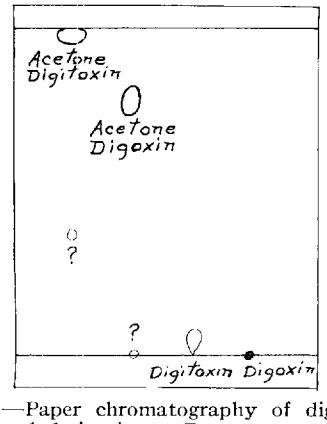


Fig. 1.—Paper chromatography of digoxin, digitoxin, and derivatives. Benzene as mobile phase.

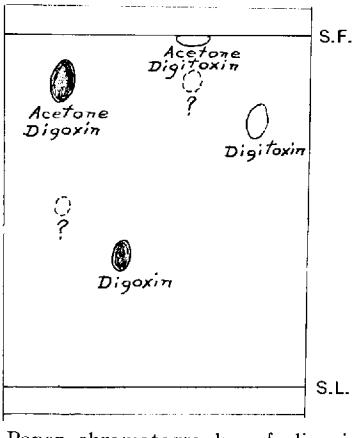

Fig. 2.—Paper chromatography of digoxin, digitoxin, and derivatives. System II as mobile phase.

isopropylidene derivatives. The Raymond reagent was used to detect the glycosides and their reaction products on paper.

Preparation of Isopropylidene Derivatives.—Reagent grade acetone was dried overnight with anhydrous calcium sulfate. It then was carefully decanted or filtered into a flask that was dried in the oven at 110°. (*Caution:* no powdered calcium sulfate should be in the distilling flask.) The acetone was distilled into a 250-ml. conical flask equipped with a drying tube. A forerun of 20% was discarded and subsequently 200 ml. of acetone was collected. The dry glycoside, 100 mg. of digoxin or ouabain or 400 mg. of digitoxin, was added to the flask and the flask carefully heated and shaken to dissolve as much as possible of the glycoside. After cooling to room temperature, 5 Gm. of anhydrous copper sulfate (Allied Chemical) was added. The flask was stoppered with a close fitting stopper and the mixture shaken continuously. The course of the reaction was followed by examining a sample by paper chromatography using formamide-impregnated paper and solvent system II. A period of 22 to 24 hr. of shaking was necessary to completely eliminate the presence of the parent glycoside, although in all cases a small amount of some other slower moving product also could be detected. This slower moving product gave an initial blue color with the Raymond reagent

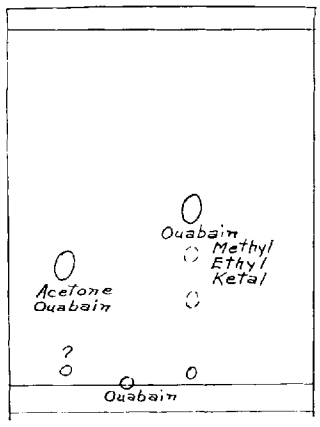

Fig. 3.—Paper chromatography of ouabain and derivatives. System II as mobile phase.

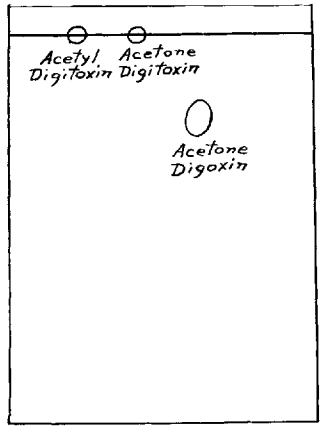

Fig. 4.—Reversed phase paper chromatography of derivatives of digoxin and digitoxin.

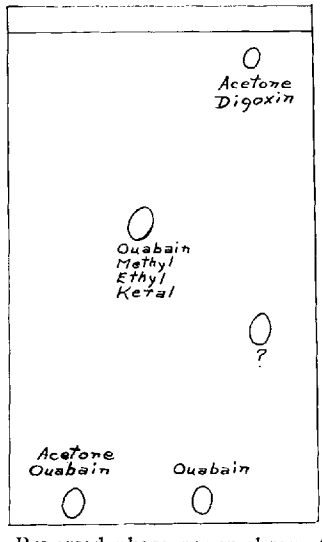

Fig. 5.—Reversed phase paper chromatography of ouabain and derivatives of ouabain and digoxin.

but very shortly turned a yellow green. This was not true with the faster moving isopropylidene derivative that retained its blue color as do the parent glycosides. The reaction mixture then was allowed to stand to permit most of the copper sulfate to settle out, after which time it was filtered through a dense filter paper to remove all the very finely divided suspended copper sulfate. The acetone was removed by distillation with the aid of a water pump and in the absence of air. The amorphous residue readily dissolved in 35 ml. of anhydrous ether in the case of digoxin and digitoxin; somewhat more ether was necessary in the case of ouabain. The ether was concentrated until turbidity appeared. The flask was stoppered, and upon standing a crystalline product was obtained. Upon further concentration, and in the case of digitoxin and digoxin the addition of a judicious amount of isopropyl ether, additional amounts of the crystalline product were obtained. In the case of ouabain the first and second crops of crystals exhibited homogeneity as manifested by their behavior on paper chromatograms using solvent system II and formamide-impregnated paper. Mono-*O*-isopropylidene ouabain melted at 174°.

Anal.—Calcd. for mono-*O*-isopropylidene ouabain, $C_{32}H_{48}O_{12}$: C, 61.54; H, 7.70. Found: C, 61.64; H, 7.42.

In the case of digitoxin and digoxin all attempts to fractionally crystallize their isopropylidene derivatives yielded products that still showed the presence of a small amount of a second product.

An attempt was made to improve upon the above described general method by adding drying agents anhydrous calcium sulfate or a molecular sieve[2] type 3A, to the reaction mixture. In the first case no advantage was gained in the yield of the acetonide. Furthermore, diacetone alcohol was obtained upon removal of the acetone. This substance moved with the solvent front on a paper chromatogram and gave a violet color. A combination of anhydrous calcium sulfate and a small crystal of *p*-toluenesulfonic acid was not satisfactory. In the case of the use of a molecular sieve, quite unsatisfactory results were obtained.

Prolonged shaking beyond 24 hr. did not lead to complete conversion of the glycosides to the acetonides. As the time of shaking was increased, the isopropylidene derivative slowly was converted to a secondary product. This was demonstrated by paper chromatography when the single spot of the original product appeared as two adjacent spots. About equal intensity of these two spots (Raymond reaction) was obtained after 120 hr. of shaking. No further investigations have been completed in this area at the time of this writing.

The general procedure used for the preparation of the isopropylidene derivatives was used with methyl ethyl ketone with analogous results. The derivatives were more lipid soluble and less water soluble than the acetonides. At the present time these derivatives have not been prepared in a homogeneous state. These studies have been suspended until more data have been obtained on the biological activities of the acetonides.

Purification of Mono-O-isopropylidene Digitoxin.—Microcrystalline cellulose,[1] 15 Gm., was

[2] Linde Molecular Sieves, Union Carbide Corp., Linde Division, New York, N. Y.

mixed with 25 ml. of 30% formamide and carefully dried on a large watch crystal with constant stirring. The microcrystalline cellulose then was intimately mixed with an equal volume of finely powdered quartz. A column 8 × 2.2 cm. was packed in a tube 10 × 2.2 cm. Mono-*O*-isopropylidene digitoxin, 100 mg., was powdered and intimately mixed with a small amount of the cellulose–quartz mixture and placed at the top of the above column. The column then was developed with benzene saturated with formamide. One-milliliter fractions were collected and those from 1 to 8 contained only mono-*O*-isopropylidene digitoxin (detected by paper chromatography). Fraction 16 contained only digitoxin and some of the intermediate fractions contained mixtures. This experiment was repeated three more times, and the rate of flow of the benzene held to 15 drops/min. Similar results were obtained as with the first trial. The mono-*O*-isopropylidene digitoxin fractions from all the runs were dissolved in a small amount of methylene chloride, isopropyl ether was added, and the methylene chloride was removed by distillation. The mono-*O*-isopropylidene digitoxin readily crystallized and appeared to be homogeneous by paper chromatographic analysis. It melted at 213–215°.

Anal.—Calcd. for mono-*O*-isopropylidene digitoxin, $C_{44}H_{68}O_{13}$: C, 65.60; H, 8.44. Found: C, 66.11; H, 8.95.

Purification of Mono-O-isopropylidene Digoxin.—When the same column technique as applied to mono-*O*-isopropylidene digitoxin was applied in an attempt to purify this derivative, very unsatisfactory results were obtained. This was not expected because of the similar results that were obtained on paper under the same conditions where only the desired derivative moved on paper impregnated with formamide and benzene saturated with formamide as the mobile phase. As an expediency measure, purification *via* Whatman No. 31 paper was carried out using the descending technique. The crude acetone digoxin product was heavily spotted all along the starting line which was 10 cm. from the end of the paper. This fast running paper provided complete elution of the mono-*O*-isopropylidene digoxin within 1 hr. with the retention of the unwanted products at the starting line. Two and even three starting lines, 2 cm. apart, equally impregnated with the same amounts of crude acetonated digoxin on the same length of paper gave results equally as good, with the retention of the unwanted products at each of the starting lines. Concentration of the benzene eluates left an amorphous residue that was stirred with water several times to remove the small amount of formamide that was present. This resulted in a solid product that gave a single spot on a paper chromatogram. Crystallization of this product was most difficult. A crystalline product readily can be obtained directly from the acetonation reaction; however, it will contain a small amount of the secondary reaction product. It melted at 155°.

Anal.—Calcd. for mono-*O*-isopropylidene digoxin, $C_{44}H_{68}O_{14}$: C, 64.31; H, 8.28. Found: C, 63.70; H, 8.14.

Establishment of Ketal Structure.—The periodate-benzidine test (7) on paper can be used very effectively to detect the presence of a *cis* glycol structure. The substance is spotted on paper and then sprayed with a saturated aqueous solution of potassium metaperiodate. After a suitable time it then is sprayed with a benzidine reagent (10 vol. of 0.1 *M* benzidine in 50% aqueous ethanol is mixed with 2 vol. of acetone and 1 vol. of 0.2 *N* HCl). The presence of a *cis* glycol structure is indicated by a colorless area surrounded by a blue background. Four milligrams each of digoxin, mono-*O*-isopropylidene digoxin, digitoxin, mono-*O*-isopropylidene digitoxin, ouabain, and mono-*O*-isopropylidene ouabain were dissolved in 1 ml. each of methanol. Equal quantities of each of these solutions were spotted on Whatman No. 1 paper and sprayed with the periodate solution. In the case of digoxin and digitoxin and their mono-*O*-isopropylidene derivatives a 5-min. waiting period was necessary. The parent glycosides all gave a positive test for the presence of a glycol structure, whereas the mono-*O*-isopropylidene derivatives gave a negative test.

It should be pointed out here that much of the benzidine in this reagent will crystallize out upon standing a few hours. If the mixture is warmed the benzidine will redissolve, and this reagent can be used directly with satisfactory results.

Bioassay of the Glycoside Acetonides.—These derivatives were assayed by Chen (6), who obtained the following mean $LD_{50} \pm$ S. E. mg./Kg. values. Ouabain acetonide, 0.8837 ± 0.0714 (10 cats); digitoxin acetonide, 2.520 ± 0.2147 (6 cats); and digoxin acetonide, 0.6392 ± 0.0356 (10 cats).

Subsequent to the review of this manuscript, oral studies (6) in cats indicated that mono-*O*-isopropylidene digoxin had 50% absorption from the jejunum which is the same as digoxin.

Role of Ascorbic Acid Oxidase in the Hyoscyamine–Scopolamine Ratio in *Datura innoxia*

By HELEN LOUISE ROWLAND and MELVIN R. GIBSON

Isolated root cultures of *Datura innoxia* Miller to which benzoin anti-oxime (Cupron) was added showed a change in the habit of growth but no change in the weight of the roots nor in the hyoscyamine and scopolamine content, indicating that ascorbic acid oxidase activity was not involved in alkaloid biosynthesis. An improved method for the germination of *D. innoxia* seeds was developed.

ASCORBIC ACID OXIDASE, which is widespread in higher plants (1–3), has been implicated as a terminal oxidase in cellular respiration (4–7). Ascorbic acid itself is required for the rapid synthesis of large amounts of collagen and may be involved in the conversion of proline to hydroxyproline (8, 9). There is some question as to whether proline is hydroxylated before or after incorporation into collagen (9–11). The use of ^{18}O has shown that the hydroxyl oxygen of hydroxyproline is incorporated directly from the atmosphere (12, 13); ascorbic acid may act directly by generating free hydroxyl radicals (8); a direct effect of ascorbic acid on the collagen-synthesizing fibroblasts has also been suggested (14).

Proline is also involved in the biosynthesis of alkaloids in *Datura* species (15). Proline-^{14}C was incorporated into both hyoscyamine and scopolamine and other alkaloidal constituents of both *D. innoxia* Miller and *D. stramonium* L. variety *tatula* Torrey. However, hydroxyproline is apparently not a direct precursor of scopolamine or of the other alkaloids of *D. innoxia* (16). Scopolamine is apparently synthesized from hyoscyamine (17).

The present study was made to determine the possible relationship between ascorbic acid oxidase and tropane alkaloid biosynthesis in *D. innoxia*, since both the enzyme and the alkaloids appear to be related to proline–hydroxyproline metabolism. Ascorbic acid oxidase was inhibited by benzoin anti-oxime (C_6H_5-$CHOHC{:}NOHC_6H_5$)[1] since under physiological conditions it chelates only cupric ion (18).

EXPERIMENTAL

Growth and Processing of Root Cultures.—The methods used in this investigation for the growth and processing of root cultures were modified from those developed in this laboratory by French and Gibson (19) and Sullivan and Gibson (15).

Previous work in this laboratory was hindered by the low germination rate of *D. innoxia* as well as other species of *Datura*. When the seeds were incubated on damp filter paper, only 1 to 2% sprouted. Other workers have used various treatments to hasten the germination of *D. innoxia* (20, 21). Trials at the beginning of this investigation showed that when the seeds were presoaked in sterile White's nutrient solution (22), the germination rate increased to over 30%; also, the rate of injury to the radicles was less than when mechanical methods were used to weaken the seed coat. White's nutrient solution as used throughout this work was sterilized in an autoclave.

Seeds of *D. innoxia* were sterilized by shaking for 15 min. with 3% hydrogen peroxide. Then the seeds were placed on sterile filter papers in Petri dishes. The seeds were covered with 20 ml. of White's nutrient solution and placed in an incubator at 26–27°. After 3 days, the seeds were removed from the incubator; aseptically transferred one seed at a time, using forceps, to new sterile Petri dishes; and moistened with 5 ml. of sterile, demineralized, distilled water. The seeds usually started to germinate after the fourth day. The radicles were severed from the seed when they were 1 to 1.5 cm. long and placed in 50 ml. of nutrient solution. At the end of the first week the roots were transferred to fresh nutrient solution. After 2 weeks the roots were removed from the nutrient solution and dried at 55° to a constant weight.

Control roots were cultured in White's nutrient solution; the test roots were cultured in White's nutrient solution containing 10^{-3} *M* of benzoin anti-oxime.

Extraction and Separation of Alkaloids.—The procedure used for the extraction of the alkaloids from the dried root cultures was based on earlier work by French and Gibson (19), except that the root extract was allowed to drip directly onto a thin-layer chromatography plate rather than chromatographic paper strips.

Preliminary tests showed that it was necessary to combine roots in groups of four to seven, weighing about 25 mg., in order to obtain a concentration of hyoscyamine and scopolamine that could be measured spectrophotometrically. However, in computing the alkaloid contents, the weight of the crushed root samples was converted to a base of exactly 25 mg. These roots were weighed and then crushed together with a mortar and pestle. The crushed root powder was placed on top of a

cotton pledget in an extractor cut from the lower end of a 50-ml. needle-valve buret, the extractor having a capacity of about 10 ml. The root powder was moistened with a 1:1 mixture of 10% ammonium hydroxide and 95% ethanol and allowed to stand for 1 hr. Then 2 ml. of chloroform was added to the extractor and 1 ml. of chloroform for each milligram of root powder was added to the reservoir above the extractor. The extract was allowed to drip directly onto a thin-layer chromatography plate, adjusting the stopcock of the extractor so that each drop dried completely before the next drop fell onto the plate. A jet of cool air was directed at the spot to facilitate drying.

The procedure used for the separation of alkaloids was developed by Sullivan and Gibson (15). The alkaloids of the root extract were separated on a 0.5-mm. thick matrix of Silica Gel G.[2] The root extract was placed 1.5 cm. from the bottom of the 8 by 8 in. plate and 3.0 cm. from the left edge of the plate. The chromatogram was developed in two directions, 15 cm. in each direction, using 10 ml. of diethylamine and 90 ml. of chloroform as the developing solvent for the first phase, and 15 ml. of diethylamine and 85 ml. of chloroform for the second phase. Both phases were developed in an incubator at 30°. Between phases and after the second phase the plates were dried at 55° for 15 min. in a Freas circulating dry air oven and then allowed to cool for 30 min. Preliminary chromatograms indicated the location on the plates of hyoscyamine and scopolamine. After cooling, the probable areas of location of hyoscyamine and scopolamine were covered for protection; then the rest of the plate was sprayed with iodoplatinic acid solution (23) to verify the position of the alkaloids. The hyoscamine and scopolamine spots were removed from the plate with a razor blade and a camel's hair brush.

The alkaloids were extracted from the Silica Gel G in an apparatus developed by Gibson in this laboratory (unpublished work). The extraction was set up in the following manner. Two circles of Whatman No. 2 filter paper, 6 mm. in diameter, were inserted into the bottom of the barrel of a 1-ml. hypodermic syringe. The alkaloid-containing silica gel was put on top of the filter paper. A small pledget of cotton was put on top of the silica gel, and the column was tamped down. A 2.5 in. long 19-gauge needle was attached to the syringe and the entire apparatus was inserted through the hole of a rubber stopper plugging

[2] The Silica Gel G is a product of E. Merck AG., Darmstadt, Germany, and is distributed by Brinkmann Instruments, Inc., Great Neck, L. I., N. Y.

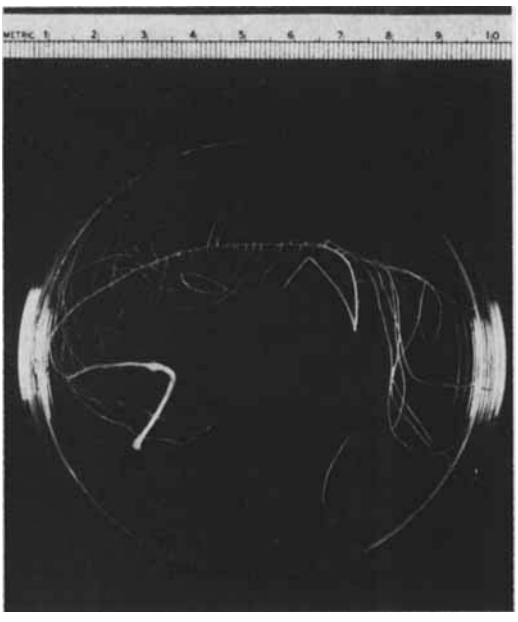

Fig. 1.—*D. innoxia* control root grown in White's nutrient solution.

the top of a small bell jar. One milliliter of absolute methanol was allowed to be in contact with the silica gel column for 30 min. Then 9 ml. of methanol was added to a reservoir above the extractor consisting of a 10-ml. hypodermic syringe attached to a 19-gauge needle inserted through a cork in the top of the 1-ml. syringe. By creating a vacuum in the bell jar, the extract was drawn into a 3-in. evaporating dish. The extract was evaporated to dryness over a water bath adjusted to approximately 65°.

Assay of Alkaloids.—The alkaloids hyoscyamine and scopolamine were quantitatively assayed spectrophotometrically using the Vitali-Morin reaction in a technique developed by French (24). Two-tenths of 1 ml. of fuming nitric acid was added to the dried methanol extract of silica gel containing hyoscyamine or scopolamine. The acid was then evaporated to dryness for 3 min. on a boiling water bath. The residue was redissolved in 4 ml. of acetone and made up to 25 ml. with successive 3-ml. washings of acetone. To determine the amount of alkaloid in each sample, 0.1 ml. of 3% w/v potassium hydroxide in absolute methanol was added to each 25-ml. flask of acetone solution of alkaloid. Each sample was measured against a blank prepared from 25 ml. of acetone and 0.1 ml. of 3% potassium hydroxide in methanol. The transmittance at 560 mμ with a 1-cm. light path was measured in a Beckman DU spectrophotometer, 3 min. after the addition of 3% potassium hydroxide in methanol for scopolamine, 7 min. for hyoscyamine.

RESULTS

The dry weights of both the control roots and the benzoin anti-oxime treated roots are summarized in Tables I and II. The confidence intervals indicate that there is no significant difference at the 5% level in dry weight between the control roots and the benzoin anti-oxime treated roots. However, benzoin anti-oxime does change the habit of growth of roots, as shown in Figs. 1 and 2.

To determine alkaloid content standard curves were prepared by plotting on semilog paper the transmittance values against known concentrations of pure hyoscyamine and scopolamine dissolved in 50% ethanol. The straight line curves then obtained showed adherence to Beer's law. The k values for hyoscyamine and scopolamine were computed from the standard curves and the Bouger-Beer relationship (25). The concentrations of alkaloid in milligrams were computed from these k values. The results of the alkaloidal assays of the control roots and benzoin anti-oxime treated roots are summarized in Tables III and IV. The overlapping confidence intervals indicate that there is no significant difference at the 5% level in alkaloid content between the control roots and the benzoin anti-oxime-treated roots.

DISCUSSION

The results obtained in this investigation seem to indicate that ascorbic acid oxidase is not related to hyoscyamine and scopolamine biosynthesis, nor is any other copper-containing enzyme.

At least five enzymes could serve as terminal oxidases in plants: polyphenol oxidase, lactase, ascorbic acid oxidase, cytochrome oxidase, and peroxidase (4). The first three, being copper-containing enzymes, are apparently eliminated from participation in alkaloid biosynthesis by the results of this study. The last two are iron-containing enzymes, which still may be considered, since they were not inactivated in this study. However,

copper has also been suggested to be involved in cytochrome oxidase activity (26–28), but this has been disputed (29).

The effect on the habit of growth appears to be due to a growth inhibiting effect on the secondary roots compensated for, however, in total weight by greater primary root elongation. Another chelating agent, EDTA, has been shown to suppress the elongation of wheat roots by suppressing cell multiplication (30).

SUMMARY

The benzoin anti-oxime, at a concentration of 10^{-8} *M*, changes the habit of growth of isolated 2-week-old root cultures of *D. innoxia* but has no significant effect on the dry weight of the roots. At this concentration, the benzoin anti-oxime also has no significant effect on the amount of the hyoscyamine or scopolamine found in the roots, and these results indicate the lack of ascorbic acid oxidase involvement in the oxidation of hyoscyamine to scopolamine under the conditions of this study.

It was also concluded that the low germination rate of *D. innoxia* could be improved by presoaking the seeds in White's nutrient solution. The use of nutritive solutions to stimulate the germination of species of *Datura* is suggested.

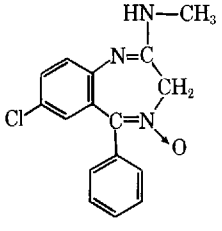
Metabolic *N*-Demethylation of Chlordiazepoxide

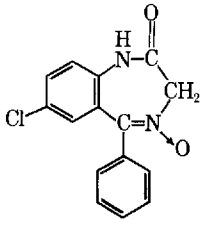
By MORTON A. SCHWARTZ and EDWARD POSTMA

Chlordiazepoxide was *N*-demethylated to 7-chloro-2-amino-5-phenyl-3H-1,4-benzodiazepin-4-oxide (metabolite D-M) when incubated aerobically with either rat or dog liver preparations. Pretreatment of rats with phenobarbital resulted in an approximately threefold increase in the chlordiazepoxide metabolized to metabolite D-M after 2 hr. incubation with the liver microsome fraction. A fluorometric assay for metabolite D-M was developed which when used in conjunction with the Koechlin and D'Arconte fluorometric assay for chlordiazepoxide allowed for a specific determination of each compound in blood. The application of this assay to the study of chlordiazepoxide metabolism in man is illustrated.

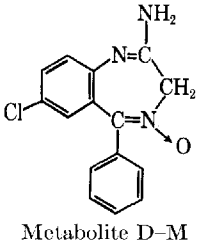
CHLORDIAZEPOXIDE,[1] 7-chloro-2-methylamino-5-phenyl-3H-1,4-benzodiazepin-4-oxide, is metabolized in the dog and man to 7-chloro-1,3-dihydro - 5 - phenyl - 2H - 1,4 - benzodiazepin-2-one-4-oxide ("lactam") (1) which is then metabolized to "opened lactam" metabolites (2). These metabolites have not as yet been detected in the rat which metabolized chlordiazepoxide to unidentified products (2). The present work, which was initiated to obtain information on the site and mechanism of the metabolic conversion of chlordiazepoxide to "lactam," has resulted in the discovery of a new chlordiazepoxide metabolite, 7-chloro-2-amino-5-phenyl-3H-1,4-benzodiazepin-4-oxide (metabolite D-M), which is common to man, dog, and rat. The structures are given below.



Chlordiazepoxide



"Lactam"



Metabolite D-M

METHODS AND MATERIALS

In Vitro Studies.—Chlordiazepoxide hydrochloride (100 mcg. in 0.1 ml. of water) was incubated for 2 hr. at 37° with liver slices (450–490 mg.) or liver homogenate (0.3 ml. of a 1:4 homogenate in 1.15% KCl) prepared from 200–300 Gm. male rats. Also used as enzyme sources were 9000 × g supernatants (0.3 ml.) prepared as described by Fouts and Brodie (3) from 1:3 liver homogenates in 1.15% KCl. Liver supernatants prepared from four control rats were pooled as were those prepared from four rats given i.p. injections of 37.5 mg./Kg. of phenobarbital twice a day for 4 days to stimulate the drug-metabolizing enzymes of the liver microsomes. In addition, a liver supernatant from a dog who had been pretreated with phenobarbital (2 daily oral 20 mg./Kg. doses followed by 10 daily oral doses of 10 mg./Kg.) and which had been stored at −20° for 3 months was used. Besides substrate and enzyme source, the incubation mixture contained the cofactors described by Conney *et al.* (4): 0.2 ml. of 0.01 *M* ATP, 0.1 ml. of 0.003 *M* NADP, 0.1 ml. of 0.003 *M* NAD, 0.1 ml. of 0.6 *M* nicotinamide, 0.2 ml. of 0.03 *M* glucose-6-phosphate, 0.1 ml. of 0.1 *M* $MgCl_2$, 0.1 ml. of 2 *M* KCl, 1.0 ml. of 0.1 *M* potassium phosphate buffer, pH 7.4, and sufficient water to bring the total volume to 3.0 ml.

Following the 2-hr. incubation each sample was extracted twice with 6 ml. of ether. The ether extracts were evaporated to dryness, brought to 0.1 ml. with ethanol, and 0.025 ml. of the ethanol solutions were examined by thin-layer chromatography (TLC) using fluorescent silica gel (Camag Kieselgel DF-5) plates and a solvent system of ethyl acetate–ethanol (90:10) (system *1*). In this system the chlordiazepoxide R_f varied from 0.2–0.4 while the R_f values of "lactam" were 0.7–0.8. A second solvent system which proved useful for identifying metabolite D-M was heptane–chloroform–ethanol (1:1:1) (system *2*). Under shortwave U.V. light compounds on the plate appeared as dark areas against a fluorescent background. The plates were then sprayed with 10% sulfuric acid and viewed under long-wave U.V. light to detect compounds which were fluorescent against a dark background.

A quantitative determination of the amount of chlordiazepoxide metabolized to metabolite D-M was obtained by using as substrate chlordiazepoxide-2-^{14}C (specific activity of 1690 dpm/mcg.) which was purified by sublimation as previously described (2). The ^{14}C which was extracted from the incubation media by ether and which migrated on TLC as chlordiazepoxide and metabolite D-M was determined by the liquid scintillation techniques with the POPOP–PPO fluors previously described (5) and a Nuclear-Chicago Mark I liquid scintillation spectrometer equipped with a ^{133}Ba external standard. The instrument was programmed so that the ratio of the external standard counts in channel B/channel A was convertible from a standard curve into counting efficiency which when divided into the

channel C sample counts yielded the sample ^{14}C content in dpm.

Fluorometric Determination of Metabolite D-M, Chlordiazepoxide, and "Lactam." —The development of the fluorometric determination of metabolite D-M is given under *Results*. This assay has been incorporated into a slightly modified Koechlin and D'Arconte (1) assay for chlordiazepoxide and "lactam" so as to yield a fluorometric determination of each compound when all three are present in a single blood sample. All fluorometric determinations were made in a Farrand spectrofluorometer.

Reagents

A 1.0 *M* potassium phosphate buffer, pH 7.0–7.2, and 0.2 *M* potassium phosphate buffer, pH 6.7–6.8; 0.10 *N* H_2SO_4 and 7 *N* H_2SO_4, 5 *N* NaOH and 0.10 *N* NaOH, and 0.15 *M* diethanolamine aqueous solution.

Procedure

A 2-ml. control blood or plasma (blank) and 2 control bloods (or plasmas) containing internal standards are run with each set of unknowns. Five micrograms of chlordiazepoxide in 0.1 ml. of ethanol and 5 mcg. of "lactam" in 0.1 ml. of ethanol are added to one control blood, while 5 mcg. of metabolite D-M in 0.1 ml. of ethanol is added to the other; each control containing internal standard is taken through the entire procedure. Specimens of whole blood (heparinized or oxalated) and plasma (separated immediately after drawing the blood) must be kept frozen if the assay is not performed within 24 hr.

Two milliliters of blood is first diluted with 2.0 ml. of water and 4.0 ml. of 1.0 *M* phosphate buffer, pH 7.0–7.2, and is then extracted with 15 ml. of ether. A 12-ml. aliquot of the ether phase is extracted with 4 ml. of 0.1 *N* NaOH to remove "lactam" but not chlordiazepoxide or metabolite D-M from the ether. Two 5.0-ml. aliquots (to be used for the metabolite D-M and chlordiazepoxide assays) are then removed from the remaining ether phase.

Analysis A for "Lactam."—The 0.1 *N* NaOH extract is washed by extraction with 5 ml. of ether and is then placed 8 10 in. from a Pyro-Lux R-57 lamp (Luxor Lighting Products, Inc., New York, N. Y.) and light-exposed for 1 hr. This photochemical reaction may also be accomplished by exposure to bright sunlight for 1 hr. The fluorescence is then determined at 380 mμ excitation and 460 mμ emission.

Analysis B for Metabolite D-M.—One 5-ml. ether aliquot is extracted with 3.5 ml. of 7 *N* H_2SO_4 and the ether is removed by aspiration. After standing for 1 hr. (no light exposure required) the fluorescence of the acid extract is determined at 370 mμ excitation and 460 mμ emission.

Analysis C for Chlordiazepoxide.—The other 5-ml. ether aliquot is extracted with 1.5 ml of 0.1 *N* H_2SO_4. To the acid extract 0.5 ml. of 0.2 *M* phosphate buffer, pH 6.7–6.8, and 1 ml. of 0.15 *M* diethanolamine solution are added and the mixture is kept in a boiling water bath for 2 hr.[2] After cooling, 0.2 ml. of 5 *N* NaOH is added, and the sample is then exposed to light for 1 hr. and its fluorescence determined exactly as described above for the "lactam" determination.

Calculations

Analysis A ("Lactam").—The fluorescence reading (F) for the "lactam" internal standard (5 mcg.) corrected for the blood blank fluorescence (B) is divided by 5 to yield F-B per microgram of "lactam." This specific fluorescence value divided into the corrected fluorescence (F-B) obtained with each unknown yields microgram "lactam" per 2 ml. of blood and final division by 2 then gives the "lactam" concentration in mcg./ml.

Analysis B (Metabolite D-M).—The metabolite D-M internal standard fluorescence is used to get the specific fluorescence (F-B/mcg.) and the calculations proceed as described above.

Analysis C (Chlordiazepoxide.)—Since both chlordiazepoxide and metabolite D-M yield fluorescence in this part of the method, a correction for metabolite D-M fluorescence must be made before the fluorescence in an unknown due to chlordiazepoxide can be determined. The specific fluorescence for metabolite D-M in analysis *C* is determined. This value multiplied by the micrograms of metabolite D-M found in each unknown in analysis *B* yields the fluorescence in analysis *C* which is due to metabolite D-M. Subtraction from the total analysis *C* fluorescence (F-B of each unknown) yields the F-B value of each unknown which is due only to chlordiazepoxide. The remainder of the calculations are identical to those of the above analyses: the F-B per mcg. of chlordiazepoxide (obtained from the fluorescence of the chlordiazepoxide internal standard) is divided into the F-B of each unknown attributed to chlordiazepoxide to get the chlordiazepoxide content per 2 ml. of blood.

Comments

The sensitivity of this assay is 0.2–0.3 mcg. of each compound per ml. of blood or plasma.

The chlordiazepoxide assay is the least accurate of the three because it involves the subtraction of one fluorescence from another. An error in the determination of metabolite D-M will cause an error in the chlordiazepoxide determination.

RESULTS

In Vitro Metabolism of Chlordiazepoxide.—Aerobic incubation of chlordiazepoxide with rat liver slices, rat liver homogenate, and the 9000 × g supernatant of liver from a dog pretreated with phenobarbital all gave essentially the same results when the ether extracts were chromatographed in system *1*. A metabolite (metabolite D-M), which was not completely separated on the plate from nicotinamide (a constituent of the incubation medium which was also extracted by ether), was seen under shortwave U.V. light. The metabolite migrated 54–58% of the distance chlordiazepoxide migrated in this system. When the plates were sprayed with 10% sulfuric acid and examined under long-wave U.V. light this metabolite was seen more clearly because it fluoresced while nicotinamide did not. The metabolite was not detected in control samples incubated without chlordiazepoxide or in complete samples which were extracted immediately with

[2] This hydrolysis of chlordiazepoxide to "lactam" is a modification of the Koechlin and D'Arconte procedure suggested by M. Roth and J. Rieder, Hoffmann-LaRoche and Co., Basle, Switzerland.

ether without prior incubation. Furthermore, when chlordiazepoxide was incubated anaerobically (in evacuated Thunberg tubes) with rat liver homogenate the metabolite was not found, indicating that it was formed by an oxidative process. In none of these *in vitro* experiments, however, was any conversion of chlordiazepoxide to "lactam" detected.

Metabolite D-M was suspected of being *N*-desmethyl chlordiazepoxide because this compound would be a logical intermediate in the metabolism of chlordiazepoxide to "lactam" (see introduction for formulas). Authentic 7-chloro-2-amino-5-phenyl-3H-1,4-benzodiazepin-4-oxide (*N*-desmethyl chlordiazepoxide) was therefore spotted on TLC plates alongside an aliquot of the ether extract obtained after incubation of chlordiazepoxide with the 9000 × g supernatant of dog liver. *N*-Desmethyl chlordiazepoxide and metabolite D-M in the extract migrated identically in system *1* (R_f 0.25) and also in system *2* (R_f 0.53). The authentic *N*-desmethyl chlordiazepoxide also fluoresced under long-wave U.V. light after the plates were sprayed with 10% sulfuric acid. It was therefore concluded that metabolite D-M was *N*-desmethyl chlordiazepoxide.

The effect of phenobarbital pretreatment of rats on the metabolism of ^{14}C-labeled chlordiazepoxide by the liver microsome fraction (9000 × g supernatant) is shown in Table I. The first two flasks demonstrated the validity of the quantitation technique in that incubation of chlordiazepoxide-2-^{14}C in the absence of enzymes resulted in 95 and 94% of the ^{14}C being extracted by ether and 98% of the extracted ^{14}C being recovered on TLC as intact chlordiazepoxide. When labeled chlordiazepoxide was incubated with pooled liver supernatant from control rats (flasks 3 and 4) 90 and 92% of the ^{14}C was ether-extracted but only 74% of the extracted ^{14}C was recovered as unmetabolized chlordiazepoxide while 20% was found as metabolite D-M. Incubation with the pooled liver supernatant from phenobarbital-treated rats (flasks 5 and 6) resulted in a striking increase in chlordiazepoxide metabolism. Only 78% of the ^{14}C was extracted by ether indicating that significant quantities of polar metabolites were now formed. In addition the ether-soluble ^{14}C was mostly present in metabolite D-M (77 and 66%) while 22 and 23% was present as chlordiazepoxide and a significant amount of ^{14}C (5 and 6%) was now found at the origin. Calculation of the chlordiazepoxide-derived ^{14}C which was actually recovered as metabolite D-M yielded 18% for flask 3 and 56% as an average for flasks 5 and 6; this demonstrates that *N*-demethylation had been stimulated at least threefold (the metabolites not extracted by ether may also be *N*-demethylated) by pretreatment of the rats with phenobarbital. The stimulation of over-all chlordiazepoxide metabolism was similarly estimated to be approximately fourfold.

TABLE I.—EFFECT OF PHENOBARBITAL PRETREATMENT ON *In Vitro* METABOLISM OF CHLORDIAZEPOXIDE-2-^{14}C BY 9000 × g SUPERNATANT OF RAT LIVER[a]

Flask	Source of 9000 × g Supernatant	^{14}C Extracted by Ether After 2 hr. Incubation, %	^{14}C of Ether Extract in[b] Chlordiaz., %	Met. D-M, %	Origin, %
1	None, no enzyme	95	98	1	1
2	None, no enzyme	94			
3	Control rats	90	74	20	1
4	Control rats	92			
5	Phenobarb-treated rats	78	23	77	5
6	Phenobarb-treated rats	78	22	66	6

[a] Labeled chlordiazepoxide (100 mcg.) was incubated with the cofactors described under *Methods and Materials* and each designated enzyme source for 2 hr. at 37°. The 9000 × g supernatants of liver from four phenobarbital-treated rats were pooled as were the supernatants from four control rats. The pooled supernatant was run in duplicate as enzyme source. [b] Distribution of ether-extracted ^{14}C determined by TLC in system *1* and counting of the silica gel segments containing chlordiazepoxide, metabolite D-M, and origin. Chlordiazepoxide and metabolite D-M were spotted as internal standards with each extract.

Detection of Metabolite D-M in Blood.—The possibility that metabolite D-M was present in blood following the administration of chlordiazepoxide was investigated in three species. Blood (2 ml.) drawn from a squirrel monkey 4 hr. after an oral dose of 5 mg./Kg. of chlordiazepoxide was first mixed with equal volumes of water and 0.1 *M* potassium phosphate buffer, pH 7.4, and then extracted twice with 3 vol. of ether; the combined ether extracts were concentrated for TLC. In a similar manner ether extracts for TLC were prepared from rat blood (5 ml.) obtained 3.5 hr. after i.p. doses of 7.5 mg./Kg. and 15 mg./Kg. of chlordiazepoxide and from human blood (5 ml.) obtained from a woman who had taken an overdose of chlordiazepoxide. TLC in system *1* of each of the above concentrated ether extracts followed by inspection of the plates under U.V. light before and after acid treatment revealed the presence of both chlordiazepoxide and metabolite D-M. These findings established the need for an assay for metabolite D-M in blood.

Development of Metabolite D-M Assay.—Further studies revealed that the Koechlin and D'Arconte fluorometric determination of chlordiazepoxide (1) did not discriminate between chlordiazepoxide and metabolite D-M; 5 mcg. of metabolite D-M added to 1 ml. of blood and analyzed by this method resulted in approximately the same fluorescence as that obtained from 5 mcg. of chlordiazepoxide per ml. of blood. This made imperative the development of an assay specific for one or the other of these two compounds. Such an assay was developed for metabolite D-M using as the starting point the observed fluorescence of this compound on thin-layer plates which had been sprayed with 10% sulfuric acid. The compound was found to fluoresce in 10% sulfuric acid solution and an excitation wavelength of 370 mμ and emission wavelength of 460 mμ yielded the highest fluorescence reading. The fluorescence of 5 mcg./ml. of metabolite D-M increased sharply from 66 units after standing in the acid for 15 min. to 111 units after 1 hr. and then rose only to 119 units after 2 hr. It was further found that this was not a photochemical reaction; the same fluorescence was obtained whether metabolite D-M in 10% sulfuric acid was kept for 1 hr. in the dark or in daylight. Investigation of the effect of acid concentration on fluorescence revealed that metabolite D-M developed maximum fluorescence in 7 *N* H_2SO_4. Accordingly, 7 *N* H_2SO_4 was used to obtain data on the relationship of fluo-

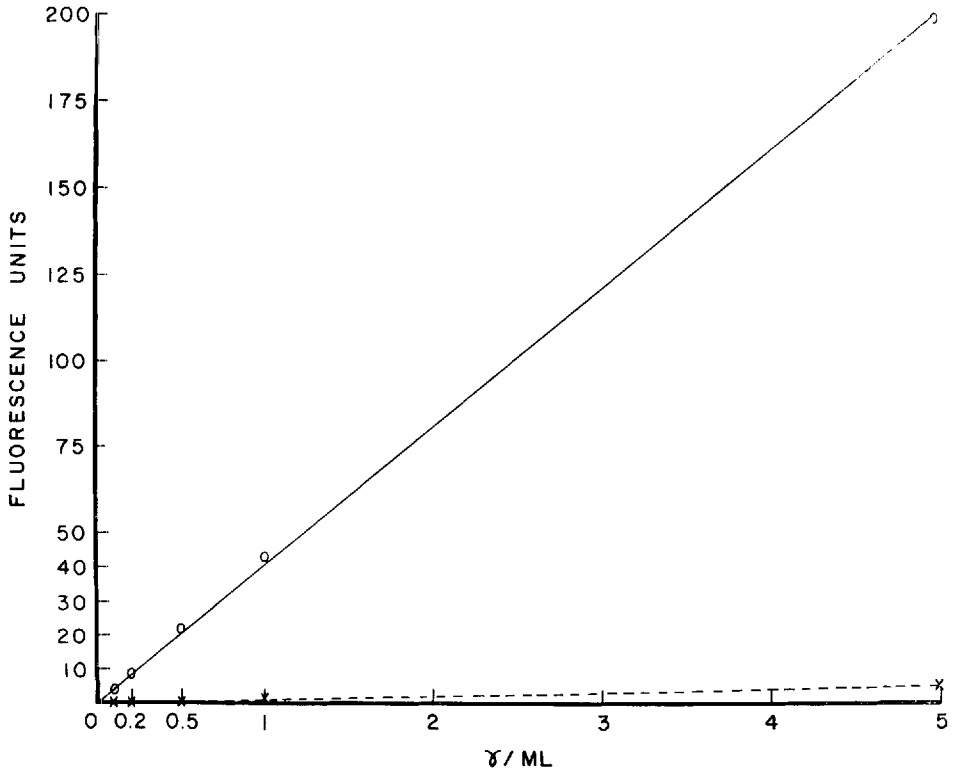

Fig. 1.—Relationship of fluorescence to concentration of metabolite D-M and chlordiazepoxide in 7 *N* sulfuric acid. After standing 1 hr. at room temperature, the solutions were read at 370 mμ excitation and 460 mμ emission. Key: O, metabolite D-M; X, chlordiazepoxide.

TABLE II.—RECOVERY OF CHLORDIAZEPOXIDE, "LACTAM," AND METABOLITE D-M IN BLOOD AND PLASMA CONTAINING ALL THREE COMPOUNDS[a]

		Recovery of Each Compd.								
		"Lactam"			Metabolite D-M			Chlordiazepoxide

[a] The method for metabolite D-M was incorporated into the Koechlin and D'Arconte assay to yield the combined method described under *Methods and Materials*.

rescence to metabolite D-M concentrations. As seen from Fig. 1 the fluorescence of metabolite D-M was a linear function of the concentration from 0.5 mcg./ml. The fluorescence obtained from 0.1–1 mcg./ml. of chlordiazepoxide under these conditions was barely measurable while the fluorescence from 5 mcg./ml. of chlordiazepoxide was about the same as that obtained from 0.1 mcg./ml. of metabolite D-M.

This metabolite D-M assay was therefore of sufficient specificity so that it could be used together with the Koechlin and D'Arconte assay to achieve specific determinations of chlordiazepoxide, "lactam," and metabolite D-M. This combined assay (described under *Methods and Materials*) was tested by determining the recoveries of each compound added to the same blood sample. It is seen from Table II that good recovery of each compound from blood and plasma was obtained in a series of recovery experiments in which the ratio of one compound to another in the added mixture was varied.

Applications of the Combined Assay for Chlordiazepoxide, Metabolite D-M, and "Lactam."—The plasma levels of each compound following 100 mg. of chlordiazepoxide hydrochloride given intravenously to each of two subjects are shown in Fig. 2. In both subjects the half-life of plasma chlordiazepoxide was roughly 16 hr. In subject No. 1 metabolite D-M appeared before "lactam," reached higher levels, and fell off faster; in subject No. 2

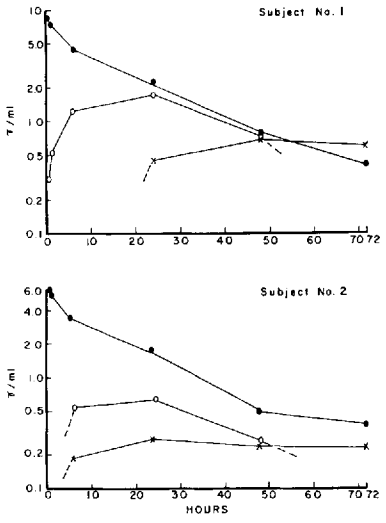

Fig. 2.—The plasma levels of chlordiazepoxide (●), metabolite D-M (O), and "lactam" (×) plotted logarithmically as a function of time. Each of the two subjects received a 100-mg. intravenous dose of chlordiazepoxide hydrochloride. The broken lines denote that the levels have either risen from or descended to levels which were below the sensitivity of the assay.

TABLE III.—PLASMA CHLORDIAZEPOXIDE, METABOLITE D-M, AND "LACTAM" IN A SUBJECT WHO RECEIVED 10 mg. OF CHLORDIAZEPOXIDE HYDROCHLORIDE q.i.d. FOR 14 DAYS

Time,[a] Days	Plasma Levels of— Chlordiazepoxide, mcg./ml.	Metabolite D-M, mcg./ml.	"Lactam," mcg./ml.
2	1.69	0.47	Nil
4	3.13	1.17	0.70
6	1.61	1.27	1.06
10	3.13	1.17	1.41
12	1.90	1.27	1.41
14	3.42	1.17	1.27
22	Nil	Nil	(0.24)[b]

[a] Blood was drawn on each day listed immediately before the first of the 4 doses was administered. Day 22 values represent residual plasma levels after 7 days of no drug.
[b] This value is at the limit of sensitivity of the assay.

both metabolites appeared at 6 hr., but the metabolite D-M levels were more than twice the "lactam" levels and metabolite D-M again fell off faster.

Table III presents the plasma levels of each compound in a subject who received chlordiazepoxide hydrochloride chronically. The levels of the metabolites are of particular interest because it is again seen that metabolite D-M is detectable in the blood before "lactam" and that after drug administration was stopped for 1 week both metabolite D-M and chlordiazepoxide were no longer detectable while a very slight amount of "lactam" appeared to be still present.

The limitation of the combined assay was illustrated when 30 mg. of chlordiazepoxide hydrochloride was administered intravenously to a subject. The chlordiazepoxide blood levels declined from 2.3 mcg./ml. 15 min. after the dose to approximately 0.4 mcg./ml. at 48 hr.; metabolite D-M was not seen until the eighth hour and from 8–48 hr. low levels at the sensitivity threshold of the assay appeared to be present; and "lactam" was not detected in any of the blood samples. In this subject the blood levels of metabolite D-M were too low for accurate measurement, and since the determination of blood chlordiazepoxide is dependent on an accurate assay of metabolite D-M, it was not possible to get an accurate measurement of chlordiazepoxide.

DISCUSSION

The *in vitro* studies demonstrate that rat and dog liver are capable of producing metabolite D-M by oxidative *N*-demethylation of chlordiazepoxide. This metabolite is also formed *in vivo* as evidenced by its detection in the blood of chlordiazepoxide-treated rats, squirrel monkeys, and humans. In previous studies with ^{14}C-chlordiazepoxide (2) most of the radioactivity excreted as neutral or basic urinary metabolites by two humans was identified as "lactam." It is possible that a small but significant amount of metabolite D-M was excreted but escaped detection. In the rat the basic metabolite fraction of the urine contained at least two labeled metabolites which were not identified. Studies on the characterization of chlordiazepoxide metabolites in rat urine have been reinstituted to determine if metabolite D-M is one of these excretion products.

Although the structure of metabolite D-M makes this compound a logical intermediate in the formation of "lactam" from chlordiazepoxide, only indirect evidence for this pathway is presently available. In all human blood level studies to date, including those reported above, the appearance of "lactam" in the blood of chlordiazepoxide-treated subjects has never preceded the appearance of metabolite D-M indicating that this latter compound may be the immediate precursor of "lactam" in man and dog. It must be noted, however, that *in vitro* experiments with dog liver aimed at demonstrating "lactam" formation from either chlordiazepoxide or metabolite D-M have been unsuccessful.

Hydrolytic Behavior of Isoalloxazines Related to Riboflavin II

Kinetics of Degradation of 9-Methylisoalloxazine in Alkaline Media

By DEODATT A. WADKE and DAVID E. GUTTMAN

The kinetics of hydrolysis of 9-methylisoalloxazine under aerobic conditions was investigated at hydroxide-ion concentrations both below and above its pKa. The nature of the pH profile indicated that a specific base-catalyzed reaction was responsible for the degradation and that the unionized species was much more susceptible to hydrolysis than the ionized form. The hydrolysis in pH 9.0 borate buffer and in strongly alkaline medium was investigated rather extensively. Here quantitative separation of the reaction intermediates and products was achieved by the use of ion-exchange chromatography. Rate studies showed that under strongly basic conditions the parent isoalloxazine disappeared faster than the intermediate anil, while the reverse was true at pH 9.0. These studies also showed that the rate of disappearance of the anil paralleled the rate of appearance of its decomposition products. Evidence was obtained to indicate that the degradation of the isoalloxazine involved an initial hydroxide-ion attack at the C_α position to yield a carbinolamine which underwent further reaction to yield the anil or the ureide and then the final products.

A PREVIOUS COMMUNICATION (1) summarized the results of some preliminary studies on the hydrolytic degradation of 9-methylisoalloxazine. These studies showed that at least three different products could be formed from the parent compound and that these were 1,2-dihydro-1-methyl-2-keto-3-quinoxaline carboxylic acid, 1,2,3,4 - tetrahydro - 1 - methyl - 2,3 - dioxoquinoxaline, and 1,2-dihydro-1-methyl-2-oxoquinoxaline. The relative concentrations of the products formed were seen to depend on the pH of the reaction medium. It was further shown that 5-(6-methylaminophenylimino)barbituric acid anil was formed from the parent isoalloxazine and subsequently disappeared from the reaction mixture. Evidence was presented to suggest that the anil existed in equilibrium with 1,2-dihydro-1-methyl-2-oxo-quinoxaline-3-carboxy ureide, and it was postulated that the ureide could further decompose by at least three mechanisms to yield three different products.

In the present investigation the kinetics of various reactions involved in the transformations of the isoalloxazine to products were investigated. Studies were restricted to reactions occurring in solutions which were exposed to air. Anaerobic systems which were shown to exhibit more complex behavior (1) were not investigated. The pH profile for the disappearance of the isoalloxazine in the alkaline range of pH was determined and extensive kinetic studies were conducted on reactions which occurred in strongly basic solution and in pH 9.0 buffer. These quantitative studies showed that in strongly alkaline medium 80% of the parent isoalloxazine was transformed into the keto acid, that the anil was formed and disappeared at the same rate as the formation of the keto acid, and that another transient intermediate, possibly a carbinolamine, was initially formed from the parent isoalloxazine. The data also revealed that the rate of disappearance of the suspected carbinolamine closely paralleled that of the anil and suggested the possibility that the anil and the suspected carbinolamine were in equilibrium in solution. Studies at pH 9.0, where the major product was the dioxo compound, showed that the rate of appearance of this compound paralleled the rate of disappearance of the parent compound and indicated that the rate-determining step in the formation of the dioxo compound was one involving the loss of 430 mμ absorbance of the isoalloxazine.

EXPERIMENTAL

Materials.—9 - Methylisoalloxazine (I), 5 - (6-methylaminophenylamino)barbituric acid anil (III), 1,2-dihydro-1-methyl-2-keto-3-quinoxaline carboxylic acid (V), and 1,2,3,4-tetrahydro-1-methyl-2,3-dioxo-quinoxaline (VI) were obtained as described previously (1, 2).

All other materials used in this study were obtained from commercial sources.

Procedure.—*Kinetic Studies.*—The experimental method used was the same as that described previously (3). The rate of disappearance of 9-methylisoalloxazine was determined by following the decrease in absorbance at 430 mμ. The rates of hy-

Received May 5, 1966, from the Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo 14214.

Accepted for publication August 8, 1966.

This investigation was supported in part by research grant GM 12806 from the National Institutes of Health, U. S. Public Health Service, Bethesda, Md.

Previous paper: Wadke, D. A., and Guttman, D. E., *J. Pharm. Sci.*, **55**, 1088(1966).

drolysis were investigated over the pH range 7.9 to 14.0 and at 35° ± 0.01°. In addition, systems in pH 9.0 borate buffer and in 0.5 *N* sodium hydroxide were also studied at 45° ± 0.01°.

The degradation of the anil (III) was investigated in pH 9.0 borate buffer and in 0.5 *N* sodium hydroxide. This study was conducted at 45°. Samples were withdrawn at various time intervals and complete spectra were determined using a Beckman DB spectrophotometer.

Ion-Exchange Chromatography.—One and one-half grams of a strongly basic, anion-exchange resin,[1] 100–200 mesh, was made into a slurry with distilled water and packed in a 25-ml. buret using a glass wool plug as a support. Prior to use, the column was washed with 100 ml. of 2 *M* sodium chloride followed by distilled water until the washings were free from chloride. Preliminary studies with the synthetic mixtures of the isoalloxazine (I), the anil (III), and the keto acid (V) showed that when such a mixture at about pH 5 was introduced on the column and eluted with water, the eluate (which will be subsequently referred to as the neutral fraction) contained the isoalloxazine. When the solvent was changed to 0.01 *M* acetic acid, the eluate (which will be referred to as the acidic fraction) contained the anil. Finally, elution with 2 *M* sodium chloride effected removal of the keto acid. These studies also showed that the recovery of the three compounds was quantitative within experimental limits.

This technique was utilized to effect quantitative separation of the residual isoalloxazine, the anil, and the keto acid at various stages of degradation of the isoalloxazine. Forty-five-milliliter samples were withdrawn from the reaction mixture at different times and mixed with 1 ml. of glacial acetic acid in the case of pH 9.0 samples and with 2 ml. in the case of high pH (0.5 *N* base) samples in a 50-ml. volumetric flask and the volume was adjusted to the mark with distilled water. The pH of the resulting solution was approximately 5. Forty milliliters of the acidified sample was introduced on the ion-exchange column and elution carried out in three stages to obtain the neutral fraction, the acidic fraction, and the salt fraction. Each fraction was collected in a 100-ml. volumetric flask. After adjusting to volume, the spectrum of each was recorded using a Beckman DB spectrophotometer.

RESULTS

pH Profile for the Hydrolysis of 9-Methylisoalloxazine.—Loss of absorbance at 430 mμ was used to indicate the disappearance of the isoalloxazine from solution. When the logarithm of the absorbance at 430 mμ was plotted as a function of time, a typical pseudo first-order plot resulted. Figure 1 illustrates such a plot for 9-methylisoalloxazine which was hydrolyzed in 0.5 *N* sodium hydroxide. As is seen, some deviation from linearity became apparent beyond approximately three half-lives. Similar behavior was also observed by Song *et al.* (4) in their study on photochemical degradation of flavins. As a result, rate constants were determined from initial straight line portions of the curves. The results of the studies conducted over a range of hydroxide-ion concentrations are summarized in Fig. 2, where logarithm of the observed rate constant was plotted as a function of the logarithm of the hydroxide-ion concentration. This pH profile shows that the reaction was approximately first order with respect to hydroxide ion at pH values below and above the pKa (9.82), but that in the region of the pKa, the order was changing.

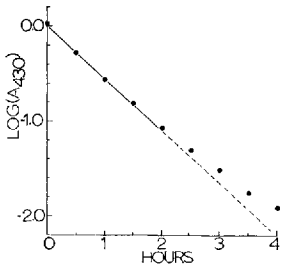

Fig. 1.—A plot illustrating the first-order disappearance of 9-methylisoalloxazine in 0.5 *N* sodium hydroxide and at 45°.

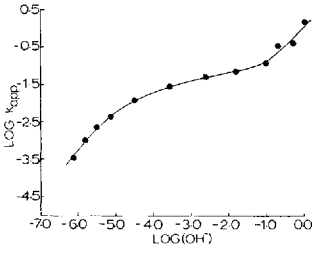

Fig. 2.—The pH profile for the hydrolysis of 9-methylisoalloxazine at 35°.

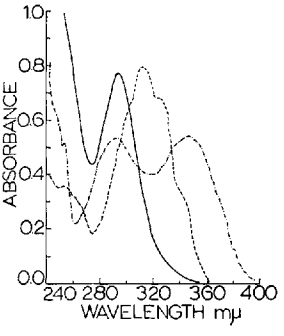

Fig. 3.—Spectra of the anil at a concentration of 1.8 × 10^{-4} *M* (———), the keto acid at a concentration of 8 × 10^{-5} *M* (– · – · –), and the dioxo compound at a concentration of 7.3 × 10^{-5} *M* (– – – –).

Kinetic Studies on the Hydrolysis of the Anil (III).—The kinetics of transformations involving the anil was also followed spectrophotometrically. Figure 3 shows the spectra of the anil (III), the keto acid (V), and the dioxo compound (VI). It is seen that the anil possesses negligible absorbance at 340 mμ, where both the keto acid and the dioxo compound exhibit significant absorbance. The increase in absorbance at this wavelength was thus used to follow the progress of the reactions. Although it was shown in a previous study (1) that the anil probably existed in solution in equilibrium with the ureide (IV), the predominant species, under the pH conditions of this study, was the anil. The concentration of the ureide was apparently so small that it did not contribute to the absorbance at this wavelength. Figure 4 illustrates that, in 0.5 *N* sodium hydroxide solution, the rate of appearance

[1] Marketed as Amberlite CG-400 by the Rohm & Haas Co., Philadelphia, Pa.

of the keto acid exhibited a first-order dependency on anil concentration. The rate constant was calculated to be 0.18 hr.$^{-1}$ at 45°. In a pH 9 system it was found that rate of appearance of the major product here, the dioxo compound, was also first order with respect to anil and that the rate constant for the reaction at 45° was 5.0×10^{-2} hr.$^{-1}$.

Quantitative Ion-Exchange Chromatography.—Figure 5 illustrates the results of kinetic studies which were conducted with 9-methylisoalloxazine in 0.5 *N* sodium hydroxide. It is seen that there occurred in this system a rapid disappearance of the parent isoalloxazine, appearance and disappearance of the anil, and appearance of the keto acid. From these data, rate constants were estimated for the various processes and are tabulated in Table I.

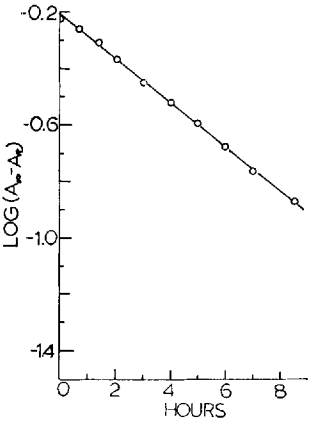

Fig. 4.—A plot illustrating the first-order dependency of keto acid formation on the concentration of the anil compound in 0.5 *N* sodium hydroxide and 45° ± 0.01°. A_∞ represents the maximum absorbance achieved at 340 mμ, while A_t represents the absorbance observed at this wavelength at time *t*.

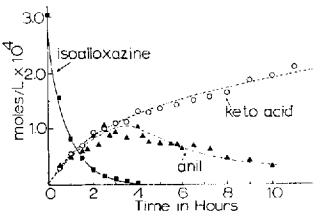

Fig. 5.—A plot of concentration *versus* time for the isoalloxazine, the anil, and the keto acid as observed in the reaction mixture that was degraded in 0.5 *N* sodium hydroxide and at 45°.

TABLE I.—RATE CONSTANTS FOR APPEARANCE AND DISAPPEARANCE OF VARIOUS COMPOUNDS IN 0.5 *N* NaOH AT 45° ± 0.01°

Reaction	Rate Constant, hr.$^{-1}$
Disappearance of isoalloxazine	1.3
Disappearance of the anil in the degrading soln. of isoalloxazine	0.19
Appearance of the keto acid from isoalloxazine	0.17
Disappearance of the suspected carbinolamine	0.22

It is pertinent to note that the rate constant characterizing the appearance of the keto acid is approximately the same as that found for the disappearance of the anil and that these constants are close to that obtained when pure anil was used as the starting material under similar conditions of temperature and hydroxide-ion concentration. The study also showed that approximately 80% of the parent isoalloxazine was eventually transformed to the keto acid. It is also apparent from the figure that the relatively rapid disappearance of 9-methylisoalloxazine from solution was not accompanied by as rapid an appearance of the anil. This was rather surprising in view of the evidence that the anil is an intermediate in the transformation of the parent compound to products. It was also interesting to observe that, in the initial stages of the reaction, the final product, the keto acid, was found in concentrations which were approximately the same as those formed for the anil. This behavior strongly suggested that another reactive intermediate was formed and that it was in equilibrium with the anil. The existence of such a species in the reaction mixture was also indicated by spectral examination of the neutral fractions obtained in the chromatographic procedure. The spectrum of such a fraction is shown in Fig. 6. It appears to be that of a mixture. The spectrum of 9-methylisoalloxazine alone is also shown for comparative purposes. It was assumed, based on the first-order decay of absorbance at 430 mμ, that absorbance at this wavelength was due solely to 9-methylisoalloxazine and its concentration in the fraction was calculated. Absorbance values at other wavelengths, resulting from this concentration, were then determined using appropriate molar absorptivities. When these values were subtracted from those obtained for the fraction, a difference spectrum was generated which is also shown in Fig. 6. The difference spectrum has a maximum at 350 mμ and is apparently due to a transient intermediate. Difference spectra were obtained for a number of fractions representing different reaction times and the logarithm of the absorbance at 350 mμ of the difference spectrum was plotted as a function of time. Figure 7 represents this plot and shows that this unknown intermediate initially formed rather rapidly and as time progressed disappeared from the medium at a rate which was slower than the rate of formation. The rate content for the disappearance was estimated from the later linear portion of the curve to be 0.22 hr.$^{-1}$ and is tabulated with other rate constants in Table I. This value is reasonably close to that obtained for the disappearance of anil and further supports the possibility of the existence of a rapidly achieved equilibrium between the unknown intermediate and the anil. The absolute concentration of the unknown compound at any time cannot be determined. However, if it was in equilibrium with the anil and if the equilibrium was established fairly rapidly then, at any time [unknown] = $K_{eq.}$[anil], where $K_{eq.}$ = equilibrium constant and the brackets represent concentrations. From the knowledge of the absorbance at 350 mμ due to the unknown compound and the concentration of the anil at the same time, one can calculate a term equivalent to the product of the molar absorptivity of the unknown at 350 mμ and the equilibrium constant.

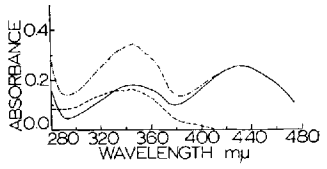

Fig. 6.—Spectrum of the aqueous fraction isolated from the reaction mixture that was partially degraded in 0.5 *N* sodium hydroxide (– · – · –) and that of the pure isoalloxazine (————). The dotted line represents the difference spectrum (see text).

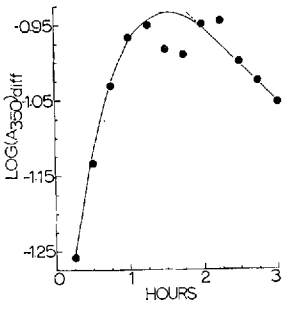

Fig. 7.—A curve showing the appearance and subsequent disappearance of the suspected carbinolamine intermediate.

Table II shows the values of this parameter calculated from data obtained at different times. The concentrations of the anil used in these calculations were obtained from the smooth curve represented in Fig. 5. It can be seen that the values agree fairly well among themselves and further support the hypothesis concerning the equilibrium. It is rather surprising that this supporting evidence was obtained since the analytical method employed does physically separate the two compounds which are thought to be in equilibrium, *i.e.*, the anil was held on the column while the unknown compound was passed through. Apparently, the forward and the reverse rates for the equilibrium are quite slow at the pH of the acid-quenched samples as compared to the rate of passage of solutions through the column.

[a] See text.

Solutions of 9-methylisoalloxazine which were maintained at a pH of 9 did not contain measurable concentrations of the anil or the keto acid. Consequently, quantitative studies here were restricted to the determination, as a function of reaction time, of the concentrations of residual isoalloxazine and dioxo compounds. Both compounds appeared in the neutral fraction of the chromatographic elution scheme. Figure 8 shows the spectrum of such a fraction. Since the dioxo compound does not absorb in the visible region of the spectrum, a simultaneous spectrophotometric analysis of the two component mixture was readily made. Figure 9 shows the time course for the disappearance of isoalloxazine and appearance of the dioxo compound. It was determined that 70% of the parent compound was eventually converted to dioxo compound. The data shown in Fig. 9 were used to estimate rate constants for the processes and these are tabulated in Table III. The rate constant describing the disappearance of the isoalloxazine is sufficiently close to that found for the appearance of dioxo compound to suggest that the rate-determining step in the formation of the product from the parent compound was that involving the ion of the 430 mμ bond of the isoalloxazine. Intermediates such as the anil, the ureide, or the unknown species referred to earlier were apparently present in steady-state concentrations which were too low to detect. It is apparent from the data of Table III that the anil, under these conditions, degraded more rapidly than the parent isoalloxazine. This is in agreement with results obtained in the earlier study (1) where the anil could not be detected in degrading solutions of 9-methylisoalloxazine maintained at a pH of 9.

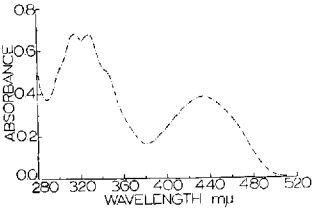

Fig. 8.—Spectrum of a neutral fraction obtained by ion - exchange chromatography of a reaction mixture which was partially degraded in pH 9.0 borate buffer at 45°.

DISCUSSION

As is seen in Fig. 2, the pH profile for 9-methylisoalloxazine exhibits curvature over the pH range bracketing the pKa of the compound (9.82). This was not unexpected and indicated that both ionized and unionized species underwent a base-catalyzed reaction, but at different rates. Thus, the apparent rate constant for the reaction can be defined in terms of ionization of the compound as:

$$k_{app.}(I_t) = k_1(OH^-)(I^-) + k_2(OH^-)(IH) \quad \text{(Eq. 1)}$$

where

$k_{app.}$ = the observed pseudo first-order rate constant,
I_t = the total concentration of the isoalloxazine,
IH = the stoichiometric concentration of the unionized isoalloxazine,
I^- = the stoichiometric concentration of the ionized isoalloxazine,
k_1 = the second-order rate constant for the disappearance of the ionized form,

k_2 = the second-order rate constant for the disappearance of the unionized form.

Equation 1 can be rearranged in the manner suggested by Schwartz *et al.* (5) to show:

$$k_{app.}/OH^- = k_1 + (k_2 - k_1)f_{1H} \quad \text{(Eq. 2)}$$

where, f_{1H} = the fraction unionized of the isoalloxazine. Equation 2 predicts a linear relationship between $k_{app.}/OH^-$ and f_{1H}. Such a plot for the system investigated is shown in Fig. 10. The excellent linearity observed over a wide range of hydroxide-ion concentrations supports the underlying hypothesis. The values of k_1 and k_2 can be calculated from the slope and the intercept of such a plot. These values as determined by the method of least squares were found to be 4.45 L. mole.$^{-1}$ hr.$^{-1}$ for k_1 and 5.01 $\times$ 10^2 L. mole^{-1} hr.$^{-1}$ for k_2. As would be expected from electrostatic considerations the rate constant characterizing the reaction of the negatively charged species is considerably smaller than that of the neutral species.

TABLE III.—RATE CONSTANTS FOR APPEARANCE AND DISAPPEARANCE OF VARIOUS COMPOUNDS IN pH 9.0 BORATE BUFFER AT 45° ± 0.01°

Reaction	Rate Constant, hr.$^{-1}$ $\times$ 10^2
Disappearance of isoalloxazine	1.6
Appearance of the dioxo compd. from isoalloxazine	1.8
Disappearance of the anil	5.0

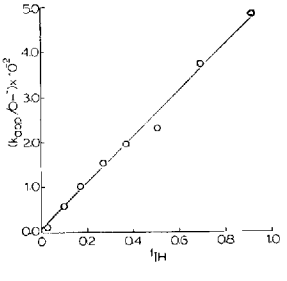

Fig. 10.—A plot showing the relationship expressed by Eq. 2 for 9-methylisoalloxazine at 35° ± 0.01°.

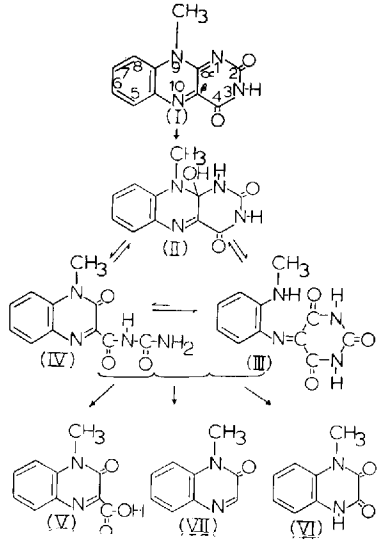
The reaction shown in Scheme I was presented and discussed earlier (1). It was suggested at that time that a carbinolamine intermediate could be initially formed from the isoalloxazine. It is indeed possible that the compound detected in the neutral fraction during the course of this study was this carbinolamine intermediate. It would result from the attack of hydroxide-ion at the Cα position of the isoalloxazine. Thus loss of absorbance at 430 mμ can be explained on this basis since such an attack would destroy the conjugated system $-N_{10} = C_\beta - C_\alpha = N_1-$, which is responsible for absorption of radiation in the visible region of the spectrum. The carbinolamine would be expected to possess a pKa similar to the parent compound and to appear, therefore, in the neutral fraction of the ion-exchange separation. In addition, the charge-density calculations for isoalloxazines reported by Pullman and Pullman (6) suggest that Cα is a good center for nucleophilic attack. Tetrahedral carbinolamine intermediates have been postulated by others in, for example, the hydrolysis of Schiff bases (7) and iminolactones (8). The work of Cunningham and Schmir (8) on the hydrolysis of iminolactones is of special interest here. According to their reasonings, a carbinolamine of the postulated structure (II) could undergo rupture of Cα—N$_9$ bond to yield the anil or breaking of Cα—N$_1$ bond to yield the ureide. It is conceivable then that both the anil and the ureide existed in equilibrium with the carbinolamine and the suspected ureide–anil equilibrium, reported earlier (1), occurred through the carbinolamine compound.

Results have been presented to show that the major products of alkaline hydrolysis of 9-methylisoalloxazine, in the presence of air, were the keto acid (V) and the dioxo compound (VI). In the earlier study (1) the presence of a third product—namely, 1,2 - dihydro - 1 - methyl - 2 - oxoquinoxaline (VII)—was reported. This compound could



Over-all Reaction Mechanism for the Degradation of 9-Methylisoalloxazine.

Scheme I

be detected only under anaerobic conditions at pH 9 where the competing reactions leading to the formation of the dioxo compound and the keto acid were suppressed. Quantitative studies of the kinetics of the anaerobic hydrolysis are presently being conducted and will be reported at a later time.

Proteinaceous Antitumor Substances from Plants II

Mirabilis multiflora

By AYHAN ULUBELEN* and JACK R. COLE

Preliminary screening of the aqueous extract of *Mirabilis multiflora* (*Nyctaginaceae*) has shown antitumor activity against Sarcoma 180 in mice. The isolation, purification, and partial characterization of proteinaceous material is reported. This material has shown activity against Lewis lung carcinoma, Walker carcinosarcoma 256 (intramuscular), and lymphosarcoma.

As a result of a routine screen of southwestern plants for potential antitumor activity, the aqueous extract of *Mirabilis multiflora*[1] (*Nyctaginaceae*) Britton and Rusby demonstrated activity toward the Sarcoma 180 test system in mice.[2] This screening program was carried out by the Cancer Chemotherapy National Service Center (CCNSC), Bethesda, Md. Further fractionation has resulted in activity in the Lewis lung carcinoma, Walker carcinosarcoma 256 (intramuscular), lymphosarcoma, and Sarcoma 180 test systems.

The plant is an herbaceous perennial with a large tuberous root. The above-ground portion of the plant dies during freezing weather or extended drought and regrowth occurs from subterraneous parts of the plant.

Part of the collection used in this study was obtained on rocky slopes about 5 miles south of St. David, Ariz., at an elevation of about 3,700 ft., May 31, 1962. Another part of the collection was obtained at the Boyce Thompson Southwestern Arboretum near Superior, Ariz., on July 1, 1964. It was in cultivation in a sandy loam soil within a grove of eucalyptus.

EXPERIMENTAL

Fresh roots of *M. multiflora* (3.5 Kg.) were extracted with approximately 15 L. of petroleum ether followed by 15 L. of water at room temperature. The water solution was then washed with benzene and chloroform and lyophilized in a Repp Industries model 15 sublimator. The yield was 320 Gm. One-hundred grams of this crude material was dissolved in 1000 ml. of water at room temperature. The insoluble part was separated by centrifuge and discarded (32 Gm.). The remaining aqueous portion was extracted with 5 × 200 ml. of ether to remove the remaining fatty materials. The aqueous solution was increased in volume threefold by the addition of 95% ethanol. A light-colored precipitate formed and was separated by centrifuge. It was dissolved in water and lyophilized. Twenty-one grams of the material was obtained. This crude material showed an activity against the Sarcoma 180 test system of the CCNSC. The requirement for activity in this system is two successive dose response tests showing a reduction of at least 56% in tumor size. The crude material showed a decrease in tumor size of 84% at a dose of 22 mg./Kg. The elementary analysis of this material showed 13.4% inorganic material which consists mostly of magnesium and phosphate ions and also the presence of sulfur and nitrogen. Upon hydrolysis of the material a number of amino acids were obtained. Two grams of the crude material was dissolved in water and dialyzed against distilled water, using a dialyzing tube of $^5/_8$ in. diameter (Arthur H. Thomas Co., No. 4465-A2, Philadelphia, Pa.). After a period of 7 days, the precipitate in the dialysis tube was separated from

[a] "Protocols for Screening Chemical Agents and Natural Products Against Animal Tumors and Other Biological Systems," Cancer Chemotherapy National Service Center, *Cancer Chromatography Rept.*, No. 25, December 1962. [b] The criteria for activity is defined as being a per cent T/C (test/control) value of less than 42 in a satisfactory dose response test.

TABLE II.—TUMOR INHIBITION OF SEPHADEX-TREATED FRACTIONS

Sephadex	Dose, mg./Kg.	% T/C
G-50	10	13
G-100	10	29
G-200a	10	15
G-200b	10	20

the solution. The solution was then lyophilized, with a yield of 957.7 mg. (47.8%) which contained only 2.1% inorganic compounds. The lyophilized material (compound *A*) was subjected to screening against several test systems. The results are indicated in Table I.

A series of column chromatographic purifications were attempted. They included column substrates of DEAE Sephadex A-50, CM Sephadex C-50; G-50, G-100, and G-200 Sephadex. The first two substrates were ineffective, whereas the latter three were successful. A series of fractions were collected and the presence of protein was indicated by means of absorption at 280 mμ in an ultraviolet spectrophotometer. One protein fraction was obtained from the G-50 and G-100 Sephadex columns and two different protein fractions were obtained from the G-200 Sephadex column. After subsequent dialysis and lyophilization, the materials obtained were submitted to tests on Sarcoma 180. The results are tabulated in Table II. Comparison of Tables I and II shows that essentially no increase in activity was obtained by purification techniques.

Physical and Chemical Characteristics of Compound A.—Paper electrophoresis of compound *A* was run utilizing a barbital buffer of pH 8.6, 0.05 ionic strength in a Spinco model instrument, and after 18 hr. of electrophoresis using a 5-ma. current, the papers were developed by two different procedures. Bromophenol blue indicated the presence of two proteins. One appeared at the point of application and the other had a mobility of 6.6×10^{-7} cm.²/sec. v. (Fig. 1). The second development procedure used was periodic acid and Schiff reagent which indicated a glycoprotein at the application point. The closed aldehyde groups in the polysaccharide conjugate are oxidized by periodic acid, then fuchsin sulfite stains the polysaccharides. Other substances such as glucose, glycogen, and the amino acids, serine and threonine, can be stained with fuchsin sulfite, but they are removed in the prerinse.

The above would indicate that compound *A* is a combination of a glycoprotein and protein. The two proteins were separated by a Sephadex G-200 column using a series of phosphate buffer systems pH 8.6, ionic strength 0.075. The compound was then hydrolyzed with 6 *N* hydrochloric acid in a sealed and evacuated glass tube at 105°. The resulting solution was applied on Whatman No. 1 paper using the same solvent system reported in a previous paper (1). Figure 2 shows the presence of 22 amino acids and perhaps some polypeptide residues.

[a] Based on three determinations of the dried sample.

One-hundred milligrams of compound *A* was hydrolyzed with 3 *N* hydrochloric acid in a boiling water bath for 24 hr. in order to determine the sugars. Using Whatman No. 1 paper and the solvent system *n*-butanol–pyridine–water (6:4:3) and comparing with standard sugar samples the following were detected: galactose, mannose, galactosamine, and fucose. The latter two were present in very small amounts. Two additional solvent systems were employed to verify the presence of the above sugars. They were (*a*) ethyl acetate–acetic acid–ethanol–benzene–water (325:93:236:200:146) and (*b*) *n*-butanol–acetic acid–water (4:1:2).

Ultraviolet absorption of compound *A* showed maxima at 280, 243, and 210 mμ. Infrared curve shows characteristic peaks at 3350, 3150, 3030, 2900, 1600, and 1535 cm.$^{-1}$. (See Fig. 3.) Nitrogen determination of compound *A* using microkjeldahl method yielded 14.06% nitrogen. Results of a preliminary amino acid analysis utilizing a Beckman model 120B instrument are shown in Table III.

DISCUSSION

In the work being carried out in this laboratory, glycoproteins have been found on several occasions to be antitumor agents.

A review of the literature has shown a number of publications concerning the relationship of malignant tumors and the increase of glycoprotein concentration in the blood of test animals and humans. There are, however, several varied opinions as to the cause of this increase. Seibert and co-workers (2) reported that the source of glycoproteins was the breakdown of the products of tissue necrosis. Several other workers (3–5) suggested complex mechanisms involving increased hepatic synthesis and release of glycoproteins into the circulation in response to an appropriate stimulus which has a tumor or inflammation. Patterson *et al.* (6) suggest the increase in glycoprotein is a function of bacterial contamination. Other groups of workers (3, 7, 8) reported that this increase is due to a liberation of products of the metabolic activity of rapidly reproducing cells. Catchpole (9) has found a high concentration of glycoprotein in the neighboring tissues of a malignant tumor. Therefore, this could be the depolymerization of the ground substance of this adjacent connective tissue with subsequent release into the circulation. Engel (10), Gilmore and Schwarz (11) are in accord with this theory. The carbohydrate portion of these serum glycoproteins has been shown to contain mannose, galactose, glucosamine, fucose, and sialic acid (12, 13). Macbeth *et al.* (14–18), in a private communication (19), indicated that the liver is the most active agent in the synthesis of these glycoproteins. By using isotopic techniques they also have shown that the tumor system is capable of synthesizing and subsequently liberating glycoproteins into the blood stream. This work was done on intact and hepatectomized rats.

The authors believe that further investigation should be carried on to determine whether the introduction of a certain type of a plant glycoprotein into tumor-implanted animals may result in an inhibition of the synthesis and a reduction of the serum glycoprotein followed by a reduction in overall tumor size. In addition to the two plants mentioned above, there are three other plants under investigation in our laboratories which appear to have glycoproteins as the active antitumor agents.

Rheological Evaluation of Lipophilic Suspending Agents I

Dimethyl Dialkyl Ammonium Hectorite

By CHARLES T. LESSHAFFT, JR.

A modified Brookfield viscometer was used to evaluate dispersions containing various concentrations of dimethyl dialkyl ammonium hectorite (DDAH) and ethanol in light mineral oil. The optimum amount of ethanol needed to disperse the DDAH in the oil was found to be an amount equal to the weight of the DDAH. A new method of determining the static yield value was used as one of the rheological parameters in the evaluation. The static yield value (Y_s) in dynes/cm.^{2} was found to be related to the percentage concentration (C) of the DDAH as follows: log $Y_s = mC + \log b$ in which the constants m and b equal 1 and 2, respectively, for dispersions containing an ethanol content equal to the DDAH; and equal to 0.6 and 3.5, respectively, for dispersions containing an ethanol content twice that of the DDAH. A 1.25 per cent DDAH–1.25 per cent ethanol dispersion was evaluated for its ability to suspend several drugs. It was postulated from the sedimentation data that the small amount of supernatant liquid which occurred in these suspensions was due to syneresis.

THE EVALUATION of hydrophilic suspending agents as stabilizers for aqueous suspensions has been the subject of numerous investigations. However, there are no such lipophilic suspending agents in use for preparing pharmaceutical oil suspensions with the exception of aluminum monostearate. Aluminum monostearate is used to gel the oil in the preparation of oily suspensions of procaine penicillin G, not for the purpose of stabilizing the suspension (even though it does this), but for the purpose of prolonging the absorption of the penicillin.

Oily mediums still serve a need as vehicles for dermatological drugs as attested to by the number of U.S.P. XVII (1) and N.F. XII (2) ointments that use the petrolatums as the base. Rheologically, petrolatum has a high yield value at room temperature. The yield value becomes greater as solid substances are incorporated. This makes the resulting ointment difficult to spread and the excessive pressure needed for its application may be painful. It would seem that a liquid vehicle, such as mineral oil, might serve the same purpose as an ointment prepared with petrolatum and be easier to apply.

Mineral oil is a viscous liquid but is not a good suspending medium because of its Newtonian character. A good suspending medium should have a yield value, yet it should be capable of being poured from a bottle (3–6). The evaluation of a substance that would alter the flow properties of mineral oil to produce such an effect is of interest here. Previous reports indicate that dimethyl dialkyl ammonium hectorite[1] (DDAH) might be a likely candidate to produce this effect. For example, it has been used to prepare ointments with heavy mineral oil (7) and with hexamethyltetracosane (8). Viscous dispersions of DDAH in volatile organic solvents have been tested as granulators and binders in the production of tablets (9).

DDAH is a finely divided light cream-colored powder. Unlike hectorite, which is highly hydrophilic, this organic derivative of hectorite is hydrophobic and organophilic. As a result, it produces gels with organic liquids. The mechanism of the gelling process has been investigated by Jordan and co-workers (10–12). Although they worked with organic derivatives of bentonite, their results and interpretations can be applied to DDAH because both bentonite and hectorite have the same montmorillonite lattice structure (13). In the gelling process it is necessary for the solvating liquid to first penetrate between the small primary particles and effect a separation of them before solvation can occur. The liquid must possess some degree of polarity which is needed to overcome the attractive forces that hold these particles together and allow its penetration. Liquids consisting primarily of hydrocarbons, such as mineral oil, do not possess sufficient polarity to accomplish this. The use of polar additives and mechanical shear can be used to overcome these forces and allow the penetration of the oil. The low molecular weight alcohols, such as methanol and ethanol, are recommended as polar additives for this purpose.

Received April 26, 1966, from the College of Pharmacy, University of Kentucky, Lexington.
Accepted for publication September 8, 1966.
Presented to the Pharmaceutical Technology Section, A.PH.A. Academy of Pharmaceutical Sciences, Dallas meeting, April 1966.

[1] Made by the National Lead Co. under the name of Bentone 38. The alkyl groups are a mixture of C_{18} and C_{16} in a ratio of approximately 70 to 30, respectively.

TABLE I.—DIMENSIONS OF CYLINDRICAL SPINDLES

Spindle No.	Radius (R_b), cm.	Ht., cm.	Effective Ht. (h),[a] cm.
1	0.942	6.510	7.493
2	0.513	5.395	6.121
3	0.294	4.288	4.846
4	0.159	3.101	3.396

[a] The effective height is the actual height plus the correction for the end effect.

It is also suggested that the alcohols contain 5% water (14).

The amount of ethanol recommended as a polar additive for organic derivatives of montmorillonite clays is about 45% based on the weight of the clay derivative (14). It is likely that the amount of ethanol would vary, depending on the particular derivative and the polarity of the vehicle. The purpose of this investigation was to determine the optimum concentration of DDAH and ethanol and the most efficient procedure for the preparation of an oily suspending medium. Rheological evaluations of the dispersions were used to select the combination of DDAH and ethanol in light mineral oil that could be used as a suspending medium. Various rheological parameters were used in the evaluation for the purpose of correlating concentrations with a rheological parameter.

EXPERIMENTAL

Instrumentation.—A Brookfield viscometer (LVT model)[2] was modified so that it would function as an absolute rheometer. The No. 2 and No. 3 disk shaped spindles were replaced with cylindrical spindles. The dimensions of the spindles are given in Table I. The guard that is supplied with the viscometer was removed to prevent the guard from interfering with shearing and also to facilitate the use of a cup having a smaller diameter and volume than the cup recommended for use with the guard attached to the instrument. These modifications were similar to those of Wood *et al.* (15) with the exception of the cup. The cup used in this investigation was a 100-ml. graduated cylinder having a diameter of 2.6 cm. and cut at the 70-ml. mark to reduce its height.

The shearing stress (F) was calculated utilizing the following equation

$$F = \frac{M}{2\pi R_b^2 h} \qquad \text{(Eq. 1)}$$

in which M is the torque, R_b is the radius of the spindle, and h is the effective height of the spindle (16). The effective height of the spindle is the actual height plus a correction factor for the end effect of the spindle. The torque is obtained by multiplying the dial reading of the instrument by 6.737. Each unit division of the dial is equal to 6.737 dynes-cm. for the Brookfield LVT model. The equation for calculating the shearing stress for this instrument is then

$$F = \frac{6.737D}{2\pi R_b^2 h} \qquad \text{(Eq. 2)}$$

in which D is the dial reading.

The rate of shear (G) was calculated at the wall of the spindle by the following equation

$$G = \frac{2\omega R_c^2}{R_c^2 - R_b^2} \qquad \text{(Eq. 3)}$$

in which ω is the angular velocity, R_c is the radius of the cup, and R_b is the radius of the spindle (16).

Rheograms could now be prepared by plotting rate of shear in sec.$^{-1}$ *versus* shearing stress in dynes/cm.^{2}. These flow curves would visually describe the flow character and relative viscousness of the liquid. However, a mathematical description of the curve would be more useful.

Plastic Viscosity and Bingham Yield Value.—The rheogram of a Newtonian liquid is a straight line which passes through the origin. The reciprocal of the slope of this line is the coefficient of viscosity in poises. Theoretically, the rheogram for a plastic liquid is a straight line which does not pass through the origin but intercepts the shearing stress axis at zero rate of shear. The reciprocal of this line is the plastic viscosity in poises and the intercept is known as the Bingham yield value in dynes/cm.^{2}. Both parameters, the plastic viscosity and the Bingham yield value, are needed to describe a plastic liquid. In an actual experimental determination the rheogram of a plastic liquid will not be a straight line throughout the whole range of shear rates but will curve toward the origin at the lower rates of shear. This curve is due to an instrumental characteristic. The low angular velocity of the spindle is not great enough to cause the liquid to flow throughout the annular space between the walls of the spindle and cup. The straight line portion of the curve can be projected to the shearing stress axis for the determination of a Bingham yield value, the reciprocal of the straight line being the plastic viscosity. In this study these parameters were calculated from the straight line connecting the two highest shear rates of the rheogram.

Power Law Equations.—Two power law equations have been used to describe the flow curve for non-Newtonian liquids. Equation 4 has been used by a number of investigators (17–19).

$$F^N = \eta' G \qquad \text{(Eq. 4)}$$

Written in logarithmic form the equation is

$$\log G = N \log F - \log \eta' \qquad \text{(Eq. 5)}$$

Equation 6 has also been frequently used (20–22).

$$F = K G^{1/N} \qquad \text{(Eq. 6)}$$

The logarithmic expression for this equation is

$$\log F = 1/N \log G + \log K \qquad \text{(Eq. 7)}$$

While both equations have shearing stress (F) and rate of shear (G) in common, Eq. 4 utilizes the slope (N) of the curve and Eq. 6 uses the reciprocal of the slope ($1/N$). The slope or its reciprocal indicates deviation from Newtonian behavior. The

[2] Brookfield Engineering Corp., Stoughton, Mass.

slope and the reciprocal of the slope are equal to one for Newtonian liquids; $N > 1$ and $1/N < 1$ for pseudoplastic (shear thinning) liquids; $N < 1$ and $1/N > 1$ for dilatant (shear thickening) liquids. The η' in Eq. 4 is the reciprocal of the intercept on the rate of shear axis, while the K in Eq. 6 is the intercept on the shearing stress axis at a rate of shear of 1 sec.$^{-1}$. Therefore, K is the apparent viscosity in poises at a shear rate of 1 sec.$^{-1}$. The relationship between K and η' is given in Eq. 8.

$$\log K = 1/N \log \eta' \qquad \text{(Eq. 8)}$$

Static Yield Value.—Newtonian liquids flow when acted on by any force, however small. Some liquids, other than Newtonian, do not flow until the applied shearing stress exceeds a certain minimum value. This minimum stress necessary to initiate flow is the yield value of the liquid. The present methods of determining yield value either measure the stress at a very low rate of shear or project a stress at zero rate of shear. These methods are referred to as dynamic since the yield value is determined as a result of shearing.

A method of determining static yield value was reported by Levy (23). The advantage of his method is that a different and previously undisturbed region of the liquid is continuously sheared as the Helipath spindle descends into the liquid. The method has the disadvantage in that the instrumental design does not permit the yield value to be expressed in terms of dynes/cm.^{2}. It is also questioned whether the method is static since the spindle was rotated at 6 r.p.m.

It was noticed in the preliminary rheological evaluations of the dispersions made in this study that the pointer of the Brookfield viscometer did not move immediately after the instrument was turned on, even though the dial moved at the designated r.p.m. The pointer started to move only after some stress value was reached as indicated by the dial reading. This condition did not occur when known Newtonian liquids were tested. It was determined that the spindle did not move until the pointer moved, which meant that the liquid was not being sheared. It was reasoned that the liquid prevented the spindle from moving until the strain on the torsion spring of the instrument overcame the yield value of the liquid. It was also determined that the yield value taken at zero rate of shear was independent of the spindle size used.

It was known prior to this investigation that a yield value could be determined directly with a Brookfield viscometer using cylindrical spindles (24). If the liquid has a yield value the pointer will not drift to zero when the motor of the instrument is stopped. Instead, the pointer will drift and come to rest at some position on the dial before reaching zero. The stress equivalent to the dial reading would be the yield value. This yield value, however, would depend on the shear history of the sample even though the yield value was determined at zero rate of shear.

Methodology.—The method used in this study for taking the static yield value consisted of a repeated on-off technique of operating the instrument. The viscometer was turned on at a speed of 0.3 r.p.m. and then off almost immediately. The pointer would remain stationary after the instrument was turned off until the yield value was exceeded, then it would drift toward zero, stopping at some distance from zero. The last stationary reading taken before the pointer started to drift toward zero was taken as the static yield value.

It was necessary to control the shear history of the samples since the dispersions were time-dependent; that is, at a constant rate of shear the shearing stress decreased with time. All of the rheological evaluations were made 2 days after the preparation of the dispersion unless otherwise specified. The sample was transferred to the cup. The cup was immersed in a water bath and held in place by a clamp. The temperature of the bath was regulated at 25° ± 0.1° by a constant-temperature circulator.[3] After the spindle was immersed in the sample, a period of 30 min. was allowed to elapse before taking the static yield value. Immediately after taking the static yield value, the sample was sheared for exactly 10 min. at each r.p.m. of the instrument starting at the highest r.p.m. The stress was recorded at the end of each 10-min. shearing period. Preliminary investigations of the methodology and instrumentation of the rheological evaluation indicated that results could be satisfactorily duplicated.

Preparation of the Dispersions.—The dispersions of DDAH were prepared in quantities of 900 Gm. The percentages used to express the concentration of the ingredients are by weight. Light mineral oil N.F. which had a specific gravity of 0.8379 and a viscosity of 25 cps. was used as the vehicle. Alcohol U.S.P. which is referred to in this paper as ethanol was used as the polar additive.

Various orders of mixing were investigated to determine the most efficient procedure for dispersing DDAH in light mineral oil. Dispersions containing 1% DDAH and 0.5% ethanol were prepared by each of the following methods.

Method A.—Add the ethanol to a suspension of DDAH in the oil while mixing with the Dispersator.[4]

Method B.—Add the ethanol to the DDAH contained in a beaker and lightly mix with a stirring rod. Add this damp powder to the oil while mixing with the Dispersator.

Method C.—Add the ethanol to the DDAH contained in a beaker and lightly mix with a stirring rod. Add 100 ml. of the oil to the damp powder. Transfer this thick slurry to the remaining oil and mix with the Dispersator.

Method D.—Mix the ethanol intimately with the DDAH in a mortar. Incorporate 100 ml. of the oil with this mass. Transfer this mixture to the remaining oil and mix with the Dispersator.

The mechanical mixing was uniform for all of the above methods. The high viscosity head of the Dispersator was used for 5 min. with a Powerstat setting of 45 which was equivalent to approximately 4500 r.p.m. The use of this head was necessary in order to disperse the large clumps of DDAH resulting from the preliminary mixing in methods *C* and *D*. The Simplex head was then used to shear the dispersion for 10 min. at a full Powerstat setting 120 which was equivalent to approximately 13,000 r.p.m. The sample prepared by method *D* was sheared for an additional 10 min. with the

[3] Bronwill's Constant Temperature Circulator, Bronwill Scientific, Rochester, N. Y.

[4] Series 2000 Standard Premier Dispersator, 1/3 HP, single phase, universal type motor. Made by Premier Mill Corp., Temple, Pa.

TABLE II.—RHEOLOGICAL PARAMETERS OF DISPERSIONS PREPARED BY VARIOUS METHODS[a]

Method	Static Yield Value	Bingham Yield Value	Plastic Viscosity	K	$1/N$
A	None	0.77	0.36	0.57	0.89
B	0.3	3.1	0.39	1.5	0.67
C	2.	6.2	0.79	4.9	0.47
D	3.	12.	1.18	10.	0.39

[a] Spindle No. 2 used to collect data.

Simplex head at the full Powerstat setting. No change in the rheological properties of the sample was detected. No attempt was made to find the minimum time or shearing rate necessary to prepare an equivalent sample. Since method D produced the most viscous sample, this method was used throughout the rest of this investigation.

In order to remove the air entrapped by the mixing, the dispersions were subjected to reduced pressure for 1 hr. at approximately 35 mm. of mercury immediately after their preparation. It was reasoned that some ethanol would be removed in the process of removing the air and it was of interest to determine what effect this alcohol would have on the dispersion if allowed to remain for a longer period of time before evacuating. A 1% DDAH dispersion was prepared using 2% ethanol. Half of this dispersion was subjected to reduced pressure immediately after preparation and a rheological evaluation was made 2, 6, and 8 days after preparation. The other half was subjected to reduced pressure 4 days after preparation and a rheological evaluation made 6 and 8 days after preparation.

Various concentrations of ethanol were used to prepare 1% dispersions of DDAH. The concentrations of ethanol used were 0.25, 0.5, 0.75, 1, 2, and 3%. A sample was also prepared without ethanol.

Dispersions of various concentrations of DDAH were then prepared with ethanol concentrations equal to that of the DDAH and with ethanol concentrations twice that of the DDAH.

RESULTS

Methods of Preparation.—The results of the rheological evaluation of the dispersions which were prepared by the various methods and which contained 1% DDAH and 0.5% ethanol are recorded in Table II. All of the rheological parameters indicate that maximum gellation occurred in the sample prepared by method D.

Although the various methods of preparing the dispersions appear to be similar, it should be emphasized that the principal difference is in the manner of incorporating the ethanol. In method D the ethanol was intimately mixed with the DDAH resulting in a mass that was visibly wet and of a pilular consistency while in methods B and C the mixture was a flowable powder.

In method B the DDAH–ethanol powder was added to all of the oil, while in method C the powder was initially mixed with only a portion of the oil. The greater concentration of ethanol in this preliminary mix of method C is probably the reason for the greater degree of gellation in the sample prepared by method C as compared to method B.

The least contact of DDAH with ethanol occurred in method A in which the ethanol was added to the mixture of DDAH and the oil. The sample prepared by this method also exhibited the least gellation.

These results seem to substantiate the mechanism of the gelling process proposed by Jordan and co-workers (10–12) in which the polar additive must first effect a separation of the primary particles in order for the oil to penetrate and solvate these particles. The preliminary investigation of these methods of preparing the dispersions indicated that reproducibility could be obtained within an acceptable range of ±10%.

There was no change in any of the five samples of the 1% DDAH dispersion prepared with 2% ethanol during 8 days of storage, regardless of whether the entrapped air was removed immediately after preparation or 4 days after preparation. It was thought that a longer storage period before the air was removed might affect the viscosity of the dispersion. It was possible that some ethanol would be removed in the process of removing the air. A longer storage period before evacuation would mean that the ethanol would be in contact with the DDAH for a longer period of time. Since there were no rheological differences between these samples, it would seem to indicate that the small amount of ethanol lost during the evacuation of the air was too minimal to affect their rheological properties. It is possible that the attraction of DDAH for the ethanol minimized or prevented its removal during the evacuation process.

Rheological Evaluations.—The results of the rheological evaluations of the 1% DDAH dispersions prepared with various concentrations of ethanol are recorded in Table III. All parameters indicate that the dispersion prepared with 1% ethanol was the most viscous. The sample prepared without ethanol does not appear in the table since it had a Newtonian viscosity of 27 cps. which was practically the same as the light mineral oil. Table IV lists the results of the rheological evaluations of the dispersions containing various concentrations of DDAH with ethanol concentrations equal to that of the DDAH and with ethanol concentrations twice that of the DDAH.

Figures 1 and 2 illustrate the flow curves of the dispersions containing various concentrations of DDAH with ethanol concentrations equal to that of the DDAH and with ethanol concentrations

Table III.—RHEOLOGICAL PARAMETERS OF DISPERSIONS[a] PREPARED WITH VARIOUS CONCENTRATIONS OF ETHANOL[b]

twice that of the DDAH, respectively. The upper portion of the flow curve for the 1.75% DDAH dispersion in Fig. 1 could not be determined because the stress exceeded the upper limits of the instrument for the No. 3 spindle at this high r.p.m. Even though a reading could not be made, the spindle was allowed to revolve at the designated velocity (60 r.p.m.) for the specified time (10 min.) so that the shear history would be the same as the other samples. The upper portion of this curve could be projected on a log-log plot of shear rate *versus* stress (see Fig. 3) to obtain a projected stress at the rate of shear equivalent to 60 r.p.m. For this reason the plastic viscosity and Bingham yield value given in Table IV for this sample are recorded as projected values.

A 2% DDAH dispersion using 2% ethanol was not prepared since it would have been too viscous to evaluate with the No. 3 spindle. Because of the time-dependency of these systems a comparison could not be made between data collected from two different spindles.

A log-log plot of shear rate *versus* stress for the DDAH dispersions prepared with ethanol concen-

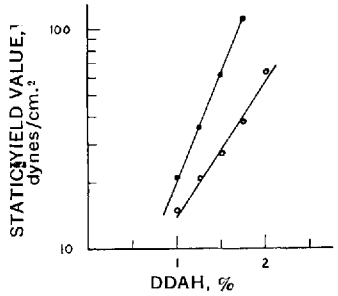

Fig. 5.—Plot of the log static yields value *vs.* the DDAH concentration. Key: ●, dispersions containing an ethanol concentration equal to that of the DDAH; ○, dispersions containing an ethanol concentration twice that of the DDAH.

trations equal to the DDAH is presented in Fig. 3. These log-log rheograms are representative of the others encountered in this study and are presented here for the purpose of showing the apparent effect of the static yield value upon them. A straight line relationship was found to exist between log rate of shear and log stress at the higher shear rates but not for the very lowest ones. It is interesting to note that the break in the straight line always occurred near a stress corresponding to the static yield for that particular dispersion. From this observation it is assumed that the straight line relationship between log shear rate and log stress does not exist throughout the whole shear rate range due to interference of the yield value of the dispersion at the low shear rates.

Effect of DDAH and Ethanol Concentrations on the Static Yield Value.—The static yield value of the dispersions containing 1% DDAH and various concentrations of ethanol were plotted against the ethanol concentrations. The results of this plot are presented in the lower portion of Fig. 4. The static yield value increases with an increase in ethanol concentration until a concentration of 1% ethanol is reached. As the concentration of ethanol is further increased a decrease in the static yield value occurs. From these results it is evident that the optimum ethanol concentration for a 1% DDAH dispersion is 1% ethanol which is equal to the concentration of the DDAH.

The static yield value of the dispersions containing various concentrations of DDAH with ethanol concentrations equal to that of the DDAH and with ethanol concentrations twice that of the DDAH are also illustrated in Fig. 4. As can be seen in this figure, the slopes of the lines become greater as the DDAH concentration increases. These slopes represent a decrease in static yield value as the ethanol concentration increases. The slope of each line was determined and the log of the slopes plotted against the DDAH concentrations. This semilog plot produced a straight line represented by the following equation:

$$\log \frac{\Delta Y_s}{E_2 - E_1} = -1.204\ C + \log 0.375 \qquad \text{(Eq. 9)}$$

The $\Delta Y_s/E_2 - E_1$ in Eq. 9 is the slope of the lines in Fig. 4 having a negative value; ΔY_s is the decrease in static yield value due to an increase in the percentage concentration of ethanol from E_2 to E_1; C is the percentage concentration of DDAH.

The log of the static yield value of the dispersions containing various concentrations of DDAH with ethanol concentrations equal to that of the DDAH and with ethanol concentrations twice that of the DDAH were plotted against the percentage concentrations of DDAH. These results, as illustrated in Fig. 5, are represented by the following equation

$$\log Y_s = mC + \log b \qquad \text{(Eq. 10)}$$

in which Y_s is the static yield value, m is the slope, b is the intercept on the y axis, and C is the concentration of DDAH. For the dispersions containing an ethanol concentration equal to the DDAH concentration, $m = 1$ and $b = 2$. For the dispersions containing an ethanol concentration twice that of the DDAH concentration, $m = 0.6$ and $b = 3.5$.

The results obtained from the plots in Figs. 4 and 5 indicate the validity of the static yield value as a rheological parameter. Although plots of the other rheological parameters were similar to those in Figs. 4 and 5, they were not so symmetrical and equations were not derived from them. These results also indicate that the ethanol concentration is an important factor in the formulation of a DDAH dispersion and that the optimum amount of ethanol needed to disperse DDAH in light mineral oil is an amount equivalent to the weight of the DDAH.

The dispersion having the highest static yield value would likely be the most effective in suspending insoluble material. However, it would also be impractical as a suspending medium because it would be too viscous to be pourable. Of the dispersions containing an ethanol concentration equivalent to the DDAH concentration, the 1% and 1.25% dispersions could be easily poured from a 2-oz. narrow-mouth bottle having an orifice of 14 mm.

Sedimentation Study.—The effectiveness of the

[a] A film of light mineral oil, too small to measure, was observed on the surface.

1.25% DDAH–1.25% ethanol dispersion as a suspending medium was determined by comparing the sedimentation rate of various drugs suspended in this medium with the sedimentation rate of drugs suspended in light mineral oil. The drugs used were boric acid, precipitated calcium carbonate, precipitated sulfur, and zinc oxide in 5% w/v concentrations. All were of U.S.P. quality. The suspensions were prepared in a mortar and transferred to 50-ml. glass-stoppered cylinders having an internal diameter of 22 mm. A sample of the DDAH dispersion was also transferred to a cylinder and observed along with the suspensions. The height of the settled phase (H_s) was determined at various intervals of time and compared with the height of the original suspension (H_0). The sedimentation ratio (H_s/H_0) at the various time intervals are given in Table V for the light mineral oil suspensions and Table VI for the suspensions prepared with the DDAH dispersion.

A film of light mineral oil, too small to measure, was observed on the surface of the DDAH suspensions of calcium carbonate, boric acid, and sulfur on the 13th day of aging. At the same time a similar film was noticed on the surface of the DDAH dispersion which served as the control. It is likely that this separation of oil in the DDAH dispersion was due to syneresis. This phenomenon can also be observed in bentonite magma on standing. The fact that this separation occurred in the suspensions of calcium carbonate, boric acid, and sulfur at the same time as the control seems to indicate that syneresis also occurred in these suspensions.

The supernatant liquids of the DDAH suspensions of zinc oxide and sulfur could be measured after the 6th and 21st day, respectively. The supernatant liquids were perfectly clear throughout the 12-week aging period and were obviously light mineral oil. For practical purposes these drugs were considered as settling. However, syneresis cannot be ignored in these suspensions for it is possible that interaction between the DDAH particles and the drugs could occur to increase this effect.

A comparison of the sedimentation rates of boric acid and zinc oxide lends support to the theory that zinc oxide increased the syneresis of the DDAH dispersion. Boric acid settled at a much greater rate than zinc oxide in light mineral oil. Yet when suspended in the DDAH dispersion zinc oxide had a greater apparent rate of sedimentation than boric acid. A similar comparison can be made with boric acid and sulfur. Boric acid settled faster than sulfur in light mineral oil. However, the apparent sedimentation rate of sulfur was greater than boric acid in the DDAH suspending medium. From these observations it appears that the development of the supernatant liquid in the DDAH suspensions was due, not to the settling of the drugs as normally envisioned, *i.e.*, the insoluble particle falling in the suspending medium due to gravity, but rather the squeezing-out of the light mineral oil as the DDAH gel shrinks.

SUMMARY

The ability of dimethyl dialkyl ammonium hectorite (DDAH) to alter the flow properties of light mineral oil was evaluated for the purpose of preparing an oily suspending medium.

Dispersions of various concentrations of DDAH and ethanol in light mineral oil were prepared and rheologically evaluated by the use of a modified Brookfield viscometer. The optimum amount of ethanol needed to disperse DDAH in the oil was found to be an amount of ethanol equal to the weight of DDAH.

A new method of determining static yield value was found to be reliable. The static yield value (Y_s) in dynes/cm.^{2} was found to be related to the concentration (C) of DDAH as follows:

$$\log Y_s = mC + \log b$$

in which the constants m and b equal 1 and 2, respectively, for dispersions containing an ethanol content equal to the DDAH; and equal to 0.6 and 3.5, respectively, for the dispersions containing an ethanol content twice that of the DDAH.

A dispersion containing 1.25% DDAH and 1.25% ethanol in light mineral oil was used to prepare suspensions with several drugs. It was postulated that the formation of the small amount of supernatant liquid which occurred in these suspensions was due to syneresis rather than sedimentation of the insoluble particles.

Phytochemical Investigation of *Arctostaphylos columbiana* Piper and *Arctostaphylos patula* Greene (*Ericaceae*)

By GEORGE H. CONSTANTINE, JR., PHILIP CATALFOMO, KIRTI SHETH, and LEO A. SCIUCHETTI

Improved methods of extraction and new techniques of isolation and identification of 11 components from the title plants were conducted. A solvent mixture of diverse polarity extracted four polycyclic compounds, a hydrocarbon, two flavonoids, and four phenols. Another phenolic, assumed to be widespread in the family, could not be shown to be present. Antibacterial and antifungal activity was found in the extracts obtained from both plants.

ETHNOBOTANICAL and early medical literature have often cited the usefulness of various *Arctostaphylos* species for a variety of medicinal uses. Members of the genus have been used by the Pacific Northwest Indians. These include their uses as healing poultices and as a curative for severe colds (1), as an eyewash and styptic (2), as a food (3–5), and as smoking tobacco (6). In fact, Reagan (7) reported drunken and erratic behavior of Indians who smoked the leaves of *A. uva-ursi* and stated that it was smoked as a medicine and in religious ceremonies.

The most widely known member of the genus, *A. uva-ursi*, reportedly was used by the early Greeks and Romans (8). Griffith (9), however, stated that DeHaen in the 18th century be given credit for its use as a remedy in kidney and bladder diseases. *A. uva-ursi* was official in the first U.S.P. in 1820, remained in the N.F. until 1946, and still is found in a few proprietary urinary tract remedies.

Previous phytochemical examination of the genus has been mainly restricted to *A. uva-ursi*. Arbutin was isolated in 1852 (10). Rosenthaler (11) isolated methylarbutin in 1927 and Britton and Haslam (12) have very recently identified three galloyl esters of arbutin. Two flavonoid compounds, isoquercitrin (13) and hyperin (14), have also been isolated. Hermann (14) reportedly found "*A. uva-ursi* tannin" to consist of gallic acid, ellagic acid, and glucose, whereas Britton and Haslam (12) have reported the tannin to consist of penta- to hexa-*o*-galloyl-β-D-glucose derivatives. Ibrahim (15) recently identified *o*-pyrocatechuic acid in *A. uva-ursi* as well as in other members of the family. The triterpenoid ursolic acid was first isolated from *A. uva-ursi* (10). The corresponding alcohol, uvaol, was also isolated from this plant (16).

Members of the genus have not been thoroughly investigated for biological activity. *A. uva-ursi* extracts were found to inhibit Ehrlich ascites tumor growth (17). Antibacterial activity has also been exhibited against *B. subtilis*, *E. coli*, and *S. aureus* (18). *A. patula*

extracts were reported to inhibit cultures of *Mycobacterium tuberculosis* (19).

EXPERIMENTAL

Plant Collection and Treatment

A. columbiana and *A. patula* were gathered in Marion County, Oreg., during the fall of 1965.[1] The plants were allowed to air-dry on greenhouse benches for not less than 2 weeks. They were then divided into their morphological parts, *i.e.*, leaves, roots, and stems, and ground to a course powder in an Abbé mill. The powdered material was then stored in air-tight plastic bags in the dark until time for analysis.

Preliminary Investigation.—Five-gram samples of each plant part were subjected to selective solvent extraction using petroleum ether U.S.P., chloroform U.S.P., alcohol U.S.P., and distilled water, successively. The extracts were then chromatographed (ascending technique) on Whatman No. 1 paper with the solvent systems *n*-butanol–acetic acid–water (4:1:5, organic phase) and *n*-butanol–pyridine–water (2:1:1). Antimony trichloride (10% w/w in chloroform) detected positive triterpene/sterol compounds (pink to red) in all except the aqueous fractions of both plants. Dragendorff's spray reagent demonstrated negative results in all of the extracts. Ferric chloride (1% in ethanol) and phosphomolybdic acid (5% in methanol) detected the presence of phenolic compounds. The alcoholic and aqueous extracts of *A. patula* contained 11 phenolic compounds, whereas, seven phenolic compounds were found in *A. columbiana*.

Additional testing was conducted on all of the selective solvent fractions from above. Anisaldehyde and Liebermann-Burchard spot tests also indicated the presence of triterpene/sterols in all but the aqueous fractions. Dragendorff's, Mayer's, and Wagner's reagents indicated the absence of alkaloid substances. Ferric ammonium sulfate (3% in water) and vanillin (1% in HCl) reagents also indicated the presence of phenolic compounds in the alcoholic and aqueous fractions.

Extraction and Fractionation.—One kilogram of the leaves from each plant was extracted individually for 72 hr. in a Soxhlet apparatus with 6 L. of methanol–skelly B (1:1). The dark green residue obtained after concentration in a flash evaporator was dissolved in skelly B–water (1:1) and placed in a large separator. On standing, a copious green interphase developed which was removed along with the organic phase and washed with water (3 × 125 ml.). The aqueous phase and washings (fraction II) were set aside for later examination of phenolic constituents. The organic phase (fraction III) was examined for triterpenes and sterols.

Triterpenes and Sterols.—Samples of fraction III were saponified according to the method of Huneck and Snatzke (20). Refrigeration of the acidified mixture yielded a copious greenish-yellow precipitate (fraction IV). The mother liquor was subjected to liquid–liquid extraction for 48 hr. using hexane (analytical reagent) as the lighter solvent. The soluble components were designated fraction V. Fractionation steps are summarized in Scheme I.

[1] Identified by Dr. K. L. Chambers, Professor and Curator of the Oregon State University Herbarium. Voucher specimens of both plants are located at same.

Isolation of Ursolic Acid.—Fraction IV gave a positive Liebermann–Burchard test (red to immediate purple) and anisaldehyde test (red). Thin-layer chromatography (TLC)[2] of fraction IV employing chloroform–acetone (9:1) as a solvent system and antimony trichloride as a spray reagent indicated only one spot (R_f 0.14) identical to ursolic acid which was also chromatographed on the same plate. The crude material (fraction IV) after repeated washings with cold chloroform was crystallized from ethanol. Fine needles of ursolic acid were obtained, m.p. 277–280°.[3] Literature values for ursolic acid range from 224° (21) to 291° (22). Superimposable infrared spectra were obtained in comparing the isolate with ursolic acid.

Column Chromatography of Fraction V.—Fraction V, when chromatographically screened on a thin-layer plate (chloroform–acetone, 9:1), revealed the presence of three compounds when sprayed with antimony trichloride spray reagent (R_f 0.39, 0.49, and 0.58). An 8-Gm. sample of fraction V was mixed with 10 Gm. of activated alumina[4] and placed atop a 300-Gm. alumina column (50 × 240 mm.). The column was eluted with successive solvents of increasing polarity. The results are summarized in Table I.

Fraction A upon drying gave a white lustrous product (1.1 Gm.) which was recrystallized from acetone, melted sharply at 64°, and was tentatively identified as nonacosane, m.p. 64–65°. Fractions B and C were combined, treated as above, and yielded additional nonacosane (0.7 Gm.).

Thin-layer chromatography of fraction D revealed the presence of only one compound which had an R_f value comparable to that of β-amyrin. Evaporation *in vacuo* yielded a semisolid yellow residue (0.8 Gm.) which was recrystallized from petroleum ether and yielded β-amyrin, m.p. 194–196°. A mixed melting point with an authentic sample of β-amyrin,[5] m.p. 192–196°, showed no depression. The infrared spectra of the compound and authentic β-amyrin were identical.

Fraction E (0.7 Gm.) contained a mixture of three compounds which had R_f values comparable to those of β-amyrin, β-sitosterol, and uvaol. The dried fraction was deposited on top of a small column of alumina (100 Gm., 30 × 240 mm.) and carefully eluted. Fraction E′ [chloroform–ether (3:1)] eluted only β-sitosterol (as revealed by TLC) which was crystallized from chloroform–methanol and gave a m.p. of 135°. Mixed melting points with an authentic sample of β-sitosterol,[5] m.p. 133–135°, did not cause any depression. Superimposable infrared spectra were obtained in comparing the isolate with the authentic sample.

Fractions F and G contained only one component which had an R_f value comparable to that of uvaol. The dried fraction (0.8 Gm.) was recrystallized from ethanol and yielded fine white needles, m.p. 222–224°. Reference uvaol, m.p. 223–224°, was prepared by lithium aluminum hydride reduction of ursolic acid utilizing a modified procedure of Nystrom and Brown (23). Mixed melting points of

G	Chloroform–methanol (1:1)	2000	0.39

[a] Detected by TLC in chloroform–acetone (9:1); 10% w/w $SbCl_3$ in $CHCl_3$ as spray reagent and heating in an oven at 110° for 5 min.

isolated and reference uvaol showed no depression and the infrared spectra of the two were identical.

Co-Chromatography.—In these experiments the identity of β-amyrin, β-sitosterol, uvaol, and ursolic acid isolated from the extract was also verified by means of TLC. The isolated compound and the corresponding authentic sample were co-spotted. Controls of the isolated compound and the reference compound were spotted singly. These plates were then run in three different solvent systems and when developed showed that the co-spot which did not separate had the same R_f value as that of the two control spots. The results of co-spotting experiments are summarized in Table II.

Rather than repeating the entire procedure of isolation of compounds from *A. columbiana* a sample of fraction III of this plant was co-spotted along with standard β-amyrin, β-sitosterol, ursolic acid, and uvaol in three different solvent systems. The results are shown in Table III and indicate the presence of the same compounds in *A. columbiana*.

Phenolic and Related Compounds.—Portions of fraction II (Scheme I) of both plants were subjected to liquid–liquid extraction using ethyl acetate and ether, successively. Portions of fraction II were also subjected to acidic or alkaline hydrolysis and the hydrolysates were then extracted with ether. The extraction scheme is summarized in Scheme II. Samples were spotted in several channels on chromatoplates. Spots corresponding to reference compounds were removed from the plates with a vacuum-zone extractor (24) and the compounds were eluted from the extractor with hot methanol. Ultraviolet spectra of the methanolic solutions were run and the solutions were then co-spotted in three different solvent systems. Arbutin (hydroquinone-β-D-glucoside) was identified in fraction A by co-spotting and absorption maximum of 283 mμ. Ellagic acid was identified by co-spotting and absorption maximum of 253 mμ. Gallic acid was obtained from fraction D and identified by co-spotting and absorption maximum of 273 mμ. Hydroquinone was found both in the free state (fraction A) and in the acid hydrolyzed fraction (fraction D). Co-spotting identified its presence as did the absorption maxima, 289–290 mμ. Hyperin (quercetin-3-galac-

toside) was also found in fraction A and identified by co-spotting and absorption maxima of 360 and 255 mμ. Free quercetin was also identified in fraction A and by its absorption maxima of 370 and 252 mμ. The results of the co-spotting experiments are found in Table IV.

Ibrahim (15) recently isolated *o*-pyrocatechuic acid from various members of the *Ericaceae*, including *A. uva-ursi*. A standard sample[6] was chromatographed in six different solvent systems along with all of the plant phenolic fractions (A–G), and no evidence could be obtained for its presence in *A. columbiana* or *A. patula*. The six solvent systems used were BAW, BMA, CEF, TEF (*cf.* Table IV), BPA (benzene–pyridine–acetic acid, 36:9:5) and BDA (benzene–dioxane–acetic acid, 90:25:4).

Antibacterial–Antifungal Screen.—The small tube method of Catalfomo and Schultz (25) was used for screening the crude plant extracts and the compounds found to exist in the plants. Crude extracts consisted of skelly B–methanol (1:1) and 70% ethanol fractions (5 Gm./150 ml.) from each plant. These fractions were then dried *in vacuo* and redissolved in 70% ethanol shortly before use. The known compounds were also dispersed in 70% ethanol. Controls, tubes innoculated with the organism only, and blanks, tubes with the solvent and the organism, showed adequate growth. The results are shown in Table V.

[6] Obtained through the courtesy of Dr. R. V. Ibrahim, Alexandria, Egypt, U.A.R.

RESULTS AND DISCUSSION

A new procedure was devised in order to remove as many components of interest in one extraction procedure. Miscible solvents of diverse polarity had to be selected and experimentation demonstrated that a skelly B–methanol (1:1) mixture was best suited for this need.

Five compounds were isolated from the sterol/triterpene fraction of *A. patula*. Ursolic acid and uvaol had been previously identified in the genus but β-amyrin, β-sitosterol, and nonacosane had not. All of the compounds were identified in *A. columbiana* by means of co-chromatography except for nonacosane which was also isolated.

The new extraction solvent also removed phenolic components which were fractionated from other components by physical and chemical methods and were separated from one another by TLC. Ultraviolet spectra and co-spotting verified the presence of two flavonoids, quercetin and hyperin; two quinonoids, arbutin and hydroquinone; and two phenolic acids, gallic and ellagic acid. *o*-Pyrocatechuic acid, previously assumed to be widespread in the family, could not be shown to be present in the two species investigated.

Antibacterial–antifungal screening was conducted on the crude plant extracts and the compounds found to be present in the plants. All of the crude extracts demonstrated fungicidal activity against *Trichophyton mentagrophytes* which could not be attributed to the known compounds. Further frac-

tionation of these extracts is in progress to determine wherein this activity may reside. The skelly B–methanol extract from *A. columbiana* also demonstrated fungicidal activity against *Candida albicans*, whereas neither of the *A. patula* extracts did. In contrast, the skelly B–methanol extract of *A. patula* was antibacterial against *Escherichia coli* but neither *A. columbiana* extract was so effective.

Hydroquinone was effective against both bacteria, *E. coli* and *Staphylococcus aureus*, whereas the glycoside arbutin was effective only in higher concentrations against *S. aureus*.

Quercetin demonstrated equivocal results against all organisms except *S. aureus*, whereas no such activity was noted with the galactoside, hyperin.

The triterpene, β-amyrin, demonstrated the widest spectrum of activity among the triterpene/sterols and the triterpene alcohol, uvaol, contained no activity.

Newer applications of techniques for the extraction, fractionation, and identification of compounds from two diverse chemical classes have been demonstrated. Eleven compounds from two previously uninvestigated plants have been identified and the microbiological activity of the crude plant extracts and the compounds have been recorded.

Catecholamine-Induced Release of 5-Hydroxytryptamine (5-HT) from Perfused Vasculature of Isolated Dog Intestine

By T. F. BURKS* and J. P. LONG

The ability of exogenously administered epinephrine, norepinephrine, and tyramine and stimulation of sympathetic nerves to release 5-HT from the vasculature of isolated dog intestinal segments has been investigated. These stimuli were all found to produce significant release of 5-HT. Administration of an α-receptor blocking agent (tolazoline) significantly reduced the 5-HT release by norepinephrine but not by epinephrine.

IT HAS BEEN demonstrated recently (1) that isolated segments of dog small intestine release 5-hydroxytryptamine (5-HT) into physiological solution perfusing the vasculature. Stimuli which produced smooth muscle contraction or enhanced motility of the perfused segment increased its release of 5-HT. Such stimuli as acetylcholine, angiotensin, $BaCl_2$, increased intraluminal pressure, and scratching the serosal surface of the gut section all significantly increased 5-HT release. It was felt that such increased 5-HT release could simply be due to mechanical distortion of the tissues produced by the various stimuli.

More recent work indicates that the above explanation may be oversimplified since some stimuli that relax the intestinal musculature also release 5-HT.

METHODS

Adult mongrel dogs of either sex weighing 8 to 15 Kg. were anesthetized with 15 mg./Kg. of sodium thiopental and 250 mg./Kg. of sodium barbital administered intravenously. The small intestine was exposed and a small branch of the superior mesenteric artery with its juxtaintestinal arterial fan was cannulated with polyethylene tubing. The artery was perfused with warmed Krebs bicarbonate solution which was aerated by bubbling with a mixture of 95% oxygen and 5% carbon dioxide. Perfusion pressure, provided by use of a Sigmamotor model T-8 constant-flow peristaltic infusion pump, was maintained at 80–100 mm. Hg and was measured from a T-tube between the pump and the artery by a Statham pressure transducer and recorded on an Offner Dynograph (type RS). Since flow into the artery was held constant, changes of perfusion pressure were then proportional to changes in arterial resistance.

After flow was established through the artery, the associated vein was cannulated so that the venous effluent could be collected. Ligatures were tied around the intestinal segment supplied by the cannulated arterial fan and the segment surgically removed, placed on a cotton pad, and covered with a warm, saline-soaked gauze sponge. The section was then kept warm by use of an incandescent lamp.

In some of the experiments a balloon, attached to a Statham pressure transducer, was tied into the lumen of the intestinal section and intraluminal pressure recorded on either an Offner Dynograph or a Gilson (GME) polygraph.

In one preparation the venous effluent from the dog intestinal segment was superfused over an isolated uterus horn from an oestrus rat.

A constant recording of 5-HT concentration in the venous effluent was obtained by use of a flow-through cell in an Aminco-Bowman spectrophotofluorometer. The excitation monochromator of the spectrophotofluorometer was set at 295 mμ and the fluorescence monochromator was set at 330 mμ where the native fluorescence of 5-HT is maximal at neutral to slightly alkaline pH. Calibration of the instrument was performed with appropriate concentrations of 5-HT dissolved in Krebs solution placed in the cell. An illustration of the preparation employed is provided in Fig. 1.

The 5-HT concentration in the venous effluent was recorded in mcg./ml. of the effluent solution, then this figure was divided by the weight (to the nearest 0.1 Gm.) of the gut segment to give a 5-HT estimation of ng./ml./Gm. of wet tissue. The data are all reported in ng./ml./Gm.

In preparations from 15 dogs, the periarterial sympathetic nerves were isolated and fixed on a stimulating electrode. Nerve stimulation was performed with a Grass Instrument Co. model S4 stimulator. Parameters of stimulation were within the following ranges: frequency 20–30 c.p.s., duration 10–20 msec., and at 6–15 v. for 5 30 sec.

Test drugs were injected in volumes of 0.002–0.1 ml. intra-arterially *via* the arterial cannula. Agents employed were l-epinephrine hydrochloride, l-norepinephrine bitartrate (calculated as the base), tyramine hydrochloride, and tolazoline hydrochloride.

Experiments were so designed that each preparation served as its own control, and statistical comparisons were performed by the Student's t test (2). A P value equal to or less than 0.05 was considered significant.

RESULTS

The initial observation responsible for this series of experiments is illustrated in Fig. 2. It was noted that stimulation of the periarterial sympathetic nerve of the isolated intestinal section resulted in enhanced contraction of the rat uterus being superfused with the venous effluent from the gut segment.

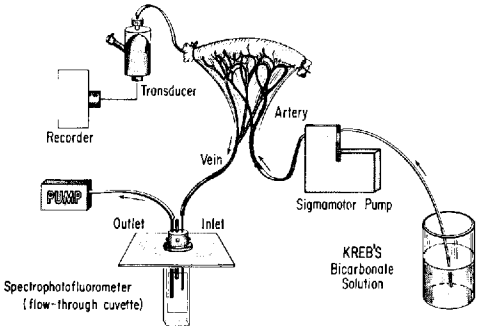

Fig. 1.—A drawing of the isolated intestinal preparation employed. A T-tube was inserted between the pump and the artery to monitor perfusion pressure. Intraluminal pressure was measured from a baloon in the lumen of the isolated intestinal segment. The effluent solution from the cannulated vein could be allowed to superfuse a rat uterus or to flow through the cell for analysis. A quartz baffle plate divides the quartz cell into two compartments, and the solution flows past and around this divider.

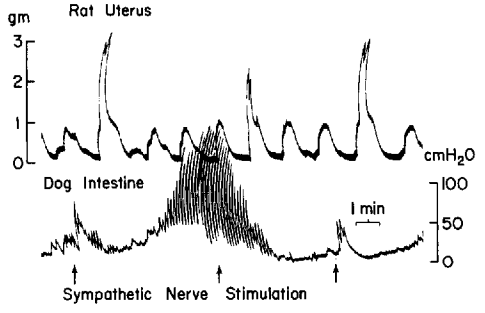

Fig. 2.—Key: top, tracing produced by an isolated rat uterus superfused with venous effluent from the dog intestinal segment; bottom, intraluminal pressure of intestinal segment. Stimulation of the periarterial sympathetic nerves of the intestinal segment produced contractions of the rat uterus which were not blocked by atropine.

Since norepinephrine usually produces only relaxation of the rat uterus, it was felt that the stimulation of the sympathetic nerve and catecholamine administration might release 5-HT.

In preparations from 16 dogs, epinephrine (4 mcg./dose) was found to significantly release 5-HT from the intestinal segment (see Table I). The musculature of the segment was relaxed by the epinephrine, but often enhanced activity of the section was observed after the period of relaxation. This increased activity occurred after the release of 5-HT and may have been produced by the released 5-HT (Figs. 3 and 4). It was noted that repeated injections of epinephrine into the vasculature of the section released progressively diminishing amounts of 5-HT. On some occasions when there was no longer any release of 5-HT by the epinephrine, 2-mcg. doses of acetylcholine were injected, and these treatments invariably released additional 5-HT.

Injected norepinephrine (4 mcg./dose) behaved qualitatively in the same manner as epinephrine (Figs. 3 and 4). In preparations from 10 dogs, the norepinephrine significantly ($p < 0.01$) increased 5-HT release (see Table I).

Since the above catecholamines were found to be active as releasers of 5-HT from the perfused intestinal vasculature, tyramine (200 mcg./dose) was injected to determine if endogenous catecholamines would similarly produce 5-HT release. In preparations from 10 dogs, the administered tyramine resulted in 5-HT release ($p < 0.01$) which is illustrated in Fig. 3 and Table I.

In perfused intestinal segments from 15 dogs, stimulation of the periarterial sympathetic nerves resulted in significant ($p < 0.01$) release of 5-HT (see Table I). The effects of nerve stimulation on intraluminal pressure were no different from that observed following the above agents (Fig. 4). Similarly, after repeated nerve stimulation there was loss of ability to release additional 5-HT, in which case administration of epinephrine, norepinephrine, or tyramine would not usually produce any 5-HT release. On some occasions administration of 2 mcg. of acetylcholine under these conditions would produce some 5-HT release.

A separate study was undertaken to determine if 5-HT release by the catecholamines was dose related. Five isolated intestinal segments were prepared from each of 13 dogs. One segment received first a low (0.2 mcg.) dose of epinephrine followed by a high (0.4 mcg.) dose of epinephrine; a second preparation received the same treatments but in reverse order; a third section received a low (0.3 mcg.) dose of norepinephrine followed by a high (0.6 mcg.) dose of norepinephrine; a fourth seg-

ment received the norepinephrine doses in the reverse order; a fifth segment first received tolazoline hydrochloride (250 mcg./dose) then 0.6 mcg. norepinephrine and 0.4 mcg. epinephrine, the order of the latter two agents being alternated from dog to dog. The treatments were randomly applied to each of the five loops from each dog. The results of these experiments may be seen in Tables II and III.

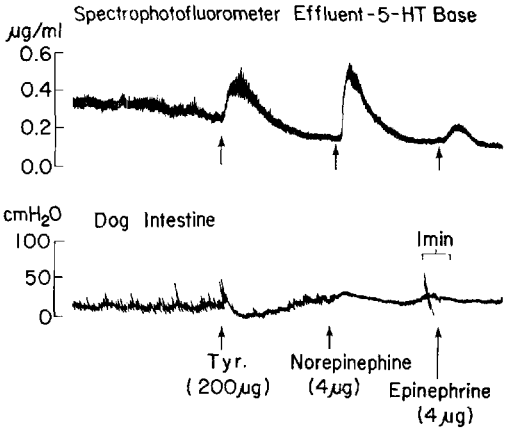

Fig. 3.—Demonstration of release of 5-HT from dog intestinal segment by tyramine (Tyr.), norepinephrine, and epinephrine. Key: top, continuous recording of 5-HT concentration in venous effluent; bottom, intraluminal pressure in dog intestinal section. The relatively small response to epinephrine was due to its being third in this particular series.

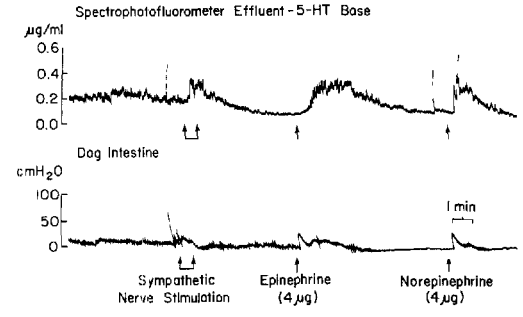

Fig. 4.—Release of 5-HT by 30-sec. stimulation of periarterial sympathetic nerves, epinephrine, and norepinephrine. Key: top, 5-HT content of venous effluent; bottom, intraluminal pressure of intestinal segment.

A dose-response curve was obtained for 5-HT release by the catecholamines and this release appeared to be related to pressor responses observed. It was noted that tolazoline alone was capable of producing pressor responses and releasing 5-HT and is therefore included in Table II.

Comparison of the responses to epinephrine and norepinephrine after tolazoline to the mean responses produced by the same doses of these agents in the absence of tolazoline revealed that while the pressor response to 0.4 mcg. epinephrine was significantly antagonized ($p < 0.05$) there was no statistically significant difference in 5-HT release by this agent whether or not tolazoline was present. On the other hand, the release of 5-HT by 0.6 mcg. norepinephrine was significantly antagonized by tolazoline ($p < 0.05$) but there was no significant antagonism of the norepinephrine pressor response. These data are summarized in Table III.

DISCUSSION

The ability of catecholamines, whether endogenous or added exogenously to release 5-HT from perfused dog intestinal segments does not constitute evidence for the hypothesis that intestinal 5-HT is released only by mechanical distortion of that organ. Since the catecholamines relax the musculature of the dog intestine and also release 5-HT, the above hypothesis must be considerably modified. It is possible that there is more than one method (perhaps there are many) by which the intestine can be stimulated to release 5-HT. Some agents, such as acetylcholine, $BaCl_2$, angiotensin (1), increased intraluminal pressure (1, 3), hydrochloric acid (4), and intraluminal hypertonic sucrose solutions (5) could produce intestinal contractions with incidental, secondary release of 5-HT. Catecholamines, however, may release 5-HT in some other manner, perhaps by a more direct mechanism. The 5-HT released by these latter agents may represent a second source or "pool" of 5-HT, perhaps another binding site in the intestinal mucosa, which is separate or distinct from that released by mechanical deformation. Evidence for this may be represented by the fact that acetylcholine can still release 5-HT after catecholamines have lost the ability to do so; the converse situation has also been observed.

The means by which the catecholamines release 5-HT in the dog intestine is open to speculation.

[a] Number of animals employed in each experiment. [b] Mean ± standard error. [c] Significantly ($p < 0.05$) decreased after tolazoline.

Perhaps the most plausible explanation would be that of displacement by the catecholamine of 5-HT at its mucosal binding sites. Stacey has stated (6) that tyramine, for example, can inhibit the uptake of 5-HT by blood platelets. Bertler *et al.* (7) have found that injected norepinephrine can replace 5-HT in its pineal gland sympathetic nerve storage sites. Similarly, administered metaraminol causes a pronounced depletion of pineal 5-HT. Born *et al.* (8) have suggested as an intracellular storage site for 5-HT, a 5-HT–ATP complex similar to that proposed for catecholamines in the adrenal medulla. In the fraction of the dog small intestine rich in 5-HT (mucous membrane) there is a molar ratio of approximately 3 to 1 between 5-HT and ATP (9). So it is quite possible that either exogenously administered catecholamines or those released by sympathetic nerve stimulation or tyramine could simply displace 5-HT from its storage granules in the intestinal mucosa.

More evidence will be required to demonstrate a positive role for 5-HT as a neurotransmitter in autonomic innervation of the small intestine. There have been some data presented, however, that may help define any such function. Van Harn found that, in the cat, stimulation of the thoracic sympathetic chain is inhibitory when the jejunum is spontaneously active but may cause an increase in activity in a previously inactive gut (10). It seems possible from the data reported in this communication, that the intestinal stimulation reported by Van Harn could have been due to 5-HT release. Klingman (11) has reported that immunosympathectomized rats have decreased levels of norepinephrine in their intestines, but that there is no alteration in that tissue in DOPA-decarboxylase activity. Since DOPA-decarboxylase and 5-hydroxytryptophan decarboxylase may be the same enzyme (12), it would be interesting to know whether there is a concomitant alteration of 5-HT levels in immunosympathectomized animals. A decrease in gastrointestinal 5-HT following immunosympathectomy could suggest that an intact sympathetic system is required for 5-HT elaboration, storage, or participation in transmission. An increase in 5-HT levels might indicate that there is competition between 5-HT and catecholamines for common storage sites in the intestine.

Ahlquist (13) states that the canine intestine has both α and β adrenergic receptors which produce intestinal inhibition. There may be "receptor sites" in the dog intestine with which catecholamines interact to produce 5-HT release which are different from the usual α and β receptors. The present data indicate that by use of an α-receptor blocking agent, tolazoline, some separation of pressor activity in the intestinal vasculature and 5-HT-releasing activity can be achieved with epinephrine and norepinephrine.

There may be some evidence for a homeostatic role of 5-HT in the intestine, as has been proposed for this substance in the cardiovascular system (14). It has previously been reported (1) that 5-HT release from the dog intestine can occur after either an increase or a decrease in intraluminal pressure. Similarly, agents that produce intestinal constriction (acetylcholine) or relaxation (catecholamines) similarly produce 5-HT release. Van Harn's experiments (10) contain related suggestions. It could be proposed that 5-HT somehow serves a buffer capacity, or as one component of a buffer system for intestinal motility. Any such function, of course, as yet eludes elucidation.

Effect of pH on the *In Vitro* Absorption of Flufenamic Acid

By ARMANDO J. AGUIAR and RICHARD J. FIFELSKI

The effect of pH on the *in vitro* absorption of flufenamic acid is studied using the "everted sac" technique. The study reveals that the passage of this drug through the gut membrane is by passive diffusion. The amount diffusing through is dependent on the pH. Using Fick's diffusion law, a method is presented to calculate the apparent permeability constant at each pH value, and to determine the permeability constant. The relative surface area of the membrane through which diffusion of the drug takes place is estimated from the amount of "bound" drug.

AFTER ORAL administration, a drug to act systemically must be absorbed from the gastrointestinal tract. The rate of absorption is dependent on two independent processes: the rate of solution of the drug in the media and its rate of permeation through the gastric wall or intestinal lumen. For a relatively insoluble drug (less than 0.01 mg./ml.), the rate of solution becomes a fundamental factor affecting the rate of absorption. The reason is that unless the drug dissolves at a sufficiently rapid rate the necessary build-up of an effective concentration at the site of absorption will never occur. On the other hand, a relatively soluble drug will immediately saturate the system. In this case, the permeation rate becomes the important factor.

There have been many *in vitro* and *in vivo* studies (1, 2) dealing with the passage of drugs through the gut. However, as far as the authors have been able to determine, there has been no attempt to treat the data quantitatively as a diffusion phenomenon.

This study is concerned with the effect of pH on the *in vitro* absorption of flufenamic acid,[1] [*N*-(α,α,α-trifluoro-*m*-tolyl) anthranilic acid], with a pKa of 3.9 and solubility of 1 mg./ml. at pH 7.0. Based on Fick's law of diffusion, the apparent permeability constant at each pH value is calculated and the permeability constant is determined. A method is presented to estimate the relative surface area of the gut membrane through which diffusion of the drug takes place.

THEORETICAL CONSIDERATIONS

It has been known for many years (1) that cellular permeability to weak electrolytes may be dramatically affected by relatively small changes in the pH of the suspending medium. Although this phenomenon is of general significance in all cells, only recently were good examples described in the case of the intestinal absorption (3–8).

Absorption involves the transfer or permeability of materials from the intestinal lumen into the mucosal blood and lymph vessels. In the classification of permeability, a primary division is made between passive diffusion and special mechanisms such as active transport, facilitated diffusion, and pinocytosis. It has been shown that most drugs are absorbed by passive diffusion (3–5, 9).

Passive or simple diffusion describes the passage of a molecule across a barrier from a region of high to a region of low concentration. This phenomenon is quantitatively described by Fick's law (10), which states that the driving force which causes the transfer of a substance from regions of high to low concentrations is proportional to the concentration gradient or,

$$\frac{ds}{dt} = \frac{K\,(A)\,(C_0 - C_1)}{h} \qquad \text{(Eq. 1)}$$

where

$\frac{ds}{dt}$ = rate of movement of solute, s in mcg./min.,
A = area of the membrane in cm.^{2},
K = constant,
C_0 = amount of solute on the outside in mcg.,
C_1 = amount of solute on the inside in mcg.,
h = thickness of the membrane in cm.

When dealing with membranes, such as biological specimens, the thickness, h, of the membrane is not known. This factor is then commonly combined with the constant K to give a new constant P_1, the apparent permeability constant. Equation 1 then becomes

$$\frac{ds}{dt} = P_1(A)(C_0 - C_1) \qquad \text{(Eq. 2)}$$

If the permeability rate follows Eq. 2, a plot of amount *versus* time should be linear initially. The slope (l_1) of this line is equal to the change in amount with time, *i.e.*, to $\frac{ds}{dt}$.

Differentiating Eq. 2 with respect to area (A), we get

$$\frac{d^2s}{dt} = dA\,P_1(C_0 - C_1) \qquad \text{(Eq. 3)}$$

or

The authors thank Mr. D. Russell, Bioassay Department, for supplying the intestinal segments and Dr. P. Bass, Experimental Therapeutics Department, for suggestions during the initial phases of this work, and Dr. L. M. Wheeler for his interest.
[1] To be marketed as Arlef, Parke, Davis & Co., Detroit, Mich.

$$P_1 = \frac{d^2s}{dtdA(C_0 - C_1)} \qquad \text{(Eq. 4)}$$

The term $d^2s/dtdA$ can be evaluated by plotting the slope l_1 *versus* the area A and determining the slope l_2 of the resulting line. l_2 is then numerically equal to $d^2s/dtdA$. Knowing $C_0 - C_1$, P_1 can be calculated from Eq. 4.

If the permeation rate is measured at different pH values, P_1 can be calculated for each pH. Furthermore, the fraction of unionized moiety of the drug at different pH values can be determined theoretically, and assuming that it is only the unionized species that traverse the barrier, the permeation constant P can then be calculated, from the relationship

$$P = \frac{P_1}{U} \qquad \text{(Eq. 5)}$$

where U is the fraction of the unionized drug. P should then be a constant and independent of the pH.

The determination of the surface area of the membrane is difficult, particularly due to the presence of the villi on the surface of the intestinal wall. In this study, the concept of relative surface area is used. The apparent permeability constants derived are, therefore, relative; nevertheless, they are useful for comparing the transfer of the drug under different conditions.

Flufenamic acid is "bound"[2] to the intestine. At a particular concentration, the quantity "bound" is directly proportional to the surface area exposed or one can write

$$Q = kA \qquad \text{(Eq. 6)}$$

where Q = quantity of drug "bound" at a given concentration, k = constant, A = surface area.

If, then, for a series of experiments, at a particular concentration of the drug, one determines an average Q and assumes that A is 1, for the series, k can be calculated. This k can then be used to calculate other relative surface areas if the concentration of "bound" drug is known.

METHODOLOGY

To study adsorption of drugs both *in vivo* and *in vitro* procedures have been used. The selection of the method depends on the type of information desired. In this connection, Laster (11) points out that *in vivo* methods, *e.g.*, measuring the disappearance of a test substance from the gut or its appearance in the body fluids, tend to yield over-all results determined by a number of processes of which absorption is only one. On the other hand, he states that if excised intestinal tissue is studied *in vitro*, discrete absorption patterns may be established. However, it must be remembered that excised segments are deprived of their blood and lymph flows and depend on their oxygen supply on the diffusion of the gas across the epithelium.

From a number of *in vitro* methods available to study absorption, the authors used in these studies the everted-sac technique as modified by Crane and Wilson (12).

[2] The use of the term "bound" does not imply adsorption. The exact nature of physical and/or chemical interaction of flufenamic acid with the gut membrane is being investigated and will be the subject of a future presentation.

An excised segment (about 6 cm. in length) of the small intestine of a golden hamster is everted so that the mucosa faces outward. The segment is suspended in a glass tube, with a side arm, by tying to a cannula which in turn is supported by a rubber stopper. Forty-five milliliters of a buffered solution at the desired pH containing a known amount of the drug is added to the tube and bathes the mucosal surface of the intestine. A mixture of 95% oxygen and 5% carbon dioxide is bubbled through the solution through a longer cannula. Two milliliters of the buffer (without the drug) is placed inside the sac. The whole assembly is placed in a constant-temperature bath set at 37° ± 0.5°.

At known time intervals, the solution inside the intestine is removed for assay of flufenamic acid. Two milliliters of buffer is added to the inside of the intestine to rinse out any adhering drug and the solution is assayed. At the same time period, 1 ml. of the outside solution is removed for assay.

At the end of a run, the intestinal segment is taken out from the assembly, both surfaces washed 3 times with water, dried at 65°, powdered and extracted with 10 ml. of 0.1 N sodium hydroxide solu-

tion to remove any "bound" drug. It was necessary to follow this procedure to remove the "bound" drug since it adhered quite strongly to the gut membrane and could not be removed by simple washing with water or buffer solutions.

All samples are assayed using an Aminco Bowman spectrophotofluorometer, employing the assay procedure of Glazko and Dill (13).

The composition of the buffer used is:

	mmoles/L.
Sodium chloride	145
Potassium chloride	4.56
Calcium chloride	1.25
Sodium phosphate (dibasic)	1.33
Sodium phosphate (monobasic)	0.33
Distilled water	*q.s.*
pH of buffer 7.2	

The buffer is adjusted to pH 5.0, 3.9, and 2.5 by adding 20 mmoles of aspartic acid to the above solution and adjusting the pH with sodium hydroxide or hydrochloric acid solution.

RESULTS AND DISCUSSION

The quantity of drug which permeates through the intestine at different time intervals at pH 7.2 is given in Table I. This quantity represents the sum of the assays of the sample withdrawn from the inside of the intestinal segment, and the 2-ml. sample used to wash the inside. The initial concentration of the drug in the outside solution is 20 mcg. of flufenamic acid per ml. The results of four separate determinations are shown.

The quantity of "bound" drug for each of the runs and the relative surface area calculated from this are given in Table II. It is apparent from Table II that th rcelative surface area of the gut membranes, as gauged from the "bound" drug, varies considerably. This was due to the difference in thickness of the gut segments of the different animals used in this study.

The quantity of drug which permeates at pH 7.2 is plotted against time in Fig. 1. The slope of the

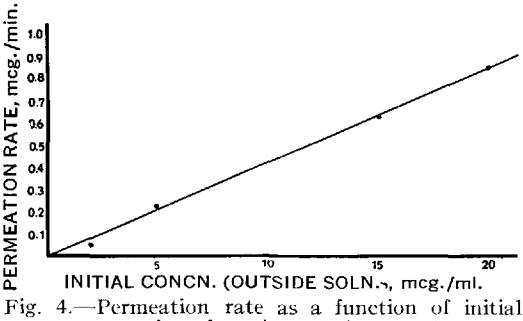

Fig. 4.—Permeation rate as a function of initial concentration of outside solution, pH 5.0.

Similarly, the quantity of drug which permeates at pH 5.0, when a concentration of 20 mcg./ml. is maintained on the outside, is given in Table III and shown in Fig. 3.

The quantity of "bound" drug, relative surface area, and rate of permeation at pH 5.0 are given in Table IV.

If Fick's law is applicable, the permeation rate should vary with the concentration of the drug in the outside solution, since the gradient across the membrane is proportional to the concentration. To test this hypothesis, permeation rates were determined at pH 5, using solutions containing 2, 5, and 15 mcg. of the acid per ml. The results are given in Tables V, VI, and VII. For convenience, the rate of permeation and concentration of "bound" drug are also included in these tables.

A plot of permeation rate *versus* concentration at pH 5.0 is shown in Fig. 4. It is apparent that a linear relationship exists between the rate and concentration of the outside solution. This is in agreement with Fick's law.

The quantity of drug "bound" in the membrane is also proportional to the concentration outside. Thus a plot of "bound" drug *versus* concentration should be linear, which is shown in Fig. 5. This is not surprising if one considers the nature of the membrane barrier. If one assumes that it is at least two to three cells thick, at a given time there is a certain amount of drug in the membrane. The quantity is proportional to the concentration gradient which in turn is determined by the concentration of the solution.

At low pH values, the solubility of flufenamic acid is limited; therefore, it is not possible to carry out studies using solutions containing 20 mcg./ml., as is done at pH 7.2 and 5.0. The studies at pH 2.5 and 3.9 are, therefore, carried out using solutions containing 2 mcg. of the drug per ml. In order to have a basis for comparison, the permeation rates for 20 mcg./ml. concentration are then computed from the value of 2 mcg./ml. It is felt that this procedure is valid since the concentration dependency should hold at pH 2.5 and 3.9 as was shown at pH 5.0.

The data are given in Tables VIII, IX, and X, and a plot of permeation rate *versus* relative surface area at these pH values is shown in Fig. 6.

pH	Unionized Drug, %	$P_1 \times 10^{-4}$	$P \times 10^{-4}$
7.2	0.05	2.6	52
5.0	7.36	3.7	50
3.9	50.0	29.1	58
2.5	96.19	52.0	54

The apparent permeability constants P_1 at each pH value is calculated using Eq. 4. This is shown in Table X, together with the values for the permeability constant P, calculated from Eq. 5, and the per cent of unionized drug.

From Table X it is evident that the permeability constant P derived for measurements at each pH value is in excellent agreement. Furthermore, it is apparent that at pH 2.5 the permeation of flufenamic acid is 20 times faster than at pH 7.2. The study also shows that flufenamic acid follows the postulation (2–4, 8) that it is only the unionized moiety of the drug that passes through a cell, due to its lipoid solubility hypothesis. Since at pH 2.5 the drug is approximately 96% unionized, it is to be expected that the rate would be much faster than at pH 7.2, at which only 0.05% of the drug is in the unionized form.

In this study a procedure is described defining the permeation of flufenamic acid in terms of Fick's diffusion law. Perhaps this approach could be used in describing the passage of other drugs through the gut membrane, particularly those drugs which have an affinity for binding with the membrane. It is also suggested that in this type of measurement, the quantity of drug in the membrane should be determined. In some instances, as was found in this study, this can be considerable.

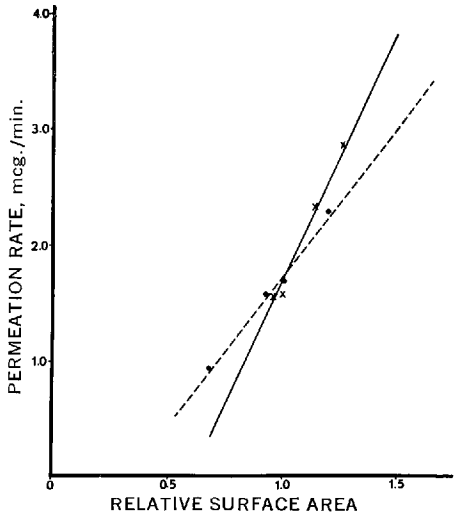

Fig. 6.—Plot of permeation rate *versus* relative surface area at pH 2.5 (×) and pH 3.9 (●).

Bioassay of Hypocholesterolemic Steroids

By R. M. TOMARELLI, T. M. DOUGHERTY, and F. W. BERNHART

The hypocholesterolemic activity of a number of natural and synthetic steroids was determined in a 3-day oral assay using male rats with hypercholesterolemia of dietary origin. The reduction in serum cholesterol was linearly related to the log dose of the administered natural or modified estrogen; the effect was evident 6 hr. after oral administration and had reached a maximum in 24 to 30 hr. Active steroids lowered the elevated serum phospholipids, cholesterol/phospholipid ratios, triglycerides, α and β lipoproteins, and β/α lipoprotein ratios, but not the elevated serum globulins. The effect of the steroids on body weight permitted a semiquantitative estimation of feminizing activity.

THE LOWER incidence of atherosclerotic heart disease in premenopausal women than in men and the demonstration that estrogen administration will lower serum lipids in man and animals have prompted a search for antilipemic steroids that have little or no feminizing activity (1,2). The present report describes the development of a 3-day bioassay for the screening of orally active hypocholesterolemic compounds and presents the results obtained with a number of natural and synthetic steroids.

EXPERIMENTAL

Analytical Procedures.—The following methods were used for determining serum constituents: cholesterol, Zlatkis *et al.* (3) and Technicon Auto-Analyzer procedure (4); triglyceride, van Handel and Zilversmit (5); phospholipid, Whitley and Alburn procedure (6); protein, Lowry *et al.* (7).

Serum lipoproteins were estimated from the cholesterol content of serum protein fractions separated by paper electrophoresis. The relative proportions and locations of the protein fractions were determined on strips stained with azocarmine G; cholesterol associated with these areas was eluted from duplicate unstained strips and determined colorimetrically. The designation of protein fractions as α or β lipoproteins was according to Searcy *et al.* (8).

Assay Procedure.—The assay animals were male rats with serum cholesterol levels elevated 7 to 10 times normal by the feeding of a hypercholesterolemic diet. The diet used was essentially that of Nath *et al.* (9); it consisted of 18% casein,[1] 25% hydrogenated coconut oil,[2] 4% salts, (U.S.P. XIV) 1% cholesterol, 0.5% cholic acid, 0.2% choline chloride, an adequate amount of all required vitamins (10), and sucrose to make 100%. Groups of 70 to 80 young male Sprague-Dawley rats, 100–120 Gm. body weight, were prepared for assay by feeding this diet *ad libitum* for 3 weeks. Average weight gain during this period was 70–100 Gm. Average serum cholesterol levels determined on 0.01 ml. of serum from tail blood varied from 600–1000 mg.%.

The rats were divided into groups of six with nearly equal average body weights and serum cholesterol levels. Steroids were given orally for 3 days in 0.2 ml. cottonseed oil solution; the control group received oil vehicle alone. Three groups received graded doses of an appropriate standard steroid; test compounds were administered at a single 1-mg. dose level. On the morning of the fourth day the rats were weighed and serum cholesterol was determined. The average serum cholesterol values of the three standard groups, plotted against the log dose, gave a linear relationship from which the hypocholesterolemic activity of the test compounds were evaluated. Activity was expressed relative to the standard.

The effect of the test steroid on body weight was also evaluated by comparison with that of the standard. Since estrogen administration to a male rat will inhibit food consumption and retard body weight gain in a young animal or cause weight loss in an adult (11), a lack of effect of the steroid on body weight was accepted as an indication of a low degree of feminizing activity. Loss of weight, being nonspecific, could be considered as only suggestive evidence of feminization. The effect of the estrogenic steroids on body weight and food intake was roughly proportional to the log dose, particularly in young animals (Fig. 1). For semiquantitative evaluation the effects were graded 0 to +3, with 0 equal to the control value and +1 to that of the standard steroid. Pair-feeding experiments showed that the reduction in the intake of food (and cholesterol), comparable to that found in rats treated with estrogen for 3 days, had no appreciable effect on serum cholesterol concentration.

Fifteen days after the completion of a test, serum cholesterol was again determined and the rats regrouped for the next test which started 4 days later. Each group of hypercholesterolemic rats were routinely used for 4 to 6 assays.

The 3-day assay period followed by the 19-day rest period was selected after time studies revealed that serum cholesterol levels (*a*) decrease measurably about 5 hr. after oral administration, (*b*) drop to a constant value within 24–28 hr., and (*c*) return to pretest levels 5 days after the last dose of the steroid is given (Fig. 2). In earlier assays in which the steroids were administered for 3 weeks, no significant differences were found in the serum cholesterol levels determined at weekly intervals (Fig. 3).

The steroid used as a standard in all the tests reported in the present study was *dl*-13β-ethyl-3-methoxy-8α-gona-1,3,5(10)-trien-17β-ol (Wy-3359). This recently synthesized compound (12) has an antilipemic activity by subcutaneous injection 2.6

Received July 11, 1966, from the Research Division, Wyeth Laboratories, Radnor, Pa. 19101.
Accepted for publication August 5, 1966.
The authors are indebted to S. Savini for technical assistance throughout this study, to R. Fenichel and W. Bechmann for the lipoprotein determinations, to R. Whitley for cholesterol and phospholipid determinations, to A. Consalvi for triglyceride determinations, and to C. Knebel for statistical analysis.

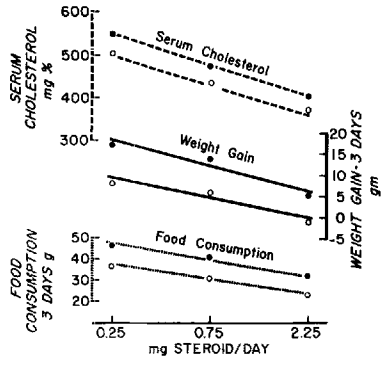

Fig. 1.—The effect of β-estradiol (○) and Wy-3359 (●) on serum cholesterol, weight gain, and food consumption of hypercholesterolemic rats.

times that of *d*-estrone but only 1% of its estrogenic activity (13). Oral administration of Wy-3359, 0.25 to 2.25 mg./day, resulted in a reasonably reproducible drop in serum cholesterol, 197 ± 10 mg./100 ml. (21 three-dose assays with six rats per group). This response, when expressed as per cent of the control, did not appear to be influenced either by the body weight in the 200–350-Gm. range, the initial serum cholesterol level, the season of the year, or the use of the animal in previous assays.

The confidence limits of the assay value could be estimated by any conventional procedure for a 4-point assay (three standards and one unknown) such as that of Gaddum (14). In practice, a convenient estimate of confidence limits was devised from the observation that the standard error was proportional to the average serum cholesterol level (9.2% ± 1.7). This value was calculated from the data obtained from 32 groups, six rats per group, which included controls and groups treated with a variety of steroids of different hypocholesterolemic activity. The 95% confidence limits were as follows: for compounds having activity near 25%, 7–75%; near 100%, 68–160%; and near 200%, 145–280%.

Serum Constituents.—Serum samples taken under routine assay conditions, *i.e.*, from unfasted rats after 3 days of oral steroid administration, were analyzed for a number of constituents in addition to cholesterol. Typical results are presented in Table I and Fig. 4. Compared with Purina chow-fed controls, the hypercholesterolemic rats had elevated serum proteins, phospholipids, cholesterol-phospholipid ratios, α and β lipoproteins, and β-to-α lipoprotein ratios. Serum triglycerides were slightly elevated with considerable individual variation presumably because of the unfasted state of the animal. The increase in the serum proteins was in the globulins, particularly in the β fraction (Fig. 4).

The oral administration of β-estradiol or Wy-3359 reduced all the lipid constituents (Table I); the decrease in cholesterol was relatively greater than that of phospholipids resulting in a reduced cholesterol–phospholipid ratio. Both α and β lipoproteins were reduced, the β considerably more than the α (Fig. 4). With increasing doses of Wy-3359, the β/α lipoprotein ratio of the hypercholesterolemic rat dropped from 1.08 to 0.59, approaching that of the chow-fed controls, 0.41. However, steroid administration had no effect on the elevated globulin fractions (Fig. 4); *i.e.*, only the cholesterol moiety of the globulin fractions was decreased.

Comparative Hypocholesterolemic Potencies.—Table II presents the hypocholesterolemic activity, as determined by the 3-day oral assay, of a number of natural and synthetic steroids. Many of these compounds have been studied previously by other investigators for antilipemic activity in the rat (see references in table). The most active compound by far was ethinyl estradiol, followed by estriol, β-estradiol, estrone, equilin, and equilenin, all with approximately equal activity. This order of activity is similar to that reported for oral estrogenicity (26). 17α-Estradiol was about half as active as the β isomer. The 3-methyl ethers of estrone and β-estradiol were slightly more active than the parent compounds. The Δ^4 steroids, methyltestosterone, progesterone, and norbolethone were inactive. The ineffectiveness of methyltestosterone corroborates the results obtained by Abel and Mosbach (20), who found that while the steroid had hypocholesterolemic activity in rats with normal or slightly elevated serum cholesterol, it was inactive in hypercholesterolemic animals.

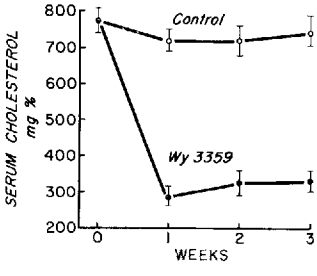

Fig. 3.—Effect of Wy-3359, 1 mg./day, 6 days a week for 3 weeks, on serum cholesterol.

Compared with the standard, Wy-3359, all of the natural steroid estrogens and diethylstilbestrol had a relatively greater adverse effect on body weight than on serum cholesterol reduction. The favorable separation of antilipemic and estrogenic activity found in the synthetic steroids, Wy-3271, Wy-3714, and Wy-6012, has previously been reported (21–23).

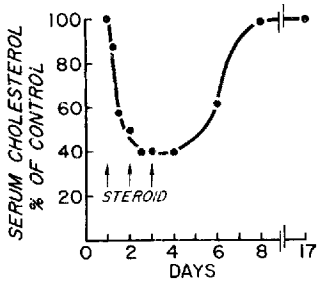

Fig. 2.—Time study of the effect of Wy-3359, 2.25 mg./day for 3 days, on serum cholesterol.

DISCUSSION

The hypocholesterolemic activity of a number of steroids, determined by this 3-day procedure with hypercholesterolemic rats, was in general agreement with values obtained by other procedures, indicating that a 3-day assay period is of adequate duration.

TABLE I.—EFFECT OF HYPOCHOLESTEROLEMIC STEROIDS ON SERUM CONSTITUENTS UNDER ASSAY CONDITIONS

Dietary Group[a]	Steroid[b]	Serum Constituent/100 ml. ± S. E. Protein, Gm.	Cholesterol,[c] mg.	Phospholipid, mg.	Chol./Phosp. Ratio	Triglyceride, mg.
Hypercholesterolemic	None	8.9 ± 0.3	643 ± 33	342 ± 4	1.87 ± 0.06	181 ± 36
Hypercholesterolemic	Wy-3359 0.75 mg.	8.8 ± 0.2	251 ± 16	235 ± 7	0.98 ± 0.06	70 ± 19
Hypercholesterolemic	β-Estradiol 0.75 mg.	8.9 ± 0.2	247 ± 37	267 ± 33	0.91 ± 0.05	39 ± 14
Chow	None	6.8 ± 0.1	73 ± 4	163 ± 10	0.46 ± 0.05	84 ± 21

[a] Six rats per group; average body weight 320 Gm. [b] Daily oral dose for 3 days. [c] Total cholesterol; the free cholesterol proportion of 20% was not affected by steroid administration.

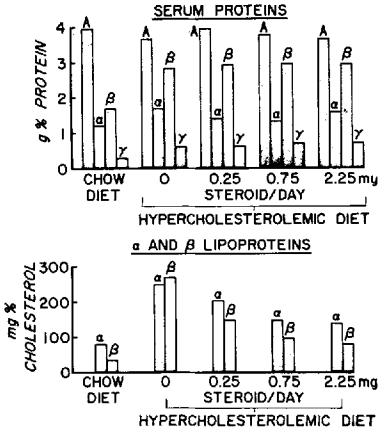

Fig. 4.—Effect of Wy-3359 on serum proteins and α and β lipoproteins. The β/α ratio was 0.41 for chow-fed rats and 1.08 for the hypercholesterolemic rats, but decreased in the latter to 0.87, 0.67, and 0.59 with the increasing doses of the steroid.

In addition to saving in time and material, the procedure has several other advantages over assays of longer duration with rats fed diets containing no added cholesterol. The small amount of hypercholesterolemic blood required for chemical analysis does not necessitate sacrifice of the animals; they can be used for a series of assays, and determinations can be run on the same animal before and after steroid administration, permitting a more precise measurement of effect. The decrease in food consumption, resulting from estrogenic steroid administration, did not lower serum cholesterol, presumably because of the high content of cholesterol in the diet and the brevity of the treatment.

While the rats varied in their response to the hypercholesterolemic diet, with serum values ranging from 400 to 1300 mg./100 ml., daily variations were small and the response to an antilipemic steroid was not related to the degree of existing hypercholesterolemia. The seasonal fluctuations in serum cholesterol in male rats fed diets without added cholesterol, noted by Thorp and Waring (24) and Edgren (27), has not been noted in our animals

TABLE II.—HYPOCHOLESTEROLEMIC ACTIVITY OF NATURAL AND SYNTHETIC STEROIDS

Common Name	Chemical Name	Hypocholesterolemic Activity	Body Wt. Effect	Ref.
Wy-3359 (std.)	*dl*-13β-Ethyl-3-methoxy-8α-gona-1,3,5(10)-trien-17β-ol	1.0	1	(12)

presumably because these changes are inconsequential in relation to the high concentration of serum cholesterol.

It should be noted that the above assay procedure is unsuitable for the screening of compounds that lower serum cholesterol by interfering with cholesterol biosynthesis, since this process is markedly reduced in rats fed high cholesterol diets (28, 29).

Interaction of Substituted Benzoic Acids with Cationic Surfactants

By LUCY S. C. WAN

The interaction of benzoic acid and a series of hydroxy, amino, chloro, and nitrobenzoic acids with surfactants of the quaternary ammonium type was studied by means of viscosity measurements. Only salicylic acid was found to interact with the surfactants leading to an increase in viscosity which reached a maximum at approximately the concentration at which the surfactant solution became saturated with salicylic acid. Apparently the interaction is specific and is limited to the *ortho* hydroxy substitution of benzoic acid, as no viscosity effect was observed with the *ortho, meta,* and *para* isomers of amino, chloro, and nitro substituted benzoic acids. In addition, sodium lauryl sulfate and cetomacrogol 1000 did not exhibit viscosity changes in the presence of salicylic acid. The viscosity effect was not related to pH.

BENZOIC ACID and its substituted isomers have been found to interact with a varied number of pharmaceutical compounds. Salicylic acid, *meta*, and *para* hydroxybenzoic acids have been shown to complex with polyethylene glycols (1) and with polyvinylpyrrolidone (2). In addition, the hydroxybenzoic acids have been found to interact with caffeine (3) and with theophylline and theobromine (4). Goodhart and Martin (5) reported that the solubilities of benzoic acid and its substituted isomers were greatest in the least hydrophilic of the polyethylene stearates. The solubilities of benzoic acid, salicylic acid, and *p*-hydroxybenzoic acid have also been found to increase in the presence of their sodium salts and the addition of a hydroxy group to the acid led to the formation of complexes (6).

Chelation of ferric and aluminum ions with salicylic acid and its amino, chloro, and nitro derivatives have been demonstrated by Foye and Turcotte (7). Results from the investigation of the action of Schardinger dextrins on benzoic acid and hydroxybenzoic acids did not seem to indicate a clear cut mechanism of the complexation involved. Apparently hydrogen bonding is an important factor in the cyclodextrin–hydroxybenzoic acid interaction (8). Schlenk and Sand (9) showed that the molecular ratio of cyclodextrin to certain benzoic acid derivatives was a function of the physical state of the complex. Monohalogenated benzoic acids and

Interaction of Substituted Benzoic Acids with Cationic Surfactants

By LUCY S. C. WAN

The interaction of benzoic acid and a series of hydroxy, amino, chloro, and nitrobenzoic acids with surfactants of the quaternary ammonium type was studied by means of viscosity measurements. Only salicylic acid was found to interact with the surfactants leading to an increase in viscosity which reached a maximum at approximately the concentration at which the surfactant solution became saturated with salicylic acid. Apparently the interaction is specific and is limited to the *ortho* hydroxy substitution of benzoic acid, as no viscosity effect was observed with the *ortho, meta,* and *para* isomers of amino, chloro, and nitro substituted benzoic acids. In addition, sodium lauryl sulfate and cetomacrogol 1000 did not exhibit viscosity changes in the presence of salicylic acid. The viscosity effect was not related to pH.

BENZOIC ACID and its substituted isomers have been found to interact with a varied number of pharmaceutical compounds. Salicylic acid, *meta*, and *para* hydroxybenzoic acids have been shown to complex with polyethylene glycols (1) and with polyvinylpyrrolidone (2). In addition, the hydroxybenzoic acids have been found to interact with caffeine (3) and with theophylline and theobromine (4). Goodhart and Martin (5) reported that the solubilities of benzoic acid and its substituted isomers were greatest in the least hydrophilic of the polyethylene stearates. The solubilities of benzoic acid, salicylic acid, and *p*-hydroxybenzoic acid have also been found to increase in the presence of their sodium salts and the addition of a hydroxy group to the acid led to the formation of complexes (6).

Chelation of ferric and aluminum ions with salicylic acid and its amino, chloro, and nitro derivatives have been demonstrated by Foye and Turcotte (7). Results from the investigation of the action of Schardinger dextrins on benzoic acid and hydroxybenzoic acids did not seem to indicate a clear cut mechanism of the complexation involved. Apparently hydrogen bonding is an important factor in the cyclodextrin–hydroxybenzoic acid interaction (8). Schlenk and Sand (9) showed that the molecular ratio of cyclodextrin to certain benzoic acid derivatives was a function of the physical state of the complex. Monohalogenated benzoic acids and

Accepted for publication September 13, 1966.

aminobenzoic acids have been reported to interact with cyclodextrins. The resultant complexes were considered to be due to inclusion formation and other attractive forces existing between host and guest molecules (10).

Higuchi and Drubulis (11) have attributed the interaction of hydroxyaromatic acids and their salts to a donor–acceptor type of mechanism. Urea has been shown to form complexes of low stability with benzoic acid while with salicylic acid it forms insoluble interaction products (12). Goudah and Guth (13) demonstrated that benzoic acid and its substituted compounds complexed with potato and arrowroot starch and postulated that attractive forces and inclusion formation were responsible for the interaction observed. Salicylic acid has been reported to exhibit the greatest binding tendency for polysorbate 80, followed by the *meta* and *para* isomers (14). This was identical with the findings of Blaug and Ebersman (15) for the behavior of hydroxybenzoic acids toward hyprose ester. Chakravarty, Lach, and Blaug (16) studied the interaction of hydroxybenzoic acids with polyoxyl 40 stearates based on solubility measurements.

It is the purpose of this investigation to study the interaction of hydroxybenzoic acids and the amino, chloro, and nitro derivatives of benzoic acid with cationic surfactants of the quaternary ammonium type as previous work has dealt with the interaction of pharmaceutical drugs with nonionic surfactants.

EXPERIMENTAL

Materials.—Recrystallized benzoic acid, m.p. 122–122.5° (Monsanto Chemicals Ltd.); recrystallized salicylic acid, m.p. 158–159°, recrystallized *m*-hydroxybenzoic acid, m.p. 205–205.5°, recrystallized *p*-hydroxybenzoic acid, m.p. 215–216°, recrystallized acetylsalicylic acid, m.p. 137–138°, recrystallized *o*-aminobenzoic acid, m.p. 145.5–146° (British Drug Houses Ltd.); recrystallized *m*-aminobenzoic acid, m.p. 174–175°, recrystallized *p*-aminobenzoic acid m.p. 187–188°, recrystallized *o*-chlorobenzoic acid, m.p. 140–141°, recrystallized *m*-chlorobenzoic acid, m.p. 155–156°, recrystallized *p*-chlorobenzoic acid, m.p. 240–241°, recrystallized *o*-nitrobenzoic acid, m.p. 146–147°, recrystallized *m*-nitrobenzoic acid, m.p. 140–141°, recrystallized *p*-nitrobenzoic acid, m.p. 241–242° (Hopkin and Williams Ltd.). The cationic surfactants were dodecyltrimethylammonium bromide,[1] tetradecyltrimethylammonium bromide,[1] and cetyltrimethylammonium bromide.[2] The anionic surfactant was sodium lauryl sulfate (Sipon Products Ltd.) and the nonionic surfactant was cetomacrogol 1000 B.P.C.[3] The melting points and the critical micelle concentrations of the surfactants are listed in Table I.

[a] Micro melting apparatus. [b] From surface tension measurements using the Du Nouy tensiometer.

Apparatus.—Portable Ferranti viscometer, model VL; Pye Tropical universal pH meter.

Measurement of the Solubilities of the Isomers of Hydroxy, Amino, Chloro, and Nitrobenzoic Acids in Surfactant Solutions.—Varying amounts of the organic acid were weighed into a series of 25-ml. graduated glass-stoppered cylinders containing the required concentration of surfactant. The cylinders were rotated in a thermostatically controlled water bath at 25 ± 0.1° for 24 hr. The end point was taken as the mean between a clear solution and one in which a slight excess of acid was present.

Measurement of Viscosity.—The required amounts of the organic acid were weighed into a series of 100-ml. volumetric flasks containing the required concentration of the surfactant. The flasks were rotated in a thermostatically controlled water bath at 25 ± 0.1° for 24 hr. The viscosities of the dispersions were measured using the portable Ferranti viscometer placed in a thermostatically controlled water bath at 25 ± 0.5°. The shear rates employed ranged from 483.0 to 78.56 sec. An interval of 30 sec. was allowed between any two readings.

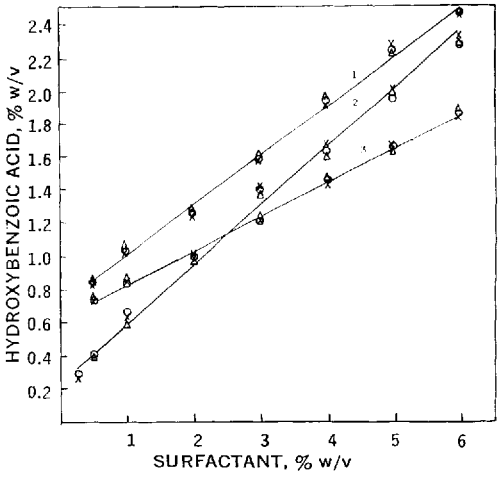

Fig. 1.—Solubilities of hydroxybenzoic acids in aqueous solutions of alkyltrimethylammonium bromide surfactants of varying chain length at 25°. Key: ×, dodecyltrimethylammonium bromide; O, tetradecyltrimethylammonium bromide; △, cetyltrimethylammonium bromide; *1*, *m*-hydroxybenzoic acid; *2*, salicylic acid; *3*, *p*-hydroxybenzoic acid.

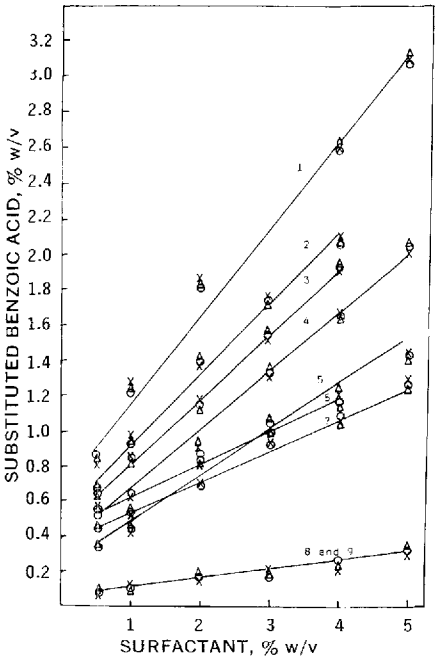

Fig. 2.—Solubilities of substituted benzoic acids in aqueous solutions of alkyltrimethylammonium bromide surfactants of varying chain length at 25°. Key: ×, dodecyltrimethylammonium bromide; O, tetradecyltrimethylammonium bromide; △, cetyltrimethylammonium bromide; *1*, *o*-nitrobenzoic acid; *2*, *m*-nitrobenzoic acid; *3*, *o*-aminobenzoic acid; *4*, *o*-chlorobenzoic acid; *5*, *m*-chlorobenzoic acid; *6*, *m*-aminobenzoic acid; *7*, *p*-aminobenzoic acid; *8*, *p*-nitrobenzoic acid; *9*, *o*-chlorobenzoic acid.

The shear rate was increased and then decreased for all viscosity measurements.

RESULTS AND DISCUSSION

Solubilities of Substituted Benzoic Acids in Surfactant Solutions.—Figures 1 and 2 show the solubilities of the isomers of hydroxy, amino, chloro, and nitrobenzoic acids in surfactant solutions. In all cases the solubilities of the acids are proportional to surfactant concentration. There is, however, no appreciable difference in the solubilities of the acids in the three surfactants. These solubility graphs seem to indicate that variation of the chain length of the lipophilic portion of the surfactant molecule has no effect on the solubilities of the acids suggesting that the solubilities of the various substituted benzoic acids studied are independent of the chain length of the surfactant molecule. Except for the hydroxy derivatives, the other acids show a decrease in solubility in the order of *ortho*, *meta*, and *para* isomers.

Viscosity Measurements.—Figures 3, 4, and 5 show the viscosities of dispersions containing varying amounts of salicylic acid. In general, there is an increase in viscosity with increasing concentration of salicylic acid in the surfactant solution up to approximately when the system becomes saturated with the acid, after which the viscosity remains constant or decreases. This behavior is seen with all the concentrations of surfactants studied, 2%, 3%, 4%, 5%, and 6% and in the range of shear rates used, the viscosity being greater at low rates of shear than at high rates of shear. These observations can be attributed to interaction of salicylic acid with the surfactants, particularly the tetradecyltrimethylammonium and cetyltrimethylammonium bromides. In the case of dodecyltrimethylammonium bromide a lesser degree of interaction with salicylic acid is apparent as no marked changes in viscosity have been observed. Probably it is due to the shorter chain length of the lipophilic portion of the surfactant molecule which may tend to discourage interaction, or it may be due to the resultant complex being smaller in size and hence is unable to produce the relatively higher viscosity seen with the longer chain surfactants. When the system becomes saturated with salicylic acid, the viscosity tends to remain constant with further additions of the acid and this is particularly noticeable at low surfactant concentration. These observations suggest that once interaction is complete the excess salicylic acid has no effect on the viscosity of the system. However, at high surfactant concentration the viscosity decreases at about the concentration at which the system becomes saturated with salicylic acid. This may be due to the unstable nature of the complex and which may manifest itself more predominantly in the presence of a large number of complexes which follows from an increased concentration of the surfactant.

When the concentration of salicylic acid in the surfactant solution is low, the system behaves like a Newtonian liquid. As the salicylic acid content is increased the system changes to a non-Newtonian liquid producing large differences in viscosities with varying rates of shear (Figs. 3, 4, and 5). It would appear that adequate salicylic acid must be present for interaction to take place to produce the viscosity effect. With a higher concentration of the surfac-

Shear rate: *1*, 234.6 sec.$^{-1}$; *2*, 195.9 sec.$^{-1}$; *3*, 155.1 sec.$^{-1}$; *4*, 117.35 sec.$^{-1}$; *5*, 78.56 sec.$^{-1}$.

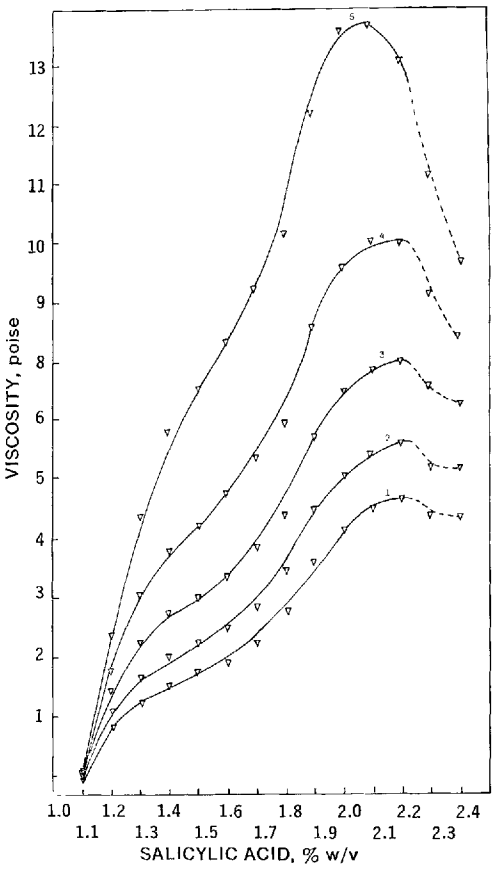

Fig. 4.—Effect of salicylic acid on the viscosity of tetradecyltrimethylammonium bromide solution (6%) at 25°. Key: ——, below saturation; - - - -, above saturation. Shear rate: *1*, 234.6 sec.$^{-1}$; *2*, 195.9 sec.$^{-1}$; *3*, 155.1 sec.$^{-1}$; *4*, 117.35 sec.$^{-1}$; *5*, 78.56 sec.$^{-1}$.

tant, more salicylic acid is required to initiate the non-Newtonian flow and this amount increases proportionately (Fig. 6). However, the ratio of salicylic acid concentration to surfactant concentration at which non-Newtonian flow commences decreases with the surfactant concentration as shown in Table II. As the ratio is probably linked up with the degree of interaction it may mean that a smaller degree of interaction is necessary for the system to exhibit non-Newtonian flow in the presence of a high concentration of the surfactant. At a low concentration of surfactant where there are less molecules of the surfactant a greater degree of interaction is required to initiate the non-Newtonian flow. In the case of dodecyltrimethylammonium bromide the viscosity effect is less marked, and the change to non-Newtonian flow is therefore less obvious.

The amounts of salicylic acid that have to be added to the tetradecyltrimethylammonium bromide solutions to produce the non-Newtonian flow initially are slightly lower than for the corresponding cetyltrimethylammonium bromide solutions as seen in Fig. 6. Furthermore, the viscosity of a tetradecyltrimethylammonium bromide solution containing the same amount of salicylic acid as in a cetyltrimethylammonium bromide solution is much higher (Figs. 3, 4, and 5) indicating that the chain length of tetradecyltrimethylammonium bromide is probably optimally favored for interaction. The maxi-

mum viscosity of salicylic acid in the tetradecyltrimethyl and cetyltrimethylammonium bromide solutions occurs in about the same concentration due to the fact that the solubility of the acid in both the surfactants are practically identical. In dodecyltrimethylammonium bromide solutions containing salicylic acid this is not clear as the viscosity effect is not marked.

m-Hydroxybenzoic and *p*-hydroxybenzoic acids were included in the investigation, but both failed to show the viscosity effect observed with salicylic acid. The viscosities of both these acids remain unchanged when compared with the corresponding concentrations of surfactant in the absence of the acid. Benzoic acid and acetylsalicylic acid also failed to show any viscosity changes. The interaction of salicylic acid with the quaternary type of surfactants is highly specific as further investigations with the *ortho*, *meta*, and *para* substituted aminobenzoic, chlorobenzoic, and nitrobenzoic acids produced no viscosity change. In addition, salicylic acid did not exhibit this viscosity effect when dispersed with an anionic surfactant such as sodium lauryl sulfate or with a nonionic surfactant such as cetomacrogol 1000. The viscosities of dodecyltrimethylammonium, tetradecyltrimethylammonium, and cetyltrimethylammonium bromide solutions are independent of the concentration of the surfactant and practically independent of each other.

The viscosity effect is not related to pH. Table III shows the pH of surfactant solutions containing hydroxybenzoic acids. There is a small change in pH with increasing concentration of the acid. The viscosity of a surfactant solution whose pH is adjusted to that of a corresponding surfactant solution containing salicylic acid remains unaffected. This is true for all the three surfactants.

The mechanism of interaction is complicated and perhaps not yet fully understood. Suggestions for interactions of compounds with surfactants of the polyether type have been made by Higuchi and Lach (1) as due to the formation of molecular complexes and by Goodhart and Martin (5), Blaug and Ebersman (15), and Autian and Shaikh (17) as due to micellar solubilization. The results from this investigation indicate that the interaction of salicylic acid with surfactants of the quaternary type involves complex formation which leads to a marked change in viscosity and is only possible with the *ortho* substituted hydroxybenzoic acid while the *meta* and *para* compounds possess structures which are unfavorable to interaction. Besides, other attractive forces are likely to play a part as it is not only the *ortho* substituent that effects a viscosity change; a hydroxy group is essential, since the amino, chloro, and nitrobenzoic acids do not exhibit this viscosity effect.

The above-mentioned complexation is of importance to pharmaceutical formulation. It can be made to stabilize emulsified preparations such as creams, ointments containing the quaternary ammonium type of surfactants, and salicylic acid due to the high viscosity resulting from the interaction.

Phosphorus–Nitrogen Compounds VI

Some Phenethylamine Derivatives

By L. A. CATES, W. H. LAWRENCE*, and R. J. MCCLAIN†

Eight diphenyl or diethyl phosphoramidates and one phenyl phosphorodiamidate containing phenethylamine moieties were synthesized for pharmacological testing. The derivatives were screened for their effect on the rabbit eye and isolated intestine, on dog blood pressure, and locomotor and anorexigenic activity in mice. The anorexigenic properties exhibited by some of these compounds may be related to their sedative effects. Three of the compounds inhibited spontaneous duodenal contractions at concentrations of 10 p.p.m. followed by tissue recovery. This antispasmodic effect was not reversed by acetylcholine or barium chloride.

THE EFFECT of *N*-substitution on the pharmacological activities of adrenergic amines has been extensively investigated and much of the work in this area has been directed toward determining the influence of various *N*-alkyl modifications on the cardiovascular and central nervous systems. Some attention has, however, been given to acyl derivatives of phenethylamines, principally in efforts to reduce cardiovascular side effects of the parent compound and to prolong the duration of adrenergic activity. One extensive synthetic program involving amides of dextroamphetamine and phenylpropanolamine resulted in the testing of an orally effective locomotor stimulant without significant cardiovascular effects (1). An attempt in protracting sympathomimetic activity is exemplified by the acetylation of epinephrine (2).

In view of these previous studies, the effect of phosphorylation on the pharmacological properties of phenethylamines was considered worthy of investigation and amphetamine, methamphetamine, ephedrine, phenylpropanolamine, and homoveratrylamine were selected as representative adrenergic agents which readily lend themselves to phosphorylation. Testing of compounds which have been previously reported in this series indicates that conversion of various amines to phosphoramidates reduces the biological activities of the parent compounds in that most of the derivatives possess low toxicities. The majority of *p*-toluidine (3), 2-aminopyridine (4), and guanidine and 2-aminopyrimidine (5) derivatives displayed little or no toxicity when administered to mice for 7 to 11 days at dosage levels of 100 to 500 mg./Kg./day.[1] These derivatives may be excreted unchanged and not undergo the desired *in vivo* enzymatic hydrolysis to liberate the physiologically active amines. To test this supposition, potent central nervous system stimulants were phosphorylated and the resulting phosphoramidates screened for their ability to increase locomotor activity in mice. Acute toxicity studies were made on all but one of the derivatives and most of the compounds were also screened for anorexigenic activity and their effects on the eye and isolated intestine. In addition, five of the derivatives were tested for their acute effects on blood pressure in the anesthetized dog.

EXPERIMENTAL

Chemical Synthesis

Phenethylphosphoramidates (Table I, Compounds I–VIII).—Compounds I–VI were prepared by refluxing the appropriate amine (2 moles) and diethyl or diphenyl phosphorochloridate (1 mole) in anhydrous benzene for 1–4 hr.

In compounds II–VI the resulting amine hydrochloride was removed by filtration and the filtrate spin-evaporated over a steam bath to yield an oil. The oil was washed with petroleum ether to give a white solid which was washed with dilute hydrochloric acid and water. The product was crystallized from ethanol (compound II) or petroleum ether (compounds III–VI).

Compound I was isolated from the precipitate formed in the reaction mixture which was washed with water and crystallized from ethanol–water as the monohydrate. The ephedrine required for this synthesis was dried over alumina prior to its use in the reaction.

Reagent chloroform was employed as the reaction solvent for compounds VII and VIII. Following a reflux period of 8 hr. the phenylpropanolamine hydrochloride was removed by filtration and the filtrate was spin-evaporated to yield an oil. The oil was converted to a white solid when crystallized from ethanol–dilute hydrochloric acid. Hemihydrolysis occurred with the more labile aryl ester

[a] All melting points are uncorrected.

product (compound VIII) during this purification step as shown by its solubility in sodium hydroxide solution, high melting point, infrared spectra, and microanalysis. The phenylpropanolamine required in this synthesis was prepared by treatment of the hydrochloride salt with an equal molar amount of sodium hydroxide.

Phenethylphosphorodiamidate (Table I, Compound IX).—Dextroamphetamine (0.1 mole) and phenyl phosphorodichloridate (0.025 mole) were refluxed 12 hr. in anhydrous benzene. The reaction mixture was filtered and the filtrate spin-evaporated over a steam bath to yield a viscous oil. The oil was dissolved in ether and dried over anhydrous sodium sulfate. Spin-evaporation of the ethereal solution gave an oil which developed crystals after 3 days. Washing of the crystals with petroleum ether yielded phenyl-*N*,*N*′-bis-(1-methyl-2-phenylethyl)-phosphorodiamidate as a white, crystalline solid.

Infrared Spectra

All starting materials and products were examined by means of a Beckman IR-8 spectrophotometer using a Nujol mull. The new derivatives showed the following characteristic absorptions, γ in cm.$^{-1}$: 1238–1250 (P=O in compounds I–VIII), 1220 (P=O in compound IX), 1140–1160 (POEt in compounds III, V, and VII), and 1070–1100 and 1200 (POCaryl in compounds I, II, IV, VI, VIII, and IX).

Derivatives of primary amines showed the N–H stretching vibration of the intermolecularly hydrogen-bonded form at 3210–3260 cm.$^{-1}$ (6), while compounds I and IV gave no bands in this region. Compound VIII showed a weak absorption at 2550 cm.$^{-1}$ which can be assigned to P–OH (7).

Pharmacological Screening

The compounds were subjected to screening tests for anorexigenic properties; central nervous system effects, as indicated by spontaneous locomotor activity; toxicity; stimulation or inhibition of isolated rabbit intestine; and pupillary dilation or constriction, topical anesthesia, and irritating effects in the rabbit's eye. Five of the nine compounds were also tested for their acute effect on blood pressure in anesthetized dogs, when administered intravenously.

Anorexigenic Screening Test.—Food was withheld from mice for 20–24 hr. prior to the test but water was

provided *ad libitum*. Each test compound was administered in three dose levels, 4, 8, and 16 mg./Kg., and each dose level was given to a group of three mice of approximately equal weight. Appropriate dilutions were prepared so a consistent volume of solution was injected into each mouse (0.01 ml./Gm.).

Each mouse was weighed and injected intraperitoneally (i.p.) with the appropriate solution and placed back in its individual cage for 30 min., after which it was permitted free access to a food pellet for exactly 10 min. The food pellet was accurately weighed to one-tenth of a milligram (0.1 mg.) using a model H-6 Mettler balance, before and after the feeding period. Control mice were employed which received a similar volume of saline and others which received 0.5, 1, and 2 mg./Kg. of dextroamphetamine.

CNS Activity. Spontaneous Locomotor Activity, 24 hr.—Each mouse was injected i.p. with 0.01 ml./Gm. of 1% propylene glycol in saline and placed in an actophotometer (Metro Scientific) for 24 hr. The instrument was located in a windowless room free of external noise and a dim light was maintained during the test period. Each breaking of the beams of infrared light by the mouse was recorded by means of a digital counter. The mouse had free access to food and water during this time. The count obtained was used as the control for this particular mouse and each animal was used at 7-day intervals. The mouse received 5 mg./Kg. of the test compound i.p. and the activity was determined for 24 hr. under the same environmental conditions.

CNS Activity. Spontaneous Locomotor Activity, 5-min. Test.—The method used was essentially that of Dews (8) as modified by Moffett and Seay (9). Five mice of approximately equal weight comprised an experimental group. Each mouse was weighed, administered 4 mg./Kg. i.p. of the compound, and returned to his cage for 30 min. The animal was then placed in an actophotometer for exactly 5 min. Solutions were prepared so each mouse received 0.01 ml./Gm.

Irritancy, Local Anesthesia, and Pupillary Reactions in the Rabbit Eye.—These three tests were run simultaneously. All compounds tested were 1% solutions (w/v) in propylene glycol. Healthy rabbits were selected and, after their careful examination, 2 drops of the test solution were placed in one eye, and 2 drops of propylene glycol in the other eye as a control. The animals were observed at 10-min. intervals during the next hour for evidence of corneal anesthesia, pupillary dilation, or constriction and irritation.

Isolated Rabbit Intestine.—A piece of rabbit small intestine, about 2 to 3 cm. long, was suspended in aerated Tyrode's solution in a constant-temperature bath. The tissue was anchored at the bottom, and the top was attached *via* a lever system to a Grass force-displacement transducer. Contractions of the isolated intestine were recorded with a Grass model 7, ink-writing polygraph. Quantities of compounds administered are all expressed in terms of final concentrations of the derivative in Tyrode's solution.

Toxicity Studies.—Acute toxicity tests were conducted according to the method of Thompson and Weil (10, 11) for estimating the LD_{50}. Four mice were used for each dose level, and four dose levels were employed for each compound. The dose levels selected represent a geometric progression in that the logarithm of adjacent doses differed by a factor of 0.176. Solutions of the compounds were prepared to give the desired quantity when 0.01 ml./Gm. was injected. The mice were weighed, injected i.p., and observed for 1–4 hr. Following this they were returned to the animal room where another check was made at the end of 24 hr.

Our definition of "acute toxicity" includes any deaths which occur within 24 hr. after administration of the compound. Since few compounds exhibited significant toxicity within the 24-hr. period, observation of these animals was continued for an additional 6 days. No further administration was given. Any deaths which occurred during these additional 6 days is reported as subacute toxicity (7-day toxicity).

Blood Pressure Effects in Dogs.—Mongrel dogs were anesthetized with sodium pentobarbital, 30 mg./Kg., intravenously, and supplemented as needed to maintain the desired level of anesthesia. The carotid artery was cannulated and attached to a Statham pressure transducer, the femoral vein was cannulated for intravenous injections, and the trachea was cannulated to permit free air flow. Arterial pressure responses were recorded using a Grass model 7 polygraph.

RESULTS AND DISCUSSION

Anorexigenic Activity.—Since some of these compounds are derivatives of potent anorexigenic drugs, amphetamine and methamphetamine, it was deemed advisable to see if these agents would exhibit any effect on food consumption of mice. As noted (Table II), most of these compounds produced some decrease in food consumption during the feeding period. Food consumption was determined for each mouse during its 10-min. feeding period; this was converted to grams of food consumed per kilogram of body weight of the mouse for uniformity in comparing one animal, or group of animals, with another. Saline-treated animals served as controls in determining relative food consumption for the various treatments. Each value presented in Table II represents the mean response of three animals.

The inconsistency of these data is probably a reflection of the variability of response as seen in the small size of animal groups (three mice). The decreased food consumption by many of these animals was apparently due to varying degrees of hypoactivity and sedation of the animals which was noted

Table II.—Anorexigenic Activity

Compd.	Food Consumption, as % of Control (Control = 100%) 4 mg./Kg.	8 mg./Kg.	16 mg./Kg.

VIII	1:10,000	NSR	Stimulation[b]	...	...
IX	1:100,000	Inhibition	NSR	NSR	...

[a] No significant response. [b] Acetylcholine concentration = 1:1,000,000.

during the period of the experiment. In a few instances this was sufficient to cause the animal to lose its righting reflex. It was thought that the 5-min. locomotor activity tests would clarify this aspect, but the results of the actophotometer tests do not correlate well with the decreased food consumption.

Spontaneous Locomotor Activity.—Initially it was thought these compounds would probably increase locomotor activity, with a slow onset and long duration of effect. Consequently, spontaneous motor activity determinations were made over a 24-hr. observation period (Table III). As testing proceeded, it became obvious that at least some of the compounds exerted their action rather promptly; therefore, spontaneous motor activity was again determined 30 min. after intraperitoneal injection. This time the observation period was reduced to 5 min., thus minimizing acclimatization of the mouse to the environment of the actophotometer.

Since the 24-hr. test was discontinued in favor of a 5-min. test, the results presented represent the response of a mouse after receiving the designated compound and comparing this response to that obtained from the same mouse after receiving 0.01 ml./Gm. of 1% propylene glycol in saline.

The 5-min. locomotor activity test utilized groups of five animals for each compound and for the saline controls. The mean for each five-animal group was used to compare the counts for the experimental animals with the controls and to compute the per cent of control values. A comparison between the means of each series of five animals and its control was made by calculating Student t values. Two compounds (I and V) showed a decrease in locomotor activity which was significant at the 5% level and compound III gave a t value which would be significant at the 10% level. None of the compounds produced any statistically significant increase in such activity, which was somewhat unexpected, particularly for the amphetamine and methamphetamine derivatives.

Fig. 1.—Typical response of isolated small intestine to compounds I, II, IV, VI, and IX. Key: A, compound (in this case, VI, 1:25,000); B, acetylcholine br, 1:1,000,000; C, acetylcholine br, 1:250,000; D, acetylcholine br, 1:100,000.

Topical Anesthesia, Pupillary Reaction, and Irritation in the Rabbit's Eye.—No local anesthesia, pupillary dilation, or constriction was noted during the period of observation (1 hr.). The solvent used (propylene glycol) irritated the eyes, as indicated by redness of the cornea. The solutions of the compounds did not appear to produce any greater irritation than the solvent, although this was difficult to assess.

Isolated Rabbit Intestine.—Three of the eight compounds tested produced a marked decrease or complete inhibition of spontaneous activity and tonus of the isolated small intestine at a concentration of 1:100,000 (compounds II, IV, and IX). While a 1:1,000,000 concentration of acetylcholine was sufficient to produce spasm of the normal intestinal strip, following administration of each of these three compounds, concentrations of acetylcholine as great as 1:100,000 failed to produce any response (Table IV). A typical response of this type is shown

TABLE V.—ACUTE AND SUBACUTE TOXICITIES[a]

IX		1	0	0	0	1	0	0	0
Propylene glycol, 0.01 ml./Gm.		0	0	0	0	0	0	0	0

[a] Number of deaths out of four animals. [b] mg./Kg. in propylene glycol given i.p. [c] Dose levels = 66.7, 100, 150, and 225 mg./Kg. [d] In propylene glycol/NaOH. Test of this solvent system without compound VI resulted in three deaths in 24 hr. and four deaths in 7 days.

in Fig. 1. In addition, barium chloride in concentrations up to 1:10,000 failed to contract the isolated intestine following these drugs. Thus, these compounds relaxed the intestinal strip and prevented it from responding to the neurogenic stimulation of acetylcholine and the myogenic stimulation of barium chloride.

Two other compounds (I and VI) produced a similar response but a higher concentration of the compound was required for this effect (1:25,000 for VI; 1:5000 for I).

One compound (V) produced stimulation of the isolated gut at a concentration of 1:10,000. This stimulation was counteracted by 1:1,000,000 adrenaline, and prevented by prior addition of 1:1,000,000 atropine.

The other two compounds (VII and VIII) did not produce any significant response upon the intestine in concentrations up to 1:10,000.

Three diethyl phosphoramidates were synthesized in order to give an indication of what different effect, if any, an alkyl ester produces compared to an aryl ester. One obvious difference in properties is the much greater water solubility exhibited by the ethyl esters. The pharmacological activity most affected by this difference in solubility appears to be that on the isolated gut. It is noted that the four compounds (II, IV, VI, and IX) most active as antispasmodics were insoluble in water, while only one water-soluble compound (I) exhibited this activity, and quantitatively it was much weaker than the others, and another water-soluble compound (V) produced intestinal stimulation. It is also interesting to note that compound VI, which produced inhibition of the intestine is the diphenyl phosphate derivative of homoveratrylamine, while compound V, which produced stimulation of the intestine, is the diethyl phosphate derivative of homoveratrylamine.

Toxicity Studies.—These tests indicate that most of the compounds are much less toxic when considered in terms of acute toxicity (24 hr. or less) than when considered in terms of subacute toxicity (7 days or less). Thus, the data suggest that most of the compounds exert their toxic effect indirectly by adversely affecting a vital organ or function (*e.g.*, possibly renal or hepatic function) or else they are retained in the body and slowly converted into some more toxic substance. No attempt was made to determine the cause of death for the mice that succumbed to these compounds. This pattern of delayed death is readily illustrated by compounds V and VI (Table V). Only one of the 16 mice which received V died within 24 hr., however, by the end of the 7th day, nine of the 16 mice were dead; compound VI produced no deaths during the first 24 hr., however, by the end of the 7th day, 13 of the 16 mice which had received the drug were dead.

Fig. 2.—Effect on arterial blood pressure of anesthetized dog from slow intravenous injection of 1.6 mg./Kg. of compound I.

Some of the other compounds did not exhibit significant toxicity at the doses utilized. Compounds VII and IX produced only one fatality each during the 7-day period, and the rapidity of death in both cases (less than 4 hr.), and the fact that both deaths were from the lowest dose, would lead one to suspect something, other than drug toxicity, as a possible cause of these deaths. Two groups of four mice each were administered an equivalent volume of propylene glycol; none of these eight mice died within the 7-day observation period.

Compound VIII presents a different problem. It is not soluble in water or propylene glycol but does form the water-soluble sodium salt. Sodium hydroxide was used to solubilize the compound; the result was seven deaths out of the 16 injected. The same quantity of sodium hydroxide as used to solubilize VIII was added to propylene glycol and an equivalent volume of this sodium hydroxide-propylene glycol solution was injected into four mice; three of these died within 24 hr. and the other died before the 7th day. This would represent the sodium hydroxide concentration in the strongest solution (337 mg./Kg.), but since the solutions for the lower doses were prepared by diluting some of this solution with propylene glycol, the lower dose levels contained correspondingly less caustic.

Blood Pressure in Anesthetized Dogs.—Five of

the nine compounds were administered intravenously to anesthetized dogs to determine their effect on systemic arterial pressure. Compounds I, III, IV, V, and VII were administered in various dosage schedules ranging from 0.5 to 10.0 mg./Kg. Only compound I produced a marked change in blood pressure. Figure 2 shows the alteration in carotid arterial pressure produced by 1.6 mg./Kg. of compound I. It will be noted that there is an increase in both systolic and diastolic pressure, however, systolic pressure increased more than diastolic, thus increasing the pulse pressure too.

A Potent α-Receptor Blocking Agent, SU-14542

By T. F. BURKS* and J. P. LONG

SU-14542 was studied in isolated cat and rabbit hearts and in *in situ* dog hearts for possible β-adrenergic receptor stimulating activity. It was determined that this compound has no demonstrable action on β receptors. Investigation of its effects on isolated mesenteric arteries demonstrated powerful α-adrenergic receptor blockade; SU-14542 was found to be 2–7 times more potent than phentolamine as an α-receptor blocking agent. The ID_{50} for SU-14542 in blocking epinephrine was determined to be $6.6 \times 10^{-9} M$.

IT HAS BEEN reported by Barrett *et al.* (1) that SU-14542, which is 3′-methoxy-4′ [(4-phenyl-1-piperazinyl)-butoxy]-acetophenone monohydrochloride, decreases arterial blood pressure in both anesthetized normotensive dogs and unanesthetized renal hypertensive dogs. Decreases in pressor responses produced by epinephrine, norepinephrine, and amphetamine were observed following oral administration of 0.20 and 1.80 mg./Kg. of SU-14542. These workers reported that the experimental compound does not possess ganglionic blocking activity but, since tachycardia was observed following administration of SU-14542, that it does possess β-adrenergic receptor stimulating activity.

Povalski *et al.* (2) reported that while 5.0 mg./Kg. SU-14542 given orally to anesthetized dogs produced a decrease in mean arterial blood pressure, cardiac output was not significantly altered. Rutledge *et al.* (3) found that SU-14542 increased femoral arterial blood flow in dogs but did not significantly increase renal blood flow.

In this communication evidence will be presented demonstrating that SU-14542 is a potent α-adrenergic receptor blocking agent that has no β-adrenergic receptor stimulating properties on dog, cat, or rabbit hearts.

EXPERIMENTAL

Cat and Rabbit Hearts.—Dutch rabbits of either sex, weighing from 1.5–2 Kg. were sacrificed by cervical dislocation, and the beating hearts were removed and flushed through the aorta with a heparin–saline solution. An aortic cannula was tied into place and the hearts perfused in the usual Langendorf preparation (4) with Locke Ringer solution for isolated hearts warmed to 35–37° and aerated by bubbling 95% O_2–5% CO_2. Aortic pressure was maintained at 40–50 mm. Hg to ensure adequate coronary perfusion. Drugs were injected in 0.5–1 ml. vol. into the aortic cannula. Force of contraction was measured from a Grass Instrument Co. force - displacement transducer (FTO3C) and recorded on a Gilson (GME) polygraph. Heart rates were obtained by direct observation of recorder pen movement.

Cat hearts were prepared in a similar manner from cats of either sex weighing 1.5–3 Kg., anesthetized by intrathoracic administration of 30 mg./Kg. sodium pentobarbital.

Dog Hearts.—Mongrel dogs of either sex, weighing 10–12 Kg., were anesthesized by 15 mg./Kg. sodium thiopental and 250 mg./Kg. sodium barbital administered intravenously. Systemic blood pressure was measured from a carotid artery cannula by a Statham pressure transducer (P23AA) and recorded by an Offner type RS Dynograph. Drugs, in volumes of 0.1–1 ml., were injected through a cannula placed in a femoral vein. Both vagus nerves were sectioned in the cervical region and each animal was administered 20 mg./Kg. hexamethon-

the nine compounds were administered intravenously to anesthetized dogs to determine their effect on systemic arterial pressure. Compounds I, III, IV, V, and VII were administered in various dosage schedules ranging from 0.5 to 10.0 mg./Kg. Only compound I produced a marked change in blood pressure. Figure 2 shows the alteration in carotid arterial pressure produced by 1.6 mg./Kg. of compound I. It will be noted that there is an increase in both systolic and diastolic pressure, however, systolic pressure increased more than diastolic, thus increasing the pulse pressure too.

EXPERIMENTAL

Cat and Rabbit Hearts.—Dutch rabbits of either sex, weighing from 1.5–2 Kg. were sacrificed by cervical dislocation, and the beating hearts were removed and flushed through the aorta with a heparin–saline solution. An aortic cannula was tied into place and the hearts perfused in the usual Langendorf preparation (4) with Locke Ringer solution for isolated hearts warmed to 35–37° and aerated by bubbling 95% O_2–5% CO_2. Aortic pressure was maintained at 40–50 mm. Hg to ensure adequate coronary perfusion. Drugs were injected in 0.5–1 ml. vol. into the aortic cannula. Force of contraction was measured from a Grass Instrument Co. force - displacement transducer (FTO3C) and recorded on a Gilson (GME) polygraph. Heart rates were obtained by direct observation of recorder pen movement.

Cat hearts were prepared in a similar manner from cats of either sex weighing 1.5–3 Kg., anesthetized by intrathoracic administration of 30 mg./Kg. sodium pentobarbital.

Dog Hearts.—Mongrel dogs of either sex, weighing 10–12 Kg., were anesthesized by 15 mg./Kg. sodium thiopental and 250 mg./Kg. sodium barbital administered intravenously. Systemic blood pressure was measured from a carotid artery cannula by a Statham pressure transducer (P23AA) and recorded by an Offner type RS Dynograph. Drugs, in volumes of 0.1–1 ml., were injected through a cannula placed in a femoral vein. Both vagus nerves were sectioned in the cervical region and each animal was administered 20 mg./Kg. hexamethon-

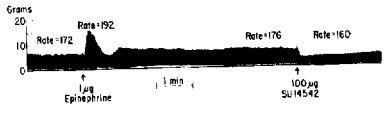

Fig. 1.—Effects of the standard β-receptor stimulant, epinephrine, and SU-14542 on rate and force of contraction of isolated rabbit heart. Note that epinephrine produced increases in both contractile force and rate. SU-14542 decreased both contractile force and rate.

ium bromide. The heart was exposed by a midline thoracic incision, the pericardium opened, and a Walton-Brodie strain gauge arch sewn directly on the myocardium. Contractile force was recorded by the Offner Dynograph. Heart rates were obtained by direct observation of recorder pen deflection.

Isolated Mensenteric Arteries.—Isolated arteries were prepared in the manner described by Rogers *et al.* (5). Dogs of either sex were anesthetized as above and the small intestine exposed *via* midline abdominal incision. Mesenteric arteries with branching fans of smaller resistance arteries and periarterial sympathetic nerves were removed from the animals and mounted in an organ bath where they were perfused with Krebs bicarbonate solution. The Krebs solution was aerated with 95% O_2–5% CO_2 and maintained at 37°. The arterial segments were immersed in a 150-ml. recirculating bath and perfused by use of a Sigmamotor model T-8 peristaltic infusion pump. Since flow was held constant, changes in perfusion pressure were directly proportional to changes in arterial resistance. Perfusion pressure was measured from a T tube between the pump and the artery by a Statham pressure transducer (P23AA) and recorded on an Offner Dynograph.

Stimulation of the periarterial sympathetic nerves was accomplished with a Grass Instrument Co. model S4 stimulator. Parameters of stimulation were within the following ranges: frequency 20–30 c.p.s., duration 5–20 msec., and at 6–15 v. for 1–10 sec. Epinephrine and norepinephrine dissolved in purified water were injected into the arterial cannula in volumes of 0.01–0.05 ml. and the blocking agents were injected directly into the bath fluid. Several test doses of the agonists were given and several stimulations performed until repeated challenge produced reproducible responses between 50–100 mm. Hg above the baseline pressure which was maintained at 80–120 mm. Hg.

After establishment of control responses, the antagonists were added to the bath and the agonists reapplied; this was repeated for a second dose of antagonists.

Chemicals.—Chemicals employed were *l*-epinephrine HCl, *l*-norepinephrine HCl (calculated as the base), phentolamine HCl, SU-14542, and hexamethionium bromide.

The isolated heart experiments were so designed that each heart served as its own control and the data were analyzed with the Student t test, paired comparisons (6). The data from the isolated arteries were analyzed by analysis of variance and a 2 × 2 parallel line bioassay (7). ID_{50} doses for the isolated arteries were calculated by the method of Litchfield and Wilcoxon (8). In all experiments a P value equal to or less than 0.05 was considered significant.

RESULTS

Hearts.—As can be seen from perusal of Table I, administration of epinephrine resulted in increases in both rate and force of contraction of the hearts in all species investigated. This is of course consistant with its well-known ability to stimulate β-adrenergic receptors. SU-14542 produced decreases in rate and/or force of contraction (Fig. 1). The effects of SU-14542 on the hearts were dose-related and doses ranging from 1–300 mcg. were applied to the cat and rabbit hearts; a 100-mcg. dose was chosen for the study. In the dogs, doses from 0.01–5.0 mg./Kg. were employed and 1.0 mg./Kg. was chosen for the study, this being a dose comparable to those used by other workers. In one instance a dog was prepared as described above except the vagi were left intact and hexamethonium was not administered. In this case, administration of 1.0 mg./Kg. SU-14542 resulted in increases in both heart rate and contractile force, the onset corresponding to the fall in arterial blood pressure. It was also interesting to note that when epinephrine was administered to the isolated hearts after SU-14542 there was no indication of β-receptor blockade when the response was compared to that produced by epinephrine before SU-14542.

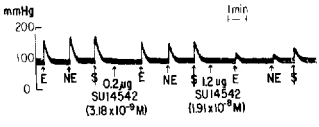

Fig. 2.—Demonstration of α-receptor blocking action of SU-14542. The stimuli applied were epinephrine (E), 0.1 mcg.; norepinephrine (NE), 0.2 mcg.; and sympathetic nerve stimulation (S with an arrow) 25 c.p.s., 5 msec./pulse, 10 v. for 3 sec. The mcg. doses and M concentrations of SU-14542 represent total bath concentration.

Isolated Arteries.—SU-14542 was found to be a potent α-adrenergic receptor blocking agent, being some 2–7 times more potent than phentolamine (Table II). Preliminary experiments determined that $3.18 \times 10^{-9}M$ and $1.91 \times 10^{-8}M$ concentrations of SU-14542 were approximately comparable to $8.41 \times 10^{-9}M$ and $5.05 \times 10^{-8}M$ concentrations of phentolamine in blocking the responses to epinephrine and norepinephrine. It was also determined that the dose-response curve to SU-14542 was relatively flat, the optimal log interval between the high and low doses was found to be 0.8 (Fig. 2). In later experiments SU-14542 was determined to be some 7 times more potent than phentolamine in antagonizing responses to sympathetic nerve stimulation. As was expected, and as can be seen from Fig. 2 and Table II, both α-receptor blocking agents were more effective antagonists of exogenously administered catecholamines than in antagonizing sympathetic nerve stimulation.

Median inhibitory doses (ID_{50}) calculated for each of these α-receptor blocking agents against epinephrine with their 95% confidence limits were as follows: SU-14542, $6.6 \times 10^{-9}M$ ($2.3–19.1 \times 10^{-9}M$); phentolamine, $16.5 \times 10^{-9}M$ ($5.9–46.2 \times 10^{-9}M$).

Analysis of variance and parallel line bioassay provided evidence for good regression lines for each agent at the 0.8 log interval of doses, no deviation from parallelism and good matching of doses. A typical table of analysis of variance is provided in Table III.

DISCUSSION

From the data presented it may be concluded that SU-14542 is a potent antagonist of the α-adrenergic receptor stimulation resulting either from addition of exogenous catecholamines or from stimulation of sympathetic nerves in isolated mesenteric arteries. SU-14542 was determined to be some 2–7 times more effective than phentolamine as an α-receptor blocking agent, and, therefore, could well find use in experimental and perhaps in clinical situations where the use of such a property might be indicated. The relatively flat dose-response curve demonstrated for this agent may be beneficial to its employment in diverse circumstances.

It is evident, however, that this compound is not a stimulant of the β-receptors of cat, rabbit, or dog hearts. It is suggested that the heart stimulation observed by other investigators following administration of SU-14542 was mediated reflexly as compensation for the fall in arterial blood pressure resulting from the intense α-receptor blockade produced by this compound. The single experiment described above in which a dog with intact cardiovascular reflexes responded to SU-14542 by heart stimulation may be contrasted to the other animals with reflexes blocked by vagatomy and hexamethonium that failed to show any such heart stimulation.

Comparison of an Immunoassay and the U.S.P. Bioassay for Determining Potency of Extracted Insulin

By G. W. PROBST, W. F. BROWN, and H. J. HENRY

An immunoassay procedure is described for determining the potency of extracted insulin. The method, based on salt precipitation for the separation of antibody bound and free insulins originally described by Grodsky and Forsham, was modified and simplified to obtain greater precision and reliability of results. Repetitive immunoassay results, conducted on different days with pork, beef, and mixed source zinc insulins, commercial insulin products, and insulin preparations from different stages of manufacture, were compared with the corresponding U.S.P. bioassay results. Statistical analysis of the immunoassay data revealed a confidence coefficient of ±11.2 per cent ($p = 0.95$) for a single immunoassay. This value is within the limits established by the U.S.P. for insulin potency bioassay. A desired variation of ±5–6 per cent is obtained by statistical combination of several bioassay results. Similar variation is achieved by repeating the immunoassay on 4 different days. An analysis of variance indicated that the immunoassay, under the conditions employed, is not subject to variations due to species specific insulins if the antigen used to produce antiserum is a mixed species insulin. The beef and pork zinc insulins, originally selected to serve as standards for immunoassay, were found to have a significantly different potency by immunoassay when compared to the potency established by bioassay. In order to establish an immunoassay secondary reference standard equivalent to the U.S.P. reference standard, the reaction of three lots of pooled insulin was determined repetitively at all standard curve values. Statistical analysis by least squares, of the data obtained at 20, 30, and 40 milliunits/ml. (munits/ml.) insulin concentrations, yielded a calculated common slope which lies within the computed individual slope confidence interval. These data further support the validity of the immunoassay in establishing the potency of extracted insulin and was given credence by comparing immunoassay and bioassay results obtained on large manufactured lots of crystalline zinc insulins.

FOR MORE than two decades the potency of extracted insulin has been determined by the official U.S.P. bioassay (1). Like all bioassays, the "twin crossover" rabbit blood sugar-lowering assay, used as the official method for determining insulin potency, is beset with many shortcomings. These include inherent biological variation, high cost of facilities, considerable time consumption, and lack of sensitivity. The development of specific and sensitive immunological assays (2–6) provided rapid, accurate, and economic methods for the quantitative determination of insulin. These methods are based on isotope dilution as a quantitative index for measuring the competitive reaction of labeled and unlabeled insulins for specific antibody. The separation of the antigen–antibody complex from the free antigen in the immunological reaction is achieved by different means in these reported methods. A sensitivity great enough for measuring microunit quantities of insulin found in plasma and serum is a cardinal feature of the immunoassay. However, for control of insulin development and production, milliunit sensitivity is satisfactory. In the present study, the immunoassay method of Grodsky and Forsham (3) as modified by Baum *et al.* (7) was further explored and appropriately modified to determine the best conditions for reproducible results. Immunoassays possess the potential capability of determining insulin with an accuracy equivalent to that obtained with the bioassay. Although the immunoassay and bioassay measure quite different properties of the insulin molecule, attainment of analytical equivalence makes the immunoassay attractive for establishing insulin potency followed, when indicated, by a simplified animal response as a means of confirming the hormonal activity of extracted insulin.

Experiments were designed to determine the precision of the immunoassay under specifically defined conditions, utilizing a series of insulin preparations. The results of the immunoassay were compared with the results of the U.S.P. bioassay for these same insulin samples. Statistical analysis of the results reveal that the immunoassay exhibits precision and reliability for establishing insulin potency well within the confidence limits for computed potency defined in the U.S.P.

Accepted for publication September 13, 1966.

MATERIALS AND METHODS

Antibody Production.—Mixed source insulin (75% beef crystalline zinc insulin and 25% pork crystalline

zinc insulin, by weight) is used as the antigen in the production of antibody used in routine analysis.

The antigen is prepared as follows. To a sterilized 250-ml. (Virtis 45) homogenizer cup add 250 mg. of heat killed *Mycobacterium tuberculosis* (BP008), cells (Biological Production, Eli Lilly and Co.), 50 Gm. of a mixture of 45 Gm. mineral oil[1] plus 5 Gm. sorbitan ester,[2] and 0.23 ml. of liquefied phenol. Sterilize the mixture of mineral oil and the sorbitan ester separately and weigh directly into the homogenizing cup. Add 50 ml., 80 units/ml., of mixed source insulin solution and homogenize the mixture for 5 min. at full speed. Prepare 80 units/ml. of insulin by weighing an appropriate mixed beef-pork insulin (potency previously established by U.S.P. bioassay) and dissolve the solid in insulin diluent (1).

Use the resulting emulsion of "complete" antigen immediately for immunization. If injection delay is encountered, repeat the homogenizing step. A "modified" antigen is also prepared using 40 units/ml. of mixed source insulin in the same manner but without the heat killed *M. tuberculosis* cells. Smaller or larger quantities of the emulsion can be prepared using proportional quantities of the components in the mixture.

Inject mongrel guinea pigs (500–600 Gm. each) subcutaneously with 1.0 ml. of the "complete" antigen divided into 0.2-ml. increments at five hind quarter sites on the initial day of immunization. Repeat same treatment with "complete" antigen on the 15th day. On the 30th day of the immunization regimen and every 30 days, thereafter, further stimulate the animals with a 0.5 ml. intraperitoneal injection of the "modified" antigen. Seven days after antigenic stimulation; namely, the 37th, 67th, 97th, etc., day of the immunization regimen, recover 10 ml. of blood from each animal by cardiac puncture. Use clear antiserum, obtained in the conventional manner, immediately for determining insulin antibody titer or freeze and store at −25° for future antibody determination.

The presence of antibody in the individual guinea pig antisera is readily detected by substituting 100 μl. of 160 munits/ml. insulin standard, 20 μl. of antiserum and 1.0 ml. of immuno-diluent into the standard immunoassay procedure. An antiserum is considered to have suitable antibody concentration if 50% or more of the labeled insulin in the system is bound. Those antisera exhibiting suitable antibody concentration are pooled and freeze-dried. This freeze-dried antiserum is stored at −25° indefinitely and serves as a uniform source of antibody for extended periods of routine analysis.

Prior to use in the immunoassay, a given lot of freeze-dried antiserum is carefully titered against insulin concentrations (10–50 munits/ml. range) chosen from the standard reference curve at three selected antibody concentrations. Experience indicates that antisera, selected on the basis of the detection assay, should be diluted in a range of 1:1000–1:2000 to provide a linear relationship when per cent radioactivity remaining in the supernatant liquid is plotted as a log function of insulin concentration, as shown in Fig. 1. In this manner, a five-point reference curve is prepared for each antibody concentration. A visual inspection of the linearity of the three resulting curves permits a selection of the proper antibody concentration to be used in the immunoassay system in the range of the selected insulin concentrations.

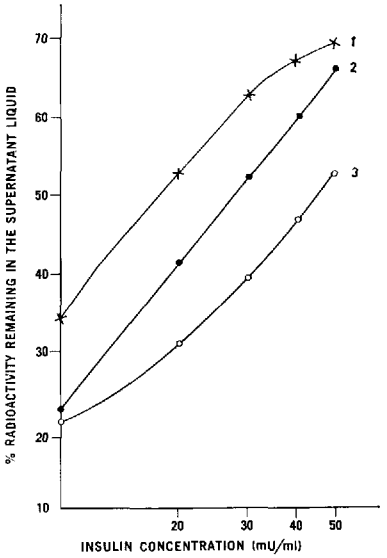

Fig. 1.—A typical insulin antibody titer determination and standard reference curve obtained with pork zinc insulin (lot PJ-5682) and guinea pig antiserum. Key: curve 1, antiserum diluted 1:1000 (1.0 μl./ml.), exhibits the effect of excess antibody; curve 2, a typical standard reference curve for insulin immunoassay is obtained with antiserum diluted 1:1500 (0.67 μl./ml.); curve 3, antiserum diluted 1:2000 (0.50 μl./ml.), shows the effect of insufficient antibody in the immunological reaction.

Due to inherent biological variation in antibody production from individual animals, the results obtained in this type antibody titer determination may indicate a repetition of the determination at higher or lower antibody concentrations. In addition to determining antibody titer, this assay adjustment system is also used to check new lots of human serum albumin, γ-globulin, or other reagents and standards.

REAGENTS

Immuno-Diluent.—*0.25% Serum Albumin-Borate Buffer.*— The immuno-diluent (pH 8.2, 0.1 ionic strength) is prepared with 6.18 Gm. of boric acid, 5.00 Gm. of sodium tetraborate, 4.62 Gm. of sodium chloride, and 10 ml. of 25% salt-poor human serum albumin (Cutter Laboratories) per liter. Stock of 10–20 L. can be prepared and stored at room temperature for 2 months.

Urea–γ-Globulin Reagent.—Urea solution (17%) containing 0.1% bovine γ-globulin (Cohn, fraction II) is prepared by dissolving 510 Gm. of urea, 3.0 Gm. of bovine γ-globulin, and diluting to 3 L. with immuno-diluent. The solution is adjusted to pH 8.2 with 5.0 *N* HCl. The reagent is stored under refrigeration (5°) when not in use and is stable for 6 weeks.

[1] Marketed as Drakseol-6VR by Pennsylvania Refining Co., Butler, Pa.
[2] Marketed as Arlacel A by Atlas Chemical Industries, Inc., Wilmington, Del.

Labeled Insulin.—Insulin labeled with ^{131}I or ^{125}I is satisfactory as a tracer in the immunoassay. ^{131}I insulin is obtained from Abbott Laboratories with a specific activity of 250–300 mc./mg. The concentrate, supplied in 1% human serum albumin with glycine buffer at pH 8.2, is diluted for use with immuno-diluent to 0.266 μc./ml. ^{125}I insulin is prepared at Eli Lilly and Co. with a specific activity of 6–12 mc./mg. and is diluted for use with immuno-diluent to 0.133 μc./ml. The diluted ^{125}I insulin is portioned into 25-ml. aliquots. A fresh aliquot of labeled insulin is used each week, the remainder is stored at −25°. A lot of ^{131}I insulin can be used for a 2-week period and then must be replaced with a freshly prepared material. On the other hand, a lot of ^{125}I insulin,[3] when frozen in aliquots as described, can be used for 3 months. The weekly supply of ^{125}I insulin is stored under refrigeration (5°) when not in use.

Insulin Standards.—Two reference standards used in the present study were selected at random; namely, pork zinc insulin, lot No. PJ-5682 (U.S.P. bioassay: 23.9 unit/mg. ±5.51%) and beef zinc insulin, lot No. 836550 (U.S.P. bioassay: 25.4 units/mg. ±5.59%). Fifty units/ml. stock solution of the reference standards are prepared in insulin diluent and carefully diluted (two steps) to 0.25 units/ml. with insulin diluent. In the final dilution of the 0.25 unit/ml. solution to 10–50 munits/ml. solutions used for the preparation of the standard reference curve, immuno-diluent is used for the dilutions. The mixed source insulin reference is prepared by mixing the 50 units/ml. stock reference standards in the ratio of 25% pork, 75% beef zinc insulin, and appropriately diluting the mixed stock for use. Fresh reference standards are prepared weekly.

Protein Precipitant.—A 1.25 *M* sodium citrate dihydrate solution is prepared by dissolving 367.6 Gm. in distilled water and diluting to 1 L. It is essential that analytical reagent grade sodium citrate be used in the preparation of this salt solution.

INSULIN IMMUNOASSAY METHOD

Sample Preparation.—In order to minimize volumetric error, samples are carefully diluted with conventional laboratory pipets and volumetric flasks; or, micro dilutions are prepared by employing a syringe microburet (Micro-metric Instruments Co.). If micro dilutions are utilized in sample preparation, volumetric error is avoided if the delivery volume from the syringe microburet is not less than 50 μl. with highly concentrated insulin solutions. The first step dilution is performed to about 50 units/ml. using insulin diluent. The final dilutions are made with immuno-diluent. After the final dilution, the samples are conveniently stored overnight at 5°.

Assay Procedure.—Clean all glassware with detergent (Alconox), rinse with 2% (w/v) HCl, then deionized water, and dry in an oven before use. Number a set of seventy-two 10-ml. conical flasks, 12-ml. double strength centrifuge tubes, and plastic counting tubes in sequence. Add 100 μl. of 0.133 μc./ml. ^{125}I insulin (by syringe microburet) and 1.8 ml. urea–γ-globulin reagent to all flasks. Flasks 1 and 2 serve as control blanks for labeled insulin; add 1.10 ml. immuno-diluent to each in place of the sample and antibody. Flask 3 (reference zero) serves as a guide in measuring the binding capacity of the antibody with the labeled insulin. It contains 100 μl. of immuno-diluent in place of the sample. The insulin reference standard (flasks 4–18) and the samples (flasks 19–72) are run in triplicate. Using the syringe microburet, deliver 100-μl. aliquots of each of the insulin reference standards (10, 20, 30, 40, and 50 munits/ml., respectively) and aliquots of the unknown samples into the appropriate flask. Initiate the immunological reaction by the sequential addition of 1.0 ml. of antibody solution (flasks 3–72). Momentarily agitate the mixture by hand and continue gentle agitation on a rotary shaker (A. H. Thomas No. 3623) for 15 min. at room temperature. Commence all timing sequences after additions are made to the last flask. Precipitate the antigen–antibody complex (bound form) by adding 6.0 ml. of 1.25 *M* sodium citrate into each flask. Again agitate this mixture on the rotary shaker for 15 min., then transfer the contents to the appropriate numbered centrifuge tube, and centrifuge in a refrigerated angle head centrifuge at 2400 × g for 45 min. at 15°.

Following centrifugation, carefully remove 5 ml. of the supernatant liquid and transfer the liquid to the appropriately numbered plastic tube.

Radioactivity Measurement.—Measure the radioactivity of the sample in the plastic tube in an automatic gamma spectrometer (model 410A, Packard Instrument Co.) precalibrated for a peak emission of ^{125}I or ^{131}I. The counting efficiency of the instrument is measured with a γ-ray emission reference source (^{133}Ba) lot No. B-508 (Abbott Laboratories).

Prepare a radioisotope control tube for monitoring a given lot of labeled insulin during the entire period of time that the particular lot is used for routine assay. Dilute a 100-μl. aliquot of diluted labeled insulin (0.133 μc./ml.) with 8.9 ml. of immuno-diluent and transfer a 5-ml. aliquot of this mixture to a plastic tube. Tightly seal the tube with a rubber stopper and tape.

The above control tube is followed by an empty plastic tube used to measure background radiation. Counting time is usually 5 min./tube. A radioactivity concentration is selected such that the 5-min. count of the "reference zero" tube is never less than 5000.

Calculation of Potency.—By convention, correct the individual tube counts for background and decay. Calculate the amount of radioactivity remaining in the supernatant liquid and express as per cent (average corrected sample count × 100 divided by average corrected blank count). Plot a five-point curve of the standard reference insulin concentration, 10, 20, 30, 40, and 50 munits/ml., respectively, on semilog graph paper. Curve 2, Fig. 1, represents a typical standard response curve exhibited by a plot of these concentrations. Sample concentration is estimated from this graph or calculated on a point-to-point linear assumption as a logarithmic function of the insulin concentration. For greater reliability, the calculation is limited to three center standard reference points; namely, 20, 30, and 40 munits/ml. of insulin. For sample values (per cent radioactivity in the supernatant) equal to

[3] ^{125}I insulin was prepared by Dr. R. E. Crabtree, Analytical Research, Eli Lilly and Co., Indianapolis, Ind.

or less than the midpoint of the standard curve, the following equations are used to calculate insulin concentration in the sample. (Assuming 20, 30, and 40 munits/ml. = standard curve.)

$$\text{slope} = \log 30 - \log 20/(\%\text{ at } 30) - (\%\text{ at } 20)$$
$$\log \text{sample} = \log 30 - (\text{slope})(\%\text{ at } 30 - \%\text{ sample})$$
$$\text{antilog sample} = \text{sample concentration}$$
$$\%\text{ estimate} = (\text{sample concentration/midpoint standard concentration}) \times 100$$
$$(\%\text{ estimate})(\text{estimate}) = \text{unknown insulin concentration}$$

For sample values (per cent radioactivity in the supernatant) equal to or greater than the midpoint of the standard curve, the equations are the same as above except for calculation of the slope, which is:

$$\text{slope} = \log 40 - \log 30/(\%\text{ at } 40) - (\%\text{ at } 30)$$

Immunoassay results are reported with their 95% confidence interval values. The variance of the indicated sample potency is calculated as described by Baum *et al.* (7). For routine immunoassay of insulin, a digital computer (IBM 360) is programed to perform the calculations.

Insulin Bioassay Method.—The potencies of all standard insulins and insulin samples used in this study were established in accordance with the official U.S.P. bioassay (1) utilizing the U.S.P. zinc insulin reference standard for comparison. Sufficient individual bioassay results were combined to yield 95% fiducial limit in the range of 5–8%.

Insulin Testing Samples.—Triplicate sample of regular pork, beef, mixed source master lots of crystalline zinc insulin, NPH (isophane) insulin, and protamine zinc insulin were selected at random for establishing assay precision. The samples, to be subjected to repetitive immunoassay, were the same trial dilutions of the respective insulin master lots used previously in establishing their insulin potency by the official U.S.P. bioassay. In addition to the commercial insulin products, several process samples from insulin manufacture were obtained and assayed with both beef and pork insulin standards. Two of these samples, 174-A and 9CR40 + 41-A, were subjected to U.S.P. bioassay to establish the biological potency for comparison with the immunoassay results.

The initial aspects of the study revealed the desirability of having a secondary reference standard which is equivalent to the U.S.P. standard. For this purpose three pooled lots of pork, beef, and mixed source insulin were carefully selected from a number of lots which had previously been thoroughly tested by U.S.P. bioassay. Lot 14GP-257, pork zinc insulin crystals, was obtained from two pooled lots of pork insulin, and the average biopotency value was used as a basis of preparing a solution of this pork zinc insulin at 40 units/ml. Similarly, lot 14GP-258, beef zinc insulin crystals, was obtained from six different beef lots of established potency and lot 14GP-259, a mixed source zinc insulin, was a pool of 32 lots of mixed pork and beef zinc insulin crystals with potency also established by bioassay. The average potency value of these pooled lots of insulin should be closely related to the potency of the U.S.P. reference standard. Therefore, the lot, which under conditions of the immunoassay, gave results equivalent to the U.S.P. reference standard, would provide an insulin standard that permits immunoassay results to be expressed in terms of the U.S.P. standard.

Requirements for Immunoassay Precision.—The experimental plan was designed to yield results which were considered as "maximum capability" of the immunoassay under presently recognized conditions. "Maximum capability" is defined as those conditions of procedural operations which would yield the smallest possible variation from one daily assay to another. These conditions place special demand on the technical operators which would not be imposed on the regular daily "routine" testing.

Samples were prepared for each day's assay by a two-step dilution from the concentrated sample. The same pipet was used with a given sample each time that sample was diluted. In order to achieve more accuracy throughout, each technical operator used only one syringe for the ^{125}I insulin and only one syringe for the sample in the micrometric delivery. The sample syringe was carefully rinsed each time with the sample to be delivered into the reaction mixture. Every effort was made to keep dilutions and volumetric errors to a minimum. All reagents utilized throughout the testing sequence were prepared, as necessary, from the same lots of antibody, γ-globulin, human serum albumin, urea, sodium citrate, and borate buffer.

In all experimental testing, each sample was evaluated 10 times on different days by each of two technical operators. The experiments in each sequence were carried out over a period of a month with daily runs scheduled not to interfere with the routine insulin immunoassays also being performed. The tabulated results were submitted for statistical calculation and an analysis of variance.

RESULTS AND DISCUSSION

Comparative Assay Results.—*Regular Insulin.*—Table I shows the comparative results of the U.S.P. bioassay and the immunoassay of three lots each of pork, beef, and mixed zinc insulin. Both the bioassay and the immunoassay were conducted on a 40 units/ml. sample solution of each lot of insulin. The results were calculated in terms of units/mg. so that both assay systems could be directly compared. The 95% confidence limits of the immunoassay results are expressed for 4 and 10 daily repetitive tests. The insulin test samples were measured against the randomly selected pork standard, beef standard, and the mixed standard to determine the degree, if any, of species specificity affecting the immunoassay. The results reveal that the deviation of the immunoassay values for 4 repetitive tests is generally less than that of the corresponding bioassay and is always less in the case of 10 repetitive immunoassays. The test sample potency values obtained with the immunological assay using the pork insulin reference standard closely coincides with the bioassay results which were established with the U.S.P. insulin standard. On the other hand, the immunological data obtained with the beef insulin reference standard are consistently higher than the corresponding bioassay results. The statistical analysis indicates a significant difference in the assigned bioassay potencies of the two randomly selected reference standards. The overall results revealed that the beef zinc insulin refer-

ence standard (lot No. 836550) gave consistent values which were higher than expected in the immunoassay when compared to the bioassay. This suggests that the original bioassay of this lot of beef zinc insulin crystals, although within the bioassay fiducial limit, was unrealistic as an estimate of the true potency; hence, in preparing the beef reference standard based on the mean biopotency, more insulin was introduced into the standard than would normally be expected. This was further supported by the analysis of variance and cross checking the reference standards in the immunoassay. Of the two immunoassay reference standards, randomly chosen, the pork zinc insulin (PJ-5682) compares most favorably with the U.S.P. reference standard.

The effect of species specificity on immunoassay reliability could be determined by an analysis of variance of the data obtained in Table I. The analysis of variance revealed no interaction of the groups studied under the conditions employed in the immunoanalysis.

Therefore, immunoassay, performed with antiserum obtained from guinea pigs immunized with mixed pork and beef insulin as the antigen, can be used with either pork or beef insulin as a standard in the immunoassay of beef, pork, or mixed source insulin samples. The fact that species specificity has no effect upon the method employed in this study is important for a satisfactory method for control of insulin development and manufacture.

Immunoassay precision is influenced from two principal sources: the variation encountered within a single day's testing and the variation experienced between days. The within-day assay variation is largely dependent upon sample replication, instrumentation, etc. Differences between days which exceed the within-day variation, are less amenable. The result of these two types of variation often produced deviations as large as ±15–25% in the immunoassays obtained by the salt precipitation procedure as described by Baum *et al.* (7). By carefully modifying the procedure, standardizing reagents, practicing rigid analytical techniques, and strict attention to details, the assay variation was reduced to ±11.2% when expressed as a 95% con-

[a] The symbols indicated as $2\sigma_4$ and $2\sigma_{10}$ represent the 95% confidence limit of the mean of 4 and 10 daily immunoassays, respectively. [b] All samples were prepared at 40 units/ml. based on the insulin potency established by bioassay. [c] Acidified with 30 µl. concentrated HCl/10 ml. of mixture for solution prior to dilution with immuno-diluent.

fidence limit for a single assay. The data in Table I were used to calculate such a generalized confidence interval of 88.8–111.2%.

The U.S.P. regulates the potency of insulin with a 95% fiducial limit of 87–115%. However, specifications for establishing insulin potency at Eli Lilly and Co. require a 95% fiducial limit of ±5–6% for the U.S.P. insulin bioassay. The number of daily immunoassays which give equivalent results is predicted from the average variation observed in the data summarized in Table I. Under the assumption that the daily immunoassays of a single sample are normally distributed, the required sample size (repetitive immunoassays conducted on different days, n) is calculated as:

$$\pm 5.5 = \pm 11.2\sqrt{\frac{}{n}}$$

$$n = 4.15$$

Hence, four daily immunoassays must be conducted to be within the Eli Lilly and Co. specifications.

The coefficient of variation (±5.6%) established from the data in Table I was obtained under conditions of "maximum capability." These rigid analytical techniques are impractical in the routine immunoassay for insulin. Therefore, the same series of insulin samples was re-evaluated under conditions defined as "routine capability." "Routine capability" permits the technician to utilize different syringes and pipets for all analytical measurements. Table II shows a comparison of the confidence limits of the U.S.P. bioassay and the insulin immunoassay conducted under conditions of "maximum" and "routine" capability. In this series of immunoassays, only the pork insulin standard was used since it has a potency very similar to that of the U.S.P. reference standard. Visual inspection of the "routine capability" results reveals little difference from the results of "maximum capability." The results further support the validity of the calculated coefficient of variation (±5.6%) as originally determined and indicate that the between-days variation encountered in the immunoassay is not due to operator error or analytical measurement.

Immunoassay of Some Commercial Insulin Products and Manufacturing Intermediates.—The reliability of the immunoassay for determining insulin concentrations in commercial products containing protamine is shown in Table III. NPH (isophane) insulin and protamine zinc insulin were from lots with potency established previously by bioassay. The immunoassay results under "maxi-

[a] The symbols indicated as $2\sigma_4$ and $2\sigma_{10}$ represent the 95% confidence limit of the mean of 4 and 10 daily immunoassays, respectively.

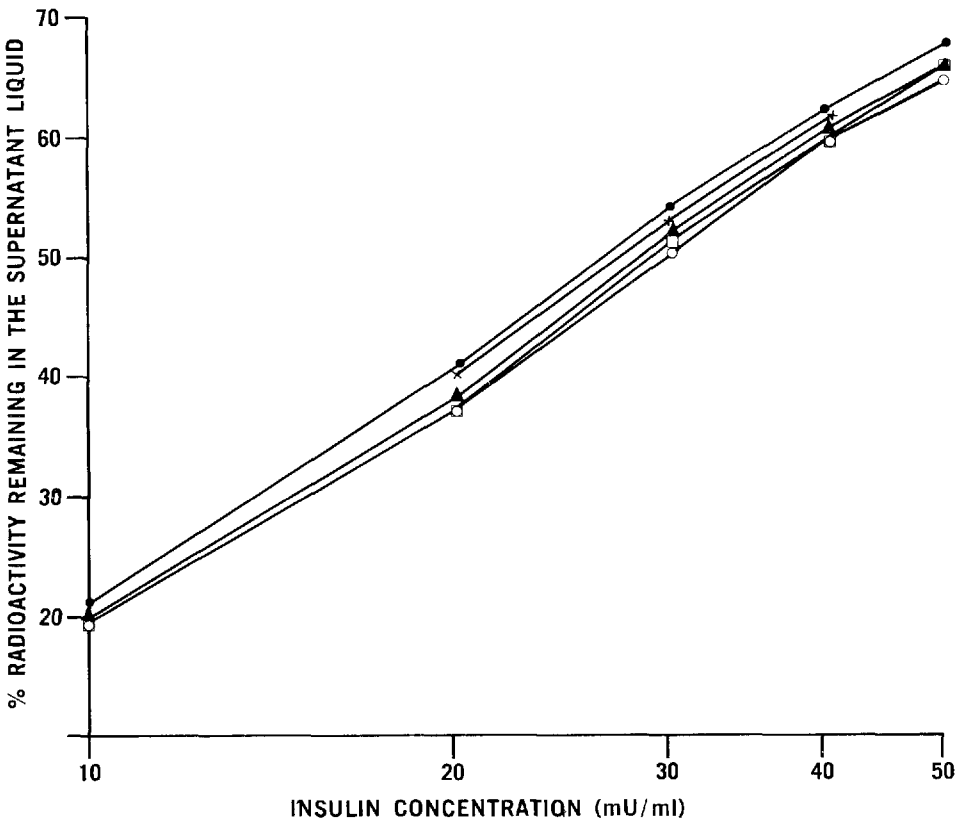

Fig. 2.—Full-scale response curves of the mean value of 10 immunoassays conducted on different days. Key: ●, pork zinc insulin, lot PJ-5682 (served as the reference standard); ○, pooled samples of pork insulin, 14GP-257; □, beef insulin, 14GP-258; ▲, mixed pork and beef insulins, 14GP-259, diluted based on the calculated mean of the individual bioassay result; ×, U.S.P. reference standard, W-3930, diluted based on the established biopotency of 24 units/mg. and determined at three of the five standard concentrations.

mum capability" conditions were obtained with a mixed source insulin reference standard having the same ratio of pork to beef insulin as that of the sample. The immunoassay values are slightly high compared to the bioassay figures. This is accounted for by the fact that the beef reference standard, lot 836550, which constitutes 75% of the mixed source reference standard, was found to give consistently high results, as previously noted. The unrealistic high results obtained with the mixed standard and the similarity of the pork insulin standard with the U.S.P. reference standard suggested that pork insulin standard should be used in the series conducted under "routine capability." The results readily reflect the difference in the absolute potency of these two randomly selected reference standards. The confidence limits, expressed for 4 and 10 repetitive tests, are slightly greater than the values presented in Tables I and II, but are within the expected range of the coefficient of variation. The results in Table III support the view that commercial insulin products can be analyzed effectively with this immunoassay.

Table IV provides evidence that the immunoassay can be used in monitoring insulin manufacture. Immunoassay results on samples selected at different stages of the insulin process show a variation that is within the limits of the coefficient of variation and agree satisfactorily with the U.S.P. bioassay. The immunoassay possesses a distinct advantage over the U.S.P. bioassay in its ability to determine insulin concentration in crude samples that cannot be satisfactorily handled under the conditions of the bioassay system.

The pooling of many lots of crystalline zinc insulin of established biological potency would seem to provide a material with a mean biopotency which would closely correspond to the U.S.P. reference standard. Three types of pooled samples were prepared by mixing aliquots of zinc insulin crystals from lots that were thoroughly assayed in the U.S.P. method; namely, 14GP-257 from two lots of pork zinc insulin crystals with an average potency of 25.45 units/mg., 14GP-258 from six lots of beef zinc insulin crystals with an average potency of 25.50 units/mg., and 14GP-259 from 32 lots of mixed source zinc insulin crystals with an average potency of 24.79 units/mg. The average potency value was used to prepare 40 units/ml. insulin solutions of each for 10 repetitive immunoassays on different days. To further substantiate and extend the findings of the initial study, these samples were tested at all concentrations used

TABLE V.—SIMILARITY OF THE INDIVIDUAL COMPUTED OF POOLED ZINC INSULIN SAMPLES

Sample	Type	Range, munits/ml.	Slope[a]	95% Confidence Interval of the Slope
PJ5682	Pork	20–40	69.57	66.96–72.18
14GP-257	Pork	20–40	70.05	67.44–72.66
14GP-258	Beef	20–40	73.60	70.99–76.21
14GP-259	Mixed	20–40	73.36	70.75–75.98
W-3930	U.S.P.	20–40	69.93	67.32–72.54
Common slope—all species from statistical analysis.		20–40	71.30[b]	

[a] Individual slopes by least squares. [b] Least squares common slope lies within each of the computed individual slope confidence intervals.

in the standard reference curve. According to the procedure described, a sample for immunoassay is diluted to a concentration which is estimated to be equivalent to that of the midpoint standard (30 munits/ml.). The statistical analysis and the interpretation of results are limited to this single point. On the other hand, a comparison of the slopes of the curves obtained from determining these pooled samples at five different concentrations would avoid this limitation. If the slopes of the curves obtained from the pooled samples are identical, within the experimental limits, with that of the randomly chosen standard (in this case pork zinc insulin PJ-5682), the original interpretation would be confirmed.

Figure 2 shows a plot of the mean values of 10 repetitive immunoassays of the pooled samples, standard PJ-5682, and three concentrations of the U.S.P. reference standard. Visual inspection indicates the curves to have similar slopes in the range of 20–40 munits/ml. insulin concentrations, respectively. In view of the fact that this immunoassay has been limited to the determination of potency of extracted insulin by definition, only the most sensitive portion of the standard curve was subjected to statistical analysis to substantiate the use of one sample concentration for routine analysis.

Statistical analysis, by least squares, of the data obtained at 20, 30, and 40 munits/ml. insulin concentrations gave 95% confidence limits for the individual slopes as shown in Table V. The value of the calculated common slope, 71.30, lies within the limits of the individual slopes. Furthermore, by a more refined technique of regression analysis, no significant differences in slopes were detected. Figure 3 shows the dose response curves of these

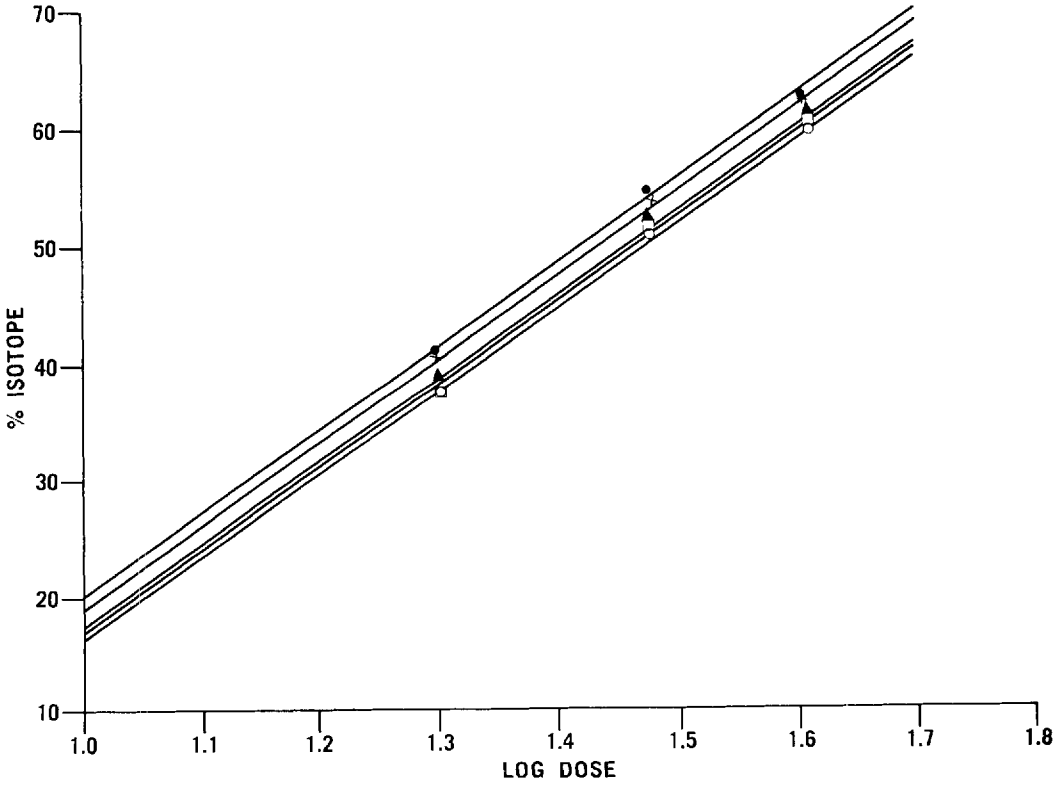

Fig. 3.—Dose response curves based on the common slope calculated by least squares for the selected concentrations at 20, 30, and 40 munits/ml. Key: ●, PJ-5682, ○, 14GP-257; □, 14GP-258; ▲, 14GP-259; ×, U.S.P. reference standard W-3930 as in Fig. 2.

[a] Pork zinc insulin (lot PJ-5682) used as the immunoassay reference standard.

insulin samples plotted with the common slope. Consequently, species specificity does not affect the validity of the immunoassay result if mixed antigen is used in production of antibody in guinea pigs. The individual regression lines for the different samples, although parallel, are not superimposable, thus revealing slight errors in the assigned potency of these samples. In order to express insulin immunoassay results in terms of the U.S.P. reference potency, a secondary reference standard would need to be experimentally adjusted to the potency of the U.S.P. reference standard. Any of these pooled insulin samples can serve as a secondary reference after appropriate matching with the U.S.P. reference by repetitive immunoassay.

Application of the Immunoassay for Establishing the Potency of Manufactured Insulin.—The information obtained in this investigation was applied to the determination of potency of several lots of manufactured insulin. Table VI compares the U.S.P. bioassay and the immunoassay of four lots of zinc insulin crystals. Instead of four repetitive immunoassays on different days as required under "maximum capability" conditions, five immunoassays were conducted (except on ML-9GZ30) under routine conditions. The mean value of insulin potency established by immunoassay compares favorably with the bioassay result being well within the limits defined in the U.S.P. (1). However, the standard deviation of the mean of the individual values, particularly with ML 48, varied somewhat more than would be predicted. The cause of this excessive variation could not be readily determined, but suggests the necessity of vigilant attention to detail in immunoassay conduct.

The results of this investigation indicate that the insulin immunoassay, in accordance with the described procedure, is a rapid and economic method, with satisfactory precision and sensitivity for establishing the potency of extracted insulin. The use of this immunoassay for extracted insulin fills an important need in monitoring the manufacture of insulin and assessing insulin concentration in commercial insulin products. The information provided in this investigation can serve to promote interest and support in establishing the immunoassay as a U.S.P. method for determining insulin potency.

Irreversible Enzyme Inhibitors LXVII

2-Amino-6-(*p*-bromoacetamidophenylbutyl)-5-phenylbutyl-4-pyrimidinol, an Active-Site-Directed Irreversible Inhibitor of Dihydrofolic Reductase

By B. R. BAKER and JOHANNES H. JORDAAN

2-Amino-5-phenylbutyl-4-pyrimidinols substituted by a *p*-bromoacetamidophenylbutyl group (XIII) or a *p*-bromoacetamidophenethyl group (XIV) on the 6-position can inactivate dihydrofolic reductase with a half-life of 18 and 12 min. at 37°, respectively. These inactivations have the kinetic parameters expected for enzyme inactivation by the active-site-directed mechanism, that is, an inactivation proceeding by a neighboring group reaction within the reversible complex formed between dihydrofolic reductase and XIII or XIV. Neither iodoacetamide nor *p*-bromoacetamidophenylbutyric acid showed any inactivation of dihydrofolic reductase at a concentration equal to XIII under conditions where XIII gave 65–70 per cent inactivation. The rate of inactivation of dihydrofolic reductase by XIII and XIV was slowed by the reversible inhibitors, folic acid (I) and 2,4-diamino-5-(3,4-dichlorophenyl)-6-ethylpyrimidine (XV). The inactivation was also slowed by TPNH, but not by DPNH or adenosine diphosphate.

BEFORE THE strong hydrophobic bonding to dihydrofolic reductase was discovered (1)—with its conformational implications (2–8)—more than 30 potential active-site-directed irreversible inhibitors for this enzyme had been synthesized and evaluated on the premises discussed below.

THEORETICAL

It should theoretically be possible to modify folic acid (I) with a chloromethyl ketone group in place of one of the carboxyls in order to obtain an active-site-directed irreversible inhibitor that would operate by the endo-mechanism (9) by alkylation of the enzymic binding point for one of the carboxyl groups. The synthesis of such a pteridine is fraught with monumental incompatibilities of functional groups. Since the anilino propylpyrimidine (II*a*) (10) without a carboxy-L-glutamate moiety was still about one-eighth as good an inhibitor as II*b* (10, 11), compounds II*c* (n = 0,2,4,6) and II*d* were synthesized as potential active-site-directed irreversible inhibitors of dihydrofolic reductase (11). Although these five compounds were good reversible inhibitors, they failed to show irreversible inhibition. In retrospect, these failures were most probably due to the possibility that the anilinopropyl group of II*a*, *c*, and *d* was not complexed to the enzyme at the *p*-aminobenzoyl locus for folic acid, but was complexed in the hydrophobic region in a conformation such as III where the pyrimidine moiety has been twisted 60° with respect to the "normal" complexing of the pteridine of folic acid in conformation I. A conformation such as II would destroy the juxtaposition of the nucleophilic groups on the enzyme—which complex the glutamate carboxyls—with the alkylating functions of III*c* and *d;* that is, if the anilinopropyl side chains of III*c* and *d* are complexed in a hydrophobic region, then by definition there are not apt to be hydro-

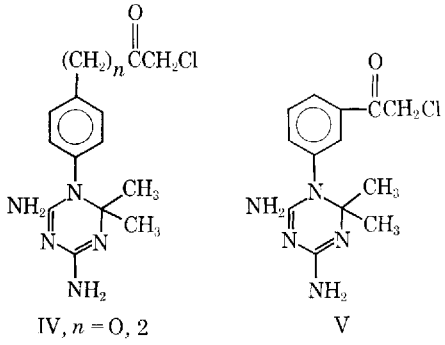
For a preliminary announcement of this work see *Reference 7*.

Previous paper: Baker, B. R., Santi, D. V., Coward, J. K., Shapiro, H. S., and Jordaan, J. H., *J. Heterocyclic Chem.*, to be published.

The previously published papers on "Nonclassical Antimetabolites" and on "Analogs of Tetrahydrofolic Acid" have been combined into one series, since they have the common objective of the design of active-site-directed irreversible enzyme inhibitors. A collected list of references on "Irreversible Enzyme Inhibitors" will be sent on request.

philic nucleophilic groups on the enzyme in this hydrophobic area needed for covalent bond formation in a neighboring group reaction within the enzyme–inhibitor complex.

Some related types of potential active-site-directed irreversible inhibitors were synthesized and evaluated—namely, the 1-phenyl dihydro-*s*-triazine derivatives, IV and V (12). These compounds were excellent reversible inhibitors but failed to show irreversible inhibition since the phenyl moiety is complexed in a hydrophobic region (3). Similarly, compounds V–VIII were good reversible inhibitors, but failed to show irreversible inhibition (13).



IV, $n = 0, 2$ V

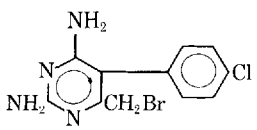
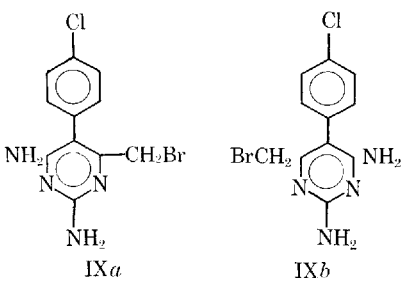
VII, R = $BrCH_2CONH(CH_2)_2$–
VIII, R = $BrCH_2CONH$–C$_6$H$_4$–$(CH_2)_3$–

A different type of potential active-site-directed irreversible inhibitor was constructed on the proposition that there might well be an enzymic proton donor, such as imidazole, near the 8-position of folic acid when it is complexed to the enzyme; such a proton donor could aid in the TPNH reduction of folic acid. The pyrimethamine-type analog (IX) was synthesized and found to be an excellent reversible inhibitor, but not an irreversible inhibitor of dihydrofolic reductase (14). Again, in retrospect, it is probable that the 5-phenylpyrimidine (IX) binds its phenyl to the hydrophobic region in a "twist" conformation as depicted in IX*a*; if such were the case, then IX*a* would not have its bromomethyl in close enough proximity to the supposed enzymic proton donor. A similar conclusion could be drawn if IX complexed to dihydrofolic reductase in a "twist-flip" conformation (IX*b*).



IX



IX*a* IX*b*

As a result of a study on possible pyrimidine conformations when these inhibitors are complexed to dihydrofolic reductase, it was suggested that a pyrimidine such as X would have the conformation shown (with respect to conformation I for folic acid), since the strong hydrophobic bonding could be determinant for the binding conformation (7). Such a conformation for X suggests that chain lengthening of the R group should project it into a hydrophilic region. That this might be the case was supported by the observation that the *n*-propyl group caused XI to be a thirtyfold less effective inhibitor than the 6-methylpyrimidine (X) (7); this result could be due to the repulsion of a hydrophobic group from a hydrophilic area on the enzyme or to a steric interaction unfavorable to complex formation between the enzyme and the inhibitor. That steric interaction was less likely was indicated by the increase in the size of the R group to phenylbutyl (XII) (15); XII was a fivefold better inhibitor of dihydrofolic reductase than XI, also indicating that the phenyl group on the 6-side chain was complexed to the enzyme. Therefore, the 6-bromoacetamidophenyl butyl pyrimidine (XIII) was selected as a likely candidate for an active-site-directed irreversible inhibitor of dihydrofolic reductase with the premise that the 5-phenylbutyl group would complex in the hydrophobic area, and the 6-phenylbutyl group could project into a hydrophilic area on the enzyme; the corresponding 6-phenethyl derivative (XIV) was also investigated.

XV

RESULTS

The bromoacetamido pyrimidine (XIII) was about equal to XII when assayed (16) as a reversible inhibitor of dihydrofolic reductase; that is, XIII showed 35% inhibition at a concentration of 100 μM—the maximum solubility in 10% *N*,*N*-dimethylformamide—in the presence of 6 μM di-

hydrofolate. It was estimated (1) that the K_i was about 4×10^{-5} M. When XIII was incubated with dihydrofolic reductase at 37° in the absence of TPNH, inactivation occurred with a half-life of about 18 min. When XIII, iodoacetamide, and *p*-bromoacetamidophenylbutyric acid (17), all at 40 μM, were simultaneously incubated with the enzyme at 37° for 25 min., XIII gave 65% inactivation, but the other two compounds gave only 2–3% inactivation (Table I, *A*); thus, the random bimolecular inactivation of dihydrofolic reductase was ruled out (21).

[a] Dihydrofolic reductase from pigeon liver in 0.05 M Tris buffer (pH 7.4) plus 10% *N*,*N*-dimethylformamide was incubated in the absence of TPNH at 37° for 25 min. with the additions indicated; the amount of remaining enzyme was then assayed (14). In each experiment an enzyme control was run simultaneously with the two or three other solutions; only 0–4% thermal inactivation of the enzyme occurred. [b] In similar simultaneous experiments, adenosine diphosphate or DPNH at 36 μM showed no protection, whereas 36 μM TPN protected about half as well as 36 μM TPNH.

Table I summarizes experiments on the protection against this inactivation. The reversible inhibitors, folic acid (18) and 2,4-diamino-5-(3,4-dichlorophenyl)-6-methylpyrimidine (XV) (19), slowed the rate of inactivation, evidence that the active site was involved in the inactivation (20, 21). Surprisingly, TPNH also protected against inactivation; since the reversible inhibition by XIII was found to be independent of TPNH concentration, the protective effect of TPNH was not due to the complexing of the bromoacetamidophenyl moiety of XIII to the enzymic region normally complexing TPNH. Two other possible explanations are that (*a*) the complex between XIII and dihydrofolic reductase juxtaposes the bromoacetyl group to a TPNH binding point or (*b*) TPNH causes a conformational change in the enzyme which moves the enzymic nucleophilic group from juxtaposition with the bromoacetyl group in the XIII–enzyme complex. These two possibilities cannot as yet be distinguished.

It was noted that 36 μM adenosine diphosphate or DPNH showed no protection. TPN at 36 μM showed half the protection given by 36 μM TPNH at this pH of 7.4. These results exclude the destruction of the inhibitor by the phosphate mono ester group. DPNH binds poorly to dihydrofolic reductase at pH 7.4 (22); the binding of TPN is quite good at pH 5.5 (22), but its binding at pH 7.4 has not been measured. Thus, these protection experiments are best explained on the relative binding of the various phosphates to dihydrofolic reductase.

Increasing incubation time did not lead to total inactivation, but inactivation leveled off at 80–90%. This result is similar to that observed (23) with the action of *p*-nitrophenyl α-bromoacetamidoisobutyrate on chymotrypsin where 80–90% inactivation occurs; the remaining activity was shown to be due to a modified enzyme where K_m was increased, but $V_{max.}$ remained nearly the same (23, 24). It will be of interest in the future to determine if $V_{max.}$ or K_m has changed for dihydrofolate or TPNH or both after dihydrofolic reductase has been inactivated with XIII.

If the inactivation of dihydrofolic reductase proceeds through an obligatory complex between the enzyme and the inhibitor (XIII), then a "rate-saturation" effect should be observed, that is, the rate of inactivation is dependent upon the concentration of enzyme–inhibitor complex, EI (21), as shown in Eq. 1.

$$[EI] = \frac{[E_t]}{\frac{K_i}{[I]} + 1} \qquad \text{(Eq. 1)}$$

The amount of reversible complex can be calculated from Eq. 1, previously derived (21), where [EI] = concentration of complex, $[E_t]$ = total active enzyme, and [I] = inhibitor concentration. Since XIII has $K_i = 4 \times 10^{-5}$ M and the incubation is performed with 4×10^{-5} M of XIII, then $[EI] = 0.5\,[E_t]$. If $[I] = 1 \times 10^{-5}$ M, as in experiment *F* (Table I), then $[EI] = 0.2\,[E_t]$. Note that XIII at 4×10^{-5} M gave 69% inactivation in 25 min., but that XIII at 1×10^{-5} M gave 43% inactivation. It can be calculated that 1×10^{-5} M of XIII would have given 23% inactivation in 25 min. if the reaction were proceeding by a bimolecular reaction, but 40% if inactivation occurred through the EI complex as in Eq. 1. Thus, the observed 43% at 25 min. with 1×10^{-5} M represents a rate-saturation effect as a first approximation.

The 5-phenylbutyl-4-pyrimidinol (XIV) with the shorter phenethyl side chain containing a *p*-bromoacetamido group was also found to be an active-site-directed irreversible inhibitor of dihydrofolic reductase. XIV was a reversible inhibitor with $K_i = 3 \times 10^{-5}$ M; when incubated with dihydrofolic reductase at 37°, inactivation occurred with a half-life of about 12 min. With extended time the enzyme became 80–90% inactivated, but did not inactivate completely, as also noted with XIII. The phenethyl pyrimidine (XIV) showed the same protection pattern as observed with XIII in Table I.

Whether XIII and XIV attack the same amino acid on dihydrofolic reductase must await inactivation experiments with the pure enzyme; that the same amino acid would be attacked is unlikely, due

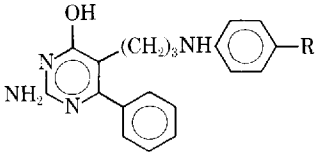
to the conformational changes that either XIII or the enzyme would have to undergo. Such conformational changes on XIV would most likely be energetically unfavorable, but the energetics of such a conformational change in the enzyme are unknown.

DISCUSSION

An active-site-directed irreversible enzyme inhibitor theoretically operates by first forming a complex with the enzyme, then the complex undergoes a facile neighboring group reaction between an enzymic nucleophilic group and a leaving group on the inhibitor (9, 25, 26). There are two types of these irreversible inhibitors: (*a*) those that operated by covalent bond formation inside the active-site—the so-called endo-mechanism—and (*b*) those that operate by covalent bond formation outside of the active-site—the so-called exo-mechanism. Examples of both types are known (9, 25, 26).

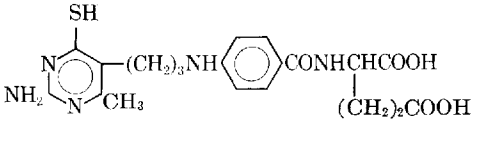
The endo-type of irreversible inhibitor is preferred by protein structure chemists since they wish to "label" amino acids in the active-site by attachment of a covalently linked moiety that can be identified; the specific "labeled" amino acid is determined by total hydrolysis of the protein and its position in the amino acid sequence by partial hydrolysis (26). It has been anticipated (26) that the endo-type would be much less effective for chemotherapy than the exo-type since the active site of an enzyme can vary only little from species to species and still be operational. In contrast, the exo-type could be expected to be far more species and tissue specific since covalent bond formation is taking place outside the active site where numerous changes can be made without disrupting the protein's function (26, 27).

At the time our program on active-site-directed irreversible inhibitors for dihydrofolic reductase was initiated in 1961, the factors in the design of irreversible inhibitors for enzymes was just beginning to emerge (21, 25, 28); since then the field has developed considerably in both concept and practice (9, 26). Therefore, at the start we set goals toward both the endo-type and exo-type of irreversible inhibitors (25) for dihydrofolic reductase. It soon became apparent that the active-transport system for cell wall penetration by folic acid and its derivatives (10, 29) was sensitive to the wrong positioning of bulky groups. It was noted that the folic acid analog (XVIII) (30), was cytoxic to S-180 cells in culture, but the 6-phenylpyrimidine analog of folic acid (XVI) (31) was inert; however, when the carboxy-L-glutamate moiety of XVI was not present, as in XVII (31), XVII was cytoxic.[1]



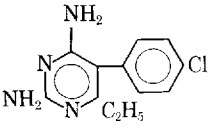
XVI, R = $-CONHCHCOOH$ with CH_2CH_2COOH

XVII, R = H



XVIII

The carboxy-L-glutamate moiety has been implicated as being essential for active transport of folic acid and its close analogs (10), but less related dihydrofolic reductase inhibitors such as pyrimethamine (XIX) entered cells by passive diffusion (10, 29). It then follows that perhaps XVI was inert because the 6-phenyl group was too bulky to be



XIX

accommodated by the active transport system for folic acid, but, in addition, the ionized carboxy-L-glutamate aborted any possible passive diffusion. For this reason all of our subsequent work avoided the presence of the carboxy-L-glutamate moiety so that the inhibitors would be able to penetrate the cell membrane by passive diffusion. Furthermore, certain 2,4-diamino heterocycles without the carboxy-L-glutamate moiety can complex to dihydrofolic reductase even better than folic acid (1) (16, 19, 26, 29), and such molecules without carboxy-L-glutamate moiety are considerably easier to synthesize and purify.

The removal of the carboxy-L-glutamate moiety led to the discovery of the useful hydrophobic bonding area on dihydrofolic reductase (1) with its species differences in conformational tolerances (4, 8, 29). Although the presence of the hydrophobic region on dihydrofolic reductase aborted the success of more than 30 candidate active-site-directed irreversible inhibitors, knowledge now developed on the hydrophobic region (1–8) should be usable for the design of species- or tissue-specific irreversible inhibitors of this enzyme.

Note that the irreversible inhibition of dihydrofolic reductase by XIII (Table I) is slowed by the presence of TPNH. If XIII is alkylating a point on the enzyme that normally complexes TPNH, then by definition XIII is operating by the endo-mechanism; if XIII is alkylating some other point not essential for enzyme activity, but TPNH causes a conformational change in the enzyme which removes this attackable function on the enzyme from juxtaposition with the alkylating function of XIII, then the exo-mechanism is operating. In either case the hydrophobic region can be used to introduce a new parameter for tissue- or species-specificity.

The maximum specificity should be observed if an alkylating function on the inhibitor can be bridged back from the hydrophobic region on the enzyme to the more polar nucleophilic region. In this way the ability of an irreversible inhibitor to bridge between the pyrimidine locus in the active-site and the enzymic nucleophilic site can be controlled by the nature of the hydrophobic site, which is outside the active site and where the greatest

[1] The authors thank Dr. M. Hakala for these assays.

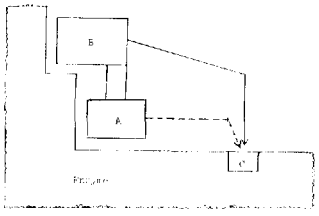


Fig. 1.—Schematic representation of an active-site-directed irreversible inhibitor that utilizes hydrophobic bonding for specificity. Key: A, the pyrimidine of an inhibitor; B, the hydrophobic group of an inhibitor; C, an enzymic nucleophilic group. The solid arrow represents a covalent-forming group on one inhibitor that can bridge properly from the hydrophobic bonding region to a nucleophilic site on the enzyme; the dotted arrow represents a covalent-forming group on a second inhibitor that can bridge from the pyrimidine region to a nucleophilic site on the enzyme (see *Discussion*).

evolutionary differences can occur (26, 27) (Fig. 1). It should also be possible to obtain specificity by varying the group that complexes in the hydrophobic region; this could alter the position of the alkylating function (dotted arrow, Fig. 1) by positioning the pyrimidine slightly differently; this can be likened to a fulcrum where a slight shift on the hydrophobic side will shift the alkylating side in the opposite direction where a part of the pyrimidine is the axis of the fulcrum.

Although studies of this type for tissue specificity could be pursued with the 2-amino-4-pyrimidinol type of inhibitors such as XIII, an additional important problem should be solved before such studies are initiated. Since XIII and XIV have K_i's near 3×10^{-5} M, it is unlikely that these inhibitors would be effective below 3×10^{-6} M since the amount of intracellular enzyme in the enzyme–inhibitor complex would only be about 10% of the total enzyme. There is a definite practical limitation on the intracellular concentration of inhibitor that can be obtained in a whole animal system, which is in turn partially dependent upon dosage. A reasonable maximum limit for intracellular inhibitor concentration is 10^{-6} M; the more dilute the inhibitor can be and still form 50% reversible complex with the available enzyme, the more potent the inhibitor will be irreversibly (32) and the less dosage will have to be used. 2,4-Diaminopyrimidines are 300–1000-fold more potent reversible inhibitors than the corresponding 2-amino-4-pyrimidinols (1, 16). For example, pyrimethamine (XIX) has $K_i = 7 \times 10^{-9}$ M with the folic reductase from rat liver (10); therefore, an active-site-directed irreversible inhibitor of dihydrofolic reductase that has a K_i approaching the 10^{-8} M of pyrimethamine (XIX) would at 10^{-8} M complex half the enzyme. Since the inactivation rate is dependent upon the concentration of reversible enzyme–inhibitor complex, such a hypothetical irreversible inhibitor should be effective at 10^{-8} M or less; such a concentration is readily achieved within a cell by passive diffusion.

The solution to such a problem may not be simply the conversion of XIII or XIV[2] to the corresponding 2,4-diamino pyrimidines since there seems to be some conformational differences in the manner in which 2,4-diaminopyrimidines and 2-amino-4-pyrimidinols complex to dihydrofolic reductase (7). The vigorous pursuit of the 2,4-diaminopyrimidine and 4,6-diamino-1,2-dihydro-*s*-triazine types of active-site-directed irreversible inhibitors for dihydrofolic reductase is continuing in this laboratory.

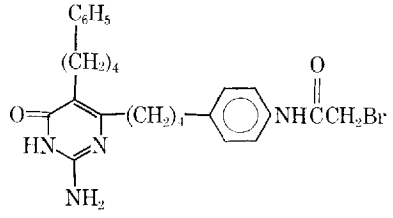
Irreversible Enzyme Inhibitors LXVIII

2-Amino-5-(*p*-bromoacetamidophenoxypropyl)-6-phenyl-4-pyrimidinol, an Active-Site-Directed Irreversible Inhibitor of Dihydrofolic Reductase

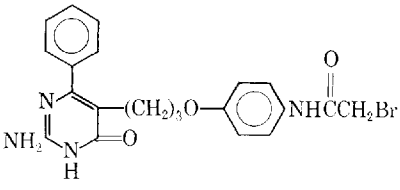
By B. R. BAKER and HOWARD S. SHAPIRO

2-Amino-5-(*p*-bromoacetamidophenoxypropyl)-6-phenyl-4-pyrimidinol (II), when incubated with dihydrofolic reductase at 37°, inactivated the enzyme with a half-life of about 45 min. In contrast, iodoacetamide and *p*-bromoacetamidophenylbutyric acid at the same concentration showed no inactivation of the enzyme in the same time. An interesting contrast to II was the 6-methyl analog (III) of II which inactivated the enzyme at about one-seventh the rate of II. This result gives unequivocal support for a previous suggestion that 6-methylpyrimidines and 6-phenylpyrimidines do not reversibly complex with dihydrofolic reductase in the same manner, else II and III should have inactivated the enzyme at the same rate at equal concentrations of reversible complex. These experiments are best explained on the basis of active-site-directed irreversible inhibition of dihydrofolic reductase.

OVER THIRTY attempts[1] to create an active-site-directed irreversible inhibitor (1) of dihydrofolic reductase were aborted prior to the discovery of the strong hydrophobic region on the enzyme adjacent to the active-site (2–8) and the realization that the pyrimidine type of inhibitor may have any one of several possible rotational conformers when complexed to the enzyme (8–10). Attention was then turned to the synthesis of candidate active-site-directed irreversible inhibitors that were substituted with one group on the 5- or 6-position that could complex to the hydrophobic region but also had a 6- or 5-substituent that could project into the hydrophilic region of the enzyme such as I and II. Efforts to synthesize the 5-phenylbutyl pyrimidine (I) and the 6-phenyl pyrimidine (II) started about the same time; I was found to be the first example of the long-sought active-site-directed irreversible inhibitors of dihydrofolic reductase, and II was found to be an irreversible inhibitor shortly thereafter. The synthesis and enzymic evaluation of I was presented in the previous paper of this series (11); the synthesis and enzymic evaluation of II is the subject of this paper.



I



II

DISCUSSION

Due to the lack of solubility, the maximum concentration in 10% *N,N*-dimethylformamide that could be reached with the 6-phenylpyrimidine (II) was 200 μM; at this concentration II showed 20% reversible inhibition in the presence of 6 μM dihydrofolate (12). From these data the 50% inhibition concentration was estimated to be 800 μM, and the K_i was estimated (3) to be $1 \times 10^{-4} M$. From Eq. 1, it could be estimated that at a concentration of 40 μM, 25% of the enzyme was in the form of an enzyme–II complex. It is the concentration of this complex that determines the rate of irreversible inhibition with an active-site-directed irreversible inhibitor (13–15) where [EI] = the enzyme–inhibitor reversible complex, E_t = the total active enzyme, [I] = the inhibitor concentration, and K_i = the reversible dissociation constant of EI (14, 15).

$$[EI] = \frac{[E_t]}{\frac{K_i}{[I]} + 1} \qquad \text{(Eq. 1)}$$

When dihydrofolic reductase was incubated in the absence of TPNH at 37° with 40 μM II at pH 7.4 in 10% *N,N*-dimethylformamide by the procedure previously described (9, 11), the enzyme was inactivated with a half-life of about 50 min.; thus, cor-

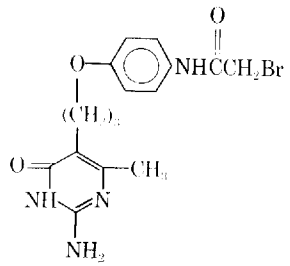
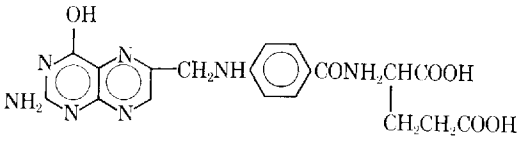
IIIa



IIIb



IV

rected for equal concentrations of reversible E · · · I complex, II inactivates dihydrofolic reductase about one-half the rate of I. When 40 μM each of II, iodoacetamide, and *p*-bromoacetamido phenylbutyric acid (16) were incubated with dihydrofolic reductase simultaneously for 60 min. at 37°, only II showed irreversible inhibition; thus, the bimolecular mechanism of inactivation was readily eliminated (14, 15). Protection against inactivation was shown by the reversible inhibitors, folic acid (IV) and 2,4-diamino-5-(3,4-dichlorophenyl)-6-methylpyrimidine, as noted with the inactivation of dihydrofolic reductase by I (11).

An interesting comparison as irreversible inhibitors are the 6-phenylpyrimidine (II) and the 6-methylpyrimidine (III), both having the identical *p*-bromoacetamidophenoxypropyl side chain at the 5-position. From previous studies on hydrophobic bonding (8), it was suggested that the data were best rationalized if a 6-phenylpyrimidine, such as II, has a conformation as depicted in II when compared to an assigned conformation of the pteridine ring in folic acid indicated in IV. In contrast, it was suggested that a 6-methylpyrimidine, such as III, would have its large 5-group complexing with the hydrophobic region as in conformation III*b*, but III would not complex in conformation III*a* or the conformation taken by II (8, 11). If II and III assumed identical conformations when complexed to the enzyme, then the alkylating function of both would be positioned in the enzyme complex in an identical fashion and both should attack an enzymic nucleophilic group at the same rate. The 6-methylpyrimidine (III) slowly inactivated dihydrofolic reductase with a half-life of about 220 min. at 37°, compared to II with a half-life of 45 min. Since III has K_i about $8 \times 10^{-5} M$, 40 μM III would convert 33% of the total enzyme to a reversible E · · · I complex; thus compared to 40 μM II—which gives 25% E · · · I complex—II inactivates dihydrofolic reductase about seven times the rate of III. This sevenfold difference in rate proves unequivocally that the main mode of reversible complexing to dihydrofolic reductase by II and III is different as previously suggested for 6-phenylpyrimidines (8). This slow inactivation by III is probably not due to a random bimolecular reaction (1, 14, 15); a more plausible explanation is that one out of seven times III complexes in the same conformation as II—then inactivates through the reversible complex—although this mechanism is not certain.

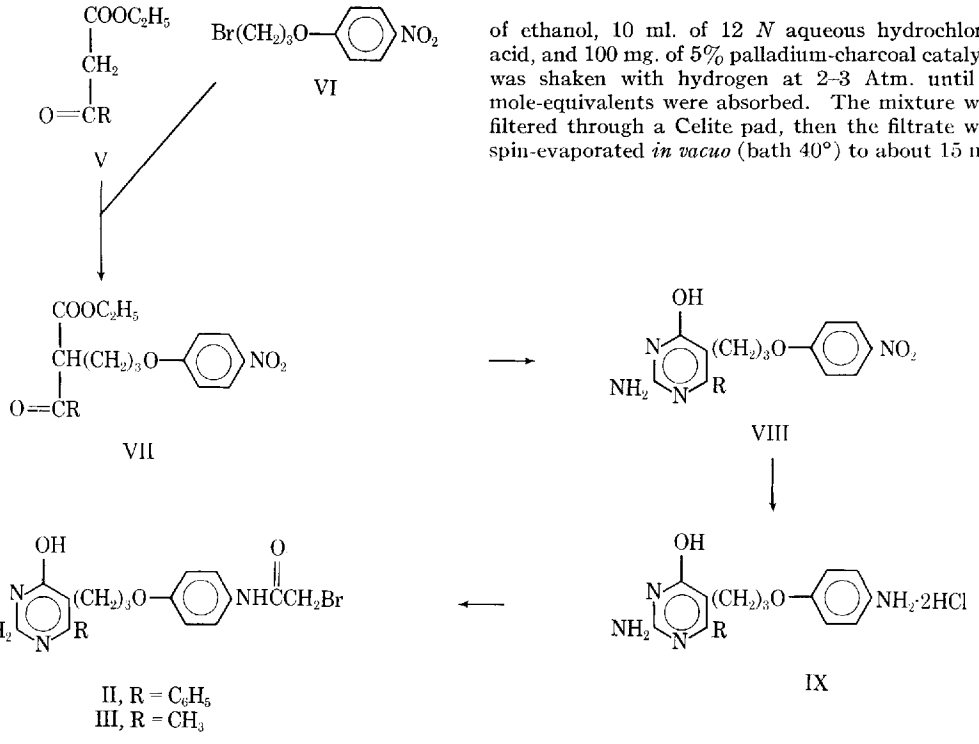
CHEMISTRY

Methods.—The general method of synthesis of 2-amino-6-R-4-pyrimidinols bearing a functionalized phenyl in a 5-side-chain developed earlier in this program (17) worked smoothly for the synthesis, the requisite precursors bearing a terminal nitrophenoxy group on the 5-side-chain (VIII). (Scheme I.) Alkylation of ethyl benzoylacetate (V*a*) with *p*-nitrophenyl-3-bromopropyl ether (VI) (18) in dimethylsulfoxide in the presence of sodium hydride gave the crude β-keto ester (VII*a*); condensation of VII*a* with guanidine carbonate in *tert*-butyl alcohol (19) gave the 4-pyrimidinol in 31% over-all yield of pure material. Earlier ethyl acetoacetate (V*b*) had been converted to VIII*b* *via* VII*b* (20).

Hydrogenation of the 5-nitrophenoxypropyl pyrimidinols (VIII) in ethanolic hydrochloric acid with a palladium-charcoal catalyst afforded pure IX*a* and IX*b* in 69 and 64% yields, respectively. The selective bromoacetylation of IX with bromoacetic anhydride in *N*,*N*-dimethylformamide has been previously described in a paper from this laboratory on selective bromoacylation methods for a variety of types of side-chain amino groups on a variety of 2-aminopyrimidines (16).

Synthesis.—Melting points were determined in capillary tubes on a Mel-Temp block, and those below 230° are corrected. Ultraviolet spectra were determined in 10% ethanol with a Perkin-Elmer 202 recording spectrophotometer. Infrared spectra were determined in KBr pellet with a Perkin-Elmer 137B recording spectrophotometer.

2 - Amino - 5 - (p - nitrophenoxypropyl) - 6-phenyl-4-pyrimidinol (VIIIa).—To a magnetically stirred solution of 3.84 Gm. (20 mmoles) of ethyl benzoylacetate in 10 ml. of reagent dimethylsulfoxide protected from moisture was added 0.866 Gm. of 55.6% sodium hydride dispersed in mineral oil. When hydrogen evolution had ceased, 4.70 Gm. (18 mmoles) of VI (18) was added in one portion. After being stirred at ambient temperature for 18 hr., the



a series, R = C_6H_5
b series, R = CH_3

Scheme I

mixture was heated on a steam bath for 1 hr., then acidified with acetic acid, and poured into 100 ml. of 1:1 benzene–water with good stirring. The separated aqueous phase was extracted with 50 ml. of benzene. The combined benzene solutions were washed with two 50-ml. portions of ice cold 3% aqueous sodium hydroxide to remove unchanged V*a*, then washed with water. Dried with magnesium sulfate, the solution was spin-evaporated *in vacuo* leaving 6.3 Gm. of crude VII*a* as an oil.

The oil was dissolved in 50 ml. of *tert*-butyl alcohol, 1.8 Gm. (10 mmoles) of guanidine carbonate was added, then the mixture was gently refluxed with magnetic stirring for 48 hr. The cooled mixture was filtered and the product was washed with cold ethanol; yield, 2.65 Gm. By dilution of the filtrate with water an additional 0.90 Gm. (total 54%) of crude product was obtained. Two recrystallizations of the combined crude products from aqueous 2-methoxyethanol gave 2.05 Gm. (31%) of pure product as white crystals, m.p. 277–278°; $\lambda_{max.}$ (pH 1): 242 (ϵ 17,200), 290 mμ (ϵ 16,800); (pH 7): 242 (ϵ 17,800), 310 mμ (ϵ 21,900); (pH 13): 242 (ϵ 15,800), 310 mμ (ϵ 16,800); $\lambda_{max.}$ 2.92 (NH); 6.08, 6.31, 6.67 (NH, C=O, C=C, C=N); 6.72, 7.50 (NO_2); 7.93 (ether C—O—C); 11.88 (*p*-C_6H_4); 13.33, 14.40 μ (C_6H_5).

Anal.—Calcd. for $C_{19}H_{18}N_4O_4$: C, 62.3; H, 4.92; N, 15.3. Found: C, 62.3; H, 5.12; N, 15.1.

2 - Amino - 5 - (p - aminophenoxypropyl) - 6-phenyl-4-pyrimidinol Dihydrochloride (IXa).—A mixture of 500 mg. (1.37 mmoles) of VIII*a*, 90 ml. of ethanol, 10 ml. of 12 *N* aqueous hydrochloric acid, and 100 mg. of 5% palladium-charcoal catalyst was shaken with hydrogen at 2–3 Atm. until 3 mole-equivalents were absorbed. The mixture was filtered through a Celite pad, then the filtrate was spin-evaporated *in vacuo* (bath 40°) to about 15 ml. The solution was diluted with ether to turbidity, then chilled at 3° for about 18 hr. The product was collected on a filter and washed with ether; yield, 473 mg. (93%), m.p. 185–190°. Recrystallization from absolute ethanol–ether with the aid of decolorizing carbon gave 315 mg. (69%) of pure product as nearly white crystals, m.p. 187–190°; $\lambda_{max.}$ 2.99 (NH); 5.98 (C=NH^+), 6.15, 6.50 (NH, C=O, C=C, C=N); 8.04 (ether C—O—C); 12.23 (*p*-C_6H_4); 13.35, 14.29 μ (C_6H_5).

Anal.—Calcd. for $C_{19}H_{20}N_4O_2 \cdot 2HCl \cdot H_2O$: C, 53.5; H, 5.63; N, 13.3. Found: C, 53.7; H, 5.77; N, 13.3.

2 - Amino - 5 - (p - aminophenoxypropyl) - 6-methyl-4-pyrimidinol Dihydrochloride (IXb).—Reduction of 304 mg. (1 mmole) of VIII*b* (20), as described for the preparation of IX*a*, gave 288 mg. (83%) of product, m.p. 265–268°. Recrystallization from 2-methoxyethanol–ether with the aid of decolorizing carbon afforded 222 mg. (64%) of pure product as white crystals, m.p. 271–272°; $\lambda_{max.}$ 2.98, 3.10 (NH); 5.94 (C=NH^+); 6.03, 6.31, 6.66 (NH, C=O, C=N, C=C); 8.00 (ether C—O—C), 11.85, 12.05 μ (*p*-C_6H_4).

Anal.—Calcd. for $C_{14}H_{18}N_4O_2 \cdot 2HCl$: C, 48.4; H, 5.76; N, 16.1. Found: C, 48.3; H, 5.88; N, 16.0.

Chemistry and Pharmacology of a Glycoside of *Vallaris solanacea*

By M. M. VOHRA, G. K. PATNAIK, R. S. KAPIL, and N. ANAND

One of the glycosides of *Vallaris solanacea* has been identified as *O*-acetyl-solanoside (*O*-acetyl acofreosyl-digitoxigenin). It possesses potent cardiotonic activity. Its pharmacological properties have been compared with those of lanatoside C and digoxin.

In a previous communication (1) it was reported that the glycoside mixture obtained from the leaves of *Vallaris solanacea* Kuntze (N.O. *Apocynaceae*) possesses powerful digitalis-like activity. Two recent publications by Kaufmann *et al.* (2, 3), describing the isolation and determination of the structure of six new glycosides from the seeds of *V. solanacea*, have prompted the authors to report the observation of glycoside B, one of the glycosides obtained from the leaves.

EXPERIMENTAL

Chemistry

Shade-dried leaves of *V. solanacea*, collected from Kashmir, India, were percolated with ethanol and the percolate was concentrated to about one-fifth its volume. The concentrate was diluted with an equal volume of water and extracted with benzene. The aqueous phase was concentrated *in vacuo* and extracted with chloroform. The residue from the chloroform extract was taken up in chloroform and chromatographed on a column of silica gel (E. Merck, fine grade), and the column developed with chloroform containing increasing proportions of methanol when three major glycoside fractions A, B, and C were obtained. On thin-layer chromatography [Silica Gel G; solvent system, ethyl methyl ketone–cyclohexane (1:1)] fractions A and C showed up as two spots, while fraction B gave only one spot (spots detected by spraying with water). Preparative thin-layer chromatography of fraction B [Silica Gel G; solvent system, chloroform–isopropyl alcohol (19:1)] gave glycoside B, which was crystallized from chloroform–hexane and ethanol–water mixture, m.p. 137–139° (Kofler block). The angle of rotation was $[\alpha]_D^{20} - 16$ (±2) (c, 1 in methanol). The homogeneity of the glycoside was established by thin-layer chromatography (Silica Gel G) in four solvent systems: ethyl acetate; chloroform–isopropyl alcohol (19:1); ethyl methyl ketone–cyclohexane (1:1); benzene methanol (3:1).

Anal.—Calcd. for $C_{32}H_{48}O_9$: C, 66.6; H, 8.39. Found: C, 67.05; H, 8.75.

Mannich hydrolysis of glycoside B gave a single sugar which was identified as acofreose by paper chromatographic comparison with an authentic sample [solvent systems: methyl ethyl ketone–*n*-butanol (1:1)/borate buffer; toluene–*n*-butanol (1:1)/water], while Killiani hydrolysis yielded digitoxigenin. The highly nonpolar character of glycoside B suggested the possibility of one of its hydroxyl groups being blocked. Its I.R. absorption spectrum and color reactions indicated its identity with *O*-acetyl-acofreoside of digitoxigenin (*O*-acetyl-solanoside) (3). This was confirmed by comparison with an authentic sample of *O*-acetyl-solanoside using thin-layer chromatography as described above.

A thin-layer chromatographic comparison kindly carried out by Reichstein of fractions A and C with the glycosides obtained from the seeds (2, 3), showed that the glycosides contained in the leaves are very similar to those present in the seeds.

Pharmacological Activity

Materials and Methods.—A stock solution of glycoside B containing 500 mcg./ml. was prepared

Received March 4, 1966, from the Central Drug Research Institute, Lucknow, India.
Accepted for publication September 8, 1966.
The authors are grateful to Professor T. Reichstein for direct comparison of the glycosides obtained by us with those isolated in their laboratory, to Mr. P. A. George for statistical analysis, to Dr. (Mrs.) S. Nitya Nand for help in ECG studies, and to Dr. C. Ray for his interest in the work.

Chemistry and Pharmacology of a Glycoside of *Vallaris solanacea*

By M. M. VOHRA, G. K. PATNAIK, R. S. KAPIL, and N. ANAND

One of the glycosides of *Vallaris solanacea* has been identified as *O*-acetyl-solanoside (*O*-acetyl acofreosyl-digitoxigenin). It possesses potent cardiotonic activity. Its pharmacological properties have been compared with those of lanatoside C and digoxin.

In a previous communication (1) it was reported that the glycoside mixture obtained from the leaves of *Vallaris solanacea* Kuntze (N.O. *Apocynaceae*) possesses powerful digitalis-like activity. Two recent publications by Kaufmann *et al.* (2, 3), describing the isolation and determination of the structure of six new glycosides from the seeds of *V. solanacea*, have prompted the authors to report the observation of glycoside B, one of the glycosides obtained from the leaves.

EXPERIMENTAL

Chemistry

Shade-dried leaves of *V. solanacea*, collected from Kashmir, India, were percolated with ethanol and the percolate was concentrated to about one-fifth its volume. The concentrate was diluted with an equal volume of water and extracted with benzene. The aqueous phase was concentrated *in vacuo* and extracted with chloroform. The residue from the chloroform extract was taken up in chloroform and chromatographed on a column of silica gel (E. Merck, fine grade), and the column developed with chloroform containing increasing proportions of methanol when three major glycoside fractions A, B, and C were obtained. On thin-layer chromatography [Silica Gel G; solvent system, ethyl methyl ketone–cyclohexane (1:1)] fractions A and C showed up as two spots, while fraction B gave only one spot (spots detected by spraying with water). Preparative thin-layer chromatography of fraction B [Silica Gel G; solvent system, chloroform–isopropyl alcohol (19:1)] gave glycoside B, which was crystallized from chloroform–hexane and ethanol–water mixture, m.p. 137–139° (Kofler block). The angle of rotation was $[\alpha]_D^{20} - 16$ (±2) (c, 1 in methanol). The homogeneity of the glycoside was established by thin-layer chromatography (Silica Gel G) in four solvent systems: ethyl acetate; chloroform–isopropyl alcohol (19:1); ethyl methyl ketone–cyclohexane (1:1); benzene methanol (3:1).

Anal.—Calcd. for $C_{32}H_{48}O_9$: C, 66.6; H, 8.39. Found: C, 67.05; H, 8.75.

Mannich hydrolysis of glycoside B gave a single sugar which was identified as acofreose by paper chromatographic comparison with an authentic sample [solvent systems: methyl ethyl ketone–*n*-butanol (1:1)/borate buffer; toluene–*n*-butanol (1:1)/water], while Killiani hydrolysis yielded digitoxigenin. The highly nonpolar character of glycoside B suggested the possibility of one of its hydroxyl groups being blocked. Its I.R. absorption spectrum and color reactions indicated its identity with *O*-acetyl-acofreoside of digitoxigenin (*O*-acetyl-solanoside) (3). This was confirmed by comparison with an authentic sample of *O*-acetyl-solanoside using thin-layer chromatography as described above.

A thin-layer chromatographic comparison kindly carried out by Reichstein of fractions A and C with the glycosides obtained from the seeds (2, 3), showed that the glycosides contained in the leaves are very similar to those present in the seeds.

Pharmacological Activity

Materials and Methods.—A stock solution of glycoside B containing 500 mcg./ml. was prepared

Received March 4, 1966, from the Central Drug Research Institute, Lucknow, India.
Accepted for publication September 8, 1966.
The authors are grateful to Professor T. Reichstein for direct comparison of the glycosides obtained by us with those isolated in their laboratory, to Mr. P. A. George for statistical analysis, to Dr. (Mrs.) S. Nitya Nand for help in ECG studies, and to Dr. C. Ray for his interest in the work.

Fig. 1.—Isolated papillary muscle of cat. Muscle stimulated supramaximally (12 v., 30/min., 1 msec. duration). At arrow glycoside B (10 mcg./ml.) was added to the bath. Key: 1, normal amplitude of contraction; 2, typodynamic state; 3, onset of improvement in the amplitude of contraction after 8 min. of addition of glycoside B; 4, complete restoration of the amplitude of contraction 40 min. after the addition of the glycoside; 5, decrease in the amplitude of contraction 60 min. after the addition.

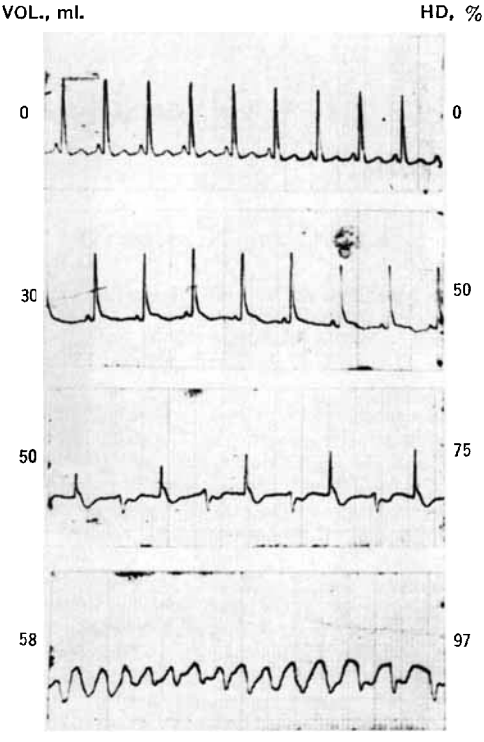

Fig. 2.—Electrocardiographic changes in an anesthetized cat (3.2 Kg.) recorded on standard lead II. Glycoside B was perfused (i.v.) at the rate of 20 mcg./ml./min. Key: 0 ml., normal record, sinus rhythm, T-wave upright, heart rate 210/min.; 30 ml., sinus rhythm, reverted biphasic T-wave, heart rate 180/min.; 50 ml., irregular ventricular extra systoles; 58 ml., ventricular tachycardia and fibrillation. Numbers on the right side denote the percentage of Hatcher dose against volume perfused shown on the left side.

by dissolving 10 mg. in 1 ml. of 90% alcohol and diluting with 19 ml. of normal saline. Further dilutions were made as required just before the experiment.

Cardiotonic Activity.—Direct proof of the cardiotonic activity of glycoside B was obtained by (*a*) perfusing the frog heart (*Rana tigrina*) through the inferior vena cava, (*b*) perfusing isolated hypodynamic guinea pig heart, prepared according to the method of Vick and Kehn (4), and (*c*) studying its action on the hypodynamic papillary muscle of cats (5).

Indirect evidence of the cardiotonic activity of the glycoside was obtained by (*a*) recording electrocardiographic (ECG) changes on standard lead II in anesthetized cats following continuous perfusion, as well as after single 10–50% of Hatcher dose (HD), (*b*) studying its effects on guinea pig or rabbit ileum *in vitro* and on intestinal movements of anesthetized cats.

Intensity of Biological Activity.—This was determined in chloralosed cats (80 mg./Kg. i.v.) by infusing continuously a solution of 25 mcg./ml./min. The concentration was so adjusted as to cause cardiac arrest within 50–60 min. of perfusion. The British Pharmacopoeia (1958) method was employed for the assay in guinea pigs. A concentration of 50 mcg./ml. of glycoside B was used which brought about cardiac arrest in 20–40 min.

Absorption, Persistence, and Cumulative Toxicity.—Its absorption from the gastrointestinal tract after oral feeding was measured in unanesthetized cats by the method of Purdum (6), and in anesthetized cats by the method of Dille and Whatmore (7). The persistence of the glycoside was studied in cats after intravenous administration of 40% HD. Cumulative toxicity was determined by the method described earlier (8) by daily subcutaneous injections of 20 and 40% HD for 21 days, or less if death took place earlier. For comparative purposes digoxin and lanatoside C were used in most of these studies.

RESULTS

Cardiotonic Activity.—*Direct Evidence.*—(*a*) Perfusion of the frog heart with glycoside B in concentrations of 5–30 mcg./ml. produced an initial increase in the amplitude of contraction and a slowing of the heart rate. This was followed by partial A-V block and systolic standstill of the heart.

(*b*) Perfusion of the hypodynamic guinea pig heart with 5 and 10 mcg./ml. concentrations of glycoside B produced a marked positive inotropic effect within 5–7 min. Further perfusion resulted in cardiac irregularities followed by cardiac arrest in 15–20 min.

(*c*) Glycoside B, in a concentration of 0.4–0.5 mcg./ml., restored the contractility of the hypodynamic papillary muscle of the cat. At low concentrations (0.04–0.1 mcg./ml.) improvement in the amplitude of contraction appeared within 5–7 min. of addition, the prefatigue amplitude being attained in 20–30 min. and being well maintained for about 2 hr. At high concentration (0.5 mcg./ml.) the restored contractility lasted for 45–60 min.; there-

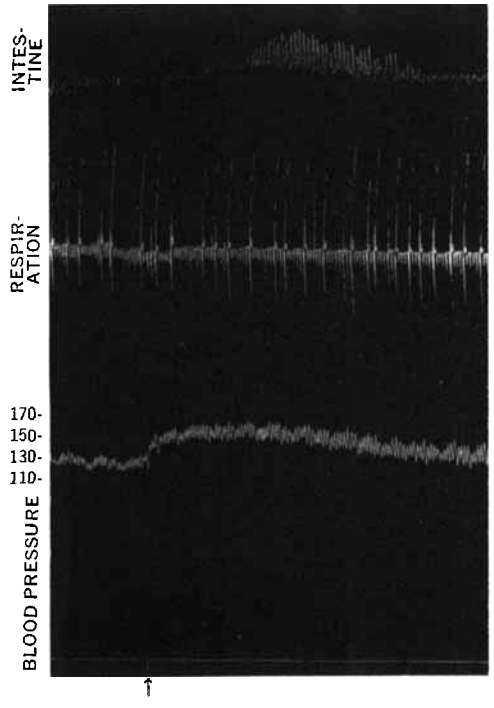

Fig. 3.—The effect of 25% Hatcher dose (arrow) of glycoside B in an anesthetized cat.

TABLE I.—MEAN LETHAL DOSES OF GLYCOSIDE B, LANATOSIDE C, AND DIGOXIN IN CATS AND GUINEA PIGS

Drug	Mean Lethal Dose (mcg./Kg.) Mean ± S.E. Cat	Guinea Pig
Glycoside B	388.2 ± 10.85 (8)[a]	1093.0 ± 29.05 (6)
Lanatoside C	200.2 ± 8.75 (5)	483.9 ± 22.00 (6)
Digoxin	278.0 ± 7.56 (4)	838.17 ± 31.67 (7)

[a] Figures in parentheses indicate the number of animals used.

after, the amplitude of contraction declined steadily and ultimately the muscle became unresponsive to the stimuli (Fig. 1). Occasionally, this concentration increased the irritability of the preparation.

Indirect Evidence.—(*a*) The ECG record following continuous infusion with glycoside B showed bradycardia, prolongation of PR interval, sagging of ST segment, PR dissociation, ventricular extra systoles followed by irregular ventricular rhythm, and cardiac standstill (Fig. 2), typical effects of a cardenolide.

The therapeutic index of glycoside B was calculated from the ECG records. Bradycardia, prolongation of PR interval, inversion of T wave, or sagging of ST segment were considered as the therapeutic stage, the appearance of extra systoles and bundle block as the early toxic stages, and ventricular tachycardia and fibrillation as the severe toxic stage. Results showed that 25–50% of the lethal dose was required to produce the therapeutic stage while 60–90% of the same produced the severe toxic stage. In comparative studies with ouabain (10 mcg./ml.) these changes were produced with 30–35 and 55–75% of the lethal dose, respectively.

A study of the effect of single intravenous doses of glycoside B on the ECG changes in anesthetized cats revealed that 10 and 25% HD produced prolongation of PR from 0.066 to 0.0825 sec., 10–14% bradycardia, and slight increase in QRS within 5–10 min. of administration; change in the T wave was also noticed. On the other hand 50% HD produced inversion of T wave and sagging of ST segment followed by ventricular tachycardia after 25 min. and death after 40 min.

(*b*) In pigeons, intravenous doses of 100, 150, 200, and 300 mcg./Kg. of glycoside B produced 16, 42, 71, and 100% emesis, respectively. The lag period decreased as the dose was increased.

(*c*) Glycoside B in a concentration of 3×10^{-5} produced a marked contraction of isolated segments of guinea pig ileum and increased the tone and amplitude of contraction of isolated rabbit ileum.

Intravenous administration of 25% HD of glycoside B in anesthetized cats produced a slight rise in blood pressure and an increase in the tone and

TABLE III.—CUMULATIVE TOXICITY OF GLYCOSIDE B, LANATOSIDE C, AND DIGOXIN

Drug	Cats, No.	Hatcher Dose Administration Subcutaneously, %	Deaths, No.	Av. Day of Death	Observations
Lanatoside C	3	20	3/3	12	1 died on 9th day, 1 on 11th day, and 1 on 15th day
		40	3/3	7	2 died on 7th day, and 2 on 9th day
Glycoside B	3	20	2/3	8	2 died on 8th day
	5	40	5/5	4	2 died on 2nd day, 1 on 3rd day, 1 on 5th day, and 1 on 9th day
Digoxin	2	20	2/2	6	1 died on 5th day, and 1 on 7th day

amplitude of contraction of the intestines. The latter effect lasted for 5–10 min. (Fig. 3).

Intensity of Biological Activity.—Table I shows that glycoside B is more active in cats than in guinea pigs, that its potency is three-fourths that of digoxin and one-half that of lanatoside C, both in cats and guinea pigs.

Absorption.—The comparative absorption of glycoside B and of lanatoside C was studied in unanesthetized cats following oral administration of one HD of each. The results, calculated in terms of the absolute absorption, are shown in Table II. Glycoside B was found to be very well absorbed (63.9%) from the gastrointestinal tract, while the absorption of lanatoside C was only 15.2%. Furthermore, the oral absorption of the former was found to be consistent and dependable since it varied only from 52.9 to 70.0% in a series of six animals.

The absorption of the glycoside from the small intestine was studied in five anesthetized cats by administering one HD to the intestine isolated between two ligatures. All animals died between 20–55 min. after administration, indicating that the main site of absorption is the intestine. In these experiments lanatoside C and digoxin showed 14.4 and 29.13% absorption, respectively.

Persistence.—The persistence of glycoside B showed a biphasic phenomenon (Fig. 4). At 72 hr. the glycoside appeared to have been completely eliminated from the system as shown by the percentage of HD required to kill the treated animals. However, after 96 hr. this dose decreased, so much so that at 144 hr. the dose was even lower than that required at the beginning of the experiment. The implication of this observation is discussed later.

Cumulative Toxicity.—The results are shown in Table III along with those obtained with lanatoside C and digoxin. The average number of days taken for the animals to die indicate that the cumulative toxicity of glycoside B lies between that of digoxin and lanatoside C. All the treated animals showed marked emaciation, apparently due to loss of appetite and body weight.

DISCUSSION

Glycoside B obtained from the leaves of *V. solanacea* has been identified as *O*-acetyl-solanoside which is present in the seeds.

Glycoside B is found to possess marked cardiotonic activity which is one-half that of digoxin and one-half and one-fourth that of lanatoside C in cats and guinea pigs, respectively. Its therapeutic index is the same as that of ouabain. It has a quick onset of action like that of ouabain and lanatoside C which may be an advantage over digoxin. This may be attributed to its highly nonpolar character. Its good, consistent, and dependable absorption after oral administration resembles digoxin more than lanatoside C.

The fact that administration of one HD into the intestine invariably produced cardiac standstill within 20–25 min., while the same dose given orally failed to produce cardiac arrest within 6 hr. would indicate that glycoside B is inactivated to some extent by the gastric juices.

In persistence studies glycoside B has been found to possess medium duration of action as the effect of a single dose lasts for 72 hr. In this respect it resembles lanatoside C more than digoxin. However, a peculiar behavior of glycoside B has been observed. At 72 hr. the effect of a single dose was found to have disappeared, but observations carried out at 96 and 144 hr. indicated the reappearance of the effect so much so that at the latter interval it was even greater than the effect produced initially when the glycoside was administered. Obviously, this phenomenon cannot be explained on the basis of the actual reappearance of the glycoside B itself in the system, but must be due to the sensitization of the receptors to the action of the drug so that at 96 and 144 hr. a lesser dose of the glycoside can produce the same effect. Rothlin (9) has reported the phenomenon of sensitization and desensitization, tachyphylaxis, and tolerance with digoxin, digilanid A, and digilanid C in cats. The observation regarding the medium duration of action of glycoside B is also supported by the cumulative toxicity data which show that it possesses a low toxicity compared to digoxin but a high value as compared to lanatoside C.

It may be concluded that glycoside B is a potent cardenolide with a therapeutic index similar to that of the cardiac glycosides used clinically. It has a quick onset, medium duration of action, and shows consistent and dependable oral absorption with low cumulative toxicity.

Interaction of a Group of Weak Organic Acids and Phenols with a Polyamide

By MICHAEL B. RODELL*, WALLACE L. GUESS, and JOHN AUTIAN

A drug–plastic sorption study was conducted using six compounds of interest to pharmaceutical and medical scientists. The compounds studied were (*a*) benzoic acid, (*b*) salicylic acid, (*c*) *p*-hydroxybenzoic acid, (*d*) methyl *p*-hydroxybenzoate, (*e*) propyl *p*-hydroxybenzoate, and (*f*) butyl *p*-hydroxybenzoate, while the plastic material was an insoluble polyamide (nylon-6). Sorption and diffusion experiments were conducted at several original concentrations and at three different temperatures, from which it was possible to calculate a number of constants for each agent. Evaluation of the various constants indicated that drug–plastic interactions were due to hydrogen bonding of the agents to the polyamide, but that secondary valence forces of van der Waals type most likely play a predominate role in the interaction or binding mechanism for the more hydrophobic molecules studied. The apparent diffusion coefficients were of the order of 10^{-8} cm.²/sec., while activation energies of diffusion fell within a range of 13.2 Kcal./mole for benzoic acid to 15.5 Kcal./mole for butyl *p*-hydroxybenzoate. Permeation constants had values approaching 10^{-7} cm.²/sec.

In the past this laboratory has reported the interaction of a number of weak organic acids or compounds acting as weak organic acids with several insoluble polyamides (1–5). This report is a continuation of these studies. Six compounds and one specific polyamide[1] were employed in this specific study. Sorption and permeation experiments were conducted on all the compounds at several concentrations and at several temperatures. The data permitted the evaluation of a number of constants, both of a thermodynamic and kinetic nature which in turn helped to propose the mechanism of interaction.

EXPERIMENTAL

Equipment and Supplies.—A Beckman DB spectrophotometer (Beckman Instruments, Inc., Fullerton, Calif.), benzoic acid (A. R., J. T. Baker Chemical Co., Phillipsburg, N. J.), salicylic acid (A. R., Mallinckrodt Chemical Works, St. Louis, Mo.), *p*-hydroxybenzoic acid (A. R., Eastman Organic Chemicals, Rochester, N. Y.), methyl *p*-hydroxybenzoate (A. R., Eastman Organic Chemicals, Rochester, N. Y.), propyl *p*-hydroxybenzoate (A. R., Eastman Organic Chemicals, Rochester, N. Y.), butyl *p*-hydroxybenzoate (A. R., Eastman Organic Chemicals, Rochester, N. Y.), and nylon-6[2] were employed.

Method of Analysis of Solutions.—The assay for each compound was based upon a spectrophotometric method, using enough diluent to give a final concentration of solute in the range of 2×10^{-3} mg./ml. to 6×10^{-3} mg./ml. for spectrophotometric examination. The absorbance was determined at the optimum wavelength for each compound, using matched 1-cm. silica cells as the sample and reference holders. Table I presents the wavelength of maximum absorbance and diluting vehicle for each compound.

Equilibrium Sorption Studies.—Solutions of benzoic, salicylic, and *p*-hydroxybenzoic acid, as well as methyl *p*-hydroxybenzoate, were prepared in five concentrations, ranging from 0.05 to 0.025%.[3] Due to limited solubility in water, five concentrations of propyl- and butyl *p*-hydroxybenzoate were made in ranges of 0.005 to 0.025%. In all cases, freshly prepared distilled water was utilized as the solvent medium.

Exactly 100 ml. of each solution was pipeted into specially constructed cylindrical glass tubes, measuring 12 in. in length and 1.5 in. in diameter. The tubes were fitted with ground glass stoppers, attached by metal or rubber springs, allowing for total immersion into a water bath at the desired temperature. After a period of time, adequate for equilibrium temperature to be reached in the tubes, the tubes were lifted from the bath, and strips of polyamide (accurately weighed to a total of 2 Gm.) were placed into each tube. The tubes were once again stoppered and carefully placed back into the water bath. Determinations of solute concentrations were made on each solution after sufficient time (approximately 14 days) had elapsed to ensure that equilibrium had been reached. Since blank solutions, exposed to similar temperatures, showed no loss of solute for the time period under consideration, any loss of solute in the test solutions was assumed to have been sorbed by the polyamide. These experiments were conducted at three different temperatures (50 ± 0.02°, 60 ± 0.02°, and 70 ± 0.02°).

The data obtained from these sorption experiments were then treated to determine the solubility coefficient or distribution ratio for each individual compound in the polyamide at the various temperatures under consideration. This solubility coeffi-

Butyl *p*-hydroxybenzoate	93.17	87.98	80.90

cient was evaluated by the use of the following equation:

$$S = C_s/C_L \qquad \text{(Eq. 1)}$$

where S is the solubility coefficient relating the quantity of solute in the solid phase to the quantity of solute in the liquid phase; C_s is the equilibrium concentration of solute in the solid phase (nylon) in moles/Kg.; and C_L is the equilibrium concentration of solute in the liquid phase in moles/L. By plotting values of C_s against the corresponding values for C_L, a linear relation resulted for all the compounds at the three temperatures. From the slopes, the solubility coefficients were deduced. Table II presents the calculated C_s/C_L or solubility coefficients for the six compounds at each of the temperatures studied.

Standard Affinity, Heat of Sorption, and Entropy of Sorption.—To gain an insight into the attraction forces between the various compounds and the polyamide, standard affinities ($-\Delta\mu°$) were calculated by the use of the expression:

$$-\Delta\mu° = RT \ln S \qquad \text{(Eq. 2)}$$

where S is the equilibrium sorption constant and is equal to the solubility coefficient depicted in Eq. 1 while R and T are the usual gas constant and absolute temperatures, respectively. Table III includes the standard affinities for all the compounds at each of the three temperatures.

In a relatively narrow temperature range, the standard affinity is related to the standard heat of sorption ($\Delta H°$) through the equation shown below:

$$\Delta\mu°/T = \Delta H°/T + C \qquad \text{(Eq. 3)}$$

where all the terms are as previously defined, while C stands for a constant of integration. From the slope of the line, the heat of sorption may be calculated. Calculated values for the heats of sorption for each of the compounds are found in Table III.

Since the standard affinity, $\Delta\mu°$, may be considered as a change in free energy as the solute migrates from the solution to the solid phase (nylon), and $\Delta H°$ represents the heat of sorption or enthalpy, it follows that the entropy ($\Delta S°$) of sorption may be evaluated through the thermodynamic relationship:

$$\Delta\mu° = \Delta H° - T\Delta S° \qquad \text{(Eq. 4)}$$

The entropy values have also been included in Table III.

Permeation and Diffusion Studies.—Since the sorption process of dyes and other agents in nylon is governed primarily by the diffusion step in the substrate, experiments were conducted to evaluate the apparent diffusion coefficient and permeability constant for each compound at the three temperatures given earlier and at a number of original concentrations.

Solutions of benzoic, salicylic, and *p*-hydroxy-

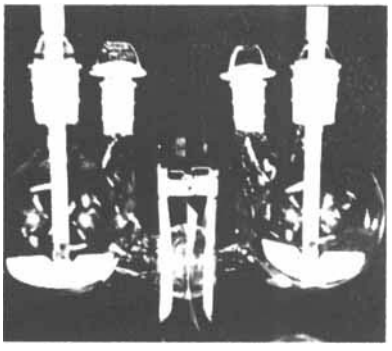

Fig. 1.—Photograph showing permeation cell with plastic film dividing the two chambers.

benzoic acids and methyl *p*-hydroxybenzoate were prepared in three concentrations ranging from 0.10 to 0.30%.

Through the use of a specially designed permeation cell, as shown in Fig. 1, permeation and diffusion studies were conducted in the following manner. Since the cell was composed of two separate flasks, divided by a square of polyamide (approximately 4 in. square with a thickness of 0.010 in.), exactly 500 ml. of the solution under investigation was added to one flask, simultaneously with the addition of an equal volume of distilled water to the other flask. The cell was then lowered into the water bath, and the stirring sleeves connected to an external power source to apply a constant rate of agitation in each flask. At periodic time intervals, aliquots of equal volume were removed from each flask, and set aside until they had reached room temperature. Spectrophotometric assays were made on those samples taken from the flask originally containing only distilled water, to determine the quantity of solute transversing the film barrier. Since the amount of solute passing through the film during the initial portions of the experiment was insignificant in comparison to the amount originally present in the high-concentration side, no assays were made of samples taken from this side of the cell. Sample withdrawal was continued until a steady state transmission was well established, with equal quantities of solute entering the low concentration flask per unit time.

Figure 2 demonstrates the permeation of *p*-hydroxybenzoic acid through the polyamide as a function of time. By plotting the total amount of solute permeating the nylon barrier against time, it is noted that following a short build-up period, a steady state of transmission is reached. The slope of the line representing the attainment of the steady state was then calculated by the method of least squares, and converted into units of moles of solute entering the flask/sec., so that the permeability constant could be obtained through the use of:

$$P = C/t \cdot LV/CA \qquad \text{(Eq. 5)}$$

where C/t is the slope of the linear portion of the permeation plot in moles/sec.; L is the thickness of the film barrier in cm.; V is the total volume under consideration in cm.^{3}; C is the initial concentration of the solution in moles per total volume; and A is the surface area of the nylon barrier through which the solute is permeating in cm.^{2}. Through the cancellation of terms, P, the permeability constant is reduced to the units of cm.^{2}/sec.

From the same figure it is possible to evaluate the apparent diffusion coefficient by use of the time-lag equation of Barrer (6), given as:

$$D = L^2/6\tau \qquad \text{(Eq. 6)}$$

where D is the apparent diffusion coefficient in cm.^{2}/sec., L is the thickness of the film in cm., and τ is the time-lag intercept obtained by extrapolation of the steady state slope to the time axis of the permeation plot, converted into seconds.

Table IV presents the values for the apparent diffusion coefficients and the permeability coefficients for all six compounds investigated in the study, at each of the three concentrations and temperatures involved.

Activation Energies of Diffusion and Permeation.—In all compounds studied, it was noted that the rates of diffusion and permeation were temperature dependent. This temperature dependence may be quantitatively expressed by determining the activation energies of diffusion and permeation and can be evaluated through the following equation:

$$\log D = \log D_0 - \Delta E_D/2.303\ RT \qquad \text{(Eq. 7)}$$

where D is the diffusion coefficient, ΔE_D the activation energy, and R and T the usual constants. A similar expression for permeation may be used to evaluate the activation energy of permeation (ΔE_P). Plots of log D *versus* $1/T$ or log P *versus* $1/T$ for each of the compounds gave linear relationships from which the activation energies were calculated. These values are shown in Table V.

Thermodynamic Constants from Kinetic Experiments.—Barrer (6) was able to show that the permeability constant and the apparent diffusion coefficient are related by the following expression:

$$S = P/D \qquad \text{(Eq. 8)}$$

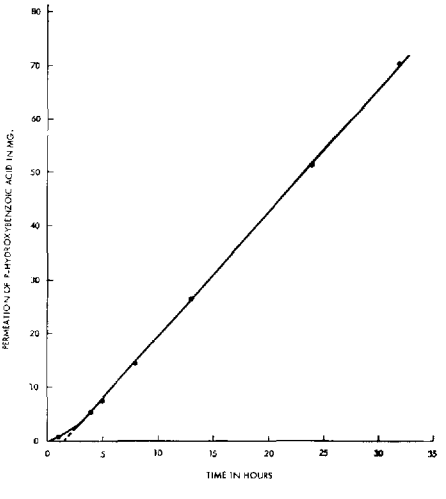

Fig. 2.—A plot of the concentration of *p*-hydroxybenzoic acid permeating through polyamide film *vs.* time.

where P is the permeability constant expressed in cm.²/sec.; D is the apparent diffusion coefficient in similar units; and S is defined as the solubility coefficient.

TABLE V.—ACTIVATION ENERGIES OF DIFFUSION AND PERMEATION FOR A GROUP OF WEAK ORGANIC ACIDS AND PHENOLS IN THE POLYAMIDE FILM

Compd.	ΔE_D (Kcal./mole)	ΔE_P (Kcal./mole)
Benzoic acid	13.2	9.22
Salicylic acid	16.3	10.4
p-Hydroxybenzoic acid	15.9	10.1
Methyl *p*-hydroxybenzoate	13.6	10.2
Propyl *p*-hydroxybenzoate	14.1	11.9
Butyl *p*-hydroxybenzoate	15.5	13.5

Values for the solubility coefficient, S, were obtained using Eq. 8, and were seen to closely approximate values for this constant obtained by equilibrium sorption studies and calculated by Eq. 1. Using solubility coefficients obtained through permeation and diffusion studies, it was then possible to calculate the standard affinity through Eq. 2, the standard heat of sorption *via* Eq. 3, and with Eq. 4 the standard entropy of sorption.

Table VI presents these thermodynamic constants derived from permeation and diffusion studies; generally, close correlation is seen to those in Table III obtained by equilibrium sorption studies.

DISCUSSION

Equilibrium Sorption Studies.—Examination of Table II in which the solubility coefficients for the six compounds in the polyamide are given, reveals that benzoic acid, salicylic acid, and *p*-hydroxybenzoic acid have similar values with salicylic acid being somewhat more soluble in the polyamide. Upon esterification of the carboxyl group of *p*-hydroxybenzoic acid, solubility of the compounds in the nylon phase is seen to increase markedly as the hydrophobic nature of the ester is increased.

With all compounds, and more prominently with the weak organic acids, it was noted as the temperature increased, the solubility coefficients were reduced. This would seem to suggest that the binding process between the nylon and these solutes was temperature dependent, with increased temperature serving to hinder solute-plastic binding.

Standard Affinity, Heat of Sorption, and Entropy of Sorption.—Standard affinity may be considered as being the ability of a particular substrate to attract and hold solute molecules, and is mathematically dependent upon the distribution of solute in the solid and liquid phases at equilibrium, as depicted in Eq. 2.

As seen in Table III, in most cases the standard affinity decreases with increased temperature, thus paralleling what has been shown for dyes and other weak organic acids (7). With the higher molecular weight esters of *p*-hydroxybenzoic acid, however, this effect is not noted, since the mechanism of interaction of these solutes is not so temperature dependent as with the weak organic acids.

An examination of the standard heats of sorption and standard entropies of sorption for these solutes sorbed by the polyamide (Table III) leads to several suggestions concerning the mechanisms of interaction.

In regard to benzoic, salicylic, and *p*-hydroxy-

benzoic acids, and methyl *p*-hydroxybenzoate, it is seen that the standard heats of sorption range from −3.7 to −5.6 Kcal./mole. Since the energy requirement for hydrogen-bond formation is considered to be from −4 to −6 Kcal./mole, these experimental values indicate, at least on an energy requirement basis, the formation of a hydrogen bond between these solutes and the polyamide. Presumably, bonding in the case of the weak organic acids would occur between the carboxyl group of the acid and the amide linkages in the nylon chains. Due to the presence of a phenolic hydroxyl group in methyl *p*-hydroxybenzoate, bonding would likely occur between this moiety and the amide linkages in the nylon. Heats of sorption for the propyl and butyl esters of *p*-hydroxybenzoic acid are −2.1 and −1.6 Kcal./mole, respectively, thus leading to the assumption of weak secondary valence forces as being responsible for the binding process between these compounds and the polyamide.

A consideration of the experimental values for the standard entropies of sorption for these compounds may shed further light upon the binding processes.

The concept of entropy as related to drug–plastic interactions encompasses two realms of reasoning. One trend of thought is to consider entropy as being indicative of the probability of a combination occurring between solute and substrate. The greater the increase in entropy, or entropy of sorption, the greater will be the probability of combination between the interactants. Table III reveals that the entropy of sorption is increasing in the cases of the propyl and butyl esters of *p*-hydroxybenzoic acid, while this increase is not noted with the weak organic acids and methyl *p*-hydroxybenzoate. Based upon changes in entropy, as the solute migrates from one phase to another, there would be a greater probability of combination between the higher molecular weight esters and the polyamide than with the weak organic acids and the same substrate. This viewpoint seems to be well taken, in that the propyl and butyl esters show greater solubility coefficients and higher standard affinities for the polyamide.

The second method of interpreting entropy calculations is to relate them to the degree of randomness and disorder of a given system. Classically, it is well accepted that the more natural system will have a completely randomized distribution of components within the system. As randomness and disorder increases, a corresponding increase in the entropy of the system is also seen. Thus, the system with the higher entropy value will be the one in which the greater degree of random distribution is present. Therefore, should entropy calculations for a particular drug–plastic interaction indicate an increase in entropy, then the solute is traveling into a more random distribution. Conversely, should calculations result in a decrease in the entropy of the system, then the solute is being firmly bound at fixed specific sites in the plastic.

Table III shows that a decrease in entropy occurs for the binding of the weak organic acids and methyl *p*-hydroxybenzoate by the polyamide. When one considers both the entropy change and the standard heats of sorption for these compounds sorbed by the polyamide, the assumption of hydrogen-bond formation at the amide linkages of the polymer appears rational. Reduction of the entropy of these systems indicates that the solutes are being held in fixed, specific sites in the plastic. The higher entropy of sorption values for propyl and butyl *p*-hydroxybenzoate indicate that these compounds are being more randomly distributed throughout the polymer, *via* the formation of weak secondary valence forces at various nonspecific sites along the polymer chain. It is felt that the phenolic hydroxyl group present in these two compounds serves as a primary attractive force, bringing the molecules into the proximity of the amide linkages. However, as the size of the ester moiety is increased, the solute is pulled away from these amide linkages, and becomes more randomly distributed throughout the chains.

Permeation and Diffusion Studies.—The data presented in Table IV, listing the permeability constants and apparent diffusion coefficients for these compounds in the polyamide, allow certain relationships to be drawn.

It is noted that in general the rate of permeation is directly dependent upon the quantity of solute originally present in the high-concentration side of the cell. Thus, as the initial concentration of a given solute is lowered, there will be a decrease in the permeation rate for that compound through the polyamide. Since permeation follows a steady state relationship, the concentration of solute within the film remains constant, and as much solute escapes from one side of the film as enters the other side. As the amount of solute entering the film is increased, more solute appears in the low concentration side per unit time, and the rate of permeation increases.

Where the permeation process is concerned with the rate of escape of solute molecules from the film into another phase, the actual travel of these molecules through the matrix of the plastic is considered to be the diffusion process. The time between initial contact at the one side and the final escape from the opposite side is the time during which the diffusion process occurs.

It is also noted that the original concentration of solute will affect the diffusion rate, but in a different manner than with permeation. Diffusion concerns itself only with the amount of solute within the matrix of the film, and not with the concentration surrounding it. Thus, diffusion is a function of the number of solute molecules capable of entering the polymer matrix, which may not be dependent upon the external environment.

Table IV shows that as the initial concentration of benzoic and *p*-hydroxybenzoic acids is increased, the diffusion rate is lowered. Due to the probability of greater degrees of dimerization in higher concentrations, through random movement and collision of molecules in solution, there would result the formation of complexes too large and bulky to enter the polymer matrix. As concentration is reduced, more individual molecules are available to diffuse into the film, and the diffusion rate increases. This effect has also been noted by Barrer and Barrie in the diffusion of water through ethyl cellulose (8). Vasenin (9) reported on the formation of clusters with increased concentrations of various paraffins and olefins in studies on their diffusion through certain polymers, while Peters (10) encountered similar phenomena with the diffusion of dye molecules through polymer films and fibers.

This effect is not noted with salicylic acid, probably due to the formation of intramolecular hydrogen bonds between the *ortho*-hydroxyl group and the carboxyl group, thus reducing the possibility of dimer formation. Since the esters have no carboxyl groups, dimerization is eliminated, and diffusion rates increase directly with increased original concentrations.

As the size of the solute is increased in a homologous series, (as with the esters of *p*-hydroxybenzoic acid), a decrease in the rates of permeation and diffusion is noted.

Activation Energies of Diffusion and Permeation.—Activation energy refers to the amount of energy a given molecule must acquire in order for it to be capable of overcoming the restraint of its surroundings. This energy is obtained through random exchange with neighboring molecules, and is temperature dependent in that molecular movement is directly related to increased temperature.

Table V presents the activation energies of diffusion and permeation for the compounds studied in this investigation. As in the cases of permeation and diffusion, increases in the molecular weight of a homologous series of compounds will affect the activation energy for the process. Thus, more energy is needed for the movement of the bulkier and heavier butyl *p*-hydroxybenzoate than for methyl *p*-hydroxybenzoate.

Kinetic Studies Versus Equilibrium Sorption Studies.—Table VI lists the thermodynamic constants calculated from permeation and diffusion studies, and shows the close agreement with similar constants derived from equilibrium sorption studies for each compound studied (Tables II and III).

Since sorption studies require a time period of approximately 14 days to complete, and permeation studies may be completed in less than 48 hr., it is apparent that the latter method is of extreme value. Permeation and diffusion studies reveal data of a kinetic nature as well as valid approximations of thermodynamic constants leading to possible suggested mechanisms of interaction.

SUMMARY

Studies were conducted on the interaction of six weak organic acids and phenols with a polyamide, at a number of concentrations and three temperatures. From these experiments, it was possible to evaluate several constants for each individual interaction, such as (*a*) the solubility coefficient of the solute in the polyamide, (*b*) the standard affinity, (*c*) the standard heat of sorption, (*d*) the standard entropy of sorption, (*e*) the apparent diffusion coefficient, (*f*) the permeability constant, and (*g*) the activation energies of permeation and diffusion.

Values obtained for the standard heats of sorption and standard entropies of sorption for the interaction of the polyamide with benzoic, salicylic, and *p*-hydroxybenzoic acids and methyl *p*-hydroxybenzoate, indicate the formation of hydrogen bonds between these compounds and the polyamide at the amide linkages of the nylon chains. Constants calculated for the propyl and butyl esters of *p*-hydroxybenzoic acid show that these compounds are bound to the polyamide through weak secondary valence forces, and are randomly distributed throughout the polymer chains.

Apparent diffusion coefficients for the diffusion of benzoic acid and *p*-hydroxybenzoic acid in the polyamide reveal that increased initial concentrations lead to lower apparent diffusion coefficients, due to the formation of dimers incapable of entering the polymer matrix.

Rate Studies on the Anaerobic Degradation of Ascorbic Acid IV

Catalytic Effect of Metal Ions

By PER FINHOLT, HARALD KRISTIANSEN, LESZEK KRÓWCZYŃSKI*, and TAKERU HIGUCHI†

The effect of different metal ions on the rate of the anaerobic degradation of ascorbic acid in aqueous solution has been studied. Among the bivalent metal ions tested, Pb^{2+} was the most powerful catalyst, followed by Zn^{2+}, Co^{2+}, Fe^{2+}, Mn^{2+}, Ni^{2+}, Ca^{2+}, and Mg^{2+}. Also the trivalent metal ions Al^{3+} and Cr^{3+} catalyzed the process, Al^{3+} being more active than Cr^{3+}. The experimental results seem to indicate that the metal ions form complexes with ascorbic acid.

ALTHOUGH the catalytic effect of metals on the oxidative degradation of ascorbic acid has been well studied (1–6), no papers have appeared dealing with the influence of metals on the anaerobic degradation. Since the degradation of ascorbic acid in many liquid pharmaceutical preparations appears to follow largely the non-oxidative route, and since these preparations may contain or may be contaminated by metals, a study of the effect of metal ions on the rate of the anaerobic degradation of ascorbic acid in aqueous solution was felt necessary.

Several authors (7–11) have shown that ascorbic acid is decarboxylated when heated in aqueous solution under anaerobic conditions. It is known from other papers that metal ions may catalyze the decarboxylation of keto-acids (12, 13). By the decarboxylation of dimethyloxaloacetic acid in the presence of heavy metals a complex between the metal ion and the diion of the acid is formed and this complex undergoes a rapid decarboxylation (12).

EXPERIMENTAL

Materials.—The following metal salts were used in this study: $Ca(NO_3)_2$, $MgSO_4$, $NiSO_4$, $MnSO_4$, $Mn(NO_3)_2$, $FeSO_4$, $CoCl_2$, $ZnSO_4$, $Zn(NO_3)_2$, $Pb(CH_3COO)_2$, $Pb(NO_3)_2$, $CuSO_4$, $AlCl_3$, and $CrCl_3$. Solutions of the metal salts were standardized when necessary with sodium ethylenediaminetetraacetate.

The ascorbic acid used was of P. Nord. (Pharmacopoea Nordica) quality. The metal salts and all reagents were of analytical grade. The water used was distilled water redistilled from a neutral glass still, boiled, and cooled under oxygen-free nitrogen.

Assay.—The residual ascorbic acid concentration of the heated solutions was determined iodometrically. An aliquot part of the sample, usually 5.00 ml., was acidified with diluted sulfuric acid and titrated under nitrogen with 0.01 *N* iodine using a few drops of starch T.S. as indicator. The metal salts added did not interfere.

Kinetic Studies.—Quantities of 0.01 *M* ascorbic acid solutions, buffered or unbuffered, containing the actual metal salt, and a sufficient amount of sodium chloride or potassium nitrate[1] to give the solutions an ionic strength of 0.5, were prepared. The solutions were filled into 5-ml. ampuls, and the air in the ampuls was replaced by nitrogen. The ampuls were sealed and heated at 96° in a constant-temperature bath. At appropriate intervals ampuls were taken out from the bath, cooled on ice, and the solution analyzed.

RESULTS AND DISCUSSION

Order of Reaction with Respect to Ascorbic Acid.—The anaerobic degradation of ascorbic acid in the presence of each of the metal salts tested was found to be strictly first order with respect to ascorbic acid.

Catalytic Effect of Bivalent Metal Ions on the Anaerobic Degradation of Ascorbic Acid.—Figure 1 shows the effect of Mn^{2+}, Fe^{2+}, Co^{2+}, Zn^{2+}, and Pb^{2+} on the rate of the anaerobic degradation of ascorbic acid at pH 2–6. (Amount of metal salt added, 0.05 moles/L.; buffer, 0.3 *M* acetate.) The effect of Ni^{2+}, Ca^{2+}, and Mg^{2+} was also tested, but the results for these cations are omitted in Fig. 1. Ni^{2+} showed very close to the same effect as Mn^{2+}. Ca^{2+} and Mg^{2+} had virtually no effect.

No rate studies were carried out at pH >6, because most metals caused precipitations in the ascorbic acid solutions at pH >6.

Experiments with Cu^{2+} as catalyst showed that ascorbic acid at pH >2 was oxidized by this metal even in the absence of air. At pH 0.4 addition of 0.01 moles/L. of $CuSO_4$ had a slight catalytic effect on the anaerobic degradation of ascorbic acid.

Figure 1 shows that all active metals have the highest effect at pH 4–6. Because of this all further studies of the catalytic effect of the different metals were made at pH values within this region.

The effect of addition of different amounts of

[1] Potassium nitrate was used in experiments involving lead because of the low solubility of lead chloride. In experiments involving the other metals tested sodium chloride was used, if not otherwise stated.

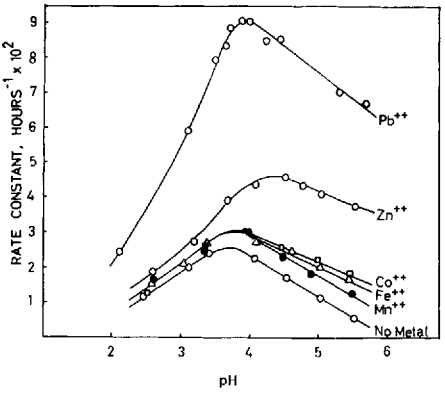

Fig. 1.—Effect of bivalent metal ions on the pseudo first-order rate constant of the anaerobic degradation of ascorbic acid at different pH values and 96°. Metal salts used: $MnSO_4$, $FeSO_4$, $CoCl_2$, $ZnSO_4$, and $Pb(CH_3COO)_2$. Amount of metal salt added, 0.05 moles/L.; buffer, 0.3 *M* acetate; ionic strength, 0.50.

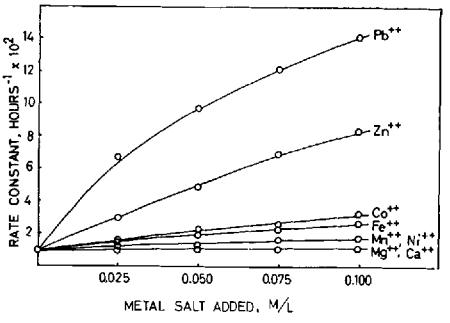

Fig. 2.—Effect of bivalent metal ions on the pseudo first-order rate constant of the anaerobic degradation of ascorbic acid at pH 5 and 96°. Metal salts used: $Ca(NO_3)_2$, $MgSO_4$, $NiSO_4$, $MnSO_4$, $FeSO_4$, $CoCl_2$, $ZnSO_4$, and $Pb(CH_3COO)_2$. Buffer, 0.1 *M* acetate; ionic strength, 0.50.

bivalent metal salts on the rate of the anaerobic degradation of ascorbic acid at pH 5 (0.1 *M* acetate as buffer) is shown in Fig. 2. The results given for Zn^{2+} in Fig. 2 are from two parallel series of runs, one series made with NaCl, the other with KNO_3 for correction of ionic strength. There was no difference in the results from the two series of runs.

Since acetate may form complexes with metal ions, the two most active metals, lead and zinc, and one of the less active metals, manganese, were also tested in buffer-free solutions. The nitrates of the metals were used because nitrate ions have a very low tendency to form complexes with metal ions. For comparison lead was also tested as acetate and zinc as sulfate. The studies were made at pH 4. This pH value was chosen because ascorbic acid has such a buffer capacity at pH 4 that no addition of buffer was needed to keep the pH of the ascorbic acid solutions constant during the experiments.

The solutions were made up to an ionic strength of 0.5 with KNO_3. The results are found in Fig. 3. It will be seen that the nitrate of lead is a little more active than the acetate. The reason for this must

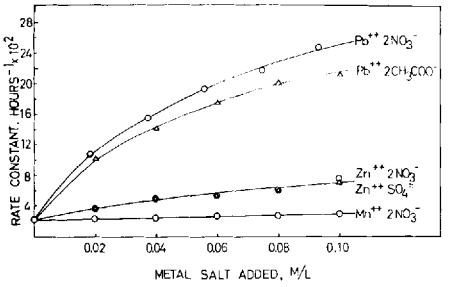

Fig. 3.—Effect of different salts of bivalent metals on the pseudo first-order rate constant of the anaerobic degradation of ascorbic acid at pH 4 and 96°. Ionic strength, 0.50; no buffer added.

be that the lead ions in the acetate are partly bound as complex. The nitrate and the sulfate of zinc have the same effect. Manganese nitrate is nearly noncatalytic.

Most of the lines in Figs. 2 and 3 are slightly curved. This may be explained by assuming a weak complex formation between ascorbic acid (HA) and metal ions (Me^{2+}) and a subsequent degradation of ascorbic acid in these complexes.

The following reactions may be assumed to take place at pH 2–6:

$$HA + Me^{2+} \rightleftharpoons AMe^+ + H^+ \quad \text{Reaction } 1$$

$$HA \xrightarrow{k_1} \text{products}$$

$$A^- \xrightarrow{k_2} \text{products}$$

$$AMe^+ \xrightarrow{k_3} \text{products}$$

The following equations are valid:

$$-\frac{d[A_T]}{dt} = k_1[HA] + k_2[A^-] + k_3[AMe^+] \qquad \text{(Eq. 1)}$$

$$A_T = [HA] + [A^-] + [AMe^+] \qquad \text{(Eq. 2)}$$

$$-\frac{d[A_T]}{dt} = k[A_T] \qquad \text{(Eq. 3)}$$

$$\frac{[AMe^+][H^+]}{[HA][Me^{2+}]} = k' \qquad \text{(Eq. 4)}$$

$$\frac{[A^-][H^+]}{[HA]} = k_a \qquad \text{(Eq. 5)}$$

$$[Me^{+2}] + [AMe^+] = b \qquad \text{(Eq. 6)}$$

In the experiments the amount (b) of metal salt added (in moles per liter) is 2 to 10 times the total ascorbic acid concentration. Since the lines in Figs. 2 and 3 are but *slightly* curved, only a small part of the ascorbic acid has formed complex with the metal ions even at the highest metal salt concentrations. For these reasons it is evident that $[Me^{2+}] \gg [AMe^+]$ in all the experiments. We may, therefore, without introducing any great error, put $[Me^{2+}] = b$ in Eq. 4. Doing so and combining Eq. 4 with Eqs. 1, 2, 3, and 5 give

$$k = \frac{k_1[H^+] + k_2k_a + k_3k'b}{[H^+] + k_a + k'b} \qquad \text{(Eq. 7)}$$

TABLE I.—STABILITY CONSTANTS (k') OF METAL ION ASCORBIC ACID COMPLEXES AND RATE CONSTANTS (k_3) FOR THE DEGRADATION OF ASCORBIC ACID IN THESE COMPLEXES

Metal Ion	pH	$k' \times 10^3$	k_3 hr.$^{-1}$ × 10
Pb^{2+}	4	3.5	4
Zn^{2+}	4	3.8	1.1
Zn^{2+}	6	0.9	1.9

The experiments, the results of which are given in Figs. 2 and 3, are made at constant pH and ionic strength. $[H^+]$ is therefore a constant and Eq. 7 becomes the equation of a hyperbola with k and b as the two variables. Consequently, plots of rate constants found *versus* amount of metal salt added have to yield curved lines.

From the experiments with $Pb(NO_3)_2$ at pH 4 (Fig. 3) k_3 and k' in Eq. 7 could be calculated. The earlier found values for k_1 and k_2 were used. ($k_1 = 8.9 \times 10^{-3}$ hr.$^{-1}$, $k_2 = 5 \times 10^{-3}$ hr.$^{-1}$) (14). The calculation gave $k_3 = 4 \times 10^{-1}$ hr.$^{-1}$ and $k' = 3.5 \times 10^{-3}$. According to this calculation, the rate of degradation of ascorbic acid in the lead complex is about 50 times faster than the rate of degradation of the free ascorbic acid. (Table I.)

Similar calculations based on the experiments with $Zn(NO_3)_2$ at pH 4 (Fig. 3) gave $k_3 = 1.1 \times 10^{-1}$ hr.$^{-1}$ and $k' = 3.8 \times 10^{-3}$.

The stability constant (k') is nearly the same for the zinc–ascorbic acid complex as for the lead–ascorbic acid complex. The rate of degradation of ascorbic acid, however, is considerably faster in the lead complex than in the zinc complex.

In Fig. 4 the relation between amount of $ZnSO_4$ added and rate constant found at pH 6 is given. Addition of buffer proved not to be necessary to keep pH constant during the runs. At pH 6 the term $k_1[H^+]$ in the numerator of Eq. 7 becomes negligible compared to the other terms in the numerator and may be omitted, thus giving

$$k = \frac{k_2 k_a + k_3 k' b}{[H^+] + k_a + k' b} \qquad \text{(Eq. 8)}$$

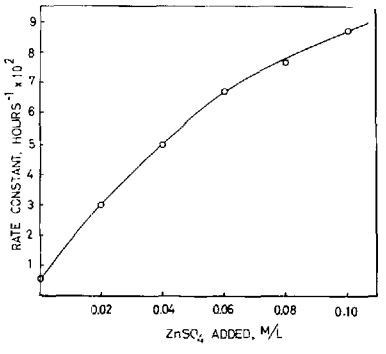

Fig. 4.—Effect of $ZnSO_4$ on the pseudo first-order rate constant of the anaerobic degradation of ascorbic acid at pH 6 and 96°. Ionic strength, 0.50; no buffer added.

At pH 6 $[H^+] \ll ka_1$, and $[H^+]$ may be omitted:

$$k = \frac{k_2 k_a + k_3 k' b}{k_a + k' b} \qquad \text{(Eq. 9)}$$

Equation 9 may also be written

$$\frac{k - k_2}{k_3 - k} = \frac{k'}{k_a} \cdot b \qquad \text{(Eq. 10)}$$

Inserting the results from the experiments with 0.04 moles/L. and 0.10 moles/L. of $ZnSO_4$ added, gave $k_3 = 1.9 \times 10^{-1}$ hr.$^{-1}$ and $k' = 9 \times 10^{-4}$. These values for k_3 and k' deviate somewhat from the values found at pH 4 ($k_3 = 1.1 \times 10^{-1}$ hr.$^{-1}$ and $k' = 3.8 \times 10^{-3}$). There may be several reasons for these deviations: other reactions than those postulated may occur. Zinc may form basic compounds at pH 6; k_3 may be pH dependent.

In Fig. 5 $k - k_2/k_3 - k$ is plotted *versus* b. In accordance with Eq. 10, a straight line is obtained. The slope of this line is $k'/k_a = 8$.

Experiments with lead similar to those made with

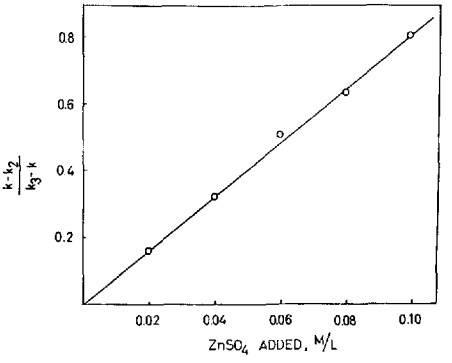

Fig. 5.—Relationship between amount of $ZnSO_4$ added and $k - k_2/k_3 - k$ (*cf.* Eq. 10) by the anaerobic degradation of ascorbic acid at pH 6 and 96° Ionic strength, 0.50; no buffer added.

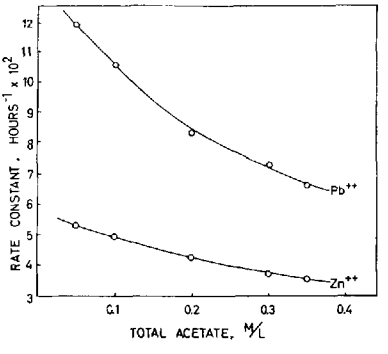

Fig. 6.—Effect of acetate buffer concentration on the pseudo first-order rate constant of the lead and zinc catalyzed anaerobic degradation of ascorbic acid at pH 5 and 96°. A quantity of 0.05 moles of $Pb(CH_3COO)_2$ or $ZnSO_4$ added per liter. Ionic strength, 0.50.

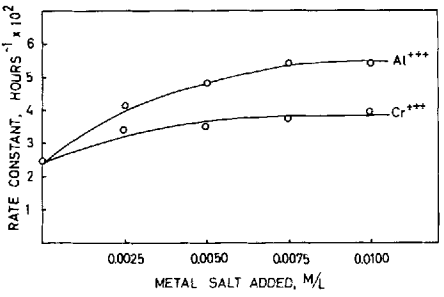

Fig. 7.—Effect of trivalent metal ions on the pseudo first-order rate constant of the anaerobic degradation of ascorbic acid at pH 4 and 96°. Metal salts used, $AlCl_3$ and $CrCl_3$; buffer, 0.3 *M* acetate; ionic strength, 0.50.

zinc (that is at pH 6 without buffer), were impossible because of the formation of precipitate.

Effect of Acetate on the Lead and Zinc Catalyzed Degradation of Ascorbic Acid.—A series of runs were made keeping pH, ionic strength, and lead concentration constant, but varying the acetate buffer concentration. The results of the runs are found in Fig. 6. There is a decrease in rate with increasing buffer concentration, probably due to an increasing complexation of lead by the buffer. Similar runs made with zinc instead of lead gave similar results (Fig. 6).

Since acetate has such a strong effect on the rates of the lead and zinc-catalyzed degradation of ascorbic acid, Eq. 7, which is applicable only to the process in buffer free solution, cannot be used for calculation of the rate constant at different pH values in solutions containing acetate. It is thus not possible to use Eq. 7 for calculation of a theoretical line fitting the experimental points in Fig. 1.

Attempts to Prove the Formation of Ascorbic Acid Metal Complexes.—According to Reaction *1*, the complex formation between ascorbic acid and metal ions in aqueous solution should cause a decrease in pH. Some experiments were made to test if this was the case.

It became necessary to use more concentrated ascorbic acid solutions than 0.01 *M* to get any measurable change in pH. A 25.00 ml. quantity of 0.1 *M* ascorbic acid solution made up to an ionic strength of 1.5 with KNO_3 and having an initial pH of 2.65, was titrated with 0.5 *M* $Pb(NO_3)_2$ solution to which nitric acid had been added to pH 2.65. The pH of the mixture decreased during the titration and reached a value of 2.29 after addition of 25.00 ml. of 0.5 *M* $Pb(NO_3)_2$ solution. A similar experiment carried out with zinc nitrate instead of lead nitrate gave a decrease in pH from 2.54 to 2.44.

The pH decreases observed may be an indication of complex formation between ascorbic acid and lead and zinc. It is of course not possible from these experiments, which are made at 25° and at an ionic strength of 1.5, to make any calculation of the stability constants of the metal–ascorbic acid complex at 96° and ionic strength of 0.5.

Catalytic Effect of Trivalent Metal Ions on the Anaerobic Degradation of Ascorbic Acid.—The evaluation of the catalytic effect of the trivalent ions Al^{3+} and Cr^{3+} presented some problems. If the aluminum concentration was 0.01 moles/L. and pH >4.1 a precipitate was formed in the ascorbic acid solutions during the runs. At pH 4 (0.3 *M* acetate as buffer) precipitations occurred at aluminum concentrations >0.015 moles/L. At the same time pH dropped 0.2–0.3 units. At aluminum concentrations $\leq$0.01 moles/L. there was no precipitation and the pH drop was only about 0.1 unit. The results of experiments at these low metal salt concentrations are given in Fig. 7. It will be seen that aluminum is a powerful catalyst at pH 4. An addition of 0.005 moles of $AlCl_3$ per liter doubles the rate of the anaerobic degradation of ascorbic acid. The shape of the curve may indicate that the major part of the ascorbic acid exists as a complex at an aluminum concentration of 0.01 moles/L.

At pH 3 (0.3 *M* acetate as buffer) aluminum showed nearly no catalytic effect.

With chromium as catalyst it turned out to be impossible to keep the pH of the ascorbic acid solutions constant during the runs when the chromium concentration was more than 0.02 moles/L. At pH 4 (0.3 acetate as buffer) and chromium concentrations $\leq$0.01 moles/L. there was only a slight decrease in pH (about 0.05 units). The results of runs at this pH are given in Fig. 7. It will be seen that the catalytic effect of Cr^{3+} is less than that of Al^{3+}.

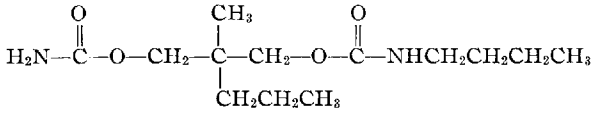
Qualitative and Quantitative Tests for Tybamate

By EDWARD F. SALIM*, JEROME I. BODIN†, HARRY B. ZIMMERMAN†, and PHILIP REISBERG†

Provisional, unofficial monographs are developed by the Drug Standards Laboratory, in cooperation with the manufacturers of the drug concerned, for publication in the *Journal of Pharmaceutical Sciences*. The ready availability of this information affords discriminating medical and pharmaceutical practitioners with an added basis for confidence in the quality of new drug products generally, and of those covered by the monographs particularly. Such monographs will appear on drugs representing new chemical entities for which suitable identity tests and assay procedures are not available in the published literature. The purity and assay limits reported for the drugs and their dosage forms are based on observations made on samples representative of commercial production and are considered to be reasonable within expected analytical and manufacturing variation.

2-METHYL-2-PROPYLTRIMETHYLENE BUTYLCARBAMATE CARBAMATE; $C_{13}H_{26}N_2O_4$; mol. wt. 274.36. The structural formula of tybamate may be represented as



Physical Properties.—Tybamate occurs as a white crystalline powder or a clear viscous liquid which may congeal to a solid form on standing. It has a mild characteristic odor and a bitter taste. The dried powder melts within a range of 2° between 49° and 54°, U.S.P. class I. It is very slightly soluble in water, very soluble in alcohol and in acetone, and freely soluble in ether.

Identity Tests.—Transfer 1 ml. of a 0.04% chloroform solution of tybamate into a glass-stoppered test tube and add 1 ml. of a mixture of acetone–glacial acetic acid (3:1), 1 ml. of a 1 in 100 solution of *p*-dimethylaminobenzaldehyde in benzene, and 5 ml. of antimony trichloride solution (dissolve 3.6 Gm. of antimony trichloride in 20 ml. of chloroform and add 5 ml. of acetic anhydride). Heat the solution at about 55° for 15 min.: a red color is produced.

Dissolve 1 Gm. of tybamate and 0.8 Gm. of xanthydrol in a mixture of 10 ml. of dehydrated alcohol and 10 ml. of glacial acetic acid. Heat the solution on a steam bath for 90 min., taking care to avoid excessive evaporation. Cool and add cold water: an oil, which may crystallize on standing, separates from solution. Filter the mixture through paper, wash the residue with water until free from acetic acid odor, and dry at 105° for 2 hr. The dried residue when recrystallized from a mixture of trichloroethylene–hexane (1:2) melts between 127° and 130°.

The infrared spectrum of a 0.5% dispersion of tybamate in potassium bromide, in a disk of about 0.82 mm. thickness, is shown in Fig. 1.

Purity Tests.—Dry about 1 Gm. of tybamate, accurately weighed, in vacuum at 30–35° for 4 hr.; it loses not more than 0.5% of its weight.

Char about 1 Gm. of tybamate, accurately weighed, cool the residue, add 1 ml. of sulfuric acid, heat cautiously until evolution of sulfur trioxide ceases, ignite, cool, and weigh: the residue does not exceed 0.1%. Retain the residue for the heavy metals test.

Dissolve the sulfated ash obtained from 1 Gm. of tybamate in a small volume of hot nitric acid and evaporate to dryness on a steam bath. Dissolve the residue in 2 ml. of diluted acetic acid, dilute to 25 ml. with water, and determine the heavy metals content of this solution by the U.S.P. heavy metals test, method 1: the heavy metals limit for tybamate is 10 p.p.m.

Assay.—Transfer about 750 mg. of tybamate, accurately weighed, into a conical flask, add 20 ml. of pyridine, and neutralize the solution with 0.1 *N* sodium methoxide to the first pink color of phenolphthalein T.S. Add 50.0 ml. of 0.1 *N* sodium methoxide, a few boiling chips, and reflux with an air condenser on a steam bath for 30 min. Cool, add 40 ml. of neutralized alcohol, and titrate with 0.1 *N* hydrochloric acid to the absence of a pink color. Perform a blank determination. The difference between the two titrations represents the volume of 0.1 *N* sodium methoxide equivalent to

† Wallace Laboratories, Cranbury, N. J. Wallace Laboratories has cooperated by furnishing samples and data to aid in the development and preparation of this monograph.

The authors express their appreciation to Mervin Meyer and Stephen M. Lipcsey, Wallace Laboratories, and Carolyn Damon, Drug Standards Laboratory, for valuable contributions to the monograph.

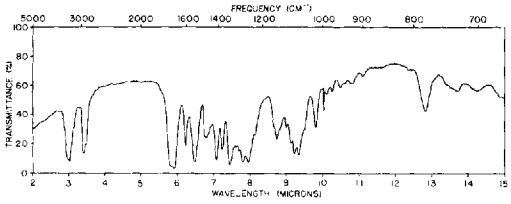

Fig. 1.—Infrared spectrum of tybamate in potassium bromide disk (0.5%); Perkin-Elmer model 21 spectrophotometer, sodium chloride prism.

the weight of $C_{13}H_{26}N_2O_4$ in the sample. Each milliliter of 0.1 *N* sodium methoxide is equivalent to 27.44 mg. of $C_{13}H_{26}N_2O_4$. The amount of tybamate found is not less than 98% and not more than 102% of the weight of the sample taken.

DOSAGE FORMS OF TYBAMATE

Tybamate Capsules

Identity Tests.—Transfer a sample of the capsule content, equivalent to about 10 mg. of tybamate, into a separator containing 75 ml. of water. Shake the aqueous solution with 25 ml. of chloroform and filter a portion of the chloroform extract. Transfer 1 ml. of the filtrate into a glass-stoppered test tube and add 1 ml. of a mixture of acetone–glacial acetic acid (3:1), 1 ml. of a 1 in 100 solution of *p*-dimethylaminobenzaldehyde in benzene, and 5 ml. of antimony trichloride solution (dissolve 3.6 Gm. of antimony trichloride in 20 ml. of chloroform and add 5 ml. of acetic anhydride). Heat the solution at about 55° for 15 min.: a red color is produced.

Transfer a sample of the capsule content, equivalent to about 1 Gm. of tybamate, into a separator containing 100 ml. of cold water. Shake vigorously for 2 min. and discard the aqueous layer. To the oily layer in the separator add 25 ml. of chloroform, 75 ml. of cold water, and shake vigorously. Allow the layers to separate, transfer the chloroform extract into a beaker, and add anhydrous sodium sulfate. The chloroform solution filtered through paper exhibits infrared absorption maxima only at the same wavelengths as that of a similar preparation of tybamate standard.

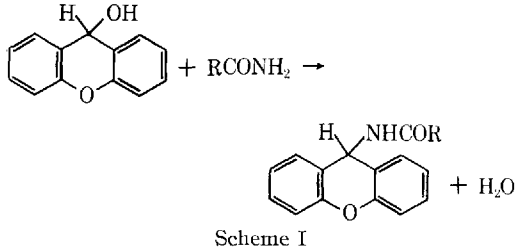
Assay.—Transfer an accurately weighed sample of the capsule content, equivalent to about 750 mg. of tybamate, into a conical flask, add 20 ml. of pyridine, and neutralize the solution with 0.1 *N* sodium methoxide to the first pink color of phenolphthalein T.S. Add 50.0 ml. of 0.1 *N* sodium methoxide, a few boiling chips, and reflux with an air condenser on a steam bath for 30 min. Cool, add 40 ml. of neutralized alcohol, and titrate with 0.1 *N* hydrochloric acid to the absence of a pink color. Perform a blank determination. The difference between the two titrations represents the volume of 0.1 *N* sodium methoxide equivalent to the weight of $C_{13}H_{26}N_2O_4$ in the sample. Each milliliter of 0.1 *N* sodium methoxide is equivalent to 27.44 mg. of $C_{13}H_{26}N_2O_4$. The amount of tybamate found is not less than 95% and not more than 105% of the labeled amount.

DISCUSSION

U.S.P. and N.F. terminology for solubility, melting range, reagents, etc., has been used wherever feasible.

Tybamate,[1] synthesized by Berger and Ludwig (1), is a tranquilizing agent which affords symptomatic improvement in a variety of psychoneurotic disorders, especially in the treatment of the anxiety and tension components of psychoneuroses.

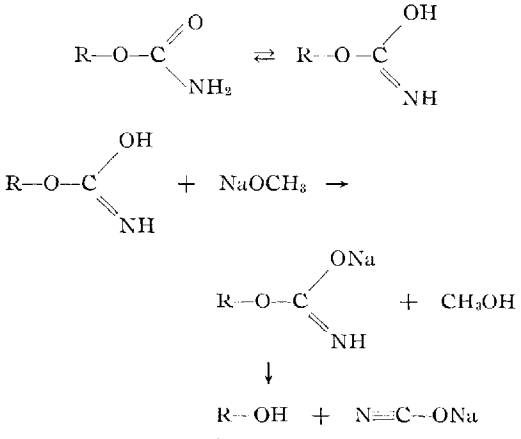
Identity Tests.—Crystalline derivatives of primary amides can be prepared with xanthydrol in glacial acetic acid. (Scheme I.)



Scheme I

The reaction is useful in characterizing aliphatic amides or carbamates (xanthylamides) and sulfonamides (*N*-xanthylsulfonamides).

Quantitative Tests.—Analysis for bulk tybamate and tybamate capsules is based on the reaction of alkali on carbamates of the general type $ROOCNH_2$ in nonaqueous media. Cerri *et al.* (2) have postulated the reaction sequence shown in Scheme II.



Scheme II

In anhydrous pyridine, the equilibrium shown in the first equation is shifted strongly to the right and the enolic species is reacted with the sodium methoxide. In aqueous systems the equilibrium favors the keto form and the reaction with alkali is no longer quantitative. The presence of small quantities of water in the solvents can induce errors in the procedure, but this effect can be nullified by increasing the methanol content in the reaction mixture by about 5% and increasing the reflux time to 55 min. (3).

The assay of bulk tybamate by the volumetric procedure gave an average recovery of 100.2 ±

[1] Marketed as Solacen by Wallace Laboratories, Cranbury, N. J.

1.2%.[2] The titration can be conducted with 0.1 *N* benzoic acid in benzene using thymol blue T.S. eliminating the addition of neutralized alcohol. In this instance, care must be exercised to prevent absorption of atmospheric carbon dioxide during the titration. Analysis of commercial tybamate capsules gave an average value of 97.2 ± 1.2%[2] of the labeled amount of tybamate.

[2] Maximum deviation from the mean value.

Particle Size Distribution and Hopper Flow Rates

By EDWARD D. SUMNER*, HERMAN O. THOMPSON, WILLIAM K. POOLE, and JAMES E. GRIZZLE

The rate of flow of varying ratios of four sieve size fractions of rock salt through the hopper of a rotary press was represented by a second degree polynomial equation. This fitted polynomial accounted for 90 per cent of the variation in the mean flow rates. No correlation was found between the tangent of the angle of repose and flow rate. High positive correlation was found between flow rate and bulk density, while high negative correlation between flow rate and porosity was observed. There was no significant increase or decrease in flow rates with regard to the quantity of rock salt remaining in the hopper.

One of the most important considerations in pharmaceutical manufacturing is the flow of particulate solids through hoppers and feeders. Capsules, divided powders, and tablets are examples of solid dosage forms which require measured filling for the production of each unit. Thus, the uniformity of the final product requires a uniform flow rate of these solid mixtures. Modern tablet machines are capable of compressing from 5000 (1) to 22,000 (2) tablets per minute. Uniformity of flow rate and flow rate of particulate solids must be considered in order to meet the requirements of these high speed units.

The laws which govern static pressures of fluids do not apply to particulate masses. Some properties of liquids in containers are: pressure is identical throughout at the same depth, pressure exerted on any point is transmitted undiminished to every portion of the enclosed liquid, and pressure exerted by a liquid on the walls of the container is always at right angles to the surface of the container.

Unlike liquids, pressures of bulk solids contained in hoppers varies with direction at different points, pressure is dependent on the shape and size of the receptacle, and the weight of a solid is transferred to the walls by shearing between particles in addition to pressure.

The principal factors affecting flow rates of particulate solids are: particle size, particle size distribution, particle shape, density, surface characteristics, and relative size and geometry of the hopper (3).

A review of the literature (3–15) reveals that the majority of the investigations and research on flow of particulate solids have been conducted on monodisperse systems and hoppers of much larger or smaller dimensions than those ordinarily used in some pharmaceutical manufacturing processes. This work was conducted to ascertain what relationship existed between particle size distribution, bulk density, porosity, and tangent of angle of repose in regard to flow rates and uniformity of flow rates.

MATERIALS AND METHODS

Material.—The particulate solid used was rock salt in the following sieve size fractions: 8/10, 10/20, 20/40, 40/60.

Particle Size Distribution and Hopper Flow Rates

By EDWARD D. SUMNER*, HERMAN O. THOMPSON, WILLIAM K. POOLE, and JAMES E. GRIZZLE

The rate of flow of varying ratios of four sieve size fractions of rock salt through the hopper of a rotary press was represented by a second degree polynomial equation. This fitted polynomial accounted for 90 per cent of the variation in the mean flow rates. No correlation was found between the tangent of the angle of repose and flow rate. High positive correlation was found between flow rate and bulk density, while high negative correlation between flow rate and porosity was observed. There was no significant increase or decrease in flow rates with regard to the quantity of rock salt remaining in the hopper.

One of the most important considerations in pharmaceutical manufacturing is the flow of particulate solids through hoppers and feeders. Capsules, divided powders, and tablets are examples of solid dosage forms which require measured filling for the production of each unit. Thus, the uniformity of the final product requires a uniform flow rate of these solid mixtures. Modern tablet machines are capable of compressing from 5000 (1) to 22,000 (2) tablets per minute. Uniformity of flow rate and flow rate of particulate solids must be considered in order to meet the requirements of these high speed units.

The laws which govern static pressures of fluids do not apply to particulate masses. Some properties of liquids in containers are: pressure is identical throughout at the same depth, pressure exerted on any point is transmitted undiminished to every portion of the enclosed liquid, and pressure exerted by a liquid on the walls of the container is always at right angles to the surface of the container.

Unlike liquids, pressures of bulk solids contained in hoppers varies with direction at different points, pressure is dependent on the shape and size of the receptacle, and the weight of a solid is transferred to the walls by shearing between particles in addition to pressure.

The principal factors affecting flow rates of particulate solids are: particle size, particle size distribution, particle shape, density, surface characteristics, and relative size and geometry of the hopper (3).

A review of the literature (3–15) reveals that the majority of the investigations and research on flow of particulate solids have been conducted on monodisperse systems and hoppers of much larger or smaller dimensions than those ordinarily used in some pharmaceutical manufacturing processes. This work was conducted to ascertain what relationship existed between particle size distribution, bulk density, porosity, and tangent of angle of repose in regard to flow rates and uniformity of flow rates.

MATERIALS AND METHODS

Material.—The particulate solid used was rock salt in the following sieve size fractions: 8/10, 10/20, 20/40, 40/60.

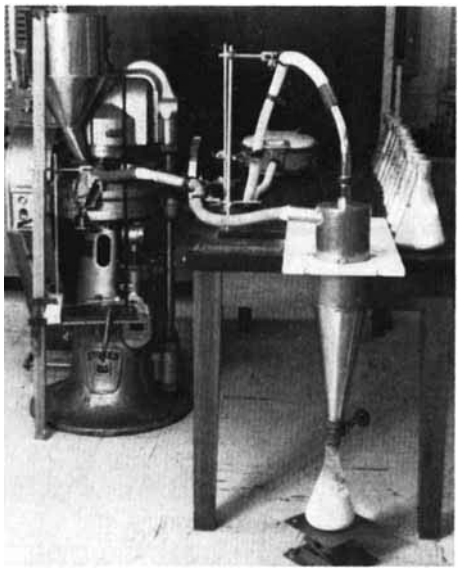

Fig. 1.—Pictorial view of flow apparatus.

Preliminary Investigation.—Since the distance between the hopper orifice and die table of the Stokes rotary press, model D-3, has some regulatory effect on flow rates of particulate solids, the position of the hopper must be stabilized in order to eliminate sagging when the hopper is charged. Preliminary studies revealed that if the hopper height was not controlled, the flow rates gradually increased as the hopper empties due to an increase in the hopper orifice–die table height. Classification studies of rock salt flowing from the rotary press hopper could not be carried out because of fracturing and attrition in the feed frame and cyclone separator.

Flow Rate.—An over-all view of the experimental layout for measuring the rate of flow is shown in Fig. 1. The rotary press, model D-3, was run at a speed of 13.3 r.p.m. throughout the study. The upper punches were left out and the lower punches were adjusted to a depth of 2 cm. The height of the hopper orifice was set at a distance of 0.7 cm. from the die plate.

The hopper supplied with the machine was charged with 22 Kg. of rock salt for each run. The main vacuum nozzle and the auxiliary nozzle were placed in such a position to make collections of all material falling on the die plate as well as material filling the dies. The vacuum for the cyclone separator was furnished by a vacuum cleaner equipped with 1.5-hp. motor.

After placing a 2000-ml. conical flask in position under the cyclone separator, the vacuum system and machine were started. The initial 1-min. collection was discarded and not used in the data. This was done in order to allow the machine and flow to become stabilized.

At 1 min., the shut-off valve on the separator was closed, the flask removed, an empty flask was again placed beneath the separator, and the shut-off valve was opened. The samples were numbered 1, 2, etc., in the order collected. This procedure was continued until the hopper was nearly empty or as long as 1-min. collections could be removed. The rock salt was used over again after subjecting it to sieving to remove fractured material.

Bulk Density.—The bulk density was determined by the procedure set forth by Butler and Ramsey (16). The reported value is an average of three determinations.

Porosity.—Porosity was calculated from the following formula (17):

$$\%e = V_b - V_p/V_b \times 100$$

where V_b and V_p represent the bulk and true volumes, respectively.

Moisture Determination.—All moisture determinations were made on the Ohaus moisture balance, model 6000. The heater was set at a distance of 1.25 in. from the pan, and the samples were dried for a period of 1 hr. One sample was taken initially and the second was taken after total discharge of rock salt from the hopper. The percentage of moisture never exceeded 0.3%, and the initial and final samples seldom varied.

Angle of Repose Measurements.—Instrumentation for measuring the angle of repose is shown in Fig. 2. The glass cylinder was charged with 1000 Gm. of the respective rock salt combination. The funnel on top of the cylinder permitted uniform loading from batch to batch. The plug in the center of the base was removed, and the material flowed out of the orifice. The height of the cone remaining on the platform was measured to the nearest ±0.05 cm. A total of three determinations was made and the reported value is an average of these. The tangent, ϕ, was calculated from the formula (18): tangent ϕ = H/R, where H is the height of the cone, and R is the radius of the platform.

Determination of Hydrostatic Pressures.—Although some relationships have been determined between height of particulate solids and unit pressure in hoppers (5), it seemed desirable to conduct some work utilizing the rotary press hopper.

The rotary press hopper was leveled and clamped in such a manner that the orifice rested on the table

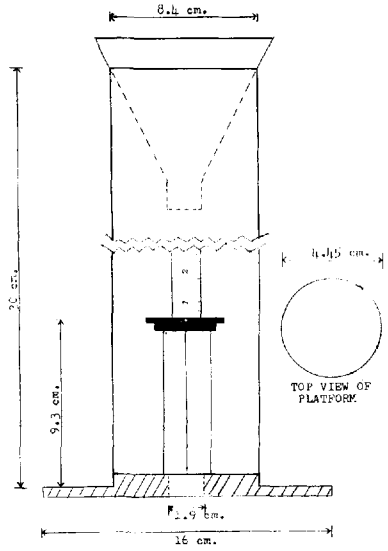

Fig. 2.—Instrumentation for determining angle of repose.

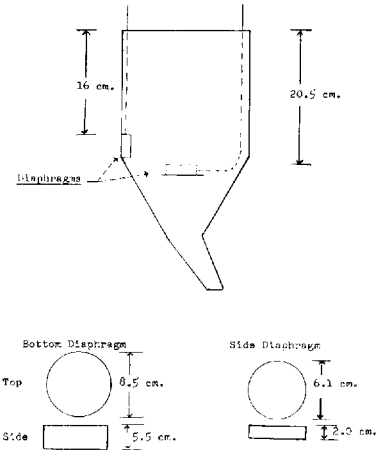

Fig. 3.—Apparatus for determining hydrostatic pressures.

surface. At first, the hopper was partially filled with rock salt. This was done to determine pressures in the larger section of the hopper.

The diaphragms were made from cylindrical metal containers which were covered on the top surface with a sheet of thin rubber. A combination of copper and glass tubing was used for retaining the water from the diaphragms. The diaphragms and tubing were filled to an arbitrary point.

The bottom diaphragm rested on a metal plate above the stationary level of material. The positions of the diaphragms are shown in Fig. 3. Fifteen kilograms of the respective rock salt combination was loaded into the hopper and lightly leveled on the surface. Under pressure of the loaded material, the rubber covering was compressed which resulted in an increase of the water level in the tubing. The water levels of the vertical and lateral diaphragms were measured from the initial markings within 1 min. after the hopper was charged. The experiment was carried out at 27 ±1°.

STATISTICAL ASPECTS OF THE INVESTIGATION

Design of the Experiment.—If the assumption is made that conditions in the machine such as speed, particle size distribution of a given mixture, hopper height, etc., remain constant throughout the entire experimentation, it is reasonable to assume that the response (rate) may be represented by some mathematical function of the constituents being used. This gives rise to what is commonly called a response surface. In this experiment, it was decided that a second degree equation should be tried, and then unneeded terms of this equation could be eliminated. The proposed model (*A*) is shown below.

$$Y = \beta_0 + \sum_{i=1}^{3} \beta_i X_i + \sum_{i=1}^{3} \beta_{ii} X_i^2 + \sum_{i=1}^{2} \sum_{j=i+1}^{3} \beta_{ij} X_i X_j + E \quad \text{(Model } A\text{)}$$

where

Y = flow rate for a given set of X's (*i.e*, a given mixture),
β = regression coefficients (unknown),
X_i = proportions of each sieve size rock salt,
E = random uncontrollable error.

The substance at any filling may be represented by

$$X_1 + X_2 + X_3 + X_4 = 1$$

where X_1 = % of 8/10, X_2 = % of 10/20, X_3 = % of 20/40, X_4 = % of 40/60. Percentages are expressed in decimals.

Much work has been done in setting up designs in response surfaces, and in these works optimum properties are achieved by properly placing the design points (*i.e.*, X_1, X_2, X_3, X_4). However, no one seems to have considered the case where the independent variables are restricted by inequalities as in this experiment. This being the case, it was felt that the best that could be done would be to choose a design which (*a*) permits estimation of all regression coefficients of the equation (β's) and (*b*) permits analysis of the variability in response at different combinations of the X_i's.

The design of the experiment chosen was one in which (*a*) each sieve size was run separately, (*b*) sieve sizes were run in pairs, (*c*) sieve sizes were run in triplets, and (*d*) all sieve sizes were run at the same time. These various combinations are shown in Table I. Note that some of the mixtures were run twice, (*i.e.*, *7* and *24* are the same, *15* and *25*, etc.).

RESULTS AND DISCUSSION

A summary of the average flow rates and standard errors, tangent of the angle of repose, bulk density,

[a] Standard deviation of mean flow rate.

and porosity is shown in Table II. Table III shows the results of the hydrostatic pressure measurements.

Statistical Analysis.—In the discussion, the following conventions have been adopted: *observation*, a single determination for a specific combination; *sample*, the aggregate of observations for a specific combination; *experiment*, the totality of samples for all combinations. After running the first 19 combinations shown in Table I, plots of each sample were made on a time scale and on separate pieces of graph paper. The main purpose of this was to determine if any trend existed in flow rate from the first observation taken in each sample to the last. It is noted that the model proposed assumes no such trend (*i.e.*, it assumes each observation in a sample to be about like any other observation, apart from random error). The plots suggested that in some instances there appeared to be trends. Statistical tests showed, however, that the "apparent trends" could be attributed to chance variation in the data, and thus, model A was considered adequate.

As a by-product of this investigation mentioned above, a preliminary fit[1] of a modified form of the proposed model was obtained. This modified model is shown as model B.

$$Y = \beta_0 + \sum_{i=1}^{3} \beta_i X_i + \sum_{i=1}^{3} \beta_{ii} X_i^2 + E \quad \text{(Model } B\text{)}$$

This fitted equation provided an estimate (perhaps rough) of the design point which would produce the greatest flow rate. This was:

[1] The term "fit" refers to the estimation of the unknown β's from the data. The least squares technique was used in estimating these coefficients.

TABLE III.—HYDROSTATIC PRESSURES OF ROCK SALT IN ROTARY PRESS HOPPER

Sieve Size	Pressure in cm. Water[a] Vertical	Lateral	Increase of Lateral Above 8/10 Fraction, %
8/10	6.35	1.45	...
40/60	8.65	1.85	27.6
8/10 40/60[b]	6.60	2.03	40.0

[a] Glass tubing with inside diameter of 0.3 cm. [b] 50% of each mixed together.

$$\hat{X}_1 = 0.1794 \ (\%\ 8/10 \text{ fraction})$$
$$\hat{X}_2 = 0.0000 \ (\%\ 10/20 \text{ fraction})$$
$$\hat{X}_3 = 0.0000 \ (\%\ 20/40 \text{ fraction})$$
$$\hat{X}_4 = 0.8206 \ (\%\ 40/60 \text{ fraction})$$

It is noted that the design point tested producing the maximum flow rate in the experiment was

$$X_1 = 0.5000 \ (\%\ 8/10 \text{ fraction})$$
$$X_2 = 0.0000 \ (\%\ 10/20 \text{ fraction})$$
$$X_3 = 0.0000 \ (\%\ 20/40 \text{ fraction})$$
$$X_4 = 0.5000 \ (\%\ 40/60 \text{ fraction})$$

At this point in the investigation it seemed advisable to take a few more samples in order to get a good fit of model A in the region of the suspected maximum flow rate (*i.e.*, the predicted maximum) and so that differences in flow rate and variation could be examined for repeated sampling of the same mixture. Since no trend existed with regard to the time an observation was taken, the means of the flow rates were thought to be indicative of the performance of a particular combination. Also, in using the means of the flow rates a source of varia-

tion was eliminated in fitting the model (*i.e.*, within combination variation).

With this in mind, model A was fitted to the means arising from samples *1* through *26*. Tests were carried out to determine whether any of the regression coefficients could be eliminated, and the results indicated that β_3 and β_{33} could be considered as zero. If these coefficients are set equal to zero in model A, the resulting model may be called model A'.

Model A' then is the one that should be used for this experiment. The data were fitted to model A' (*i.e.*, model A with $\beta_3 = \beta_{33} = 0$), and the resulting fitted equation along with the standard deviation of the estimated parameters (in parentheses) are given below.

$$\hat{Y} = \hat{\beta}_0 + \sum_{i=1}^{2} \hat{\beta}_i X_i + \sum_{i=1}^{2} \hat{\beta}_{ii} X_i^2 + \sum_{i=1}^{2} \sum_{j=i+1}^{3} \hat{\beta}_{ij} X_i X_j$$

$$\begin{aligned}
\hat{\beta}_0 &= 1812.7531 \quad (32.3132) \\
\hat{\beta}_1 &= 1311.3557 \quad (187.9531) \\
\hat{\beta}_2 &= 778.7229 \quad (248.3857) \\
\hat{\beta}_{11} &= -1878.3369 \quad (194.3749) \\
\hat{\beta}_{22} &= -935.3288 \quad (257.8770) \\
\hat{\beta}_{12} &= -2261.2628 \quad (408.3098) \\
\hat{\beta}_{13} &= -510.4626 \quad (262.2961) \\
\hat{\beta}_{23} &= -589.9348 \quad (340.8922)
\end{aligned}$$

The estimates of the X_i's from the above equation which would produce the maximum flow rate were calculated to be:

$$\begin{aligned}
\hat{X}_1 &= 0.3491 \ (\%\ 8/10 \text{ fraction}) \\
\hat{X}_2 &= 0.0000 \ (\%\ 10/20 \text{ fraction}) \\
\hat{X}_3 &= 0.0000 \ (\%\ 20/40 \text{ fraction}) \\
\hat{X}_4 &= 0.6509 \ (\%\ 40/60 \text{ fraction})
\end{aligned}$$

Since model A' has fewer parameters than model A, it is natural to inquire as to what is lost, if anything, by choosing the simpler model. This question is generally answered by using the multiple correlation coefficient, M, associated with each fitted model. The square of M is actually the percentage of the total variation in the sample means which is accounted for by the fitted model. The M corresponding to the fitting of A was found to be 0.9552, while that for A' was 0.9501; hence, the fitted A' is just about as good a predictor of flow rate as is the fitted A. In fact, it was found that if all regression coefficients with a three in the subscript were set equal to zero (*i.e.*, $\beta_3 = \beta_{33} = \beta_{13} = \beta_{23} = 0$), then the fitted model had an M of 0.9270. This means that knowledge of X_3 helps very little in predicting mean flow rates. In other words, the absence or presence of the $^{21}/_{40}$ fraction in the mixture has little effect on the mean of the flow rates.

Linear Correlation of Flow Rates with Angle of Repose, Bulk Density, and Porosity.—The sample correlation coefficient between flow rate and various other measurements is defined as

$$r = \frac{\sum_{i=1}^{n} (X_i - \bar{X})(Y_i - \bar{Y})}{\left[\sum_{i=1}^{n} (X_i - \bar{X})^2 \cdot \sum_{i=1}^{n} (Y_i - \bar{Y})^2\right]^{1/2}}$$

where $X_1, X_2, \ldots, X_n$ are the mean flow rates of the 26 samples and $Y_1, Y_2, \ldots, Y_n$ are the values corresponding to the variable whose linear correlation with flow rate is to be investigated.

Tangent of Angle of Repose.—$r_1 = +0.1022$. A statistical test showed that the true correlation could be considered zero, and the conclusion was made that the tangent angle of repose is uncorrelated with flow rate.

Bulk Density.—$r_2 = +0.8123$. This suggests a positive correlation and hence the conclusion was made that flow rate is positively correlated with bulk density.

Porosity.—$r_3 = -0.8160$. This indicates a negative correlation with flow rate.

Variation of Flow Rates.—The usual standard deviation of the mean was computed for each combination and used as a measure of variation of flow rate (see Table II). A statistical comparison revealed that not only are there significant differences in the variation for different mixtures (*i.e.*, combinations *1* and *13*), but there are also significant differences in the variation of flow rate of the same mixture run two different times (*i.e.*, combinations *13* and *26*). The differences in the first case were not so surprising as those in the second case due to changing bulk density, porosity, and particle size in the former. No explanation can be offered at this time as to why combinations *1*, *7*, and *10* had the greatest standard deviation. The variation of the standard error in the second case (*i.e.*, combination *13* and *26*) was probably due primarily to differences in the particle size distribution at different times. This, however, was not verified.

SUMMARY

Flow rates were obtained from constantly flowing material which approached tableting operations. There was a maximum point at which the further addition of 40/60 fraction of rock salt to the 8/10 fraction decreased the flow rate. This maximum point, among those tested, was when 50% each were mixed. The fitted model places the maximum at 35% of the 8/10 fraction and 65% of the 40/60 fraction. No correlation was found to exist between the angle of repose and flow rate.

Other factors had an effect on the flow rate. Bulk density increased with a decrease in porosity when different particle size systems were mixed. Hence, flow rate was increased due to more weight per unit volume being delivered from the hopper orifice. The flow rate was increased by the addition of smaller particles to larger particles which appeared to act as a lubricant when the voids were partially filled. Lateral hydrostatic pressure measurements on 8/10, 40/60, and 50% of 8/10 and 40/60 fractions of rock salt showed that the flow rate increased with increasing pressures, though the same relationship with vertical hydrostatic pressure does not seem to exist.

The standard error varied from a low of 2.1633 to a high of 13.8786 for various combinations of rock salt. There is an apparent difference in the uniformity of flow rate from one combination to another. However, no obvious simple trend exists since the highest variability was associated with the lowest flow rate, while the second highest variability was associated with the highest flow rate.

Direct Titrimetric Determination of Aromatic Quaternary Ammonium Salts and Long Chain Aliphatic Sulfates and Sulfonates

By JOYE A. BILLOW and H. WELDON BAKER

Aromatic quaternary ammonium salts and long chain aliphatic sulfates and sulfonates can be assayed by a rapid, single phase aqueous titration. Sodium tetraphenylboron serves as a direct standard in the assay of the quaternaries and benzalkonium chloride as the titrant for anionic detergents. Bromophenol blue indicator gives a purple to blue color change when the anionic substances are titrated in strongly alkaline solution. The results of this method show excellent agreement with the standard chloroform extraction titration.

THE aromatic quaternary ammonium salts official in U.S.P. XVII and N.F. XII are assayed by many different methods. Sodium lauryl sulfate, the only official long chain aliphatic sulfate, is not directly assayed. It was believed that a single method type, direct titration of large anions with large cations, could be used for all aromatic quaternary ammonium salts and for the long chain aliphatic sulfates and sulfonates.

A direct titration of sodium tetraphenylboron with cetyltrimethylammonium bromide using bromophenol blue indicator was used by Schall (1) in the determination of potassium. This suggested that aromatic quaternary ammonium compounds could be assayed by direct titration of sodium tetraphenylboron, and, conversely, that large anions could be titrated directly with quaternary ammonium compounds.

Cetylpyridinium chloride is officially assayed (2) by titration with standard sodium tetraphenylboron using bromophenol blue indicator. The official method differs from that proposed by Schall in that the end point depends upon the extraction of the indicator from a chloroform layer.

A similar chloroform extraction titration, using tetrabutylammonium iodide as the standard, is official (3) for the assay of the aliphatic sulfonate dioctyl sodium sulfosuccinate. This method is adapted in method *A* as the general chloroform extraction method against which the proposed method is compared.

REAGENTS

Tetrabutylammonium Iodide (Primary Standard Cation).—A 0.01000 *M* solution prepared considering the material to be 100% pure. Titration in triplicate against sodium tetraphenylboron by method *A* gave 0.01000 *M* ± 0.00005 *M*.

Sodium Tetraphenylboron (Primary Standard Anion).—A 0.01000 *M* solution prepared on the basis of labeled 99.6% assay. This should be freshly prepared before each use because of decomposition on standing in solution.

Benzalkonium Chloride (Secondary Standard Cation).—Approximately 0.01 *M* solution prepared by diluting about 30 ml. of 12.8% benzalkonium chloride[1] to 1 L. and standardized against sodium tetraphenylboron by N.F. XII procedure for cetylpyridinium chloride (2).

Received June 3, 1966, from the School of Pharmacy, Temple University, Philadelphia, Pa. 19140.
Accepted for publication September 19, 1966.

TABLE I.—COMPARISON OF METHODS *A* AND *B*

Soln.	Method *A* No. Assays	Method *A* Av. *M*	Method *A* S. D.	Method *B* No. Assays	Method *B* Av. *M*	Method *B* S. D.
Benzalkonium chloride I	6	0.00902	0.00001	6	0.00903	0.00001
Benzalkonium chloride II	6	0.01030	0.00001	6	0.01029	0.00001
Dioctyl sodium sulfosuccinate	6	0.01159	0.00001	6	0.01159	0.00001
Sodium lauryl sulfate I	5	0.00906	0.00004	6	0.00910	0.00005
Sodium lauryl sulfate II	3	0.01000	0.00006	5	0.01016	0.00004
Cetylpyridinium bromide	3	0.01135	0.00001	3	0.01136	0.00001

Sodium Octylphenoxyethoxypolyether Sulfate (Secondary Standard Anion).—Dilute approximately 20 ml. of alkyl phenoxyethanesulfonate[2] concentrate to 1 L. Standardize against tetrabutylammonium iodide using the N.F. XII procedure for dioctyl sodium sulfosuccinate (3).

Bromophenol Blue T.S.—A 0.1% quantity bromophenol blue in a mixture of equal volumes of water and alcohol.

Salt Solution.—Prepared according to N.F. XII directions for assay of dioctyl sodium sulfosuccinate (3).

Chloroform.—Reagent grade.

Sodium Hydroxide Solution.—Twenty per cent.

METHODS

Method A.—*Adapted from N.F. XII Method for Dioctyl Sodium Sulfosuccinate.*—Place a sample containing about 25 mmoles cation such as tetrabutylammonium iodide in 25 ml. of water, 50 ml. of salt solution, 25 ml. of chloroform, and 0.4 ml. of bromophenol blue T.S. in a flask. Titrate with an approximately 0.01 *M* anion solution, using a magnetic stirring device to insure thorough mixing of the layers to replace the shaking procedures in the official method. Add the anion dropwise in the vicinity of the end point, allowing sufficient time for mixing and separation. Continue the titration until the blue color is completely removed from the chloroform layer.

Method B.—*Proposed Direct Method.*—This procedure is the same whether the anionic or cationic component is to be determined. Pipet 25 ml. of an approximately 0.01 *M* anion solution into a flask, add 50 ml. of water, 2 ml. of 20% NaOH, and 0.4 ml. of bromophenol blue T.S. The solution will be purple. Using a magnetic stirrer, titrate with the cation, adding it dropwise near the end point, which is a color change to a distinct, bright blue.

Two benzalkonium chloride solutions were prepared as indicated under *Reagents*. These were standardized by titration against the secondary standard anion using method *A* and the proposed method *B*. Results are given in Table I.

Dioctyl sodium sulfosuccinate was assayed by titration against standardized benzalkonium chloride solution by both methods. The dioctyl sodium sulfosuccinate solution was prepared by diluting approximately 7.5 ml. of a type of dioctyl sodium sulfosuccinate[3] to 1 L. and allowing to stand with occasional shaking until complete dissolution was obtained. Results are given in Table I.

Sodium lauryl sulfate was assayed by titration against standard benzalkonium chloride solution, using both methods *A* and *B*. Results are given in Table I.

Cetylpyridinium bromide was assayed by titration against standard sodium tetraphenylboron solution, using both methods *A* and *B*. Results are given in Table I.

DISCUSSION

Tetrabutylammonium iodide can only be used in method *A*; attempts to use it in method *B* gave no color change at the end point. Sodium tetraphenylboron can be used in both methods *A* and *B*.

As previously stated, the color change in method *B* is from purple to blue. A trial is necessary to obtain a correct end point, so that a purple-tinged blue may not be mistaken for the true end point by those not thoroughly familiar with the color change.

In method *B* the formation of a greasy precipitate in the vicinity of the end point has not been found to interfere with end point detection.

The following sulfonphthalein indicators were investigated for use in method *B* and were found unsatisfactory: thymol blue, bromocresol purple, cresol red, phenol red, dibromopyrogallol sulfonphthalein, pyrogallol sulfonphthalein, pyrocatechol sulfonphthalein.

CONCLUSIONS

The data show that the proposed direct titration (method *B*) yields results in excellent agreement with the chloroform extraction titration (method *A*) for the compounds studied, which were U.S.P., N.F., or closely related materials. No investigation of interferences was made in this study; the scope was limited to the method types presented in the official compendia. The advantages of method *B* include: reliable primary standards, inexpensive secondary standards, faster, easier titration. This method also eliminates the use of chloroform, which is both expensive and toxic.

Sodium Chloride Equivalents, Cryoscopic Properties, and Hemolytic Effects of Certain Medicinals in Aqueous Solution

By E. ROY HAMMARLUND and GERALD L. VAN PEVENAGE*

A supplemental table of NaCl equivalents and freezing point depressions at various concentrations for 21 different medicinal substances in aqueous solution is presented. Also given in the table is the isosmotic concentration of each of the materials which can form such a solution. The degree of hemolysis of human erythrocytes was determined in 45 different isosmotic solutions and the data are presented in a table to supplement the previously published values. Freezing point depression graphs for five substances—bromodiphenhydramine HCl, dexchlorpheniramine maleate, hydroxyzine HCl, sodium nafcillin, and valethamate bromide—are presented because they showed one or more discontinuities caused by some type of association or aggregation in their solutions.

THE NaCl equivalents and freezing point depressions for various aqueous medicinal solutions have been determined experimentally and reported (1, 2). Likewise, the amount of hemolysis of fresh human erythrocytes in certain aqueous isosmotic solutions was determined using the hemolytic method and has been reported previously (3).

The objective of the present investigation was to study in a similar manner a number of additional substances not included in the earlier cryoscopic and hemolytic investigations and to present the data in suitable tables to supplement the previous data. Furthermore, since it has been reported by Hammarlund and Pedersen-Bjergaard (4) and by Johnson, Goyan, and Tuck (5) and others that certain amine salts and other substances tend to aggregate in aqueous solution, data are presented for five such substances which have been found to show this behavior.

EXPERIMENTAL

Freezing Point Measurements.—The method used for most of the measurements of the freezing points of the solutions was the same as that reported previously in detail (1). The freezing point depression measurements were made directly on aqueous solutions of the compounds at selected concentrations by means of a Beckman differential thermometer. For several of the compounds used in the latter portion of the study, a cryoscopic osmometer[1] was employed for the freezing point depression measurements. Several substances were determined by both instruments and the data correlated almost exactly.

The freezing point measurements were corrected for the amount of disengaged ice, and −0.52° was used as the comparative freezing point for aqueous 0.9% NaCl solution which is isotonic with blood and tears. The materials used were of official grade of purity or better, and for those nonofficial substances, the grade of purity of each complied with the manufacturer's specifications. The NaCl equivalents and isosmotic concentrations are reported to the nearest 0.01.

Table I lists the NaCl equivalents at various concentrations for all of the currently studied substances. To use these data, one should employ the NaCl equivalent which represents the concentration nearest to the desired concentration of medicinal substance used.

Because of interest in the colligative properties of some medicinal solutions, the freezing point depressions and NaCl equivalents are included for several preparations which are not used necessarily as isotonic solutions. The term "isotonic solution" is used in its customary sense in this report—meaning that the solution freezes at the same temperature as normal saline solution, blood, and tears.

Hemolysis of Human Erythrocytes.—The method used was essentially the same as that employed by Husa and co-workers (6, 7) and is a modification of the method by Hunter (8). The principal deviations from Husa's method were that only isosmotic concentrations were employed, and an aqueous saponin solution, 100 mg./L., was used as the 100% hemolyzing solution for the erythrocytes. A fresh sample of human venous blood was used daily, and each investigation was completed within 3 hr. from the time the blood was drawn. The method employed in this study was identical with that previously described by Hammarlund and Pedersen-Bjergaard (3) except that the absorbance of each centrifuged supernatant liquid was determined in a Spectronic[2] 20 photoelectric colorimeter at 540 mμ instead of the previously used instrument employing a standard green filter.

The per cent of hemolysis found for the 45 compounds studied is listed in Table II including the isosmotic concentration used for each and its approximate pH. The few experimental solutions which were colored before the addition of blood were handled in the same manner as described previously (3). For those solutions which developed a color or cloudiness upon the addition of blood, the proportional decrease in volume of the packed, unhemolyzed, centrifuged erythrocytes was estimated visually. Any change in appearance of the erythrocytes or the solution was referred to in the footnotes for Table II.

Cryoscopic Behavior of Certain Aggregate-Formers.—When the freezing point depression data were plotted for the various substances, it was noted that the graphs for five of them had a definite discontinuity at certain concentrations. This observation suggested that there could be some type of association of the solute or aggregation taking place above a

[a] The values first listed for the chemical substances are NaCl equivalents. [b] The second values, in *italics*, are freezing point depression values in ° C. [c] The percentage concentration (w/v) at isotonicity (isosmotic) is given in parentheses in the last column.

particular concentration of the solute at the freezing temperature of the solution. In order to obtain a more definite estimation of the various points of discontinuity, the freezing point depression graphs for the five substances were plotted as the log of the freezing point depression *versus* the log of the molar concentration of the solutions. These are shown in Figs. 1 and 2 and the concentrations of the substances at their points of discontinuity in the figures were found to be as follows: bromodiphenhydramine HCl, 0.058 *M* (2.15% w/v) and 0.248 *M* (9.19% w/v); dexchlorpheniramine maleate, 0.088 *M* (3.44% w/v); hydroxyzine HCl, 0.055 *M* (2.48% w/v); sodium nafcillin, 0.062 *M* (2.52% w/v); and valethamate bromide, 0.098 *M* (3.80% w/v).

DISCUSSION

Isosmotic solutions of 20 substances prevented hemolysis of erythrocytes and solutions of 25 other substances failed to prevent hemolysis, the degree of hemolysis varying from slight to complete. This type of result has been discussed previously in considerable detail (3).

Figures 1 and 2 show that five of the substances studied undergo a solute association or aggregation similar to that found for dibucaine HCl, tetracaine HCl, and pramoxine HCl and which was discussed previously by Hammarlund and Pedersen-Bjergaard (4) and by Johnson, Goyan, and Tuck (5).

The freezing point depression data for bromodiphenhydramine HCl (Fig. 2) presented an anomaly as at 0.248 *M* concentration the freezing point curve broke sharply back to exactly the same slope that it had prior to its point of the initial aggregation at 0.058 *M*.

One objection to the use of the freezing point depression method for the sole determination of aggregation is that it cannot reveal any temperature dependence of the aggregation. This is so, since, for a given concentration, observations are restricted to only one temperature, the freezing temperature. A substance might exhibit a freezing point depression curve similar to that of any other aggregate-forming substance; however, in this instance a break in its curve would not indicate some critical concentration, but would indicate rather a particular temperature

below which some other change takes place in the system such as the occurrence of a solute–solvent interaction. In order to determine whether aggregation depends significantly upon temperature, it is necessary to resort to other analytical techniques in which measurements are made on corresponding solutions over a range of temperatures. Johnson, Goyan, and Tuck (5) have done this for various substituted amine salts by employing a thermoelectric vapor-phase osmometer at 25°, and they found evidence of aggregation at this temperature for several substances. Likewise, Farhadieh (9) in a study of the aggregation of dibucaine HCl, tetracaine HCl, diphenhydramine HCl, procaine HCl, tripelennamine HCl, pyrilamine HCl, and bromodiphenhydramine HCl employed both a vapor pressure osmometer and a Dike-Jones[3] con-

ductivity bridge at 25°. The data from both of the analytical procedures demonstrated that there was some aggregation at 25° for each substance which had shown aggregation previously at its freezing temperature, except for pyrilamine HCl which did not aggregate at 25° in the concentration range studied. Moreover, with both the conductivity and vapor pressure methods bromodiphenhydramine HCl data showed an initial aggregation point at 0.052 *M* which agreed quite well with the freezing depression data of the initial aggregation concentration (0.058 *M*), but it did not show the second break in the curve at 0.248 *M* which was disclosed by the freezing point method. The fact that this second break was not found at 25° could mean that it was temperature dependent or resulted from some other condition not controlled in the study. This point needs further investigation.

Attempted Mannich Condensation with Indanedione-1,3

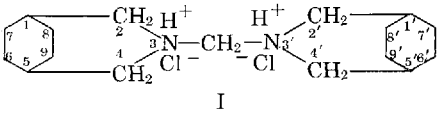
By RAJENDRA S. VARMA and W. LEWIS NOBLES

All attempts to prepare Mannich bases of indanedione failed. In every instance the end product was an amorphous solid with a high melting point and insoluble in most organic solvents. In one instance, while using 3-azabicyclo (3.2.2)nonane as the secondary amine component, a small amount of white crystalline substance was isolated from the mother liquor and identified as methylenebis-3-azabicyclo (3.2.2)nonane dihydrochloride with the help of infrared and NMR spectra. The structure of this compound was confirmed by unambiguous synthesis.

THE CONDENSATION between an amine (primary or secondary) or its salt with formaldehyde and a compound having an active hydrogen is known as the Mannich reaction.

Numerous Mannich bases are recorded in the literature (1–9); these have been prepared for pharmacological screening as antispasmodics, analgesics, chemotherapeutics, and local anesthetics.

In an effort to prepare Mannich bases of indanedione-1,3 for pharmacological testing, the condensation reaction was attempted several times utilizing dimethylamine, diethylamine, morpholine, piperidine, and 3-azabicyclo (3.2.2)nonane (AZBN) as the secondary amine component. Formaldehyde was used either as its aqueous solution or paraformaldehyde. Each synthesis resulted in a high yield of amorphous solid which was insoluble in most organic solvents. This solid material was washed several times with ether and ethanol, dried, and analyzed for elemental content. The analytical data did not correspond with the desired Mannich base. In one instance while using AZBN the mother liquor was refrigerated after adding acetone. This gave a white crystalline solid in small amounts. A pure sample was prepared after three recrystallizations from ethanol. The analytical values corresponded with methylenebis-3-azabicyclo(3.2.2)-nonane dihydrochloride (I). The infrared spectrum showed no carbonyl absorption. This ruled out the possibility of its being an indanedione Mannich base. The infrared spectrum was somewhat similar to that of AZBN.



I

The NMR spectrum was consistent with the proposed structure (I). Bands at δ = 1.95 (16H, singlet) are due to methylene protons at 6,7,8,9,-6′,7′,8′,9′ and those at δ = 2.17 (6H, multiplet) correspond to protons at 1,5,1′,5′ and the methylene group between the two nitrogens. Bands at δ = 3.36 (8H, triplet) may be assigned to protons at 2,4 and 2′,4′. Bands at δ = 7.47 (2H, singlet) represent protons at 3 and 3′. When D_2O was added, the peak at δ = 7.47 disappeared due to the exchange of the protons on the nitrogen atoms.

Methylenebis-3-azabicyclo(3.2.2)nonane dihydrochloride was synthesized by utilizing another route. The melting point and infrared spectrum of the resulting product were identical in every respect to those relative to the Mannich (AZBN) mother liquor product. The mixed melting point showed no depression. On the basis of the above evidence the structure (I) of methylenebis-3-azabicyclo(3.2.2)-nonane dihydrochloride is assigned to the product isolated from the mother liquor. Isolation of similar types of by-products are recorded in the literature (10, 11). Thus *N,N′*-tetraethylmethylenediamine (10) and methylenedipiperidine (11) have been obtained when using diethylamine and piperidine, respectively.

The mechanism of the Mannich reaction has been investigated by Hellmann and Opitz (12) and Cummings and Shelton (13). It is proposed (14) that the reaction is initiated by a condensation between the amine and formaldehyde to yield an amino-

methanol. The attack of a proton on the oxygen atom of the amino-methanol followed by expulsion of water leads to a resonance established carbonium-immonium ion. This electrophilic carbonium ion then reacts with a nucleophile which, under Mannich conditions, is usually the carbanion resulting from the ionization of the active hydrogen containing compound. It appears that under Mannich conditions AZBN acts as the nucleophile as well as condensing with the formaldehyde.

EXPERIMENTAL

Melting points were taken on a Thomas-Hoover capillary melting point apparatus and are uncorrected. The infrared spectra were charted on a Perkin Elmer model 137 spectrophotometer in Nujol mull. The NMR spectrum was recorded with a Varian A-60 spectrometer in $CDCl_3$, using tetramethylsilane as the internal standard.

Attempted Mannich Condensation of Indanedione-1,3 with AZBN.—AZBN (12.51 Gm., 0.10 mole) dissolved in 50 ml. of ethanol was acidified to pH 4 by dropwise addition of concentrated hydrochloric acid. Indanedione (14.6 Gm., 0.10 mole) was added followed by 4.5 Gm. (0.15 mole) of paraformaldehyde. The reaction mixture was heated on a water bath for 4 hr. The reaction mixture was cooled and filtered. This gave a product weighing 11.5 Gm. which could not be recrystallized because of its insolubility in most organic solvents. The mother liquor was diluted with 100 ml. of acetone and refrigerated overnight. A crystalline solid (6.5 Gm.) was obtained; this was recrystallized from ethanol, m.p. 301° dec. NMR data, δ = 1.95 (16H, singlet); 2.17 (6H, multiplet); 3.36 (8H, triplet); 7.47 (2H, singlet).

Anal.—Calcd. for $C_{17}H_{32}Cl_2N_2$: C, 60.90; H, 9.59; Cl, 21.74; N, 8.35. Found: C, 60.13; H, 9.77; Cl, 21.81; N, 8.55.

Methylenebis-3-azabicyclo(3.2.2)nonane Dihydrochloride (I).—AZBN (6.25 Gm., 0.05 mole) dissolved in 25 ml. of ethanol was acidified with concentrated hydrochloric acid to pH 4. Paraformaldehyde (1.11 Gm., 0.037 mole) was added and the reaction mixture refluxed on a boiling water bath for 3 hr. At the end of this period the contents were cooled and 100 ml. of acetone was added. The solution was refrigerated overnight. The desired product which was obtained as white needles, was recrystallized from ethanol or ethanol–acetone, m.p. 301° dec. Yield, 5.5 Gm. (65%). The mixed melting point obtained with the product isolated from the Mannich condensation (AZBN) showed no depression. Infrared spectra of both products were identical.

Anal.—Calcd. for $C_{17}H_{32}Cl_2N_2$: N, 8.35; Found: N, 8.53.

Antidiabetic Effect of Tecomine and Tecostanine

By YOUSSEF HAMMOUDA and M. SAMIR AMER*

The hypoglycemic properties of tecomine citrate and tecostanine hydrochloride on fasting blood sugar, glucose tolerance, depancreatized, and alloxan-diabetic rabbits is described. The two drugs proved to be effective antidiabetic agents only in the presence of the pancreas.

TECOMINE (I) and tecostanine (II) are two alkaloids isolated by Hammouda and Motawi (1) and Hammouda *et al.* (2) from the leaves of *Tecoma stans* (Juss.). The leaves of the various species of *Tecoma* have long been used by the natives in Mexico for the control of diabetes (3, 4). Since the structure of the two alkaloids isolated therefrom was elucidated (5–7), it was of interest to determine whether the two alkaloids are responsible for the long known antidiabetic properties of the leaves. The present study was initiated to determine the hypoglycemic properties of the two alkaloids and to determine the possible mechanism by which they produce this effect. A short note was previously published on this subject (8).

methanol. The attack of a proton on the oxygen atom of the amino-methanol followed by expulsion of water leads to a resonance established carbonium-immonium ion. This electrophilic carbonium ion then reacts with a nucleophile which, under Mannich conditions, is usually the carbanion resulting from the ionization of the active hydrogen containing compound. It appears that under Mannich conditions AZBN acts as the nucleophile as well as condensing with the formaldehyde.

EXPERIMENTAL

Melting points were taken on a Thomas-Hoover capillary melting point apparatus and are uncorrected. The infrared spectra were charted on a Perkin Elmer model 137 spectrophotometer in Nujol mull. The NMR spectrum was recorded with a Varian A-60 spectrometer in $CDCl_3$, using tetramethylsilane as the internal standard.

Attempted Mannich Condensation of Indanedione-1,3 with AZBN.—AZBN (12.51 Gm., 0.10 mole) dissolved in 50 ml. of ethanol was acidified to pH 4 by dropwise addition of concentrated hydrochloric acid. Indanedione (14.6 Gm., 0.10 mole) was added followed by 4.5 Gm. (0.15 mole) of paraformaldehyde. The reaction mixture was heated on a water bath for 4 hr. The reaction mixture was cooled and filtered. This gave a product weighing 11.5 Gm. which could not be recrystallized because of its insolubility in most organic solvents. The mother liquor was diluted with 100 ml. of acetone and refrigerated overnight. A crystalline solid (6.5 Gm.) was obtained; this was recrystallized from ethanol, m.p. 301° dec. NMR data, δ = 1.95 (16H, singlet); 2.17 (6H, multiplet); 3.36 (8H, triplet); 7.47 (2H, singlet).

Anal.—Calcd. for $C_{17}H_{32}Cl_2N_2$: C, 60.90; H, 9.59; Cl, 21.74; N, 8.35. Found: C, 60.13; H, 9.77; Cl, 21.81; N, 8.55.

Methylenebis-3-azabicyclo(3.2.2)nonane Dihydrochloride (I).—AZBN (6.25 Gm., 0.05 mole) dissolved in 25 ml. of ethanol was acidified with concentrated hydrochloric acid to pH 4. Paraformaldehyde (1.11 Gm., 0.037 mole) was added and the reaction mixture refluxed on a boiling water bath for 3 hr. At the end of this period the contents were cooled and 100 ml. of acetone was added. The solution was refrigerated overnight. The desired product which was obtained as white needles, was recrystallized from ethanol or ethanol–acetone, m.p. 301° dec. Yield, 5.5 Gm. (65%). The mixed melting point obtained with the product isolated from the Mannich condensation (AZBN) showed no depression. Infrared spectra of both products were identical.

Anal.—Calcd. for $C_{17}H_{32}Cl_2N_2$: N, 8.35; Found: N, 8.53.

[a] Average of four to six experiments. [b] Calculated as the free base.

MATERIALS AND METHODS

The animals used in the present study were healthy male rabbits weighing 1.5–2.5 Kg. fed *ad libitum* on a balanced diet. Blood samples for the assay of blood sugar were obtained by bleeding the ear vein into a heparinized pipet. Blood sugar was determined by the method of Nelson (9). Alloxan diabetes was produced by injecting alloxan monohydrate[1] intravenously in a dose of 200 mg./Kg. in 4 divided doses over a period of 24 hr. Alloxan was dissolved in isotonic saline to make a 3% solution immediately before injection. The animals were allowed to drink a 5% glucose solution for the entire period of the alloxan diabetes. Hyperglycemia developed slowly and reached a maximum after 2 weeks. The animals were used only after producing glucosuria continuously for 3 consecutive days. Tecomine citrate and tecostanine hydrochloride were prepared from the dried fresh leaves of *T. stans* (1) and were tested for purity before use.

RESULTS

Fasting Animals.—The rabbits used in this study were fasted for 12–18 hr. before the experiments were started. The drugs were dissolved in physiological saline and given either intravenously or orally *via* a stomach tube. The results are given in Table I.

It is clear from the table that both alkaloids are potent hypoglycemic agents producing severe reductions in the blood sugar of fasting rabbits when given in a dose of 20 mg./Kg. i.v. or 50 mg./Kg. orally. When given intravenously the maximum hypoglycemic effect is reached earlier than when given orally even in higher doses. This is to be expected since the drugs have to be absorbed from the alimentary tract. The absorption from the alimentary tract would account for the 1–2-hr. lag when the drug is given orally. When given intravenously, the effect on the blood sugar reaches maximum (179% of tolbutamide) after 3 hr. and 14 min. for tecomine citrate and after 3 hr. and 23 min. for tecostanine hydrochloride (186% of tolbutamide). Some of the animals experienced hypoglycemic coma at the height of the hypoglycemic effect.

Glucose Tolerance.—The rabbits used in this series were fasted for 12 hr. before the start of the experiment. The drugs, dissolved in isotonic saline, were injected intravenously, followed 40 min. later with 3 Gm. of glucose as a 5% solution. The results are shown in Fig. 1. It is clear from the figure that both tecomine citrate and tecostanine hydrochloride in the dose used, *i.e.*, 20 mg./Kg., reduced the time needed for the blood sugar to return to normal from about 3.5 to 2.5 hr. There was a statistically significant difference between the control values and the values obtained with either drug at 3.5 hr. after the administration of glucose.

Depancreatized Rabbits.—After complete depancreatization, the rabbits developed hyperglycemia in 24 hr. After the hyperglycemia was established and glucosuria produced, tecomine citrate (20 mg./Kg.) and tecostanine hydrochloride (20 mg./Kg.) were injected i.v. Blood samples were collected 3 hr. later, since the alkaloidal salts exhibited maximum hypoglycemic effect at this time when given intravenously (see Table I), and assayed for sugar content. The results obtained are shown in Table II.

A Student *t* test was carried out on the values obtained before and after treatment, and the probability ratios (*P*) are included in the table. From the table it could be seen that the two alkaloids

TABLE III.—EFFECT OF TECOMINE CITRATE AND TECOSTANINE HYDROCHLORIDE ON THE BLOOD SUGAR LEVEL IN ALLOXAN DIABETIC RABBITS

Substance Administered	Rabbit No.	Blood Sugar Level, mg./100 ml. Fasting Before Alloxan	Fasting After Alloxan[a]	Days After Alloxan[d] 16	22	45
Saline (control)	1–4[b]	103.7	275.6	289.7	310.0	
Tecomine citrate, 20 mg.[c]/Kg.	5	105.3	270.4	115.0	124.0	131.3
	6	110.3	320.1	107.3	113.4	123.3
Tecostanine hydrochloride, 20 mg.[c]/Kg.	7	92.7	303.7	100.1	97.2	101.6
	8	99.0	256.4	123.3	139.3	143.1

[a] Before drug treatment was started. [b] Average of four rabbits. [c] Calculated as the free base. [d] Treatment instituted

are not significantly effective in reducing the blood sugar of depancreatized rabbits since the difference between the treated and control is not statistically significant ($P > 0.05$). Doses of 50 mg./Kg. were also given and were unable to produce statistically significant reduction in the blood sugar of the depancreatized animals used.

Alloxan Diabetes.—Alloxan diabetic rabbits with blood sugar above 250 mg. % and exhibiting glucosuria were prepared for this study. The two alkaloidal salts were injected intravenously in isotonic saline. Three hours later, blood samples were collected and assayed for reducing sugar. Only eight animals were used in this study, *viz.*, four controls given saline and four experimental.[2] The results are shown in Table III.

It is clear from Table III that both tecomine citrate and tecostanine hydrochloride in the daily dose of 20 mg./Kg. were effective in reducing the hyperglycemia produced by alloxan to near normal levels. It should be noted that the four controls died on the 23rd, 27th, 29th, and 33rd day after alloxan administration while the experimental animals were living until the 45th day when the experiment was terminated.

DISCUSSION

From the results obtained in this study, it is clear that the salts of tecomine and tecostanine, the two alkaloids isolated from the leaves of *T. stans*, have valuable properties as antidiabetic agents. They are effective both orally and intravenously with a high margin of safety (LD_{50} 300 mg./Kg. in mice) (7), in the doses used in the present study. The two alkaloids present an entirely new nucleus for hypoglycemic activity which provides new possibilities toward the production of hypoglycemic agents. Structure-activity relationships of the new nucleus are presently under study in this laboratory to determine the active site on the two molecules.

From the mechanistic point of view, the two alkaloids seem to need a minimum of active β-cells of the pancreas for action, and in this respect resemble other orally active antidiabetic drugs, *i.e.*, sulfonylureas (10). The two alkaloids were inactive in depancreatized animals. The beneficial effects observed with the two alkaloids in alloxan diabetes are in favor of introducing them for clinical trial. The two alkaloids are without noticeable toxic effects on the rabbits used in the doses applied.

[2] The limited quantities of the alkaloidal salts available prevented the use of a larger number of animals.

Utility of Two Convulsant Techniques as Indicators of CNS Excitability

By HAROLD H. WOLF and GERARD A. STOCK, JR.*

A study was undertaken to evaluate the relative usefulness of pentylenetetrazol (PTZ) *versus* hexafluorodiethyl ether (HFE) as chemoconvulsive agents which could be employed to quantitate CNS excitability in mice. The PTZ was given by constant i.v. infusion, whereas the HFE was administered by inhalation. Levels of excitability were altered with several doses of (+)-amphetamine and pentobarbital. The results indicate that the PTZ infusion procedure is considerably more sensitive and less variable than the HFE inhalation technique for the determination of drug-induced fluctuations in central activity.

THE OBSERVATION made by Krantz and his coworkers (1) that hexafluorodiethyl ether (HFE) caused convulsions when inhaled has led to the usage of this agent as a convulsant in psychiatric treatment. In recent years, a number of authors have commented on the utility of this procedure as a tool for the laboratory evaluation of central nervous system activity. For example, Davis and Webb (2) have employed the drug to quantitate a circadian rhythm of chemoconvulsive response and also to demonstrate that, in mice, susceptibilities to auditory and chemical convulsive stimuli are not necessarily correlated in a positive manner (3). Other workers have found the technique valuable for predicting the activity of anticonvulsants (4) and for demonstrating increased sensitivity of the central nervous system following cortical ablations (5).

Several of these studies (4, 5) have shown that the type of seizures produced by the inhalation of HFE are similar to those seen following the intravenous administration of pentylenetetrazol (PTZ). Moreover, the HFE technique has been shown to be considerably easier to employ. However, whereas much evidence is available concerning the sensitivity and reliability of the i.v. PTZ technique as a means of evaluating drug-induced fluctuations in central activity (6–9), comparatively little similar information is available for the inhalation of HFE. Therefore, a series of experiments were designed to compare the sensitivity and variability of the two techniques when used to quantitate changes in CNS activity induced by drugs.

EXPERIMENTAL

The experimental animals employed were 20 to 25 Gm., adult, male, albino mice of a random bred Swiss strain obtained from Maxfield Animal Supply. All experiments were conducted during the same time of day and room temperature was maintained between 23–26°.

PTZ was administered by timed intravenous infusion, employing a modification of a technique originally described by Orloff (10). In this procedure, the animal is briefly restrained while a 0.5% solution of the convulsant in saline is infused into a tail vein at a constant rate of 0.247 ml./min. The amount of time which elapses from onset of infusion until the animal displays 3 sec. of continuous clonic activity is recorded. From this information and the body weight of the mouse, the number of mg./Kg. of PTZ required to induce seizure can be calculated.

HFE[1] was administered as a 10% solution in 95% ethyl alcohol by means of a timed inhalation technique. The apparatus employed was a modified version of that described by Adler (5). With this procedure, the convulsant solution is infused at a constant rate of 0.136 ml./min. onto a gauze wick fixed near the top of a 300-ml. bell jar. The jar, whose open bottom edge had been coated with stopcock grease, is first placed over a mouse on a glass plate containing a filter paper mat, thus providing a relatively airtight container. A wire mesh screen dividing the chamber approximately in half effectively prevents the mouse from rising on its hind legs in an attempt to avoid the vapors of HFE which sink to the bottom of the jar. As with the PTZ technique, the amount of time which elapses from onset of infusion to 3 sec. of continuous clonic activity is recorded and the mg./Kg. of HFE required to induce seizure are calculated. Following each convulsive episode, the vapors are removed by means of a vacuum water pump which is connected to a side arm of the bell jar.

Employing these two techniques, several experiments were conducted to quantitate the fluctuations in central activity induced by pentobarbital and (+)-amphetamine. Aqueous solutions of soluble salts of these drugs, *i.e.*, sodium pentobarbital and (+)-amphetamine sulfate were administered intraperitoneally in a constant volume of 1 ml./100 Gm. body weight. Preliminary investigations, employing the chemoshock threshold procedures, revealed that the times of peak effect for pentobarbital and (+)-amphetamine were 10 and 15 min., respectively.

In order to compare the sensitivity and variability of the two convulsant techniques, groups of 14 mice each were given graded doses of pentobarbital, (+)-amphetamine, or requisite volumes of saline (controls) and evaluated for seizure susceptibility at the appropriate times of peak effect. From the accumulated data, a series of threshold ratios, *i.e.*, the mean mg./Kg. of convulsant required to produce clonic seizure in drug-treated animals divided by the mean mg./Kg. of convulsant required to reach the same end point in controls was computed for both PTZ and HFE. The 95% confidence intervals for the individual threshold ratios were calculated by a method described by Goldstein (11).

RESULTS AND DISCUSSION

The results obtained with five doses of pentobarbital, *i.e.*, 2, 4, 8, 16, and 32 mg./Kg., are shown in Fig. 1. The vertical bracketed lines represent 95% confidence intervals for the calculated ratios and any line which does not cross 1.0 indicates that the dose of pentobarbital under consideration had a significant ($p < .05$) effect on convulsive threshold.

It is obvious from the results presented that a decrease in CNS excitability, as expressed by an increase in threshold ratio, can be demonstrated for pentobarbital using either convulsant technique. However, it is also quite clear that the HFE procedure is considerably less sensitive than that employing PTZ. Thus, within the dose range examined, twice as much pentobarbital (16 *versus* 8 mg./Kg.) was required to demonstrate a significant elevation in threshold by the inhalation *versus* i.v. infusion technique. Moreover, in all instances the amount of CNS depression induced by equivalent doses of pentobarbital was more readily apparent by the PTZ procedure. The magnitude of this difference is statistically significant at doses of 8, 16, and 32 mg./Kg.

In this study the amount of data variability, as portrayed by the length of the vertical bracketed lines, was essentially the same for both convulsant procedures at four of the five doses of barbiturate tested. At the highest dose of pentobarbital the PTZ technique manifested more variability than inhaled HFE, but the former procedure was, as indicated, 1.6 times more sensitive.

The results of a similarly designed experiment employing (+)-amphetamine to alter level of CNS excitability are presented in Fig. 2. Here it can be seen that the PTZ technique is also considerably more sensitive to the effects of a central stimulant. In fact, with HFE, the authors were not able to demonstrate a significant decrease in threshold ratio with any dose of (+)-amphetamine tested. On the other hand, with PTZ, significant CNS excitability was evident at both 8 and 16 mg./Kg. of (+)-amphetamine.

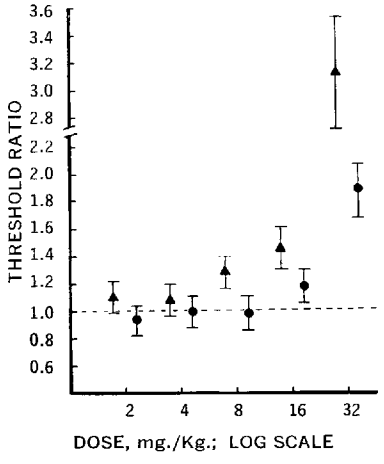

Fig. 1.—Alterations in CNS activity induced by pentobarbital. Key: ▲, PTZ technique; ●, HFE technique.

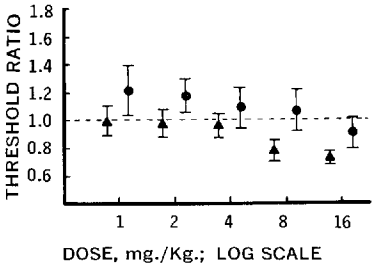

Fig. 2.—Alterations in CNS activity induced by (+)-amphetamine. Key: ▲, PTZ technique; ●, HFE technique.

It will be noted that small doses of (+)-amphetamine (1 and 2 mg./Kg.) induced a slight, but statistically significant, elevation in convulsive threshold as determined by the HFE technique. This seemingly paradoxical effect of (+)-amphetamine has been observed by other workers (12, 13) employing electroshock procedures and has been attributed to amphetamine's desynchronizing action in the frontal cortex (14) and its inhibitory action at the level of the reticular formation (15). The reasons for the inability of the PTZ technique to detect this phenomenon remain, as yet, unclear.

An examination of the 95% confidence intervals in Fig. 2 reveal that, in all instances, the inhalation of HFE provided more variable data than did the i.v. administration of PTZ. The maximum difference in variability between the two techniques amounted to 19% and was observed following the administration of 16 mg./Kg. of (+)-amphetamine.

The results obtained in this study are essentially in agreement with those reported by Truitt *et al.* (4), who observed that PTZ provided the most sensitive index of a change in convulsive threshold produced by phenobarbital. On the other hand, our results differ somewhat from those observed by Adler (5), who reported that, although an increased sensitivity to both PTZ and HFE results from ablations of either the frontal or posterior cortex, the data obtained with HFE manifest less variability. This apparent discrepancy in findings may result from species differences (mice *versus* rats) or from the methods employed to produce changes in level of central activity (drugs *versus* cortical ablations).

In summary, it would appear that although the HFE technique has the obvious advantage of simplicity of operation and lack of animal restraint, the utility of the procedure is hampered by a relative lack of sensitivity. Moreover, when the technique is employed to evaluate drug-induced changes in CNS excitability, the data collected manifest somewhat more variability than similar information obtained using timed intravenous infusion of PTZ.

Determination of Carbonyl Compounds by Sodium Nitrite Titration of Excess 2,4-Dinitrophenylhydrazine in the Presence of Hydrazone

By LEON KURLANSIK and EDWARD F. SALIM

Numerous methods have been developed for the quantitative determination of carbonyl compounds with 2,4-dinitrophenylhydrazine. Generally, it is necessary to separate the prepared hydrazone from excess reagent before final measurement. A simplified method for the determination of aldehydes and ketones is presented in which excess 2,4-dinitrophenylhydrazine in the presence of hydrazone is titrated with standard sodium nitrite solution.

Since Mathewson (1) prepared hydrazones of water-soluble carbonyl compounds with 2,4-dinitrophenylhydrazine, this reagent has been used extensively for qualitative characterization and quantitative estimation of carbonyl compounds. Applications of gravimetric (2–4), spectrophotometric (5–7), and titrimetric procedures for quantitative determinations of aldehydes and ketones have been reported. Among the titrimetric methods developed are solution of the hydrazone in standard base and determination of excess sodium hydroxide (8), nonaqueous titration of hydrazone in pyridine with tetrabutylammonium hydroxide (9), determination of reduced nitro-groups of the hydrazone (10) or excess hydrazine (11), and direct amperometric titration of the carbonyl with 2,4-dinitrophenylhydrazine solution (12).

A common feature of most published methods is the separation of prepared hydrazone from excess reagent before the final measurement is conducted. The preponderance of procedures deals with the hydrazone and relatively few involve the determination of excess reagent. Isolation of hydrazones which are slightly soluble in the reaction media generally results in low recoveries.

Vulterin and Zyka (13) have described the potentiometric titration of 2,4-dinitrophenylhydrazine with 0.1 *M* sodium nitrite and have postulated the reaction to proceed by formation of the 2,4-dinitrophenylnitrosohydrazine. Since the β nitrogen of the hydrazone is substituted, corresponding nitroso addition presumably does not occur. Baldinus and Rothberg have reported the titration of hydrazones with sodium nitrite but only after vigorous treatment with sulfuric acid and tetrahydrofuran (14). Based on this information a simplified method for the determination of carbonyl compounds has been developed by an initial reaction with 2,4-dinitrophenylhydrazine and subsequent titration of excess reagent in the presence of prepared hydrazone using standard sodium nitrite.

Received July 5, 1966, from the Drug Standards Laboratory, American Pharmaceutical Association Foundation, Washington, D. C. 20037.
Accepted for publication August 22, 1966.

EXPERIMENTAL

All titrations were conducted potentiometrically using a Beckman Expandomatic pH meter equipped with a calomel and platinum electrode system.

Reagents.—*2,4-Dinitrophenylhydrazine Reagent Solution.*—Add 9 Gm. of finely powdered 2,4-dinitrophenylhydrazine (2,4-DNPH) to a stirred mixture of 100 ml. of 85% phosphoric acid, 100 ml. of ethanol, and 20 ml. of sulfuric acid. Stir for 30 min., add 100 ml. of ethanol, and continue mixing for an additional hour. Cool and filter prior to use. (The reagent is approximately 0.1 *M* and is stable for at least 3 weeks.)

Sodium Nitrite, 0.1 M.—Dissolve 7.5 Gm. of sodium nitrite in sufficient water to make 1000 ml. The solution was standardized against U.S.P. sulfanilamide reference standard, previously dried at 105° for 3 hr., by potentiometric titration using calomel *versus* platinum electrodes.

General Procedure.—Transfer about 1 meq. of test compound to a glass-stoppered, 125-ml. conical flask and dissolve or suspend in 20 ml. of ethanol. Add 25.0 ml. of 2,4-DNPH reagent, insert the stopper, and place the flask in a constant-temperature bath maintained at 50–55° for 1 hr. (*Note:* aldehydes are allowed to react at room temperature for the prescribed 1 hr.) Cool and transfer the contents of the flask to a 400-ml. beaker with the aid of 100 ml. of water. Add 10 ml. of hydrochloric acid, 5 Gm. of potassium bromide, and titrate slowly

Determination of Carbonyl Compounds by Sodium Nitrite Titration of Excess 2,4-Dinitrophenylhydrazine in the Presence of Hydrazone

By LEON KURLANSIK and EDWARD F. SALIM

Numerous methods have been developed for the quantitative determination of carbonyl compounds with 2,4-dinitrophenylhydrazine. Generally, it is necessary to separate the prepared hydrazone from excess reagent before final measurement. A simplified method for the determination of aldehydes and ketones is presented in which excess 2,4-dinitrophenylhydrazine in the presence of hydrazone is titrated with standard sodium nitrite solution.

Since Mathewson (1) prepared hydrazones of water-soluble carbonyl compounds with 2,4-dinitrophenylhydrazine, this reagent has been used extensively for qualitative characterization and quantitative estimation of carbonyl compounds. Applications of gravimetric (2–4), spectrophotometric (5–7), and titrimetric procedures for quantitative determinations of aldehydes and ketones have been reported. Among the titrimetric methods developed are solution of the hydrazone in standard base and determination of excess sodium hydroxide (8), nonaqueous titration of hydrazone in pyridine with tetrabutylammonium hydroxide (9), determination of reduced nitro-groups of the hydrazone (10) or excess hydrazine (11), and direct amperometric titration of the carbonyl with 2,4-dinitrophenylhydrazine solution (12).

A common feature of most published methods is the separation of prepared hydrazone from excess reagent before the final measurement is conducted. The preponderance of procedures deals with the hydrazone and relatively few involve the determination of excess reagent. Isolation of hydrazones which are slightly soluble in the reaction media generally results in low recoveries.

Vulterin and Zyka (13) have described the potentiometric titration of 2,4-dinitrophenylhydrazine with 0.1 *M* sodium nitrite and have postulated the reaction to proceed by formation of the 2,4-dinitrophenylnitrosohydrazine. Since the β nitrogen of the hydrazone is substituted, corresponding nitroso addition presumably does not occur. Baldinus and Rothberg have reported the titration of hydrazones with sodium nitrite but only after vigorous treatment with sulfuric acid and tetrahydrofuran (14). Based on this information a simplified method for the determination of carbonyl compounds has been developed by an initial reaction with 2,4-dinitrophenylhydrazine and subsequent titration of excess reagent in the presence of prepared hydrazone using standard sodium nitrite.

Received July 5, 1966, from the Drug Standards Laboratory, American Pharmaceutical Association Foundation, Washington, D. C. 20037.
Accepted for publication August 22, 1966.

EXPERIMENTAL

All titrations were conducted potentiometrically using a Beckman Expandomatic pH meter equipped with a calomel and platinum electrode system.

Reagents.—*2,4-Dinitrophenylhydrazine Reagent Solution.*—Add 9 Gm. of finely powdered 2,4-dinitrophenylhydrazine (2,4-DNPH) to a stirred mixture of 100 ml. of 85% phosphoric acid, 100 ml. of ethanol, and 20 ml. of sulfuric acid. Stir for 30 min., add 100 ml. of ethanol, and continue mixing for an additional hour. Cool and filter prior to use. (The reagent is approximately 0.1 *M* and is stable for at least 3 weeks.)

Sodium Nitrite, 0.1 M.—Dissolve 7.5 Gm. of sodium nitrite in sufficient water to make 1000 ml. The solution was standardized against U.S.P. sulfanilamide reference standard, previously dried at 105° for 3 hr., by potentiometric titration using calomel *versus* platinum electrodes.

General Procedure.—Transfer about 1 meq. of test compound to a glass-stoppered, 125-ml. conical flask and dissolve or suspend in 20 ml. of ethanol. Add 25.0 ml. of 2,4-DNPH reagent, insert the stopper, and place the flask in a constant-temperature bath maintained at 50–55° for 1 hr. (*Note:* aldehydes are allowed to react at room temperature for the prescribed 1 hr.) Cool and transfer the contents of the flask to a 400-ml. beaker with the aid of 100 ml. of water. Add 10 ml. of hydrochloric acid, 5 Gm. of potassium bromide, and titrate slowly

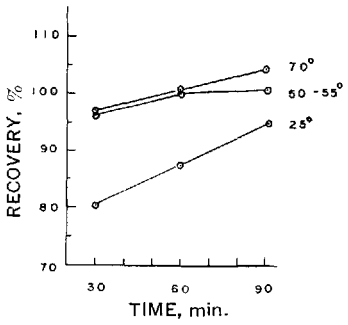

Fig. 1.—Reactivity of methylprednisolone with 2,4-dinitrophenylhydrazine reagent at various temperatures.

with moderate stirring, adding 0.1 *M* sodium nitrite in 0.1-ml. increments near the end point. Perform a blank determination. The difference between blank and sample titrations represents the volume of 0.1 *M* sodium nitrite equivalent to the carbonyl content in the sample.

The end point was determined by means of differential curves ($\Delta E/\Delta$ ml. *versus* ml.). It was noted that the volume of titrant added at the point of maximum rise in potential was the equivalent volume, thereby eliminating the necessity to construct a differential curve for each titration.

RESULTS AND DISCUSSION

Initial studies were conducted using standard 2,4-DNPH reagents. Johnson's reagent (15) consisting of ethanolic phosphoric acid was considered too viscous to allow the uniform additions necessary in the proposed method and was noted to yield quantitative hydrazone formation only after prolonged reaction. The reagent developed by Brady (16) utilizing ethanolic sulfuric acid was observed to accelerate formation of hydrazone but produced undesirable side reactions as demonstrated by high recoveries with methylprednisolone. Experiments using various combinations of phosphoric and sulfuric acids to resolve the difficulties associated with each reagent led to the formulated solution used throughout subsequent investigations.

A supplemental study was performed to determine the optimum time and temperature conditions for reactivity. The results shown in Fig. 1 indicate that the reaction for methylprednisolone was quantitative at 50–55° after 1 hr. The conditions established for methylprednisolone were believed to express the parameters by which sterically unhindered ketones could be readily quantitated. Analogous tests for aldehydes showed that quantitative results could be obtained at room temperature within a 1-hr. period. A summary of these data is included in Table I. For the limited number of aldehydes tested, no pronounced effects were observed for increased number of carbons in aliphatic compounds nor the addition of electron donating or withdrawing groups *ortho* or *para* to the aromatic aldehydes.

The determination of ketones was found to be influenced by certain factors so that the method was not so generally applicable as with the aldehydes. Ketones successfully determined are included in Table II. The general procedure was found to be

TABLE II.—DETERMINATION OF KETONES AS 2,4-DINITROPHENYLHYDRAZONES

	Recovery, %
Benzophenone[a]	99.8

quantitative for mono-ketones above C_5. Lower aliphatic ketones produced the following results: acetone (84.8%), methyl ethyl ketone (89.8%), and methyl isopropyl ketone (93.7%). The low values may be explained on the basis of nitrous acid oxidation of methyl or methylene groups adjacent to a carbonyl group. In aqueous HCl solution the reaction proceeds to the formation of a 1,2-dicarbonyl compound and hydroxylamine hydrochloride (17). The hydrazones of lower molecular weight ketones contain the grouping CH_3—C=N— which is the nitrogen analog of the carbonyl group and may undergo a similar reaction during the final titration with sodium nitrite.

Several steroids were included in this general survey because of the varied positions occupied by carbonyls and in light of the wide use of such compounds as medicinal agents. Steroids containing a keto group in the 3 or 17 position were quantitative in the alloted reaction time. Dehydrocholic acid

with carbonyls in the 3, 7, and 12 positions required 3 hr. at 50–55° for quantitative reactivity. Prednisone, a 3,11,20-trione compound, gave 66.7% recovery after 3 hr. and no further reaction was evident after 17 hr. elapsed time. Since the 11 keto position is known to be extremely unreactive, the result at 3 hr. can be considered quantitative based on hydrazone formation at the 3 and 20 positions only. Progesterone, prednisolone, and methylprednisolone which represent 3,20 di-ketones yielded quantitative bis-hydrazones. Prednisolone, esterified as the acetate, gave an incomplete reaction—81.5%—after 3 hr. The presence of the bulkier substituent adjacent to carbon 20 appears to be sufficient to drastically hinder the formation of hydrazone at the C_{20} carbonyl.

SUMMARY

The titration of excess 2,4-dinitrophenylhydrazine using sodium nitrite without prior separation of the precipitated hydrazone allows a shorter analysis time for the determination of aldehydes and a substantial number of ketones. The procedure was found to be reproducible to ±0.5% and the results for ethyl vanillin, formaldehyde solution U.S.P., prednisolone, menadione, and prednisone were consistently within 0.5% of comparative values obtained by official or other recognized methods of analysis.

The method is neither applicable to certain aliphatic ketones nor to sterically hindered steroids. Carbonyl compounds which contain a functional group such as an amine or phenol capable of reacting with sodium nitrite cannot be determined by the proposed procedure.

Amides Derived from Hepta- and Octamethyleneimine

By HEINO A. LUTS, W. A. ZUCARELLO*, W. LEWIS NOBLES†, and JEROME F. GRATTAN

Some new physiologically active amides of hepta- and octamethyleneimine moiety have been prepared. Their preparation and biological activities are given.

THE KNOWLEDGE that a number of biologically important compounds occurring in nature contain trimethoxyphenyl or trimethoxybenzoyl groups as a part of their molecule has prompted considerable investigation into the various ways which this moiety can be incorporated into molecules and elicit various pharmacological actions.

Vargha and his associates (1) have reported on the tranquilizing and analgesic effects of the simple benzamide containing the above moiety as well as a number of heterocyclic amides. In varying the amine moiety of the amide, they noted that morpholine and 2-methylmorpholine exhibited the most desirable therapeutic properties among the compounds studied. Correspondingly, Schlager (2) in a review article has reported on a large number of derivatives containing 3,4,5-trimethoxybenzoyl moiety.

Previously, the authors (3) have reported on the use of heptamethyleneimine in the Mannich reaction. It may be worthy of note that in this earlier work, the Mannich base obtained from 2-acetylthiophene and heptamethyleneimine exhibited significant analgesic activity at a dosage level of 150 mg./Kg.

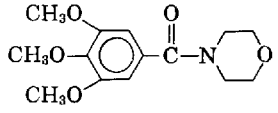
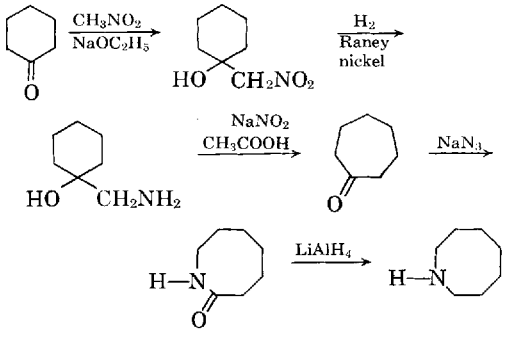
exhibited marked analgesic activity at a dosage level of 32 mg./Kg.

In addition to the work of Vargha and associates (1), the pharmacological activities of a number of different amides have been observed; these have exhibited sedative, analgetic, anticonvulsant, and cardiotonic activity (4). It is perhaps particularly noteworthy that *N*-3,4,5-trimethoxybenzoylmorpholine has elicited marked neurodepressive as well as analgetic activity (5, 6).



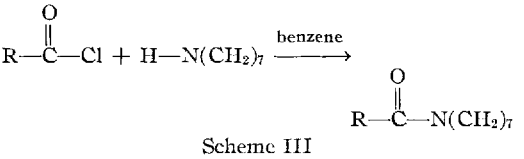
III

It is apparent in a review of the literature that the heterocyclic amine moiety has not been studied in molecules possessing seven to eight methylene groups



Scheme I

as an integral part of the structure. Hence, a concerted literature review was carried out as a prelude to the extension of the authors' studies to rings larger than pyrrolidine and piperidine, *i.e.*, heptamethyleneimine and octamethyleneimine. It was anticipated that the enlargement of the carbon



Scheme III

content of the amine moiety would increase the lipid solubility, and perhaps differ in enzymatic attack.

With the increasing availability of furan derivatives, considerable interest has been evidenced in the preparation of furan relatives of compounds of the benzene series which possess medicinal value; the same is true of a great number of pyridine derivatives. Thus, also drawing from previous knowledge of the activity of *N*-3,4,5-trimethoxybenzoylmorpholine, the hepta- and octamethyleneimine amides of this same acid moiety have been prepared and submitted for pharmacological study. In addition, certain heterocyclic acids have been condensed with these same amines. Furthermore, α-phenyl, α-cyclohexenyl acetic acid was utilized as an acid moiety because of the widespread use of acids of this general type in antispasmodics.

The method of preparing cyclohepta- and cyclooctanones was that of Boeseken and Derx (7); for hepta- and octamethyleneimine, the method was that of Blicke and Doorenbos (8) (Scheme I). The α-phenyl, α-cyclohexene acetic acid was by the Neesby *et al.* (9) (Scheme II) method. All the acid chlorides were prepared by the standard method of using thionyl chloride. The amides were prepared by reacting acid chlorides with heptamethyleneimine in benzene (Scheme III).

EXPERIMENTAL

General Procedure.—To a solution of 0.05 mole of appropriate acid chloride in 150 ml. of benzene solution was added dropwise 0.1 mole of appropriate amine. The reactants were then refluxed for 30 min. and formed crystals, separated by filtration. The benzene solution was then evaporated to dryness and the formed crystalline product washed twice with petrolcum ether.

PHARMACOLOGICAL DATA

The preliminary pharmacological findings demonstrate that compound I (Table I) is a mild stimulant, and not a depressant, with a poor over-all activity. No analgesic activity was found. Compound II exhibited depressant effect; following a brief period of mild excitation, it also exhibited anticonvulsant activity and at a low dose level. Furthermore, compound II antagonized strychnine and exerted a weak analgesic effect and had local anesthetic effect at the 1% dose level when instilled repeatedly in rabbit's eye. Compound III also exhibited depressant activity and was a spasmolytic agent. It antagonized the tremors consequent on tremorine injection, although it did not antagonize the parasympathomimetic effects of the drug. Furthermore, it also exerted a mydriatic effect. Compound IV acted as a stimulant; no reserpine antagonism, but compound V was a mild depressant. Both compounds were cholinergic and peripheral vasodilators. Compound VI has shown some antispasmodic activity; the compound is still under investigation. A more detailed report will be presented in another publication.

Determination of Codeine in Terpin Hydrate and Codeine Elixir

By MARTIN I. BLAKE and BRUCE CARLSTEDT

Ion exchange chromatography and nonaqueous titrimetry are applied to the analysis of codeine in terpin hydrate and codeine elixir. The method is simple and accurate.

ALTHOUGH terpin hydrate and codeine elixir has been official for many years, it has been only recently that an assay procedure (1) has been included in the monograph. The assay involves the extraction of the alkaloid from the elixir with chloroform, followed by titration with perchloric acid in dioxane using methanolic methyl red as the indicator. The Association of Official Agricultural Chemists (2) recognizes a spectrophotometric procedure for both the terpin hydrate and codeine in the elixir. It is based on a report by Milos (3). The codeine is determined by measuring the absorbance of an aqueous solution of the hydrochloride salt at 285 mμ. Interfering substances are removed by ether extraction.

In a recent paper (4) Milos extracted the codeine from the elixir as the *p*-toluenesulfonic acid complex on a column of chromatographic siliceous earth.[1] The complex was eluted with chloroform–acetic acid solution and passed through a second column of chromatographic siliceous earth containing $NaHCO_3$ as the stationary phase. The codeine in the eluate was determined spectrophotometrically at 278 mμ.

Ion-exchange resins have been employed in the determination of alkaloids and alkaloidal salts. These have been noted in a previous paper (5). The analysis of alkaloids and their salts by nonaqueous titration and by ion-exchange chromatography has been extensively reviewed by Higuchi and Bodin (6). Kucharsky and Safarik (7) have thoroughly reviewed the literature on the determination of alkaloids by titration in nonaqueous media.

In the present paper the techniques of ion-exchange chromatography and nonaqueous titrimetry are applied to the analysis of codeine in the elixir of terpin hydrate and codeine.

EXPERIMENTAL

Preparation of the Ion-Exchange Column.—The strongly acidic cation-exchange resin Dowex 50-×8 (200–400 mesh) was used in this study. The chromatographic column was prepared as described in an earlier paper (5). Five grams of resin was added to the tube as a slurry in water. The column was washed with 250 ml. of distilled water, 50 ml. of 2 *N* HCl, and distilled water until the eluate gave a negative test with $AgNO_3$ T.S. The column was ready for use.

Assay Procedure.—Exactly 20 ml. of terpin hydrate and codeine elixir[2] was transferred by pipet to a 150-ml. beaker. About 40 ml. of ethanol was added to reduce the viscosity of the elixir and permit a more rapid flow rate through the column. The solution was passed through the resin column. The beaker was rinsed several times with small amounts of ethanol and the washings were added to the column. The column was washed with an additional 50 to 75 ml. of ethanol.

The codeine was eluted from the column with 10% ammonia in ethanol prepared by diluting stronger ammonia water with ethanol. A total of 100 ml. of eluate was collected. The solution was evaporated to dryness by gentle aeration by directing a fine stream of air above the surface of the liquid. The residue was dissolved in ethanol and the solution was evaporated to dryness. This procedure was repeated.

The codeine content of the residue was determined by dissolving in 30 ml. of glacial acetic acid and titrating visually with 0.01 *N* perchloric acid in acetic acid. The indicator for the titration was 0.2% methyl violet in glacial acetic acid. The exact indicator color change was noted by using indicator solution in conjunction with a potentiometric titration. The color change corresponding to the graphic end point was from violet to dark blue. A blank determination was performed with each series of titrations, and any necessary corrections were made.

Comparison was made with the N.F. XII assay procedure (1).

RESULTS AND DISCUSSION

On the basis of 10 consecutive determinations the proposed procedure gave an average per cent recovery (based on labeled amount) of 99.66 with a standard deviation of ± 1.17. By the N.F. method the per cent recovery was 98.04 with a standard deviation of ± 1.64.

The proposed assay for codeine in terpin hydrate and codeine elixir is simple, rapid, and accurate. The codeine is extracted from the elixir by passage through a sulfonic acid ion-exchange resin. This obviates the tedious and time-consuming solvent extraction procedure. The codeine is readily eluted from the column by displacement with the stronger base ammonia. The codeine is recovered from the eluate by aeration which removes the ammonia, ethanol, and any water which may be present. The codeine is then titrated in glacial acetic acid with acetous perchloric acid using methyl violet as the indicator. This technique produces a much sharper and more readily detectable end point than the official method. Considerable difficulty was experienced in end point detection when the official assay procedure was performed. In addition, lower results were obtained with a higher standard deviation.

Stirring Apparatus for the Investigation of Unstable Strongly Adsorbing Chemicals

By R. J. SAUCHUK, J. M. ANDERSON, and J. G. NAIRN

An apparatus is described which is useful for the evaluation of adsorption phenomena. The mixing apparatus provides the following features: an inert atmosphere to maintain maximum stability, a smooth, all-glass surface to eliminate spurious adsorption, a convenient method of analysis to permit maximum accuracy for rapid reactions, constant temperature, and controlled, measurable mixing speeds.

IN ORDER to provide an inert atmosphere for the adsorption studies of compounds subject to oxidation by air, a tightly-stoppered flask with a magnetic stirring device was employed. This method also provided a rapid, convenient method of analysis for kinetic studies. It was found that strong adsorption took place on all stirring bars covered with either Teflon or Tygon. Over short periods of time, a Pyrex sealed stirring bar was found to be satisfactory. However, prolonged use resulted in the formation of a ground-glass surface, both on the stirring bar and on the bottom of the reaction flask. This rough surface, which acted as an adsorption site, invalidated experimental results.

A floating, magnetic stirrer was designed to overcome this problem of spurious adsorption (Fig. 1). A Pyrex-covered magnetic bar $^3/_8$ in. × $^7/_8$ in. was sealed to the bottom of a cylindrical float. The size of the float is dependent upon the following factors: the density of the solution, the height of the float above the magnetic stirrer, the speed of rotation, and the dimensions of the reaction flask. A mirror was enclosed within the float so that the speed of rotation could be determined by a photoelectric counting device. A hook was formed at the top of the float for ease of manipulation. The extent of agitation in the vessel can be controlled by varying the dimensions of the flat portion of the float.

To facilitate spectrophotometric analysis, a cell was sealed by means of a short extension onto the shoulder of a 250-ml. conical flask fitted with a standard taper $^{34}/_{45}$ stopper. The flask was placed in a constant-temperature bath, under which a magnetic stirrer was positioned. This closed system eliminated loss of volatile components and prevented exposure of the reaction mixture to atmospheric oxygen.

The speed of rotation was determined by allowing a beam of light from a 12-v. lamp to fall upon the mirror in the rotating float. The reflected light was allowed to sweep across a photoelectric cell, which by means of the electrical circuit (Fig. 2) activated an impulse counter. The magnetic stirring motor was maintained at moderate temperatures by allowing cold water to pass through Tygon tubing encircling the housing. A more precise control of the mixing speed was obtained by supplying power to the magnetic stirrer through a variable transformer.

Satisfactory performance for counting and float stability up to 400 r.p.m. was obtained.

Reaction of Aspirin with Amines. Potential Mechanism for Aspirin Allergy

By MICHAEL A. SCHWARTZ and GORDON L. AMIDON*

A possible explanation for the lack of hypersensitivity to salicylic acid by patients known to be allergic to aspirin is offered. It is shown that while aspirin reacts with amino acids to produce salicylamide derivatives, salicylic acid does not. This may be the mechanism by which aspirin combines with protein to form antigen.

IT IS NOT yet clear whether hypersensitivity to aspirin is immunologic in origin or is a direct effect of aspirin on tissues which is not mediated by an antigen–antibody reaction. On the hypothesis that an allergic reaction is involved, several studies have been made of the immunogenicity of synthetic aspirin–protein conjugates in animals (1–4). These conjugates were prepared by treatment of protein with acetylsalicyl chloride or azide. In each case it was shown that antibodies to the aspiryl or salicyl hapten were produced, but attempts to demonstrate the presence of these antibodies in humans known to be aspirin hypersensitive were not successful.

One remarkable characteristic of aspirin hypersensitivity is the fact that individuals who react to aspirin rarely do so with salicylate (5). If it is assumed that aspirin hypersensitivity is mediated by an antigen–antibody reaction, then the antigen must be formed *in vivo* by coupling of aspirin to protein. One explanation of the lack of reactivity to salicylate may be that salicylate is unable to react with protein to form the antigenic conjugate as does aspirin.

The anhydride nature of aspirin has been noted by Davidson and Auerbach (6) who found that aspirin reacted in pyridine at 100° with *p*-toluidine to produce a small yield (0.13%) of *N*-salicyloyl-*p*-toluidide. Salicylic acid itself could not react in the same way. Surprisingly little attention has been paid to the reactions of aspirin with nucleophiles in aqueous media. Troup and Mitchner (7) have found acetylated phenylephrine resulting from reaction of aspirin with the latter in tablet formulations and Jacobs *et al.* (8) recently reported a similar reaction between codeine and aspirin. There has been no demonstration of any salicyloyl derivative being formed in these reactions.

The present work reports the results of experiments in model systems where a deliberate search was made for salicyloyl derivatives in the reaction of aspirin with amino acids.

EXPERIMENTAL

Preparation of N-Salicyloyl Derivatives of Amino Acids.—To a solution of 0.03 mole of the amino acid in 25 ml. of water was added 3.2 Gm. (0.08 mole) sodium hydroxide and 4.4 Gm. (0.02 mole) phenyl salicylate and the mixture was refluxed 2–4 hr. (until the phenyl salicylate had dissolved). The mixture was cooled, acidified, and the precipitate collected and recrystallized from an appropriate solvent. Details are listed in Table I.

Preparation of N-Acetyl Derivatives of Amino Acids.—In 4 ml. of glacial acetic acid was suspended 1.5–2.0 Gm. of the amino acid and 2.0 ml. acetic anhydride was added. The mixture was heated gently until all the amino acid had dissolved and on cooling the *N*-acetyl derivatives crystallized. Details of each compound are listed in Table I.

For both the salicyloyl and acetyl derivatives, infrared spectra showed those bands expected.

Products of Reaction of Aspirin with Amino Acids.—*ε-Aminocaproic Acid.*—Six and one-half grams of ε-aminocaproic acid was mixed with one equivalent of sodium hydroxide and 1.8 Gm. aspirin was added. The reaction was allowed to proceed 15 min. at 40° and then acidified to pH 2, the precipitate filtered off, and the filtrate evaporated to dryness. The residue was extracted with benzene and the benzene removed under reduced pressure. The resulting residue was dissolved in chloroform and subjected to thin-layer chromatography.

Glycine.—The reaction was carried out exactly as above except that methanol was substituted for benzene and acetone for chloroform.

Thin-Layer Chromatography.—Separation of the products of reaction of aspirin with glycine and ε-aminocaproic acid was accomplished by thin-layer chromatography on Silica Gel G using either benzene–acetic acid–water, 2:2:1 (I) or 4:8:3 (II), as the developing solvent. The spots were detected by exposing the plates to iodine vapor, and the R_f values are given in Table II. As a control, the experiment with glycine was repeated substituting salicylic acid for aspirin.

RESULTS AND DISCUSSION

The thin-layer chromatograms of the extracts from workup of the reaction mixtures are shown in Fig. 1. It is quite clear from these plates that the *N*-salicyloyl derivatives of both glycine and ε-aminocaproic acid are formed in the reactions of aspirin with the respective amino acids. This is the first demonstration of a salicylamide derivative resulting from reaction of aspirin with an amine. The amount formed is quite small. From the size of the spots on the thin-layer plates, it is estimated that only about 0.01–0.1% of the aspirin reacted by this route. Nevertheless, these results show the feasibility of reaction of aspirin with amino groups on proteins to produce conjugates which may be antigenic. When salicylic acid was substituted for aspirin, no salicyluric acid could be detected in the reaction mixture. The over-all reaction taking place may be depicted as in Scheme I. Direct nucleophilic attack by amine will result in aminolysis of the ester producing salicylic acid and an acet-

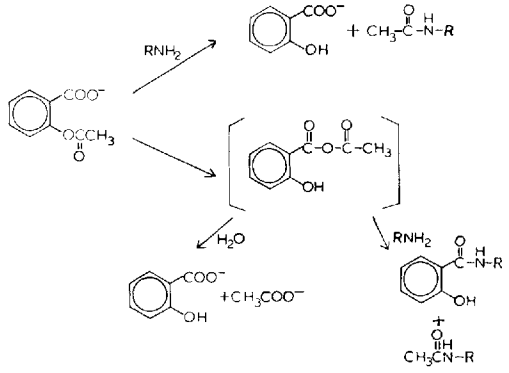
amide derivative. Competing with this reaction is the intramolecular hydrolysis of aspirin which proceeds through an anhydride of acetic and salicylic acids (9). It seems likely that in the presence of amine both acetyl and salicyloyl derivatives might be formed depending on the relative electrophilicity of the respective carbonyl carbons. In the presence of H_2O^{18} it was found that aspirin hydrolysis produced salicylic acid containing 6% of the O^{18} which had taken part (10). Of course the amine competes with water as the nucleophile, and as a result only a very small proportion of the



Reaction of Aspirin with Amines
Scheme I

original aspirin would become salicylamide derivative.

If salicyloyl–protein is indeed proved to be the antigenic determinant in hypersensitivity to aspirin in humans, then it can be intimated that such compounds as salicyl–salicylic acid and aspirin anhydride would be potentially allergenic drugs. The product of reaction of the former, as can be seen by analogy with Scheme I, would be a salicyloyl amide by both pathways. Aspirin anhydride is quite labile (11) and probably subject to aminolysis to produce acetyl–salicyloyl amide derivatives.

Use of 2-(4-Hydroxybenzeneazo) Benzoic Acid for Protein Determination

By RONALD G. LEONARDI and VINCENT DE PAUL LYNCH

The compound, 2-(4-hydroxybenzeneazo) benzoic acid, also known as HBABA, was evaluated for its ability to detect cell protein. While this test may be suitable for large protein concentrations, it is not sensitive enough for the stated purpose with concentration below 1.0 mg.

THE CANCER Chemotherapy National Service Center describes a technique used for the determination of cell growth or inhibition in its program using the cell culture system as a primary screen for the detection of antitumor agents (1, 2). Their protocol is based upon the Folin-Ciocalteu method for the measurement of cell protein as modified by Eagle and Oyama (3). This involves the colorimetric determination of cell protein as an indirect measurement of cell growth.

In 1954, Rutstein *et al.* suggested that blood or serum protein levels could be determined quantitatively by interaction of the protein with the anionic dye, 2-(4-hydroxybenzeneazo) benzoic acid (4). Their method was reported to be more accurate and more rapid than electrophoretic methods (5).

In this research, an attempt was made to adapt Rutstein's procedure to the determination of cell growth along the lines of the CCNSC protocol.

EXPERIMENTAL

Rutstein's original standard curve was duplicated by using the procedure he described (4). Since this work was done within the range of normal concentrations of human serum albumin (approximately 3.5 to 4.5 mg.%), the aliquots of serum needed were small but the original quantity of reagents was large. The total volume of the reaction mixture was 25 ml. The range of detection of the standard curve was from 0 to 14 mg. The curve was found to be linear up to a level of 8 mg.

In this study, using the CCNSC protocol (1, 2), cell protein concentration of HeLa cell cultures was found to be in the range of 0.005 to 0.1 mg. Initially, to determine whether HBABA would detect protein at these levels, a series of protein concentrations within these ranges were prepared. Armour's protein standard solution[1] was used as the protein source. Because of the low quantity of protein which the authors desired to detect, a modification of the volume of reagents used was required.

To determine if the dye would detect cellular protein levels, a series of protein concentrations ranging from 0.005 to 0.1 mg. was prepared. The procedure followed was the same as that described by Rutstein (4) for serum albumin determinations, but the volume of the reactants was adjusted as follows.

A sufficient quantity of acetate buffer was added to the specified quantity of bovine albumin to give a total volume of 2 ml. To this was added 1 ml. of normal saline followed by 4 ml. of the HBABA solution. Ten minutes were allowed for completion of the reaction and development of color. Per cent transmittance and absorbance was read in a colorimeter at 520 mμ. The final solution volume was maintained at 7.0 ml., and pH adjusted to 6.2.

TABLE I.—STANDARD CURVE FOR HBABA[a]

Protein Concn.	Transmittance, %[b]	Absorbance
0.0	93.8	0.0278
1.0	92.3	0.0348
2.0	91.6	0.0381
3.0	89.1	0.0501
4.0	87.4	0.0585
5.0	85.5	0.0680
6.0	84.4	0.0736
7.0	83.2	0.0799
8.0	82.4	0.0841
9.0	81.5	0.0888
10.0	81.1	0.0910

[a] 2-(4-Hydroxybenzeneazo) benzoic acid. [b] Each reading is the average of three tests.

In the determination of cell protein levels, the following procedure was applied.

Two milliliters of a suspension containing 100,000 cells/ml. was centrifuged at 2500 × g for 10 min. The supernatant liquid was removed from the packed cells by decantation. To the cells was added 2 ml. of a 0.05% trypsin solution and 5 drops of 0.01 *N* hydrochloric acid, for the purpose of lysing the cells. Two milliliters of acetate buffer solution was added to the lysate and the mixture shaken vigorously. Finally, the HBABA solution was added, 10 min. allowed for color development, and the per cent transmittance and absorbance read in a suitable colorimeter at 520 mμ.

RESULTS AND CONCLUSIONS

Using this modified procedure, it was determined that HBABA could be used to detect protein concentrations above 1.0 mg. However, this dye does not give consistent or reproducible results below a concentration of 0.3 mg. (Table I).

Similar results were found when this procedure was used to determine the protein concentration of cell cultures standardized to contain 100,000 cells/ml. of media.

It is to be concluded that while this assay may be adequate enough to be used in the clinical evaluation of serum protein levels, it is not sensitive enough to apply to the determination of cellular protein concentrations.

Mesoionic Ψ-Oxatriazoles as Hypotensive Agents

By LEMONT B. KIER*, A. AL-SHAMMA, R. HAHN, and A. TYE

A number of alkyl substituted mesoionic Ψ-oxatriazoles were investigated as hypotensive agents. They were found to produce rapid, deep, and sustained hypotension with no observable side effects. The potency followed a reverse order of mesomeric contribution of the alkyl substituents. Molecular orbital calculations revealed a large positive character on the N_3 and, in comparison with the corresponding 3-alkylsydnone and 4-acylsydnone nitrogen atom, appears to correlate with hypotensive potency.

Over the past several years studies in this laboratory on the mesoionic sydnones (I) have revealed a marked pharmacological activity in the form of CNS stimulation (1–3). In addition it was found that the sydnones possess a moderate diuretic and hypotensive property (4). Unfortunately, this hypotensive activity manifested itself at a dose level very close to the convulsive dose level, so that useful information concerning structure–activity relationships, mechanism of action, and the development of a potentially useful drug was denied.

With these problems in mind, the authors have studied a modified sydnone structure in the hope of finding a greater hypotensive activity and a reduced convulsive activity. The approach, in this study, was to consider a change in the ring which would not alter the over-all mesoionic character, *i.e.*, it was decided to study an isoconjugate heterocycle. An example of such a ring system is the mesoionic pseudooxatriazole (II). This compound is identical to the sydnone ring except for the replacement of the No. 4 carbon atom of the sydnone with a nitrogen atom.

The pseudooxatriazoles have been known since 1933, when Ponzio (5) prepared the phenyl derivatives by treating a phenyl diazonium salt (III), with nitroform (IV). More recently, Boyer and Canter (6) have prepared alkyl Ψ-oxatriazoles from the action of nitrous acid (V) on the appropriate semicarbazide (VI). Hashimoto and Ohta (7) have prepared the methyl derivative from the action of carbonyl chloride (VII) on *N*-nitroso-*N*-methylhydrazine (VIII). The most recent contribution to the synthesis of these compounds has been by Farrar (8), who synthesized the phenyl derivative from potassium diazomethane-disulfonate (IX), and a benzenediazonium salt (III) followed by treatment with nitrous acid. The Ψ-oxatriazoles studied in this work were previously described (9). The authors have confined their study to a few simple alkyl substituted Ψ-oxatriazoles in order to minimize partition coefficient effects and yet to study the electronic effect of substituents on the ring (Scheme I.)

In order to examine the electronic alterations produced in the ring by replacement of the —CH— of the sydnone with an —N— in the Ψ-oxatriazoles, the electronic structure was calculated using molecular orbital methods previously described for the sydnones (10). The ground state structure is shown in Fig. 1 for methyl Ψ-oxatriazole. The calculations have been tested by the use of the equation derived for the sydnones (10) relating the U.V. absorption maximum with the energy difference between the highest filled and lowest vacant molecular orbital (characteristic of an approximation of a $\pi \rightarrow \pi^*$ transition). From the authors' calculations of methyl Ψ-oxatriazole a value of 264 mμ for the predicted transition was obtained, which is quite close to the experimental value of 260 mμ obtained in a methanol solution. Thus, it was felt that the calculations have some validity in reproducing the electronic structure of the Ψ-oxatriazoles.

A comparison between the electronic structures of methyl Ψ-oxatriazole and 3-methyl sydnone (Fig. 1) is illuminating. The exocyclic oxygen of methyl Ψ-oxatriazole has a lower charge density while the No. 3 nitrogen atom has a substantially more positive character.

The two flanking nitrogen atoms both have charge densities in the negative range, while the —CH— flanking the No. 3 nitrogen of the sydnones is positive in character.

EXPERIMENTAL

In mice, the six Ψ-oxatriazoles under study, methyl, ethyl, isopropyl, 3-pentyl, *sec*-butyl, and *tert*-butyl, in doses of 200 mg./Kg. i.p. caused no apparent signs of toxicity. Doses of 600–800 mg./Kg. were required to produce death.

Administration of the liquid compounds in doses of 20 mg./Kg. i.v. in anesthetized dogs produced a prompt depressor effect in all cases. After the initial fall in blood pressure, there was, characteristically a small short-lived rise followed by a long period of hypotension which lasted for several hours in the case of the more potent compounds (Table I). During this period of hypotension, the animals remained normal with regard to respiration, EKG pattern, and gross and general appearance. The heart rate showed no important changes, being sometimes slightly increased or slightly decreased, although usually unaltered. The hypotensive effect ranged from approximately a 10% decrease for methyl Ψ-oxatriazole to over a 40% decrease for the *tert*-butyl Ψ-oxatriazole. There was a tendency to longer duration of effect with the more potent compounds (Table I). Hypotensive activity was also found in the spinal cat which indicates that in the cat the action is not centrally mediated. Pretreatment in dogs with atropine (1–2 mg./Kg.) or pyribenzamine (5 mg./Kg.) did not block the hypotensive effects, indicating that cholinergic effects or histamine release are unlikely causes of the hypotensive effects. Pressor responses in the dog to DMPP (25 mcg./Kg.) and epinephrine or norepinephrine (2–4 mcg./Kg.) were not reduced by the Ψ-oxatriazoles, indicating that ganglionic or α-receptor blockade are also unlikely causes.

When the compounds were tested on an isolated rabbit ileum and rat ileum or uterus maintained in a muscle bath, they produced a prompt inhibition of the smooth muscle activity in concentrations of 1–5 μl./ml.

tert-Butyl	54	34	43		53	57

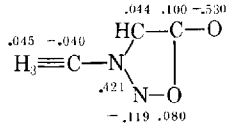

Fig. 2.—Electronic structure of methyl sydnone. (From *Reference 10.*)

The Ψ-oxatriazoles then, in doses that produce no obvious toxic effects, produce in dogs prompt, prolonged hypotensive effects which may well be due to the relaxation of smooth muscle at the periphery.

DISCUSSION

From Table I it is evident that the decreasing order of potency at the dose level studied is *tert*-butyl > *sec*-butyl ≧ 3-pentyl ≧ isopropyl > ethyl > methyl. This is in the increasing order of mesomeric contribution of the alkyl group to the aromatic ring. A minimum mesomeric contribution to ring then appears to improve the hypotensive potency.

An examination of the electronic structure of methyl Ψ-oxatriazole in Fig. 2 reveals that a major portion of the positive character of the ring resides on the trisubstituted nitrogen atom. The possible significance of the positive character of the ring, and especially the positive character of the trisubstituted nitrogen atom is revealed in a comparison of the Ψ-oxatriazoles, the 3-phenyl-4-acylsydnones, and the alkylsydnones. Greco and Kier (11) have shown that the 3-phenyl-4-acylsydnones possess a moderate hypotensive potency, while the alkylsydnones show less hypotensive activity (4). The order of potency and the corresponding charge densities of the trisubstituted nitrogen atoms for these three series of compounds are:

Ψ-oxatriazoles	>	3-phenyl-4-acylsydnones	>	3-alkylsydnones
q_n = +.476		q_n = +.448		q_n = +.421

This trend suggests an important role for the trisubstituted nitrogen atom as a partial cationic moiety in the interaction of the compound with a receptor. If this correlation is correct, the prediction follows that the as yet untested phenyl-Ψ-oxatriazole with a trisubstituted nitrogen charge density of +.484 should be a more potent hypotensive agent than the compounds reported.

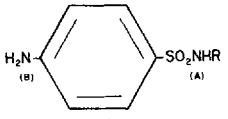
Molecular Orbital Calculations on Some Sulfanilamides

By A. CAMMARATA

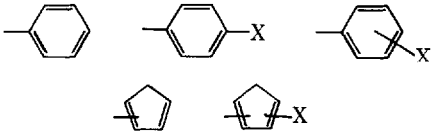
Simple HMO-calculations on three sulfanilamides have been done using semi-empirical parameters for the SO_2 group which intrinsically take into account the effects of *d*-orbital overlap. Charge variations at the sulfonamido and at the aromatic *p*-amino position are noted which are in qualitative agreement with expectations.

RECENTLY a number of quantum chemical calculations on substituted sulfanilamides have been reported (1, 2). These calculations indicated that a variation in R in structure I results in a variation



I

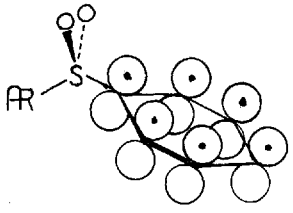
of the positive formal π-electronic charge on nitrogen A whereas the positive formal π-electronic charge on nitrogen B remains unaffected. When these compounds were classified into groups depending on the nature of R, where R was



and where any of these R may contain heteroatoms (2), it was found that the variation in formal charge on nitrogen A was consistent with their pKa's, *i.e.*, higher formal charge, lower pKa. Hence, it was concluded that (*a*) the well known relationship between bacteriostatic activity and pKa (3) has a quantum chemical foundation; and (*b*) although a *p*-amino group may be necessary for activity, the insensitivity of the formal charge on nitrogen B to variations in R did not support the view (4–6) that the bacteriostatic action of the sulfanilamides is primarily associated with the *p*-amino group.

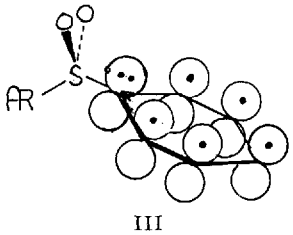
Since Seydel (5, 6) has presented evidence, based on infrared studies, indicating that substituents placed on the sulfonamido-nitrogen are able to influence the electronic environment of the *p*-amino group, it is expected that charge variations at the *p*-amino position should be calculable by making a suitable choice of Hückel parameters for the SO_2 group. Apparently, any choice of parameters which is made for the SO_2 group should somehow include the contribution by the sulfur *d*-orbitals to the overall conjugation, for neglect of such participation, as found by Martin (1, 2), does not lead to variations in charge at the *p*-amino position.

The approach taken here is to utilize semiempirical parameters derived for the SO_2 group from electron paramagnetic resonance (EPR) studies on diphenyl and *p*,*p*′-ditolyl sulfone anion radicals (7) in simple Hückel molecular orbital (HMO) calculations on substituted sulfanilamides. While objections may be raised to the application to sulfanilamides, of parameters derived from ESR studies on diarylsulfones, a rationalization for their use can be provided. Pictorially, a diarylsulfone may be represented as in II, where only one of the aromatic rings has its π-



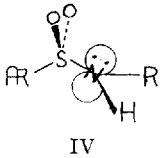
II

network described, and where the dot inside of each *p*-orbital represents the electron which may be associated with that orbital.[1] Formation of a diarylsulfone anion radical infers that an extra electron is being donated to the π-network. For conjugation to occur across the sulfur atom at some time the *p*-orbital adjacent to the sulfur atom must contain two electrons (this in keeping with the simple pictorial representation in II), one electron which was originally associated with that orbital and the other the electron which was donated to the π-network. This situation may be represented as in III, which at the atom adjacent to sulfur is



III

formally analogous to a similar representation of sulfanilamide, and presumably its derivatives (IV).



IV

Note, it is also tacitly assumed that the amido-nitrogen is in an sp^2-hybridized state to enable

Received June 20, 1966, from the Department of Chemistry and Pharmaceutical Chemistry, Medical College of Virginia, Richmond 23219.

Accepted for publication September 9, 1966.

[1] This type of description appears generally accepted: "For delocalization of π-electron density along the length of a chain or the circumference of a ring, it is necessary that *each atom* comprising the chain or ring have associated with it at least one *p*-type electron that is not being employed in formation of single bonds" (11). "Each p_z-electron is paired with its neighbor, and the *p*-orbitals overlap in the π-manner around the ring" or along the length of a chain (12). The description is equivalent to one in which only molecular orbitals are considered, as in arriving at molecular orbitals one must make linear combinations of these one-electron atomic orbitals.

conjugation through the *d*-orbitals of the sulfur atom. Such conjugation would require overlap of a sulfur *d*-orbital with the *p*-orbital on nitrogen (8, 9).

Using the Hückel parameters $\alpha_{SO_2} = \alpha_C - 2.60\ \beta_{C-C}$ and $\beta_{C-SO_2} = 0.99\ \beta_{C-C}$ which were derived for the sulfone group in the above-mentioned EPR studies, and which intrinsically take into account *d*-orbital participation, the formal π-electronic charges of three sulfanilamides were calculated. As these calculations were performed without the aid of a computer the following simplifying assumptions were made for the exchange integrals involving the sulfone group: $\beta_{C-SO_2} = \beta_{C-C}$ and $\beta_{N-SO_2} = \beta_{C-C}$.[2] The Coulomb and exchange integrals used for all other atoms and bonds were those suggested by Streitwieser (10).

The compounds selected were chosen primarily to establish whether, by using this approach, charge variations could be noted at the *p*-amino position for select sulfanilamide derivatives. Thus, in Fig. 1 there are reported the calculated formal π-electronic charges for: (*a*) an electron-donating substituent, (*b*) unsubstituted sulfanilamide, and (*c*) an electron-withdrawing substituent. Inspection of the calculated formal π-electronic charges on the sulfonamido and on the *p*-amino position indicate their respective values to be in accord with expectations. The charge at the *p*-amino position appears to vary in accord with the type of substituent placed on the amido nitrogen, *i.e.*, low for an electron-donating substituent, high for an electron-withdrawing substituent, and the charge at the amido position also appears consistent for the type of group substituted on it. Furthermore, the apparent magnitudes of the charge variation at the amido position (0.07) relative to the *p*-amino position (0.02) is consistent with the observation of Bell and Roblin (3) that whereas the pKa's of a series of sulfanilamides may vary over a wide range their pK_b's (for the *p*-amino group) remain within a very narrow range. It should be emphasized that, at present, these calculations must be considered as being more qualitative than quantitative. Although the trends suggested are in reasonable accord with observation it must yet be demonstrated that these trends provide a correlation. This aspect is currently under investigation. These calculations, however, do suggest that if the effects of *d*-orbital overlap, due to the sulfur of the SO_2 group, are taken into account, variations in electronic charge at the *p*-amino position of sulfanilamides could be noted.

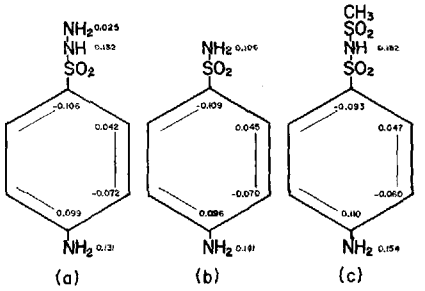


Fig. 1.—Calculated formal π-electronic charges. Key: a, an electron-donating substituent; b, unsubstituted sulfanilamide; c, an electron-withdrawing substituent.

[2] The error introduced by the approximation $\beta_{N-SO_2} = \beta_{C-C}$ is expected to be no greater than that introduced in calculations on hydrocarbons in which it is assumed that all β's are equal. This arises from the following considerations: k is generally assumed to be proportional to the overlap integral, S (13) and is linearly related to the bond distance (*Reference 10*, pp. 104–105). Aromatic double bonds have lengths 1.33–1.35 Å., while single sp^2–sp^2 bonds, *e.g.*, the central bond in butadiene, have lengths 1.48–1.50 Å. For precise work with hydrocarbons it is apparent that different β-values should be used depending upon the type of bond. This is seldom done in comparative studies. The S—N and S—C bond distances for sulfanilamides are 1.62 and 1.75 Å., respectively (14, 15). As can easily be seen, the difference in bond distance between aromatic and single sp^2–sp^2 bonds is approximately equal to the difference in bond distance between the S—N and S—C bonds in sulfanilamide. Thus, since $\beta_{C-SO_2} = \beta_{C-C}$ is a semiempirically determined quantity, it appears valid to assume $\beta_{N-SO_2} = \beta_{C-C}$. The approximation is not expected to greatly affect the calculated charge densities (*cf. Reference 10*, p. 106). The largest source of error is expected to be due to the Hückel theory itself, especially when applied to materials containing heteroatoms. However, while the absolute magnitudes of the calculated quantities cannot be considered significant, their values *relative* to those for other homologs have direct bearing on their physical interpretation.

Microbiological Testing of Aerosol Preparations Using *Chaetomium globosum*

By J. W. BLASECKI, JR.*, and M. IANNARONE

Chaetomium globosum, **a common fungus of the soil, and a member of the class *Ascomycetes,* is a cellulolytic organism, whose growth is dependent primarily upon the degradation of cellulose material. This study explores the possibility of utilizing a modified growth and test procedure applicable to the A.O.A.C. recommended prescribed method for testing antifungal activity of aerosols. The test procedure developed brings the method to the organism under conditions that are applicable to the natural growth habits. A convenient method is described employing the inhibition of growth of *C. globosum* on sterile filter paper after exposure to certain aerosols. Sterile phenol solutions and certain blends of quaternary ammonium compounds were used as the challenging agents.**

THE USE of aerosol preparations in the treatment of fungal infestations requires appropriate microbiological testing procedures. At present, the A.O.A.C. (1) employs a method involving a *Trichophyton* sp., a pathogen, as the test object. In these laboratories, a simplified, convenient, and reliable method has been developed utilizing a nonpathogenic fungal organism, *C. globosum*. *C. globosum* (ATCC-6205) a common fungus of the soil, is a cellulolytic organism, depending primarily upon the degradation of cellulose materials for its growth (2). A sterile strip of filter paper was placed on a cooled tube-slant of a suitable medium,[1] and the strip was inoculated with spores. This was used as the stock culture after incubation for 7 days at 25–30°. Sterile Whatman No. 2 filter paper was used as the source of cellulose. This growth pattern and property was adapted to the evaluation of antifungal activity, since the inhibition of growth of this organism on sterile filter paper was easily observed after exposure to certain aerosols.

PROCEDURE

The A.O.A.C. spray test procedure (1, 3, 4) for evaluating the antifungal activity of aerosol preparations recommends that a standardized spore suspension of *Trichophyton interdigitale* (ATCC-640) be spread over an area of 1 sq. cm. Thus, it was decided that the test organism for this study would be the spores and vegetative structures of *C. globosum*. This stage of growth was produced on 1-cm. squares of filter paper at the end of 7 days at 25–30°. Spray testing (1) was performed at this stage of growth.

A 1-cm. square containing the test organism was removed from the medium, using sterile forceps, and placed on a sterile glass slide in a Petri dish, the bottom of which was layered with two disks of sterile filter paper. This was repeated for all of the remaining squares (10 per test). The above were placed in an incubator at 25–30° for 2 hr. to allow the squares to dry.

At the end of this period, the plate was supported at a 45° angle, and the respective squares were sprayed using phenol controls and test compounds (Table I) under test for the specified period of time,[2] at a distance of 8 to 10 in. from its surface. The above procedure was repeated for all plates under test. A DeVilbiss No. 251 atomizer was used to produce the spray of the phenol control solutions.

After all squares were sprayed, each one was aseptically removed, respectively, from the glass slide, and was placed on the filter paper bed Petri dish. The dishes were placed in an incubator 24 hr. for drying the sprayed filter squares.

Using aseptic technique, a 2 × 2-cm. square of sterile filter paper was placed on the medium in a Petri dish and the dried 1-cm. square was transferred on to the 2 × 2-cm. square. This was repeated for all the recommended number (ten) of 1-cm. squares. All of the above dishes were incubated for 7 days at 25–30°. Untreated 1-cm. squares containing the viable test organism, were transferred to 2 × 2-cm. squares to serve as controls. This insures the viability of the test organism on both the 1 and 2 × 2-cm. squares and serves to establish a base for the growth pattern of the organism. Growth of the test organism on to the 2 × 2-cm. square at the end of the 7 days was read as positive, while no growth was read as negative (Tables II and III).

The 1 and 2 × 2-cm. squares displaying no apparent growth 7 days after spraying were divided into two groups of equal number. Control procedures were initiated on one group immediately, while the other group was reincubated for an additional 7 days. The same control procedures were then repeated on this second group. (Those squares exhibiting no growth after the first 7 days of incubation remained so for the additional 7 days.)

The following control procedures were utilized for the negative no-growth squares.

A.—The 1-cm. square was removed from the original backup square, inverted on a new 2 × 2-cm. square on fresh medium, and reinoculated with spores from a stock culture. The above was repeated until half of the 1-cm. squares were treated.

B.—The remaining 1-cm. squares were inverted

directly on fresh medium and reinoculated with spores from a stock culture.

C.—All 2 × 2-cm. backup squares, on the original medium, were inoculated directly with spores from a stock culture.

Controls were incubated for 7 days. Growth of the organism in each of the controls at the end of this period indicates antifungal activity of the test material, and could not be due to stasis caused by possible absorption of the test material by the filter paper.

In addition, an uninoculated square was sprayed,[3] according to the prescribed procedure, and placed in an incubator for 24 hr. It was transferred to a Petri dish and challenged with spores from a stock culture.

All stasis controls displayed growth in 7 days.

CONCLUSIONS

The results presented in this paper suggest the possiblity of utilizing the prescribed procedure for testing the antifungal activity of certain aerosol preparations using *C. globosum*. Similar organisms could be adapted to the test method. Since the only challenging chemical employed was phenol, and the problem of differentiating between stasis and cidal effects in any procedure of this kind was complicated by the substantive properties of the chemical and its ability to diffuse into the media and/or the back-up 2 × 2-cm. squares in this instance, it would appear that differentiation between stasis and cidal activity is valid.

The test organism, used throughout the procedure, consisted of both the spores and the entire vegetative structure. It will be recognized, however, that if the material under test was effective against spores, it should be similarly effective against the vegetative cells. It could be assumed that the use of the test material on the entire structure of the organism was a more drastic test and closely simulates the use of the test material under the natural growth conditions.

The use of the 1-cm. square of filter paper for the growth of the test organism and its use in the aerosol testing procedure was considered to be valid, since the spores inoculated on any given square were under the exact same growth conditions, with respect to time, temperature, and medium, as those on other squares. This was further substantiated by the fact that the growth of the organism was restricted to the 1 sq. cm. area of the filter paper. Thus, it could be assumed that any given 1-cm. square, at the end of 7 days, contains approximately the same amount of vegetative growth and about the same number of spores.

Experience in these laboratories indicate that the procedure described is simpler, more convenient, more reliable, and safer than the present A.O.A.C. method.

Sympathetic Blocking Action of Iproniazid in the Unanesthetized Dog

By J. N. SPENCER

Iproniazid, on intravenous injection in the unanesthetized dog, inhibited the increase in arterial blood pressure resulting from the intravenous injection of epinephrine, DMPP, and tyramine. Adrenergic blockade appeared to be an important factor in this action of iproniazid, although the possibility of inhibition of the release of norepinephrine from nerve terminals could not be eliminated. These results confirm *in vitro* studies of previous investigators.

THERE is abundant clinical and experimental evidence that drugs which inhibit monamine oxidase (MAO) are capable of altering sympathetic responsiveness. Patients receiving these drugs commonly exhibit orthostatic hypotension (1). On the other hand, the same patients on eating a food high in tyramine, such as cheese, may develop an alarming hypertension (2). The mechanism responsible is not clear. Goldberg and Da Costa (3) as well as Gertner (4) noted that a number of MAO inhibitors block transmission through the superior cervical ganglion of experimental animals. However, Zbinden *et al.* (5) and Brodie (6) are of the opinion that MAO inhibitors do not act at the ganglion, but at the receptor site, preventing the release of norepinephrine from the nerve endings. Either site of action could account for the above effects. Both views, however, are based on *in vitro* studies or studies conducted on animals under barbiturate anesthesia. Barbiturates are known to alter neurohormone release (7) even to the point of reversal of the response to common autonomic stimuli (8). In view of this, it was deemed of value to determine the effect of a MAO inhibitor on the autonomic responsiveness of trained unanesthetized dogs.

EXPERIMENTAL

Healthy, adult, mongrel dogs of either sex, weighing from 12 to 29 Kg., were used in the study. The animals were trained to lie quietly on their backs, with minimal restraint during the recording of arterial blood pressure from a femoral arterial puncture. Records of the blood pressure and the circulatory response to the intravenous injection of epinephrine (0.002 mg./Kg.), DMPP[1] (0.08 mg./Kg.), acetylcholine (0.006 mg./Kg.), and tyramine (0.1 mg./Kg.) were obtained every 48 to 72 hr. until the blood pressure had stabilized and a consistent circulatory response to the above agents had been obtained in at least three successive tests. The average of the values obtained in the three tests served as the experimental control.

The MAO inhibitor, iproniazid,[2] was dissolved in normal saline and injected intravenously in terms of base content in a single dose of 10 or 20 mg./Kg. or in two doses of 20 mg./Kg. each, 24 hr. apart. Records were obtained of the blood pressure and the circulatory response to the injection of epinephrine, DMPP, acetylcholine, and tyramine 24, 48, 72, 96, and 120 hr. after the injection of the iproniazid.

RESULTS

The administration of iproniazid in a single dose of 10 or 20 mg./Kg. was without significant effect on the blood pressure or the circulatory response to the injection of epinephrine, DMPP, acetylcholine, or tyramine. However, following two doses of 20 mg./Kg., each 24 hr. apart, within 24 to 48 hr. there was a marked and statistically significant inhibition of the pressor reaction to the injection of epinephrine, DMPP, and tyramine (Table I). This occurred in the absence of any significant alteration in the recumbent blood pressure or in the depressor action of acetylcholine and was evident for 96 to 120 hr. after the injection of iproniazid. The effect on the action of tyramine was the most marked, the pressor response being reversed to one of the depressor within 24 hr. (Table I and Fig. 1). The alteration in the action of epinephrine and DMPP was not as marked as that of tyramine, although reversal of the pressor action of both agents was observed.

From the above it would appear that iproniazid has an adrenergic blocking action. Adrenergic blockade would account for the inhibition of the action of epinephrine and DMPP as well as the reversal of the pressor action of tyramine. Tyramine not only releases norepinephrine from tissue stores but also acetylcholine (9). In the presence of adrenergic blockade, its cholenergic action predominates. Excitement following the administration of atropine prevented the determination of the involvement of acetylcholine in the depressor action of tyramine in the unanesthetized dog, but in animals anesthetized with chloralose 24 hr. after the injection of iproniazid, atropine completely blocked the tyramine depressor response. Thus, acetylcholine release appeared to be implicated in the reversal of the pressor action of tyramine. However, it cannot be determined from this study if adrenergic blockade was the only factor involved in the alteration of autonomic responsiveness produced by iproniazid. The fact that the pressor action of both DMPP and tyramine were blocked at a time when the inhibition of the action of epinephrine was minimal (120 hr. observation) suggests the possibility of an interference with norepinephrine release from nerve terminals. Such an action, like adrenergic blockade, would uncover the cholinergic action of tyramine (9).

Results comparable to those obtained with iproniazid were observed on occasion in unanesthetized dogs following the intravenous injection of tranylcypromine or β-phenylisopropylhydrazine.

Received June 9, 1966, from the Department of Physiology and Pharmacology, School of Medicine, University of South Dakota, Vermillion 57069.

Accepted for publication September 19, 1966.

TABLE I.—EFFECT OF IPRONIAZID ON BLOOD PRESSURE AND THE ACTION OF EPINEPHRINE, DMPP, ACETYLCHOLINE, AND TYRAMINE (MEAN OF 5 EXPERIMENTS)

Observation Time After Iproniazid	Blood Pressure, mm. Hg			Action of Epinephrine		Action of DMPP		Action of Acetylcholine		Action of Tyramine	
	Systolic Pressure	Diastolic Pressure	Change (Systolic/Diastolic)	mm. Hg Change in Systolic Pressure	% Decrease from Control	mm. Hg Change in Systolic Pressure	% Decrease from Control	mm. Hg Change in Systolic Pressure	% Deviation from Control	mm. Hg Change in Systolic Pressure	% Decrease from Control
0 (control)[a]	119 ± 5[b]	66 ± 3	...	34 ± 6	...	44 ± 7	...	−31 ± 7	..	22 ± 8	...
24 hr.	116	68	−3/2	11	68	27	39	−33	6	−10	145[d]
48 hr.	120	62	1/−4	21	38[c]	21	52[c]	−31	0	−10	145[d]
72 hr.	112	63	−7/−3	13	62[c]	12	73[c]	−26	16	0	100[d]
96 hr.	107	55	−12/−11	13	62[d]	13	70[c]	−38	22	−15	169[c]
120 hr.	116	61	−3/−5	28	18	16	64[c]	−35	13	−4	118[c]

[a] Mean of all control observations. [b] ± Standard error of mean. [c] P, 0.05 (Wilcoxon test of rank sums). [d] P, 0.02 (Wilcoxon test of rank sums).

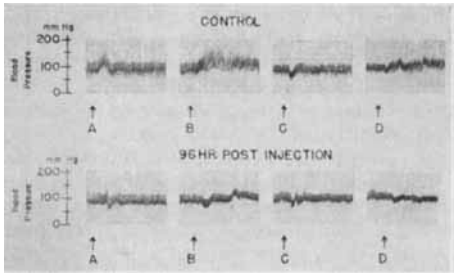

Fig. 1.—Effect of iproniazid on the response of the blood pressure to the injection of autonomic agents. Arrows indicate points of intravenous injection of autonomic agents. Key: A, 0.08 mg./Kg. DMPP; B, 0.002 mg./Kg. epinephrine; C, 0.006 mg./Kg. acetylcholine, D, 0.1 mg./Kg. tyramine. (Dog 4, 23.5 Kg. male.)

The effect, however, tended to be masked by the amphetamine-like action of these drugs (10, 11). Thus, tranylcypromine and β-phenylisopropylhydrazine as well as iproniazid inhibit autonomic responsiveness in the unanesthetized dog. Adrenergic blockade appears to play an important role in this action, although inhibition of norepinephrine release from nerve terminals may be a factor. These observations confirm previous results obtained in *in vitro* studies and in studies conducted on anesthetized animals (5, 6).
