Drug Standards

Standardization of Papain Activity

Report of a Collaborative Study

By EDGAR A. LAZO-WASEM

Methods of assay for the enzyme papain were evaluated, and those endorsed are presented. A procedure which measures the hydrolysis of casein under standardized conditions was found to be the method of choice.

PAPAIN, a crude or purified proteolytic enzyme derived from the tropical plant *Carica papaya*, has been used in the pharmaceutical and food industries for over half a century. Twenty years ago, a monograph for papain was included in the eighth edition of the "National Formulary" (1). The then official assay procedure consisted of a limit test based on digestion of beef muscle.

After deletion of papain from the "National Formulary," many procedures came into use for the standardization of commercial papain. For pharmaceutical and food grade papain, the most widely used procedures have been milk-clotting (2), casein digestion (3), and digestion of hemoglobin (4, 5). For crystalline papain, most laboratories have, at least recently, relied on the initial rate of hydrolysis of synthetic peptide substrates such as *N*-benzoyl-L-arginine ethyl ester hydrochloride.

In an attempt to bring about unification in methods of assay throughout United States laboratories, a committee was established within the Quality Control Section of the Pharmaceutical Manufacturers Association in the fall of 1962. This group was to study current prevailing methods and recommend a generally acceptable method for use throughout the industry. This report describes the findings and recommendations of that committee.

PLAN OF STUDY AND RESULTS

Member firms of the Pharmaceutical Manufacturers Association, representing manufacturing suppliers and pharmaceutical firms marketing papain in dosage forms, were invited to supply their procedures. The methods received involved either milk-clotting, casein digestion, or hemoglobin digestion. From the procedures received, three assays based on the above principles were prepared and forwarded to eight laboratories for collaborative study. "Standard" and "unknown" papain preparations were also forwarded, and thus an effort was initiated whereby

Received March 15, 1966, from Strong Cobb Arner, Inc., Cleveland, Ohio.
Accepted for publication May 4, 1966.
A study by the Committee on Papain, Quality Control Section, Pharmaceutical Manufacturers Association. Committee Membership: J. E. Giesemann, Brayten Pharmaceutical Co.; N. Kartinos, Baxter Laboratories, Inc.; G. F. McCutcheon, S. B. Penick & Co.; C. F. Peterman, Kremers-Urban Co.; J. V. Saenger, Warner-Chilcott Laboratories; I. S. Shupe, Winthrop Laboratories; L. A. Underkoffler, Miles Chemical Co.; and E. A. Lazo-Wasem, Strong Cobb Arner, Inc. (Chairman).
After the study reported here was underway, it was learned that efforts toward uniformity of enzyme assays, including papain, were being made by the International Commission for the Standardization of Pharmaceutical Enzymes, Fédération Internationale Pharmaceutique. Since then this writer has been kept informed of the efforts of this predominantly European group, the initial studies of which have been excellently summarized in the commission's First Report (6). For papain, the commission has endorsed a method based on the initial rate of hydrolysis of a synthetic substrate, *N*-benzoyl-L-arginine ethyl ester hydrochloride, for both crystalline papain and less purified preparations. A comparison of the unit of activity reported here with that adopted by the commission will be the subject of a future report.

the potency of the preparations using each procedure was compared. An analysis of intra- and inter-laboratory variation showed all three procedures to be equally reliable. The milk method (visual observation of the clotting of milk by the enzyme, an initial step in the proteolysis of casein) was found to require personal experience by the analyst to correctly time the corresponding subjective end point, but was found to be the simplest of the methods tried, and thus, worthy of further work. Difficulty was encountered at some laboratories in the duplication of the hemoglobin procedure studied, and thus no further study with this procedure was recommended. The milk-clotting and casein digestion methods were adopted as choice methods. Details of the two adopted assay procedures, as used by the committee, are described below.

Casein Digestion Assay

Reagents.—*Sodium Phosphate, 0.05 M.*—Dissolve 7.1 Gm. of anhydrous disodium phosphate in sufficient water to make 1000 ml. Add a drop of toluene as preservative.

Citric Acid, 0.05 M.—Dissolve 10.5 Gm. of citric acid monohydrate in sufficient water to make 1000 ml. Add a drop of toluene as preservative.

Casein Substrate.—Disperse 1 Gm. of Hammersten type casein in 50 ml. of 0.05 *M* sodium phosphate. Place in a boiling water bath for 30 min. with occasional stirring. Cool to room temperature and add 0.05 *M* citric acid to pH 6.0 ± 0.1. Solution must be stirred rapidly and continuously during addition of the 0.05 *M* citric acid to prevent precipitation of the casein. Dilute to 100 ml. with water. Prepare fresh daily.

Phosphate–Cysteine Disodium Ethylenediaminetetraacetate Buffer Solution.—Dissolve 3.55 Gm. of disodium phosphate in 400 ml. of water in a 500-ml. volumetric flask. Add 7.0 Gm. of disodium ethylenediaminetetraacetate and 3.05 Gm. of cysteine hydrochloride monohydrate. Adjust to pH 6.0 ± 0.1 with 1 *N* HCl or 1 *N* NaOH solutions, and dilute to volume with water. Prepare fresh daily.

Trichloroacetic Acid, 30% (TCA).—Dissolve 30 Gm. of reagent grade trichloroacetic acid in water and dilute to 100 ml. with water.

Standard Test Dilution (Standard).—Accurately weigh 100 mg. of N.F. papain reference standard in a 100-ml. volumetric flask and add buffer solution to dissolve. Dilute to volume with buffer solution. Further dilute 2 ml. of this solution to 50 ml. with buffer solution. Use within 30 min. after preparation.

Assay Test Dilution (Unknown).—Accurately weigh an amount of sample containing an activity equivalent to 100 mg. of reference standard and proceed exactly as in the preparation of the *Standard Test Dilution.*

Procedure.—Into each of 12 test tubes (18 × 150 mm.) pipet 5.0 ml. of casein substrate. Place in a 40° water bath and allow 10 min. to reach bath temperature. Into each of two of the tubes (tests are run in duplicate except for the blanks) labeled S_1, pipet 1 ml. of standard and 1 ml. of buffer solution, mix by swirling, note zero time, stopper, and replace in the bath. Into each of two other tubes labeled S_2, pipet 1.5 ml. of standard and 0.5 ml. of buffer solution, and proceed as before. Repeat this procedure for two tubes labeled S_3, to which 2 ml. of standard is added, and for two tubes labeled U_2, to which 1.5 ml. of unknown and 0.5 ml. of buffer solution are added. After exactly 60 min., add to all 12 tubes 3 ml. of 30% TCA and shake vigorously. With the four tubes to which no standard or unknown solutions were added, prepare blanks by pipetting, respectively: 1 ml. standard plus 1 ml. buffer solution, 1.5 ml. standard plus 0.5 ml. buffer solution, 2 ml. standard, and 1.5 ml. unknown plus 0.5 ml. buffer solution. Replace all tubes in the 40° bath for 30–40 min. to allow to fully coagulate the precipitated protein. Filter through Whatman No. 40 or equivalent filter paper, discarding the first 3 ml. of filtrate (filtrates must be completely clear). Read the absorbance at 280 mμ of the filtrates of all solutions against their respective blanks. Plot the readings for S_1, S_2, and S_3 against the enzyme concentration of each corresponding level. By interpolation from this curve, taking into consideration dilution factors, calculate the potency of the sample in units/mg.

Calculation of Potency.—

$$C \times \frac{100}{\text{sample wt. (mg.)}} \times \frac{50}{2} \times \frac{10}{1.5} \times A = \text{units/mg.}$$

where C = mg./ml. obtained from the standard curve, and A = activity of reference standard in units/mg.

Milk-Clotting Assay

Reagents.—*pH 4.5 Buffer Solution Concentrate.*—Mix 2 vol. of 1 *M* acetic acid with 1 vol. of 1 *M* sodium hydroxide. Check pH and adjust.

Dilute Buffer Solution.—Dilute 2 vol. of the pH 4.5 concentrated buffer solution to 15 vol. with water.

Milk Substrate.—Mix thoroughly 50 Gm. of milk powder with 215 ml. of dilute buffer solution in a Waring blender or similar device. Add a trace of octyl-alcohol (2-ethyl-1-hexanol) to decrease foaming during the blending operation. Filter through cheesecloth into a clean bottle. Add a few drops of toluene as a preservative. Allow to stand a few hours before use. Use the day of preparation. Keep refrigerated.

Phosphate–Cysteine–Disodium Ethylenediaminetetraacetate Buffer Solution (P–C–EDTA Buffer).—Dissolve 3.55 Gm. of disodium phosphate in 400 ml. of water in a 500-ml. volumetric flask. Add 7.0 Gm. of disodium ethylenediaminetetraacetate and 3.05 Gm. of cysteine hydrochloride monohydrate. Adjust to pH 6.0 with 1 *N* HCl or 1 *N* NaOH solutions, and dilute to volume with water. Prepare fresh daily.

Standard Test Dilution (Standard).—Accurately weigh 100 mg. of N.F. papain reference standard in a 50-ml. volumetric flask and add P–C–EDTA buffer solution to dissolve. Bring to volume with more P–C–EDTA buffer solution. Use within 30 min. after preparation.

Assay Test Dilution (Unknown).—Accurately weigh about 100 mg. of sample and dilute with P–C–EDTA buffer solution to obtain an activity approximately equivalent to that of the standard test dilution.

Procedure.—Pipet 25 ml. of milk substrate into each of a series of test tubes (25 × 150 mm.), close with rubber stoppers, place in a water bath at 40 ± 0.5°, and allow the contents of the tubes to reach bath temperature. (The assay is quite sensi-

tive to temperature. Variations of 1.0° can introduce errors of about 10%.) At zero time, pipet 2 ml. of standard and discharge the contents into one of the tubes. Stopper the tube, shake briefly but gently, so as to avoid the inclusion of air bubbles, and return to the bath. Using a stopwatch, measure the time from the addition of the standard test dilution until clotting of the milk begins. Roll the tube gently back and forth in a horizontal position while in the bath. (Less than 1 min. prior to clotting, the milk will appear to thicken somewhat and will no longer drain readily from the walls of the tube.) Watch the smooth film of milk closely from this point on. The end point is the almost instantaneous appearance of a granular character in the milk film. The time required for the end point to be reached should not be less than 100 sec. and not more than 150 sec. If not, the test should be repeated using a higher or lower enzyme concentration level. Once the right time limit of activity has been found, the test should be repeated at least once, and the average time recorded. Repeat the determination using the assay test dilution in the same volume as used for the standard.

Calculation of Potency.—Determine the relative potency of the sample in terms of the reference standard preparation by the equation:

$$\frac{w^S \times t^S}{w^U \times t^U} \times D = \text{units/mg.}$$

where

w^S = mg. of reference standard added to milk,
t^S = time in seconds for standard to produce clotting,
w^U = mg. of sample added to milk,
t^U = time in seconds for sample to produce clotting,
D = activity of reference standard in units/mg.

A second collaborative study further comparing milk-clotting and casein digestion again showed total equivalence of the two procedures. Interlaboratory variation in determining relative potency of two preparations by either method was below 5%. At this point, the committee felt that in view of the objective end point of the casein procedure (spectrophotometric measurement of released products of casein digestion), this method was the one of choice.

After selection of the assay procedure, the committee turned its attention to the selection of a suitable reference standard preparation. This study involved assay of preparations of varying potency, type, and origin.

The adopted standard preparation was tested for its tyrosine-releasing activity when allowed to act on a standard casein substrate. Definition of a unit of activity was done essentially following the conditions recommended by the International Union of Biochemistry, which states that an enzyme unit should be defined as the amount which catalyzes transformation of a stated amount (1 μm.) of substrate per unit time under defined conditions.

After experimental study at various laboratories, the committee agreed on the following definition of a papain unit: one unit represents the activity which releases the equivalent of 1 mcg. of tyrosine from a standard casein substrate, under specified conditions and at the enzyme concentration which liberates 40 mcg. of tyrosine per ml. of test solution. Using this unit definition, the preselected reference standard was found to contain 6600 units per mg. This N.F. papain reference standard is being made available through the offices of the National Formulary, American Pharmaceutical Association, Washington, D. C. The method of assay has been adopted by the Food Chemicals Codex. The committee agreed that papain for pharmaceutical use should have a potency of not less than 6000 papain units in each mg., when tested by the above described method.

SUMMARY AND CONCLUSIONS

1. Prevailing methods in the U. S. pharmaceutical and food industry for papain standardization have been studied by a Committee of the Pharmaceutical Manufacturers Association. Of the methods evaluated, that which measures hydrolysis of casein under standardized conditions was endorsed.

2. A preparation to be used as the reference standard in conjunction with the assay procedure was selected.

3. The papain reference standard has been submitted to the National Formulary for storage and distribution. The casein digestion method of assay has been adopted by the Food Chemicals Codex.

4. It is hoped that as many segments of industry as possible will begin using the recommended method and unit for routine quality control and for the labeling of papain activity.

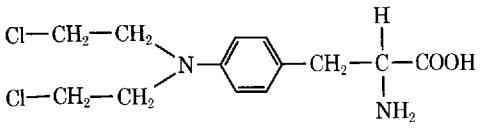
Qualitative and Quantitative Tests for Melphalan

Provisional, unofficial monographs are developed by the Drug Standards Laboratory, in cooperation with the manufacturers of the drug concerned, for publication in the *Journal of Pharmaceutical Sciences*. The ready availability of this information affords discriminating medical and pharmaceutical practitioners with an added basis for confidence in the quality of new drug products generally, and of those covered by the monographs particularly. Such monographs will appear on drugs representing new chemical entities for which suitable identity tests and assay procedures are not available in the published literature. The purity and assay limits reported for the drugs and their dosage forms are based on observations made on samples representative of commercial production and are considered to be reasonable within expected analytical and manufacturing variation.

L - 3 - p - [BIS(2 - chloroethyl)amino]phenylalanine; $C_{13}H_{18}Cl_2N_2O_2$; mol. wt. 305.21. The structural formula of melphalan may be represented as



Physical Properties.—Melphalan occurs as an off-white to buff-colored powder with a faint odor. It is slightly soluble in methanol and in alcohol, and practically insoluble in water. It is soluble in dilute mineral acids.

Identity Tests.—Transfer 1 ml. of a 0.01% alcoholic solution of melphalan into a glass-stoppered test tube and add 1 ml. of U.S.P. phthalate buffer, pH 4.0, 1 ml. of a 5 in 100 solution of 4-(*p*-nitrobenzyl)pyridine (NBP) in acetone, and 1 ml. of saline T.S. Heat on a water bath at 80° for 20 min. and cool the solution quickly. Add 10 ml. of alcohol and 1 ml. of 0.1 *N* potassium hydroxide: a violet to red-violet color is produced.

A 1 in 100,000 solution of melphalan in alcohol exhibits an ultraviolet absorbance maximum at about 260 mμ [absorptivity (*a*) about 72] and a minimum at about 226 mμ. The spectrum is shown in Fig. 1.

The infrared spectrum of a 0.5% dispersion of melphalan in potassium bromide, in a disk of about 0.82 mm. thickness, is shown in Fig. 2.

Purity Tests.—Dry about 1 Gm. of melphalan, accurately weighed, *in vacuo* at 105° to constant weight: it loses not more than 7% of its weight.

Char about 1 Gm. of melphalan, accurately weighed, cool the residue, add 1 ml. of sulfuric acid, heat cautiously until evolution of sulfur trioxide ceases, ignite, cool, and weigh: the residue does not exceed 0.1%.

Determine the nitrogen content by the U.S.P. XVII nitrogen determination, method II, using about 325 mg. of melphalan, accurately weighed, and 0.1 *N* sulfuric acid for the titration. Each milliliter of 0.1 *N* sulfuric acid is equivalent to 1.401 mg. of nitrogen (N). The amount of nitrogen found is not less than 8.90% and not more than 9.45% calculated on a dried sample weight.

Received April 5, 1966, from the Drug Standards Laboratory, AMERICAN PHARMACEUTICAL ASSOCIATION FOUNDATION, Washington, D. C.

Accepted for publication April 19, 1966.

Burroughs Wellcome & Co., Inc., Tuckahoe, N. Y., has cooperated by furnishing samples and data to aid in the development and preparation of this monograph.

Assay.—Transfer about 200 mg. of melphalan, accurately weighed, into a titrating beaker and dissolve in 20 ml. of 0.5 *N* sodium hydroxide. Cover the beaker with a watch glass and boil the solution for 30 min., adding water as necessary to maintain the volume. Cool, neutralize to phenolphthalein T.S. with acetic acid, add 1 ml. excess acetic acid, and titrate potentiometrically with 0.1 *N* silver nitrate. Each milliliter of 0.1 *N* silver nitrate is equivalent to 15.26 mg. of $C_{13}H_{18}Cl_2N_2O_2$. The amount of melphalan found is not less than 93% and not more than 100.5% calculated on the dried basis. (*Note.*—Based on the assay result, melphalan is factored to 100% for use in the tablet formulation.)

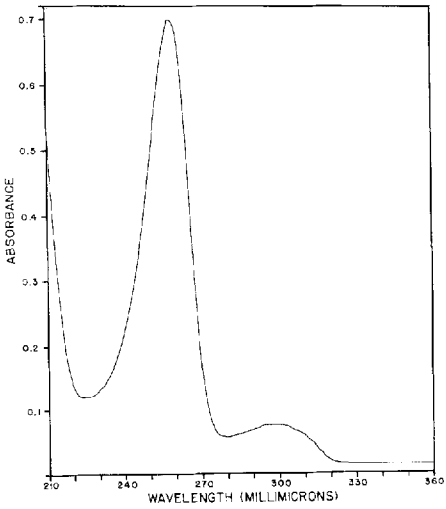


Fig. 1.—Ultraviolet absorption spectrum of melphalan in alcohol (10 mcg./ml.). Beckman model DK-2A spectrophotometer.

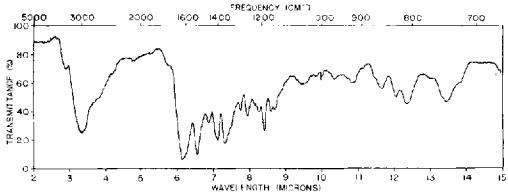

Fig. 2.—Infrared spectrum of melphalan in potassium bromide disk (0.5%). Perkin-Elmer model 21 spectrophotometer; sodium chloride prism.

DOSAGE FORMS OF MELPHALAN

Melphalan Tablets

Identity Tests.—Transfer 2 ml. of the assay solution (5 mg. of melphalan in 100 ml.) into a glass-stoppered test tube and add 1 ml. of U.S.P. phthalate buffer, pH 4.0, 1 ml. of a 5 in 100 solution of 4-(*p*-nitrobenzyl) pyridine (NBP) in acetone, and 1 ml. of saline T.S. Heat on a water bath at 80° for 20 min. and cool the solution quickly. Add 10 ml. of alcohol and 1 ml. of 0.1 *N* potassium hydroxide: a violet to red-violet color is produced.

Assay.—*Standard Preparation.*—Transfer about 10 mg. of melphalan reference standard, accurately weighed, to a 100-ml. volumetric flask, dissolve in alcohol, dilute to volume with alcohol, and mix. Transfer 10.0 ml. of this solution to a second 100-ml. volumetric flask, dilute to volume with alcohol, and mix.

Procedure.—Weigh and finely powder not less than 20 melphalan tablets. Transfer to a 100-ml. volumetric flask an amount of powdered tablets, accurately weighed, equivalent to about 5 mg. of melphalan. Add 10 ml. of water, swirl the sample, then add 10 ml. of alcohol. Warm on a steam bath for about 2 min. with intermittent shaking and cool the solution. Add alcohol to volume and mix. Centrifuge a portion of the mixture, transfer 10.0 ml. of the clear liquid to a 50-ml. volumetric flask, make to volume with alcohol, and mix. Concomitantly, determine the absorbance of this solution and that of the *Standard Preparation* in 1-cm. cells, at the maximum at about 260 mμ with a suitable spectrophotometer, using alcohol as the blank. Calculate the quantity, in mg., of $C_{13}H_{18}Cl_2N_2O_2$ in the portion of the tablets taken by the formula $0.5C\ (A_u/A_s)$, where C is the exact concentration, in mcg./ml., of melphalan in the *Standard Preparation*, calculated on the dried basis, A_u is the absorbance of the solution from the tablets, and A_s is the absorbance of the *Standard Preparation*. The amount of melphalan found is not less than 93.0% and not more than 107.0% of the labeled amount.

DISCUSSION

U.S.P. and N.F. terminologies for solubility, melting range, reagents, etc., have been used wherever feasible.

Melphalan,[1] synthesized by Bergel and Stock (1), is an orally active alkylating agent of the nitrogen mustard class which is useful in the treatment of multiple myeloma. Early literature references to this compound may be found under the synonym sarcolysin.

Identity Tests.—The colorimetric identification of melphalan is based on the procedure of Petering and Van Giessen (2) for the determination of alkylating agents. An additional identification test for melphalan drug is obtained by comparing the absorbances of the alcoholic solution at 226 mμ (minimum) and at 260 mμ (maximum). The ratio A_{226}/A_{260} is about 0.15.

Quantitative Methods.—Argentimetric determination of melphalan gave an average value of 95.7 ± 0.2%.[2] The titration was conducted using a silver electrode and a calomel electrode modified to contain saturated potassium sulfate solution. A rapid, precise measure of the chloride content may be determined by the oxygen flask method included for butyl chloride, N.F. XII, First Supplement. Analysis of commercial melphalan tablets by the spectrophotometric method gave an average value of 101.7 ± 1.5%.[2]

Anhydrous Lactose in Direct Tablet Compression

By NICHOLAS H. BATUYIOS

The use of anhydrous lactose U.S.P. XVII, tablet grade, as a diluent in direct tablet compression was investigated. It was found that it possesses excellent tableting properties and can be run on a high-speed tablet machine. The placebo and active tablets produced were not affected by elevated temperatures, high humidity, and direct sunlight.

IN TERMS of economics and product stability, direct tablet compression offers distinct advantages over double compression, known also as "slugging," and the wet granulating method (1). Also, direct compression should produce tablets of faster dissolution rates because no colloidal binders, (*e.g.*, starch and gelatin) are used to envelop the granules.

Received December 2, 1965, from the Pharmacy Research Department, McNeil Laboratories, Ft. Washington, Pa.
Accepted for publication April 18, 1966.
The author is grateful to Dr. C. A. Janicki for carrying out the analytical determinations and dissolution rates and to Mr. J. J. Tighe for his technical assistance.

TABLE I.—WEIGHT VARIATION

Random Sample Size	Target Wt.	Sample Mean	S. D.	Coeff. of Variation
100	175.0	174.5[a]	1.1	0.63

[a] The mean ±3 standard deviations included every tablet weight of the sample.

The materials were mixed in a Twin-Shell blender for approximately 15 min. Then the blend was compressed at a weight of 125 mg. on a Stokes 551 tablet machine at various speeds using $^{9}/_{32}$-in. special flat-faced beveled edge, engraved punches. At a speed up to 3500 tablets/min., tablets of excellent quality were produced. When 100 tablets were weighed collectively and individually, it was found that no tablet varied more than ±4.5% from the mean.

	6	99.9	98.7	103.3	102.1	100.1	100.8	97.0

[a] Low. [b] High.

There are several tablet diluents commercially available that can be compressed directly (1–3). Because of high cost, physical and chemical properties, and poor tableting characteristics, they have only limited use.

In this laboratory, it was found that anhydrous lactose[1] U.S.P. XVII, tablet grade, possesses excellent flow and compression properties. It produces highly elegant tablets on a high-speed rotary tablet machine without requiring induced feeding and/or metered hoppers. It contains no more than 1.0% free and bound moisture, and its price is comparable to spray-dried lactose.

EXPERIMENTAL

Anhydrous Lactose Particle Size

	Sieve Analysis Mesh Size	%
Retained on:	40	0
	60	13.3–14.1
	80	22.2–24.5
	100	15.4–16.7
	200	26.5–28.7
Through:	200	16.7–21.6

Formulations

Several small experimental batches indicated that anhydrous lactose U.S.P. XVII, tablet grade, has good tableting characteristics. Therefore, in order to fully determine its tableting properties, a placebo batch of approximately 500,000 tablets of the following composition was made:

Formulation I

	%
Anhydrous lactose U.S.P., tablet grade	89.25
Starch U.S.P.	10.00
Calcium stearate U.S.P.	0.75

[1] Marketed by Sheffield Chemical.

Samples of tablets were placed at 50°, 80% R. H. at R. T. and sunlight for 6 weeks. No significant change with respect to color, hardness, and disintegration time was found.

When results indicated that a satisfactory placebo tablet could be made, then the following active formulations of 200,000 tablets each were made:

Formulations II, III, IV, and V

	per tablet, mg. II	III	IV	V
McN-JR-2498[2] hydrochloride	0.5	1.0	2.0	5.0
Anhydrous lactose U.S.P. XVII	155.7	155.2	154.2	151.2
Starch U.S.P.	17.5	17.5	17.5	17.5
Calcium stearate U.S.P.	1.3	1.3	1.3	1.3
	175	175	175	175

The active ingredient was passed through a 100-mesh screen and mixed with the inert materials in a 2-cu. ft. Twin-Shell blender for 30 min. The blend was compressed on a Stokes B-2 tablet machine at a speed of 44 r.p.m. A set of four special, flat oval, engraved punches was used (only four punches were available). No attempt was made to control the humidity during the compression of the four formulations which was done over a period of 2 months.

In all formulations tablets of excellent quality were obtained. All formulations were subjected to various tests, and the results were satisfactory. Formulation III, containing 1 mg. active ingredient per tablet, was tested more extensively, and the results are reported below. The solubility of McN-JR-2498 hydrochloride in water is 5 mg./ml.

Test Methods

Moisture Contents.—Moisture content was determined on a Cenco moisture balance operating at

[2] A No. code designation for trifluperido

120 v. with a 125-w. infrared lamp. The test was continued until a constant weight was reached at 50°.

Hardness.—Hardness was determined by the Strong-Cobb Arner hardness tester.

Friability.—Friability was measured with a Roche Friabilator using a 4-min. cycle and at least a 6.0-Gm. tablet sample.

Disintegration.—Disintegration time was determined using water and the U.S.P. apparatus; no disks were used.

Dissolution Rates.—The dissolution rate was determined in a 1-L. three-necked round-bottom flask fitted with a mechanical stirrer and a 7.5-cm. Teflon stirring paddle. The stirring paddle was adjusted to 2.5–3.5 cm. above the bottom of the flask and the stirring rate was maintained at 50 r.p.m. The flask contained 750 ml. of fluid and was immersed in a constant-temperature water bath maintained at 37° ± 0.1°. Each run consisted of 15 tablets and a Swinny hypodermic adapter filter was used for sampling. The fluids used were U.S.P. simulated gastric fluid without pepsin and U.S.P. simulated intestinal fluid without pancreatin.

Sieve Analysis.—Sieve analysis was done on a Cenco-Meinzer sieve shaker operating at 115 v. 50/60 cycles and at a setting of No. 5. Harshaw Scientific 5-in. diameter sieves were employed. A 100-Gm. sample per determination was used, and the range reported represents three determinations.

Table III.—Dissolution Rates

% McN-JR-2498 Released in Modified, Simulated Gastric Fluid

1/2	25.3
1	31.9
2	42.0
2 3/4	47.4
5	61.8
7	72.0

DISCUSSION

The placebo batch showed that this anhydrous lactose formulation can be run on a high-speed tablet machine, using 9/32-in. special, flat-faced beveled edge, engraved punches, producing excellent tablets. Also, the four batches containing up to 5 mg. of active ingredient per tablet produced tablets

[a] The 50° sample and the 80% R. H. sample were tested immediately upon removal from their respective stations and after standing at R. T. for approximately 2 hr. The results were the same. [b] NSC, no significant change. [c] NC, no change.

of excellent quality using special, flat oval, engraved punches.

The criteria used in evaluating the tablets were appearance, distribution of active ingredient, weight uniformity, friability, binding, sticking, capping, hardness, disintegration time, dissolution rates, and the effects of elevated temperatures, high humidity, and sunlight. No attempt was made to control the relative humidity during compression which took place over a period of approximately 2 months.

The data in Table I show excellent tablet weight uniformity. Table II shows that the active material was uniformly distributed and that no separation occurred during a 3-day compression period. Table III shows that the dissolution rates in simulated gastric fluid were not affected by high temperature. In simulated intestinal fluid the tablets disintegrated in 3–4 min., but the dissolution rates were slow due to poor solubility of the active compound at pH 7.5 (0.06 mg./ml.). Table IV shows that the tablets were not affected chemically or physically by high temperature, high humidity, and direct sunlight. Assays not reported here on tablets exposed to sunlight and high humidity showed good stability. The tablet color did not change significantly after 12 weeks at 50°. A very slight off-white color developed which could be detected only when the room temperature and the 50° samples were observed together.

SUMMARY

1. Placebo and active tablets were made by direct compression using anhydrous lactose U.S.P. XVII, tablet grade, as a diluent.

2. A placebo batch of approximately 500,000 tablets was run at a speed of 3500 tablets/min. on a Stokes 551 tablet machine resulting in excellent tablets. Special $^{9}/_{32}$-in. flat beveled edge, engraved punches were used.

3. Four batches of 200,000 tablets each, containing 0.5, 1, 2, and 5 mg. active material per tablet, were made using a set of four special, flat oval, engraved punches, on a stokes B-2 tablet machine at a speed of 44 r.p.m.

4. The placebo and active tablets were excellent as shown by the elegance, small tablet weight variation, uniform distribution of the active ingredient, fast disintegration and dissolution rates, good hardness, low friability, and lack of binding, sticking, and capping.

5. No induced feeding and/or metered hoppers were required.

6. Physical and chemical stability studies showed that high temperature, high humidity, and direct sunlight had no effect on the formulations.

Quantitative Determination of Iodochlorhydroxyquin by Infrared Analysis

By T. URBÁNYI, D. SLONIEWSKY, and F. TISHLER

A quantitative infrared procedure for the determination of iodochlorhydroxyquin and its intermediates is described. The method is based on measurements of absorption in the 14.4 and 14.9 μ regions of a carbon disulfide solution of the compound. By measurements at other wavelengths in the infrared region, 5,7-diiodo-8-hydroxyquinoline, 5-chloro-8-hydroxyquinoline, and 5,7-dichloro-8-hydroxyquinoline, present as impurities, can also be quantitatively determined.

THE OFFICIAL U.S.P. XVII procedure (1) for the determination of iodochlorhydroxyquin, based on halogen content, suffers from the fact that the method frequently does not distinguish between the parent compound and its intermediates, which may occur as contaminants. The thin-layer chromatographic procedure of Korzun, Brody, and Tishler (2) offers a semiquantitative method for the determination of iodochlorhydroxyquin; however, 5,7-dichloro-8-hydroxyquinoline, which was found in many of the commercial samples examined, cannot be separated from iodochlorhydroxyquin by this method. Until now, phase solubility has been the only quantitative technique available for determining the absolute purity of iodochlorhydroxyquin. This procedure, although accurate and specific, is time consuming.

Bigeard *et al.* (3) have recently developed an infrared spectrophotometric method for the semiquantitative determination of iodochlorhydroxyquin

Quantitative Determination of Iodochlorhydroxyquin by Infrared Analysis

By T. URBÁNYI, D. SLONIEWSKY, and F. TISHLER

A quantitative infrared procedure for the determination of iodochlorhydroxyquin and its intermediates is described. The method is based on measurements of absorption in the 14.4 and 14.9 μ regions of a carbon disulfide solution of the compound. By measurements at other wavelengths in the infrared region, 5,7-diiodo-8-hydroxyquinoline, 5-chloro-8-hydroxyquinoline, and 5,7-dichloro-8-hydroxyquinoline, present as impurities, can also be quantitatively determined.

THE OFFICIAL U.S.P. XVII procedure (1) for the determination of iodochlorhydroxyquin, based on halogen content, suffers from the fact that the method frequently does not distinguish between the parent compound and its intermediates, which may occur as contaminants. The thin-layer chromatographic procedure of Korzun, Brody, and Tishler (2) offers a semiquantitative method for the determination of iodochlorhydroxyquin; however, 5,7-dichloro-8-hydroxyquinoline, which was found in many of the commercial samples examined, cannot be separated from iodochlorhydroxyquin by this method. Until now, phase solubility has been the only quantitative technique available for determining the absolute purity of iodochlorhydroxyquin. This procedure, although accurate and specific, is time consuming.

Bigeard *et al.* (3) have recently developed an infrared spectrophotometric method for the semiquantitative determination of iodochlorhydroxyquin

Received February 24, 1966, from the Research Department, Ciba Pharmaceutical Co., Summit, N. J.
Accepted for publication May 4, 1966.
The authors acknowledge Miss M. Pagliery and Mr. H. Hagman for assistance in carrying out some of the analyses.

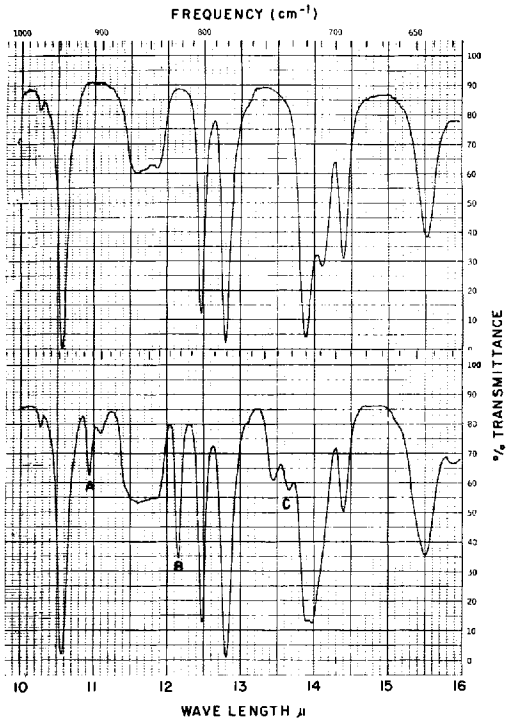

Fig. 1.—Infrared spectrum of iodochlorhydroxyquin (upper curve). Iodochlorhydroxyquin adulterated with: A, 5,7-diiodo-8-hydroxyquinoline; B, 5-chloro-8-hydroxyquinoline; C, 5, 7-dichloro-8-hydroxyquinoline (lower curve).

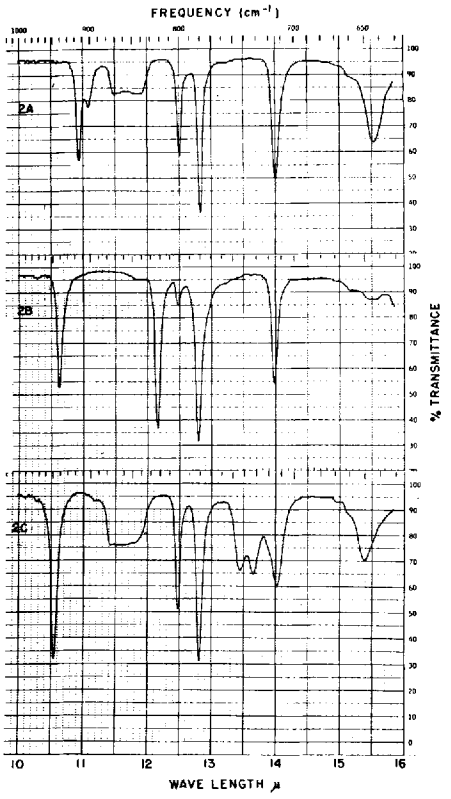

Fig. 2.—Infrared spectrum of: 2A, 5,7-diiodo-8-hydroxyquinoline; 2B, 5-chloro-8-hydroxyquinoline; 2C, 5,7-dichloro-8-hydroxyquinoline.

and its intermediates. The method, however, not only suffers from the typical experimental problems which arise in the potassium bromide disk technique, but also requires an infrared spectrophotometer capable of measurements in the far infrared region.

The modified infrared method described below fulfills the desired requirements for an analytical method—namely, specificity, rapidity, accuracy, and precision.

EXPERIMENTAL

All compounds used in this study were pure as determined by either phase solubility or by thin-layer chromatography. The infrared spectra were recorded on a Beckman I.R. 5 spectrophotometer and a Perkin-Elmer I.R. 621 spectrophotometer using reagent grade carbon disulfide as the solvent.

A calibration curve for the iodochlorhydroxyquin was prepared by dissolving various concentrations (2–10 mg./ml.) of the compound in carbon disulfide. The per cent transmittance at 14.4 and 14.9 μ was determined *versus* a carbon disulfide blank using 3-mm. cells equipped with sodium chloride plates. The ratios $[(T_{14.4\ \mu}/T_{14.9\ \mu}) \times 10]$ were calculated and the values plotted on the ordinate axis of 1-cycle semilogarithmic paper *versus* concentration. In a similar manner, calibration curves were prepared for 5,7-dichloro-8-hydroxyquinoline $[(T_{13.45\ \mu}/T_{15.25\ \mu}) \times 10]$, 5-chloro-8-hydroxyquinoline $[T_{12.15\ \mu}/TA\mu) \times 10]$,[1] and 5,7-diiodo-8-hydroxyquinoline $[(T_{10.95\ \mu}/TB\mu) \times 10]$.[1] A 0.5% solution of the sample in carbon disulfide was used in the spectrophotometric analysis of the synthetic mixtures and commercial samples. The phase solubility analyses were carried out in a nitrogen atmosphere using redistilled benzene as the solvent (4).

[1] A and B represent the transmittance readings at wavelengths 12.15 and 10.95 μ which are determined by the base line technique for the respective compounds.

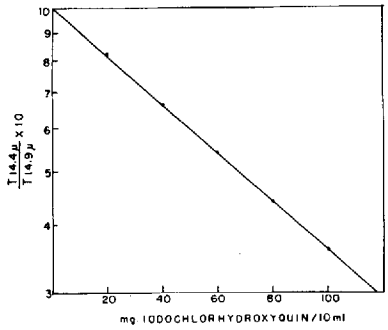

Fig. 3.—Linearity plot for iodochlorhydroxyquin.

DISCUSSION

A qualitative infrared examination of samples of iodochlorhydroxyquin U.S.P. currently on the market indicated the presence of the following impurities: 5,7-diiodo-8-hydroxyquinoline, 5,7-dichloro-8-hydroxyquinoline, and 5-chloro-8-hydroxyquinoline.

TABLE I.—ANALYSIS OF SYNTHETIC MIXTURES USING THE BECKMAN I.R. 5

Compd.	Mixture 1		Mixture 2	
	Added, %	Found, %	Added, %	Found, %
5-Chloro-8-hydroxyquinoline	3.0	2.85	5.0	5.2
5,7-Dichloro-8-hydroxyquinoline	3.0	2.80	5.0	5.0
5,7-Diiodo-8-hydroxyquinoline	3.0	2.70	5.0	5.5
Iodochlorhydroxyquin	91.0	89.0	85.0	84.0

TABLE II.—COMPARISON OF INFRARED AND PHASE SOLUBILITY METHODS

Manufacturer	Iodochlorhydroxyquin Content		
	I.R. 5, %	I.R. 621, %	Phase Solubility, %
Synthetic mixture[a]	89	90	90
A[b]	97	99	100
B	96	97	98
C[c]	60[d]	...	70
D	38	...	38
E	30	...	...

[a] Synthetic mixture contains 9% impurity. [b] Samples A and B are typical production batches prepared at Summit, N. J., and Basle, Switzerland. [c] Samples C, D, and E represent material sold as U.S.P. iodochlorhydroxyquin. [d] Insoluble material present.

5-Iodo-8-hydroxyquinoline was not observed in any samples and is not considered to be an important contaminant. The same technique described below can be used, however, for its determination.

The infrared spectrum between 10 and 16 μ for phase solubility pure iodochlorhydroxyquin is shown in the upper curve of Fig. 1. A sample of pure iodochlorhydroxyquin adulterated with 20%, 5,7-dichloro-8-hydroxyquinoline, 10% 5-chloro-8-hydroxyquinoline, and 20% 5,7-diiodo-8-hydroxyquinoline is shown in the lower curve of this figure. The infrared spectra of the three intermediates, 5,7-diiodo-8-hydroxyquinoline (2A), 5-chloro-8-hydroxyquinoline (2B), and 5,7-dichloro-8-hydroxyquinoline (2C) are shown in Fig. 2. It is quite obvious from Fig. 1 that the intermediates have a great effect on the spectrum of the pure material, especially at 10.95 μ (diiodo-), 12.15 μ (monochloro-), 13.45 μ (dichloro-), and 14.4 μ (iodochlorhydroxyquin).

Examination of the spectra of solutions of iodochlorhydroxyquin shows that the intensity of the absorption band occurring at 14.4 μ decreases as the amounts of impurities present increase. It can be seen from Fig. 2 that the three intermediates exhibit no significant absorption at this wavelength. Semilogarithmic plots of the ratio of per cent transmittance at 14.4 μ/per cent transmittance at 14.9 μ *versus* concentration of iodochlorhydroxyquin are linear. Figure 3 shows this relationship. Although similar plots are not shown for the three intermediates, they also exhibited linearity.

Even though the plots are linear over a wide range of concentration, it was observed that the most reproducible results were obtained in the range of 40–60% transmittance. It was found that samples containing these intermediates in substantial amounts were not soluble to the extent of 1% in carbon disulfide. They did give clear solutions, however, at a concentration of 0.5%. In order to maintain the absorption of the 14.4 μ band in the transmittance range of 40–60%, a light path of 3 mm. was employed.

In order to determine the accuracy of the procedure, synthetic mixtures were prepared and analyzed spectrophotometrically as described. The results appear in Table I.

Samples of U.S.P. quality iodochlorhydroxyquin from various commercial sources were analyzed using a Beckman I.R. 5 spectrophotometer and a Perkin Elmer I.R. 621 spectrophotometer. These results were compared with phase solubility analyses and are shown in Table II.

It can be seen from Table II that the accuracy of the method is increased if a more accurate and better resolving infrared spectrophotometer is used. In the case of the I.R. 5 spectrophotometer the accuracy is ±3% and with the I.R. 621 spectrophotometer, ±1%.

Analysis of samples C, D, and E by the current U.S.P. XVII procedures for chlorine and iodine and identity showed that two of the three samples passed all tests and could be considered of U.S.P. quality, even though they contain 60% or less of iodochlorhydroxyquin as determined by infrared measurements.

Since it has been demonstrated that iodochlorhydroxyquin may contain considerable amounts of intermediates as impurities and still meet present U.S.P. specifications, it is apparent that a more specific method of determination of purity of iodochlorhydroxyquin is necessary. The infrared procedure described provides a rapid, highly specific, and quantitative method for this purpose.

Quantitative Determination of Hexachlorophene in Ointments Containing Salicylic Acid and Methyl *p*-Hydroxybenzoate

By RHYS BRYANT, DONALD E. MANTLE, and DAVID S. YODER

Hexachlorophene in ointments is determined spectrophotometrically by the "difference" method after selective removal of all interfering components.

THE PRESENTLY available colorimetric (1, 6–10, 14, 15) and spectrophotometric (2–5, 11, 12) methods for quantitative estimation of hexachlorophene [2,2′-methylenebis(3,4,6-trichlorophenol)] are unsuitable for the determination of hexachlorophene in ointment preparations containing both salicylic acid and methyl *p*-hydroxybenzoate.

The colorimetric method using 4-aminoantipyrine requires the color complex to be in aqueous solution (6). In the case of sulfur-containing ointments, the sulfur remains suspended[1] in the aqueous solution and causes considerable interference (*cf. Reference 13*).

Attempts to remove salicylic acid from both ether and chloroform extracts of the ointments with sodium bicarbonate resulted in emulsion formation. The emulsions were extremely stable and permitted only a 50% recovery of hexachlorophene.

To measure the absorbance of hexachlorophene at 257.5 mμ, where the absorbance of salicylic acid is independent of pH change (5), would result in interference due to methyl *p*-hydroxybenzoate, which absorbs (5) at 257 mμ in pH 7.5 buffer.

A procedure for hexachlorophene assay which overcomes the above difficulties is reported here. The organic components of the ointments are extracted into ether from a methanol–aqueous sodium chloride suspension which suppresses emulsion formation. The salicylic acid is removed selectively into pH 8 buffer, and the methyl *p*-hydroxybenzoate saponified. The hexachlorophene may then be measured spectrophotometrically by the "difference" method (2, 5), with no interference from other components.

EXPERIMENTAL

Apparatus.—A Cary model 14M was used in this work.

Reagents.—All solutions are aqueous unless otherwise specified. The hexachlorophene standard solution is prepared by dissolving 100 mg. of hexachlorophene U.S.P. in 100 ml. of methanol.

Procedure.—A quantity of ointment containing 2 mg. of hexachlorophene was weighed into a 125-ml. separator and shaken with 15 ml. of methanol. Fifteen milliliters of 7% sodium chloride was added to the solution which, after cooling to room temperature, was extracted with 25 ml. of ether. The aqueous-methanol layer was re-extracted with 25 ml. of ether in a second 125-ml. separator. Each ether extract was washed by allowing 1 ml. of 7% sodium chloride to pass through the ether layer without shaking. After draining and discarding the sodium chloride layer, 1 ml. of 35% sodium chloride and 10 ml. of pH 8 Clark and Lubs buffer were added to each ether extract. Each separator was shaken gently, and the aqueous layers were combined in a single 125-ml. separator. After extracting the aqueous layer with 25 ml. of ether, the aqueous portion was discarded. The three ether extracts obtained were combined into a 100-ml. volumetric flask and evaporated to dryness. The residue was dissolved in 5 ml. of methanol and 10 ml. of 1 *N* sodium hydroxide and the solution heated at 75° for 30 min. The solution was cooled, diluted to volume with methanol, and filtered. Exactly 20 ml. of the solution was placed in a 25-ml. volumetric flask and diluted to volume with methanol. This solution was placed in the sample cell of the spectrophotometer. Another 20 ml. of the solution was placed in a second 25-ml. volumetric flask and diluted to volume with 1 *N* methanolic hydrochloric acid. This solution was placed in the reference cell of the spectrophotometer and the maximum differential ultraviolet absorbance of hexachlorophene measured at 320 mμ. The concentration of hexachlorophene was determined by comparison with a standard hexachlorophene solution which had been carried through the above procedure beginning with the methanol–1 *N* sodium hydroxide treatment.

DISCUSSION

The presence of fairly large quantities of surfactant in ointments resulted in incomplete extraction of hexachlorophene due to formation of stable emulsions. When the extractions were preceded by treatment with sodium chloride–methanol, a quantitative separation of the hexachlorophene was obtained. Attempts to separate the salicylic acid using sodium carbonate or sodium bicarbonate were unsuccessful due to emulsion formation and concomitant loss of hexachlorophene.

The saponification of methyl *p*-hydroxybenzoate is necessary for the quantitative estimation of the hexachlorophene. The maximum absorbance of methyl *p*-hydroxybenzoate both at pH 0.8 (the pH of the final methanolic acid solution) and at pH 11.5 (the pH of the final alkaline methanol solution) is 298 mμ, and the hexachlorophene absorption is seen only as a shoulder on the larger methyl *p*-hydroxybenzoate peak. Sodium *p*-hydroxybenzoate in methanolic solution at pH 11.5, when read using the "difference" method against the acid solution at pH 0.8, absorbs at 286 mμ. This hypsochromic shift is sufficient to separate completely the *p*-hydroxybenzoate absorption from that of the hexachlorophene, which can then readily be measured. The use of acidified 90% methanol suggested in U.S.P. XVII (16) was precluded for the following reason: it was necessary to hydrolyze the methyl *p*-hydroxybenzoate with strong alkali. Neutralization of the solution with acidified 90% methanol gave a final solution of pH 7.7. At this pH, the higher absorbance of the *p*-hydroxybenzoate inter-

[1] The reviewer of the manuscript suggests the use of 2-oz. stainless steel syringes fitted with disposable membrane holders for the removal of sulfur by membrane filtration. This is an excellent suggestion, although it was not used in this case.

fered with the hexachlorophene absorbance. The wavelength of hexachlorophene absorbance is pH dependent. In the system reported here (pH 0.8/11.5), the absorbance was at 320 mμ. Using the U.S.P. XVII buffer–acid system, the absorbance is at 312 mμ, causing slight interference with the *p*-hydroxybenzoate absorbance.

RESULTS

The recovery of standard hexachlorophene carried through this method was 99 ± 2%. The accuracy and reproducibility of the spectrophotometric "difference" method have already been well documented (5).

Identification of 1-, 2-, 3-, and 4-Chlorophenothiazine Isomers

By I. B. EISDORFER, R. J. WARREN, W. E. THOMPSON, and J. E. ZAREMBO

The infrared and ultraviolet spectral data for four monochloroisomers of phenothiazine are presented and discussed. From these data it is possible to make a positive and rapid identification of any of the isomers with a minimum amount of sample. The method can be used to identify the isomers alone or in combination.

THE PRESENCE of isomers in the preparation of chlorinated phenothiazines is always a possibility. The problem of determining the presence of an isomer and identifying the specific isomer present is a frequent analytical problem. A simple, rapid method for identifying the 1-, 2-, 3-, and 4-chlorophenothiazine isomers is presented.

EXPERIMENTAL

Reagents. — 1 - Chlorophenothiazine, 2-chlorophenothiazine, 3-chlorophenothiazine, and 4-chlorophenothiazine. All chemicals are of analytical grade as prepared at Smith Kline & French Laboratories.

Spectrophotometers.—The infrared spectra were recorded with a Perkin-Elmer model 21 double beam spectrophotometer with a sodium chloride prism. The phenothiazines studied were prepared as mineral oil mulls.

The ultraviolet spectra were recorded with a Cary model 14 recording spectrophotometer using matched fused silica cells with a 1-cm. light path.

RESULTS AND DISCUSSION

Infrared Spectra.—Figure 1 shows the infrared spectra obtained for the four chlorophenothiazine isomers. The area of greatest interest is the region between 1000 and 650 cm.$^{-1}$. This is the region which contains absorption bands due to C–H out-of-plane deformations in aromatic ring systems. Each of the isomers has its own unique pattern in this area owing to the particular position of the chlorine atom on the ring. The infrared pattern here is specific enough to distinguish one isomer from another, and the absorption bands are so located as to permit detection of one or more isomers in the presence of another.

Spectrum A, which is that of the 1-chloro isomer, shows strong absorption bands between 770 and 700 cm.$^{-1}$ which are assignable to 3 and 4 adjacent free hydrogen atoms in an aromatic ring (1). Spectrum B is that of the 2-chloro isomer with absorption

Identification of 1-, 2-, 3-, and 4-Chlorophenothiazine Isomers

By I. B. EISDORFER, R. J. WARREN, W. E. THOMPSON, and J. E. ZAREMBO

The infrared and ultraviolet spectral data for four monochloroisomers of phenothiazine are presented and discussed. From these data it is possible to make a positive and rapid identification of any of the isomers with a minimum amount of sample. The method can be used to identify the isomers alone or in combination.

THE PRESENCE of isomers in the preparation of chlorinated phenothiazines is always a possibility. The problem of determining the presence of an isomer and identifying the specific isomer present is a frequent analytical problem. A simple, rapid method for identifying the 1-, 2-, 3-, and 4-chlorophenothiazine isomers is presented.

EXPERIMENTAL

Reagents. — 1 - Chlorophenothiazine, 2-chlorophenothiazine, 3-chlorophenothiazine, and 4-chlorophenothiazine. All chemicals are of analytical grade as prepared at Smith Kline & French Laboratories.

Spectrophotometers.—The infrared spectra were recorded with a Perkin-Elmer model 21 double beam spectrophotometer with a sodium chloride prism. The phenothiazines studied were prepared as mineral oil mulls.

The ultraviolet spectra were recorded with a Cary model 14 recording spectrophotometer using matched fused silica cells with a 1-cm. light path.

RESULTS AND DISCUSSION

Infrared Spectra.—Figure 1 shows the infrared spectra obtained for the four chlorophenothiazine isomers. The area of greatest interest is the region between 1000 and 650 cm.$^{-1}$. This is the region which contains absorption bands due to C–H out-of-plane deformations in aromatic ring systems. Each of the isomers has its own unique pattern in this area owing to the particular position of the chlorine atom on the ring. The infrared pattern here is specific enough to distinguish one isomer from another, and the absorption bands are so located as to permit detection of one or more isomers in the presence of another.

Spectrum A, which is that of the 1-chloro isomer, shows strong absorption bands between 770 and 700 cm.$^{-1}$ which are assignable to 3 and 4 adjacent free hydrogen atoms in an aromatic ring (1). Spectrum B is that of the 2-chloro isomer with absorption

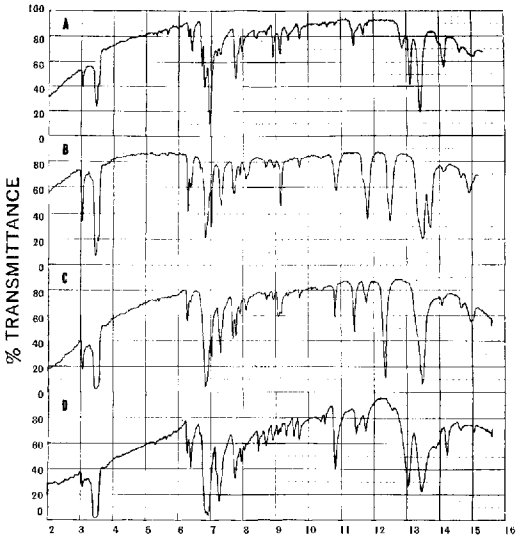

Fig. 1.—Key: A, 1-chlorophenothiazine; B, 2-chlorophenothiazine; C, 3-chlorophenothiazine; D, 4-chlorophenothiazine.

Received February 21, 1966, from Smith Kline & French Laboratories, Philadelphia, Pa.
Accepted for publication May 10, 1966.
The authors are grateful to Mr. Alex Pavloff and Mr. Arnold Krog of these laboratories for the samples of the phenothiazines discussed here.

bands at 750, 800, 825, and 920 cm.$^{-1}$ which are assignable to a 2-substituted phenothiazine (2). Spectrum C is the 3-chloro isomer with absorption bands at 750, 810, 850, 875, and 925 cm.$^{-1}$ which are all assignable to 4 and 2 adjacent free hydrogen atoms and one free hydrogen atom on an aromatic ring (1). Spectrum D is the 4-chloro isomer with strong absorption bands at 740 and 765 cm.$^{-1}$ which are in agreement with out-of-plane bending vibrations of 3 and 4 adjacent free hydrogen atoms on an aromatic ring system (1). From these infrared data it is possible not only to identify each isomer alone but also in combination with the other three isomers. An illustration of how these data may be used to identify the isomers in combination is shown in Fig. 2. Spectrum A is that of 2-chlorophenothiazine. Spectrum B is a mixture containing 6% of 3-chlorophenothiazine. Spectrum C is the spectrum of a 10% mixture of the 3-isomer in 2-chlorophenothiazine. There is no absorption whatever at 11.45 μ in the 2-chloro isomer but in the spectra of both mixtures an absorption band at 11.45 μ is noted. This band is due to the presence of the 3-chloro isomer (see spectrum C in Fig. 1). Preparation of a series of standards or mixtures of known concentrations makes it possible to prepare a calibration curve from which quantitative data and minor components could be derived.

The infrared spectra of the four isomers complements the ultraviolet data which follow and is very valuable indeed in identifying chromatographic fractions from gas chromatography or spots from thin-layer or paper chromatography. It also provides a rapid means of identification of isomers in a given preparation of chlorinated phenothiazines.

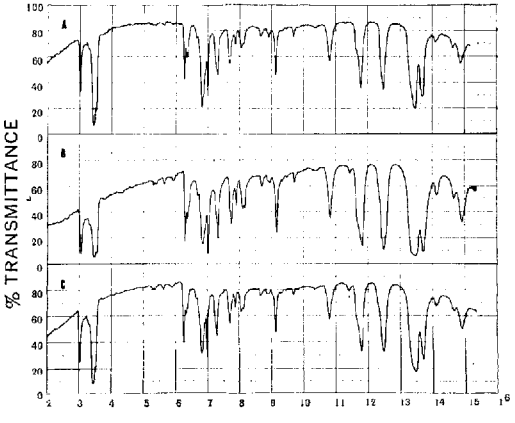

Fig. 2.—Key: A, 2-chlorophenothiazine; B, 6% 3-chlorophenothiazine in 2-chlorophenothiazine; C, 10% 3-chlorophenothiazine in 2-chlorophenothiazine.

Ultraviolet Spectra.—Table I lists the ultraviolet maxima and corresponding log ϵ values for the four

TABLE I.—U.V. SPECTRAL DATA FOR CHLOROPHENOTHIAZINES[a]

chloro isomers. The effect of the position of the chlorine on the ring can readily be seen in the various wavelength shifts. The infrared data complemented by these ultraviolet data for the isomers make possible a quantitative estimation of the amount of various isomers present in a given preparation.

SUMMARY

Data are given to show that 1-, 2-, 3-, and 4-chlorophenothiazines each possess a unique infrared and ultraviolet spectrum. This information provides a basis for determining the presence or absence of isomers in a given preparation of chlorinated phenothiazine.

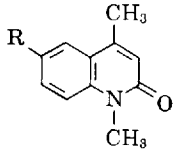
Nitration of 1,4-Dimethyl-2-quinolone and 1,2-Dimethyl-4-quinolone

By I. NABIH and M. NASR

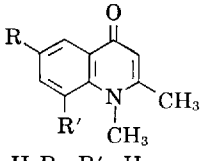
Nitration occurred at position 6 in 1,4-dimethyl-2-quinolone and at 6 and 8 in 1,2-dimethyl-4-quinolone. Structures were confirmed by alternate synthesis.

EXTENSIVE work has been carried out on the nitration of quinolines (1). In the case of quinolones, nitration of 1 - methyl - 2 - quinolone with nitric and sulfuric acids has given 6-nitro-1-methyl-2-quinolone, which on further nitration gave 3,6,8 - trinitro - 1 - methyl - 2 - quinolone (2, 3). 1-Methyl-4-quinolone has been treated with 68% nitric acid to give 3 - nitro - 1 - methyl - 4 - quinolone, and further nitration led to 3,6-dinitro-1-methyl-4-quinolone (4). 1,4-Dimethyl-2-quinolone (I) has been treated with an excess of fuming nitric acid to give a mixture of compounds tentatively assigned the structures of 6-nitro-1,4-dimethyl-2-quinolone (III) and 3,6,8-trinitro-1, 4-dimethyl-2-quinolone (5). The purpose of the present work was to establish structure III, and also to carry out similar studies on the nitration of 1,2-dimethyl-4-quinolone (II) and to establish the structures of the nitration products. Their assignments were mainly dependent upon using compounds of accurate structural assignment as possible starting materials.

Thus, compound III was identified through the preparation of 6-nitro-2-hydroxy-4-methylquinoline (6), which upon treatment with methyl iodide and potassium methoxide gave 6-nitro-1,4-dimethyl-2-quinolone which is identical with III (as shown by mixed melting point).



I, R = H
III, R = NO_2
IV, R = NH_2



II, R = R′ = H
V, R = R′ = NO_2
VI, R = NO_2, R′ = H

NMR spectra were determined for both I and II. The vinyl hydrogen at the 3-position appears in both spectra as a singlet at 3.65 τ and 4.1 τ, respectively, while the aromatic hydrogens in I appeared at 2.8 τ. They split into separate peaks in the spectrum of III at 3.2 τ and 2.3 τ. These correspond to the hydrogen atoms at the 5-position and 7- and 8-positions as shown from their integration values, but the signal arising from the vinyl hydrogen at the 3-position (3.65 τ) remained unchanged, an indication of nonsubstitution at that position.

Reduction of III with stannous chloride and hydrochloric acid led to 6-amino-1,4-dimethyl-2-quinolone (IV).

Nitration of 1,2-dimethyl-4-quinolone (II) in sulfuric–nitric acid medium led to substitution at both the 6- and 8-positions to give V, the structure of which was assigned by alternative synthesis.

6-Nitro-1,2-dimethyl-4-quinolone (VI) was prepared by the action of dimethyl sulfate in an alkaline solution of 6-nitro-2-methyl-4-hydroxyquinoline (7), and further nitration of VI gave 6,8-dinitro-1,2-dimethyl-4-quinolone, which was identical with V. 8-Nitro-2-methyl-4-hydroxyquinoline (8), when subjected to further nitration, led to the 6,8-dinitro derivative, which upon treatment with dimethyl sulfate in an alkaline medium gave V.

EXPERIMENTAL

All melting points are uncorrected and measured on Kofler hot stage.

6 - Nitro - 1,4 - dimethyl - 2 - quinolone (III).—*Method A.*—To a solution of 1,4-dimethyl-2-quinolone (9) (3 Gm., 0.017 mole) in 10 ml. of concentrated sulfuric acid was added 5 ml. of nitric acid (d. 1.42) mixed with 15 ml. of concentrated sulfuric acid, while the temperature was kept at 0°. The reaction mixture was kept for 24 hr. at room temperature, and when poured onto crushed ice, a yellow precipitate formed, m.p. 223–225°. Recrystallization from ethanol gave 3.46 Gm. (90% yield) of III, m.p. 225–227°. [Lit. m.p. 228.5–229° (7).]

Anal.—Calcd. for $C_{11}H_{10}N_2O_3$: C, 60.55; H, 4.59; N, 12.84. Found: C, 60.51; H, 4.75; N, 12.89.

Method B.—To a mixture of 6-nitro-4-methyl-2-hydroxyquinolone (8) (2.04 Gm., 0.01 mole) in 10 ml. of 2 *N* potassium methoxide and 15 ml. of absolute methyl alcohol was added 4 Gm. of methyl iodide. The mixture was heated under reflux for 3 hr., then allowed to cool overnight. The precipitated potassium iodide was separated, the filtrate was diluted with water and made alkaline by addition of sodium hydroxide solution, and a yellow substance precipitated, m.p. 224–225°. Recrystallization from ethanol gave m.p. 225–227° which was undepressed on admixture with an authentic sample, prepared by *Method A*.

Anal.—Calcd. for $C_{11}H_{10}N_2O_3$: C, 60.55; H, 4.59; N, 12.84. Found: C, 60.75; H, 4.52; N, 12.96.

6 - Amino - 1,4 - dimethyl - 2 - quinolone (IV).—To a solution of 6-nitro-1,4-dimethyl-2-quinolone (1.88 Gm., 0.01 mole) in glacial acetic acid (15 ml.), was added a solution of stannous chloride (7.5 Gm.) in concentrated hydrochloric acid (10 ml.). The mixture was refluxed for 3 hr., then kept overnight at room temperature. The precipitated stannic chloride was filtered off, and the filtrate was boiled for 20 min. with 50% aqueous sodium hydroxide (25 ml.). The solid so obtained, m.p. 275–277°, was recrystallized from ethanol, m.p. 279–280°.

Anal.—Calcd. for $C_{11}H_{12}N_2O$: C, 70.21; H, 6.39; N, 14.89. Found: C, 70.08; H, 6.35; N, 14.66.

1,2-Dimethyl-4-quinolone (II).—To a solution of

Received January 11, 1966, from the National Research Center, Cairo, Egypt, U. A. R., and the Laboratory of Medicinal Chemistry, University of Michigan, Ann Arbor.

Accepted for publication March 21, 1966.

Abstracted from a thesis submitted by M. Nasr to the National Research Centre, Cairo, Egypt, U. A. R., in partial fulfillment of Master of Science degree requirements.

These studies were supported by contract DA-49-193-MD-2625 from the Medical Research and Development Command, Office of the Surgeon General, U. S. Department of the Army, Washington, D. C., with the University of Michigan, Ann Arbor; No. 65 from the Army research program on malaria.

2-methyl-4-hydroxyquinoline (15.9 Gm., 0.4 mole) in 150 ml. of aqueous potassium hydroxide (5%), was added dimethyl sulfate (8 ml.). After shaking the mixture for 30 min., potassium hydroxide solution (50 ml.) was added with continuous shaking during an additional 30 min. The reaction mixture was kept for 48 hr. at room temperature. The product was extracted with chloroform, then recrystallized several times from benzene to give 2.59 Gm. (15% yield) of II in the form of light-red needles, m.p. 158–160°. [Lit. m. p. 156–160° (10).]

6,8 - Dinitro - 1,2 - dimethyl - 4 - quinolone (V).—To a solution of 1,2-dimethyl-4-quinolone (0.173 Gm.) in sulfuric acid (5 ml.) was added a mixture of nitric acid (1 ml.) and sulfuric acid (3 ml.) by the same method as described for 1,4-dimethyl-2-quinolone (I). The product obtained, m.p. 258°, when recrystallized from ethanol, gave 0.17 Gm. (65% yield) of V, m.p. 259–261°.

Anal.—Calcd. for $C_{11}H_{12}N_3O_5$: C, 49.62; H, 4.51; N, 15.78. Found: C, 50.02; H, 4.45; N, 15.98.

6 - Nitro - 1,2 - dimethyl - 4 - quinolone (VI).—To a solution of 6-nitro-2-methyl-4-hydroxyquinoline (7) (2.04 Gm.) in 50 ml. of aqueous potassium hydroxide (5%) was added dimethyl sulfate (3.3 Gm.). The mixture was stirred at 70° for 30 min. and kept at room temperature overnight. The formed yellow precipitate, m.p. 215°, was recrystallized from hot benzene to give 1.27 Gm. (40% yield) of VI, m.p. 218–220°.

Anal.—Calcd. for $C_{11}H_{10}N_2O_5$: C, 60.55; H, 4.58; N, 12.88. Found: C, 60.37; H, 4.46; N, 12.75.

6,8 - Dinitro - 1,2 - dimethyl - 4 - quinolone (V).—To a solution of 6-nitro-1,2-dimethyl-4-quinolone (VI) (1.5 Gm.) in concentrated sulfuric acid (10 ml.) at 10° was added a mixture of nitric acid (d. 1.42, 1 ml.) and concentrated sulfuric acid (3 ml.). After standing for 24 hr. at room temperature, the mixture was poured onto crushed ice, the isolated product, m.p. 257°, was recrystallized from ethanol to give 1.13 Gm. (90% yield) of V, m.p. 259–261°. It was identical in melting point with an authentic sample of V, and showed no depression of mixed melting point.

Anal.—Calcd. for $C_{11}H_{12}N_3O_5$: C, 49.62; H, 4.51; N, 15.78. Found: C, 49.78; H, 4.62; N, 15.92.

6,8 - Dinitro - 2 - methyl - 4 - hydroxyquinoline.—A solution of 8-nitro-2-methyl-4-hydroxyquinoline (8) (2.04 Gm., 0.01 mole) in concentrated sulfuric acid (10 ml.) was treated with a mixture of nitric acid and sulfuric acid, as described above. The isolated product, m.p. 258°, was recrystallized from ethanol to give 1.85 Gm. of 6,8-dinitro-2-methyl-4-hydroxyquinoline (75% yield), m.p. 247–249°.

Anal.—Calcd. for $C_{10}H_7N_3O_5$: C, 48.19; H, 2.81; N, 16.86. Found: C, 48.21; H, 3.04; N, 16.85.

When this compound was treated with dimethyl sulfate in an alkaline medium, as for the preparation of 6-nitro-1,2-dimethyl-4-quinolone, the isolated product was identical with V, with no depression of the mixed melting point.

N-Aminoalkyl-α-aminoacids and Their Corresponding Ethyl Esters

By TIBERIO BRUZZESE and ELDA CRESCENZI

Fourteen *N*-aminoalkyl-α-aminoacids and their corresponding ethyl esters have been prepared for pharmacological screening. The physicochemical properties and optimal reaction conditions are reported.

DURING RECENT years, α-aminoacid derivatives have been the subject of several studies of biological interest. In particular, Goldin *et al.* (1) have reported that glycine, although free from hypnotic activity, potentiates barbiturate-induced sleep, while Edwards *et al.* (2, 3) have found that the esters of some α-phenylglycines possess good antispasmodic and local anesthetic activity. Furthermore, it has been reported that ethyl esters of *N,N*-disubstituted glycines exert antispasmodic, antihistaminic, and hypotensive activity (4), and that other similar derivatives have been studied in tuberculostatic (5) and herbicidal tests (6).

The present note deals with the preparation of a series of *N*-aminoalkyl-α-aminoacids and their corresponding ethyl esters for submitting to pharmacological screening. In addition, these compounds were useful intermediates for the synthesis of 3-substituted sydnones, as we have recently reported (7).

The esters in question were prepared by alkylation with α-bromo esters of suitable *N*-aminoalkyl-amines. Because of the side reactions resulting from the competitive aminolysis of the ester group (8), the authors studied the synthesis procedure in detail, and found it an advantage to use

2-methyl-4-hydroxyquinoline (15.9 Gm., 0.4 mole) in 150 ml. of aqueous potassium hydroxide (5%), was added dimethyl sulfate (8 ml.). After shaking the mixture for 30 min., potassium hydroxide solution (50 ml.) was added with continuous shaking during an additional 30 min. The reaction mixture was kept for 48 hr. at room temperature. The product was extracted with chloroform, then recrystallized several times from benzene to give 2.59 Gm. (15% yield) of II in the form of light-red needles, m.p. 158–160°. [Lit. m. p. 156–160° (10).]

6,8 - Dinitro - 1,2 - dimethyl - 4 - quinolone (V).—To a solution of 1,2-dimethyl-4-quinolone (0.173 Gm.) in sulfuric acid (5 ml.) was added a mixture of nitric acid (1 ml.) and sulfuric acid (3 ml.) by the same method as described for 1,4-dimethyl-2-quinolone (I). The product obtained, m.p. 258°, when recrystallized from ethanol, gave 0.17 Gm. (65% yield) of V, m.p. 259–261°.

Anal.—Calcd. for $C_{11}H_{12}N_3O_5$: C, 49.62; H, 4.51; N, 15.78. Found: C, 50.02; H, 4.45; N, 15.98.

6 - Nitro - 1,2 - dimethyl - 4 - quinolone (VI).—To a solution of 6-nitro-2-methyl-4-hydroxyquinoline (7) (2.04 Gm.) in 50 ml. of aqueous potassium hydroxide (5%) was added dimethyl sulfate (3.3 Gm.). The mixture was stirred at 70° for 30 min. and kept at room temperature overnight. The formed yellow precipitate, m.p. 215°, was recrystallized from hot benzene to give 1.27 Gm. (40% yield) of VI, m.p. 218–220°.

Anal.—Calcd. for $C_{11}H_{10}N_2O_5$: C, 60.55; H, 4.58; N, 12.88. Found: C, 60.37; H, 4.46; N, 12.75.

6,8 - Dinitro - 1,2 - dimethyl - 4 - quinolone (V).—To a solution of 6-nitro-1,2-dimethyl-4-quinolone (VI) (1.5 Gm.) in concentrated sulfuric acid (10 ml.) at 10° was added a mixture of nitric acid (d. 1.42, 1 ml.) and concentrated sulfuric acid (3 ml.). After standing for 24 hr. at room temperature, the mixture was poured onto crushed ice, the isolated product, m.p. 257°, was recrystallized from ethanol to give 1.13 Gm. (90% yield) of V, m.p. 259–261°. It was identical in melting point with an authentic sample of V, and showed no depression of mixed melting point.

Anal.—Calcd. for $C_{11}H_{12}N_3O_5$: C, 49.62; H, 4.51; N, 15.78. Found: C, 49.78; H, 4.62; N, 15.92.

6,8 - Dinitro - 2 - methyl - 4 - hydroxyquinoline.—A solution of 8-nitro-2-methyl-4-hydroxyquinoline (8) (2.04 Gm., 0.01 mole) in concentrated sulfuric acid (10 ml.) was treated with a mixture of nitric acid and sulfuric acid, as described above. The isolated product, m.p. 258°, was recrystallized from ethanol to give 1.85 Gm. of 6,8-dinitro-2-methyl-4-hydroxyquinoline (75% yield), m.p. 247–249°.

Anal.—Calcd. for $C_{10}H_7N_3O_5$: C, 48.19; H, 2.81; N, 16.86. Found: C, 48.21; H, 3.04; N, 16.85.

When this compound was treated with dimethyl sulfate in an alkaline medium, as for the preparation of 6-nitro-1,2-dimethyl-4-quinolone, the isolated product was identical with V, with no depression of the mixed melting point.

N-Aminoalkyl-α-aminoacids and Their Corresponding Ethyl Esters

By TIBERIO BRUZZESE and ELDA CRESCENZI

Fourteen *N*-aminoalkyl-α-aminoacids and their corresponding ethyl esters have been prepared for pharmacological screening. The physicochemical properties and optimal reaction conditions are reported.

DURING RECENT years, α-aminoacid derivatives have been the subject of several studies of biological interest. In particular, Goldin *et al.* (1) have reported that glycine, although free from hypnotic activity, potentiates barbiturate-induced sleep, while Edwards *et al.* (2, 3) have found that the esters of some α-phenylglycines possess good antispasmodic and local anesthetic activity. Furthermore, it has been reported that ethyl esters of *N,N*-disubstituted glycines exert antispasmodic, antihistaminic, and hypotensive activity (4), and that other similar derivatives have been studied in tuberculostatic (5) and herbicidal tests (6).

The present note deals with the preparation of a series of *N*-aminoalkyl-α-aminoacids and their corresponding ethyl esters for submitting to pharmacological screening. In addition, these compounds were useful intermediates for the synthesis of 3-substituted sydnones, as we have recently reported (7).

The esters in question were prepared by alkylation with α-bromo esters of suitable *N*-aminoalkyl-amines. Because of the side reactions resulting from the competitive aminolysis of the ester group (8), the authors studied the synthesis procedure in detail, and found it an advantage to use

ether as the solvent and 1 mole of triethylamine as scavenger of the hydrobromic acid formed during the reaction. By contrast, the use of boiling benzene and excess *N*-aminoalkyl-amine as acid scavenger (9, 10), as also the use of α-chloro esters instead of the more reactive α-bromo derivatives, were found to give rise to *N*,*N*′-diaminoalkylglycinamides as by-products. Table I gives the reaction conditions, yields, and physical and analytical properties of the esters prepared. All the compounds are colorless oils which may easily be purified by vacuum distillation.

The *N*-aminoalkyl-α-aminoacids were obtained by hydrolyzing the above esters with 20% sodium hydroxide at 60–70°. Brown products difficult to crystallize were obtained at the refluxing tempera-

[a] Crude product. [b] The compounds melt with decomposition. [c] Reported as the hydrobromide by Szarvasi, E., and Neuvy, L., *Bull. Soc. Chim. France*, **1957**, 1019. [d] Reported as the free base by Kawahara, S., and Katsuno, K., *Yakugaku Zasshi*, **82**, 912(1962).

ture. All the compounds were isolated from the reaction mixture as the dihydrochlorides; they are colorless crystalline solids, and their properties are reported in Table II.

Preliminary data on the pharmacological screening which was performed in accordance with the techniques previously described (11), have shown that some members of both series possess a certain degree of antispasmodic, local anesthetic, and antitussive activity.

EXPERIMENTAL

Boiling points are uncorrected. Melting points are corrected and were taken on a Büchi capillary melting point apparatus. The intermediates were commercial products or else obtained according to the procedures reported in the literature.

Typical preparations of both the esters and the acids are illustrated in the following examples.

N - (3 - Dimethylaminopropyl)-alanine Ethyl Ester (XIV).—Ethyl α-bromo-propionate (54.3 Gm., 0.3 mole) dissolved in ether (60 ml.) was added dropwise to a solution of 3-dimethylamino-1-propylamine (30.6 Gm., 0.3 mole) and triethylamine (30.3 Gm., 0.3 mole) and ether (150 ml.), stirring and cooling moderately to room temperature. The mixture was stirred for 1 hr., then refluxed for 2 hr., and allowed to stand overnight. The precipitated triethylamine hydrobromide was filtered off and the solvent removed under reduced pressure. The residue was then distilled, b.p. 72–74° (1 mm.), giving a colorless oil (41.9 Gm.).

N - (2 - Pyrrolidinylethyl) - glycine Dihydrochloride (XVIII).—A mixture of IV (20 Gm., 0.1 mole), sodium hydroxide (6 Gm., 0.15 mole), and water (24 ml.) was cautiously heated to 65°, with efficient stirring. At this temperature hydrolysis continued spontaneously, without necessitating further heating. The solution so obtained was washed with ether and acidified to pH 1 by cautious addition of concentrated hydrochloric acid. The reaction mixture was evaporated to dryness *in vacuo* and the residue was extracted with 300 ml. of boiling ethanol in portions. The combined alcoholic extracts were then distilled and the residue (19.8 Gm.) was crystallized from 98% ethanol. After drying at 90° *in vacuo*, colorless crystals were obtained, m.p. 190–191° dec.

Effect of Germicidal Aerosol Treatment on the Microbial Flora of Laboratory Air

By LEO GREENBERG

Metered doses of a quaternary ammonium, glycol, alcohol formulation were dispensed automatically by motorized apparatus at 15-min. intervals around the clock for 1 month, and the effects of such treatment on the microbial flora of the air in a heavily trafficked area were studied. Data indicate that, despite large variations in number and types of microorganisms found in the air, especially during periods of heavy traffic, continued aerosol treatment was capable of sharply reducing mean population values and in altering the flora from a predominantly bacterial population to one dominated by members of the *Penicillium–Aspergillus* group of fungi.

In recent years, the subjects of microbiological air pollution and air sanitation have gained considerable importance, and much information is now available concerning the immediate and latent effects caused by inhalation and retention of foreign airborne particles and bacteria. Present knowledge *indicates* that particles approximately 1–5 μ in diameter are most effective for penetration and retention in the deep pulmonary spaces (1), and in addition, larger particles bearing many organisms may infect open wounds. In light of recent experiences with hospital-associated staphylococcic infections, much attention has been devoted to the removal or inactivation of biological particles of all sizes from the air used in critical spaces.

To accomplish these ends, a widely diversified group of chemical agents and methods has been proposed, including the use of the gaseous fumigants formaldehyde, β-propiolactone, and ethylene oxide. For more limited and routine use, numerous commercial products designed to reduce air contamination have been developed, and are designed for aerosolization either by mechanical spray or by means of propellants such as the freons. Among the agents utilized for such purposes have been various alcohols, glycols, volatile oils, phenols, and quaternaries.

In general, such commercial aerosols have been

Present knowledge *indicates* that particles approximately 1–5 μ in diameter are most effective for penetration and retention in the deep pulmonary spaces (1), and in addition, larger particles bearing many organisms may infect open wounds. In light of recent experiences with hospital-associated staphylococcic infections, much attention has been devoted to the removal or inactivation of biological particles of all sizes from the air used in critical spaces.

To accomplish these ends, a widely diversified group of chemical agents and methods has been proposed, including the use of the gaseous fumigants formaldehyde, β-propiolactone, and ethylene oxide. For more limited and routine use, numerous commercial products designed to reduce air contamination have been developed, and are designed for aerosolization either by mechanical spray or by means of propellants such as the freons. Among the agents utilized for such purposes have been various alcohols, glycols, volatile oils, phenols, and quaternaries.

In general, such commercial aerosols have been

[a] Mean weekly value.

evaluated either by determining minimum inhibitory concentrations of active ingredients against standard suspensions of known microbial species or through the use of closed chamber techniques in which a synthetic atmosphere is produced which contains a known concentration of microbial forms, either vegetative or spores. *Serratia indica* and *Bacillus subtilis* var. niger (*Bacillus globigii*) are among the organisms more commonly employed for study (2). In either case, results obtained have little in common with actual conditions of use in a critical air space such as a hospital room or laboratory. The present study was undertaken to determine the effects of germicidal aerosol treatment on the microbial flora of the air in a heavily trafficked laboratory over an extended period of time.

MATERIALS AND METHODS

The laboratory chosen for study was approximately 30,000 cu. ft. with two windows at one end and a door at the opposite end. The only furniture at the beginning of the experiment consisted of several long, formica-topped tables. Table tops, floor, walls, ledges, and other exposed surfaces were cleaned by normal maintenance prior to the start of the experiment.

The aerosol formulation chosen for study contained 1.8% quaternary ammonium compounds as BTC-50[1] in an alcohol–glycol base, and a fluorinated hydrocarbon[2] propellant. A special metering valve was installed on all containers to provide for dispensing a 100-mg. spray dose at each activation. Quantitative studies indicated that such an arrangement produced a spray with a median particle size of 18 μ and that each 100-mg. spray contained approximately 12,000,000 aerosol particles.

To provide constant round-the-clock air treatment, a special dispenser was adapted to activate the container valve at 15-min. intervals. The unit was powered by a small, synchronous motor similar to that of an electric clock, operating on 115 v. 60 cycle a.c. Preliminary investigation determined that 15-min. intervals represented the most satisfactory spacing of spray bursts. Such spacing yielded barely measurable levels of germicidal particles at the end of the period but did not permit excessive build-up of concentrations in daily use.

Three units were installed on the walls of the laboratory 8 ft. above the floor level so spaced that the spray paths converged in the approximate center of the laboratory. Air samples were collected every 4 hr. during the day and at 6-hr. intervals during the night for 8 weeks. To determine pretreatment normal values, nonmedicated aerosol was employed during the first 2 weeks. Medicated aerosol was sprayed during the next 4 consecutive weeks and finally, during the next 2 weeks the nonmedicated spray was used again.

Air sampling in duplicate was done by means of a hospital contamination analysis kit[3] utilizing impingement to buffered gelatin broth and concentration and cultivation on filter disks. Samples were taken for a 5-min. period at an approximate flow rate of 12.5 L. of air per minute. Brain heart infusion agar was used for total aerobic bacterial counts while potato dextrose agar, acidified with sterile 10% tartaric acid to a pH of 3.5 was used for mold and yeast determinations (3).

Throughout the study, a constant traffic pattern was established; students entered and left at will during the hours of 10 a.m. and 4 p.m. Windows and doors were closed at other times, except for the entrance and exit of the sample taker. Parallel samples were taken in an adjoining laboratory to confirm that any gross changes in flora observed during the 8-week experiment were not simply seasonal variations in the general environment. Room temperature, relative humidity, and barometric pressure were recorded as each air sample was taken to determine if these factors seemed to influence the results.

Bacterial colony counts were made after 48-hr. incubation at 35° while yeast and mold counts were made after 7-day incubation at 32°. Following counting, simple microscopic and macroscopic criteria were used to single out the following groups of organisms: sarcina, staphylococcus types (micrococci), Gram-positive spore-forming bacilli, yeasts, and molds. Among those colonies identified as molds, members of the general *Penicillium*, *Aspergillus*, and *Alternaria* were identified routinely by conidial characteristics and *Mucor*, *Neurospora*, *Cladosporium* and other common forms diagnosed where possible by morphological characteristics.

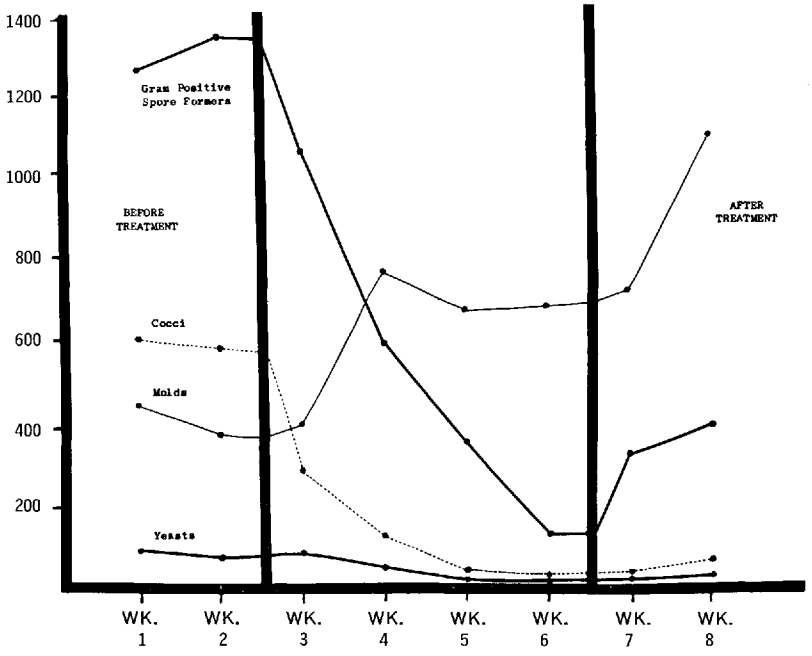

Fig. 1.—Average weekly number of colony isolates identified as Gram-positive spore-forming bacilli, cocci, molds, and yeasts.

RESULTS AND DISCUSSION

Monitoring the air during the preliminary 2-week period in both the test laboratory and the control laboratory indicated that the normal flora in this particular environment consisted of an over-all mean distribution as follows: bacteria, 82% (range 48–96%); yeasts, 3% (range 0–5%); molds, 15% (range 2–28%). As might well have been expected, mean values for total bacterial counts tended to rise sharply during periods of heavy traffic. However, values did not fall promptly on cessation of traffic. For example, during this 2-week period, the number of bacterial colonies isolated rose from 227 at 8 a.m. to 492 at 12 noon and fell only to 451 at 8 p.m. On more than half of the days sampled, total bacterial counts were higher 4 and 8 hr. after traffic periods than during traffic periods. A similar effect, although less marked, was found in total mold counts. This persistence was most evident among the penicillia and almost nonexistent with yeasts.

With the onset of air treatment, profound alterations in the microbial flora were observed which are summarized in Table I and graphically represented in Fig. 1. These changes were not found in values obtained in the control environment and may be regarded as being the result of the spray regimen rather than as normal or seasonal variations. Although there were marked fluctuations in experimental values at different times during the 4-week experimental period, the general trend was clearly toward a marked drop in total microbial species amenable to routine cultivation, and a pronounced conversion of the persistent flora from one dominated by Gram-positive spore-forming bacilli to one dominated by the *Penicillium–Aspergillus* group of molds. Among the bacteria, a relatively rapid decline in the presence of coccal forms apparently testifies to the sensitivity of such species to quaternary germicides, and the sharp quantitative drop in yeast isolates may be similarly explained.

No evident correlation could be discerned between the alterations in flora recorded during the course of the experiment and the temperature, barometric pressure, or relative humidity readings, although there remains with the experimenter the subjective impression that mold colony counts, particularly in the *Penicillium–Aspergillus* group, tended to increase during periods of relatively high humidity.

In conclusion, it seems evident that the use of germicidal aerosol is capable of changing both the quality and quantity of the microbial flora of the air even under conditions of free access and air exchange in the space evaluated. The use of a quaternary type disinfectant system is purely a personal choice, and it is probable that where air sanitation of critical spaces is desired and for one reason or another the quaternary ammonium type of germicide is undesirable, satisfactory results can be obtained with other formulations. The apparent success of the present system against coccal forms may indicate a clinical usefulness against pathogenic forms of staphylococci, currently of profound public health significance, and if such is the case, it is encouraging to note from the data that cessation of air sanitation under the conditions described did not result in the prompt re-establishment of the pretreatment flora.

Opium Alkaloids III. Isolation of α-Allocryptopine

By EINAR BROCHMANN-HANSSEN and BENDIK NIELSEN

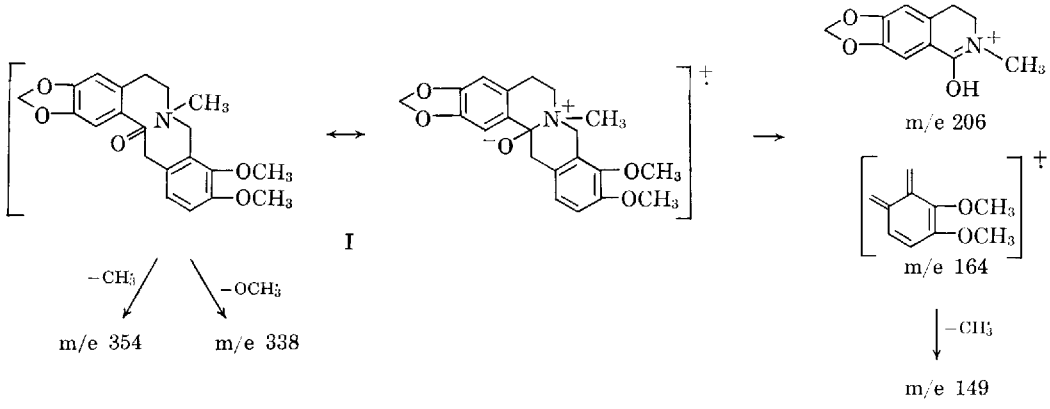
Allocryptopine has been isolated from opium in approximately 0.01 per cent yield as the α-form. The alkaloid has been identified by NMR and mass spectrometry and by comparison of its infrared spectrum with that of its allotropic modification, β-allocryptopine. The biosynthetic pathway leading to allocryptopine is discussed briefly.

RECENT STUDIES of the alkaloid composition of opium have revealed several new alkaloids, some of which have served to confirm modern theories on the biosynthetic pathways in the opium poppy (1–6). This report describes the isolation of allocryptopine which belongs to the protopine group of alkaloids.

Allocryptopine is present in many plants, especially in members of the *Papaveraceae*, and is generally found in concentrations of less than 0.1% (7). A notable exception is *Argemone squarrosa*, from which it has been isolated in quantities of approximately 1% (8). The alkaloid occurs in two allotropic modifications referred to as the α- and the β-forms with different crystal structures and melting points.

with low R_f value (between morphine and codeine) was scraped off and eluted with warm methanol. The alkaloid was purified by repeated crystallization of the picrate, m.p. 208°.[1] The base was liberated by passing through a column of neutral alumina and washing with chloroform. After evaporation of the solvent, the residue was crystallized from heptane, m.p. 160°.

Identification of α-Allocryptopine.—The NMR spectrum[2] in deuterochloroform revealed four aromatic protons in the region 3.0–3.4 τ, a methylenedioxy group at 4.08 τ, two *O*-methyl groups at 6.16 and 6.22 τ, and a *N*-methyl group at 8.15 τ. The high field absorption band of the *N*-methyl group is similar to that of protopine (10) and is probably caused by the shielding effect of the carbonyl group.



Major Fragments in Mass Spectrometry of Allocryptopine
Scheme I

EXPERIMENTAL

Isolation.—The mother liquor from the purification of morphine was extracted as described in a previous communication (2). The chloroform extract obtained at pH 1–1.5 (HCl), containing the weakly basic alkaloids, was separated into phenolic and nonphenolic bases with ether at pH 13, and the nonphenolic fraction subjected to preparative thin-layer chromatography (9). An alkaloid band

Mass spectrometry[3] gave a molecular ion with mass 369. Major fragments appeared in the mass spectrum at m/e 149, 164, 206, 338, and 354, corresponding to the expected cleavage of allocryptopine (I) as illustrated in Scheme I.

The I.R. spectrum[4] of the alkaloid base in chloroform solution was identical with that of authentic allocryptopine. The melting point agreed with that reported for α-allocryptopine (7). The β-form melts at 170° (7, 8). A mixed melting point with authentic β-allocryptopine gave a depression to 166°. When the melt was allowed to cool and crystallize, it melted at 170°. This is consistent with the observation of Soine and Willette (8). The amounts of

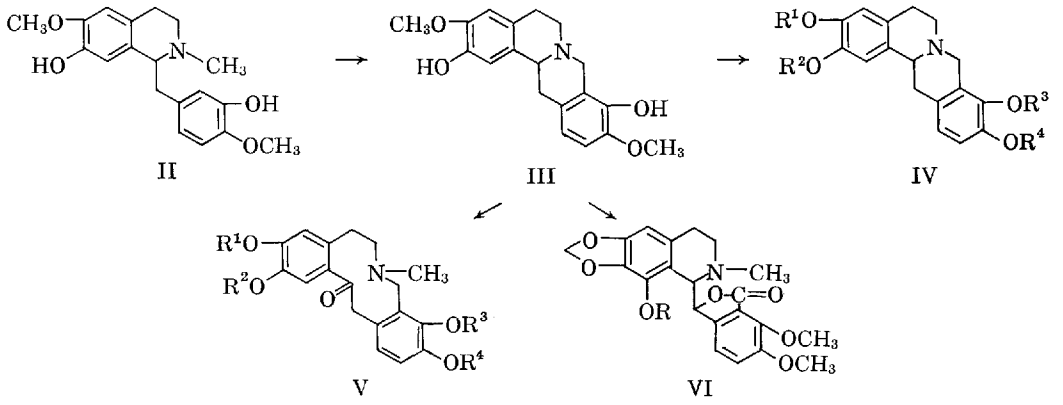
[4] Unicam SP-200 infrared spectrophotometer.



Scheme II

α-allocryptopine in opium appears to be of the order of 0.01%.

Anal.[5]—Calcd. for $C_{21}H_{23}NO_5$: C, 68.28; H, 6.28; N, 3.79. Found: C, 68.24; H, 6.03; N, 3.99.

DISCUSSION

Reticuline (II) has been shown to be a precursor for protopine in several plant species (11, 12), and there is evidence that this biotransformation proceeds by way of scoulerine (III) (12), which has recently been isolated from opium (6). Scoulerine, like reticuline, represents an important branching point in the biosynthesis of opium alkaloids from which a number of tetrahydroprotoberberine (IV), protopine (V), and phthalideisoquinoline alkaloids (VI) may be derived (Scheme II). A thorough search may well reveal other members of these alkaloid groups in the opium poppy than those which have been reported so far.

[5] The analyses were carried out by the Microanalytical Laboratory, Department of Chemistry, University of California, Berkeley.

Communications

Nonspecificity of Published Assays for Chloramphenicol Solutions

Sir:

The authors have found that the accepted spectrophotometric method (1) for chloramphenicol-containing pharmaceuticals does not yield valid results when applied to a partially degraded aqueous solution of chloramphenicol. The Code of Federal Regulations designates as acceptable various analytical methods for the antibiotic in pharmaceuticals. The procedures for two microbiological methods and one spectrophotometric method are outlined in the code (1). In addition, Higuchi, Marcus, and Bias have developed a different microbiological method and have compared this with a chromatographic method for chloramphenicol (2).

Samples of an aqueous solution of chloramphenicol containing stabilizing agents were stored at 4°, 22°, and 32° for approximately 16 months. Table I shows the chloramphenicol content of

The procedures for two microbiological methods and one spectrophotometric method are outlined in the code (1). In addition, Higuchi, Marcus, and Bias have developed a different microbiological method and have compared this with a chromatographic method for chloramphenicol (2).

Samples of an aqueous solution of chloramphenicol containing stabilizing agents were stored at 4°, 22°, and 32° for approximately 16 months. Table I shows the chloramphenicol content of

TABLE I.—COMPARISON OF METHODS[a]

Storage Temp.	Microbiological (Cup Plate)	Microbiological (Turbidimetric)	U. V. with Prior TLC Separation	Direct U. V.
Std.[b]	0.492 ± 0.011	0.507 ± 0.001	0.491 ± 0.003	0.505 ± 0.002
4°	0.517 ± 0.005	0.515 ± 0.001	0.497 ± 0.005	0.555 ± 0.000
22°	0.390 ± 0.013	0.390 ± 0.007	0.383 ± 0.001	0.556 ± 0.002
32°	Below 0.240	Not assayed	0.183 ± 0.002	0.566 ± 0.004

[a] Each figure represents the average of three determinations and is expressed as the per cent of chloramphenicol in the solution. The precision is expressed as average deviation from the values given. [b] Freshly prepared solution of the same formulation containing 0.50% chloramphenicol.

TABLE II.—ANALYSIS OF COMMERCIALLY AVAILABLE CHLORAMPHENICOL PRODUCTS[a]

	U. V. with Prior TLC Separation	Direct U. V.
Product *1*	0.189	0.242
Product *2*	0.166	0.221

[a] Each figure represents the average of two determinations and is expressed as the per cent of chloramphenicol in the solution. The label claim on these two products was 0.2% chloramphenicol.

these samples after 16 months as determined by two accepted microbiological methods (1), by the accepted ultraviolet method (1), and by an improved spectrophotometric method utilizing thin-layer chromatography. The solution was originally prepared to contain 0.55% chloramphenicol.

The improved spectrophotometric method consisted of quantitative separation of chloramphenicol from degradation products utilizing thin-layer chromatography followed by ultraviolet analysis. Standard 2 by 9 in. thin-layer chromatography plates were coated with silica gel $HF_{254 + 366}$ (Brinkmann Instruments, Inc.) and preconditioned before use by heating in an oven at 90° for 15 min. The developing medium was chloroform–isopropanol (4:1) and visualization of the antibiotic was accomplished using an ultraviolet light emitting at 2537 Å. Development time for the chromatogram was 55 min. The chloramphenicol was desorbed from the adsorbent by ethanol over a 12-hr. period and determined at 274 mμ on an ultraviolet spectrophotometer.

It can be seen from the data in Table I that all four methods of analysis agree closely on a freshly prepared aqueous solution of chloramphenicol. It is also evident from the above table that direct ultraviolet analysis of a partially degraded aqueous solution of chloramphenicol which is 16 months old yields high values. These figures are not in agreement with the two accepted microbiological methods which are specific for active antibiotic concentration. On the other hand, the results using prior separation by thin-layer chromatography followed by ultraviolet determination are in close agreement with those values obtained by the microbiological methods. In fact, if the 0.183 figure obtained by the thin-layer chromatography method on a 32° sample is used, it can be calculated that the chloramphenicol in this sample has undergone approximately 67% degradation. A determination by direct ultraviolet analysis on the same sample shows that no degradation has taken place.

The thin-layer chromatographic method and the accepted direct ultraviolet method (1) were applied to stable aqueous solutions of chloramphenicol currently available only on the foreign market. The results, shown in Table II, indicate considerably less active chloramphenicol present in samples tested by the thin-layer chromatographic method than by the direct spectrophotometric method.

British Pharmacopoeia 1963: Addendum 1966. The General Medical Council. The Pharmaceutical Press, 17 Bloomsbury Square, London W C1, England, 1966. xiii + 112 pp. 15 × 23 cm. Price 45 s.

This is the second addendum to the "British Pharmacopeia 1963." Seventy-two new monographs are included. Revisions also appear for approximately 65 monographs currently in the B.P. 1963. Most of the new monographs are for synthetic drugs and their dosage forms. Items such as amitriptyline hydrochloride, nortriptyline hydrochloride, betamethasone sodium phosphate, and sodium iothalamate injection are among the new additions. The Addendum 1966 will be official from September 1, 1966.

A review of the "Addendum 1964" appears in *J. Pharm. Sci.*, **54,** 1079(1965).

Molecular Modification in Drug Design. Advances in Chemistry Series, American Chemical Society, Washington, D. C., 1964. vii + 228 pp. 15.8 × 24 cm. Price $5.00.

A few years ago the Division of Medicinal Chemistry of the American Chemical Society held a well attended two-day symposium on the subject of Molecular Modification in Drug Design, which also has become the title of a book summarizing the lectures and discussion. The late Professor Fred W. Schueler, chairman of the symposium, succinctly stated in the preface the essence of the subject: "Molecular modification guided by deduction, induction, and serendipity *via* the prepared mind has produced in the last 25 years more potent and more useful drug agents in various areas of therapeutics than have been reported in all previous history."

Despite the idealistic yearning of the medicinal chemist for theories and laws which will assure the introduction of the best possible member of an established class of drugs as well as of entirely novel drugs, such has not yet proved to be the case. Despite worthy efforts which one day may bear fruit, the exact architecture of not a single active site is known. Until the day of full enlightenment has arrived, superior drugs will arise through molecular modification with its components of intuition, industry, theory, technical ability, flash of genius, and fortuitous circumstance.

The introductory chapter by Dr. Max Tishler combines a scholarly with a practical approach in convincing fashion. Particularly impressive is the unpredictable fact of the presence of the sulfonamide group in a variety of sructures constituting agents for bacterial infections, inhibition of penicillin excretion, gout, cardiac edema, and diabetes, not to mention the old chloramine antiseptics. Professor John C. Sheehan describes how chemists modified the penicillin molecule so as to render it effective against resistant staphylococcal infections. In the chapter by Dr. Gerhard Zbinden, one can see evidence of how, despite the deterrent effect of early theories of action which implied that better sulfas would not be found, chemists, pharmacologists, and clinicians have, nevertheless, produced valuable new sulfas.

So the story goes through 18 well-documented chapters by experts in medicinal chemistry and allied fields. Discrete molecular modifications have brought forth exciting and valuable new antihypertensives, *e.g.*, methyldopa, and antidepressants, *e.g.*, imipramine. Modifications of the steroid hormones have produced dramatic increases in biological activity beyond that of the parent hormone, and also important uses have emerged, as in the case of the antifertility agents.

Every medicinal chemist should read this book. It will teach him not to adhere rigidly to theories of drug action as we presently know them. It may help him to create valuable new drugs.

British Pharmacopoeia 1963: Addendum 1966. The General Medical Council. The Pharmaceutical Press, 17 Bloomsbury Square, London W C1, England, 1966. xiii + 112 pp. 15 × 23 cm. Price 45 s.

This is the second addendum to the "British Pharmacopeia 1963." Seventy-two new monographs are included. Revisions also appear for approximately 65 monographs currently in the B.P. 1963. Most of the new monographs are for synthetic drugs and their dosage forms. Items such as amitriptyline hydrochloride, nortriptyline hydrochloride, betamethasone sodium phosphate, and sodium iothalamate injection are among the new additions. The Addendum 1966 will be official from September 1, 1966.

A review of the "Addendum 1964" appears in *J. Pharm. Sci.*, **54,** 1079(1965).

Molecular Modification in Drug Design. Advances in Chemistry Series, American Chemical Society, Washington, D. C., 1964. vii + 228 pp. 15.8 × 24 cm. Price $5.00.

A few years ago the Division of Medicinal Chemistry of the American Chemical Society held a well attended two-day symposium on the subject of Molecular Modification in Drug Design, which also has become the title of a book summarizing the lectures and discussion. The late Professor Fred W. Schueler, chairman of the symposium, succinctly stated in the preface the essence of the subject: "Molecular modification guided by deduction, induction, and serendipity *via* the prepared mind has produced in the last 25 years more potent and more useful drug agents in various areas of therapeutics than have been reported in all previous history."

Despite the idealistic yearning of the medicinal chemist for theories and laws which will assure the introduction of the best possible member of an established class of drugs as well as of entirely novel drugs, such has not yet proved to be the case. Despite worthy efforts which one day may bear fruit, the exact architecture of not a single active site is known. Until the day of full enlightenment has arrived, superior drugs will arise through molecular modification with its components of intuition, industry, theory, technical ability, flash of genius, and fortuitous circumstance.

The introductory chapter by Dr. Max Tishler combines a scholarly with a practical approach in convincing fashion. Particularly impressive is the unpredictable fact of the presence of the sulfonamide group in a variety of sructures constituting agents for bacterial infections, inhibition of penicillin excretion, gout, cardiac edema, and diabetes, not to mention the old chloramine antiseptics. Professor John C. Sheehan describes how chemists modified the penicillin molecule so as to render it effective against resistant staphylococcal infections. In the chapter by Dr. Gerhard Zbinden, one can see evidence of how, despite the deterrent effect of early theories of action which implied that better sulfas would not be found, chemists, pharmacologists, and clinicians have, nevertheless, produced valuable new sulfas.

So the story goes through 18 well-documented chapters by experts in medicinal chemistry and allied fields. Discrete molecular modifications have brought forth exciting and valuable new antihypertensives, *e.g.*, methyldopa, and antidepressants, *e.g.*, imipramine. Modifications of the steroid hormones have produced dramatic increases in biological activity beyond that of the parent hormone, and also important uses have emerged, as in the case of the antifertility agents.

Every medicinal chemist should read this book. It will teach him not to adhere rigidly to theories of drug action as we presently know them. It may help him to create valuable new drugs.

Distribution and Biological Effects of Substance P

By H. DIX CHRISTENSEN* and THOMAS J. HALEY

CONTENTS

EXTENSIVE INVESTIGATIONS in recent years of the physiological and pharmacological properties of endogenous biologically active substances have increased interest in the polypeptide substance P (SP). Although SP is one of the oldest known peptides, discovered by Euler and Gaddum (1) in 1931 while investigating acetylcholine distribution, its biological function is largely unknown. Many speculative functions have been proposed for SP; as an essential factor for the rhythmic motility of the intestine (2–5), both as an excitatory and inhibitory neurotransmitter (6–9), as a general hyperpolarizing modulator (10, 11) or physiological tranquilizer (12, 13), as a carrier of various transmitter substances (14–16), and as a capillary permeability increasing agent (17, 18), but conclusive evidence for any or several of these functions has not been obtained.

Received from the Laboratory of Nuclear Medicine and Radiation Biology, Department of Biophysics and Nuclear Medicine, University of California School of Medicine, Los Angeles.

This article was supported by contract AT(04-1)GEN-12 between the Atomic Energy Commission and the University of California, Los Angeles.

* Supported by training grant 5-T1-GM-796 in Biophysics and Nuclear Medicine from the U. S. Public Health Service, Bethesda, Md.

Substance P exerts its pharmacological effects primarily on three organic systems: the central nervous, gastrointestinal, and circulatory systems. While the initial publication described SP as a smooth muscle stimulating substance and blood pressure depressor, it also affects the central nervous system. This review will summarize the knowledge of SP to the present, particularly on these three systems. Other reviews (19–27) cover additional details and aspects.

CHEMICAL CHARACTERISTICS

Substance P is a basic straight chain polypeptide, with molecular weight 1650 ± 350 (19, 28). Total hydrolysis gives the following 13 amino acids: lysine, arginine, aspartic acid, glutamic acid, proline, glycine, alanine, valine, leucine, isoleucine, phenylalanine, threonine, and serine (28–31). Arginine-proline-proline are the first three amino acids from the *N*-terminus, as in bradykinin, but the remainder of the chain is different (29, 32). Owing to the extreme instability of purified SP in solution, the specific sequence and synthesis have not been determined. A 10^{-6} dilution of the purified substance loses over half of its activity within 2 min., while a 10^{-3} dilution is stable for several hours (28). Cleugh and Gaddum (33) suggest that this instability of the pure SP is due to its adsorption properties.

Substance P is very soluble in water, methanol, ethanol, and acetic acid and is insoluble in ether and chloroform. It can be precipitated from

alcoholic solutions with acetone or picric acid, and from watery solutions with phosphotungstic acid, mercuric chloride, or by 70% saturation with ammonium sulfate. Substance P is thermostable from pH 1–7, but activity is rapidly lost in an alkaline state. It dialyzes rapidly through cellophane, parchment, and collodion membranes (2, 34).

Paper chromatography using different solvent systems: *n*-butanol–acetic acid–water (40:10:50), *n*-butanol–pyridine–acetic acid–water (30:20:6:24), and pyridine–acetic acid–water (30:50:15) gave R_f values for SP of 0.34–0.37, 0.46, 0.61, respectively (21, 31, 35). Zetler (35) found that SP migrated 116 mm. to the cathode during paper electrophoresis (pH 4.95, acetate buffer, duration 6 hr.). SP migrates to the cathode at pH below 10.5. Using the buffer system formic acid–acetic acid–water (15:10:75) and pH 1.9, bovine SP migrated at a velocity 0.8 times that of glutamic acid (28); horse SP, however, migrated 1.0 times that of glutamic acid (29). The isoelectric point was 8.6 ± 0.2 (28). In countercurrent distribution in the system *n*-butanol–pyridine–acetic acid–water (40:10:5:45) at 20°, SP gave a value of K = 0.61 (28).

No specific chemical reaction for substance P is known, so SP concentration is estimated using bioassays, comparing the response against a standard preparation. One unit of SP is contained in approximately 20–30 mg. of horse intestine (34). Purified SP contains 120,000–150,000 units of activity per milligram (unit/mg.) (28, 30).

The isolated guinea pig ileum provides the most specific assay available (36). The most commonly used assay (37) uses a segment from the distal ileum in a 2–5-ml. intestinal bath containing Tyrode's solution at 34–38°. Hyoscine (10^{-8} Gm./ml.), pyrilamine[1] (10^{-6} Gm./ml.), UML 491 (5×10^{-8} Gm./ml.), or other suitable blocking agents, which will antagonize acetylcholine, histamine, and serotonin, respectively, are added to the bath solution. Many other active substances which may be present in crude extracts can be eliminated by specific tachyphylaxis (36) or by enzymatic deamination (38, 39). The contraction curve for SP is very similar to acetylcholine, with the exceptions of a smaller maximum and a slightly delayed onset and maximum response time (28). Maximum contraction occurs usually within 1 min. and doses can be repeated at 3–4-min. intervals (37). In this bath 0.2 unit/ml. should give a good response and a 10% change can be detected. In a 0.05-ml. microbath the guinea pig ileum is sensitive to 0.001–0.01 unit of SP (40). Purified SP (50,000 units/mg.) in a dose of 10^{-9} Gm./ml. caused a submaximal contraction of the isolated guinea pig ileum, so SP on a molar basis is about 10 times more active than acetylcholine (28). This sample produced no tachyphylactic phenomenon, even with the time interval as short as 1 min., which is opposite to the results obtained using impure SP (41). Substance P stimulates the longitudinal but not the circular muscle (42). Below 20° contractions are inhibited (43) and highly variable results occur after storage (43, 44). Substance P is reported to increase in potency with increased pH (45) or to be unaffected (46).

Only two reasonably specific SP antagonists have been found: cystine-di-β-naphthylamide and trimethaphane-*d*-camphorsulfonate.[2] They have a slight antagonist effect against acetylcholine, histamine, and 5-hydroxytryptamine, but no effect on oxytocin, vasopressin, and bradykinin (47, 48).

The contraction of the isolated hen rectal caecum, rabbit jejunum, goldfish intestine, and fall in blood pressure of the atropinized rabbit are other bioassays which are sensitive to purified SP as well as crude preparations (36, 49–54).

Three extraction procedures are in common use. The standard extraction procedure consists of boiling the tissue at pH 4, precipitation of inactive protein by adding ethanol, and further concentrating SP by precipitation with ammonium sulfate (37, 55). Substance P is extracted from small quantities of tissue by an acid extraction of the acetone insoluble residue (37, 56, 57). Lembeck *et al.* (58) have recently developed a new chloroform–methanol extraction procedure. Crude extracts can be further purified by adsorption on an aluminum oxide column; SP is eluted with decreasing concentrations of methanol (37). Purified SP has been obtained by elaborate procedures involving repeated adsorption and ion exchange chromatography and countercurrent distribution (28–31).

Zetler (35, 59–64) in purifying SP extracts used carbon tetrachloride to remove salts and ammonium sulfate from the extract. Substance P from cattle brain treated in this way yields three biologically active polypeptides, while extracts from the horse intestinal tract gave ten. While some of the peptides may be artifacts from protein denaturation, they are probably

[1] Marketed as Neo-antergan by Merck & Co., Inc., Rahway, N. J.

[2] Marketed as Arfonad by Roche Laboratories, Nutley, N. J.

not all so. One of the active peptides was found in both the brain and intestine, which also had all of the properties of SP (62, 65). Zetler (62) concluded that the brain F_b and intestinal F_{b3} fractions are SP, which creates a slight problem, as Lembeck *et al.* (58) in their new extraction method, extract only fraction F_a from nervous tissue and found no SP activity remaining in the tissue after extraction.

Biological activity of highly purified SP is completely destroyed by chymotrypsin, but only partially by trypsin (32, 54). Impure SP is also inactivated by pepsin, cathepsin, papain, diamine oxidase, bacterial proteolytic enzymes and extracts from nervous tissue, intestinal tract, urinary bladder, ureter, and uterus (66–72). Eber and Lembeck (66) found kidney and spleen extracts most potent in inactivating SP, with no relationship between the tissue SP content and its enzymatic activity. Blood serum from gravid animals destroys SP, while normal serum has no or only slight inactivation ability (73, 74). In subcellular studies an enzyme which inactivates SP appears to be located in the cytoplasm–the supernatant fraction (75, 76). Substance P is very resistant to autolysis (66, 77, 78).

DISTRIBUTION

The gastrointestinal tract and nervous system of all investigated vertebrates contain SP (21, 79–86), but none of the noncordates (87, 88). The tunicate, *Ciona intestinalis*, is the most elementary species in which SP (0.02 unit/Gm.) has been found (87). Substance P distribution in five species is shown in Table I.

In the intestinal tract, the content is low in the esophagus and stomach, high in the duodenum and jejunum. The ileum, colon, and rectum contain moderate amounts (21). The amount of SP in the intestine varies with the species, in decreasing order: dog, monkey, horse, bovine, man, rat, guinea pig, sheep, cat, pig, ray, and dogfish (21, 87, 92). While SP is found in all layers of the gastric and intestinal walls, the muscularis mucosa contains the greatest concentration (21, 96).

Amphibians have the highest total brain concentration (200–820 units/Gm.) with moderate amounts in reptiles and smaller amounts in birds, mammals, and fish (79–81). Differences in forebrain and brain stem concentrations are less in primitive than more developed brains. With increased differentiation of the central nervous system, the concentration decreases in the whole brain (81) and in specific nuclei (90). The topographic distribution shows that while SP is present in all parts, the concentration varies over a wide range. Cell-rich phylogenetic older parts of the brain have the primary concentration with the cerebellum a notable exception.

In the cortex there is an uneven distribution, the anterior cingulate gyrus has a high concentration; the olfactory, somatomotor, and somatosensory cortices have moderate amounts, and the visual cortex has little. The cerebellar cortex contains small amounts of SP, but considered as a whole there is no more than in white matter.

Closely neighboring brain stem structures show neurohumoral differentiation (78), as the thalamus (12 units/Gm.), globus pallidus (112 units/Gm.), and putamen (64 units/Gm.); anterior (70 units/Gm.) and posterior (22 units/Gm.), hypothalamus, and mammillary body (34 units/Gm.); ala cinerea (248 units/Gm.), trigonum hypoglossi (37 units/Gm.), and area postrema (290 units/Gm.); substantia nigra (699 units/Gm.) and red nucleus (30 units/Gm.).

The concentration of SP in functional systems shows significant differences; for example, the visual system, other than the retina, has much lower concentrations than the auditory system.

In the spinal cord as in the brain, the gray matter shows a higher concentration than the white. There is more SP in the dorsal than the ventral halves of the spinal cord, except in the frog where they are the same (98). This high concentration of SP in the sensory pathway: the dorsal roots, fasciculi gracilis and cuneatus, and associated nuclei with very low concentrations of other well-known pharmacologically active substances, led to Lembeck's suggestion (6) that SP may be the transmitter of the sensory neurons.

All peripheral nerves contain SP, but in much smaller concentrations than in the central nervous system. The distribution indicates the autonomic nerves, in particular the sympathetic preganglionic, contain the largest amounts (21).

Differential and density gradient centrifugation studies of brain homogenates show that the intracellular distribution of SP is similar to acetylcholine (36, 76, 99–105). The distribution is bimodal, between the supernatant ($^1/_3$) and synaptic vesicles and the incompletely disrupted synaptosomes fractions ($^2/_3$). Substance P is found, as is acetylcholine, in the hollow or type 1 synaptic vesicle. Substance P in the vesicle-synaptosomes fractions is in a bound form and must be released before assay. Lembeck *et al.* (58) think it is bound to phosphatides. Substance P is released rapidly upon exposure to hypotonic solutions or extraction at pH 4.0.

TABLE I.—REGIONAL DISTRIBUTION OF SUBSTANCE P IN FIVE SPECIES (UNITS OF ACTIVITY/GM. OF TISSUE)

Species Ref.[a]	Human (18, 78, 89–92)	Bovine (21, 78, 90, 93–95)	Dog (21, 56, 90, 94, 96, 97)	Cat (21, 81, 95)	Ray (82, 83, 87)

(continued on next page.)

The observed intracellular distribution is similar by using various methods of preparation, or different species (rat, sheep, guinea pig, rabbit) or region of the CNS (cortex, midbrain, cerebellum, and ventral and dorsal halves of the spinal cord) except that the total amount reflects the gross regional distribution (101, 104).

Euler (76, 106) found that the intracellular distribution of SP in peripheral nerves (vagus and splenic nerves of the cow and sciatic and brachial nerves of the dog) was primarily in granules as is the case in the central nervous system.

The subcellular and regional distribution indicates that SP is found within nerve cells rather than glial cells. This is supported also by Grabner and Lembeck's finding (107) that glial tumors contain no substance P activity, and that SP increases in the proximal and decreases in the distal part of cut peripheral nerves in degeneration experiments (98, 108–110). No change occurs in SP concentration in the spinal cord of the rat after dissection between the first and second lumbar vertebrae (111).

Substance P occurs in other organs besides the nervous system and the gastrointestinal tract, but only in minute amounts (1, 21). The ureter and uterus (5 units/Gm. of tissue in the dog) show the relatively highest amounts (21). Substance P is also found in minute amounts in blood (1) but not in urine (112).

ENDOGENOUS CHANGES IN CONCENTRATION

Besides the distribution, which indicates SP's physiological role is connected with function rather than structure, there are endogenous changes under different functional states. In an ontogenetic study on the bovine fetus (113), a brain weighing only 1 Gm. has a high content (21.5 units/Gm.) of SP. The brain stem, which is active during the development of the embryo, contains SP concentrations comparable to the adult, while the forebrain has none until after birth. The intestine contains increasing amounts of SP during the second half of embryonic development. Immature undifferentiated nervous tissues, neural tumors, do not contain SP (107).

In the gravid rat, there is an increase in SP content in the uterus and a marked decrease in the brain, particularly in the second half of pregnancy (74). Up to 4 times the concentration of SP is found in the retina of cattle, whose

[a] Kopera and Lazarini (95) and Douglas *et al.* (96) used different standards from the other authors to measure the biological activity.

eyes were closed for 2 hr. as compared to those illuminated for the same length of time. The extent of change from normal is about the same for each case. No change occurs in the SP content of an isolated retina *in vitro* to illumination or darkness (114). However, in the brain of the rat and the rabbit the content increases after illumination and decreases after darkness or blindness (115, 116). Stern (116) measured also changes in brain concentration of the rat when deprived of other sensory stimuli. Elimination of smell and hearing reduced SP content, while elimination of the tactile sense or the "radar apparatus" in the bat had the opposite effect. Vestibular stimulation also reduced the SP content. Milin (117) found that exogenous SP reduces the movement of earthworms to light and vibrational stimulation. The morphodynamic changes indicated that SP's action is to preserve the integrity of the photo- and tactoreceptor cells in the epidermis.

Walaszek *et al.* (118, 119) found less SP in the hypothalamus of rabbits, which had been previously injected with serum from schizophrenic patients. Serum from normal patients produced no change. While glial tumors do not normally contain SP, 13 units/Gm. was found in 1 multiform glioblastoma of a previously irradiated patient (107).

No SP release has been found in the mammalian brain on electrical stimulation (19, 52, 120), but stimulation is reported to release SP in the frog spinal cord (121) and stomach muscles (122–124). Cervical vagotomy increases the SP content of rabbits' small intestine from 2.8 to 7.2 units/Gm., while vagus stimulation significantly decreases the SP content with a return to control levels within 30 min. (125). This is opposite to earlier findings that vagus stimulation increased SP content in the intestine (126–128).

Pernow and Wallensten (92) found the SP content of human intestinal segments was higher when their motility was increased by intraluminar administration of hypertonic glucose. In Hirschsprung's disease the proximal hyperactive part was higher than controls, and the aganglionic and inactive segments of the colon had significantly less SP (91).

PHARMACOLOGICAL EFFECTS

Most studies on the pharmacological actions of SP have used very impure preparations containing many other active substances. The usual

so-called purified samples (250–1000 units/mg.) still contain less than 1% pure SP, while the highly purified SP (50,000–120,000 units/mg.) is extremely labile in aqueous solutions, so many of the reported pharmacological actions are not completely conclusive.

Substance P has a strong stimulatory effect on the mobility of the gastrointestinal tract of most vertebrates, both in isolated segments and *in situ* (1, 21, 50, 129, 130), with a positive correlation between SP content and sensitivity (21). The amplitude and frequency of the peristaltic waves are increased, besides a lower peristaltic threshold, when SP is applied intraluminally or in the bath of isolated intestines of rabbit or guinea pig (4, 131). Substance P restores fatigue or temperature blocked peristaltic activity (4, 132). This response is dependent upon an intact mucous membrane. Intravenous injections of SP markedly increase the segmental and peristaltic movement of the small intestine *in situ* of rabbits and man (129, 131). The increase is observed within a few minutes after start of infusion (50 units/min.) and lasts for 20 min. after ceasing the infusion. In the case of patients with paralytic ileus, SP induced both segmental and peristaltic activity only for the duration of the infusion. Intravenous administration of SP has been also observed to increase the spontaneous movement of the intestinal villi (133). Substance P (50 units/Kg.) injected intra-aortally increased the tonus of the ileocaecal valve of the cat (134). A strong peristaltic response occurs with rhythmic movement of the sphincter ani in the anesthetized dog (28). There was, however, no visible effect on the intestine of mice, with doses to 50,000 units of purified SP (28).

In the guinea pig, intravenous SP has a strong bronchoconstrictor effect (17, 28, 135, 136) but no effect on inhalation (137). No tachyphylaxis occurs (17). Substance P protects against protein induced anaphylactic shock in the guinea pig (138), while plasma levels of SP are independent of occurrence of anaphylaxis induced in dog (139). Euler and Pernow (140, 141) found intraventricular administration of SP (300 units/mg.) produced both tachypnea and hyperpnea in rabbits and cats. Haefely *et al.* (142, 143) found no effect with purified SP (200 or 24,000 units/mg.) on the respiration rate, but did with a crude preparation (20 units/mg.). Substance P given intravenously has no effect on respiration in the cat (142), but subcutaneously produced bradypnea in the guinea pig (8).

Intravenous or intra-arterial infusion of SP causes peripheral vasodilation with an accompanying brief fall in blood pressure (1, 21, 25, 112, 144–146). It is about 100 times more active than acetylcholine and 5 times more active than bradykinin as a vasodilator on a molar basis (28, 50, 147). Bilateral cervical vagotomy has no effect on the depressor response (50, 112). Substance P-evoked pressure increases in the recipient head were abolished by bilateral cervical vagotomy, but not the systemic depressor effect in cross circulation experiments in dogs (148). Intravenous injections of SP in man produced tachycardia and a slight fall in arterial blood pressure. Cardiac output was increased, but not stroke volume, intracardiac, and pulmonary blood pressures (147, 149). An increase in blood flow in skin and muscles occurs within 1 min. after the start of intravenous infusion of SP, and this is coupled with an intense burning sensation in the face and a throbbing head pain. The splanchnic blood flow is, however, not altered. Intra-arterial injections (1 unit/min.) tripled the blood flow in the forearm within seconds, with increased oxygen saturation of both deep and superficial venous blood (147, 150). A transient tachyphylactic effect occurs, so tremendously high doses have only slightly greater effects than a minimum effective dose in mammals. After 15–30 min., identical hemodynamic effects can be reinduced. In the chicken the response is directly related to the amount of SP injected (112). In the conscious dog high doses of SP (7500 units/Kg. i.v.) increase the duration of the depressor effect accompanied by a marked bradycardia which persists after the blood pressure has returned to normal (28). The minimum effective dose in the cat is about 10 times that of other species (21, 28, 50). Circulatory shock could not be induced in the cat, mouse, or man (28, 147). Intraventricular administration of purified SP (24,000 units/mg.) in the cat had no effect on blood pressure (143). No changes in frequency or contractility of the myocardium were found by direct application of SP (28). Substance P has a vasoconstrictor effect on the perfused frog leg (56).

Slow intravenous infusion of an impure SP killed decerebrated mice sooner than normal. The toxic dose is 12,000–18,000 units/Kg. in normal mice. With slow infusion most animals die in convulsions, while rapid injection produces paralysis at death. Physiological saline or inactivated SP controls never produced convulsions (116).

Capillary permeability is significantly increased by small doses of SP in the guinea pig but not in

the rabbit (17, 50, 151–153). Topical application of 0.5–2 ng. of pure SP on the mesenterium of the anesthetized rat shows a clear relaxation of the venule walls followed by a diffused efflux of leukocytes (50). Lewis (154) has also found that SP causes migration and accumulation of leukocytes. Fibrinolysis is inhibited by 20–80 units of SP (155). Cutaneous injections of 10–30 ng. of pure SP produce a burning pain and erythema after a latency of 10–20 sec., which lasts for 10–30 min. (50). A burning sensation occurs when it is applied to an exposed blister base (17, 156). Intra-arterial, but not intravenous, injections of SP induce visceral pain in dogs (157).

An antidiuretic and milk ejection effect are observed, but only in doses having a marked depressor action (17). The ACTH releasing ability of SP is due to an impurity (158, 159). It has no epinephrine releasing action on the adrenal medulla (160). Substance P inhibits oxytocin induced contractions of the rat uterus *in vivo* (161).

Ten minutes after an intraperitoneal dose (3000 units/Kg.), SP increases in concentration in the brain and spinal cord of the rat, reaching a maximum in 30–40 min., and after 60–120 min. returns to normal or slightly below (116). This time course for SP uptake could account partially for many observations on the effects of exogenous SP alone and with central acting drugs on the nervous system. Sedation, *i.e.*, a reduction in spontaneous and induced motor activity, is the most often reported behavioral effect of administered SP (8, 10, 12, 13, 141, 162–165). Oral automatisms were often provoked. All of these observations are somewhat in question, as Haefely *et al.* (143) found no observable behavioral effects after intraventricular injection of purified SP in the cat, but did observe sedation with crude extracts. They showed that ammonium sulfate in the concentrations contained in the crude extracts would produce sedation. This observation does not explain, however, the chymotrypsin inactivated SP controls used by other authors which produced no effect. Also the same investigators (19, 28) reported that 7500 units/Kg. of pure SP produced sedation in the unanesthetized dog. In mice no clear effect was observed with doses up to 1000 units per animal given intravenously or intracerebrally. With 5000 units, spontaneous, but not induced, activity was reduced (28).

Ganglionic transmission in the superior cervical ganglion of the cat was not affected by high doses of the purified SP (19), although a dual effect of potentiation and inhibition has been reported using impure extracts (140, 166, 167). Caspers (10, 168, 169) correlated behavioral with bioelectrical changes in the unanesthetized rat after administration of an impure SP extract. The EEG and d.c. potential patterns of the cortex were those of natural sleep following intraperitoneal and topical SP application. Dendritic potentials are increased in voltage and duration. The reactivity of the animals to acoustic stimulation was easily depressed, while tactile stimulation was more resistant. Conditioned responses were more resistant to SP than unconditioned ones. Besides a hyperpolarizing effect at the cortex, Caspers found SP reduced the unit discharge in the brain stem reticular formation, but had little effect at the thalamic relay nuclei. Schneiderman *et al.* (170), however, found SP (75 units/Kg. i.v.) decreases the threshold of the thalamocortical evoked potential in the rabbit, depressing the amplitude of the first surface-positive component and enhancing the second and third surface-negative components. Substance P increased cortical Δ activity and the number of spindles. The onset of changes occurred within 5 min. of administration, reaching a maximum within 15, and lasting about 1 hr. Cortical activation and hippocampal synchronization have been found with intracarotid injection (7) or topical application (171) of SP, but are probably a secondary effect produced by blood pressure depression (10).

Stern *et al.* (172) found an inhibitory influence of SP on polysynaptic, but not monosynaptic reflexes in the cat, while Kissel and Domino (173) found no effect on either. No effect was found on polysynaptic reflexes in the frog (121). Substance P had no influence on conditioned reflexes, discrimination tests, and maze performance of the rat (174).

Substance P produces no change in the dorsal root potential (175–177) or the amplitude variation in the electric knife fish (*G. eigenmannia*) (11). Substance P stimulates the sensory nerve endings in the rabbit ear (178).

DRUG INTERACTION

The failure of atropine to block the contracting action of SP on the intestine led to its discovery (1). Since then the interaction of many compounds with SP on isolated intestinal tissue has been determined, primarily to find a specific antagonist. Only two reasonably specific antagonists have been found: cystine-di-β-naphthylamide and trimethaphane-*d*-camphorsulfonate (47, 48). Drugs which exert no inhibitory or an unspecific effect on the SP action on the isolated guinea pig ileum are as follows: adenosine,

adermine, γ-aminobutyric acid, *p*-aminobenzoic acid, 1-AMP, 2-AMP, 5-AMP, antimit, antazoline phosphate, antipernicin, atropine, ATP, antihistamines, camylofine, azulen benzoquinone, biotin, 2-bromo-*d*-lysergic acid diethylamide, hyoscine butylbromide, bulbocapnine, barbital, bradykinin, caffeine, catechol, chlorpromazine, ε-amino-*n*-caproic acid, citric acid, cocaine, codeine, cysteine, cyanocobalamin, dehydrocholate, deoxyribonucleic acid, dihydroergotamine, dichloroisoproterenol, buphenine, eutison, glutathione, heparin, hexamethonium, histamine, hydrochloric acid, hydrazines, pentylenetetrazol riboflavin, *d*-lysergic acid diethylamide, morphine, iproniazid, kallidine, procaine hydrochloride, NaF, NaCN, mephenesin, meprobamate, 1,2-naphthoquinone, 1,4-naphthoquinone, methysergide, α-naphthylamine, β-naphthylamine, *n*-(naphthyl)-methylenediamine, narceine, dihydralazine, nicotine, oxytocin, patulin, phenacemide, phenoxybenzamine, polyethylene sulfate, protamine, pyridoxalphosphate, pyridoxine, quiloflex, reserpine, quinine, 8-hydroxyquinoline, 6-ethoxy-7-methoxy-1-(3′,4′-diethoxybenzyl)-3-methyl isoquinoline, renin, scopolamine, prenylamine, semicarbazide, sparteine, strychnine, tetraethylammonium bromide, thiamine, thioglycerin, thiosemicarbazide, trimethadione, tripelennamine, urea, vasopressin (1, 21, 40, 41, 47, 48, 50, 96, 179–184).

A few drugs, while not specific, inhibit the SP response, as 5-adenylic acid, noscapine, acetyl thiamine, adrenochrome, papaverine, trasentin-6H, D-tubocurarine, gallamine, trihexyphenidyl hydrochloride, ibogaine, harmoline (47, 50, 182–186).

While LSD potentiates the response of SP on the guinea pig ileum (187–189), BOL-148 has an inhibitory effect (183). Succinylcholine and psilocybin also potentiate the effect of SP (185, 190). Substance P potentiates the intestinal response to acetylcholine and nicotine with slight depression of serotonin and no effect on histamine or γ-aminobutyric acid responses (184, 191).

Hexamethonium, morphine, and morphine-like analgesics inhibit the stimulating action of SP on the peristaltic reflex (132, 192). Substance P is able to restore peristalsis when abolished by either external or internal application of serotonin or tubocurarine (4, 5, 193) but not bradykinin (194). Purified SP has a potentiating effect on epinephrine induced contractions of the nictitating membrane (19).

Morphine, physostigmine, or atropine injected 30 min. before sacrifice produced no change in the SP content of the small intestine of the rat (181). Physostigmine significantly decreases the SP content of the rabbit's intestine, while hexamethonium, chlorisondamine, atropine, reserpine, chlorpromazine, *p*-hydroxymercuribenzoate, and nicotine have no definite effect (125). Intraperitoneal injections of 100 units/Kg. of SP for 3 days significantly increases the serotonin content of the rat's ileum and stomach, but not of the spleen. Intraluminal application for 30 min. of SP (60–80 units) doubles the serotonin content of the isolated guinea pig ileum (132, 195).

Acetylsalicylate, mepyramine, atropine, or lysergic acid diethylamide do not inhibit the bronchoconstrictor response of SP in the guinea pig (135, 136).

Atropine, ganglionic blocking agents, antihistamines, or guanethidine have no effect on circulatory responses of SP in mammals (21, 144, 150, 196). Dihydroergotamine, caffeine, mecamylamine, chlorisondamine, hexamethonium, and methysergide diminish the SP arterial depressor response in the intact chicken, but have no vascular effect on the isolated chicken wing preparation or cat blood pressure. The response of these drugs is nonspecific. Atropine, *p*-bromdylamine, LSD, 1-benzyl-2-methyl-5-hydroxytryptamine (BAS-phenol), phenethylamine, harmaline, ibogaine, morphine, and reserpine have no or slight antagonistic effects in the intact chicken (112). Mepyramine reduces SP-induced increased capillary permeability (17).

The effect of drugs on SP concentration in the central nervous system has been investigated by several authors with no unanimity of results. Stern (116) found that strychnine (0.5 mg./Kg. i.p.) after 1–3 hr. reduced the amount of SP in the brain and spinal cord of the rat, while procaine (50 mg./Kg. i.p.) increased the amount. Mephenesin (150 mg./Kg. i.p.) had no effect at 1 hr. and caused only a slight reduction at 3 hr. Allergic encephalitis does not change the SP concentration. Haefely (197) found no change in content in the rat's brain after giving reserpine, barbiturates, chlorpromazine, amphetamine, and LSD. Stern and Kocic-Mitrovic (198), however, found a large increase in SP in the brain of the rat after reserpine treatment, but no change in concentration after phenobarbital, chlorpromazine, meprobamate, mephenesin, or syrosingopine. No change in the rat's brain SP content occurred after giving neostigmine, epinephrine, norepinephrine, serotonin, histamine, factor I, or γ-aminobutyric acid (199). Capsaicine, given subcutaneously, significantly reduces SP in the spinal cord of the rat, but not in the brain. *p*-Bromophenylacetyl urea had no

effect on the spinal cord concentration (111). Cocaine increases SP content in the dorsal roots proximally to site of topical application (200).

No change in SP brain concentration in mice was found after LSD, reserpine, morphine, chloroform, ether, chlorpromazine, barbital, insulin, diphenylhydantoin, pentylenetetrazol, or trihexyphenidyl hydrochloride treatment (182). Zetler and Ohnesorge (201) observed an increase in SP in the mouse brain after amphetamine and morphine and a decrease after chloroform, urethan, and phenobarbital, while LSD produced no change. While no change in total brain concentration was found after picrotoxin or LSD, if the "free" and "bound," *i.e.*, easy or difficult to extract portions were separately determined; picrotoxin increased the "free" and lowered the "bound" amounts of SP and LSD decreased the "bound" form.

Physostigmine decreased the concentration of SP in the rabbit brain, while reserpine, chlorpromazine, and *p*-hydroxymercuribenzoate had no effect (202).

In anesthetized dogs there was no change in the SP content in the hypothalamus and caudate nucleus after amphetamine, ephedrine, insulin, β-tetrahydronaphthylamine, caffeine, and reserpine (94). Reserpine has no effect on SP content in peripheral nerves of the dog (76).

The effect of exogenous SP on the action of central acting drugs is no more conclusive than the effect of these drugs on the endogenous concentration of SP. Zetler (8, 203, 204) found impure SP protected mice against strychnine and picrotoxin convulsions. It prevented the central effects of harmine and methamphetamine and prolonged hexobarbital sleeping time and bulbocapnine catelepsy. Substance P also antagonized morphine analgesia and caused hyperalgesia, potentiated caffeine convulsions, and lowered the threshold to painful stimuli. It had no effect on seizures induced by electroshock, ammonium acetate, nicotine, or pentylenetetrazole. These drugs were tested after 15–30 min. of SP treatment. However, Stern *et al.* (205, 206) found that a slightly purified SP sample potentiated strychnine convulsion, and shortened hexobarbital sleeping time—the opposite to the impure sample, but still antagonized morphine analgesia. Substance P acted as an antagonist to morphine analgesia in the mouse writhing tests (207), while Bonta *et al.* (208) found a strychnine antagonist in their impure SP preparation, but it had no effect on hexobarbital sleeping time or morphine analgesia. They found the strychnine antagonistic property also in other SP-free fractions. Pure SP had no strychnine antagonistic ability (50). Gaddum *et al.* (209) later separated an antistrychnine substance from the crude SP. Kapek (210) found that intracerebral injections of SP increased seizure thresholds to convulsions induced by pentylenetetrazol, strychnine, and electroshock. Stern *et al.* (172, 211, 212) found SP has an antagonistic effect against tetanus toxin, and iminodipropionitrile, and a synergistic effect with mephenesin and meprobamate. Substance P inhibits epileptic attacks induced by audiogenic stress in mice (213).

After observing the changes in concentration with time in the central nervous system after giving exogenous SP, Stern (116) re-examined several drugs to determine the influence of time of administration on the results, using an impure SP sample. Zetler's results were confirmed when SP was given 15 min. before administration of the other drugs. Strychnine, picrotoxin, caffeine, or morphine actions are, however, potentiated when administered 60 min. after SP and hexobarbital sleeping time is shortened. The action of chloral hydrate is lengthened when administered 15 or 60 min. after SP. Bulbocapnine catalepsy is lengthened at all times. Audiogenic stress is not inhibited after 60 min., but is at 15 min. Harmine tremor is antagonized by SP at all times tested. Pentylenetetrazole convulsions are only slightly influenced by SP after 60 min. Substance P not only antagonized morphine analgesia, but also suppressed the withdrawal symptoms in addicted rats. Impure SP given 60 min. prior shortened morphine, pethantine, and heptadon analgesia. It did not act against mephenesin paralysis after either 15 or 60 min. Substance P shows protection during the first 30 min. to strychnine convulsions and hexobarbital narcosis, then excitement for the next 1.5 hr., and by the second hour a return to the central behavior pattern.

Substance P had no influence on cocaine or procaine local anesthesia. The lethal dose of slow intravenous infusion of SP after LSD administration in the decorticated mouse is one-third to one-fourth of that in the nontreated normal animal (116). Both crude and pure SP (10,000 units/mg.) enhance the fourth dorsal root potential after LSD administration (175–177). The amplitude variations of the electric knife fish are significantly decreased following LSD and SP administration (11). Local application of γ-aminobutyric acid antagonizes the effect of SP on the d.c. potential in the cortex (168).

CONCLUSIONS

The chemistry, distribution, physiology, and pharmacology of SP has been reviewed. The presence of SP in all cordates, the characteristic

distribution in the gastrointestinal tract and nervous system, the changes in endogenous concentration with different functional states, and the high pharmacological activity of the pure substance indicate teleologically that SP has a definite physiological function. However, this function is still largely obscure, particularly within the nervous system. This makes SP an interesting and important physiological and pharmacological problem.

Alkaloids of *Acronychia Baueri* Schott I

Isolation of the Alkaloids and a Study of the Antitumor and Other Biological Properties of Acronycine

By GORDON H. SVOBODA, GERALD A. POORE, PATRICK J. SIMPSON, and GEORGE B. BODER

Utilizing a differential extraction technique for the examination of the bark of the Australian plant *Acronychia Baueri* Schott (*Bauerella australiana* Borzi), has resulted in the isolation of the triterpene lupeol and the alkaloids melicopine, acronycine, and normelicopidine. The experimental antitumor activity associated with the crude alkaloidal mixture obtained from the ether extract has been shown to be attributable to acronycine. Experimental evidence is herein given, showing acronycine to have the broadest antitumor spectrum of any alkaloid isolated to date in these laboratories. By virtue of its being chemically unrelated to any of the presently utilized antitumor agents it represents a new lead in the search for agents effective in the chemotherapeutic management of human neoplasms.

THE GENUS *Acronychia*, family *Rutaceae*, consists of approximately 20 species of trees and shrubs native to Australia and tropical Asia. Of the Australian species, one is also found in New Caledonia, six others being endemic. The species are characterized by opposite or alternate leaves, sepals, petals, and other flower parts being in fours (1).

Acronychia Baueri Schott, commonly called the scrub ash or scrub yellowwood, grows 50 to 60 ft. in New South Wales and Queensland. It resembles the evergreen *A. laevis* but has rather longer leaves and a hard fruit. The wood is said to be excellent for mallet and chisel handles (2). No references to its medicinal use were found.

While this species is usually classified as follows: family, *Rutaceae*; subfamily, *Toddalioideae*; tribe, Toddalieae; subtribe, Toddaliinae; Engler (3) considers it as being *Bauerella australiana* Borzi. "Whether or not *Bauerella* is a genus distinct from *Acronychia* is basically one of evaluation of separating characters. In 1931, Engler kept them distinct, but the material in the herbaria at Harvard cannot be distinguished at sight and the characters used by Engler to separate the two concepts are trivial indeed: for *Bauerella*, he cited sepals imbricate, stamen filaments treadlike, style long; for *Acronychia*, sepals valvate, filaments short and broad, style short. None of these is biologically critical. The genus must be based upon a significant biological difference. I, therefore, cannot accept *Bauerella*. The plant described in 1836 as *Acronychia Baueri* Schott was redescribed in 1897 as *Bauerella australiana* Borzi. I believe that the proper name of this plant should be *Acronychia Baueri* Schott." [1]

The choice of plants selected in the authors' phytochemical screening program is determined

Received March 21, 1966, from the Lilly Research Laboratories, Eli Lilly and Co., Indianapolis, Ind.

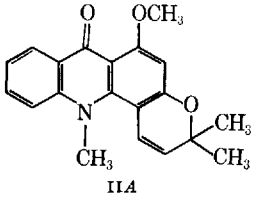
Accepted for publication May 11, 1966.

Presented to the Pharmacognosy and Natural Products Section, A.PH.A. Academy of Pharmaceutical Sciences, Dallas meeting, April 1966.

The authors thank the following for their aid in this investigation: Dr. I. S. Johnson for discussions held during this work; Mr. A. T. Oliver, Mr. D. R. Bedwell, Mr. R. E. Martello, Mr. P. E. Craig, Mr. J. W. Mattingly, and Mr. E. F. Priller and Mrs. V. P. Bothwell and Mrs. V. McNeely for laboratory assistance; Dr. H. A. Rose, Mr. R. E. Staten, Mr. P. Landis, Mr. D. O. Woolf, Jr., Mr. L. A. Spangle, Mr. D. Spurgeon, and Mr. P. Unger and Mrs. R. Laughlin and Mrs. D. Stevens for physical data; Mr. W. L. Brown, Mr. C. Ashbrook, Mr. H. L. Hunter, and Mr. R. Meister for microanalysis; and Miss E. D. Liljeblad for aid in preparing the manuscript.

The drug used in this investigation was obtained from the Meer Corp., New York, N. Y.

Added in proof: Recently an alternative structure for acronycine has been proposed (IIA) (19):



IIA

Previous work was somewhat ambiguous in that either structure was possible, and the former structure had been selected on the basis of what could be considered as tenuous NMR data.

Oxidative degradation of acronycine has produced an acid which was identified and which could only have been derived from structure IIA.

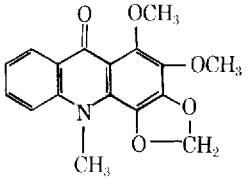
[1] Personal communication from Dr. Richard Evans Schultes, Curator, Botanical Museum, Harvard University, Cambridge, Mass.

by their reported folkloric usage and/or their reported alkaloidal content. Selection of *Acronychia Baueri* Schott falls into the second category, thereby being within the scope of the authors' original intent. Although the comprehensive work of Lahey *et al.* (4–10) had determined the alkaloidal content and the nature and structures of the various alkaloids, no biological activities were reported.

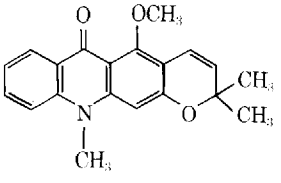
While the defatted ethanolic extract of the bark gave a negative response in the cancer screen *versus* the P-1534 leukemia, Mecca-lymphosarcoma, and adenocarcinoma 755, it elicited an interesting CNS depressant activity in the mouse behavior test (11). The observation of this latter activity was responsible for the ensuing phytochemical effort.

Inasmuch as the approach to the problem of isolation and purification involved a differential extraction technique, the results can be expected to be at variance with those of the total-extraction procedure with ethanol so frequently reported in the literature.

Defatting of the bark with *n*-hexane yielded an unexpectedly large amount of fat-soluble extractive, from which the triterpene lupeol was readily isolated. Extraction of the defatted drug with ether yielded an extract from which crystals readily deposited upon concentration. These crystals were eventually found to be a mixture of melicopine (I) and acronycine (II).



I



II

Although the original extract was inactive against the neoplasms used, it was found that the alkaloidal mixture was significantly effective *versus* the C-1498 leukemia, X-5563 myeloma, and AC-755. Fractional crystallization from methanol yielded the pure alkaloids. Melicopine was found to be ineffective against these experimental neoplasms, acronycine being responsible for the observed activity.

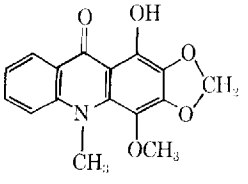
EXPERIMENTAL

A quantity of coarsely ground bark (15.0 Kg.) was extracted by stirring with two 35-L. portions of *n*-hexane. Concentration *in vacuo* yielded 253.0 Gm. of a nondrying oil. A copious quantity of fine needles deposited from the concentrate at room temperature. The oily mass was dissolved in 250 ml. of hot acetone, and the solution was allowed to cool spontaneously to room temperature, yielding 9.82 Gm. of fine colorless needles which exhibited parallel extinction and a high birefringence under polarized light, m.p. 210–212°. Its X-ray diffraction pattern was identical in all respects to that of the authentic triterpene lupeol.

The crude mother liquor (CML) elicited some activity against the C-1498 leukemia, and it was assumed that this activity was due to the acronycine content, as this alkaloid was shown to be present when examined by thin-layer chromatography (1:1 ethyl acetate–benzene on Silica Gel G).

Dissolving 128.5 Gm. of the *n*-hexane extract·CML in 2 L. of ether, with the subsequent addition of ethereal HCl to the chilled solution, produced 13.444 Gm. of a red-orange amorphous hydrochloride. Suspending the salt in H_2O and extracting with ethylene dichloride yielded 9.37 Gm. of amorphous free bases. Crystallization from acetone yielded three crops of crystals: first crop, 0.348 Gm. of what appeared to be essentially normelicopidine (III); second crop, 1.248 Gm. of acronycine contaminated with some normelicopidine; third crop, 0.644 Gm. of a mixture of apparently equal parts of acronycine and normelicopidine. A small amount of normelicopidine (0.012 Gm.) was obtained by crystallizing the mother liquor from methanol.

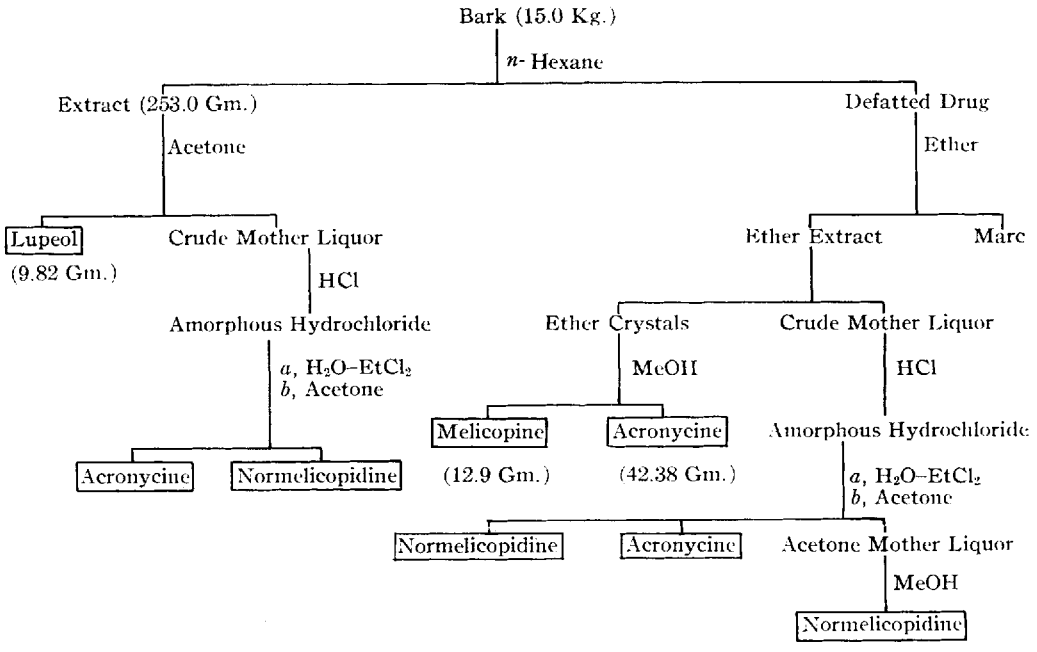
Recrystallization of the first crop from hot acetone yielded 0.298 Gm. of pure normelicopidine; recrystallization of the second crop from hot methanol yielded 0.028 Gm. of normelicopidine and 0.836 Gm. of acronycine; recrystallization of the third crop from hot methanol yielded 0.244 Gm. of normelicopidine and 0.236 Gm. of acronycine. The separation of normelicopidine from acronycine could be easily effected inasmuch as the former is quite insoluble in methanol.



III

The defatted bark was then extracted by stirring with three 40-L. portions of ether. Concentration of this extract to 10 L. produced 115.0 Gm. of yellow-gold crystals. Interpretation of physical data (X-ray, ultraviolet and infrared spectra, and TLC) indicated that this mixture was comprised of acronycine and melicopine, the former predominating.

Recrystallization of this mixture from methanol (10 ml./Gm.) afforded four crops of crystals: 12.9 Gm. of melicopine, 26.0 Gm. of slightly impure acronycine, 13.9 Gm. of a mixture of acronycine and melicopine, and 16.9 Gm. of slightly impure



Scheme I

acronycine, respectively. The second and fourth crops were combined (42.9 Gm.) and were recrystallized from methanol (8 ml./Gm.), yielding 41.4 Gm. of chromatographically pure acronycine. An additional 0.98 Gm. of pure alkaloid was obtained by crystallization of the finished mother liquor from acetone.

Treating an ether solution containing a 64.5-Gm. aliquot of the ether extract crude mother liquor[2] with ethereal HCl afforded 31.0 Gm. of a red-orange amorphous hydrochloride. The free bases were obtained (27.2 Gm.) by suspending the salt in H_2O and extracting with ethylene dichloride. Crystallization of normelicopidine (1.9 Gm.) was achieved with hot acetone (10 ml./Gm.). Concentration of the mother liquor to a low volume yielded 11.8 Gm. of essentially pure acronycine. (Chromatographic purity could be achieved by recrystallization from methanol as above.) An additional amount of normelicopidine (0.38 Gm.) was obtained by crystallization of the acetone mother liquor from methanol.

A flow diagram for the extraction scheme is presented in Scheme I.

Authentic samples of the alkaloids were not available for direct comparison, and it was necessary to resort to data published in the literature cited. All physical data[3] were in good agreement with those in the original references. As an additional aid to their identification, the infrared spectra of the individual alkaloids are presented in Fig. 1. NMR examination indicated that the integrated intensities, chemical shifts, and splitting patterns were consistent with the structures shown.

[2] Total weight = 169.0 Gm., but 100 Gm. reserved for chromatographic examination.

[3] Melting points were determined on a Kofler microstage. Ultraviolet absorption spectra were obtained using a Cary model 14 spectrophotometer; infrared spectra with a Perkin-Elmer model 21 double beam recording infrared spectrophotometer; NMR spectra with a Varian Associates 60-Mc. spectrometer. A standard Norelco powder camera, 114.6 mm. in diameter, was used in the X-ray examination.

Melicopine.—The base crystallizes from methanol as yellow orthorhombic blades elongated on the *c* crystallographic axis. Crystals show 100 and 010 faces and occasionally the 110 face crystals show pale yellow-dark yellow pleochroism, m.p. 179–181°.

Anal.—Calcd. for $C_{17}H_{15}NO_5$: C, 65.17; H, 4.82; N, 4.47; O, 25.53. Found: C, 64.62; H, 4.96; N, 4.67; O, 25.66.

$\lambda_{max.}^{EtOH}$ 270 mμ (log ε 4.74), 301 mμ (log ε 4.13).

Acronycine.—The base crystallizes from methanol as opaque, yellow, porous particles of which neither the extinction positions nor crystal shape

[a] Zeros or "no takes" are also indicative of activity, as no "no takes" in the control animals and 100% in the test animals are interpreted as 100% inhibition. [b] The number in parentheses indicates survivors on solid tumors, indefinite survivors at 45 days on leukemia or ascitic tests. [c] Seven animals. [d] Five animals.

could be determined, from ethanol as yellow clear needles in fan-shaped clumps, the long crystals of which exhibited extinction values of approximately 18° from the elongation axis. Also in evidence were some short, thick crystals (almost cubic) that had parallel extinction to one side of the crystal, from acetone as monoclinic rods, having an extinction angle of approximately 22°. There were also a number of crystals twinned on the *a* and *c* axes, m.p. 174–176°.

Anal.—Calcd. for $C_{20}H_{19}NO_3$: C, 74.74; H, 5.96; N, 4.36; O, 14.94. Found: C, 74.76; H, 6.19; N, 4.29; O, 15.01.

$\lambda_{max.}^{EtOH}$ 280 mμ (log ε 4.60), 291 mμ (log ε 4.54), 304 mμ (log ε 4.28), 392 mμ (log ε 3.84).

Normelicopidine.—The base crystallizes from either methanol or acetone as red, equant monoclinic prisms in which occasional elongated forms are seen. The crystals show pronounced yellow-red to dark red pleochroism, m.p. 210–211°.

Anal.—Calcd. for $C_{16}H_{13}NO_5$: C, 64.21; H, 4.37; N, 4.68; O, 26.73. Found: C, 64.29; H, 4.55; N, 4.74; O, 26.46.

$\lambda_{max.}^{EtOH}$ 218 mμ (log ε 4.175), 282 mμ (log ε 4.53); shoulders at 251 mμ (log ε 4.35), 304 mμ (log ε 4.088); in alkaline solution a typical phenolic shift was seen: $\lambda_{max.}^{EtOH}$ 250 mμ (log ε 4.358), 284 mμ (log ε 4.448), 312 mμ (log ε 3.968).

BIOLOGICAL PROPERTIES

Acronycine possesses the broadest antitumor spectrum (Table I) of any alkaloid isolated to date in these laboratories. The two systems of choice for assaying its activity are the C-1498 myelogenous leukemia and the X-5563 plasma cell myeloma.

Both of these experimental neoplasms are unique in some characteristics: the C-1498 leukemia does not respond to any of the known clinically active chemotherapeutic agents presently available, while the X-5563 myeloma presents most of the same features that are associated with multiple myeloma in man. Also of special interest is the activity against the Shionogi carcinoma 115, an androgen-dependent tumor which might be of value in predicting clinical activity against prostatic cancer.

Methodology.—Procedures for animal tumor testing in these laboratories have previously been described (12) but consist essentially of subcutaneous trocar implantation of solid tumors in the axilliary region and intraperitoneal inoculation of ascitic and leukemic cells with standard cell inocula. Treatment is usually initiated 24 hr. later, exceptions being made with the X-5563 myeloma, Shionogi carcinoma 115, and the S-91 melanoma. In the case of the X-5563, treatment was initiated 3 days after transplantation, while with the other two it was begun 5 days after transplantation. Activity of a compound is defined in terms of per cent inhibition, using treated *versus* controls (T/C) when testing against the solid tumors and in terms of per cent prolongation of life, using treated *versus* controls (T/C) when testing against the leukemias and ascites systems.

Preparation of Acronycine for Testing.—The relative insolubility of this alkaloid has obviously not precluded its being tested. A suitable suspension was prepared by grinding the compound with small volumes of a nonionic dispersant[4] to obtain a uniform suspension and diluting with this diluent to the desired volume. (The dispersant is a polyoxyethylated fatty acid that is H_2O-miscible and nontoxic when diluted to the proper concentration of 1:10 with either sterile distilled H_2O or sterile physiological saline solution.) Acronycine was neither soluble in, nor were satisfactory suspensions obtained with carboxymethylcellulose, saline, sesame oil, olive oil, or acacia solution.

ANTITUMOR ACTIVITY OF ACRONYCINE

In this laboratory acronycine has been shown to be a potent antitumor agent against a multiplicity of mouse neoplasms, significant activity having been demonstrated against 12 of 17 tumors tested with a wide range of dose levels. Not only is it broad

[a] Zeros or "no takes" are also indicative of activity, as no "no takes" in the control animals and 100% in the test animals are interpreted as 100% inhibition. [b] The number in parentheses indicates survivors. [c] No survivors.

spectrum in character, but it is also effective by various routes of administration. The oral and subcutaneous activities are of special interest since most of the clinically proved oncolytic agents presently used are ineffective orally and elicit intolerable side effects when administered subcutaneously.

When tested against the adenocarcinoma 755, C-1498 leukemia, and the X-5563 myeloma, acronycine also displayed significant activity by both the oral and subcutaneous routes. Furthermore, there was no evidence of skin irritation or alopecia when administered subcutaneously.

Only minimum activity was observed when the alkaloid was administered intravenously. In all probability this is attributable to its insolubility, sufficiently high blood levels not being attained. In several instances blockage of the circulatory system was evidenced, autopsy revealing an actual aortic block by the compound itself.

In determining the efficacy of a potential clinically useful compound it is always of interest to determine its effect under conditions which simulate, to the best of one's ability, the human situation, *i.e.*, its effectiveness against a well-established neoplasm. This condition can be achieved experimentally by implanting the mice with the tumors and withhold-

ing treatment until the neoplasm is ravaging its host. It should be noted that animals inoculated with the C-1498 leukemia at a known cell concentration normally live for a period of 14–18 days. Therefore, a delay of 6 days after inoculation before initiating therapy has without question allowed the tumor to become well established.

Acronycine also has the demonstrable ability to produce "cures" or indefinite survivors of animals inoculated with the C-1498 leukemia. An indefinite survivor is defined as one which survives 45 days or longer after inoculation, having undergone the usual 9- or 10-day regimen of daily treatment. Furthermore, it has demonstrated the ability to inhibit the growth of several neoplasms. These phenomena are detailed in the tables and summaries which follow.

Activity Against the C-1498 Leukemia.—As stated earlier, this neoplasm is singularly nonresponsive to chemotherapeutic agents. Table II summarizes the dose-response relationships for the various routes of administration, while Tables III and IV give the results of 3- and 6-day delayed therapy *via* various routes. It is readily seen that acronycine is effective when administered by any of several routes and even when treatment is delayed, the neoplasm having become well established.

Activity Against the X-5563 Plasma Cell Myeloma (Tables V, VI, and VII).—This neoplasm is intended to serve as a model for human multiple myeloma. In both the animal and human situations an abnormal protein is evidenced in the γ-globulin area of the blood serum.[5] The presence of this abnormal protein seems to increase with the progressive growth of the tumor in both hosts. The depression of this protein has been observed in patients responding to active chemotherapeutic agents, and this has also been seen in the serum of these experimental animals (Table VIII, Figs. 2 and 3).

[5] Beckman model R paper electrophoresis system, using Spinco procedure A, a method for serum proteins utilizing bromphenol blue dye in aqueous solution. The procedure is described in "Technical Bulletin 6095A," Spinco Division, Beckman Instruments, Inc., Stanford Industrial Park, Palo Alto, Calif.

It should be noted, however, that in man it has been possible to witness a regression of the tumor mass without a depression of this protein. In mice bearing the X-5563 neoplasm and responding to treatment with acronycine, regression of the tumor has always been accompanied by a drop in this abnormal protein. This technique, therefore, provides one with an interesting correlative tool in working with a compound active against this particular tumor.

Activity Against the Shionogi Carcinoma 115.—Of special interest in the tumor spectrum is the activity against this neoplasm. This is an androgen-dependent system which may be of value in serving as a model for activity against prostatic cancer in man. While this tumor originally arose in females, it will not grow in female mice, castrated males, or males treated with progesterone, estradiol, or other female sex hormones. Dose-response relationships are presented in Table IX.

Activity Against the Adenocarcinoma 755.—The activity of acronycine against this neoplasm by various routes of administration (Table X) is another feature which distinguishes it from the alkaloids of *Catharanthus roseus* G. Don (*Vinca rosea* Linn.).

OTHER BIOLOGICAL PROPERTIES

Electrophoretic Patterns and Leukopenia.—The methodology involved in these determinations is herein described. Sixteen C3H mice[6] were randomly set up in small hanging cages with four animals in each cage and one group serving as saline controls. The first bleeding was done on day zero, by the orbital technique, to establish both the normal white blood cell counts and the normal electrophoretic patterns for each group. After the blood samples were taken, all of the animals were implanted subcutaneously with the X-5563 tumor. Food and water were supplied *ad libitum* for the

[6] Supplied by Microbiological Associates Laboratory, Bethesda, Md.

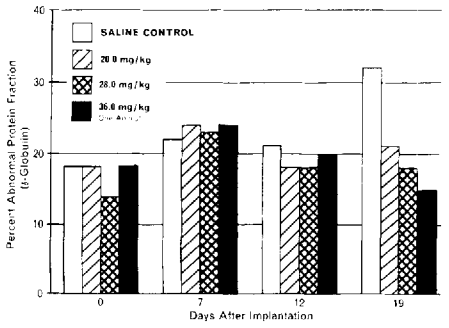

Fig. 2.—Electrophoretic patterns of X-5563 tumor-bearing, acronycine-treated mice.

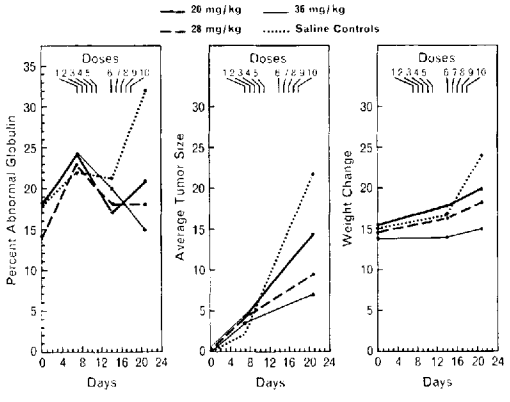

Fig. 3.—Additional parameters of electrophoresis WBC experiment.

next 6 days. On day 7 another bleeding was done, tumor measurements were made, and all animals were weighed. Intraperitoneal treatment was then initiated, three groups of mice receiving acronycine, one group receiving only saline for a total of 10 injections. Similar bleedings were done on day 12, after five injections, and on day 19, the day after the tenth and final injection. On day 19 all animals were weighed, tumor measurements were made, and the experiment was terminated (Table XI).

The electrophoresis was carried out in the following manner: 10 μl. of mouse plasma was used on each strip with Beckman B2 barbital[7] buffer, pH 8.6, having a 0.075 *M* strength. A 16-hr. run at room temperature was made, employing a constant current of 5 ma./cell. At the end of this period, the strips were stained by the Beckman method, scanned, and evaluated with a Beckman Analytrol.

Some leukopenia was evidenced at all dose levels. The method used to determine the white count was as follows: 20 μl. of whole blood was taken from each of the treated and control mice by the orbital technique. The fresh whole blood was then diluted with 10 ml. of particle-free physiological saline. Hemolysis of the red cells was achieved by adding a small amount of 2% saponin solution, allowing all of the intact white cells to be enumerated. Counts were made using a Coulter counter, the instrument being set to correlate with counts done by the hemocytometer method.

It should be noted that mice are somewhat limited in the amount of stress that can be tolerated, and that those on the electrophoresis-white blood cell count experiment were subjected to a great deal of stress because of a combination of factors—treatment with the alkaloid, several bleedings, the amount of blood withdrawn, and daily handling. The drug-treated animals were apparently unable to replenish the protein removed by the blood samplings under the conditions of daily therapy. This factor could be partly responsible for some deaths occurring during the experiments.

Mitotic Studies.—Acronycine was compared with vincaleukoblastine sulfate in several tissue culture cell lines for its ability to exert metaphase arrest. The procedures and methods have been described in detail elsewhere (13) but may be briefly summarized.

Two different cell lines were used, a diploid Chinese hamster lung and the polyploid HeLa cell. The alkaloid was dissolved in undenatured ethanol, sterile-filtered, and diluted in the appropriate tissue culture medium to a maximum concentration of 25 mcg./ml. in 0.25% ethanol. Log-phase cultures were exposed to the compounds for 4 and 24 hr. The cells were prepared according to two different methods—a hematoxylin-eosin stain (H and E) and a chromosome preparation according to the method of Puck (13).

No differences in effect were seen in the two cell lines and there was no apparent mitotic arrest associated with acronycine. At concentrations of 25 mcg./ml., acronycine exerted a very rapid cytotoxicity to cells which was produced in less than 3 hr.; yet at 10 mcg./ml. there was apparently no cytological effect. The TCD_{50} had previously been established at 13 mcg./ml. The results of a typical experiment are shown in Table XII.

Adrenal Apoplexy.—Acronycine exhibited significant activity in blocking the apoplexy effect of 7,12-dimethylbenz(a)anthracene (7,12-DMBA) when administered orally at 40 and 80 mg./rat in a single feeding 24 hr. prior to the oral administration of the 7,12-DMBA. Huggins *et al.* (14) orally administered 20 mg. of 7,12-DMBA to 50-day-old virgin female Sprague-Dawley rats and on necropsy found that the adrenals were completely engorged with blood and greatly hypertrophied. The same investigators further found that this effect could be blocked by certain other polycyclic hydrocarbons such as 3-methyl cholanthrene.

The strain, age, and sex of the animal are important factors in inducing this phenomenon. There is apparently some interrelationship between the female hormones being produced at this age, the role of the pituitary and that of the adrenal cortex, but it is not yet completely understood.

The same effects have been seen in these laboratories and the assay was performed in the following manner. Sprague-Dawley virgin female rats were received at 43 days of age. They were given food and water *ad libitum* until day 49. On this day they were weighed and dosed orally with the test compound, the controls receiving only saline. Twenty-four hours later they received the 7,12-DMBA, along with food and water *ad libitum*. On day 53 all of the animals were sacrificed by decapita-

tion and exsanguinated. The adrenals were then removed and weighed.

Determinations of hemoglobin were not done, the adrenals instead having been observed macroscopically and rated according to the degree of apoplexy present. With an active blocking agent the adrenals appeared yellowish in color as in normal untreated rats and weighed less than those of the controls. Per cent activity of a compound in preventing apoplexy was carried by the following arbitrary protocol:

4+ = total apoplexy (inactive compound)
3+ = 30% absence of apoplexy
2+ = 60% absence of apoplexy
1+ = 80% absence of apoplexy
0 = 100% absence of apoplexy

In assaying acronycine in the preceding manner 72 and 92% blocking effects were observed at 40 and 80-mg. doses per rat, respectively.

Effect of Topical Application.—Acronycine was suspended in the nonionic dispersant[4] as previously described and a suspension of 3 mg./ml. was applied daily to the skin of normal SPF-ND4 mice for a total of 22 applications. There was no evidence of skin irritation, epilation, or hyperplasia.

Algae, Protozoa, and Mammalian Cell Studies.—A dose response of acronycine was run against six algal and protozoan agar-diffusion type assays by the method of Johnson *et al.* (15). The systems involved were *Chlorella vulgaris*, *Scenedesmus basiliensis*, *Tetrahymena pyriformis*, *Ochromonas malhamensis*, *O. danica*, and *Euglena gracilis*. Trace activities were seen against the *S. basiliensis* and *T. pyriformis*, while significant measurable zones of inhibition were observed against both of the *Ochromonas* sp. from paper disks dipped into an ethanol solution containing 500 mcg./ml. of the alkaloid.

Acronycine was further found to be inactive against the bacterial agar diffusion systems of *Clostridium feseri* and *Lactobacillus casei*. However, significant activity was observed in the tissue culture bioautograph systems employing the HeLa human epidermoid cancer cells and the AV_2 human amniotic cells. While several dose levels were used, the lowest dose level employed to give significant zones of activity was 500 mcg./ml.

These data are summarized in Table XIII.

Tetrahymena Motility.—*Tetrahymena pyriformis* is an actively motile protozoan cell. The ciliate's powerful swimming ability allows it to remain in suspension for long periods despite its almost macroscopic size. Any compound exerting a gross cellular toxicity in general or a neurotoxic effect in particular would disrupt the ciliary apparatus causing sedimentation of the immobilized cell. The effect of acronycine upon *Tetrahymena* motility was studied by comparing the sedimentation rate of alkaloid-treated cell suspensions with untreated controls. Significant biological response in this system would suggest a rapid and economical method for comparison of structural modifications

of the compound and as an additional tool for future mechanism of action studies. Other workers have utilized *Tetrahymena* to study the effect of the phenothiazine tranquilizers (16) and the neuromuscular blocking action of some methonium compounds (17). This is not to say that these protozoa will detect all neurologically active agents—curare and leurocristine sulfate show no toxic effect upon motility of the organism. These motility studies represent a relatively simple method of observing the biological effect of a compound. The import of these observations depends upon possible correlation to the biological effects seen in drug-treated animals.

Dilute suspensions of viable *Tetrahymena* cells were prepared in particle-free saline. Acronycine was freshly dissolved in undenatured ethanol and added to the test suspension at zero time. The final drug concentration in the cell suspension was 50 mcg./ml., the final ethanol concentration being 1% (v/v). A similar volume of ethanol was added to the cell control. The sedimentation rate of the protozoa was measured by carefully inserting the counting stylus of the Coulter counter, an electronic particle counter, into the upper third of the suspension and counting the swimming cells at timed intervals. Rate of sedimentation would be reflected by the decreasing cell counts with time. Cell counts were obtained by utilizing three different threshold settings on the instrument to give a size distribution of the viable population at each counting interval. The protozoa were separated into three size groups: small, large, and very large, and the relative sedimentation rates were obtained for each group.

The line graph (Fig. 4) shows the profound toxic effect of acronycine upon the motility of the total cell population. The bar graphs (Fig. 5) illustrate the relative sedimentation rates of the sized cells. It is interesting to note that the rate and degree of cell immobilization is less with the very large cells than in the large and small groups. No firm explanation can be given for this phenomenon at this time.

SUMMARY

Acronycine has been shown to be a very potent alkaloid against a multiplicity of mouse neoplasms.

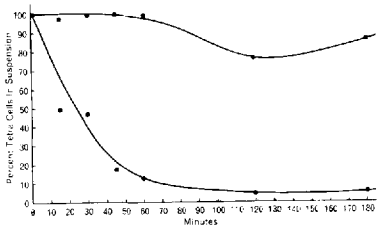

Fig. 4.—Tetrahymena motility studies. Key: upper curve with control c 1% EtOH; lower curve, acronycine, 50 mcg./ml.

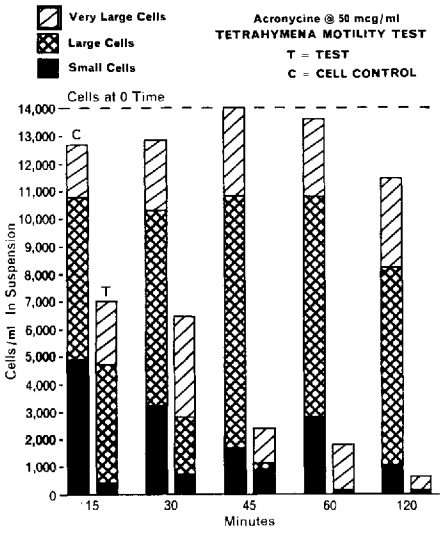

Fig. 5.—Tetrahymena motility test.

It possesses the broadest antitumor spectrum of any alkaloid isolated to date in these laboratories, being significantly active against 12 of 17 experimental neoplasms. Furthermore, it is not only effective when administered by a variety of routes, but it has demonstrated significant activity in delayed therapy experiments.

Unlike the alkaloids derived from *Catharanthus roseus* G. Don (*Vinca rosea* Linn.) (18), whose most striking experimental feature is their activity against the P-1534 leukemia in DBA/2 mice, acronycine is inactive against this neoplasm. Those systems of special interest which are responsive to this alkaloid are: the X-5563 plasma cell myeloma, a model system of multiple myeloma in man; the Shionogi carcinoma 115, an androgen-dependent tumor, potentially a model system for prostatic cancer; the C-1498 myelogenous leukemia which is nonresponsive to any of the clinically useful chemotherapeutic agents.

Other biological parameters include activity against certain protozoa and tissue culture activity against human epidermoid cancer cells and human amniotic cells. Acronycine has been shown to be an effective agent in blocking DMBA-induced adrenal apoplexy. Although some degree of leukopenia has been seen in certain experiments, the correlative weight loss associated with leukopenia was not in evidence.

No apparent mitotic arrest was seen in tissue culture studies utilizing either diploid Chinese hamster lung cells or the polyploid HeLa cells. This observation can be construed as lending credence to the theory that metaphase arrest is not a necessary function of an active oncolytic agent.

Acronycine, being an *N*-methyl acridone, possesses structural features unrelated to the *Catharanthus roseus* alkaloids or to any of the other presently known antitumor agents. Therefore, it represents a new lead toward chemotherapeutic management of a variety of neoplasms.

Studies are continuing in an attempt to ascertain as thoroughly as possible the character of the isolatable ingredients of this plant. The preparation of various derivatives and the determination of their biological activities, in an attempt to establish structure-activity relationships, are currently under way, and the results of these efforts will be reported at a later date.

Biphasic Elimination of Noscapine

By MILO GIBALDI* and NORMAN D. WEINER

Published data concerning the elimination of noscapine from various species were critically re-examined. It would appear that noscapine is distributed into a third compartment prior to exponential elimination. An analogy between the pharmacodynamics of noscapine and the barbiturate, thiopental, is considered.

NOSCAPINE, an isoquinoline alkaloid of opium, is an antitussive agent which depresses the medullary centers and suppresses the cough reflex. Pharmacological and clinical investigations have confirmed the value of noscapine as a potent nonaddictive cough suppressant (1).

Despite the antiquity of this opium derivative, little is known concerning its absorption, distribution, and elimination in the body. In 1961, Vedsö (2) studied the absorption and excretion of noscapine in man. More recently, Nayak *et al.* (3) investigated the rate of metabolism, urinary excretion, and organ distribution of noscapine in laboratory animals.

Vedsö concluded that the rapid disappearance of noscapine from the blood is attributable to rapid and cumulative tissue uptake. Conversely, Nayak and co-workers claimed that cumulation of the drug in the various tissues does not occur. These investigators indicated that the rapid disappearance of noscapine from the plasma and tissues is due to a rapid, first-order biotransformation. A further consideration of the data of both Vedsö (2) and Nayak *et al.* (3) strongly suggests that the elimination of noscapine involves a more complex mechanism than those postulated in either study.

DISCUSSION

Representative log tissue concentration *versus* time plots of noscapine, after intravenous administration of drug to rats, are shown in Fig. 1. These plots were constructed by utilizing literature data (3). As may be observed in Fig. 1, the blood, kidney, and skeletal muscle data demonstrate linearity after a lag of about 8 min. It is, therefore, apparent that after 8 min., the drug is eliminated from both the tissues and blood in a first-order fashion. In accord with Teorell's model for drug distribution and elimination (4), the rate of elimination of noscapine from the blood is in good agreement with the elimination rate found in the tissues. The half-lives for the elimination of noscapine from the blood, kidney, and muscle were calculated by the method of least squares and were found to be 12, 13, and 15 min., respectively.

Rapid first-order elimination of noscapine has been observed in a number of species. Nayak *et al.* (3) report that the first-order disappearance of noscapine from the blood of both mice and rabbits has a half-life of about 9 min. Vedsö (2), who contended that biotransformation was not involved in the elimination of noscapine, did not attempt to quantify the elimination rate in man. However, his data provide sufficient evidence to indicate that the plasma concentration-time curve contains a postabsorptive semilogarithmic phase. Representative semilog plots are presented in Fig. 2. Contrary to Vedsö's conclusions, the elimination of a significant portion of the noscapine from human plasma follows first-order kinetics with a half-life, according to our calculations, of about 40 min.

Further examination of the plots presented in Fig. 1 reveals an interesting phenomenon. Each of the plots is biphasic, consisting of a very rapid initial elimination component and a significantly slower elimination component; the latter phase is observable about 8 min. after administration. Biphasic elimination of noscapine also appears to occur in the rat brain and liver (3). To interpret the significance of these phenomena it is relevant to consider the pharmacokinetics of distribution after intravenous administration.

Theoretical Considerations of Drug Distribution.—Numerous studies have shown that a semilog plot of plasma concentration *versus* time, after rapid intravenous injections of various substances, demonstrates linearity only after a certain time has elapsed (5). The initial rapid fall in blood concentration is generally attributable to the diffusion of drug from the blood to other body fluids and tissues. The start of the linear portion of the plot is considered to coincide with the steady state of distribution where the apparent volume of distribution has reached a maximum and, thereafter, remains constant. The duration of this initial phase of elimination from the plasma is a function of the drug properties. A highly water-soluble substance, restricted to the extracellular fluid, will rapidly attain steady-state conditions. Drugs which can penetrate to deeper tissues will generally show a more prolonged initial phase prior to exponential elimination.

After intravenous administration, in a two-compartment model system, tissue concentration increases continually to a maximum and, thereafter, declines in a first-order fashion at a rate equivalent to the rate of decline of drug in the plasma. According to the steady-state approximation, the time required for maximum tissue concentration coincides with the time lag before the initiation of exponential elimination of drug from the plasma (5, 6). Furthermore, in the idealized two-compartment system, the fraction of drug in each compartment is independent of amount of drug in the body. Thus, plasma concentration is directly proportional to the amount of drug in the body. For compounds which adhere to

Received July 22, 1965, from the College of Pharmacy, Columbia University, New York, N. Y.
Accepted for publication May 5, 1966.

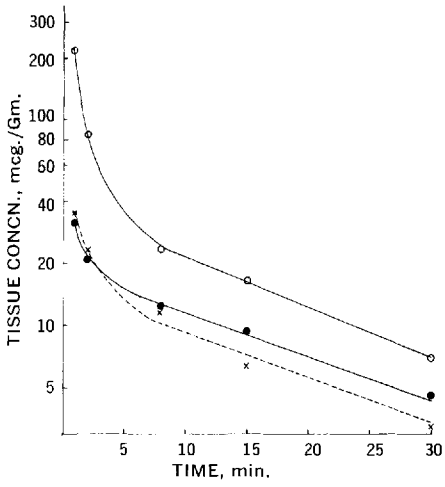

Fig. 1.—Semilog plots for the disappearance of noscapine from various tissues after intravenous administration of 25 mg./Kg. in rats. Plots were constructed with data taken from *Reference 3*. Key: O, kidney; ●, muscle; ×, blood.

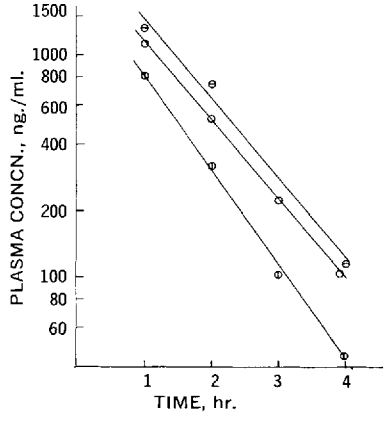

Fig. 2.—Semilog plots for the disappearance of noscapine from the plasma of three humans after oral administration of 250–300 mg. of noscapine chloride. Plots were constructed with data taken from *Reference 2*.

Teorell's model for distribution and elimination, a plot of plasma level, at time t, after intravenous administration *versus* dose, will be rectilinear (5).

Pharmacokinetic Interpretation of Noscapine Data.—Nayak *et al.* (3) state that there is a rapid disappearance of noscapine from the blood concomitant with a rapid uptake by organs perfused by a rich vascular supply. This is evidenced by the fact that drug concentration is maximal, within 1 min. after administration, in the brain, kidneys, lungs, liver, and skeletal muscle. However, as shown in Fig. 1, plasma concentration continues to decline rapidly until about 8 min. after administration. If uptake, by the tissues studied, was responsible for the very rapid initial elimination of noscapine from the plasma, drug concentration in each organ should be maximal at about 8 min. This is obviously not the case.

Although the various tissues studied constitute a compartment separate from the plasma, the rate of distribution between compartments is apparently so rapid that the defined system is kinetically indistinguishable from a one-compartment system.

Despite the fact that noscapine is very quickly distributed into a relatively large volume, it is evident from the data in Fig. 1 that, at the time of maximal tissue level, noscapine has not yet achieved its ultimate apparent volume of distribution. If the initial rapid loss of noscapine from the plasma is simply due to rapid uptake by the tissues studied, the steady-state approximation could be applied at the first minute, and each of the drug concentration-time plots in Fig. 1 could be described by a simple exponential expression. Quite to the contrary, each set of data in Fig. 1 was found to be fitted by an equation which is the sum of two exponentials. Using the method of least squares, the following equations were calculated:

$$C_B = 42e^{-0.80t} + 17e^{-0.057t} \quad \text{(Eq. 1)}$$

$$C_M = 50e^{-1.22t} + 18e^{-0.045t} \quad \text{(Eq. 2)}$$

$$C_K = 700e^{-1.33t} + 37e^{-0.055t} \quad \text{(Eq. 3)}$$

where C_B, C_M, and C_K refer to the concentrations of noscapine, at time t, in the blood, skeletal muscle, and kidneys, respectively.

At this point, it is reasonable to consider why such data are unusual. It is quite possible that many drugs really occupy a three-compartment model and distribution from the plasma into each compartment occurs at a somewhat different rate. Furthermore, sampling may be so spaced that the initial phase or phases of elimination from the plasma is not observed. For example, if Nayak *et al.* (3) had sampled at 10-min. intervals, only a single exponential elimination would be manifest. This interpretation of the noscapine data is in accord with Teorell's model but still leaves two unanswered questions.

First, since the pharmacokinetic evaluation has suggested the existence of a third compartment (real or hypothetical) what is the nature of this compartment? Second, as noted above, since a three-compartment model is not at variance with Teorell's model, one would expect a rectilinear relationship between plasma level and dose. However, as reported by Vedsö (2), noscapine plasma concentration, 2 hr. after oral administration of the drug, increased in a hyperbolic fashion as a function of dose (Fig. 3).

An explicit explanation for the pharmacokinetic behavior of noscapine is not possible without more extensive distribution and metabolism studies. However, the pharmacodynamic properties manifested by the barbiturate thiopental (7) are sufficiently analogous to consider in explaining the noscapine data.

Thiopental, like noscapine, is rapidly eliminated from the plasma and reaches maximal tissue levels in a number of organs, including the brain, liver, and muscle, almost immediately after administration. Nevertheless, plasma concentration continues to decline rapidly for a prolonged period of time after maximal tissue levels are achieved. Although drug concentration is maximal in a number of organs a few minutes after administration of thiopental, steady-state kinetics are not observed for a significant time thereafter (7). After a single 400-mg. dose of the

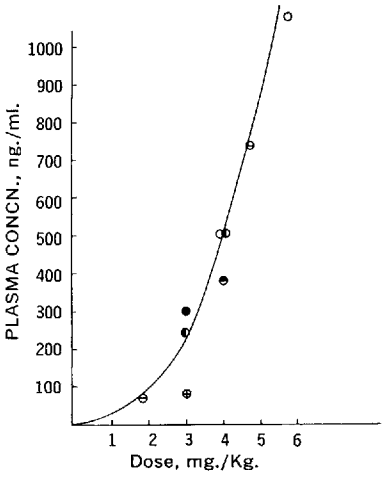

Fig. 3.—Relationship between dose of noscapine chloride and plasma concentration in various individuals 2 hr. after administration. (Taken from *Reference 2.*)

barbiturate to man, plasma levels fall abruptly and subjects awaken in about 10 min. Subsequently, the plasma level declines slowly, 10–15%/hr. (8). This rate reflects the true rate of metabolism of thiopental.

Studies designed to determine the movement of thiopental between plasma and tissue served to clarify this pharmacodynamic phenomenon. After intravenous administration, most tissue, including brain, rapidly take up considerable amounts of thiopental; the tissue levels then decline in parallel with the plasma level. In contrast, the level in fat, initially quite low, rises slowly, and approaches a peak in about 3 hr., when it is then 10 times higher than the plasma level.

The application of the thiopental distribution model to the noscapine data provides a near-perfect explanation of the results, but must remain speculative in the absence of experimental data of noscapine concentrations in adipose tissue. The organs selected by Nayak *et al.* did not include the adrenals or carcass, organs which would provide insight to drug deposition into a fat compartment.

Nevertheless, other analogies existing between noscapine and thiopental provide further support for the proposed hypothesis. The importance of lipid solubility in defining the pharmacological action of thiobarbiturates is emphasized by a comparison of thiopental and pentobarbital, its oxygen analog. Both drugs are distributed to almost the same extent in most tissues, but the concentration of pentobarbital is much less than that of thiopental in adipose tissue because of the decreased lipid solubility of the oxygen analog (8).

Noscapine, like thiopental, is a highly lipid soluble drug (9). An excellent indication of the comparable lipid characteristics of these drugs is provided by a consideration of transport across the blood-brain boundary, a process which is quite dependent on the lipid solubility of the permeating molecule. On the basis of distribution studies, both thiopental and noscapine show rate constants for entry into the central nervous system of about 0.8–1.0 min.$^{-1}$, significantly higher than rate constants observed for such drugs as pentobarbital (about 0.2 min.$^{-1}$), barbital (about 0.05 min.$^{-1}$), and salicylic acid (0.006 min.$^{-1}$) (3, 10). In view of the similar properties of noscapine and thiopental, it is not surprising that both drugs act in the central nervous system, and both show extremely prompt, but very fleeting, therapeutic activity.

Unfortunately, one piece of data does not fit well into the over-all scheme. Vedsö (2) has claimed the existence of a hyperbolic relationship between plasma level of noscapine and dose. Indirect evidence based on repetitive dosing leads one to believe that the hyperbolic relationship does not exist in the case of thiopental. For example, a dog can be anesthetized with a given dose of thiopental, then be allowed to recover, and this procedure can be repeated a number of times without having to reduce the dose to obtain the same depth of anesthesia. Each time, the recovery of the animal is due almost entirely to localization in fat, which acts as a seemingly infinite reservoir (7).

The third compartment proposed for noscapine, be it a fat compartment or not, does not share the ability of the fat compartment for thiopental, to function as a sink. Whether this difference is qualitative or simply a quantitative distinction remains to be determined.

The proposed model, based on fat distribution, is by no means the only possible way to explain the pharmacodynamics of noscapine. There are a number of other models which may be proposed to account for the data (11), including other compartments and complex biotransformation processes. Although these other models are mathematically correct, they do not appear to be as reasonable from physiologic and pharmacologic viewpoints.

Theoretical Analysis of Comparative Studies of Complex Formation

Solubility, Spectral, and Kinetic Techniques

By KENNETH A. CONNORS and JOSEPH A. MOLLICA, JR.

The stoichiometric ratios and the equilibrium constants describing the extent of formation of complexes are the basic information required in studies of complex formation between two species. Some of this information can be obtained by measuring the apparent solubility, the absorption spectrum, or the reactivity of one species (the substrate) as a function of the concentration of the other species (the ligand). The stability constant evaluated by these methods, assuming that a single complex of 1 : 1 substrate–ligand ratio is present, can be related to the actual constants of the system. Analyses of some of the complex systems most likely to be encountered show that the three experimental approaches may not always yield the same numerical result and that comparative studies with several techniques may yield valuable information concerning the natures of the complexes. The solubility, spectral, and kinetic methods for studying complexes are, in general, subject to about the same degree of nonselectivity in their responses to multiple complexes and interactions.

THE CONCEPT of complex formation has been adopted as a simple hypothesis that can account for nonadditive behavior in the physical and chemical properties of solutions of two or more species. With this hypothesis it becomes possible to utilize quantitative measures of these properties to describe the extent of interaction between the species and to investigate the nature of the interaction product, or complex. Many definitions of "a complex" have been proposed, but for the purpose of this paper it will not be necessary to limit sharply the chemical nature of the species, and the techniques to be discussed may be applicable to the study of reactions that may not be accepted as complexation reactions. Throughout this paper complex formation is considered to be a reversible chemical reaction in which the rate of attainment of equilibrium is much greater than any rates involved in the measuring processes. The system is, therefore, considered to be at equilibrium.

The basic purpose of studies of complex formation is to provide a comprehension of the properties of complexes, including their structure and reactivity. Since the reversibility of complex formation is the fundamental aspect relating all of these processes, the general reaction may be written

$$mS + nL \rightleftharpoons S_mL_n$$

where S represents the substrate and L is the ligand. (The substrate is the compound whose apparent properties are measured.) Given adequate evidence that a complex is present in a system, the first information to be sought is its stoichiometry, *i.e.*, the values of m and n. It is probable that in many (perhaps most) systems more than one complex is formed, and the stoichiometries of all species are desired. Note also that it is entirely conceivable that two or more complexes may co-exist with the same stoichiometry but different structures (1). (A single complex species will possess a unique average molecular and electronic configuration.)

The strength or stability of a complex is specified in terms of its stability (association, formation) constant. The over-all stability constant K_{mn} for the complex formation reaction is written

$$K_{mn} = \frac{[S_mL_n]}{[S]^m[L^n]} \qquad \text{(Eq. 1)}$$

where brackets signify molar concentrations, and K_{mn} is the constant applicable to the solvent system and temperature employed. The standard state of the solute is taken to be the infinitely dilute solution in the experimental solvent. Often the concentrations of S and L are sufficiently low that they do not affect the value of the stability constant. An alternative description of the stability of S_mL_n is available in the step stability constant; the assumption is that S_mL_n is formed from $S_mL_{(n-1)}$ by reaction with one L, or from $S_{(m-1)}L_n$ by reaction with one S. Rossotti and Rossotti (2) review methods for the determination of stability constants.

Most of the molecules of pharmaceutical and biological interest are of complicated structure and contain numerous functional groupings. Such molecules will, therefore, possess multiple interaction sites for complex formation. A given system of substrate, ligand, and solvent can be described as a member of one of the following two classes.

(*a*) Only one complex species is formed. This

Received February 28, 1966, from the School of Pharmacy, University of Wisconsin, Madison.
Accepted for publication April 7, 1966.
Presented to the Medicinal Chemistry Section, A.PH.A. Academy of Pharmaceutical Sciences, Dallas meeting, April 1966.
This investigation was supported in part by grant GM 11136 from the National Institutes of Health, U. S. Public Health Service, Bethesda, Md.

complex may be a resultant of multiple interactions. The possibility is admitted that the complex contains only substrate or only ligand molecules.

(*b*) Two or more complex species are formed. The several complexes may be formed by means of different types of interaction forces or by the same interactions differently oriented.

In the studies of complexation equilibria and their relation to enzyme specificity behavior from these laboratories, solubility measurements, absorption spectroscopy, and rate measurements for the determination of complex stability have been employed. These are all well-known techniques, but few investigators have systematically applied more than one of them to a complexation system (3–5). The three methods do not always yield the same numerical result (taking into account the expected experimental uncertainty), and the authors' analysis of these differences may be of value to others.

The usual procedure is to assume that a single complex of one-to-one stoichiometry is responsible for the observed effects. If the data suggest that this simple assumption is untenable, another will of course be made in its place, but the observations are not always susceptible to such an interpretation. The problem, therefore, is to find the relationship between the apparent 1:1 stability constant (as evaluated by each of the experimental methods) and the actual parameters of the system. This analysis will be carried out for each technique as applied to the systems most likely to be encountered. A comparison of the three methods will then be given.

ONE COMPLEX PRESENT

Solubility Method.—*1:1 Complex.*—The theory and practice of the solubility method have recently been reviewed in detail (6), and only a brief outline will be given here. The experimental operation entails the addition of an equal weight (in excess of its normal solubility) of the slightly soluble substrate into each of several vials. A constant amount of solvent is added to each container, then successively increasing portions of the relatively soluble ligand are added to these vessels, which are closed and brought to solubility equilibrium at constant temperature. The solution phases are analyzed for their total concentration of S, no matter what its molecular state may be. A phase diagram is constructed by plotting, on the vertical axis, the total molar concentration of S found in the solution, S_t, against the total molar concentration of L added, L_t. Here only the formation of soluble complexes is considered; these produce a phase diagram consisting of a smooth curve with a positive slope. In general, if the solution contains but one complex, S_mL_n, the concentrations at any point on the curve can be expressed (see *Appendix* for an explanation of the symbols):

$$\begin{aligned} [S] &= S_0 \\ [S_mL_n] &= (S_t - S_0)/m \\ [L] &= L_t - n[S_mL_n] \end{aligned} \qquad \text{(Eq. 2)}$$

since the concentration of free S is maintained constant by the presence of solid substrate. Consider the case in which $m = n = 1$. Then Eq. 1 for K_{11} is combined with Eq. 2 to give

$$S_t = \frac{K_{11}S_0L_t}{1 + K_{11}S_0} + S_0 \qquad \text{(Eq. 3)}$$

showing that the plot of S_t *versus* L_t is a straight line with intercept S_0 on the vertical axis; the slope of this line is $K_{11}S_0/(1 + K_{11}S_0)$, leading to

$$K_{11} = \frac{\text{slope}}{S_0(1 - \text{slope})}$$

In general, the apparent 1:1 stability constant is evaluated from solubility measurements by means of Eq. 4; if a single 1:1 complex is present, the apparent K_{11} (symbolized K'_{11}) determined in this manner is equal[1] to the actual K_{11}.

$$K_{11}' = \frac{\text{slope}}{\text{intercept}\,(1 - \text{slope})} \qquad \text{(Eq. 4)}$$

2:1 Complex.—If, more generally, $n = 1$ but m assumes any value, Eqs. 1 and 2 give

$$S_t = \frac{mK_{m1}S_0{}^mL_t}{1 + K_{m1}S_0{}^m} + S_0 \qquad \text{(Eq. 5)}$$

The phase diagram is linear as long as the complex contains only 1 molecule of L. If the slope is greater than unity, then at least one species must be present in which m is greater than 1, for it is clearly impossible for 1 mole of L to take more than 1 mole of S into solution if the complex is of the 1:1 type. On the other hand, a slope smaller than 1 does not necessarily mean that a 1:1 complex is formed, though this assumption is usually made. More definite statements concerning the order with respect to S cannot usually be made since the presence of solid substrate is responsible for maintaining a constant activity of S in the system.

If a single 2:1 complex is present, the slope is given by Eq. 6.

$$\text{slope} = \frac{2K_{21}S_0{}^2}{1 + K_{21}S_0{}^2} \qquad \text{(Eq. 6)}$$

If this quantity is less than 1, the system will be interpreted as a probable 1:1 complex, and an apparent K'_{11} will be calculated from Eq. 4. The actual nature of this quantity is found by combining Eqs. 4 and 6,

$$K_{11}' = \frac{2K_{21}S_0}{1 - K_{21}S_0{}^2} \qquad \text{(Eq. 7)}$$

where K_{11}' is the apparent 1:1 stability constant. (If the true stoichiometry were known, it would be a simple matter to evaluate the correct constant, K_{21}, but this information will seldom be available.)

This discussion has ignored the route of formation of S_2L. This can conceivably occur in three ways: $2S + L = S_2L$; $S_2 + L = S_2L$; $SL + S = S_2L$. The first of these has been employed in the preceding discussion. The other possibilities require the presence of another complex, and can be treated with methods developed later for these more complicated systems.

1:2 Complex.—When a complex is present that is second-order in L, the solubility diagram will not be linear but will show a positive curvature (6). Such a curvature would be recognized and would prevent evaluation of an apparent K_{11}'. If, however, the system contains both 1:1 and 1:2 com-

[1] This is not exactly true, of course, for the general solvent effect of S and L on the constant has been neglected; these relatively minor effects may be responsible for small differences, but can be ignored as long as S_t and L_t remain fairly small. The "statistical" or "contact" complexes formed as a result of random distribution of the molecules have also been neglected (7, 8).

plexes, the deviation from linearity may be unnoticed and misinterpretation may result. This system will be analyzed in a later section.

Substrate Dimer.—Suppose S undergoes reaction to form the dimer S_2 with dimerization constant K_{SS}. Then the total concentration $S_t = [S] + 2[S_2]$, or $S_t = S_0 + 2K_{SS}S_0^2$. Obviously the apparent complexation constant evaluated from the phase diagram will be zero, but the intercept will give $S_0 + 2K_{SS}S_0^2$ rather than S_0. No solubility experiment will reveal this anomaly, however.

Spectral Method.—*1:1 Complex.*—If the molar absorptivities of the complex and the substrate differ at the same wavelength, it may be possible to determine the stability constant spectrophotometrically. It is assumed that Beer's law is followed by all species. Then at a concentration S_t of substrate, in the absence of ligand, the solution absorbance is

$$A_0 = a_S b S_t \qquad \text{(Eq. 8)}$$

In the presence of ligand at total concentration L_t, the absorbance of the solution containing the same total substrate concentration is

$$A_L = a_S b[S] + a_L b[L] + a_{11} b[SL]$$

which, combined with the material balance on S, gives

$$A_L = a_S b S_t + a_L b L_t + \Delta a b[SL]$$

where $\Delta a = a_{11} - a_S - a_L$. By measuring the solution absorbance against a reference containing ligand at concentration L_t, the measured absorbance becomes

$$A_L' = a_S b S_t + \Delta\, ab[SL] \qquad \text{(Eq. 9)}$$

Combining Eqs. 8 and 9 with the stability constant definition leads to

$$\Delta A/b = K_{11}\Delta a[S][L]$$

where $\Delta A = A_L' - A_0$. Utilizing the expression $[S] = S_t/(1 + K_{11}[L])$, this becomes

$$\Delta A/b = \frac{K_{11}S_t\Delta a[L]}{1 + K_{11}[L]} \qquad \text{(Eq. 10)}$$

This equation can be put into several linear forms, one of these being Eq. 11, which is similar to the equation used by Benesi and Hildebrand (9, 10) to determine stability constants spectrophotometrically.

$$b/\Delta A = 1/K_{11}S_t\Delta a[L] + 1/S_t\Delta a \qquad \text{(Eq. 11)}$$

If [L] can be approximated by L_t, a plot of $b/\Delta A$ *versus* $1/L_t$ will be linear. The stability constant K_{11} is taken as the ratio *intercept/slope* of this plot. This is the operational definition of the spectrally measured 1:1 stability constant. Note that the types of interaction or their distribution in the complex are irrelevant, the only requirement in the application of the method being that Δa is not equal to zero.

No approximations have been introduced in the derivation of Eq. 11, but it is necessary to assume $[L] = L_t$ in its application. This assumption is equivalent to supposing that $1 + K_{11}[S] = 1$, because of the relationship $L_t = [L](1 + K_{11}[S])$. The assumed equality $[L] = L_t$ is, therefore, sensitive to the magnitude of the stability constant and to the substrate concentration. If K_{11} is quite large, it is essential to hold S_t to a small value if Eq. 11 is to be applied.

As noted above, Eq. 11 is exact, but its use requires an approximation. It is possible to introduce the approximation during the derivation (2), leading to the equation

$$bL_t/\Delta A = (S_t + L_t)/\Delta a S_t + 1/\Delta a K_{11}S_t$$

It can be shown that the application of this equation requires conditions that are similar to those adopted in the use of Eq. 11. Throughout this paper the spectral method will be discussed in terms of Eq. 11.

2:1 Complex.—In this system the equation corresponding to Eq. 9 is written

$$A_L' = a_S b S_t + \Delta ab[S_2L]$$

where $\Delta a = a_{21} - 2a_S - a_L$. The concentration of free substrate is given by

$$[S] = \frac{S_t}{1 + 2K_{21}[S][L]}$$

The resulting equation in its reciprocal form is

$$b/\Delta A = 1/K_{21}S_t\Delta a[S][L] + 2/S_t\Delta a \qquad \text{(Eq. 12)}$$

so the apparent spectral constant is

$$K_{11}' = 2K_{21}[S] \qquad \text{(Eq. 13)}$$

Note, however, that the plot should not theoretically be linear, since the slope is a function of [S]. This complication will be treated in more detail in later sections dealing with multiple complexes.

Substrate Dimer.—If S dimerizes with a change in spectrum, the quantity ΔA will be independent of L_t. The apparent stability constant will be zero. Beer's law will not be followed by the substrate if the dimer's molar absorptivity is not twice that of the monomer.

Kinetic Method.—*1:1 Complex.*—The kinetic method, as it has been most frequently applied, utilizes a reduction in rate of a reaction of S when L is present to obtain information about the nature of the complex; the basic assumption is that the decreased reactivity is the result of complexation, the complexed S being less reactive than free S. The kinetic scheme can be represented

$$S + L \overset{K_{11}}{\rightleftharpoons} SL$$

$$S + R \overset{k_S}{\rightarrow} \text{products}$$

$$SL + R \overset{k_{11}}{\rightarrow} \text{products}$$

If, as is usually the case, a reagent R is involved in the reaction, k_S is the second-order rate constant (often determined under pseudo first-order conditions with reagent in excess). It is assumed that R does not form complexes with S or L. The theoretical rate equation is

$$v = k_S[S][R] + k_{11}[SL][R] \qquad \text{(Eq. 14)}$$

and the experimental rate equation is

$$v = k_{obs.}S_t \qquad \text{(Eq. 15)}$$

where $k_{obs.}$ is the pseudo first-order rate constant. Setting Eqs. 14 and 15 equal and dividing through by [R] and S_t,

$$k_S' = k_S f_S + k_{11} f_{11} \qquad \text{(Eq. 16)}$$

where k_S' is the apparent second-order rate constant, f_S is the fraction of S in the uncomplexed form, and f_{11} is the fraction present as SL. The stability constant K_{11} is combined with the definitions of these fractions, giving Eq. 17.

$$f_S = \frac{1}{1 + K_{11}[L]} \qquad f_{11} = \frac{K_{11}[L]}{1 + K_{11}[L]} \qquad \text{(Eq. 17)}$$

In the special case that $k_{11} = 0$, Eq. 16 can be expressed in the forms Eqs. 18 and 19.

$$k_S' = k_S f_S \qquad \text{(Eq. 18)}$$

$$k'_S/k'_S = K_{11}[L] + 1 \qquad \text{(Eq. 19)}$$

According to Eq. 18, a plot of k_S' *versus* f_S is linear, passing through the origin, with slope k_S. Prior knowledge of K_{11} is required to calculate f_S. Equation 19, however, can be plotted without this knowledge if the equality $[L] = L_t$ may be made. Then the slope of the plot of k_S/k_S' *versus* L_t gives K_{11}.

If $k_{11} \neq 0$, the general Eq. 16 must be used. Since $f_S + f_{11} = 1$, this can be written

$$k_S - k_S' = f_{11}(k_S - k_{11}) \qquad \text{(Eq. 20)}$$

Introducing the definitions $r_{11} = k_{11}/k_S$ and $q_{11} = 1 - r_{11}$ permits Eq. 20 to be transformed to Eq. 21.

$$k_S - k_S' = q_{11} k_S f_{11} \qquad \text{(Eq. 21)}$$

or

$$k_S - k_S' = \frac{q_{11} k_S K_{11}[L]}{1 + K_{11}[L]} \qquad \text{(Eq. 22)}$$

Equation 22 can be placed in the following three forms amenable to linear graphing:

$$\frac{1}{k_S - k_S'} = \frac{1}{q_{11} k_S K_{11}[L]} + \frac{1}{q_{11} k_S} \qquad \text{(Eq. 23)}$$

$$\frac{[L]}{k_S - k_S'} = \frac{[L]}{q_{11} k_S} + \frac{1}{q_{11} k_S K_{11}} \qquad \text{(Eq. 24)}$$

$$\frac{k_S - k_S'}{[L]} = -K_{11}(k_S - k_S') + q_{11} k_S K_{11} \qquad \text{(Eq. 25)}$$

Throughout this paper the kinetic method will be treated in terms of Eq. 23, which predicts that a plot of $1/(k_S - k_S')$, or of $k_S/(k_S - k_S')$, *versus* $1/[L]$ should be linear. The kinetically determined 1:1 stability constant is then defined as the ratio *intercept/slope* of this plot. From the intercept value the quantity q_{11}, and ultimately k_{11}, can be evaluated.

Equation 19 has frequently been employed for the estimation of stability constants from rate measurements. This procedure is not recommended, however, for the reason made evident in Fig. 1. In this figure Eq. 19 is plotted for three hypothetical systems having q_{11} values of 0.5, 0.9, and 1.0; in each instance the true $K_{11} = 25.0\ M^{-1}$. Only the topmost line should be straight, since Eq. 19 is valid only when $q_{11} = 1.0$ and in fact the other lines do exhibit a slight negative curvature. But if these were experimental points based on ordinary rate data, rather than calculated theoretical points, it is probable that these curves would be interpreted as straight lines.[2] The slopes of these lines, which are

[2] As K_{11} is made larger, the curvature in these plots becomes more evident.

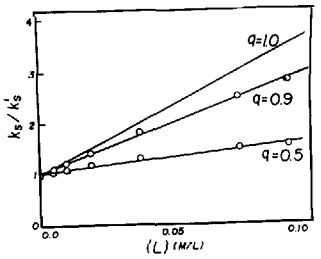

Fig. 1.—Plots of Eq. 19 for systems containing a single 1:1 complex with stability constant $K_{11} = 25.0\ M^{-1}$ and the q values shown.

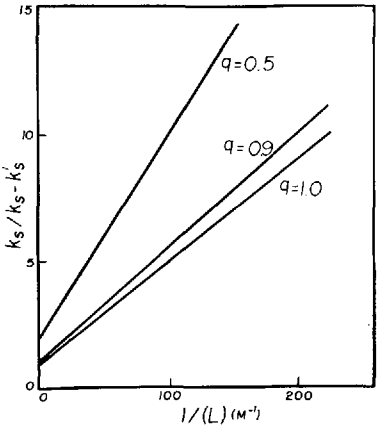

Fig. 2.—Plots of the data shown in Fig. 1 according to Eq. 23.

the apparent 1:1 stability constants according to Eq. 19, are 25 (for $q_{11} = 1.0$), 18 (for $q_{11} = 0.9$), and 5.4 (for $q_{11} = 0.5$). It is suggested that Eqs. 23, 24, or 25 be used in analyzing kinetic data. The same data plotted in Fig. 1 have been replotted in Fig. 2 according to Eq. 23; the apparent 1:1 stability constant is 25 M^{-1} in each case.

2:1 Complex.—In dealing with this system it becomes necessary to take into account various possible fates of the complex S_2L. It may undergo reaction with R to give products from one S molecule, releasing the other unreacted, or both S molecules may react, or 2 molecules of R may be required, etc. The simplest assumption will be adopted, that $k_{21} = 0$, recognizing that this places a limit on the applicability of the result. Then the basic equation, corresponding to Eq. 16, is

$$k_S' = k_S f_S \qquad \text{(Eq. 26)}$$

The fraction $f_S = [S]/S_t$, while $S_t = [S] + 2[S_2L]$. Combining these equations with the definition of K_{21} gives

$$f_S = 1/(1 + 2K_{21}[S][L])$$

which, with Eq. 26, leads to

$$k_S' = k_S/(1 + 2K_{21}[S][L]) \qquad \text{(Eq. 27)}$$

Equation 27 shows that k_S', at a given ligand concentration, is a function of substrate concentration; in other words, the apparent rate constant will vary with time as the reaction proceeds. If measurements

are made for only a small portion of the total reaction time, it is quite possible (taking into account ordinary experimental uncertainties) to overlook the variability of k_S' and to interpret the system as belonging to the 1:1 class. Equation 27 can be converted to the usual plotting form:

$$1/(k_S - k_S') = 1/2k_S K_{21}[S][L] + 1/k_S \quad \text{(Eq. 28)}$$

The kinetically evaluated K_{11}' is equal to the ratio *intercept/slope*, or

$$K_{11}' = 2K_{21}[S] \quad \text{(Eq. 29)}$$

Substrate Dimer.—If S dimerizes, and the dimeric form is essentially unreactive, the apparent constant k_S' will be related to the substrate concentration by the equation $k_S' = k_S(1 + 2K_{SS}[S])$. The apparent constant will, therefore, vary with time during a reaction. Since k_S' is not dependent upon the ligand concentration, however, the apparent 1:1 stability constant will be zero.

TWO COMPLEXES PRESENT

Solubility Method.—*Two 1:1 Complexes.*—It is possible that two complexes of 1:1 stoichiometry but different structures may co-exist. If one distinguishes between these by representing them as SL and LS, the solubility conservation equations may be written

$$S_0 = [S]$$

$$S_t = [S] + [SL] + [LS]$$

$$L_t = [L] + [SL] + [LS]$$

These are combined with the stability constants to give

$$S_t = \frac{(K_{SL} + K_{LS})S_0L_t}{1 + (K_{SL} + L_{LS})S_0} + S_0 \quad \text{(Eq. 30)}$$

which has the same form as Eq. 3 for a single 1:1 complex. Applying Eq. 4 shows that

$$K_{11}' = K_{SL} + K_{LS} \quad \text{(Eq. 31)}$$

Thus the apparent 1:1 stability constant evaluated by solubility measurements gives the sum of the individual constants. This can be generalized to any number of 1:1 complexes. Note that the slope of the phase diagram cannot exceed unity as long as only 1:1 complexes are present.

1:1 and 2:1 Complexes.—The step stability constants are defined as

$$K_{11} = [SL]/[S][L]$$

$$K_{(21)} = [S_2L]/[S][SL]$$

The development follows the lines already indicated. The equation of the phase diagram is

$$S_t = \left[\frac{K_{11}S_0 + 2K_{11}K_{(21)}S_0^2}{1 + K_{11}S_0 + K_{11}K_{(21)}S_0^2}\right] L_t + S_0 \quad \text{(Eq. 32)}$$

Combining the slope of this plot with Eq. 4:

$$K_{11}' = \frac{K_{11} + 2K_{11}K_{(21)}S_0}{1 - K_{11}K_{(21)}S_0^2} \quad \text{(Eq. 33)}$$

That a mathematically equivalent expression would be obtained if the over-all stability constant had been employed can be seen from the equality $K_{21} = K_{11}K_{(21)}$.

1:1 and 1:2 Complexes.—Combining the step constants K_{11} and $K_{(12)}$ with the material balance equations gives

$$S_t = \left[\frac{K_{11}S_0 + K_{11}K_{(12)}S_0[L]}{1 + K_{11}S_0 + 2K_{11}K_{(12)}S_0[L]}\right] L_t + S_0 \quad \text{(Eq. 34)}$$

which, with Eq. 4, leads to

$$K_{11}' = \frac{K_{11} + K_{11}K_{(12)}[L]}{1 + K_{11}K_{(12)}S_0[L]} \quad \text{(Eq. 35)}$$

According to Eq. 34 the phase diagram should show a positive curvature; but if the 1:1 complexing is much more extensive than the 1:2 type, this nonlinearity may not be noticed. Methods are available to analyze this system, when it is recognized, to obtain the individual stability constants (6).

1:1 Complex and Ligand Dimer.—The equation of the phase diagram is easily developed as before:

$$S_t = \frac{K_{11}S_0L_t}{1 + K_{11}S_0 + 2K_{LL}[L]} + S_0 \quad \text{(Eq. 36)}$$

where $K_{LL} = [L_2]/[L]^2$. The phase diagram will exhibit a negative curvature, but if the curve is mistaken for a straight line the apparent 1:1 stability constant that will be evaluated is given by Eq. 37.

$$K_{11}' = \frac{K_{11}}{1 + 2K_{LL}[L]} \quad \text{(Eq. 37)}$$

1:1 Complex and Substrate Dimer.—In this case the equation of the phase solubility diagram is

$$S_t = \frac{K_{11}S_0L_t}{1 + K_{11}S_0} + S_0 + 2K_{SS}S_0^2$$

The slope of the straight line is the same as that which would be observed in the absence of dimer formation, but the intercept is different. The apparent constant is

$$K_{11}' = \frac{K_{11}}{1 + 2K_{SS}S_0} \quad \text{(Eq. 38)}$$

Spectral Method.—*Two 1:1 Complexes.*—If the two complexes SL and LS are formed and at least one of them possesses a molar absorptivity different from free S, a spectral change will be observed. The analysis follows that given for a single 1:1 complex. The concentration of free substrate is related to the other system variables by Eq. 39.

$$[S] = \frac{S_t}{1 + (K_{SL} + K_{LS})[L]} \quad \text{(Eq. 39)}$$

The reciprocal form of the equation for this system is

$$b/\Delta A = \frac{1}{S_t(K_{SL}\Delta a_{SL} + K_{LS}\Delta a_{LS})[L]} + \frac{K_{SL} + K_{LS}}{S_t(K_{SL}\Delta a_{SL} + K_{LS}\Delta a_{LS})} \quad \text{(Eq. 40)}$$

(where $\Delta a_{SL} = a_{SL} - a_S - a_L$ and $\Delta a_{LS} = a_{LS} - a_S - a_L$), showing that the apparent 1:1 stability constant is given by

$$K_{11}' = K_{SL} + K_{LS} \quad \text{(Eq. 41)}$$

This result has been pointed out by several authors (1). Even if one of the complexes has an absorption spectrum identical with that of the free substrate,

K_{11}' will be given by Eq. 41. This may be intuitively pictured as the result of a depletion of free S by formation of this second complex, even though it is not spectrally distinctive.

1:1 and 2:1 Complexes.—This system should not, theoretically, yield a linear reciprocal plot; yet, as Johnson and Bowen have shown, the experimental plots may well appear to be linear (11). The analysis may be conducted as in earlier examples, leading to

$$\Delta A/b = K_{11}[S][L](\Delta a + \Delta a' K_{(21)}[S])$$

where $\Delta a = a_{11} - a_S - a_L$ and $\Delta a' = a_{21} - 2a_S - a_L$. For the present purpose the substrate concentration is written as

$$[S] = \frac{S_t}{1 + K_{11}[L](1 + 2K_{(21)}[S])}$$

These equations are combined to give

$$b/\Delta A = \frac{1}{K_{11}S_t(\Delta a + \Delta a' K_{(21)}[S])[L]} + \frac{1 + 2K_{(21)}[S]}{S_t(\Delta a + \Delta a' K_{(21)}[S])} \quad \text{(Eq. 42)}$$

from which it is seen that the apparent spectrally measured constant is

$$K_{11}' = K_{11} + 2K_{11}K_{(21)}[S] \quad \text{(Eq. 43)}$$

This conclusion is not always valid, however; a fuller discussion is given under the next system.

1:1 and 1:2 Complexes.—Again it is evident that the plot should be nonlinear, but Johnson and Bowen (11) have found that the curvature may be overlooked. The development of the appropriate equation is similar to that in the preceding example; the equation is

$$b/\Delta A = \frac{1}{K_{11}S_t(\Delta a_{11} + \Delta a_{12}K_{(12)}[L])[L]} + \frac{1 + K_{(12)}[L]}{S_t(\Delta a_{11} + \Delta a_{12}K_{(12)}[L])} \quad \text{(Eq. 44)}$$

where $\Delta a_{11} = a_{11} - a_S - a_L$ and $\Delta a_{12} = a_{12} - a_S - a_L$. The apparent stability constant is

$$K_{11}' = K_{11} + K_{11}K_{(12)}[L] \quad \text{(Eq. 45)}$$

That Eq. 44 is not the equation of a straight line must be kept in mind, however, and it may be expected that the range of ligand concentration over which the system is studied may affect the results. Suppose the ligand concentration is made very large, so that $\Delta a_{12}K_{(12)}[L] \gg \Delta a_{11}$; then Eq. 44 becomes

$$b/\Delta A = 1/\Delta a_{12}K_{11}K_{(12)}[L]^2 + 1/\Delta a_{12}S_t$$

and the apparent constant is

$$K_{11}' = K_{11}K_{(12)}[L] \quad \text{(Eq. 46)}$$

The necessary condition for Eq. 46 to be approached is a function not only of [L], but also of the quantities Δa_{11}, Δa_{12}, and $K_{(12)}$. This conclusion agrees with the calculations of Johnson and Bowen (11), who designed hypothetical systems to demonstrate these effects. (These remarks apply also to the system described by Eq. 42, which is, however, not as sensitive to these effects because [S] is usually much smaller than [L].) Thus, the apparent stability constant may vary with the wavelength at which the absorbance measurements are made.

1:1 Complex and Ligand Dimer.—This situation is made rather complicated because the assumption that $L_t = [L]$, made hitherto in the spectral analysis, is not valid; a very appreciable fraction of the uncomplexed ligand may exist as the dimer. This system does not appear to be amenable to a useful treatment according to the manner of the earlier examples.

1:1 Complex and Substrate Dimer.—This system does not lead to a useful analysis. The extent of dimerization will depend upon the ligand concentration (unlike the case, discussed earlier, where S_2 was the only complex present) because the free substrate concentration is a function of ligand concentration.

Kinetic Method.—*Two 1:1 Complexes.*—Proceeding as for a single complex, this basic equation is obtained

$$k_S' = k_S f_S + k_{SL} f_{SL} + k_{LS} f_{LS} \quad \text{(Eq. 47)}$$

which, since $f_S + f_{SL} + f_{LS} = 1$, leads to

$$k_S - k_S' = q_{SL}k_S f_{SL} + q_{LS}k_S f_{LS} \quad \text{(Eq. 48)}$$

where the q's are defined as before. Expressions for the fractional compositions are found by combination of the material balance and stability constant equations,

$$f_{SL} = \frac{K_{SL}[L]}{1 + K[L]} \qquad f_{LS} = \frac{K_{LS}[L]}{1 + K[L]}$$

where $K = K_{SL} + K_{LS}$. Substituting these into Eq. 48 and rearranging gives the linear form

$$\frac{1}{k_S - k_S'} = \frac{1}{(q_{SL}K_{SL} + q_{LS}K_{LS})[L]} + \frac{K_{SL} + K_{LS}}{(q_{SL}K_{SL} + q_{LS}K_{LS})} \quad \text{(Eq. 49)}$$

showing that K_{11}' is given by Eq. 50.

$$K_{11}' = K_{SL} + K_{LS} \quad \text{(Eq. 50)}$$

This result will be obtained even if one of the complexes has a reactivity equal to that of the free substrate (*i.e.*, if one of the q's equals zero).

1:1 and 2:1 Complexes.—Suppose that the S_2L complex is unreactive. Then the basic equation of the system is

$$k_S' = k_S f_S + k_{11} f_{11}$$

But the fractions f_S and f_{11} are functions of [S], so k_S' will vary during the course of the reaction, as pointed out in connection with Eq. 27. If this variability should not be evident, the usual kinetic treatment will be made. The above equation is transformed into

$$k_S - k_S' = k_S(q_{11}f_{11} + f_{21})$$

where $f_{11} = [SL]/S_t$ and $f_{21} = 2[S_2L]/S_t$. This leads finally to Eq. 51.

$$\frac{1}{k_S - k_S'} = \frac{1}{k_S K_{11}[L](q_{11} + 2K_{(21)}[S])} + \frac{1 + 2K_{(21)}[S]}{(q_{11} + 2K_{(21)}[S])k_S} \quad \text{(Eq. 51)}$$

This is not the equation of a straight line, but, if

k_S' appears to be constant during a reaction (perhaps because only a few per cent of total substrate is allowed to react during the observation period), then Eq. 51 will be essentially linear. The apparent stability constant will be

$$K_{11}' = K_{11} + 2K_{11}K_{(21)}[S] \qquad \text{(Eq. 52)}$$

If, however, $2K_{(21)}[S] \gg 1$, the apparent constant will be $K_{11}' = 2K_{11}K_{(21)}[S]$.

1:1 and 1:2 Complexes.—The basic equation is

$$k_S' = k_S f_S + k_{11} f_{11} + k_{12} f_{12} \qquad \text{(Eq. 53)}$$

which can be transformed to

$$k_S - k_S' = q_{11} k_S f_{11} + q_{12} k_S f_{12}$$

By means of the stability constant definitions and the material balance on S_t, this is converted to

$$\frac{1}{k_S - k_S'} = \frac{1}{k_S K_{11}[L](q_{11} + q_{12}K_{(12)}[L])} + \frac{1 + K_{(12)}[L]}{(q_{11} + q_{12}K_{(12)}[L])k_S} \qquad \text{(Eq. 54)}$$

This is not the equation of a straight line, but under many circumstances it will probably yield an essentially linear plot. Equation 54 has the same form as Eq. 44 for the spectral treatment of this system, and the earlier comments apply. The apparent stability constant can range from

$$K_{11}' = K_{11} + K_{11}K_{(12)}[L] \qquad \text{(Eq. 55)}$$

to

$$K_{11}' = K_{11}K_{(12)}[L] \qquad \text{(Eq. 56)}$$

depending on the relative magnitudes of q_{11} and $q_{12}K_{(12)}[L]$; thus, the value of K_{11}' may be dependent upon the quantities q_{11} and q_{12}.

1:1 Complex and Ligand Dimer.—As in the spectral method, this system does not give a simple analytical solution. If such a system is detected, perhaps the best way to treat it would be to determine by an independent method the ligand dimerization constant, then to calculate [L] as a function of L_t, and finally to treat the system as containing the single 1:1 complex (thus using Eq. 23), with the calculated monomer concentration taking the place of total concentration in constructing the graph. This procedure uses the approximation $L_t = [L] + 2[L_2]$; *i.e.*, consumption of ligand by formation of SL is ignored.

1:1 Complex and Substrate Dimer.—The experimental rate constant is a function of [S] and, therefore, varies during the reaction. This system cannot be conveniently analyzed.

DISCUSSION

Criteria for System Classification.—The operational definitions of the apparent 1:1 stability constants may be summarized as follows:

Solubility.—Plot S_t *versus* L_t; then

$$K_{11}' = \frac{\text{slope}}{\text{intercept } (1 - \text{slope})}$$

Spectral.—Plot $b/\Delta A$ *versus* $1/L_t$; then

$$K'_{11} = \textit{intercept/slope}$$

Kinetic.—Plot $1/(k_S - k_S')$ *versus* $1/L_t$; then

$$K_{11}' = \textit{intercept/slope}$$

The results of the preceding analyses, giving K_{11}' in terms of stability constants and concentrations, are gathered in Table I. The earlier discussion should be consulted for details concerning assumptions, approximations, and limits of applicability of these relationships. With their aid, it would be appropriate to consider how the comparative study of complexation systems with several techniques may yield information inaccessible with a single probe.

The usual order of investigation of a complex system will be (*a*) the determination of the stoichiometrics of all complexes present in significant concentrations or proportions, (*b*) the evaluation of stability constants for these complexes, (*c*) ultimately the determination of the structure and chemical and physical properties of each complex. Several criteria can be suggested to help in establishing stoichiometries and stability constants.

TABLE I.—THEORETICAL EQUIVALENTS OF APPARENT STABILITY CONSTANTS DETERMINED ASSUMING 1:1 COMPLEXATION

Complexes Present	K_{11}' as Found from— Solubility	Spectra	Kinetics
None	0	0	0
L_2	0	0	0
S_2	0	0	0
SL	K_{11}	K_{11}	K_{11}
S_2L	$\frac{2K_{21}S_0}{1 - K_{21}S_0^2}$	$2K_{21}[S]$	$2K_{21}[S]$
SL + LS	$K_{SL} + K_{LS}$	$K_{SL} + K_{LS}$	$K_{SL} + K_{LS}$
$SL + S_2L$	$\frac{K_{11} + 2K_{11}K_{(21)}S_0}{1 - K_{11}K_{(21)}S_0^2}$	[a]	[a]
$SL + SL_2$	$\frac{K_{11} + K_{11}K_{(12)}[L]}{1 + K_{11}K_{(12)}S_0[L]}$	[a]	[a]
$SL + L_2$	$\frac{K_{11}}{1 + 2K_{LL}[L]}$	[b]	[b]
$SL + S_2$	$\frac{K_{11}}{1 + 2K_{SS}S_0}$	[b]	[b]

[a] Variable; see text for discussion. [b] See text.

Relative Values of K_{11}' by the Solubility, Spectral, and Kinetic Techniques.—Table I shows the rationale for this criterion. If a finite value of K_{11}' is obtained (concerning this point see the later discussion), its relative value by the three methods may allow a partial assignment of stoichiometric types. Thus, if all three methods yield the same numerical value, the system probably contains only 1:1 complexes. The possibility exists, however, that identical values can be observed with two methods by a coincidental combination of constant and concentrations. This can easily be detected as pointed out below.

Dependence of K_{11}' on Initial Total Substrate Concentration by the Spectral and Kinetic Techniques.—When a complex S_mL_n is present for which m is greater than 1, K_{11}' by the spectral and kinetic methods will be a function of substrate concentration. K_{11}' should be determined with at least two appreciably different initial substrate concentrations. A significant dependence of K_{11}' on substrate concentration means that at least one complex is present with m larger than 1. The functional form of this dependence may yield further information. Because of this dependence, the substrate concentration should be specified when complex stability constants are reported.

Dependence of K_{11}' on Ligand Concentration by the Solubility Technique.—In each of the three techniques the ligand concentration is the independent variable. As noted earlier, linear spectral plots may be observed even though a curve is theoretically to be expected, and similar results will apply in the kinetic method. The solubility method offers the best chance to detect a dependence of K_{11}' on ligand concentration. If a positive curvature is noted in the phase diagram at least one complex is present of the form SL_n, where n is greater than 1. Negative curvature may indicate dimerization (or higher aggregate formation) of the ligand, as in the system $SL + L_2$. A linear phase diagram does not prove that there are no complexes of these types, for certain combinations, as, for example, the system $SL + SL_2 + L_2$, may give rise to an essentially linear curve over wide ranges of ligand concentration (12).

Dependence of k_S' on Time.—When a complex is present with two or more S molecules per complex molecule, the apparent rate constant should vary with time. In order to detect this variation it may be necessary to follow the reaction for at least two half-lives. If variability of k_S' is not observed the conclusion cannot be positive that all complexes contain only one S molecule, because of the assumptions made concerning the fate of the higher order complex, but this is a reasonable tentative inference.

Dependence of K_{11}' on Wavelength in the Spectral Technique.—This criterion has been emphasized by Johnson and Bowen (11). If K_{11}' varies with the wavelength, at least one higher order complex is present. The theoretical reason for this dependence was pointed out in connection with Eq. 46.

Independent Evidence Relating to Stoichiometry and Stability.—Some of these additional sources are: estimate of stoichiometry from isolable complexes or from the solubility phase diagram (6), Beer's law behavior of pure substrate and ligand, liquid–liquid partition studies of substrate and ligand to detect and measure the extent of self-aggregation processes, and spectral studies leading to stoichiometric ratios (*e.g.*, the method of continuous variations).

These criteria will obviously not be capable of defining the nature of all complexation systems, but they should help considerably in this problem. The possibility that systems may be encountered that are more complicated than those in Table I is very real and must be kept in mind.

It is most important to realize that when the spectral K_{11}' is smaller than either the solubility or the kinetic constant this does not constitute evidence that only the charge-transfer portion of the complex interactions is being measured. If only 1:1 complexes are present, the three methods will yield the same apparent stability constant no matter what the distribution of forces responsible for maintaining the complexes. As long as one of these complexes possesses a changed absorption spectrum this will be true, even if the other complexes cause no spectral change. The same kind of argument applies to the kinetically determined K_{11}', if only 1:1 complexes exist, and at least one of these has an altered reactivity, the apparent K_{11}' will be equal to the sum of all the true 1:1 constants. The general statement may be made that if reliable K_{11}' values for a system differ when determined by the three methods, some complexes are present other than 1:1 combinations of substrate and ligand.

The reliability of stability constants evaluated spectrophotometrically as evidence for the existence of complexes has been explored by Person (13), who suggests that as a practical guide a 1:1 stability constant must be equal to or greater than $0.1/L_{max.}'$ where $L_{max.}'$ is the highest ligand concentration used in the study, in order for the constant to be considered significantly different from zero. Suppose, for example, that the upper limit of ligand concentration in a spectral study is 0.2 M; then the borderline value of K_{11}' is 0.5 M^{-1}. A value smaller than this cannot be taken as evidence for complexing. Similar guides could be formulated for other techniques. Throughout this paper the authors have supposed that nonzero values of stability constants can be demonstrated.

Capabilities of the Solubility, Spectral, and Kinetic Methods.—The solubility method is considered by many to possess the disadvantage of nonselectivity in that it measures the results of all types of interactions. But the foregoing analysis shows that the spectral and kinetic methods are also subject to this type of nonselectivity, and, in the mathematical terms of the analysis as represented in Table I, it may be held that the solubility method is actually more selective than the other techniques. The solubility method possesses two real drawbacks: it is primarily limited to slightly soluble solid substrates, and the substrate concentration cannot be varied. In those systems where the ligand is not too soluble the second disadvantage may be eliminated by reversing the system, treating S as L and vice versa. It is of course not possible to extrapolate a solublity K_{11}' to zero concentration of substrate.

Solubility studies are carried out at constant [S], and spectral studies are at constant S_t. Part of the difficulty in analyzing spectral data follows from this difference, but the capability of varying S_t when desired is an advantage of the spectral method. (It is possible to perform some spectral complexation studies at solubility equilibrium, thus setting [S]

$= S_0$ and letting S_t vary throughout the run; this may simplify some analyses.) The great disadvantage of the spectrophotometric method is of course that a spectral change must occur upon complexation, but when a change is observed the method is very convenient, especially since it provides wavelength as an additional variable. In a general sense, the spectral technique is neither more nor less selective, when applicable, than are other methods. The mathematics developed for spectral studies can be applied to any other physical property that is directly proportional to a species concentration; examples are refractive index (14), optical rotation (15), and fluorescence intensity.

The kinetic method is carried out with neither [S] nor S_t held constant (though if initial rates were measured S_t could be considered the constant factor). Mathematically it is similar to the spectral method; but it possesses the advantage that it is applicable even if no spectral change occurs, and the disadvantage that it does not include a convenient variable corresponding to wavelength. (The parallel to wavelength is complex reactivity, but this cannot easily be altered without changing the system.) Throughout this paper the inhibition of rates by complex formation has been taken as the basis for the analysis, but the complex may in some systems exhibit an enhanced reactivity, and this phenomenon also can serve for study of the complex equilibrium (16, 17). The outstanding potential advantage of the kinetic technique is its capability for providing information about the reactivity, and thus the structure, of the complex. This capability has not yet been exploited, although some attempts have been made to utilize it (5), and further studies in the chemistry of organic complexes may find its application valuable.

Conclusions.—The application of more than one experimental technique is advisable in the study of complexation systems. By comparing the apparent stability constants evaluated by the several methods on the basis of an assumed 1:1 stoichiometry between substrate and ligand, it may be possible to establish, in part, the stoichiometries of the complexes present. If the solubility, spectral, and kinetic techniques yield essentially identical values for the apparent 1:1 stability constant (and if certain other criteria suggested in this paper are satisfied), it may be concluded that only 1:1 complexes between substrate and ligand are present. If the three techniques do not give the same value, the manner in which they differ and their dependence on variables of the system may permit a further classification. On the basis of the mathematical analysis it is concluded that the solubility, spectral, and kinetic methods for studying complex formation are about equally nonselective in their responses to multiple complexes, with the solubility method perhaps possessing a slight advantage in specificity.

APPENDIX

S, substrate molecule
L, ligand molecule
S_mL_n, general formula for complex
S_t, total (formal) concentration of S
L_t, total (formal) concentration of L
S_0, equilibrium molar solubility of substrate monomer in absence of L
$[i]$, molar concentration of species i
$f_s = [S]/S_t$, fraction of S in uncomplexed form
$f_{mn} = m[S_mL_n]/S_t$, fraction of S in form of S_mL_n
$K_{mn} = [S_mL_n]/[S]^m[L]^n$, over-all stability constant for the complex S_mL_n
$K_{(mn)} = [S_mL_n]/[S][S_{m-1}L_n]$ or $[S_mL_n]/[S_mL_{n-1}][L]$, step stability constant for S_mL_n
K'_{11}, apparent stability constant assuming 1:1 stoichiometry
k_S, specific rate constant for a reaction of S
k'_S, apparent rate constant for S in presence of L
k_{mn}, specific rate constant for a reaction of S_mL_n
$r_{mn} = k_{mn}/k_S$, relative reactivity of S_mL_n
$q_{mn} = 1 - r_{mn}$
b, cell path length
a_S, molar absorptivity of S
a_{mn}, molar absorptivity of S_mL_n
A, absorbance

Determination of Acetylsalicylic Acid and Barbiturate Combinations by Differentiating Nonaqueous Titration

By SONG-LING LIN* and MARTIN I. BLAKE

Acetylsalicylic acid and barbiturate mixtures are determined by differentiating nonaqueous titration. The titration solvent is methyl isobutyl ketone, the titrant is sodium methoxide in benzene–methanol, and the electrode system consists of the glass-calomel or antimony-calomel electrode pair. Satisfactory end points were realized when the acetylsalicylic acid-to-barbiturate ratio was as high as 14 to 1. Tetrabutylammonium hydroxide proved unsuitable as a differentiating titrant. Differentiation was not possible when dimethylformamide was the titration solvent. The barbiturates studied included phenobarbital, amobarbital, barbital, allylisobutylbarbituric acid, pentobarbital, and secobarbital.

A VARIETY of techniques have been proposed for the analysis of acetylsalicylic acid and barbiturates when used individually. These methods involve titrimetry, chromatography, colorimetry, and spectrophotometry. They have been reviewed by Zimmer and Huyck (1) and Connors (2). Titrimetric procedures in aqueous and nonaqueous media have been reviewed by Ashworth (3).

Since acetylsalicylic acid and the barbiturates are weakly acidic and since they differ significantly in their ionization constants, it seems appropriate that a suitable differentiating titration procedure can be developed by the proper selection of titration solvent, titrant, and electrode system. It was the purpose of this study to develop such a procedure.

A number of solvents have been employed in differentiating acids and bases. These have included acetone (4, 5), methyl ethyl ketone (6–8), methyl isobutyl ketone (9, 10), acetonitrile (11), isopropanol (8), *tert*-butyl alcohol (12, 13), nitrobenzene (14), dimethylformamide (10, 13), *N,N*-dimethyl fatty amides (15), pyridine (5, 13, 16), and ethylenediamine (17).

In the present report combinations of acetylsalicylic acid with a variety of barbiturates are determined by differentiating nonaqueous titration. The titration solvent is methyl isobutyl ketone and the titrant is sodium methoxide in benzene–methanol. Titration is effected potentiometrically using a glass-calomel or antimony-calomel electrode system.

Received April 8, 1966, from the Department of Pharmacy, University of Illinois at the Medical Center, Chicago.
Accepted for publication May 23, 1966.
Presented to the Medicinal Chemistry Section, A.PH.A. Academy of Pharmaceutical Sciences, Dallas meeting, April 1966.
Abstracted in part from a dissertation presented by Songling Lin to the Graduate College, University of Illinois at the Medical Center, Chicago, in partial fulfillment of Doctor of Philosophy degree requirements.
The authors acknowledge Eli Lilly and Co. and Sandoz Pharmaceuticals for supplying samples of barbiturates used in this study.
* Present address: Pharmacy Research and Development Division, Ciba Pharmaceutical Co., Summit, N.J.

EXPERIMENTAL

Apparatus.—All titrations were performed potentiometrically with a Fisher titrimeter, model 35. The following electrodes were employed: glass electrode (Beckman No. 40495), sleeve-type calomel electrode (Beckman No. 41240), antimony electrode (Beckman No. 39027), and silver-silver chloride electrode (Beckman No. 41236). The calomel electrode was used as such unless otherwise indicated.

Reagents and Solutions.—Acetylsalicylic acid U.S.P. (Mallinckrodt) was dried at 60° for 4 hr. Analysis by U.S.P. assay indicated a purity of better than 99.5%. Phenobarbital U.S.P. (Mallinckrodt) was recrystallized from diluted ethanol and dried at 100° for 2 hr., m.p. 176–178°. Analysis by U.S.P. assay indicated a purity of better than 99.0%. Amobarbital was recrystallized from diluted alcohol and dried at 105° for 4 hr., m.p. 156–158°. Analysis by U.S.P. assay indicated a purity of better than 99.0%. Allylisobutylbarbituric acid was dried at 105° for 2 hr., m.p. 138°. Analysis by N.F. X method indicated a purity of better than 99.5%. Other chemicals and all solvents used in this study were reagent grade and were employed without further purification.

Tenth normal sodium methoxide in benzene–methanol (10:1) was prepared and standardized as described by Fritz and Lisicki (18).

Differentiating Titration of Acetylsalicylic Acid and Phenobarbital.—About 0.70 meq. of acetylsalicylic acid and 0.70 meq. phenobarbital, accurately weighed, were dissolved in 70 ml. of solvent in a 150-ml. beaker. The solution, magnetically stirred, was titrated potentiometrically with 0.1 *N* sodium methoxide solution, using a sleeve-type calomel and glass electrode system. A blank titration was performed. Titration curves were obtained by plotting potential reading (mv.) *versus* volume (ml.) of titrant. The exact end point was determined by plotting $\Delta E/\Delta v$ *versus* ml. The titration solvents in this study included dimethylformamide, acetonitrile, acetone, methyl ethyl ketone, methyl isobutyl ketone, isopropanol, and *tert*-butyl alcohol.

TABLE I.—DIFFERENTIATING TITRATION OF ACETYLSALICYLIC ACID AND PHENOBARBITAL IN VARIOUS SOLVENTS

Curve Ref.[a]	Solvent	Recovery, % Acetylsalicylic Acid	Recovery, % Phenobarbital
1	Dimethylformamide	One End Point[b]	
2	Acetonitrile	99.25 ± 0.56[c]	100.49 ± 0.95
3	Acetone	100.82 ± 0.91	99.32 ± 0.82
4	Methyl ethyl ketone	101.15 ± 0.70	98.78 ± 0.62
5	Methyl isobutyl ketone	100.35 ± 0.54	99.89 ± 0.69
6	Isopropanol	100.64 ± 0.92	100.58 ± 0.62
7	*tert*-Butyl alcohol	101.72 ± 0.48	99.03 ± 0.90

[a] Numbers correspond to curves in Fig. 1. [b] Corresponds to total acetylsalicylic acid and phenobarbital. [c] Standard deviation based on at least 4 determinations.

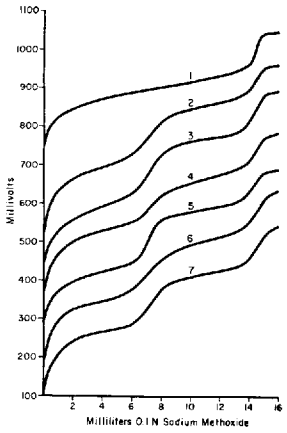

Fig. 1.—Typical curves for differentiating titration of acetylsalicylic acid and phenobarbital in various solvents. The titrant was 0.1 *N* sodium methoxide in benzene–methanol (10:1). The numbers above the curves correspond to those in Table I.

Electrode Systems.—About 0.60 meq. of acetylsalicylic acid and 0.40 meq. of phenobarbital, accurately weighed, were dissolved in 50 ml. of methyl isobutyl ketone. Three electrode pairs were employed, glass-calomel, antimony-calomel, and glass-silver-silver chloride. The sleeve-type calomel electrode was used as such or was modified by replacing the aqueous saturated potassium chloride solution in the bridge with a saturated solution of potassium chloride in methanol or with a saturated solution of potassium chloride in methyl isobutyl ketone.

Variation of Acetylsalicylic Acid-to-Phenobarbital Ratio.—A series of differentiating titrations was performed in which the milliequivalent ratio of acetylsalicylic acid to phenobarbital was varied from 1 to 1 to greater than 30 to 1. Calculated amounts of acetylsalicylic acid and phenobarbital to give the desired milliequivalent ratio of components were accurately weighed and dissolved in 70 ml. of methyl isobutyl ketone. The solution was titrated potentiometrically with 0.1 *N* sodium methoxide using the glass-calomel or antimony-calomel electrode system. The calomel electrode was employed without modification.

Analysis of Acetylsalicylic Acid Combinations with Various Barbiturates.—Accurately weighed quantities of acetylsalicylic acid and one of a number of barbiturates were dissolved in 50 ml. of methyl isobutyl ketone in a 150-ml. beaker. The solution was titrated potentiometrically with 0.1 *N* sodium methoxide using a glass-calomel or antimony-calomel electrode system. The calomel electrode was used without modification.

RESULTS AND DISCUSSION

Although acetylsalicylic acid and phenobarbital, as individual components, can be readily determined by titration in nonaqueous media, the titrimetric analysis of mixtures of these compounds has not been reported. Since the pKa of acetylsalicylic acid is 3.49 and the pKa of phenobarbital is 7.54, the differentiating titration of mixtures in a number of solvents is readily accomplished. The solvents examined in this investigation are listed in Table I, and typical titration curves are shown in Fig. 1. Titrations were effected potentiometrically with 0.1 *N* sodium methoxide in benzene–methanol using a glass-calomel electrode system. Basic solvents such as dimethylformamide, while excellent for the individual components, do not permit differentiation in the case of mixtures. Figure 1, curve 1, indicates a single end point corresponding to the total acid present when titration is performed in dimethylformamide. In preliminary studies similar results were obtained with ethylenediamine, butylamine, and pyridine.

TABLE II.—EFFECT OF ELECTRODE COMBINATION ON DIFFERENTIATING TITRATION OF ACETYLSALICYLIC ACID AND PHENOBARBITAL

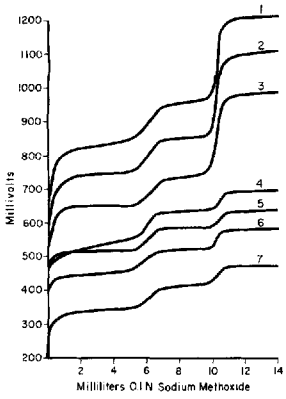

Fig. 2.—Effect of electrode combination on sensitivity of differentiating titration of acetylsalicylic acid and phenobarbital dissolved in methyl isobutyl ketone. The numbers above the curves correspond to those in Table II.

It is apparent that acetylsalicylic acid and phenobarbital are leveled to the same strength in these solvents and this precludes their differentiation. Acetonitrile and the ketones and alcohols listed in Table I did permit satisfactory differentiation. The curves in Fig. 1 show two distinct inflections, the first corresponding to the acetylsalicylic acid content and the second representing the phenobarbital end point. Methyl isobutyl ketone consistently produced the greater potential breaks for both end points when comparison is made with the other solvents tested. (See Fig. 1, curve 5.) Bruss and Wyld (9) found methyl isobutyl ketone an excellent solvent for differentiating acids or bases because of the large potential range which it affords.

Methyl isobutyl ketone was used as the titration solvent for subsequent studies reported in this investigation. The effect of electrode combination on the resolution of acetylsalicylic acid and phenobarbital mixtures was explored. The electrode systems and their modifications are listed in Table II. Typical titration curves are shown in Fig. 2. The most satisfactory results were realized with the antimony–calomel electrode pair. A comparison of the titration curves indicates that for acetylsalicylic acid the potential break was doubled and for phenobarbital the potential break was increased about ninefold when the antimony-calomel electrode pair replaced the glass-calomel electrode system. Little or no effect was noted when the supporting electrolyte in the calomel electrode was modified. In preliminary studies a number of other electrode systems were tested. The platinum-calomel and glass-antimony pairs gave poorly defined and unpredictable potential breaks corresponding to the first end point, although the second end point

representing total acid was satisfactory. Discernible end points were not obtained with the glass-platinum or antimony-platinum electrode systems.

Since in dosage forms there is usually a considerably greater amount of acetylsalicylic acid than phenobarbital, the effect of varying the ratio of concentrations of the components on the sensitivity of the differentiating titration was studied. The data for a series of titrations in which the milliequivalent ratio of acetylsalicylic acid to phenobarbital was varied from 1 to 1 to about 30 to 1 are reported in Table III. Typical titration curves are shown in Figs. 3 and 4. In one series of titrations (Fig. 3) the glass-calomel electrode pair was used, while in a second series of titrations (Fig. 4) the antimony-calomel electrode system was employed. With the glass-calomel electrodes two inflections in the titration curve were obtained when the milliequivalent ratio of acetylsalicylic acid to phenobarbital was not greater than about 7 to 1. When the ratio was greater than this, only one end point corresponding to the total acid was realized. The family of curves in Fig. 3 demonstrates clearly the effect of the ratio on the resolution of the two end points. With the antimony-calomel electrode pair the acetylsalicylic acid end point is well defined when the ratio of components was as high as 14 to 1. In Fig. 4, curve 9, two end points are clearly defined. However, in curve 10, only one end point is discernible. In general, both inflections in the curves shown in Fig. 4 are more satisfactory than those in Fig. 3.

Tetrabutylammonium hydroxide has been shown (4, 8, 9, 19, 20) to be extremely useful as a titrant for determining weak acids. This titrant in benzene–methanol (10:1) was prepared and standardized as described by Cundiff and Markunas (19). Some preliminary studies were conducted to evaluate this titrant in differentiating mixtures of acetylsalicylic acid and phenobarbital. Methyl isobutyl ketone was used as the titration solvent. In all cases only a single end point was obtained corresponding to the total acid present. When the individual components were titrated excellent results were obtained with distinct and reproducible end points. The unsuccessful differentiation with this titrant cannot be explained at this time.

The proposed procedures were applied to combinations of acetylsalicylic acid with a variety of barbiturates. The data are reported in Table IV. All titrations were performed with sodium methoxide as the titrant and methyl isobutyl ketone as the titration solvent. Both the glass-calomel and the antimony-calomel electrode pairs were employed. The maximum potential change per unit volume of titrant added is shown for each combination. While excellent results were obtained for all combinations, the antimony-calomel electrode system produced greater potential changes for the barbiturate end point than did the glass-calomel electrode pair.

The proposed procedures make possible the simple and accurate determination of combinations of acetylsalicylic acid and a variety of barbiturates without preliminary extraction of the components. The technique is applicable even when there is a disproportionate concentration of the acetylsalicylic acid which is the usual situation when these combinations are used therapeutically.

Adsorption of Phenothiazine Derivatives by Solid Adsorbents

By DONALD L. SORBY, ELMER M. PLEIN*, and JOSEPH D. BENMAMAN

In simple aqueous media, the extent of adsorption of various phenothiazine derivatives by kaolin, talc, and activated charcoal is significant. Adsorption by talc and kaolin is dependent upon pH of the medium, while adsorption by activated charcoal is less affected by pH. Adsorption of promazine hydrochloride by all three adsorbents is sensitive to the electrolyte concentration of the medium. A variety of evidence suggests that adsorption of the phenothiazine derivatives by activated charcoal is a result of physical forces related to the tendency of the solute to accumulate at the air–water interface. Adsorption of these compounds by talc and kaolin occurs through more complex mechanisms which cannot be completely elucidated from knowledge obtained in this experiment. The effects of pH and electrolyte concentration may be important to the previously observed action of adsorbents in modifying absorption of promazine from the gastrointestinal tract.

A PREVIOUS publication (1) presented a partial report of results obtained in this experiment. Various medicinally active phenothiazine derivatives were found to be adsorbed to a significant extent by kaolin, talc, and activated charcoal. The purpose of this report is to describe various aspects of the adsorption process in further detail and to present results of studies concerned with attempts to elucidate the mechanisms of the adsorption interaction. In addition, there is interest in adsorption as a potential means of altering drug absorption from the gastrointestinal tract (2, 3). Certain factors have been studied for their ability to produce release of the absorbed material from the surface of the adsorbate complex. *In vivo* experiments have involved the use of promazine hydrochloride. Thus, several experiments reported here feature this compound. Results obtained for promazine hydrochloride should be qualitatively similar for other phenothiazine derivatives.

EXPERIMENTAL

Preparation of Compounds for Study.—The phenothiazine derivatives used in this study were obtained from various sources of supply.[1] Each compound was recrystallized from an appropriate solvent until the melting point agreed with the accepted value.[2] The 15 compounds studied during various phases of the experiment are listed in Table I.

All adsorption studies were performed using compounds in the form of their hydrochloride salts. Compounds not available as the hydrochloride salt, *viz.*, methoxypromazine maleate, acepromazine maleate, trimeprazine tartrate, and prochlorperazine ethanedisulfonate, were converted to the hydrochloride form by passing 1.1×10^{-2} *M* solutions through an ion exchange column charged with a strongly basic polystyrene quaternary amine type ion-exchange resin[3] in the chloride cycle. The nonaqueous titration procedure described below was used to determine the exact concentration of the solution recovered from the ion-exchange column. The effluent solutions were tested for completeness of anion exchange by a paper chromatographic procedure (4). Ethanedisulfonate could not be detected by this method. For other compounds mentioned, no evidence of the original acid anion could be found in the effluent from the ion exchange columns. Conversion to the hydrochloride salt form was considered to be complete in all cases.

Preparation of Adsorbents for Study.—Adsorbent materials were procured from commercial sources. Activated charcoal[4] was obtained from the American Norit Co., Jacksonville, Fla.

Average screen analysis data, supplied by the manufacturer, showed that 98% is passed through a 100-mesh U. S. standard screen, 90% through a 200-mesh, and 85% through a 300-mesh screen. Talc was U.S.P. grade, 99.5% passes a 100-mesh screen. Kaolin was N.F. grade, 99.5% passes a 325-mesh screen.

The total content of commercial packages of each adsorbent was blended in a twin shell blender, dried at 120° for 5 hr., and stored in air-tight bottles until used. The total amount of each adsorbent used in this study came from one single production lot of material.

Aqueous extracts of the kaolin and talc adsorbents

Received July 6, 1965, from the School of Pharmacy, San Francisco Medical Center, University of California, San Francisco.

Accepted for publication May 11, 1966.

Presented to the Scientific Section, A.PH.A., Detroit meeting, March 1965.

Portions of this paper are abstracted from a dissertation submitted by Donald L. Sorby to the Graduate School, University of Washington, Seattle, in partial fulfillment of Doctor of Philosophy degree requirements.

The portions of this research carried out at the School of Pharmacy, University of California, were supported in part by a general research support grant FR-05453 from the Division of Research Facilities and Resources, National Institutes of Health, U. S. Public Health Service, Bethesda, Md.

* Present address: College of Pharmacy, University of Washington, Seattle.

Squibb and Sons, The Upjohn Co., Warner-Chilcott Laboratories, White Laboratories, Inc., and Wyeth Laboratories, Inc., for their generosity in supplying the compounds used in this research.

[2] Melting point data were furnished by the supplier of each compound. Isopropanol was used as the recrystallizing solvent for all compounds except acepromazine maleate and prochlorperazine ethanedisulfonate. Ethyl acetate was used for the former and water–ethanol for the latter. Ethopropazine hydrochloride and thioridazine dihydrochloride were not recrystallized.

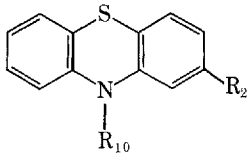
TABLE I.—PHENOTHIAZINE DERIVATIVES INCLUDED IN THIS RESEARCH



Compd.	No. 2 Substituent (R_2)	No. 10 Substituent (R_{10})
Promazine	Hydrogen	3-Dimethylaminopropyl
Mepazine	Hydrogen	(*N*-Methyl-piperidyl)-methyl
Trimeprazine	Hydrogen	3-Dimethylamino-2-methylpropyl
Promethazine	Hydrogen	2-Dimethylamino-2-methylethyl
Ethopropazine	Hydrogen	2-Diethylamino-2-methylethyl
Pyrathiazine	Hydrogen	2-(1-Pyrrolidyl)-ethyl
Chlorpromazine	Chlorine	3-Dimethylaminopropyl
Methoxypromazine	Methoxy	3-Dimethylaminopropyl
Triflupromazine	Trifluoromethyl	3-Dimethylaminopropyl
Acepromazine	Acetyl	3-Dimethylaminopropyl
Prochlorperazine	Chlorine	3-(1-Methyl-4-piperazinyl)-propyl
Thiopropazate	Chlorine	3-[1-(2-Acetoxyethyl)-4-piperazinyl]-propyl
Trifluoperazine	Trifluoromethyl	3-(1-Methyl-4-piperazinyl)-propyl
Fluphenazine	Trifluoromethyl	3-(2-Hydroxyethyl-4-piperazinyl)-propyl
Thioridazine	Methylmercapto	2-(1-Methyl-2-piperidyl)ethyl

contained small amounts of ultraviolet absorbing impurities. The magnitude of this absorption was small, however, and was nearly constant in the range of the ultraviolet absorption spectrum where the phenothiazine derivatives show absorption maxima. The aqueous extracts showed a negative potassium ferrocyanide test for ferric ion.

Analytical Methods.—Two analytical methods were employed in this research.

Nonaqueous Titration Procedure.—The concentration of all stock solutions of phenothiazine derivatives was confirmed by a nonaqueous titration procedure adapted from the method of Milne *et al.* (5, 6). Aqueous solutions containing a particular phenothiazine derivative were made strongly basic with sodium hydroxide and then were extracted[5] with four 20-ml. portions of *n*-hexane. Sufficient acetone was added to the extract to make a solvent containing a 2:1 ratio of hexane to acetone. This solution was titrated with perchloric acid, 0.05 *N* in dioxane. The end point was determined potentiometrically using a Leeds & Northrup pH indicator equipped with glass indicator and calomel reference electrodes. The end point was taken as the point of maximum inflection of a curve representing observed E.M.F. plotted against volume of titrant added. A blank correction was made for a similar system containing no phenothiazine derivative. The method was used for all phenothiazine derivatives listed in Table I except ethopropazine. Accuracy of the method was within a range of ±3% of theoretical at the 1×10^{-2} *M* concentration level. Quantitative recovery of thiopropazate could not be obtained using this procedure.

Spectrophotometric Procedure.—The nonaqueous titration procedure lacked sufficient sensitivity to be used at the concentration ranges employed in experiments which measure adsorption isotherms. In such cases, an ultraviolet spectrophotometric procedure was used to measure equilibrium concentrations of the phenothiazine derivatives. The method was adapted from a background cancellation technique proposed by Flanagan *et al.* (7) for chlorpromazine. A Beckman DU spectrophotometer was used to measure absorbance of the samples at three different wavelengths. Absorbance at the wavelength of maximum absorbance ($\lambda_{max.}$) was always measured. The other two absorbance measurements were made at wavelengths where the sample absorbed less strongly. One measurement was always made at a shorter wavelength (λ_{short}) than $\lambda_{max.}$ and one at a longer wavelength (λ_{long}). Corrections for background absorbance were made in the fashion described by Flanagan *et al.* (7). However, they were calculated algebraically.

The following expressions illustrate this method of correcting for "background" interference in samples.

$$\text{Background correction (B.C.)} = As\ \lambda_{high} + \left[(As\ \lambda_{short} - As\ \lambda_{long}) \times \frac{\lambda_{max.} - \lambda_{long}}{\lambda_{short} - \lambda_{long}}\right]$$

$$\text{Corrected absorbance } (As^*) = \text{measured } As \text{ at } \lambda_{max.} - \text{B.C.}$$

A "corrected" molar absorption coefficient was calculated for each compound from the "corrected" absorbance of samples of known concentrations measured in the absence of adsorbent. The concentration of solute in test samples was calculated from the relationship

$$C = \frac{As^*}{(l)\ (e^*)}$$

where, As^* is the corrected absorbance of the sample at $\lambda_{max.}$, l is the path length of the solution, and e^* is the "corrected" molar absorption coefficient for the compound. Table II lists the wavelengths used in determining As^* and the values of e^* for compounds studied in this experiment. The range of usefulness of this method of assay is 5×10^{-6} *M* to 4×10^{-5} *M*.

[5] A benzene–dinitromethane solvent was recommended (5) for extracting dibasic compounds. Personal communication with the author indicated that the hexane–acetone mixture also worked well with dibasic compounds. Results obtained during this research have confirmed the hexane–acetone solvent as being suitable for extracting both monobasic and dibasic compounds.

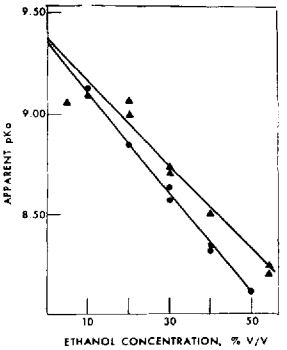

Fig. 2.—Apparent pKa as a function of ethanol concentration. Key: ▲, promazine hydrochloride; ●, pyrathiazine hydrochloride.

Preparation of Solutions.—Stock solutions of each compound were prepared on the day the adsorption isotherm was determined. Each solution was prepared to contain a 1×10^{-2} *M* concentration of the particular compound under study. Each solution also contained 0.01% sodium bisulfite.

Determination of Adsorption Isotherms.—The procedure for determining adsorption isotherms was reported elsewhere (1). Except where specified, all adsorption experiments were made at 20.0°.

Surface Tension Lowering Measurements.—The change in surface tension with concentration was measured for six phenothiazine derivatives. Dilutions of each compound in distilled water, ranging between 5×10^{-4} *M* and 1×10^{-2} *M*, were prepared. Surface tensions of the solutions were measured at 20 ± 1° with a Cenco-DuNoüy interfacial tensiometer, precision direct reading model. Fresh surfaces were prepared by flooding a small glass dish with solution, and two readings of the surface tension were immediately taken. This procedure was repeated until a total of six readings had been obtained at each concentration tested. The mean value was calculated from the six readings. A value for the surface tension of water was measured in a similar fashion. Figure 1 shows the variation of surface tension lowering with concentration for the compounds tested.

Determination of Apparent pKa.—Apparent pKa values for several compounds were measured by a titrimetric procedure similar to one employed by Marshall (8). Hydroalcohol solutions of the hydrochloride form of the appropriate phenothiazine derivative were prepared at a concentration of 1×10^{-3} *M*. These solutions were titrated with standard sodium hydroxide solution, 0.0500 *N*, at 20.0° under a nitrogen atmosphere. After each addition of titrant, the pH was measured with the instrument mentioned under *Nonaqueous Titration Procedure*. The apparent pKa was calculated at each pH reading on the titration curve using the relationship

$$\text{pKa} - \text{pH} - \log \frac{C_{R_3N}}{C_{R_3NH^+}}$$

where C_{R_3N} is the concentration of amine base, and $C_{R_3NH^+}$ is the concentration of the protonated species present at the particular pH value. Values for C_{R_3N} and $C_{R_3NH^+}$ were calculated from the amount of amine salt initially present and the amount of titrant added. An average of the several pKa values calculated in this fashion was taken as the apparent pKa for the compound in the particular hydroalcohol solvent. Titrations and apparent pKa calculations were made in duplicate for each compound at each alcohol strength, usually 10, 20, 30, 40, and 50% by volume ethanol.

The apparent pKa values measured for each compound in the various hydroalcohol solutions were plotted against alcohol concentration. The zero alcohol concentration intercept, calculated from the linear portion of the curve by the method of least squares, yielded the apparent pKa of the compound in water. Figure 2 shows a plot of apparent pKa *versus* alcohol concentration for pyrathiazine hydrochloride and chlorpromazine hydrochloride and is typical of the over-all results.

In certain cases, the amine base began to precipitate from the hydroalcohol system before a complete titration curve could be obtained. In such cases, the apparent pKa was calculated by assuming the concentration of the amine base actually in solution to be constant after the point where precipitation first occurred. The concentration of free base present at the point of precipitation was estimated from the amount theoretically present at the cloud point when a sample of identical concentration with respect to both alcohol and drug was titrated with a more dilute titrant solution. Using this method, apparent pKa values could be determined for most

TABLE III.—APPARENT pKa VALUES FOR VARIOUS PHENOTHIAZINE DERIVATIVES

Ethopropazine hydrochloride	...	9.50

[a] Values reported by Marshall (8). [b] These values are for dissociation of the second basic group. For pK_1, values of 3.90 and 4.10 were obtained for fluphenazine and trifluoperazine, respectively.

of the compounds in hydroalcohol solutions containing as little as 10% v/v alcohol. Where calculations could be made from data collected both before and after the point of precipitation, good agreement was obtained between apparent pKa values.

Values of the apparent pKa for several compounds are reported in Table III.

Adsorption at Constant pH.—Adsorption of promazine hydrochloride and fluphenazine dihydrochloride was studied at pH 2.5 and 6.5. Phosphate buffers were prepared to contain 0.03 *M* total phosphate. For the pH 6.5 buffer, 4.23 Gm. of dibasic sodium phosphate and 2.0 ml. of hydrochloric acid were made to a volume of 1000 ml. with carbonate-free distilled water. For pH 2.5 buffer, 4.13 Gm. of monobasic sodium phosphate and 1.0 ml. of hydrochloric acid were made to 1000 ml. with carbonate-free distilled water. The pH of each buffer was brought exactly to the desired values, by addition of acid or base, before adjustment to volume. Stock solutions of each phenothiazine derivative in the appropriate buffer were prepared, and the isotherms were determined by the procedure described previously (1). The method employed here differed only with respect to the fact that buffer was used as the solvent for all systems. Limited adsorption experiments carried out in varying concentrations of phosphate buffer showed that the observed effects on adsorption were not due to competition between the buffer components and the phenothiazine derivative for sites on the adsorbent surface.

Effect of Electrolyte on Adsorption.—Adsorption of promazine by the various adsorbents was measured in the presence of 0.01 and 0.10 *N* sodium chloride. Stock solutions were prepared by dissolving promazine hydrochloride in the appropriate sodium chloride solution. Isotherms were determined in a manner similar to that described previously (1) except the appropriate sodium chloride solution was used as the solvent in place of distilled water. The pH of all samples was measured at the time of analysis with a Beckman model G pH meter equipped with glass indicator and calomel reference electrodes.

Effect of Temperature on Adsorption.—Adsorption was measured at 37.0° for chlorpromazine hydrochloride and thiopropazate dihydrochloride by the method described previously (1).

RESULTS AND DISCUSSION

All of the phenothiazine derivatives were adsorbed to a significant extent by the adsorbents tested. The experimental data were plotted according to the following form of the Langmuir equation:

$$\frac{C_{EQ}}{x/m} = \frac{1}{k_1 k_2} + \frac{C_{EQ}}{k_2}$$

where C_{EQ} is the concentration of the phenothiazine derivative remaining in solution at equilibrium, x/m is defined as the amount of compound adsorbed by the quantity of adsorbent used,[6] 1.00 Gm. for kaolin and talc, 0.100 Gm. for activated charcoal, and k_1 and k_2 are constants. The constant k_1 is sometimes called the adsorption coefficient and is related to the force of the interaction between the adsorbent and the bound molecules. The value of k_2 gives the maximum amount of compound which can be adsorbed by the weight of adsorbent used in the experiment. It must be assumed that only a monomolecular layer of solute molecules can be found in order to correctly apply the Langmuir equation.

The best straight line through the experimental data was calculated by the method of least squares. The values of the constants, k_1 and k_2, were obtained from the reciprocals of the slope and intercept values of the regression equation calculated from the experimental data. In each case, linear conformity of the data to the Langmuir equation was checked by graphic plots before calculating the regression equation. In most cases, the data could be expressed in linear form by the Langmuir equation. Values of the Langmuir constant, k_2, are summarized in Table IV. Figure 3 shows the Langmuir isotherms obtained for promazine hydrochloride and fluphenazine dihydrochloride which are typical of the over-all results.

Values of k_2 show that in unbuffered media, kaolin has the weakest adsorbent capacity. Talc possesses adsorbent capacity which is similar to kaolin, although approximately twice as great for any given compound. The similarity in adsorbent capacity between kaolin and talc is not especially surprising since both are basic aluminosilicates although they do differ with respect to physical structure and exchangable cations. Adsorption of all compounds by activated charcoal is much greater in magnitude. Compared on a weight basis, the adsorbent power of charcoal ranges from 20 to 80 times that of kaolin and talc.

Values for the adsorption coefficient, k_1, are not shown in Table IV. In most cases, adsorption approached surface saturation at very low concentration ranges. As a result, due to the lack of data at low degrees of surface saturation, calculation of k_1 values from intercept values of the Langmuir equation is potentially subject to some error. A procedure recommended by Finger *et al.* (9) is equally unsatisfactory for determining k_1 values from these data. The values of k_1 were found to increase from kaolin to talc to charcoal and were generally of a similar order of magnitude within a particular adsorbent series.

The intercept value of the Langmuir equation may also be used for comparing affinities between adsorbents and the phenothiazine derivatives. At the

[6] Since x/m is determined from concentration difference measurements, it is actually the apparent amount adsorbed. Adsorption of solvent by the adsorbent may also alter the solute concentration and hence produce some uncertainty in the value obtained for x/m. Due to the relatively large ratio of solvent to adsorbent in the test systems, the effect of solvent adsorption should be minimal and the values of x/m are considered to be subject to little error from this effect.

lower equilibrium concentrations, *viz.*, at infinite dilution, the Langmuir equation reduces to

$$x/m = k_1k_2\, C_{EQ}$$

The product, k_1k_2, would be the initial slope of the adsorption isotherm and would, in a sense, be an equilibrium constant for adsorption of phenothiazine derivatives in systems well below saturation of the adsorbent surface. Thus, the k_1k_2 values should be useful in comparing the relative strength of interaction between the adsorbents and the various phenothiazine derivatives. Values of k_1k_2 taken from the reciprocals of intercept values of the Langmuir equations expressing experimental data are shown in Table IV. These values are subject to some of the uncertainty discussed for k_1 values, and it is seen that occasionally unexpectedly large variations within a particular adsorbent series are encountered. On the other hand, for a particular adsorbent, the k_1k_2 values are relatively similar and probably reflect essentially similar adsorption affinities. The values generally increase from kaolin to talc to charcoal. It must be remembered, however, that the k_1k_2 value only tells that the three adsorbents have different affinity for the compounds, and one cannot assume much about the mechanism of the interaction from these values.

Adsorption may occur as a result of several possible mechanisms (10–13). Certain mechanisms may involve a specific interaction between the surface of the solid and the adsorbed molecule. On the other hand, solutes which exhibit surface tension lowering properties are often strongly adsorbed by a wide variety of solids since these solutes often tend to accumulate at the solid–liquid interface as readily as at the solution–air interface (10, 12). Phenothiazine derivatives have been shown to exhibit surface tension lowering properties (14–16). Figure 4 presents plots of surface tension lowering *versus* extent of adsorption for the phenothiazine compounds shown in Fig. 1. The coefficient of correlation between extent of adsorption by activated charcoal and surface tension lowering is −0.843. This value is significant at the $P = 0.05$ level. Such correlation does not exist for kaolin and talc adsorbents. This suggests that the ability to accumulate at the solid–solution interface may be responsible for the charcoal–solute interaction. Such a condition is favored by the very large surface area of activated charcoal which offers an extensive interface to the solution phase.[7] The failure of talc and kaolin to exhibit adsorptive properties which correlate to surface tension lowering can be interpreted as indicating that the tendency of solute molecules to accumulate at an interface is not the sole reason why adsorption onto these substances takes place. Since surface areas of kaolin and talc are generally much smaller than for activated charcoal, a smaller interface is offered for accumulation of surface-active solute molecules. Adsorption by interfacial effects cannot be entirely ruled out for kaolin and talc, however, as it is possible that some adsorption occurs *via* this mechanism, but it is obscured by the effects of other factors also facilitating adsorption at the same time.

If adsorption of solute by charcoal is mediated primarily through ability of the solute to accumulate

[7] Cassidy reports (10) surface areas in the range of 15 M.²/Gm. for kaolin, and 500–1700 M.²/Gm. for activated charcoal. Talc could be expected to have a surface area somewere in the range below 50 M.²/Gm. While surface areas were not measured for the specific adsorbents used in this study, they would probably be of a similar order of magnitude.

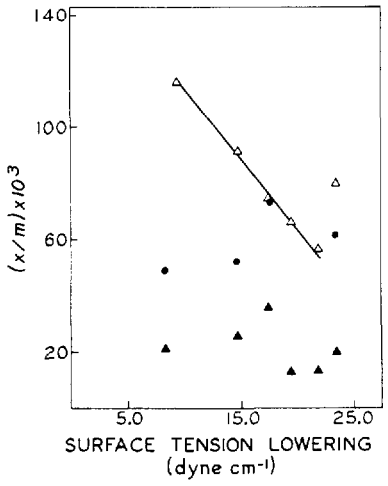

Fig. 4.—Limiting adsorptive capacity as a function of surface tension lowering produced by 1×10^{-2} M solutions of various phenothiazine derivatives. Key: △, charcoal adsorbent; ●, talc adsorbent; ▲, kaolin adsorbent.

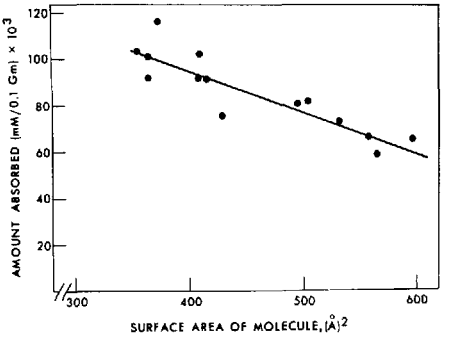

Fig. 5.—Limiting adsorptive capacity as a function of planar surface area of various phenothiazine derivatives adsorbed by activated charcoal.

at the solid–solution interface, a relationship might be expected to exist between the maximum extent of adsorption and the area occupied by the molecules in the interface. Figure 5 shows the apparent relationship between molecular surface area of the various phenothiazine derivatives and the Langmuir constant k_2.[8] The coefficient of correlation for the relationship in Fig. 5 is −0.861 and is significant at the $P = 0.001$ level. A coefficient of correlation equal to −0.886, significant at the $P = 0.01$ level, was obtained when k_2 values were compared to molecular volumes of the solutes. The total surface area of adsorbed molecules corresponds well with surface areas commonly encountered for activated charcoals. In the case of promazine, the total surface area of the molecules adsorbed at saturation of the adsorbent surface is 690 M.²/Gm. activated charcoal.

[8] Space-filling atomic models were used in calculating approximate surface areas of solute molecules. Areas were calculated on the basis of the smallest trapezoid which would contain the model. Molecular volumes were calculated as the smallest truncated pyramid which would contain the model.

Since the phenothiazine derivatives studied are capable of existence entirely or at least partially in a protonated form at the pH ranges of this experiment, it is possible that, in some cases, adsorption may be mediated by ion-exchange interactions. Both kaolin and talc particles would be expected to carry a negative charge (10) on their surface due to deficiencies in certain cations within the crystal structure of these substances. The negative charges are neutralized by exchangeable cations such as sodium and potassium. It is a well-established fact (10–13) that high molecular weight organic cations can displace these inorganic cations and preferentially adsorb to the particle surfaces. Such mechanisms would not account for the high adsorptive capacity of activated charcoal. Although certain charcoals can have some ion-exchange abilities (10), this cannot account for the high affinity of charcoal for solute molecules in the system under study.

The effect of electrolyte on promazine adsorption

is shown in Figs. 6, 7, and 8. It is seen that increasing the electrolyte concentration increases the adsorptive capacity of the adsorbent.[9] In addition, at any given solute concentration below that necessary to achieve apparent saturation of the adsorbent surface, the extent of adsorption is increased. Measurements showed that pH remained unchanged in the presence of increasing amounts of sodium chloride. Sodium ion, as well as other electrolyte species, would be expected to compete with the protonated amine for anionic sites on the particle surface or for positions in the electrical double layer around the particles. Hence, addition of large amounts of sodium ion might be expected to decrease the extent of adsorption of the protonated species of the amine if ion-exchange mechanisms were responsible for adsorption (12, 13). Failure of sodium ion to displace the organic cation suggests that adsorption of the phenothiazine derivative is mediated through other than simple ion-exchange mechanisms alone or that even in great excess, sodium ion cannot displace the amine from the adsorption sites. The fact that adsorption of the phenothiazine derivative is actually increased by the sodium ion supports the idea that ion-exchange is not the sole mechanism for adsorption. Even if the sodium ion could not displace the solute, it should not increase adsorption if ion-exchange was solely responsible for adsorption of the phenothiazine derivative. Sodium chloride may be exerting its action through effects on solubility and other physical properties of the phenothiazine derivative. The apparent result is an increasing tendency of the phenothiazine derivative to accumulate at the solution–solid interface. Electrolyte may affect physical properties of the adsorbent as well.

The effect of 0.01 *N* sodium chloride on adsorption of promazine hydrochloride by kaolin is of interest. It may be possible to explain this effect on the basis that at low promazine hydrochloride concentrations, there is competition for exchange sites which leads to decreased adsorption. At higher promazine hydrochloride concentrations, the sodium ion is displaced. Increased adsorption at high concentrations of promazine hydrochloride may be due to effects of

[9] It may be noted that data presented in Figs. 6, 7, and 8 differ from Table IV. These experiments were carried out at a later date using different adsorbent to solvent ratios. It has been pointed out (10) that limiting adsorptive capacities may vary somewhat when measured at different adsorbent–solvent ratios. Data presented in Figs. 6, 7, and 8 should be considered separately from Table IV.

TABLE V.—pH OF VARIOUS UNBUFFERED ADSORBENT–SOLUTE MIXTURES[a]

Adsorbent–Solute System	pH of System at Max. Equilibrium Concn. of Solute	pH of System at Min. Equilibrium Concn. of Solute
Kaolin–promazine	4.6	5.0
Talc–promazine	7.6	8.6
Charcoal–promazine	4.0	4.2
Kaolin–fluphenazine	3.6	4.2
Talc–fluphenazine	4.1	7.8
Charcoal–fluphenazine	3.3	3.4

[a] The pH values for adsorbent suspensions containing no solute were kaolin, 4.3; talc, 8.4; and charcoal, 5.9.

sodium chloride on solubility, etc., as discussed. On the basis of present data, it does not appear possible to either prove or disprove ion-exchange as an important mechanism in adsorption of the phenothiazine derivative by kaolin and talc.

Results of adsorption studies at constant pH are presented in Figs. 9, 10, and 11. In all cases, adsorption is seen to be greater at pH 6.5 than at pH 2.5. A possible explanation for this pH effect could be involved with changes which occur in the relative amounts of protonated and nonprotonated amine present as pH increases. If the nonprotonated form of the phenothiazine derivative is better adsorbed as is often the case for systems of this type (10, 12), then adsorption would be expected to be greater at the higher pH. Inspection of pKa values in Table III shows that even at pH 6.5, only a relatively small portion of the total amine is in the nonprotonated form since this pH is several units below the apparent pKa. It is difficult to conceive that there would be enough free base present at pH 6.5 to exert a significantly greater driving force for adsorption as compared to lower pH levels. On the other hand, the equilibrium between protonated and nonprotonated forms is dynamic. As free base is removed by adsorption, it will be replaced from the large reservoir of protonated material. Adsorption could thus continue until equilibrium is established between the adsorbent surface and the free base in solution. The free base concentration is indeed many times greater at pH 6.5 than at the lower pH. It is not impossible that this difference may account for the greater adsorption at higher pH values.

A second possible explanation for the effect of pH might lie in the possibility that hydrogen ions and the protonated amine may compete for anionic sites on the adsorbent surface of, for positions in, the electrical double layer existing around the adsorbent particles.

As compared to kaolin and talc, adsorption of phenothiazine derivatives by charcoal is less strongly influenced by hydrogen-ion concentration, although some charcoals have a moderate electrostatic charge and some affinity for hydrogen ions (10). It is probable that the observed pH effects for charcoal result from increases in the amount of nonprotonated form of the phenothiazine derivative present at the higher pH levels. The nonprotonated forms of the phenothiazine derivatives have low water solubility and hence would have a greater tendency to accumulate at the solid–solution interface than would the protonated form.

Adsorption of solute by talc is further illustrative of pH effects on adsorption. Adsorption of promazine by talc is greatest from unbuffered solution. The reason for this becomes apparent if one considers the pH of the unbuffered systems containing talc (Table V). The pH of unbuffered suspensions containing talc is usually greater than pH 6.5, and, hence, it is not surprising that absorption from unbuffered media is even greater than from the pH 6.5 system. When Figs. 9 and 10 are compared, it is seen that under conditions of controlled pH, kaolin is actually a better adsorbent than is talc. Data in Table IV, which show talc to be a stronger adsorbent in unbuffered media, are primarily a result of the more alkaline pH of the talc systems. It appears that at a given fixed pH, there is actually not much difference between talc and kaolin with respect to adsorbent capacity.

The talc–fluphenazine dihydrochloride system shows interesting pH effects (Fig. 12). In unbuffered solutions, the more acidic proton on the fluphenazine, pKa 3.90, causes production of a relatively low pH at higher solute concentrations, and the fluphenazine is adsorbed less strongly as a result. In fact, in systems containing talc, adsorption of fluphenazine from unbuffered solutions at the higher concentration ranges is very nearly identical to adsorption from buffered solution at pH 2.5. Due to the pH effect, isotherms for fluphenazine in unbuffered talc systems, as well as for other dibasic phenothiazine derivatives, pass through a maximum with increasing solute concentration (Fig. 13). Monobasic phenothiazine derivatives such as promazine, pKa 9.38, are unable to lower the pH of talc systems to an extent that similar pH effects are observed in unbuffered media.

The fact that the ionic charge on the fluphenazine molecule is approximately doubled at pH 2.5, as compared to pH 6.5, must also be considered when explaining pH effects on adsorption of the dibasic compounds. If ionic interactions are responsible for

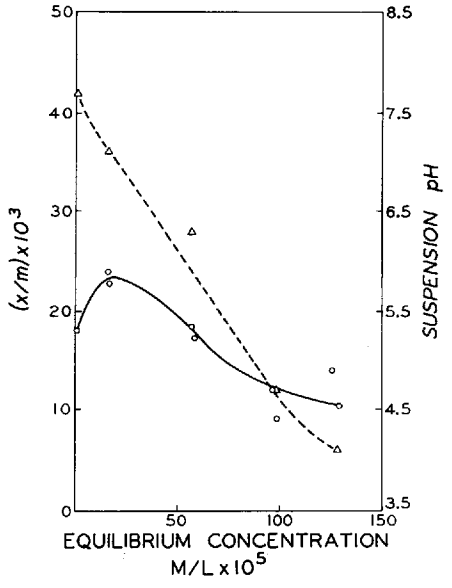

Fig. 12.—Relationship between the extent of adsorption of fluphenazine dihydrochloride by talc (O) and suspension pH (△).

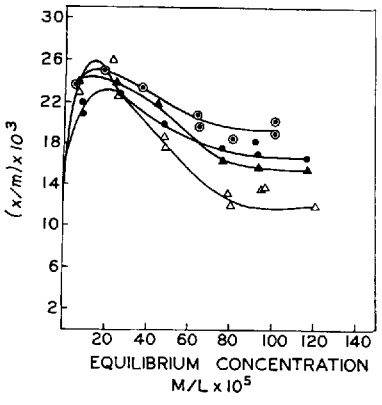

Fig. 13.—Isotherms for adsorption by talc in unbuffered media. Key: ⊙, prochlorperazine dihydrochloride; ●, trifluoperazine dihydrochloride; ▲, fluphenazine dihydrochloride; △, thiopropazate dihydrochloride.

adsorption, the compounds could potentially neutralize twice as many sites on the adsorbent surface at the lower pH and hence adsorption would be reduced to about 0.5 its value at the higher pH range. Inspection of the data shows that adsorption is decreased by a much greater factor at the lower pH. The adsorption of monobasic compounds is also decreased at low pH, even though there could be no change in the charge of the solute molecule. Thus, changes in total charge on the solute molecule do not appear to cause the observed pH effect on adsorption.

The relationship between pH and the extent of adsorption by talc lends support to the idea that the pH effect is due to changes in the amount of free base present. At pH 8.0, the midrange of the talc systems, 4% of the total amine content is in the base form. At pH 6.5, only about 0.13% exists in this form.

If adsorption is strongly influenced by the amount of free base present in the system, a correlation might be expected to exist betwen pKa and adsorption. Plots of apparent pKa *versus* the Langmuir constant, k_2, failed to show any correlation between these parameters. Likewise, apparent pKa and values for k_1k_2 could not be correlated. The lack of correlation is not surprising in view of the relatively slight differences between apparent pKa values for the compounds tested (Table III).

It is not possible to state on the basis of information obtained from these pH studies whether the observed effects are due to one specific certain mechanism. The fact that considerable adsorption occurs at pH 2.5 supports the hypothesis that adsorption of the protonated form also occurs to a considerable extent. Adsorption of solute by kaolin and talc is probably mediated through a combination of mechanisms.

Increasing temperature generally decreases the extent of adsorption. However, it is not uncommon to find that adsorption increases with temperature in certain systems (11, 12). Temperature can affect several properties of the solute molecules and the adsorbent (Table VI), as well as the adsorption interaction *per se*. The mechanism by which temperature increases adsorption in the systems under study is not known. Further investigations of the temperature effects are planned.

The effect of electrolyte and hydrogen-ion concentration is interesting with respect to potential implications regarding the effect of adsorption on the availability of certain drugs for absorption from the gastrointestinal tract. It has already been established (2) for a similar clay-type adsorbent and activated charcoal that adsorbents may alter the availability of promazine for absorption from the gastrointestinal tract. Within the stomach, the presence of hydrogen ion may cause desorption, thus favoring absorption of the drug. The electrolyte environment existing throughout the gastrointestinal tract would probably favor absorption and retard release of adsorbed drug to the fluids at the absorption site. It should be noted that the effect of electrolyte on promazine adsorption was predicted incorrectly (2). While this does not alter the validity of the research, statements made previously regarding the probable effect of electrolyte on release of promazine should be reconsidered.

It is also important that electrolyte not only changes the maximum amount of drug which can be adsorbed, but also increases the amount adsorbed at any given concentration below that which achieves surface saturation. Thus, for talc and activated charcoal, the plateau region corresponding to surface saturation is achieved at a much lower solute concentration. In terms of potential *in vivo* effects, this may be quite important. According to hypotheses presented previously (2), the amount of drug which can exist free in equilibrium with a given amount of adsorbate may be a determinant factor in modifying drug uptake from the gastrointestinal tract when adsorbents are present. These effects will bear further investigation. The reader should refer to *Reference 2* for additional discussions concerning the effects of adsorption on drug availability.

SUMMARY

It can be stated that the adsorption interaction between medicinally active phenothiazine derivatives and charcoal occurs to a significant extent in all cases studied. The mechanisms of the interaction cannot be completely defined from data obtained in experiments described in this paper. Adsorption

Table VI.—Effect of Temperature on Adsorption of Chlorpromazine Hydrochloride and Thiopropazate Dihydrochloride

	Limiting Adsorption Capacity of Adsorbent mM × 10³					
	Kaolin		Talc		Activated Charcoal	
Compd.	20°	37°	20°	37°	20°	37°
Chlorpromazine hydrochloride	24.0	27.1	51.8	70.4	102	110
Thiopropazate dihydrochloride	14.1	33.9	...[a]	...[a]	58.5	80.0

[a] The Langmuir plots for adsorption of thiopropazate dihydrochloride by talc were nonlinear and hence a limiting adsorptive capacity could not be calculated. The effect of temperature appeared to be negligible in this case, however, and the two isotherms were virtually identical.

by charcoal appears to be mediated primarily by physical forces and probably occurs as a result of the tendency of the solute to accumulate at solution–solid interfaces. This tendency to accumulate at the solution–solid interface is similar to the demonstrated surface tension lowering effects of the phenothiazine derivatives.

Adsorption of phenothiazine derivatives by clay-type materials such as kaolin and talc is more complex in nature and is probably mediated through several different mechanisms simultaneously. Mechanisms based on simple electrostatic charge interactions cannot alone explain the process. Molecular size and interfacial properties of the solute do not appear to correlate with adsorption in systems containing kaolin or talc in simple aqueous media.

The results of this experiment show that adsorption of phenothiazine derivatives is dependent upon both hydrogen-ion and electrolyte concentration. Hydrogen-ion concentration is inversely related to the extent of adsorption. The effect of hydrogen-ion may be either to determine the amount of nonprotonated form which is present or to compete with the protonated form for adsorption sites. It is probable that adsorption of phenothiazine derivatives by talc and kaolin is subject to both of these effects. The presence of sodium chloride generally increases adsorption. This is probably due to effects on various physical properties of the solute which increase its tendency to accumulate at the solution–solid interface. The failure of sodium chloride to depress adsorption tends to discount simple ion-exchange as a major mechanism of adsorption.

The effects of pH and electrolyte concentration have important implications with respect to the effect of adsorbents in altering availability of promazine for absorption from the gastrointestinal tract.

The results of these experiments will be useful in further studies of the effect of adsorbents on drug availability. They should also be of use in interpretation of drug–adsorbent interactions in general.

Inositol N.F.

New Excipient for Chewable Tablets

By S. S. NASIR and L. O. WILKEN, JR.

An investigation of the suitability of inositol as a base for chewable tablets has been conducted by studying and comparing pertinent properties of inositol, mannitol, lactose, and a lactose–sucrose mixture (9:1). The amounts of moisture absorbed by the finely powdered materials, granulations made from these powders with the aid of selected binders, and tablets compressed from some of the granulations were determined (Karl Fischer method or difference in weight) before and after storage at selected relative humidities for specified periods of time. Tablets of similar weights and volumes were prepared from inositol as well as mannitol granulations and evaluated for hardness and dissolution times before and after aging and compared. Representative chewable tablets utilizing mannitol and inositol as bases were prepared for vitamins, antacids, and for acetylsalicylic acid and evaluated for compressability, hardness, dissolution, taste, and appearance. The experimental data indicate that inositol, due to its nonhygroscopic nature, chemical inertness, nontoxicity, physical stability, superior mouthfeel, and texture can be beneficially employed as the base for the formulation of chewable tablets.

ONE OF the recent modifications in tablet dosage forms has led to the development of the chewable tablet, a compressed dosage form, conveniently carried and self-administered, which can be chewed or sucked without the aid of external liquid (1, 2). Daoust and Lynch (1) state that the ideal chewable tablet must be nonhygroscopic and chemically stable, that it

Inositol N.F.

New Excipient for Chewable Tablets

By S. S. NASIR and L. O. WILKEN, JR.

An investigation of the suitability of inositol as a base for chewable tablets has been conducted by studying and comparing pertinent properties of inositol, mannitol, lactose, and a lactose–sucrose mixture (9:1). The amounts of moisture absorbed by the finely powdered materials, granulations made from these powders with the aid of selected binders, and tablets compressed from some of the granulations were determined (Karl Fischer method or difference in weight) before and after storage at selected relative humidities for specified periods of time. Tablets of similar weights and volumes were prepared from inositol as well as mannitol granulations and evaluated for hardness and dissolution times before and after aging and compared. Representative chewable tablets utilizing mannitol and inositol as bases were prepared for vitamins, antacids, and for acetylsalicylic acid and evaluated for compressability, hardness, dissolution, taste, and appearance. The experimental data indicate that inositol, due to its nonhygroscopic nature, chemical inertness, nontoxicity, physical stability, superior mouthfeel, and texture can be beneficially employed as the base for the formulation of chewable tablets.

ONE OF the recent modifications in tablet dosage forms has led to the development of the chewable tablet, a compressed dosage form, conveniently carried and self-administered, which can be chewed or sucked without the aid of external liquid (1, 2). Daoust and Lynch (1) state that the ideal chewable tablet must be nonhygroscopic and chemically stable, that it

Received April 25, 1966, from the Pharmaceutical Technology Laboratories, School of Pharmacy, Auburn University, Auburn, Ala.

must disintegrate smoothly at a satisfactory rate, have a pleasant taste and mouthfeel, and leave no unpleasant aftertaste.

Since the excipient constitutes usually a large proportion of the substance of the tablet, the physical characteristics of the dosage form are necessarily influenced by those of the excipient, although not all to the same degree.

Extensive studies (1, 3) have been conducted on sugars and sugar alcohols in order to determine their suitability as bases for chewable tablets with the results indicating that mannitol possesses all the desirable characteristics of the "preferred excipient." No evaluation has been reported on the use of cyclic polyhydroxic alcohols for this purpose, although it was noted that inositol possesses many of the same desirable characteristics and properties (4–6). Inositol N.F. is an odorless, nonhygroscopic, chemically stable, sweet-tasting, white, crystalline material having a negative heat of solution (7) and is soluble to the extent of 1 Gm. in 5.7 ml. of water at 25°. This cyclic alcohol is widely distributed in nature being found in nearly all living cells investigated (8) and has demonstrated no toxicity.

With this information in mind and with the intent of possibly improving a well-accepted dosage form while, at the same time, extending the usefulness of an abundant natural product, a study was undertaken to determine the suitability of a cyclic polyhydroxic alcohol, inositol N.F., as a base for chewable tablets. The investigation included a comparison of some of the more pertinent properties of inositol, granulations of inositol, and tablets made from inositol with those corresponding properties of some accepted excipients.

EXPERIMENTAL

Materials.—The mannitol N.F. and inositol N.F. were obtained in powdered form from Mann Research Laboratories and the lactose U.S.P. was purchased from City Chemical Corp. Other materials used included sucrose U.S.P., gelatin U.S.P., potato starch,[1] acacia U.S.P., methylcellulose U.S.P. (1500 cps.), alcohol U.S.P., magnesium stearate U.S.P., magnesium trisilicate U.S.P., aluminum hydroxide,[1] aspirin U.S.P., liquid glucose U.S.P., and sodium saccharin N.F. The vitamins used in the preparation of the multivitamin tablets were U.S.P. grade as obtained from Mann Research Laboratories.

Preparation of Powders.—The finely powdered mannitol, inositol, and lactose were passed through a 60 mesh screen in preparation for the moisture absorption studies and prior to the preparation of the various granulations.

[1] Obtained from J. T. Baker Chemical Co., Phillipsburg, N. J.

Preparation of Granulations.—Four series of granulations were prepared using mannitol, inositol, lactose, and lactose–sucrose (9:1) as bases according to the following formula: base, 993 Gm.; sodium saccharin, 7 Gm.; binder solution, as required.

Five granulations were prepared from each of the four bases utilizing purified water, 10% acacia solution, 10% gelatin solution, 10% starch paste, and diluted alcohol U.S.P. as the binder solutions. The volumes of granulating solutions required for the granulation of 500 Gm. of each base are shown in Table I.

The dry and previously mixed materials were moistened with the binder solutions and kneaded by hand until masses were formed. The wetted masses were then passed through an Erweka F.G.S. granulator fitted with a screen having 1.5 mm. openings (approximately 14 mesh). The resulting wet granules were dried in a Glatt TR-2 fluidized bed dryer at 40° with a gate opening of 2.5 for a period of 30 min. for the mannitol and inositol granulations, and for 50 min. for those granulations containing lactose and the lactose–sucrose mixture. The increased drying times for the lactose and lactose–sucrose granulations were necessary in order to reduce the moisture content to an acceptable level as determined by the Karl Fischer method. The moisture content of each of the dried granulations expressed as averages of triplicate determinations is shown in Table I. After drying, the granules were passed through a No. 18 screen and stored in airtight containers for future use.

Additional series of granulations were prepared both from mannitol and from inositol, but using the No. 14 sieve as the final size in order to obtain larger granules. Similar granulations were prepared with 2% liquid glucose added as an additional binder solution. These granulations also were reserved for further study.

Compression of Granulations.—Portions (1000 Gm.) of each of the prepared granulations were mixed with portions (10 Gm.) of magnesium stearate as lubricant with the aid of an Erweka cube mixer. The granulations were then compressed into tablets on a Colton model 204 four-station rotary press equipped with a model 205 induced die feeder and 0.5 in. flat-faced, beveled-edged punches. The representative weight, hardness, thickness, and dissolution times of the resulting tablets are shown in Table II. The dissolution times were determined with the aid of a U.S.P. apparatus and taken at the time when all of the tablet passed through the screen of the apparatus.

Hygroscopicity Studies.—*Powdered Materials.*—Accurately weighed samples (approximately 100 mg. each) of the powdered inositol, the powdered mannitol, and the powdered lactose were placed in open wide-mouth glass vials and stored for 96 hr. in relative humidities of approximately 65 and 100%. Previous experiments indicated that similar samples of the inositol reached maximum moisture concentration in less than 72 hr. The controlled humidity chambers were prepared using desiccators containing saturated solutions of suitable salts (9) and maintaining the temperature at 24° ± 2° with relative humidities of approximately 10, 51, 65, 84, 95, and 100% being produced.

The moisture contents of the powdered materials

so treated were determined by the Karl Fischer method (10) with the aid of a Lab Industries aquametry apparatus. The results, averages of triplicate determinations, are shown in Table III.

Granulations.—Each of the granulations was analyzed for moisture content when freshly prepared (Table I) and after storage for 96 hr. in the controlled humidity chambers (Table IV). The moisture contents of powders and granulations were determined by the Karl Fischer method with minor modifications. A measured portion of anhydrous methanol (60 ml.) was titrated to the Karl Fischer end point, after which 10 ml. of this solution was removed and retained in a pipet. The sample for analysis was then washed with this 10 ml. of solution through a funnel into the receiver of the aquametry apparatus. The mixture was stirred magnetically for 2 min., after which it was titrated to a Karl Fischer end point which remained stable for 30 sec.

Tablets.—The extent of moisture absorption or desorption by tablets was determined by the differences in weights observed before and after storage for 20 days in the controlled humidity chambers.

The tablets of mannitol and inositol prepared using selected binder solutions were accurately weighed, stored for 20 days in the previously described controlled humidity chambers, then reweighed. The percentage by weight of moisture absorbed or desorbed was calculated from the change in weight of the tablets. The results are shown in Table V.

Preparation of Representative Tablets.—Three different types of tablets, antacid, multivitamin, and aspirin tablets, were prepared using inositol and mannitol as bases. The formula (11) for the antacid tablets was modified by the use of gelatin solution as the binder and the omission of the disintegrator. In one batch of the antacid tablets inositol was used in place of mannitol; batches of both types of tablets were prepared, compared, and evaluated. The results are shown in Table VI.

Aspirin tablets were prepared according to a published formula (12) modified by the use of 10% gelatin solution as the binder and the omission of a

disintegrator. Batches of tablets were prepared with both inositol and mannitol as bases and were compared and evaluated. The results are shown in Table VI.

Two batches of multivitamin tablets were prepared with mannitol as the base in one and with inositol as the base in the other. The published formula (11) was modified through use of 10% gelatin solution as the binder and the omission of the disintegrator. The prepared tablets were compared and evaluated with the results being shown in Table VI.

DISCUSSION AND RESULTS

In order to limit the maximum particle size and minimum specific surfaces for the powders examined for their hygroscopic nature, the materials were passed through a 60-mesh sieve. This procedure was considered advisable to ensure more uniform and complete moisture absorption by the powdered materials. In order to reduce the time required for maximum absorption of moisture the weights of the samples exposed at the various relative humidities were limited to approximately 100 mg. each, which were spread in thin layers.

The results of the experiment, as shown in Table III, indicate that for the range of relative humidities studied, the hygroscopic nature of inositol is very similar to that of mannitol, the hygroscopicity of both being much less than that of lactose.

A comparison of the physical properties of the various granulations (Table I) shows that the inositol granulations required less binder solution than did the mannitol granulations and that both of these required significantly more binder solution than did the others tested. The hardness of the granules and the percentages of fines in the granulations indicated that a strong binding material must be used to make satisfactory granulations from

	Mannitol	0.336 ± 0.017	4.20 ± 0.01	22.0 ± 0.3	2.0	1.5

inositol and mannitol. The data of Table I also reveal that the inositol and mannitol granulations are dried more easily and thoroughly than the others examined.

The studies of the absorption of moisture were conducted on those granulations prepared with stronger binding solutions with the results (Table IV) showing that the inositol granulations generally absorbed less moisture than did those others tested. The inositol and mannitol granulations both showed little tendency to absorb moisture even at 95% relative humidity, with the inositol granulations demonstrating significantly less absorption of moisture at all the higher relative humidities. It should be noted that both of these granulations showed a sharp increase in moisture content and that the lactose–sucrose (9:1) granulation liquified at 100% relative humidity. This demonstrated that low degree of hygroscopicity can be expected to enhance the stability of solid dosage forms prepared from the inositol granulations.

The compression of the inositol and mannitol granulations into tablets was accompanied by considerable capping. Attempts to modify the granulations by decreasing the percentage of fines and by increasing the granulation size to 14 mesh produced no significant improvement in compressibility. Although the compression characteristics of both granulations were greatly improved by the addition of 2% liquid glucose as an auxiliary binder, the tablets prepared by these granulations were not studied because of the known and undesirable hygroscopic nature of liquid glucose. Suitable tablets were prepared from the original granulation (18 mesh) but with reduced hardness as measured by a Stokes hardness tester.

The hardness of these tablets increased considerably on aging, as indicated in Table II. The dissolution times of the prepared tablets show that those prepared from the inositol granulations dissolved in a shorter period of time than did those prepared from the mannitol granulations. This quality, although not too important in "chewable tablets," does deserve mention.

The period of time that the tablets prepared with inositol and mannitol as excipients were stored at controlled relative humidities was limited by mold growth to 20 days. The behavior of the tablets in respect to moisture absorption compares very closely, with each series demonstrating almost identical absorption as shown in Table V.

The problem of capping did not occur during the compression of representative tablets in which the bases, inositol and mannitol, were diluted with the therapeutically active substances. Excellent antacid and aspirin tablets were easily prepared having smooth, glossy surfaces and having equally elegant appearances, but the multivitamin tablets could not be compressed to a hardness above 2.0 Kg. When special granulations using methylcellulose and alcohol as binders were prepared and compressed, the maximum hardness achieved was 2.5 Kg. as measured by the Stokes hardness tester. All of the vitamin tablets had sufficient surface hardness such that chipping, powdering, and breaking did not occur.

The dissolution times of these representative tablets prepared with inositol as the base were consistently less than the corresponding tablets prepared with the mannitol.

One of the important qualities of mannitol which contributes to its utility as a base for chewable tablets is the ability to mask the unpleasant tastes of some drugs. It was noted that inositol possesses this same characteristic as reported by randomly selected and untrained subjects. In addition, inositol has a mouthfeel as comparably pleasant and cool as that described for mannitol.

CONCLUSIONS

1. Inositol N.F. possesses those properties described as characteristic of the ideal excipient for chewable and other compressed tablets.
2. Granulations prepared from inositol N.F. generally absorbed less moisture from varied environmental conditions than did granulations prepared from mannitol N.F. and other excipients.
3. Tablets prepared from inositol granulations compare favorably with those prepared from mannitol granulations in respect to appearance, taste, dissolution times, low degree of moisture absorption, and hardness.
4. The results of the study indicate that further evaluation of tablets prepared from granulations of inositol N.F. in order to determine stability, drug release characteristics, and drug availability is warranted.
5. In view of the results of this study, inositol N.F. should be seriously considered as an excipient for chewable and other compressed tablets.

Production of Pantothenic Acid and Inositol by *Chlorella vulgaris* and *C. pyrenoidosa*

By ROBERTSON PRATT and EVELYN JOHNSON

Two unicellular green algae, *Chlorella vulgaris* and *C. pyrenoidosa*, were compared with respect to pantothenic acid and inositol content at different times during a 3-week culture cycle. Pantothenic acid was found in the cells and in the external medium at all times: the concentration in the cells (mmcg./mg. dry weight) decreased sharply toward the end of the first week and then less abruptly through most of the remaining 2 weeks. However, due to increase in the cell mass, the absolute yield (mmcg./ml. harvested culture) increased. The concentration in the external medium, after a relatively small decline during the first week, rose substantially and at the end of the culture period far exceeded that in the cells. Inositol content of the cells increased slowly throughout the culture period. No extracellular inositol was detected at any time. *C. pyrenoidosa* excels *C. vulgaris* as a source of both compounds.

PREVIOUS investigations have revealed that the unicellular green algae, *Chlorella vulgaris* and *C. pyrenoidosa*, compare favorably with conventional vegetable dietary sources of several important vitamins, *e.g.*, biotin, folic acid, niacin, pyridoxine, riboflavin, and thiamine (1, 2). Morimura has reported consistent variations in vitamin content at different stages during the division and reproduction cycle of *C. ellipsoidea* grown in synchronous culture for short periods (3), and others have found that the vitamin content of *C. vulgaris* and of *C. pyrenoidosa* changes during 3 weeks of normal nonsynchronous growth (1, 2). Under the latter conditions, the content of biotin, folic acid, riboflavin, and thiamine (relative to dry weight of the cells) rises to a maximum and then declines during the 3-week culture period while the content of niacin and pyridoxine decreases continuously. However, because of the 16- to 17-fold gain in total cell mass, the absolute yield (mmcg./ml. of harvested culture) of all these vitamins, except folic acid, increases throughout the 3 weeks. The absolute yield of folic acid tends to decrease during the later portion of the culture period.

Of the six vitamins above, only riboflavin occurs in substantial quantities in the supernatant culture medium, the amount sometimes equaling or exceeding that in the cell mass after 3 weeks. The folic acid and the niacin content of the supernatant may be approximately 5% of that in the cells; the corresponding figure for pyridoxine may approximate 20%. Neither thiamine nor biotin appears in the supernatant in concentrations detectable by the microbiologic assay methods that were employed.

The present report deals with the pantothenic acid and inositol content of *Chlorella*. The rationale for pursuing this line of investigation has been reviewed by the authors (1, 2, 4) and others (5, 6). The view has been expressed that the vitamin content of *Chlorella* is sufficient to give the alga "premium value . . . as human or animal food" but is insufficient to render the plants suitable for recovery of vitamin concentrates (7). However, the latter point, being merely a matter of technology and of the economics of supply and demand, could well be subject to revision in the future.

EXPERIMENTAL

Chlorella Cultures and Procedures

The pedigree of the strains of *C. vulgaris* and of *C. pyrenoidosa* employed and the procedures adopted as standard for working with them in this laboratory have been described in detail elsewhere (4). In brief, experimental cultures were inoculated with a sufficient number of organisms from a 4-day liquid culture (inoculated from the most recent of a series of at least six 4-day cultures) to give an initial population of 100 cells/mm.^{3} (100,000/ml.); light was supplied continuously from a Mazda source (intensity 600 f.c. at the position of the culture vessels); aeration was provided by a mixture consisting of 5% CO_2 and 95% air continuously passed through the cultures in finely dispersed bubbles; and the temperature was 20.5 ± 0.5°. The specific source of illumination and the geometry of the culture vessels have been described (4). The culture medium consisted of KNO_3, 0.025 *M*; $MgSO_4 \cdot 7H_2O$, 0.02 *M*; KH_2PO_4, 0.018 *M*; $FeSO_4 \cdot 7H_2O$, 5×10^{-5} *M*; potassium citrate, 5×10^{-5} *M*; Zn (as $ZnSO_4 \cdot 7H_2O$), 0.4 p.p.m.; Cu (as $CuSO_4 \cdot 5H_2O$), 0.004 p.p.m.; Mn (as $MnSO_4 \cdot 4H_2O$), 0.4 p.p.m.; and B (as H_3BO_3), 0.02 p.p.m.

Microbiologic Assays

Pantothenic Acid.—Harvested *Chlorella* cells were steamed for 30 min. in 0.1 *M* sodium acetate buffer at pH 6.8 and enzymatically digested by exposure for 4 hr. at 37° to a chicken liver extract[1]

[1] Prepared as described by Nielands and Strong (8).

and alkaline phosphatase.[2] Cellular debris was removed by filtration and the residual extract was assayed for pantothenic acid, using *Lactobacillus plantarum* ATCC 8014 as the test organism in bacto-pantothenate medium U.S.P. (9).

Inositol.—Inositol was extracted according to the method of Wooley as modified by Snell (10). This involved refluxing the cells in 18% HCl for 6 hr., evaporating *in vacuo* to near dryness, and neutralizing. After filtration, the extract was assayed for inositol, using *Saccharomyces carlsbergensis* ATCC 9080 as the test organism in bacto-inositol assay medium (11).

Reliability of the Assays.—Two extracts were prepared from each sample at each harvest time, and each extract was assayed (in duplicate) at two levels. The S.D. for each such set of eight values was determined. All values for pantothenic acid were within the range ±10% of the mean. All inositol assay values for any given single extract were within the same range but to include all S.D. values from multiple extracts the range was ±15%.

RESULTS AND DISCUSSION

The over-all data, averaged from results of three successive experiments, are presented in Table I. Inositol was found only in the cell mass. At none of the six harvest times spaced over the 3-week culture period could it be detected, by the microbiologic assay technique employed, in the culture fluid. In this respect, its pattern of distribution is similar to that found previously for biotin and thiamine (2). In contrast substantial amounts of pantothenic acid occurred in the culture milieu, and during the latter half of the growth period the concentration in the medium was several times that in the cells, whether results were expressed relative to the dry weight of the cell mass (Table I, A) or in terms of absolute yield (Table I, B).

Examination of Table I, A, reveals a distinct difference in the patterns of pantothenic acid and of inositol content of the cells, relative to dry weight, in both species of *Chlorella*. Pantothenic acid is present in relatively high concentrations during the early phases of the culture period, and then the concentration decreases sharply between the fifth and the seventh days after which it continues to decrease, although less abruptly, for about another week to week and a half when it tends to reach a minimum and then to rise slightly during the remaining few days.

Inositol displays much less variation in level, increasing less than 50% between days 5 and 21 in *C. vulgaris* and approximately 15% in *C. pyrenoidosa*. These figures are in sharp contrast to the decrease of about 95% in pantothenic acid concentration between days 5 and 18 in *C. vulgaris* and of about 85% between days 5 and 14 in *C. pyrenoidosa*.

[2] Obtained from the Mann Research Laboratories, New York, N. Y.

The concentration of pantothenic acid in the culture milieu, expressed in relation to dry weight of the cells, swings through a smaller range but it too decreases (about 30%) between days 5 and 7, after which it rises slowly during the following 2 weeks. At the end of the culture period, it is substantially higher than at day 5 and is from 5 to 8 times higher than in the cells of *C. vulgaris* and of *C. pyrenoidosa*, respectively, at that time.

Despite the decrease in pantothenic acid content and the relatively stable content of inositol in the cells, relative to dry weight of the cells, the absolute yield of both compounds (Table 1, B) increases during the 3-week growth period because of the large (16- to 17-fold) increase in total cell mass. This is true also for the total yield of pantothenic acid, *i.e.*, content in cells plus that in supernatant (Table I, B).

The data summarized above differ in two significant respects from those found earlier for other vitamins. First, the abrupt decrease in concentration of pantothenic acid in the cells (Table I, A) and in total production of pantothenic acid (cells + supernatant), expressed relative to dry weight of cells, has not been observed in analyses for other vitamins. Changes in the concentration of other vitamins, from high to low (or vice versa), during the culture period occur gradually and more or less uniformly over a period of several days (1, 2).

Second, the high levels of pantothenic acid in *C. vulgaris* relative to those in *C. pyrenoidosa* during the early days of growth seem unique. In the authors' studies of eight vitamins, only one other (niacin) was found which occurs in higher concentration in *C. vulgaris* than in *C. pyrenoidosa*. In that case the difference in favor of the former species ranged from about 8% at 1 week to about 47% after 3 weeks, when results were calculated in terms of dry weight, *i.e.*, mmcg. of vitamin/mg. dry weight of cells, although when results were expressed in absolute terms, *i.e.*, mmcg./ml. harvested culture, the yield from *C. vulgaris* exceeded that from *C. pyrenoidosa* by 14 to 18%, irrespective of the time of harvest. In contrast, at day 5 the concentration of pantothenic acid in cells of *C. vulgaris* exceeds that in cells of *C. pyrenoidosa* by as much as 73% when expressed in terms of dry weight (Table II, A) and by 44% when calculated as absolute yield from the cells (Table II, B). This advantage of *C. vulgaris* decreases during the next several days but the species still holds a 15% lead at the end of the second week (Table II, A). However, by the end of the third week the two species are essentially equal in pantothenic acid content of the cells. Examination of Tables I and II reveals that the advantage *C. vulgaris* seems to hold over *C. pyrenoidosa* in pantothenic acid content of the cells stems in part from the fact that in cultures of the latter species relatively more of the total pantothenic acid content is found in the external medium. This is shown more specifically by Table III. Thus, except for the first week of the growth period the total pantothenic acid (cells + supernatant) is substantially higher in cultures of *C. pyrenoidosa* than in those of *C. vulgaris*, and the difference in favor of the former increases with time (Tables I and II). At each harvest time (except one) the percentage of the total pantothenic acid found in the supernatant was greater in cultures of *C. pyrenoidosa* than in those of *C. vulgaris* (Table III).

TABLE III.—PANTOTHENIC ACID IN RESIDUAL CULTURE SOLUTION EXPRESSED AS PER CENT OF THE TOTAL (CELLS + SUPERNATANT) CONTENT

Harvest Day	*C. vulgaris*	*C. pyrenoidosa*
5	31.3	48.6
7	40.1	52.2
11	72.8	83.3
14	81.6	86.9
18	89.1	87.6
21	82.6	89.3

It is suggested that the high concentration of cellular pantothenic acid in cultures of *C. vulgaris* relative to *C. pyrenoidosa* at day 5 followed by continuous diminution of the apparent advantage of the former thereafter is essentially a syndrome that stems coincidentally from the culture conditions and the harvest times chosen. Others have shown that in cultures of *C. ellipsoidea* undergoing synchronous growth the cells are largest during the "ripening and maturing" stage which precedes release of daughter cells and that this is a stage of development when pantothenic acid content of cells is greatest (3, 12). At that stage the cells have high respiratory activity, suggesting enhanced formative metabolism and an important role for pantothenic acid as a component of coenzyme A (12). Concomitant with the increase in cell size and in pantothenic acid content, there is a striking decrease in the ratio of dry weight/volume during the early ripening phase, suggesting more active absorption of water by the algal cells during that process (13). The accompanying decrease in glucosamine content of the cell wall (14) may indicate significant alteration in the permeability and other characteristics of the cell.

In the present work it was observed that early harvests, in contrast to later ones, appeared to contain a greater percentage of larger cells, perhaps comparable to the "ripening and maturing" stage of development reported by others to precede release of daughter cells. Accordingly, a study was made of the size distribution and settling rates of cells harvested at different times. The results will be the subject of a later communication, and it will suffice for the present to mention that the percentage of "large" cells, *i.e.*, 6 μ or more in diameter does indeed vary during the growth period, increasing approximately threefold between the time of inoculation and the third day and nearly fivefold in the first 5 days. By the seventh day postinoculation, the percentage (but not the absolute number) of "large" cells has decreased to a value below that found in the inoculum.

To determine rate of settling, cells were spun down, washed with 0.002 *M* K_2SO_4, spun down again, and resuspended in 2% NaCl. Transmission was determined with a Klett-Summerson colorimeter. (Initial Klett reading of suspensions = 200.) The decrease in Klett values after 1 hr. for suspensions prepared from 3-, 4-, 7-, and 11-day harvests was 140, 70, 41, and 20, respectively, and suggests that cells from the younger cultures were less dense, and thus remained in suspension longer, than those from older cultures. This is consistent with the observation of a decrease in the ratio dry weight/volume during the "ripening" stage (13).

In view of the foregoing observations of size distribution and settling rates in our cultures con-

TABLE IV.—PANTOTHENIC ACID AND INOSITOL CONTENT OF *Chlorella* AND OF SOME CONVENTIONAL FOODS (mcg./100 Gm. OF EDIBLE PORTION)[a]

Item	Pantothenic Acid	Inositol

[a] Values for food from Sebrell, W. H., and Harris, R. S., "The Vitamins," vol. III, Academic Press Inc., New York, N. Y., 1954; and "Nutritional Data," 5th ed., H. J. Heinz, Pittsburgh, Pa., 1962.

sidered in conjunction with the very detailed observations on physical characteristics of cells at different stages of development cited in the literature (3, 12), it seems reasonable to suggest that, under the conditions of the experiments in this laboratory (relatively small inoculum, adaptation to new medium, different light intensity, etc.), there may be a tendency toward partial or simulated synchronized growth at the time of the first harvest—day 5. Expressed another way, it may be plausible to suggest that a larger percentage of cells of the total population divides about the third to fifth day postinoculation than at earlier or later times. Since *C. pyrenoidosa* develops more rapidly than *C. vulgaris* during the early phases of culture and enters the log phase and reaches the stationary phase sooner (1, 4), it is not unreasonable to assume that at the time of first harvest (day 5) cultures of *C. vulgaris* were just approaching or entering the critical time of the major burst of division (percentagewise, although not in terms of total number of cells dividing or produced) and that cultures of *C. pyrenoidosa* had already passed that peak.

Bearing in mind that pantothenic acid level is greatest in cells in the "ripening and maturing" stage of development (3, 12), the above hypothesis is consistent with the higher cell content of that constituent found in *C. vulgaris* in the first half of the culture period. It is interesting to note also that Morimura (3) reported formation of pantothenic acid to be related primarily to the process of "ripening" rather than directly to the process of photosynthesis or "growing." If greatest production occurs during the phase preceding release of daughter cells, it may not be unreasonable to assume that upon release of the daughter cells some of the vitamin would also be released to the external medium. If such does in fact occur, since *C. pyrenoidosa* cultures develop more rapidly than those of *C. vulgaris*, it could account for the higher percentage of the total pantothenic acid found in the external medium of the *C. pyrenoidosa* cultures (Table III).

The pantothenic acid and inositol content of the two *Chlorella* species and of several conventional dietary items is shown in Table IV. In comparing *Chlorella* with the other items listed, it should be remembered that data for *Chlorella* are for dried cells but that values of the other items (except lima beans, oats, dried peas, peanuts, and soy beans) are for fresh material. Therefore, since the water content of *Chlorella* is about 90%, values expressed in terms of fresh weight would be about 10% of those recorded.

SUMMARY

In cultures of *C. vulgaris* and of *C. pyrenoidosa* the cellular content of inositol, expressed relative to dry weight of the cells, increased throughout the 21-day culture period—the increase being less than 50% between days 5 (first harvest) and 21 in *C. vulgaris* and about 15% in *C. pyrenoidosa*. The increase in total yield (mmcg./ml. of harvested culture) was approximately 14-fold during the same period in both species. At all harvest times, *C. pyrenoidosa* exceeded *C. vulgaris* in inositol content. At no harvest time was inositol detected in the external culture medium.

In contrast, pantothenic acid was recovered from the cells and from the external culture solution at all harvest times. The concentration in the cells, relative to dry weight decreased sharply during the first week, then less abruptly for another week or week and a half. Except during the first week, when there was a decline, the concentration in the external solution increased throughout the culture period, and at terminal harvest the concentration in the external medium was severalfold that in the cells.

During the first week postinoculation *C. vulgaris* excelled *C. pyrenoidosa* in yield of pantothenic acid, but after that initial period the relative positions of the two species as sources of the vitamin were reversed.

Mechanism of Action of Phenolic Disinfectants VII

Factors Affecting Binding of Phenol Derivatives to *Micrococcus lysodeikticus* Cells

By JOSEPH JUDIS

Whole cells of *Micrococcus lysodeikticus* ATCC 4698 bound approximately 2–4 per cent of phenol-^{14}C (P-^{14}C), 20 per cent of 2,4-dichlorophenol-^{14}C (DCP-^{14}C), and 30 per cent of *p-tert*-amylphenol-^{14}C (PTAP-^{14}C) when exposed to the latter in trace amounts. Protoplasts bound approximately 20 per cent less, respectively, of each of the phenol derivatives. With increasing pH (from 4.9 to 9.6), whole cells bound decreasing amounts of DCP-^{14}C, but binding of P-^{14}C and PTAP-^{14}C was relatively constant over the same pH range. Human serum decreased binding of DCP-^{14}C and PTAP-^{14}C by *M. lysodeikticus* cells and a similar effect, although less marked, was found with crystalline human serum albumin. The decrease was proportional to protein concentration. Human serum γ globulin in the same concentration as serum albumin did not reduce binding of the labeled phenols to the bacterial cells while a sonic disintegrate of *M. lysodeikticus* cells caused some reduction in binding.

A BASIC ASSUMPTION in previous work (1–6) on the mechanism of action of phenol disinfectants has been that the lipophilic properties of the latter lead to association of these disinfectants with microbial lipids and exertion of biological activity at such sites in which lipid is contained, *e.g.*, the cell membrane. In support of this assumption has been the work on uncoupling halophenols, the biological action of which has been correlated with lipid solubility (7, 8). However, in the light of the recent work by Weinbach and Garbus (9–11) on the restoration of halophenol-uncoupled oxidative phosphorylation by serum albumin and binding of halophenols by serum albumin and mitochondrial protein, it seemed imperative to re-examine the role of proteins in the bactericidal effects of phenolic disinfectants. Organic matter, including serum (12, 13), has long been known to interfere with the activity of germicides. One of the features generally listed for the ideal disinfectant is activity in the presence of organic matter and in a number of the commonly used testing procedures, activity is determined in the presence of serum. Yet, very few studies have been made on possible associations between serum proteins and disinfectants, especially phenolic disinfectants.

The ability of proteins to bind chemical substances was observed a number of years ago, and much of the work has centered on binding of small ions, dyes, fatty acids, and surface-active ions (14–18) by plasma albumin and studies have been carried out on the binding of thyroid hormones, especially of thyroxine by serum proteins (19). In previous studies (3), the binding of certain phenolic disinfectants by bacterial cells was demonstrated and the affinity of the latter for these disinfectants was related to antibacterial potency. This laboratory felt it would be useful to extend the studies to determine the extent to which several entities affect this binding process—namely, bacterial cell walls, human serum, human serum albumin, and pH. *Micrococcus lysodeikticus* was chosen as the test organism because of its well-characterized cell wall (20, 21) and the occurrence of lipid primarily in its cell membrane (22).

MATERIALS AND METHODS

Bacterial Culture.—*M. lysodeikticus* ATCC 4698 was used throughout and was maintained on nutrient agar. Cells for experimental use were grown on a medium with the following composition: yeast extract, 10 Gm.; bacto-tryptone, 10 Gm.; dibasic potassium phosphate, 2 Gm.; distilled water, to make 1 L. Glucose was sterilized separately as a 50% w/v solution and added aseptically at the time of inoculation. Cultures were started by inoculation of 7 ml. of the culture medium, supplemented with 0.1 ml. of 50% glucose solution, and grown on a rotary shaker for 24 hr. All incubations were at 37°. The same medium in 200-ml. quantities contained in 500-ml. conical flasks was inoculated with 0.5 ml. of the test tube culture and supplemented with 0.5 ml. of 50% glucose solution. These cultures were shaken for 24 hr., the cells recovered by centrifugation, washed twice with distilled water, and resuspended in distilled water to a concentration equal to approximately 15 mg. dry weight per ml. Each reaction mixture contained 0.6 ml. of this cell suspension.

The radioactive derivatives used in this study were synthesized by New England Nuclear Corp., Boston, Mass., and had the following specific activities: phenol-^{14}C, 50 μc./3.04 mg.; 2,4-dichlorophenol-^{14}C, 50 μc./12 mg.; and *p-tert*-amylphenol-^{14}C, 50 μc./30.4 mg. The label in all three

Presented to the Medicinal Chemistry Section, A.PH.A. Academy of Pharmaceutical Sciences, Dallas meeting, April 1966.
This work was supported in part by a grant from the University of Toledo Research Foundation.
Previous paper: Commager, H., and Judis, J., *J. Pharm. Sci.*, 54, 1436(1965).

compounds was uniformly distributed in the rings. Phenol was used in aqueous solution while the other derivatives were dissolved in 0.1% sodium hydroxide and all stock solutions contained 5 μc./ml. Radioactivity was assayed in a Nuclear-Chicago liquid scintillation system. All radioactive samples were diluted to a total volume of 2 ml. with water and added to 13 ml. of scintillation solution of the following composition: naphthalene, 120 Gm.; PPO (2,5-diphenyloxazole), 7 Gm.; dimethyl POPOP (1,4-bis-2-4 methyl-5 phenyloxazolylbenzene), 50 mg.; and *p*-dioxane to make 1 L. Enough counts were accumulated to give a nine-tenth error of less than 5%.

Preparation of Protoplasts.—Six-tenths of a milliliter of cell suspension was placed in a centrifuge tube, the cells were sedimented by centrifugation, and suspended in 0.9 ml. of 1.2 *M* sucrose in 0.01 *M* phosphate buffer (pH 6.8). Then 0.1 ml. of lysozyme solution, 1 mg./ml., was added and the mixture incubated for 30 min. at room temperature (24°). After centrifugation the protoplasts were suspended in the reaction mixtures described below. Whole cell suspensions were made up in the same reaction mixtures in the controls comparing binding of phenol derivatives. A control to determine extent of protoplast formation consisted of cells treated with lysozyme in the absence of sucrose. Complete clearing of the cell suspension resulted.

Experimental Procedure.—In the experiments involving comparison of binding of the phenol derivatives by whole cells and protoplasts, the reaction mixtures were prepared as follows: protoplasts were suspended in a mixture of 1.5 ml. of 82% w/v sucrose, 0.3 ml. of 0.1% sodium hydroxide, 0.9 ml. of 0.067 *M* phosphate buffer, pH 6.7, and 0.2 ml. of radioactive phenol or phenol derivative. Stock solutions of the latter (5 μc./ml.) were diluted 1:20 with distilled water before use. The reaction mixtures were incubated for 20 min. at room temperature, centrifuged for 5 min. at 15,000 r.p.m., and aliquots of the pellet and supernatant assayed for radioactivity. Whole cells were treated with the same reaction mixtures. The final pH value of the reaction mixtures was 7.2.

In the studies on the effect of pH on binding of phenol derivatives to whole cells, the reaction mixtures consisted of 0.9 ml. of 0.067 *M* phosphate buffer, 0.6 ml. of cell suspension, 0.2 ml. of radioactive phenol derivative solution (stock solutions diluted 1:10 with distilled water), and 1.3 ml. of water. The pH values of the phosphate buffers were chosen to give the desired final pH of the reaction mixtures. In those experiments in which human serum, human serum albumin, or other proteins were used, the solution of the latter replaced a corresponding volume of distilled water. Reaction mixtures contained either 0.3 ml. of human serum, 0.3 ml. of crystalline human serum albumin (42 mg./ml.), or 0.3 ml. of γ globulin (42 mg./ml.). The general experimental procedure was the same. Human serum was obtained from Difco Laboratories or Grand Island Biological Co. (tissue culture grade), and human serum albumin (crystallized 4X), γ globulin, and lysozyme were products of Nutritional Biochemicals Corp. The sonic disintegrate was prepared by treating a suspension of bacterial cells with a Branson sonic disintegrator, model 125, for 15 min. at maximum energy output, followed by centrifugation at 15,000 r.p.m. The supernatant contained 8 mg. of protein per ml. using crystalline human serum albumin as a standard and the Folin-Ciocalteau reagent for protein assay. Reaction mixtures contained 0.3 ml. of the sonic disintegrate in 3 ml. of total volume.

Table I.—Binding of Phenol Derivatives to Cells and Protoplasts of *M. lysodeikticus*

Phenol Derivative	Total c.p.m. Added	Radioactivity, % Associated with: Cells	Protoplasts
Phenol-^{14}C	12,300	2.33	1.78
2,4-Dichlorophenol-^{14}C	80,563	17.9	13.7
p-tert-Amylphenol-^{14}C	14,860	30.5	23.6

RESULTS AND DISCUSSION

In general, the same patterns of binding of phenol and the derivatives used were obtained as with *Escherichia coli* (3) in that the more potent the phenol derivative as a germicide, the higher the proportion of the latter was found to be associated with the cells (Table I). Protoplasts bound somewhat less of each of the phenol derivatives than whole cells, in all cases amounting to a decrease of approximately 20%. This observation would suggest that cell walls do bind a portion of the phenol derivatives and that the mucopeptide complex is capable of associating with these compounds. In Gram-positive bacteria, the cell wall constitutes approximately 20% of dry weight (22), corresponding to the proportion of radioactivity with which they apparently associated.

	133,866	9.6	43,378	22,642	52.2

Binding of 2,4-dichlorophenol-^{14}C was affected by changes in pH of the reaction mixture (Fig. 1), while the other compounds were bound to the same extent between pH's of 4.9 to 9.6. These observations suggest that the ionized form of a phenolic compound is bound considerably less than the unionized form. 2,4-Dichlorophenol has a Ka of 7.08×10^{-9} (23) while the other compounds have Ka values of about 10^{-10} (24–26). Thus, the latter compounds would be unionized over the range of pH values used, while 2,4-dichlorophenol would exist in the ionized form to a considerable extent above neutrality. Many organic compounds, especially weak acids, have been shown to possess greater biological activity in the unionized form (13). In contrast, however, Weinbach and Garbus claim that the ionized form of uncoupling halophenols possesses the greatest biological activity (10).

From Table II, it can be seen that human serum decreased the binding of 2,4-dichlorophenol-^{14}C and *p-tert*-amylphenol-^{14}C to *M. lysodeikticus* cells. The effects of pH variation were similar in the presence and absence of serum in the case of 2,4-dichlorophenol-^{14}C, while pH had little effect on binding of *p-tert*-amylphenol-^{14}C in the absence or presence of human serum. It would thus appear that pH changes affect the phenol derivative but not the binding potency of human serum proteins. At the highest pH value used, a slight, but consistent decrease was observed in the interference by human serum with binding of the two phenol derivatives. This may be due to the change in serum albumin structure found at extreme pH's (14), and in this altered form, perhaps serum albumin is unable to associate with the phenol derivatives. Treatment of mitochondria with 8 *M* urea or guanidine, which caused protein denaturation, was found to cause release of bound pentachlorophenol, providing an example in which change in protein structure changed the latter's ability to associate with a phenol derivative (9).

The major protein in human serum is albumin, and thus it seemed appropriate to determine whether albumin in the same concentration in which it is normally found in human serum could duplicate the effects observed with the latter. From the data in Table III, it is clear that human serum albumin does interfere with the association of the two phenol derivatives tested and the bacterial cells, but the extent of interference is less than that found with whole serum. It is conceivable that other components of serum, such as lipids and lipoproteins with which phenolic compounds would tend to associate, might account for the effects of whole serum. The effects of pH variation were also different with human serum albumin as compared to whole serum in that increasing the pH caused a decrease in the amount of *p-tert*-amylphenol-^{14}C associated with the cells in the presence of albumin beyond the effect of the latter. This pH effect was not found with whole serum. Since the phenol derivative would be unlikely to ionize at any of the pH's used, the effect thus must be on the albumin. Variation in pH was shown to have no effect on binding of *p-tert*-amylphenol-^{14}C to *M. lysodeikticus* cells (Fig. 1).

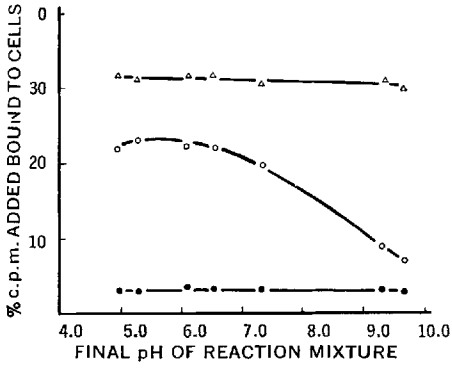

Fig. 1.—The effect of pH on binding to *M. lysodeikticus* cells. Key: ●, phenol-^{14}C; ○, 2,4-dichlorophenol-^{14}C; △, *p-tert*-amylphenol-^{14}C.

In a preliminary fashion, the ability of proteins in general to interfere with the association of phenol derivatives and cells was surveyed. In Tables IV and V, human serum γ globulin and a sonic disintegrate of *M. lysodeikticus* cells were examined for their ability to duplicate the effects observed with human serum and human serum albumin. γ Globulin, in a concentration equal to that of human serum albumin used in previous experiments, had no effect on the amounts of 2,4-dichlorophenol-^{14}C or *p-tert*-amylphenol-^{14}C associated with the cells. The sonic disintegrate, however, did cause some decrease in association of radioactivity with the cells. This suggests that certain bacterial proteins have an affinity for these phenol derivatives and in further work, specific bacterial proteins, as isolated by electrophoresis, are being examined for their phenol derivative-binding properties. Weinbach and Garbus (11) surveyed a large number of proteins for ability to associate with uncoupling phenols and found this effect limited to serum albumin and mitochondrial protein. They found, further, that there was a definite relationship between the amounts of human serum albumin and that of

phenol derivative bound (11). In Table VI, it can be seen that while not stoichiometric, there is a definite relationship between concentration of human serum or human serum albumin and decrease in radioactivity associated with the bacterial cells.

At least two hypotheses suggest themselves as explanations for the ability of serum or serum albumin to decrease association of phenol derivatives with bacterial cells. It is possible that the proteins compete with the bacterial cells for the phenol derivatives and the relative proportions of each determine how much of the phenol derivatives will be found in the cells. An alternative hypothesis would hold that the proteins coat the bacterial cells, making a portion of the latter's surface unavailable for penetration by the phenol derivatives. The latter hypothesis was tested experimentally in a preliminary fashion by preparing the same reaction mixtures containing albumin at various pH's and adding radioiodinated (^{131}I) serum albumin. These reaction mixtures contained 2,4-dichlorophenol-^{14}C only. With an increase in pH, as expected, there was a decrease in the amount of ^{14}C associated with the cells in the presence or absence of serum or serum albumin. One would also expect, if the second hypothesis is valid, that the amount of ^{131}I associated with the cells due to binding of albumin would be higher with higher pH values if it were competing with the phenol for the cell surface. The reverse, however, was found in that at the lowest pH tested (4.9), the cells contained the most ^{131}I. The amount of ^{131}I associated with the cells in all cases, was very low, equal approximately to the same proportion that the pellet of cells constituted of the reaction mixtures, except at pH 4.9, where it was about 3 times as high. It would thus appear, that the most attractive hypothesis at this time is that serum albumin is able to bind phenol derivatives.

Any general hypothesis for the mechanism of action of phenolic disinfectants would have to explain the observations of the effect of pH on binding of the former. Weinbach and Garbus (10) concluded that the ionic form of the halophenol uncoupling agents they studied was the active form and the interaction between the halophenol and the binding sites on the albumin molecule, amino groups, was an anion–anion interaction. Yet, phenol and *p-tert*-amylphenol, especially the latter, are bound to whole cells and protoplasts at high pH's at which alkylated phenols would not ionize to any considerable degree.

Perhaps the suggestion by Davis and Dubos (27) that serum albumins associated with negatively

charged molecules due to the ω amino groups in lysine residues and with lipophilic chains through the side chains of leucine residues should lead to the conclusion that this protein has not only different binding capacities for different compounds, but also different mechanisms by which it binds. If bacterial proteins rather than lipids are the compounds with which phenolic disinfectants associate, it should be possible to demonstrate as much binding of the latter to bacterial proteins as to whole cells as was shown by Weinbach and Garbus (10, 11) with mitochondria and mitochondrial protein in their studies with uncoupling halophenols. These possibilities are currently being tested by examining reaction mixtures containing serum proteins or bacterial proteins and phenol derivatives for complexes using Sephadex chromatography, electrophoresis, density gradient ultracentrifugation, difference spectrophotometry, and reduction in bactericidal and bacteriostatic effects. It is felt that an intimate knowledge of the reaction between phenol derivatives and organic matter such as serum proteins would be useful in the design of disinfectants, the activity of which would not be affected by organic matter. An ultimate goal in these studies is a complete knowledge of the site(s) of action of phenolic germicides in bacterial cells.

Molecular Orbital Calculations of the Electronic Structure of the Sydnones

By LEMONT B. KIER and EDWARD B. ROCHE*

The electronic structure of the sydnone ring has been calculated from an ω-HMO technique. Several new parameters for the calculation have been derived, in conjunction with previously used parameters. Charge densities derived have yielded accurate calculations of dipole moments. Energy levels have yielded values which correlate well with observed U.V. maxima. A general discussion of the calculated structures is presented.

OUR INTEREST in the medicinal chemical aspects of the mesoionic compounds known as the sydnones has required a further understanding of the chemistry of these aromatic heterocycles (1–6). Recent reviews of these compounds have summarized their chemical and physical properties (7–10) but have not added much basic information concerning their electronic structure and the electronic changes involved in their reactions. This information is essential if the relationships between their structure and pharmacological activity is to be evaluated.

A classical resonance theory or valence bond approach to the electronic picture of the sydnones is not illuminating since, embodied within the definition of a mesoionic compound is the requirement that no covalent structure can be drawn for the system (11). Furthermore, it has been shown that at least 20 polar structures can be drawn for phenylsydnone (12). The total number of such

charged molecules due to the ω amino groups in lysine residues and with lipophilic chains through the side chains of leucine residues should lead to the conclusion that this protein has not only different binding capacities for different compounds, but also different mechanisms by which it binds. If bacterial proteins rather than lipids are the compounds with which phenolic disinfectants associate, it should be possible to demonstrate as much binding of the latter to bacterial proteins as to whole cells as was shown by Weinbach and Garbus (10, 11) with mitochondria and mitochondrial protein in their studies with uncoupling halophenols. These possibilities are currently being tested by examining reaction mixtures containing serum proteins or bacterial proteins and phenol derivatives for complexes using Sephadex chromatography, electrophoresis, density gradient ultracentrifugation, difference spectrophotometry, and reduction in bactericidal and bacteriostatic effects. It is felt that an intimate knowledge of the reaction between phenol derivatives and organic matter such as serum proteins would be useful in the design of disinfectants, the activity of which would not be affected by organic matter. An ultimate goal in these studies is a complete knowledge of the site(s) of action of phenolic germicides in bacterial cells.

3-Phenylsydnone	6.47	6.48	(50)
3-Methylsydnone	7.06	7.31[a]	...

[a] This value was determined by the authors employing the method described by Smyth (51). Dielectric constants were determined on a General Radio Co-type No. 1610-A capacitance bridge.

structures which must be considered in a valence bond approach is many more, and the real problem arises in weighting each structure in the overall equation for the wave function of the molecule. Thus, the valence bond or classical resonance theory approach to the electronic structure of sydnones presents immense difficulties.

A more reasonable approach to the solution of the wave equation of the system is the LCAO–MO (linear combination of atomic orbitals–molecular orbital) method.

The approximations involved and the various techniques employed for solution of electronic structures have been adequately described (13–15). A number of studies of this type have been done on the sydnones, using simple Hückel procedures (16–18). The results of these calculations failed to reproduce physical experience, such as dipole moment. This failure undoubtedly was partly a result of a poor selection of heteroatom parameters, certainly unrefined at the time these calculations were made, and the failure of the simple Hückel method to consider electron correlation.

In previous calculations performed in this laboratory, the authors have empirically treated the the effect of electron correlation within the framework of the Hückel method (19, 20). This has been done by employing a disposable parameter which serves to alter the Coulomb integrals of the atoms as a function of the calculated charge densities, q, of the respective atoms (21). The procedure, known as the "ω-technique," produces new values of the Coulomb integral, in terms of β_0, the standard resonance integral for the carbon-carbon bond in benzene (22).

$$\alpha_i = \alpha_0 + \omega\, q_i\, \beta_0$$

This technique involves iterating the calculation until self-consistency is achieved in the charge densities at each position in the molecule. The value of ω used in this study was 1.4, which corresponds to the value used by several other authors (23, 24) and appears to give results that correlate well with experimental data.

PARAMETERS

An essential feature for the successful use of this method of calculation is the choice of parameters for heteroatoms. The parameter used to modify the Coulomb integral of a heteroatom, h_x, must reflect its modified electronegativity and electronic configuration with respect to an aromatic carbon atom. This modification is again made in terms of the standard resonance integral, β_0

$$\alpha_x = \alpha_0 + h_x\, \beta_0$$

A second parameter, k_{xy}, is employed to reflect the alteration in electron exchange between the heteroatom in question and its neighbors with respect to an aromatic carbon-carbon bond:

$$\beta_{xy} = k_{xy}\, \beta_0$$

In previous work (19, 20) the authors have approached this problem with the desire to obtain calculated values of eigenfunctions and eigenvalues of heteroatom-containing molecules which would adequately approximate chemical and physical experience. These calculations have resulted in the close approximation of dipole moments from eigenfunctions (19) and relative chemical reactivities from eigenvalues (20). The ability to produce these results from the same set of heteroatom parameters lends a measure of confidence in their values.

In the present work, these same values have been used with only one modification. In the previous study on dipole moments (19) an experimental value of 1.54 *D* for pyrrole and a model for the nitrogen atom identical to that for the nitrogen of aniline were used. It is now felt that the value of 1.80 *D* for pyrrole is a better experimental value (25, 26). Also, the model for the nitrogen atom must be reevaluated. The unshared electron pair on nitrogen of aniline is not in a pure *p* orbital; hence the Coulomb integral should reflect a greater electronegativity than that of the nitrogen in pyrrole (27). Furthermore, since the pure *p* orbital of nitrogen in pyrrole is more available for delocalization, a higher resonance integral should be used for the C-N bond. This improved model with the accompanying parameters has permitted us to calculate suc-

cessfully the dipole moments of pyrrole and *N*-methylpyrrole. (See Table I for parameters and Table II for dipole moments.)

Although the heteroatom model has previously been used for the treatment of a methyl group on an aromatic ring (28), the authors felt that a more realistic model of this group is provided by the conjugative model (29) in which the electron distribution of both the hydrogens and the methyl carbon atom is specifically designated and the methyl hydrogens are collected into a pseudo π orbital. Using the parameter values proposed by Coulson and Crawford (30) for this model, the authors have again successfully calculated the dipole moment of toluene.

For the calculation of the electronic structure of the sydnone molecule, two new parameters had to be introduced, and their values had to be consistent with other parameters employed. These parameters were the resonance integral for the Ṅ-Ö bond ($k_{\dot{N}\ddot{O}}$) and the resonance integral for the Ṅ-N̈ bond ($k_{\dot{N}\text{-}\ddot{N}}$). The value of 0.6 has been derived for $k_{\dot{N}\ddot{O}}$ for use in simple Hückel calculations (18). The value of 0.5 was found to reproduce successfully the value of the dipole moments of furazan and isoxazole. For the parameter $k_{\dot{N}\ddot{N}}$, the value of 0.87 has been derived from a proportionality to overlap integrals (31). The value of 0.9 has been employed successfully to calculate the dipole moments of *N*-methylpyrazole and *N*-phenylpyrazole.

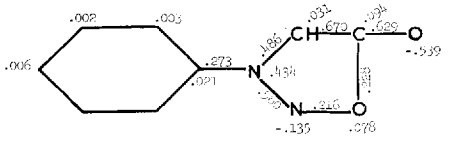

Fig. 1.—3-Phenylsydnone. Numbers shown are calculated π-bond orders and charge densities.

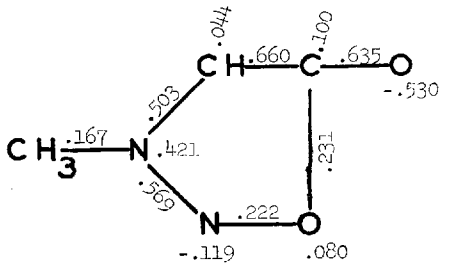

Fig. 2.—3-Methylsydnone. Numbers shown are calculated π-bond orders and charge densities.

CALCULATIONS

The computations were made using the computer program previously described (20). Due to the greater complexity of some of the sydnones, convergence of charge densities to self-consistency required a substantially larger number of iterations. The versatility of this program permitted this with no difficulty. The values from consecutive calculations of the charge densities were tested until an increment no larger than 0.001 electron existed between the final iteration and the average of all preceding calculations. The test was simultaneously applied to all atoms by the program. The calculated charge densities for the ring atoms are shown for 3-phenylsydnone in Fig. 1 and for 3-methylsydnone in Fig. 2. The π-bond order for each of these compounds was calculated from the eigenfunctions and is shown for the appropriate bonds in Figs. 1 and 2.

The dipole moments were calculated from charge densities as previously described (19) and are listed in Table II along with experimental values.

From the eigenvalues of the matrices the $M_m \rightarrow M_{m+1}$ transition energies were calculated. These are recorded in Table III along with the corresponding wavelengths for a series of variously substituted sydnones. The energy levels in units of β for 3-phenylsydnone and 3-methylsydnone are listed in Table IV. The values of ΔM, in units of β, are plotted against the corresponding frequencies of maximum absorption in Fig. 3.

DISCUSSION

As can be seen from Table II, the agreement between the calculated and experimental dipole moments for the sydnones is excellent. This, in the authors' opinion, attests to the reasonableness of the values for the charge densities calculated (32).

Several observations can be made from an inspection of the charge densities and bond orders of 3-phenyl and 3-methylsydnone (Figs. 1 and 2). The exocyclic oxygen atom in both compounds bears a high charge density, being over 0.15 electron higher than what was calculated for butyrolactone (33). This clearly implies significant participation from all ring atoms, in the total delocalization of the π-electrons. The number 3 nitrogen atom bears a high positive charge, particularly in the case of the 3-phenylsydnone. This observation, combined with the highest bond order calculated, between the carbon atoms, indicates the substantial participation of

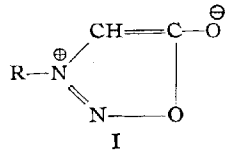
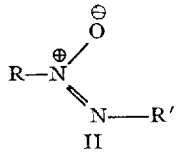
valence bond representation, I, in the total wave equation of the molecule, a conclusion also reached by dipole moment studies of Hill and Sutton (34).

A comparison of the two calculated structures indicates that the phenyl group in the 3 position makes a greater mesomeric contribution of electrons to the sydnone ring than the 3-methyl group. The phenyl ring is deactivated at all positions by the sydnone ring; hence electrophilic attack on the benzene ring would be expected to be retarded. This is borne out by experiment (12, 35). This fact may in reality be the result of electron withdrawal by the sydnone ring rather than donation by the phenyl ring. The phenyl ring is known to be an electron withdrawing group in most systems (36).

In the work cited previously (35), the sydnone ring was found to be comparable to the β-azoxy group (II), with respect to its activating effect on nucleophilic displacement reactions on p-chlorophenyl derivatives. The proposed transition state in reactions of this type is stabilized by electron-withdrawing substituents (37). The comparison between these two substituents is also observed in electrophilic substitutions on benzene in which both groups are deactivating. This is not true for α-azoxy substituents (35).



I



II

This relationship between the sydnone ring and β-azoxy groups lends further support for the charge distributions shown in Fig. 1. A larger bond order between the two nitrogens would also be required for conjugation with the phenyl ring leaving the bond order between nitrogen and oxygen somewhat deficient. This situation might also be expected from electronegativity considerations (35).

Further support for the bond order calculated between nitrogen and oxygen (Fig. 1) is found in a comparison of bond lengths. An X-ray study of p-bromophenyl sydnone has shown (38, 39) the length of the N—O bond to be 1.34 Å. The bond length of the N—O single bond has been reported to be 1.46 Å. while that of an N=O double bond is 1.14 Å. (40). Thus, in general terms, the N—O bond in the sydnone ring is largely of a single bond nature which corresponds favorably with the relatively low π-bond order calculated for these compounds.

To determine the reliability of the eigenvalues obtained from solution of the secular equations, an examination of the ultraviolet spectra of a number of substituted sydnones seemed appropriate. A single peak in the 290 to 350 mμ region has been attributed to the sydnone ring (41). This maximum is quite intense ($\epsilon > 4700$) and experiences a bathochromic shift from 3-alkyl to 3-aryl substitution indicating an extended interannular conjugation (Table III) (42). Increase in delocalization also appears to be more effective with the aryl substituent in the 4-position of the sydnone ring than in the 3-position. This is expected from the increased ability of carbon π-orbitals to participate in electron delocalization compared to that of the nitrogen.

Other bands in the spectra of aryl-substituted sydnones appear at lower wavelength and have been attributed to benzenoid K absorption (41).

General considerations of ultraviolet spectra of aromatic compounds within the framework of molecular orbital calculations have led to the general conclusion that the more intense peaks at longer wavelengths are due to transitions occurring between the highest filled energy level (m) and the lowest unoccupied level ($m+1$) (43). In empirical LCAO–MO calculations, such as are presented here, the over-all electronic transition energy is considered to be larger than any energy differences due to configuration interaction or singlet-triplet splitting (43). The transition is then taken to be the perpendicular Franck-Condon transition. The frequency of such a transition is given by

$$h\nu = E^* - E$$

where E^* is the energy of the excited state, and E is the energy of the ground state.

In the total π-energy expressions from LCAO–MO calculations, the energy of the two states are given by

$$E^*_\pi = n\alpha + M^*\beta$$

$$E_\pi = n\alpha + M\beta$$

Thus, the frequency should be proportional to the difference in the coefficients of β:

$$h\nu = (M^* - M)\beta = \Delta M\beta$$

This operation is equivalent to taking the difference between M_m and M_{m+1}.

Table III shows the $\lambda_{max.}$ and ΔM for a number of substituted sydnones, and Fig. 3 shows the relationship between the frequency in cm.$^{-1}$ and ΔM.

The correlation of these data is good. The correlation coefficient of 0.931 indicates that about 86.6% of the variance is accounted for. The maximum deviation of the experimental $\lambda_{max.}$ from that calculated by the correlation equation from Fig. 3

$$\nu(\text{cm.}^{-1}) = 60533\,(\Delta M) + 4794$$

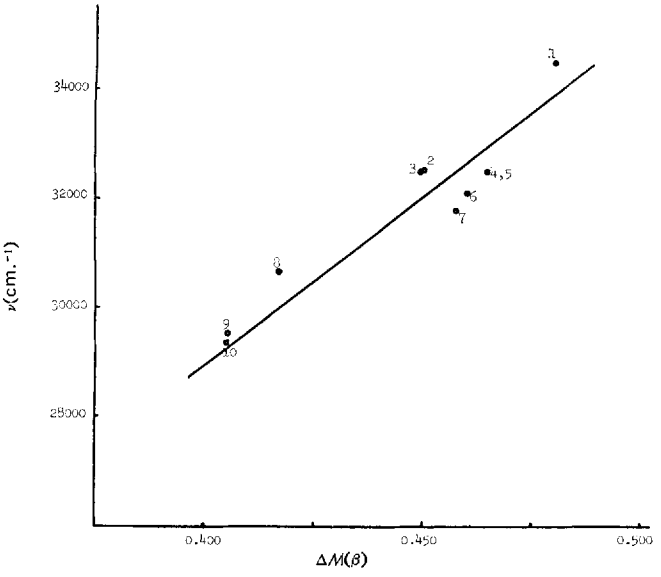


Fig. 3.—Correlation plot of the frequency of maximum absorption of the sydnone ring *vs.* the calculated ΔM in units of β.

is ± 7 mμ, and the average deviation of points from the line is ± 0.010 ΔM units. Thus, it appears that the relative energy levels calculated by the present method are in good agreement with the major electronic transition energy of the substituted sydnone rings.

The deviations from calculated values are not unexpected considering the empirical nature of the calculations. In the ω-HMO technique, no distinction is made between the geometry of the ground and excited state or between singlet and triplet state. A perpendicular Franck-Condon transition is assumed which may involve a promotion to a higher level than the lowest available level in the excited state.

Further error is involved with the nonexplicit consideration of electron repulsion. When the energy difference between the ground and excited state is small, the energy levels will interact. This repulsion will result in a larger separation between the levels. More sophisticated methods employing configuration interaction are required to take this phenomenon into account.

Through an application of the ω-HMO technique in conjunction with parameters previously derived (19) and parameters derived in this present work, the dipole moments of some representative heterocyclic systems including 3-methyl and 3-phenylsydnone have been successfully calculated (Table II). These same parameters have also given relative energy levels that correspond well with the maximum ultraviolet absorptions of the variously substituted sydnone rings (Table III and Fig. 3). Thus, the authors feel that the values of these parameters when employed in this type of an LCAO–MO calculation produce a reasonable electronic structure of the sydnones.

Gas Chromatographic Analysis of Trichloroethanol, Chloral Hydrate, Trichloroacetic Acid, and Trichloroethanol Glucuronide

By EDWARD R. GARRETT and HOWARD J. LAMBERT*

A sensitive and specific assay has been developed for trichloroethanol, chloral hydrate, trichloroacetic acid, and trichloroethanol glucuronide utilizing gas chromatography and electron capture detection. Trichloroethanol and chloral hydrate are extracted from alkalinized water or urine with ether, and a portion of the ether extract is assayed with chlorobutanol and chloroform as internal standards. Trichloroacetic acid and trichloroethanol glucuronide are not extracted under these conditions. The trichloroacetic acid is decarboxylated as the potassium salt and the resultant chloroform extracted into ether and assayed. The trichloroethanol glucuronide is enzymatically hydrolyzed and the hydrolysate assayed for the trichloroethanol formed. Sensitivities obtained were 0.5 mcg. of trichloroethanol and chloral hydrate (3.3 and 3.02 mμmoles, 10^{-9} moles, respectively), 1.0 mcg. of trichloroacetic acid (6.1 mμmoles) in 2.0 ml. of sample and 0.5 mcg. of trichloroethanol glucuronide (1.54 mμmoles) in 3.0 ml. of sample. Statistical analysis of assays on urinary mixtures of the four compounds demonstrates the reliability of the method.

THERE ARE no sensitive specific assays for the hypnotic drug trichloroethanol (TCE), its precursor chloral hydrate (CH), or its detoxification products trichloroacetic acid (TCA) and trichloroethanol glucuronide (TCE-G), in the available literature.

Extant methods (1–3) are mostly modifications of the colorimetric method of Fujiwara (4) and were not sufficiently sensitive or specific for a planned pharmacokinetic study of TCE in this laboratory. Friedman and Cooper (2) obtained a sensitivity of 20 mμmoles of TCA and CH and 100 mμmoles of TCE in mixtures but found that some tissue preparations interfered with chromophore production as much as 25% and lessened the reliability of the Fujiwara procedure. Leibman and Hindman (3) improved the assay sensitivity down to 5 mμmoles of TCA and CH and 15 mμmoles of TCE, but separation of the components prior to reaction would be required as the procedure was nonspecific. A gas chromatographic separation of CH, TCA, and chlorobutanol, but not TCE, with a sensitivity of 306, 302, and 281 mμmoles, respectively, has also been reported (5). This sensitivity of detection is not as good as the modified Fujiwara (2, 3).

The purpose of this investigation was to develop a specific procedure for the quantitative determination of TCE and its metabolites separately and in mixtures with gas-liquid chromatography and the electron capture detector. If possible, this method would have greater sensitivity than those previously reported.

EXPERIMENTAL

Materials.—The TCE (Calbiochem, Inc.) used in the preparation of calibration curves and synthetic mixtures in water and urine was redistilled at 152° before use.

Chloral hydrate U.S.P., chlorobutanol U.S.P., and TCA (reagent grade and 5% solution) were obtained from the Fisher Scientific Co. Ether (Baker) was redistilled over sodium before use. The purity of these components was verified chromatographically, and only one peak was observed.

The sodium salt of trichloroethanol glucuronide

Received March 11, 1966, from the College of Pharmacy, University of Florida, Gainesville. 32603.
Accepted for publication May 13, 1966.
Presented to the Scientific Section, A.PH.A., Detroit meeting, March 1965.

Gas Chromatographic Analysis of Trichloroethanol, Chloral Hydrate, Trichloroacetic Acid, and Trichloroethanol Glucuronide

By EDWARD R. GARRETT and HOWARD J. LAMBERT*

A sensitive and specific assay has been developed for trichloroethanol, chloral hydrate, trichloroacetic acid, and trichloroethanol glucuronide utilizing gas chromatography and electron capture detection. Trichloroethanol and chloral hydrate are extracted from alkalinized water or urine with ether, and a portion of the ether extract is assayed with chlorobutanol and chloroform as internal standards. Trichloroacetic acid and trichloroethanol glucuronide are not extracted under these conditions. The trichloroacetic acid is decarboxylated as the potassium salt and the resultant chloroform extracted into ether and assayed. The trichloroethanol glucuronide is enzymatically hydrolyzed and the hydrolysate assayed for the trichloroethanol formed. Sensitivities obtained were 0.5 mcg. of trichloroethanol and chloral hydrate (3.3 and 3.02 mμmoles, 10^{-9} moles, respectively), 1.0 mcg. of trichloroacetic acid (6.1 mμmoles) in 2.0 ml. of sample and 0.5 mcg. of trichloroethanol glucuronide (1.54 mμmoles) in 3.0 ml. of sample. Statistical analysis of assays on urinary mixtures of the four compounds demonstrates the reliability of the method.

THERE ARE no sensitive specific assays for the hypnotic drug trichloroethanol (TCE), its precursor chloral hydrate (CH), or its detoxification products trichloroacetic acid (TCA) and trichloroethanol glucuronide (TCE-G), in the available literature.

Extant methods (1–3) are mostly modifications of the colorimetric method of Fujiwara (4) and were not sufficiently sensitive or specific for a planned pharmacokinetic study of TCE in this laboratory. Friedman and Cooper (2) obtained a sensitivity of 20 mμmoles of TCA and CH and 100 mμmoles of TCE in mixtures but found that some tissue preparations interfered with chromophore production as much as 25% and lessened the reliability of the Fujiwara procedure. Leibman and Hindman (3) improved the assay sensitivity down to 5 mμmoles of TCA and CH and 15 mμmoles of TCE, but separation of the components prior to reaction would be required as the procedure was nonspecific. A gas chromatographic separation of CH, TCA, and chlorobutanol, but not TCE, with a sensitivity of 306, 302, and 281 mμmoles, respectively, has also been reported (5). This sensitivity of detection is not as good as the modified Fujiwara (2, 3).

The purpose of this investigation was to develop a specific procedure for the quantitative determination of TCE and its metabolites separately and in mixtures with gas-liquid chromatography and the electron capture detector. If possible, this method would have greater sensitivity than those previously reported.

EXPERIMENTAL

Materials.—The TCE (Calbiochem, Inc.) used in the preparation of calibration curves and synthetic mixtures in water and urine was redistilled at 152° before use.

Chloral hydrate U.S.P., chlorobutanol U.S.P., and TCA (reagent grade and 5% solution) were obtained from the Fisher Scientific Co. Ether (Baker) was redistilled over sodium before use. The purity of these components was verified chromatographically, and only one peak was observed.

The sodium salt of trichloroethanol glucuronide

Received March 11, 1966, from the College of Pharmacy, University of Florida, Gainesville. 32603.
Accepted for publication May 13, 1966.
Presented to the Scientific Section, A.PH.A., Detroit meeting, March 1965.
This investigation was supported in part by an unrestricted research grant from Smith Kline & French Laboratories, Philadelphia, Pa.
* Recipient of the Lunsford Richardson Pharmacy Award, Region III, 1965.

(hereafter referred to as TCE-G) was isolated from rabbit urine by the method of Seto and Schultze (6).

Assay solutions of TCA were prepared by diluting the 5% stock solution and the final concentration verified by titration. TCE, CH, and TCE-G were weighed to within 0.1 mg., transferred to a clean 100-ml. volumetric flask, and brought to volume with water or urine.

Apparatus.—An F&M model 700 gas chromatograph with either a flame ionization or electron capture detector and equipped with a Minneapolis Honeywell recorder and disc integrator was used.

Column.—The column for calibration curve determination and studies with mixtures was an 8 ft. × 1/4 in. stainless steel tube containing 20% Carbowax 20 M on 60–80 mesh Chromosorb W. Other columns investigated but not chosen due to incomplete peak resolution or tailing were a 4 ft. × 1/4 in. stainless steel, 10% diethylene glycol succinate; a 4 ft. × 1/4 in. glass, 5% Carbowax 20 M and a 4 ft. × 1/4 in. glass, 5% Carbowax 20 M plus 2% H_3PO_4, all on 80–100 Diatoport S.

Flame Ionization Detector.—The temperatures used were: injection port, 120°; column, 100°; and detector, 290°. The flow rate of the helium carrier gas was 60 ml./min. Hydrogen and air flow rates 60 and 500 ml./min. (20 p.s.i.), respectively.

Electron Capture Detector.—The optimum temperatures were: injection port, 160°; column, 125°; and detector, 190°. Carrier gas (helium) flow rate was 60 ml./min. while the purge gas (90% argon–10% methane) was fixed at 140 ml./min.

Sample Assay

Trichloroethanol and Chloral Hydrate.—Five-microliter aliquots of aqueous solutions of TCE and CH were injected directly on-column when the flame ionization detector was used. For electron capture detection, 2 ml. of the solution was shaken with 2 ml. of diethyl ether in a 10-ml. rubber-sealed injectable vial and 5 μl. of the ether extract was assayed. The ether contained 1.6 mg./100 ml. of chlorobutanol and 0.004 mg./100 ml. of chloroform as internal standards.

Trichloroethanol Glucuronide.—One milliliter of water or urine containing TCE-G was added to 1.0 ml. of pH 4.5 acetate buffer (ionic strength = 0.1 *M*) containing 5 mg. of β-glucuronidase (beef liver, 360 Fishman units/mg., Calbiochem). The mixture was sealed and allowed to react at 37.5° overnight. Two milliliters of diethyl ether (plus chlorobutanol) was then added, the mixture was shaken, and a 5-μl. aliquot of the ether extract assayed for TCE using the electron capture detector. No analysis was run on TCE-G using flame ionization.

To determine the purity of the TCE-G isolated, 1 ml. of a 5.14 mg./100 ml. solution was hydrolyzed overnight at 80° with 1 ml. of concentrated hydrochloric acid. The TCE formed was extracted into 2 ml. of ether, a 5-μl. aliquot of the ether extract assayed, and the assay value compared with the theoretical yield. The stated enzyme concentration was optimum in that it gave results equivalent to acid hydrolysis after overnight reaction at pH 4.5, 37°.

The identity of the glycone obtained by enzymatic hydrolysis was verified by thin-layer chromatography. Twenty microliters of the hydrolysate were spotted on a Silica Gel GF_{254} (Brinkmann Instruments) plate of 0.4-mm. thickness along with reference spots of D-glucuronic acid, D-glucuronolactone, TCE, and TCE-G. The plates were then developed in 1-butanol–acetic acid–water (4:5:1) up to approximately 10 cm. The plates were then dried, sprayed with concentrated sulfuric acid, and heated until carbonization was complete. The hydrolysate was resolved into two spots with R_f values corresponding to D-glucuronic acid (0.50) and a small amount of unhydrolyzed TCE-G (0.81). No D-glucuronolactone (R_f = 0.71) was found. The volatility of TCE prohibited its visualization by this method.

Trichloroacetic Acid.—A chromatographic peak for TCA could not be resolved with the authors' columns. Alkaline decarboxylation produced chloroform which was extracted with ether and assayed with the electron capture detector. One milliliter of 0.1 *M* KOH was added to 1 ml. of water or urine containing TCA in a 10-ml. injectable vial. Two milliliters of diethyl ether (no internal standards present) was then added, the vial was sealed and heated at 100° for exactly 30 min. The vial was then cooled in an ice bath, allowed to reach room

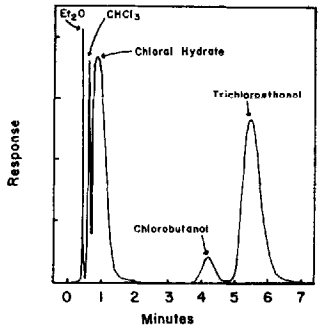

Fig. 2.—A typical chromatogram for a 5-μl. aliquot of a 1:1 ether extract of a solution of chloral hydrate and trichloroethanol (1.40 and 1.36 mg./100 ml., respectively). Pulse = 15. Sensitivity: 0.001 of maximum.

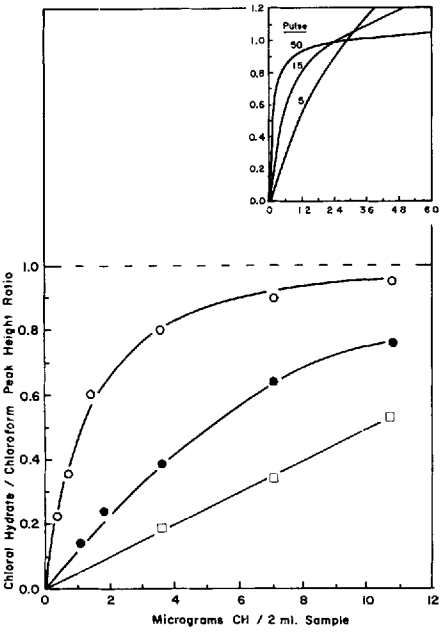

Fig. 3.—Calibration curves for chloral hydrate at three pulse intervals. Sensitivity: 0.001 of maximum. Insert shows the calibration curves for amounts of chloral hydrate up to 60 mcg./2 ml. sample. One microgram = 6.04 mμmoles. Key: ○, pulse = 50; ●, pulse = 15; □, pulse = 5.

temperature, and 5 μl. of the ether extract assayed, using the electron capture detector for the chloroform formed. No analysis was run for TCA using flame ionization.

Mixtures.—A 10-ml. sample of urine containing TCE, CH, TCA, and TCE-G was brought to pH 7.0 by dropwise addition of concentrated KOH. The volume change was negligible. Two milliliters of this urine was removed and assayed for TCE and CH. A 2.0-ml. sample was then extracted with six 10-ml. portions of ether to remove the TCE and CH, divided in half, and the 1-ml. portions assayed for TCA and TCE-G.

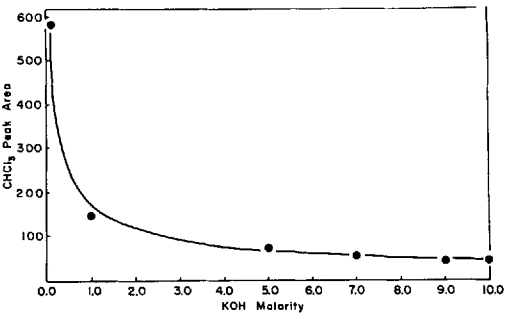

Fig. 6.—Effect of potassium hydroxide concentration on the amount of ether-extracted chloroform after trichloroacetic acid decarboxylation.

RESULTS AND DISCUSSION

Flame Ionization Detector.—The calibration curves for TCE and CH obtained by injecting 4-μl. aqueous aliquots are seen as Fig. 1. The sensitivity of flame ionization detection was only slightly greater than that obtained with the Friedman-Cooper assay. Therefore, this was not the method of choice.

Electron Capture Detector—Chloral Hydrate and Trichloroethanol.—Since direct injection of aqueous solutions gave poor peak reproducibility with electron capture detection, extraction with a nonpolar solvent was used. The distribution coefficients for several solvents are located in Table I. Figure 2 is a typical chromatogram of ether-extracted CH and TCE, with chloroform and chlorobutanol as internal standards. Better resolution of the CH and chloroform peaks could be obtained by decreasing either the carrier gas flow rate or the column temperature, but only at the expense of prolonging the retention time and increasing the width of the TCE and chlorobutanol peaks.

The potential across the detector cell was applied by the square wave pulse technique (7). The intervals available between $^3/_4$ μsec. voltage pulses were 5, 15, 50, and 150 μsec. An increased linear relationship between response and concentration was obtained by using shorter pulse intervals when high concentrations of CH or TCE were used. This is demonstrated in Figs. 3 and 4, the calibration curves for CH and TCE, respectively. However, greater sensitivity was available when the longer pulse intervals were used. These pulse intervals were more advantageous at lower drug concentrations. Thus, the pulse interval used for assay would depend on the concentration of drug which is physiologically encountered.

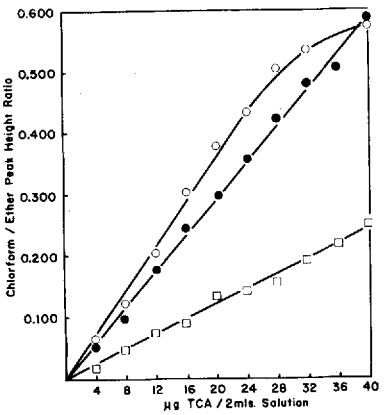

Fig. 7.—Calibration curve for trichloroacetic acid based on the assay of ether-extracted chloroform after alkaline (0.1 *M* KOH) decarboxylation. Sensitivity: 0.001 of maximum. One microgram = 6.1 mμmoles. Key: ○, pulse = 50; ●, pulse = 15; □, pulse = 5.

The assay parameter used for TCE and CH is peak height ratio (compound/internal standard). Although peak area ratios are conventionally used for compounds exhibiting broad peaks, peak height ratios gave less error when calibration curves using the two parameters were compared.

Trichloroethanol Glucuronide.—The acid hydrolysis yielded a TCE assay with peak height ratio of 6.0 at pulse = 15. Since this region of the pulse = 15 calibration curve (Fig. 4) showed a slight negative deviation from linearity, a second assay was run at pulse = 5, and a peak height ratio of 9.0 was obtained. These values corresponded to concentrations of 19.2 and 22.4 mcg. of TCE in 2 ml. of solution (87.2 and 100.3% of calculated theoretical yield) when compared with the calibration curves for TCE. Enzymatic hydrolysis at 37°, pH 4.5 with varying amounts of enzyme gave the same yield with 5 mg. of β-glucuronidase/2 ml.; 1.0 mg. of enzyme gave only 65.8% of theoretical yield.

The calibration curve for TCE-G is in Fig. 5. A pulse interval of 15 μsec. was used because it gave a linear response for physiological concentrations of TCE-G.

Trichloroacetic Acid.—The effect of KOH concentration on the assay was checked by decarboxylating a 1-ml. sample of 5 mg./100 ml. of TCA with 1.0 ml. of base ranging in concentration from 0.1 to 10 *M* and assaying after 30 min. for chloroform. The results of this experiment are depicted in Fig. 6.

Coulometric titration with a Cotlove chloridometer (Laboratory Glass and Instrument Corp.) demonstrated an increase in ionic chloride concomitant with the decrease of assayable chloroform from decarboxylation as the concentration of alkali was increased. For KOH concentrations of 1.0, 3.0, 5.0, and 10.0 *M*, the ionic chloride concentrations (and $CHCl_3$ peak heights) were 0.0296 (3.0), 0.0866 (1.20), 0.1104 (0.65), and 0.1626 meq./L.

(0.36), respectively. These data can explain the decrease in assayable chloroform with increased concentrations of alkali.

The first-order rate constants at the lowest KOH concentration (0.1 M) were checked at three different initial TCA concentrations. These rate constants were reasonably independent of the TCA concentrations, given in the parentheses, and were 15.0 (0.75×10^{-3} M), 13.8 (1.5×10^{-3} M), and 14.3 $\times 10^{-4}$ sec.$^{-1}$ (3.0×10^{-4} M). These values were in good agreement with the 13.2 $\times 10^{-4}$ sec.$^{-1}$ reported by Fairclough (8).

The 0.1 M KOH was used in the decarboxylation procedure since the greatest yield of chloroform was obtained in contrast to higher concentrations of alkali (Fig. 6).

The calibration curve for TCA (chloroform/ether peak height ratio *versus* concentration of TCA) is in Fig. 7. The use of the extraction solvent as an internal standard is deemed justifiable since the

[a] $\sigma_{x_{ij}}$, the estimated standard deviation of a single assay. The square root of the sum of the isolated components of variance (σx^2_{ij}). [b] $\bar{\bar{X}}$, the mean assay value, over all treatments, for a given level of a drug. Presented for TCE as the TCE/chlorobutanol peak height ratio, for CH as the CH/$CHCl_3$ peak height ratio, and for TCA as the $CHCl_3$/ether peak height ratio. [c] Per cent standard deviation = $\sigma_{x_{ij}} \times 100/\bar{\bar{X}}$.

TABLE VI.—STATISTICAL ANALYSIS OF ASSAY DATA FOR MIXTURES OF TRICHLOROACETIC ACID AND TRICHLOROETHANOL GLUCURONIDE IN DOG URINE

Drug Assayed	Components of Variance × 10^6	$\sigma_{x_{ij}} \times 10^3$[c]	$\bar{\bar{X}}$[d]	S.D., %[e]
TCA[a]	σ^2 TCE-G = 8.0			
	σ^2 error = 50	7.6	0.99	0.76
TCE-G[b]	σ^2 TCA = 1870			
	σ^2 error = 10430	111.0	4.11	2.70

[a] TCA concentration = 7.0 mg./100 ml.; TCE-G concentrations = 5.14, 2.57, and 0.514 mg./100 ml. [b] TCE-G concentration = 5.14 mg./100 ml.; TCA concentrations = 7.0, 3.5, and 0.7 mg./100 ml. [c] $\sigma_{x_{ij}}$, the estimated standard deviation of a single assay. The square root of the sum of the isolated components of variance ($\sigma^2_{x_{ij}}$). [d] $\bar{\bar{X}}$, the mean assay value over all treatments. Presented for TCA as $CHCl_3$/ether peak height ratio and for TCE-G as the TCE/chlorobutanol peak height ratio. [e] Per cent standard deviation = $\sigma_{x_{ij}} \times 100/\bar{\bar{X}}$.

assay conditions (sealed vials) prohibit volatilization and the ether peak height is proportional to the volume injected.

Statistical Evaluation.—Three levels of TCE (0, 0.136, and 1.36 mg./100 ml.), three levels of CH (0, 0.140, and 1.40, mg./100 ml.), and four levels of TCA (0, 1.25, 3.75, and 5.0 mg./100 ml.) were combined in all possible mixtures (a total of 36) in dog urine and assayed randomly with two assays of each component per sample on each of two days. A typical series of results, those for 0.140 and 1.40 mg./100 ml. CH, are listed in Table II. Analyses of variance (9) of the assay data were obtained for each concentration of drug in the presence of the various concentrations of the other drugs. Such analyses were run on the raw assay data; for TCE, as TCE/chlorobutanol peak height ratios and for TCA, as chloroform/ether peak height ratios. A typical analysis of variance, for 0.140 mg./100 ml. CH in mixtures of various concentrations of TCE and TCA, is given in Table III. This analysis is based on data for this CH level given in Table II.

On each of the analyses of variance performed the presence of significant factors was determined by the F test at the 5% level (Table IV). The isolated components of variance are listed in Table V along with $\sigma_{x_{ij}}$, the standard deviation of a single assay (which is the square root of the sum of the isolated components of variance, $\sigma^2_{x_{ij}}$), the mean assay value over-all treatments $\bar{\bar{X}}$, and the per cent standard deviation of the assay ($\sigma_{x_{ij}} \times 100/\bar{\bar{X}}$). From this table it was observed that the major source of variation for all components assayed was due to sampling error. Experimental error was either absent or much smaller than that for sampling.

The variance due to the presence of TCE in assays for CH was postulated to be a result of formation of a soluble chloral alcoholate (10) which was then irregularly distributed between ether and urine. This could be corrected by running CH calibration curves in the presence of varying concentrations of TCE.

If one excludes the variation due to days noted in the assay of 0.140 mg./100 ml. CH by assuming a weighing error during sample preparation, the per cent standard deviation for the remaining drug concentrations is never greater than 3.1%. Hence, the assay is both reliable and reproducible.

Two similar experiments, the first with 7.0 mg / 100 ml. TCA solution in the presence of 5.14, 2.57, and 0.514 mg./100 ml. TCE-G and the second with 5.14 mg./100 ml. TCE-G in the presence of 7.0, 3.5, and 0.70 mg./100 ml. TCA, were also run. Analyses of variance were carried out on the assay data and the results are found in Table VI. No significant effect was found for either the presence of TCA in TCE-G assays or the presence of TCE-G in TCA analyses.

Finally, to determine possible assay variation when different experimental animals were used, analyses of variance were run on assay data for TCE, CH, and TCA in aqueous solution and in the urine of three different dogs (four urine samples per dog per day on two different days). The design had unequal numbers of replicates which prohibited isolation of components of variance. No significant difference was noted among different urines using the F test (5% level).

Application of Membrane Filtration to Antibiotic Quality Control Sterility Testing

By FRANCES W. BOWMAN

Membrane filtration procedures for antibiotic sterility testing as described in the recently amended Antibiotic Regulations of the Food and Drug Administration (FDA) offer an improved approach for determining the sterility of antibiotics.

FOR ALMOST 20 years the Antibiotic Regulations[1] of the Food and Drug Administration for the sterility testing of antibiotics required 10 containers from each batch to be tested, six in thioglycollate broth for bacteria and four in Sabouraud fluid medium for molds and yeasts (1). In testing penicillin preparations, the antibiotic was inactivated by the addition of penicillinase to the thioglycollate medium. Since there were no suitable inactivators for the nonpenicillin antibiotics, no inactivator was added to the medium used for testing them, and for the most part any organisms detected were those highly resistant to the inhibitory action of the particular antibiotic.

DISCUSSION

To improve the sterility test, several possibilities were investigated. Serial dilution techniques to reduce the antibiotic to a subminimal inhibitory concentration were explored. This procedure is unsatisfactory since it also dilutes the contaminating organisms. Dilution of the antibiotic sample by large initial volumes of culture media was found to be both costly and impractical. Finally, a filtration procedure was developed employing a membrane filter composed of cellulose esters (2). The antibiotic preparations were first solubilized and the solution was filtered through a circular membrane filter approximately 47 mm. in diameter, with a porosity of 0.43–0.47 μ. Any organisms contaminating the preparation were trapped on the membrane, which was then washed with sterile water to remove any residual antibiotic without affecting the organism. Portions of the washed filter disk were placed in sterile fluid thioglycollate for 5 days at 32°.

Research on the application of the membrane filtration technique to the sterility testing of the antibiotic drugs produced practical methods for solubilizing and filtering each antibiotic preparation. Modifications were made to accommodate antibiotic powders and various formulations in which they are incorporated.

Use of the filtration technique for testing the tetracycline antibiotics eliminates two major problems. The antibiotic which would inhibit the growth of bacterial contamination, if present, is removed and degradation is avoided. When tetracyclines are added to thioglycollate medium, the breakdown products produce acidity, turbidity, and discoloration of the medium. The acidity prevents growth of most contaminating microorganisms, and the turbidity and dark color prevent visual observation of contamination.

Sodium novobiocin and amphotericin B also presented problems in that the slight acidity of Sabouraud broth rendered these antibiotics insoluble, again interfering with visual detection of growth. Filtration eliminates this difficulty. The antibiotics are dissolved in 0.1% peptone solution, filtered, and washed three times. For practical purposes no antibiotic is transferred to the Sabouraud broth because none remains on the membrane.

The procedures for the sterility testing for antibiotics published March 28, 1964 (3), gave membrane filtration procedures official status and culminated years of evaluating their merit. In addition to increasing the sensitivity of the test by the use of filtration procedures, the amended regulations increased the sample size to 20 representative units from each "filling operation" to be tested in both of the media previously mentioned. The term "filling operation" is defined as that period of time not longer than 24 consecutive hr. during which a homogeneous quantity of a drug is being filled continuously into market-size containers and during which no changes are made in the equipment used for filling. Both the direct method and the membrane filtration procedure are described in detail in the regulations. The direct method is used for insoluble preparations and the membrane filtration for soluble preparations. The membrane filtration procedure specifies that 300 mg. of a solid drug or 1 ml. by volume of a liquid drug from each of 20 immediate containers be aseptically transferred to 200 ml. of 0.1% (w/v) peptone solution. Since bacterial contamination is not related to the dosage of the antibiotic tested, a constant amount (weight or volume) of the antibiotic was selected for each sterility test. After complete solubilization, the antibiotic solution is filtered through a bacteriological membrane filter. All air entering the system is passed through air filters capable of removing microorganisms. Three 100-ml. portions of 0.1% peptone water are then filtered through the membrane to remove as much as possible of the residual antibiotic. A 17.5-mm. diameter disk is aseptically cut from the center of the filtering area and transferred to a sterile 38 × 200-mm. (outside dimensions) test tube containing approximately 90 ml. of sterile thioglycollate medium. The remaining portion of the membrane is transferred to a second similar tube containing approximately 90

[1] The Antibiotic Regulations are issued under Section 507 of the Federal Food, Drug, and Cosmetic Act.

ml. of fluid Sabouraud medium. The tubes are incubated for 7 days at 32° and 25°, respectively, and then examined for visible growth. The batch meets the requirements of the test if no tube shows growth. If growth is observed in any tube, the test is repeated with twice the number of containers. The batch meets the requirements if no tube on the repeat test shows growth.

The regulations require that specific environmental tests to assess the suitability of the testing conditions be made frequently enough to assure the validity of the test results. The responsible head of each sterility testing laboratory must determine which methods are to be used for air analysis and what levels of microbial contamination of the air are significant and tolerable. Special devices for sampling air to determine its microbial content are helpful in evaluating the conditions of the areas in which the tests are performed. Some of the devices and techniques commonly used for the microbiological analysis of air are the settling plate technique, the sieve and slit-type samplers, and liquid impingement devices. Although settling plates are easy to use, they yield a limited amount of information, since only particles of certain dimensions will settle onto the plates. Another disadvantage is that the volume of air sampled cannot be measured. The liquid impingement samplers, which force a definite quantity of air through an impingement fluid, recover all of the airborne contamination in the volume of air sampled, thus giving more quantitative information. In addition to requiring tests to assess the area in which the sterility tests are performed, the regulations specify that tubes of thioglycollate to which penicillinase has been added must be tested for sterility, either prior to use or at the time of the test. If the environmental or other tests show sufficient evidence that the results obtained in the first or second official sterility tests are not valid, additional tests may be performed.

As previously noted, 0.1% peptone solution was chosen as the diluting fluid for the filtration procedure. Sterile distilled water or physiological saline had been used for many years to dissolve antibiotics prior to transferring them to the media in the sterility tests (4). The deleterious effect of distilled water on some microorganisms has been well documented in the literature (5). (The "British Pharmacopoeia" specifies sterile physiological saline for dissolving antibiotic powders, and U.S.P. XVII requires that a sterile diluent be used to dissolve solids for the general sterility test.) A diluting fluid which would minimize the destruction of small populations of vegetative cells during the pooling, solubilizing, and filtering of antibiotics was sought. A diluting fluid affording protection to vegetative cells is a necessity when a large number of filtration sterility tests are performed on the same day because each test cannot be carried to completion before another test is started. Therefore, the diluent must protect the vulnerable vegetative cells in an antibiotic milieu until they are safely separated from the antibiotic and transferred to the growth medium.

Straka and Stokes (6) reported that destruction of vegetative bacteria can be minimized by the use of 0.1% peptone solution. Jane-Williams (7) studied the survival of bacteria in six different diluents and found that 0.1% peptone solution was the only one that did not kill one or more of the test organisms.

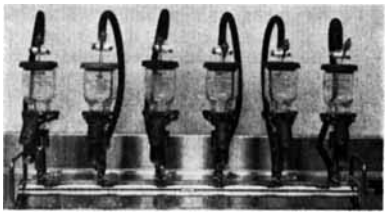

Fig. 1.—Sterility test unit.

EXPERIMENTAL

Equipment.—To accommodate the large number of samples tested daily for quality control by filtration techniques, new equipment had to be designed. The filtering apparatus used in developing the technique has been assembled by a manufacturing firm into a compact "sterility test unit" (as shown in Fig. 1) consisting of six separate filtering devices on a manifold. This unit was designed expressly for sterility testing of antibiotics and was produced to meet the specific requirements described in the Antibiotic Regulations.

The completely assembled unit is steam sterilized at 121° for 20 min., with stopcocks open and membranes in position in the funnels. It is brought into the filtering area where, after all stopcocks have been closed, the metal intake tube of the manifold is aseptically attached to an overhead bottle of sterile 0.1% peptone solution. The metal exhaust tube of the manifold is attached by means of a connecting hose to an empty bottle. The latter, in turn, is connected to a vacuum outlet. All exhaust valves are turned to an "off" position. The vacuum is then turned on, and the unit is ready for use.

Tests on Diluting Fluids.—The survival of organisms in antibiotics dissolved in 0.1% peptone solution, distilled water, and 0.85% sodium chloride solution was compared. No attempt was made to adjust the pH of the distilled water or saline. However, the pH ranged between 6.5 and 6.9 before the addition of the antibiotic, and the pH of the 0.1% peptone solution was 7.0 ± 1. Bacteriological peptone (Difco B 118) was used. The seed organisms were added to two flasks each containing 200 ml. of the given diluent in which the antibiotic powder was dissolved. One flask of each diluent was filtered immediately and the second flask was filtered after 1 hr. After the solutions containing the organisms were filtered through a 47-mm. diameter membrane having a porosity of 0.45 μ, the membranes were washed three times with 100 ml. of the individual diluent. Each membrane was then aseptically moved to the surface of sterile nutrient agar in sterile Petri dishes (20 × 100 mm.). The plates were covered with sterile porcelain tops, glazed on the outside, and incubated at 32° for 5 days. The colonies were counted and the survival was noted for each contact period, initially and after 1 hr. The amount of each antibiotic used was the amount required for the sterility test of that particular antibiotic in the Antibiotic Regulations. For example, 300 mg. of sodium penicillin G from 20 immediate containers is the amount pooled for a

TABLE I.—VIABILITY OF ORGANISMS RECOVERED FROM ANTIBIOTIC SOLUTIONS FILTERED IMMEDIATELY[a] AND AFTER 1 hr. AT 25°C.

Organism	Antibiotic	Amt., Gm.	Estimated No. Cells	Recovery After 5 Days at 32°C. Peptone, 0.1% Ini.	Peptone, 0.1% 1 hr.	Saline, 0.85% Ini.	Saline, 0.85% 1 hr.	Distilled Water Ini.	Distilled Water 1 hr.	Medium
S. aureus ATCC 6538P	Tetracycline hydrochloride	1.0	40	36	28	28	2	34	0	Peptone–casein agar
Serratia marcescens ATCC 14756	Tetracycline hydrochloride	1.0	20	18	16	16	10	18	14	Peptone–casein agar
Streptococcus pyogenes ATCC 8668	Tetracycline hydrochloride	1.0	50	34	22	2	0	6	0	Peptone–casein agar
Bacillus subtilis (spores)[b]	Dihydrostreptomycin sulfate	6.0	55	50	48	42	50	52	48	Peptone–casein agar
Aspergillus sp. (spores)	Polymyxin B′ sulfate	6.0	42	38	37	40	38	35	42	Sabouraud dextrose agar
S. aureus ATCC 6538P	Sodium penicillin G	6.0	30	20	28	18	0	12	4	Peptone–casein agar

[a] As soon as the organisms were added. [b] ATCC 6633 strain made resistant to dihydrostreptomycin.

test. Therefore, 6-Gm. portions were dissolved in each of two flasks containing 200 ml. of each of the three diluents. As shown in Table I, the survival of spores of either bacteria or fungi was not affected either by the nature of the diluent or by the time of exposure to the antibiotic solution. However, the vegetative cells added to the antibiotic solutions and immediately filtered survived to approximately the same extent in each diluent. When the filtration was delayed for 60 min., the survival rate was higher in 0.1% peptone solution.

Sodium Thioglycollate.—The fluids for solubilizing insoluble antibiotics should be nontoxic to microorganisms. Although no sterile zinc bacitracin products are in use, an aerosol spray can containing zinc bacitracin for topical use is tested. The Antibiotic Regulations require this product to contain no more than 10 microorganisms per container. To prepare it for the test it must be filtered through a membrane filter in the same way as samples tested for absolute sterility. Early attempts to solubilize zinc bacitracin (for sterility testing) were unsuccessful. For potency assay zinc bacitracin is dissolved in 0.1 *N* hydrochloric acid, but for sterility testing the acidic solution cannot be used. It was noted that zinc bacitracin is soluble in thioglycollate medium but not in Sabouraud medium. Investigation disclosed that the chelating properties of sodium thioglycollate were responsible for the solubilization. Consequently, 0.05% sodium thioglycollate is added to the 0.1% peptone solution to solubilize zinc bacitracin prior to filtration. Since the required concentration of sodium thioglycollate is the same as that in thioglycollate medium, there is no problem of toxicity to microorganisms when it is used as a component of the diluting fluid.

Polysorbate.—To overcome filtration difficulties with a tetracycline aerosol containing isopropyl myristate, 0.5% polysorbate 80 is added to the 0.1% peptone water. (Aerosols to be tested for sterility by using filtration procedures are sprayed into an empty sterile flask, and after the propellant evaporates, the residue is dissolved.)

Penicillinase.—To solubilize procaine penicillin G alone or in combination with streptomycin, the enzyme penicillinase is aseptically added to the peptone diluting fluid. Bowman (8) reported that procaine penicillin G could be solubilized rapidly by using a high-titer penicillinase. It has been found that approximately 337,000 Levy units of penicillinase will solubilize 6 Gm. of procaine penicillin G for the membrane filtration sterility test.

Isopropyl Myristate.—The use of isopropyl myristate as a diluent for petrolatum-based ointments was first suggested by Sokolski (9), who improved the recovery of viable cells from ointments by a filtration technique. Isopropyl myristate dissolves certain sterile petrolatum-based antibiotic ointments so that these preparations can also be tested by membrane filtration. The Antibiotic Regulations have been amended (10) to include a sterility test for sterile ophthalmic ointments containing bacitracin, neomycin, and polymyxin. Portions of 0.1 Gm. from each of 10 immediate ointment containers are aseptically transferred to 100 ml. of isopropyl myristate at 47°. The process is then repeated with another 10 ointment containers. After the ointment has dissolved, the solutions are filtered as described for the membrane filtration sterility test. Since it is difficult to wash residual antibiotics, especially neomycin, from membranes through which oleaginous preparations have been filtered, a rinse medium has been devised to help overcome this problem. The rinse medium contains bacteriological peptone and beef extract to protect the vegetative cells during the rinsing period. (Each filter is rinsed five times with 100 ml. of the rinse medium.) Polysorbate 80 is included in the rinse medium to decrease the filtration time, and sodium chloride 3% (w/v) is added to reverse the action of the neomycin which adheres to the membrane.

RESULTS AND CONCLUSIONS

As previously mentioned, the Antibiotic Regulations contain instructions for performing sterility tests by both membrane filtration and the direct method. Some antibiotics, sodium penicillin G for example, may be tested by either method. However, if the direct method is used, the ability of the penicillinase to inactivate all the penicillin in the

sample under test is checked by adding the proper amount of penicillin to another tube of thioglycollate medium containing the penicillinase and inoculating it with 1 ml. of a 1:1000 dilution of an 18–24 hr. culture of *Staphylococcus aureus* ATCC 6538P. Typical microbial growth must be observable after 24 hr.

The regulations also include any exceptions required for testing specific antibiotics. When 200 ml. of a 3% solution of an antibiotic cannot be filtered, as in the case of tetracyclines or chloramphenicol, 50-mg. portions are used from each of 20 containers instead of the 300 mg. required by the general method.

Investigational studies and experience have shown that the filtration procedure offers better assurance of the sterility of antibiotics. Bowman and Holdowsky (11), in a study of the survival of bacteria in dihydrostreptomycin sulfate solutions, showed the superiority of the membrane filter method over the direct method in recovering organisms sensitive to dihydrostreptomycin. Dihydrostreptomycin solutions were artificially contaminated with 50,000 spores/ml. of six different bacteria whose vegetative cells were sensitive to dihydrostreptomycin. When membrane filtration was used, organisms were consistently recovered at intervals up to 3 months (the duration of the testing period). The same solutions gave negative results when tested by the direct method.

Lightbown (12) reported on dihydrostreptomycin solution contaminated with up to 4000 viable particles per vial of a relatively resistant strain of *Klebsiella pneumoniae* or a sensitive strain of *S. aureus* and examined by the "British Pharmacopoeia" dilution method and by membrane filtration. With the resistant strain of *K. pneumoniae*, 34 samples out of 87 were found to be contaminated by the filtration test, while the dilution test detected no contamination; with *S. aureus* 54 samples out of 93 were found contaminated when tested by filtration, while the dilution test detected no contamination. He also reported that 7-year-old batches of dihydrostreptomycin sulfate tested by filtration procedures revealed the presence of contaminating organisms which had survived in the dry powder. The contamination had not been revealed by earlier dilution tests.

Twenty vials, each containing 10 ml. of a suspension of procaine penicillin G in dihydrostreptomycin sulfate solution, were tested in this laboratory and found contaminated by the filtration procedure. An additional 40 vials were retested by both the filtration method and the direct method. The membrane filtration method recovered the same contaminant, a Gram-positive bacillus. The direct method showed no growth in 40 tubes of thioglycollate or 40 tubes of Sabouraud medium after incubation for 7 days at 32° and 25°, respectively.

In the first year after the new sterility regulations became effective, a total of 8,190 sterility tests were performed. The membrane method was used for 4,743 and the direct method for 3,447. The filtration procedures were found to reduce the cost of sterility testing, the reduction being due primarily to significant savings of media and of manhours involved in the preparation of media. When a preparation was submitted for certification with 25 "filling operations" from one batch, the better coverage and the economy of the filtration method were apparent. Under the former regulations, 10 of these single-dose containers would have been tested, whereas under the new regulations, 1,000 were tested. Had this been a multiple dose container, only 500 would have been required, since each container could be used to furnish a test dose for both a thioglycollate and a Sabouraud tube. In any event, the direct method would have required 1,000 tubes of media, while the filtration method required only 50.

The membrane filtration sterility test has been officially accepted by the United Kingdom and the United States for antibiotic sterility testing. The "British Pharmacopoeia," 1963, requires filtration tests for testing the sterility of parenteral preparations of bacitracin, oxytetracycline, tetracycline, polymyxin, streptomycin, vancomycin, viomycin, and methicillin. For sterility tests of all antibiotics, U.S.P. XVII and N. F. XII refer to the Antibiotic Regulations of the Food and Drug Administration.

Mechanisms of Antithyroidal Activity of Methimazole

By ROBERT E. BROCK and W. F. HEAD, JR.

Methimazole produces a significant inhibition of iodide ion absorption by the intact thyroid which may account for the major portion of its antithyroidal action. The principal intrathyroidal effect of methimazole is shown to be due to its reactivity with elemental iodine. It neither inhibits nor serves as a competitive substrate for the hydrogen peroxide–peroxidase enzyme system. Thyroxine is displaced from its serum binding sites by methimazole; however, this mechanism is not considered to be clinically important.

THIOUREA compounds, such as methimazole, are thought to exert their antithyroidal effect by competing with tyrosine for elemental iodine or by inhibiting the oxidative enzyme system which converts iodide ion to iodine. In either case, the formation of diiodotyrosine is prevented and the biosynthetic pathway to the formation of thyroxine is blocked.

In competing with tyrosine for iodine, the thiourea derivative is thought to enolize to form a sulfhydryl group which is easily oxidized by iodine to form a disulfide. Iodine is reduced to iodide ion which is incapable of iodinating tyrosine. Since this reaction proceeds at a rate several hundred times faster than the iodination of tyrosyl groups, competition should be quite favorable for diversion of iodine from organic binding (1, 2).

It has been concluded by Astwood (3) that inhibition of a peroxide–peroxidase enzyme system in the thyroid is the most likely mechanism of antithyroidal activity of the thiourea compounds. Alexander (4, 5) recently demonstrated the existence, in thryoid homogenates, of such an enzyme system which can perform the iodide oxidation. Randall (6) has shown that sulfhydryl compounds are capable of reacting with hydrogen peroxide and that the rates of reaction are accelerated in the presence of peroxidase. It was concluded that sulfhydryl compounds do not inhibit peroxidase, but rather serve as substrates, competing successfully with other substrates. It was not demonstrated that sulfhydryl groups could successfully compete with iodide ion for the peroxide–peroxidase system.

Others have studied the inhibition of secretion or activity of hormonal TSH (7, 8) and the inhibition of the utilization of thyroid hormones at the tissue level (9, 10). The controversial studies of the mechanisms of action of thiourea antithyroid compounds have been reviewed by Pitt-Rivers (11), Astwood (1), and Trotter (12).

The purpose of this study was to determine the extent of contribution to antithyroidal activity by various possible mechanisms of action of methimazole, a typical thiourea derivative. The modes of action investigated included both extrathyroidal and intrathyroidal mechanisms.

EXPERIMENTAL

Reaction of Iodine with Methimazole and Tyrosine.—The course of reaction between iodine and a mixture of methimazole and tyrosine was determined spectrophotometrically. Iodine was allowed to react with methimazole, tyrosine, and a mixture of the two. All reactions were performed at room temperature and completion noted by the discharge of the yellow iodine color. Each of the reactants was prepared in 0.001 *M* concentration in phosphate buffer, pH 7.4.

As shown in Table I, the molar ratio of methimazole–tyrosine–iodine used was 4:1:2 which provides a stoichiometric quantity of iodine to the reactions. In the presence of a mixture of methimazole and tyrosine, iodine was added last to provide a competitive effect and was present in sufficient quantity to react completely with only one component.

After reaction, all samples were diluted to 500 ml. with phosphate buffer and their ultraviolet absorption spectra determined from 275 to 215 mμ using a Beckman model DK-2A recording spectrophotometer. The results are shown in Fig. 1.

The spectrum of the reaction product of iodine with a mixture of methimazole and tyrosine (spectrum *3*) compares very closely with the spectrum of the reaction product of iodine with methimazole to which tyrosine was added after reaction (spectrum *5*). If iodine had reacted with tyrosine to the ex-

clusion of methimazole, an absorption spectrum similar to spectrum *4* would have resulted. A mixture of reaction products would have resulted in an absorption spectrum of intermediate character. It is apparent that iodine in the presence of a mixture of methimazole and tyrosine reacts almost exclusively with methimazole.

To further verify that tyrosine failed to react with iodine in the presence of methimazole, the competitive reaction, containing twice the quantity of tyrosine, was repeated. Ultraviolet spectra indicated that methimazole had completely utilized the available iodine. Chromatography of this sample on Whatman No. 1 paper in a descending *n*-butanol–acetic acid (9:1)–water system failed to separate mono- or diiodotyrosine using 0.2% ninhydrin as detector. It was established that this system was capable of separating and detecting as little as 0.5% of the theoretical quantity of diiodotyrosine which could have been formed.

Interaction of Iodide Ion and Methimazole with Hydrogen Peroxide–Peroxidase Enzyme System.—The oxidation of iodide ion, methimazole, and a mixture of the two with hydrogen peroxide in the presence of peroxidase was studied using the manometric technique of Randall (6). All reactions were performed in the Warburg apparatus at 37.5°. The main chamber of the flask contained 1 ml. of either 0.06 *M* potassium iodide, 0.06 *M* methimazole, or both potassium iodide and methimazole in 0.06 *M* concentrations. To the flask were added 0.6 ml. of peroxidase (1 unit/ml.) and 0.4 ml. phosphate buffer, pH 7.4. After temperature equilibration for 10 min., 0.5 ml. of 0.06 *M* hydrogen peroxide was added from one sidearm and the reaction allowed to continue for the desired period of time. Catalase, 0.075 mg. contained in 0.5 ml., was added from the second sidearm to stop the reaction by decomposing the remaining hydrogen peroxide. Oxygen evolution, directly proportional to the hydrogen peroxide remaining in the flask, was read directly from the manometer after 2 min. All solutions were prepared using phosphate buffer, pH 7.4. Pressures (mm. oxygen) reported are averages of a minimum of four determinations corrected to a single manometer tube and corrected for barometric pressure changes. Reaction rates reported were all calculated using a first-order expression since the data obtained corresponded closely to this order.

In the reaction of iodide ion with hydrogen peroxide–peroxidase, a steady evolution of oxygen was noted before the addition of catalase. This was due to the catalytic decomposition of hydrogen peroxide by iodide ion as described by several investigators (13–15). This effect began after a brief induction period and continued until the hydrogen peroxide was decomposed by the addition of catalase. During the induction period, iodide ion is oxidized to a steady-state concentration of iodine. When this concentration is reached, hydrogen peroxide decomposition begins with no further iodine generation. In measuring oxygen pressures at given time intervals, it was first necessary to determine the catalytic oxygen pressure. The catalase solution was then added and the total oxygen pressure recorded after 2 min.

The difference between the catalytic oxygen pressure at various time intervals and the original peroxide oxygen pressure which was shown to be constant over the time involved is a measure of the total theoretical oxygen remaining if no other reactions are occurring. From the resulting data, as shown in Fig. 2, the rate of the catalytic decomposition of hydrogen peroxide can be calculated. This rate, $k = -0.112$, is in good agreement with the literature value (13).

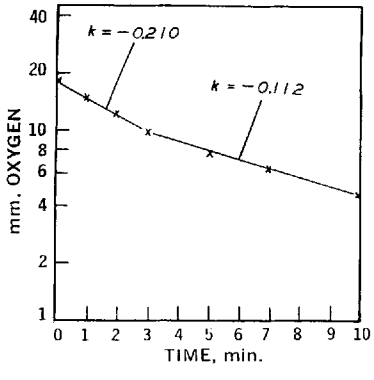

Fig. 3.—Oxidation of iodide ion and catalytic decomposition of hydrogen peroxide.

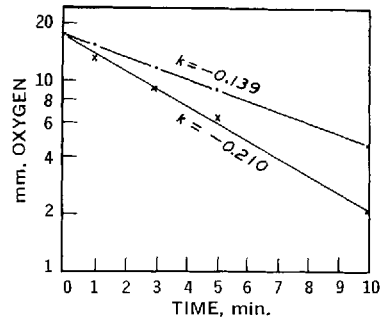

Fig. 4.—Reaction of hydrogen peroxide–peroxidase with methimazole and methimazole–iodide ion. Key: —·—·, methimazole and hydrogen peroxide–peroxidase; —×—×, methimazole, iodide ion, and hydrogen peroxide–peroxidase.

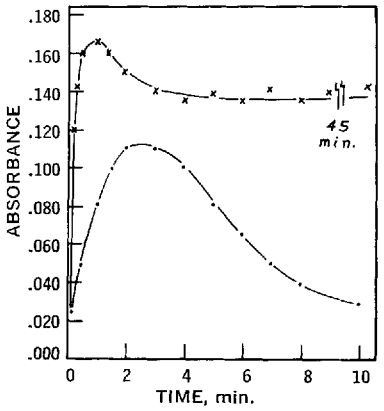

Fig. 5.—Iodine generation by hydrogen peroxide–peroxidase. Key: —×—×, iodide ion and hydrogen peroxide–peroxidase; —·—·, iodide ion, methimazole, and hydrogen peroxide–peroxidase.

The difference between the catalytic oxygen pressure and the total measured oxygen pressure after addition of catalase is equivalent to the actual peroxide oxygen remaining. These data (Fig. 3) show the initial oxidation of iodide ion to iodine during the induction period ($k = -0.210$) and the catalytic decomposition effect ($k = -0.112$). Beyond the induction period, only catalytic decomposition is occurring as evidenced from the rate constant.

Methimazole and iodide–methimazole substrates did not produce a catalytic peroxide decomposition. The rates of these reactions could be followed by direct measurement of residual oxygen pressure at a given time as shown in Fig. 4. Methimazole reacts with the hydrogen peroxide–peroxidase system at a slower rate ($k = -0.139$) than a mixed iodide–methimazole substrate. The rate constant of the latter reaction is the same as that calculated for the oxidation of iodide ion to a steady-state concentration of iodine. Since no catalytic decomposition was observed and the reaction rate was uniform over the time period measured, it would seem likely that the primary reaction is the oxidation of iodide ion in an attempt to gain a steady-state concentration of iodine which, in the presence of methimazole, cannot be attained.

The same ratio of reactants (methimazole–iodide ion–peroxide = 2:2:1) at 6 times the previous concentration also failed to display the catalytic peroxide decomposition effect. The same result was obtained at ratios of 2:2:2 and 2:2:3. At ratios of 2:2:4, 2:2:5, and 2:2:6, catalytic oxygen evolution began after a 6 to 8-min. induction period.

Further verification of iodine generation in a mixed iodide–methimazole system was obtained spectrophotometrically. During the manometric studies, a transient pale yellow color was noted in the first few minutes of reaction. The iodide ion reaction and the iodide–methimazole reaction with hydrogen peroxide–peroxidase were repeated as described and the absorbance at 400 mμ measured using a Bausch & Lomb Spectronic 20 spectrophotometer. As shown in Fig. 5, in the absence of methimazole, a steady-state concentration of iodine is reached within 2 to 3 min. and remains throughout the period of observation. In the presence of methimazole, iodine is produced; however, it never reaches a steady-state concentration. It gradually decreases in concentration probably by reaction with methimazole.

Inhibition of Thyroidal Absorption of Iodide Ion.—Methimazole has been observed to inhibit iodide ion accumulation in euthyroidal humans in doses of 0.5 mg. (16). Williams and Coker (17) have demonstrated that iodide ion absorption by surviving thyroid slices is completely inhibited upon incubation for 2 hr. in a solution containing 5 mcg. of methimazole. The following study was performed to quantitate this effect in the intact thyroid.

Sixteen male, white, Sprague-Dawley rats of the same ages, weighing from 220 to 337 Gm. (average 292 Gm.) were used for tests and controls. Eleven received 0.4 mg./Kg. of methimazole intraperitoneally 12 hr. and again 3 hr. prior to the administration of approximately 7.4 μc. of sodium radioiodide.[1] Five rats used as controls received only sodium radioiodide. Exactly 2 hr. after the administration of sodium radioiodide, the animals were exsanguinated under ether anesthesia. The thyroid glands were immediately removed, transferred to planchets, and counted for 5 min. using a Tracerlab Versamatic II scaler with a Tracerlab scintillation detector, P-20-D, and a 1 × 1.5 in. NaI (Tl) crystal. All counts were corrected for background. The results, shown in Table II, indicate an inhibition of thyroidal iodide ion absorption by methimazole of 80.9%.

Displacement of Thyroxine from Serum Binding Sites.—Diphenylhydantoin has been shown to lower the serum-bound iodine in both epileptic and normal subjects (18). To determine if methimazole exhibits the same property, a dialysis procedure was employed. Test materials were sodium diphenylhydantoin, methimazole, and histamine phosphate. Histamine was used because of its similarity in size and ring structure to methimazole. All were used in equimolar concentrations.

Four 5-ml. portions of fresh dog serum were placed in each of four preboiled 6-in. lengths of cellophane dialysis tubing which were tied at one end. To each was added 1.25 μc. of thyroxine-^{131}I contained in 0.2 ml. The serum control tube was diluted with 5 ml. of phosphate buffer, pH 7.4. To

TABLE III.—DISPLACEMENT OF THYROXINE FROM DOG SERUM BINDING SITES

Dialysis Time, hr.	Serum Sample			
	Control	Methimazole	Diphenylhydantoin	Histamine
1	2.0%	2.2%	2.6%	2.0%
4	2.8	3.7	4.0	2.1
8	5.1	29.0	33.7	4.0
12	10.2	75.0	83.2	5.1

the remaining three tubes were added 25 mcg. of methimazole, 60 mcg. of sodium diphenylhydantoin, and the equivalent of 24.3 mcg. of histamine, respectively, each in 5-ml. volume. This quantity of methimazole approximates physiological concentrations. The tubes were tied and each placed in separate capped jars containing 20 ml. of phosphate buffer, pH 7.4. The jars were agitated in a Dubnoff incubator at 37.5°. One hundred-microliter samples of the buffer were removed at 1, 4, 8, and 12-hr. intervals, placed in planchets, and counted using a scintillation detector.

Only if thyroxine is displaced from its protein binding sites will it dialyze into the phosphate buffer medium. The per cent displacement can be calculated from the count rate in the external buffer at a given interval and the known activity added to the serum. The results in Table III indicate that thyroxine is displaced by methimazole and sodium diphenylhydantoin. Histamine did not show this effect, perhaps indicating that a urea or thiourea moiety is required.

DISCUSSION

Methimazole has been shown to compete with tyrosine for elemental iodine so effectively that detectable levels of iodinated tyrosine derivatives are not formed. It neither inhibits nor serves as a preferential substrate for the hydrogen peroxide–peroxidase enzyme system. Iodide ion in the presence of methimazole and the enzyme system is converted to elemental iodine which apparently reacts with methimazole as it is formed. These data indicate that the avidity of methimazole for elemental iodine is the prime basis for its intrathyroidal activity.

It was found that a reduction in the uptake of iodide ion on the order of 80% by the intact thyroid followed the administration of methimazole. Since iodide ion absorption is the first step leading to the biosynthesis of thyroxine, this mechanism of action must be considered very significant and probably more important than the intrathyroidal effects.

In physiological concentrations, methimazole and sodium diphenylhydantoin were shown to displace thyroxine from its serum binding sites. Although sodium diphenylhydantoin causes a reduction in serum-protein bound iodine, it does not produce a clinical hypothyroidism. Therefore, it would appear unlikely that methimazole exerts a significant portion of its antithyroidal effect at this level of thyroid function.

Kinetics of Nitrous Acid Induced Reserpine Fluorescence

By R. P. HAYCOCK, P. B. SHETH*, T. HIGUCHI†, W. J. MADER, and G. J. PAPARIELLO

The kinetics of the reaction of reserpine with nitrous acid has been studied. The results show a two-step process with nitrous acid reacting with protonated reserpine to form an intermediate complex which under the influence of hydrogen ions forms a colored fluorescent product, identified as 3-dehydroreserpine. A rate expression was derived and reaction rates computed.

MANY CHEMICAL reactions used for the production of chromogenic or fluorogenic products in organic analysis are never studied beyond the point of practical utilization. Yet, further knowledge of their chemistry is desirable to extend their use.

The reaction of reserpine with nitrous acid to produce a fluorogenic-colored product has a long history of effective analytical service. It was first reported on by Szalkowski and Mader (1), who utilized its chromogenic characteristics for the determination of reserpine in pharmaceutical preparations. The procedure was later modified by Banes *et al.* (2–4) and subsequently approved as the official method (5) for pharmaceutical preparations. Since fluorometric techniques are extremely sensitive, a procedure which considered this property of the reaction was adopted by the Association of Official Agricultural Chemists for the microdetermination of reserpine in feeds (6–8). Although there is a wealth of published data on its analytical applications, there seem to have been no earlier attempts to ascertain the mechanism and kinetics of the reaction. In the present investigation, the fluorescent method has been used to study the kinetics involved in treating reserpine with nitrous acid.

EXPERIMENTAL

All fluorescent measurements were made on an Aminco-Bowman spectrophotofluorometer. As previously reported (6), the excitation maximum for the nitrous acid induced reserpine fluorescence is 390 mμ and the fluorescent maximum is 510 mμ.

In studying the effect of nitrous acid on the reaction rate, the initial concentrations of reserpine and of hydrochloric acid in the reaction flask were kept constant at 3.16×10^{-7} moles $L.^{-1}$ and 0.24 mole $L.^{-1}$, respectively. However, the concentration of the nitrous acid was varied from 1.74×10^{-3} to 5.80×10^{-5} moles $L.^{-1}$. All reactions were run and all measurements were taken at room temperature. The procedure was as follows.

Pipet 15 ml. of a 60% chloroform–40% methanol solution containing 4.8 mcg. of reserpine into a 25-ml. volumetric flask. Add several milliliters of methanol. Mix well. Add 0.5 ml. of hydrochloric acid and the desired number of milliliters of sodium nitrite solution (0.1% in 50% methanol–50% water). Dilute to mark with methanol and shake well. Measure the fluorescent development as a function of time.

In studying the effect of hydrochloric acid on the reaction rate the initial concentration of reserpine and nitrous acid in the reaction flask were kept constant at 3.16×10^{-7} moles $L.^{-1}$ and 2.9×10^{-4} moles $L.^{-1}$, respectively. However, the concentration of the hydrochloric acid was varied from 4.8×10^{-2} to 4.8×10^{-1} moles $L.^{-1}$. The procedure as described above was followed with the exception that the milliliters of hydrochloric acid added were varied while the milliliters of sodium nitrite solution added were kept constant.

RESULTS AND DISCUSSION

Postulated Reaction.—It is suggested that the reaction which takes place when one induces fluorescence in reserpine by use of nitrous acid is a two-step reaction which can be expressed as follows:

$$\text{protonated reserpine} + \text{HONO} \overset{K_1}{\rightleftharpoons} [\text{protonated reserpine} : \text{HONO}] \xrightarrow[k_2]{H^+} \text{3-dehydroreserpine (fluorescent product)}$$

That only the protonated reserpine species is involved in the reaction is quite obvious when one considers that the pKa of reserpine is 6.6 (9) and the reaction flask pH never exceeds 1.5.

3-Dehydroreserpine is considered to be the fluorescent product and the following evidence has been gathered to support this contention. (A) The wavelengths for excitation and fluorescence, *viz.*, 390 mμ and 510 mμ, are common to the nitrous acid induced reserpine fluorogen and the natural fluorogen of 3-dehydroreserpine. (B) The fluorescent yields at the above conditions are almost exactly the same for 3-dehydroreserpine and the reaction fluorophor. (C) On different paper chromatographic systems, *viz.*, (*a*) mobile phase, 10% pyridine–90% chloroform, immobile phase, 1%

† Present address: School of Pharmacy, University of Wisconsin, Madison.

benzoic acid in formamide; (*b*) mobile phase, chloroform saturated with formamide, immobile phase, 1% benzoic acid in formamide, the R_f value for the product of the reaction mixture was the same as that for 3-dehydroreserpine.

Nitrous Acid Effects.—Figure 1 is a logarithmic plot of the concentration of unreacted reserpine, expressed as the final fluorescence (F_∞) minus the fluorescence at any time, t, (F_t) *versus* time. This plot demonstrates that at all nitrous acid concentrations a linear relationship is obtained. Thus, this reaction is an apparent first-order reaction with respect to reserpine concentration, *i.e.*,

$$-\frac{d(\mathrm{R})}{dt} = k_{\mathrm{obs.}}[\mathrm{R}_t] \qquad \text{(Eq. 1)}$$

It should be noted that one can use an expression such as $F_\infty - F_t$, because the final fluorescent intensity has been determined to be a certain value which is independent of nitrous acid concentration over a wide concentration range. Figure 2 demonstrates the relationship between the rate of fluorescent formation and nitrous acid concentration. It is seen that with increasing amounts of nitrous acid there is a corresponding increase in the rate of conversion of reserpine to the fluorophor. It is also seen that all the lines asymptotically approach the same final value.

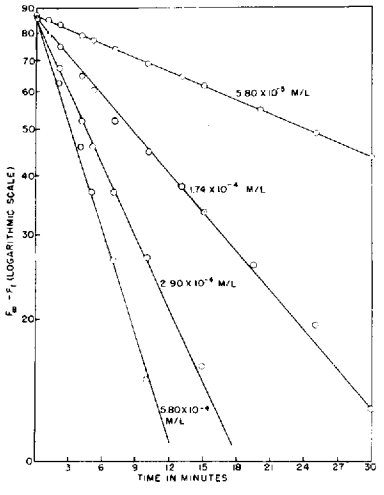

Fig. 1.—First-order plot for loss of reserpine in induced fluorescence reaction at various nitrous acid concentrations.

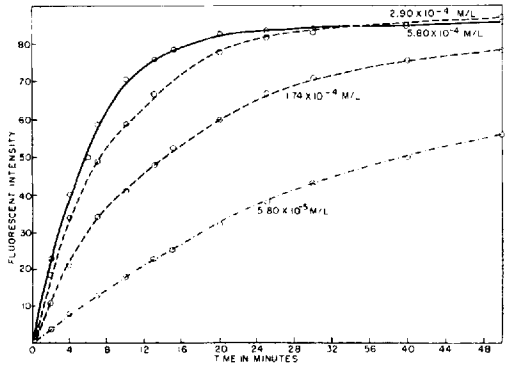

Fig. 2.—Relationship between rate of fluorophor formation and nitrous acid concentration.

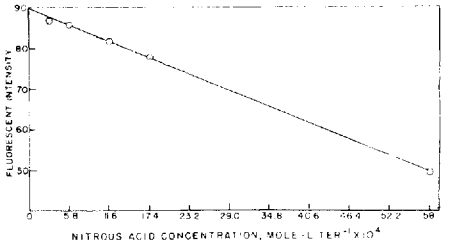

Fig. 3.—Suppression of fluorescent yield as a function of nitrous acid concentration.

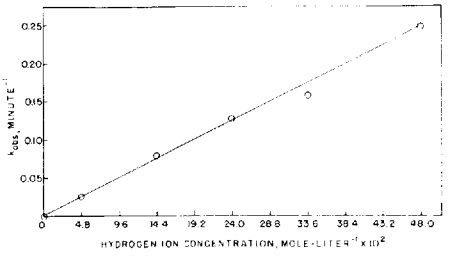

Fig. 4.—Relationship between observed rate constant and hydrogen ion concentration.

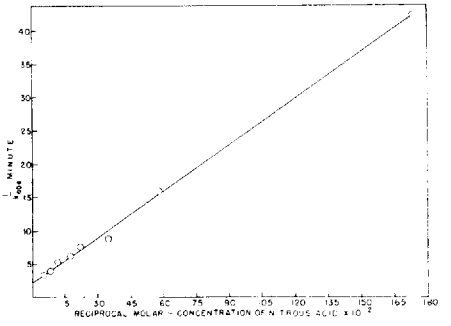

Fig. 5.—Relationship between the reciprocal observed rate constant and the reciprocal nitrous acid concentration.

However, if one extends this study to nitrous acid concentrations greater than 2.90×10^{-4} moles $L.^{-1}$ it is observed that there is a suppression of the fluorescence. The suppression of maximum fluorescence by the higher concentrations of nitrous acid is evident in Fig. 3. This straight line plot indicates that under the experimental conditions used in this study the limiting fluorescent yield is approximately 90 in the absence of the quenching effect of the nitrous acid. This type of quenching has been referred to by Bowman (10) as an inner filter effect. Apparently the excess nitrous acid absorbs some of the activating energy, or some of the fluorescent

energy, or both, thus reducing the amount of fluorescent energy reaching the measuring unit.

Rate Expression.—It was observed rather early in this work that both hydrogen ions and nitrous acid had an effect on the rate of fluorescent formation. Thus, it is obvious that the observed rate constant, $k_{obs.}$, consists of a number of component parts which can be resolved experimentally. If it is assumed that the first step in the reaction, that is the formation of the intermediate complex, is quite rapid, the rate-determining step is the second step, and the over-all rate of reaction is equal to k_2 multiplied ty the product of the concentration of the intermediate complex and the hydrogen-ion concentration, *i.e.*,

$$-\frac{d(R)}{dt} = k_2[R:HONO]\,[H^+] \quad \text{(Eq. 2)}$$

If $[R_t]$ equals the initial concentration of protonated reserpine present in the reaction mixture and [R:HONO] the concentration of the intermediate complex, then $[R_t] - [R:HONO]$ is equal to the concentration of free protonated reserpine remaining. Thus

$$K_1 = \frac{[R:HONO]}{([R_t] - [R:HONO])\,[HONO]} \quad \text{(Eq. 3)}$$

or

$$[R:HONO] = \frac{K_1\,[R_t]\,[HONO]}{1 + K_1\,[HONO]} \quad \text{(Eq. 4)}$$

By substituting Eq. 4 into Eq. 2 one obtains

$$-\frac{d(R)}{dt} = \frac{k_2\,[H^+]\,K_1[R_t]\,[HONO]}{1 + K_1\,[HONO]} \quad \text{(Eq. 5)}$$

If the right hand side of Eq. 5 is substituted into Eq. 1 the following expression for $k_{obs.}$ is obtained

$$k_{obs.} = k_2[H^+]\,\frac{K_1[HONO]}{1 + K_1[HONO]} \quad \text{(Eq. 6)}$$

If the assumptions made thus far have been correct, then one should obtain by plotting the observed rate constant *versus* the hydrogen-ion concentration a straight line which passes through the origin and whose slope is equal to k_2K_1 [HONO]/1 + K_1 [HONO]. Such a linear relationship is obtained as shown in Fig. 4. It is possible to mathematically manipulate Eq. 6 to give the following expression

$$\frac{1}{k_{obs.}} = \frac{1}{k_2K_1[H^+]}\left(\frac{1}{[HONO]}\right) + \frac{1}{k_2[H^+]} \quad \text{(Eq. 7)}$$

The above expression states that, if the original contentions are correct, a plot of the reciprocal nitrous acid concentration *versus* the reciprocal observed rate constant should yield a straight line whose intercept is equal to $1/k_2$ $[H^+]$ and whose slope is equal to $1/k_2K_1[H^+]$. Figure 5 is such a plot, and it is indeed linear. Using the above plot one is able to determine that the equilibrium constant K_1 is equal to 690 L. mole^{-1} and k_2 is equal to 2.2 L. mole^{-1} min.$^{-1}$ at a hydrogen-ion concentration of 0.24 mole L.$^{-1}$ and 25°.

The data presented above support the proposed general mechanism. However, the authors are at present unable to delineate in any great detail the nature of the nitrous acid–reserpine addition product. It apparently forms with great ease and is always in equilibrium with the unreacted alkaloid. Establishment of its chemical structure would be most interesting.

Zeta Potential in the Development of Pharmaceutical Suspensions

By ROBERT A. NASH and BRUCE E. HAEGER

A discussion of a microelectrophoretic mobility apparatus (Zeta-Meter) is presented in connection with some prerequisite studies with a model dispersed system. The limitations of the fundamental Helmholtz-Smoluchowski formula for calculating zeta potential as it applies to a study of real pharmaceutical systems is presented. A description of the apparatus, including a discussion of the advantages of the dark-field stereoscopic microscope, molybdenum-platinum electrode system, cylindrical, tube-type, plastic electrophoresis cell, and the automatic sample-transfer device is also presented. The usefulness of zeta potential in developing pharmaceutically stable, flocculated suspensions is illustrated with three different examples: (*a*) an adrenocorticoid in which flocculation was directly achieved by varying the concentration of electrolyte added; (*b*) a system in which flocculation was initially induced in the absence of an electrolyte; (*c*) the development of a diagnostic system for blood-cell agglutination testing based upon the principles of zeta potential.

ALTHOUGH the zeta potential (ZP) concept as it relates to particles in suspension has been known to colloid chemists for more than 40 years (1–3), only recently, with the introduction of new techniques for measuring electrophoretic mobility (EM), have industrial and pharmaceutical applications of its principles been possible (4–6, 15). Haines and Martin (7), studying the electrokinetic behavior of insoluble drug particles in dispersion, were able to correlate the magnitude of ZP to the caking tendencies of pharmaceutical suspensions. Since then little has been reported in the pharmaceutical literature concerning ZP. Even though the debate over the physicochemical meaning of ZP continues in the general literature (8,9), the electrokinetic behavior of dispersed systems can still be investigated in terms of an observable quantity, the EM value.

The processes involved in the formation of pharmaceutical suspensions and the concept of ZP as it applies to a study of such systems have been reviewed recently (10).

The ZP of a particle in suspension can be calculated approximately from EM with the aid of the simple Helmholtz-Smoluchowski Eq. 1. Where ZP represents the zeta potential of the suspensoid in millivolts, 4π is the Smoluchowski factor, the factor 9×10^3 converts electrostatic units to practical electrical units and microns to centimeters, η is the viscosity of the suspending liquid in poise, ϵ represents the dielectric constant of the suspending liquid, and EM represents the electrophoretic mobility of the suspensoid in μ/sec./v./cm.

$$ZP = 4\pi \cdot 9 \times 10^3 \cdot \frac{\eta}{\epsilon} \cdot EM \qquad \text{(Eq. 1)}$$

For suspensions in water at 25° Eq. 1 is reduced to

$$ZP = 12.869 \cdot EM \qquad \text{(Eq. 2)}$$

Calculation of so-called "true ZP values" in terms of the physical meaning of the system under study involves refinement of the 4π multiplication factor (9). Its magnitude, which is related to the thickness of the electrical double layer surrounding the particle, is dependent upon particle size and shape, the type and concentration of electrolyte in the bulk liquid, the distortion of the electric field by the suspended particle (electrophoretic retardation effect), the surface conductance of the electrical double layer, and ZP itself.

A series of multiplication factors for systems containing a typical 1:1 electrolyte (potassium chloride), which takes into account the influence of some of these systematic variables, have been calculated and summarized in Table I. An inspection of these values reveals that when the size of the electrical double layer is small with respect to the particle, *i.e.*, in suspensions with moderate to high concentrations of electrolyte, the Smoluchowski 4π factor can be employed with sufficient accuracy.

Received February 14, 1966, from the Pharmaceutical Product Development Department, Lederle Laboratories, Division of American Cyanamid Co., Pearl River, N. Y.
Accepted for publication May 10, 1966.
Presented to the Fifth Annual Eastern Regional Meeting, Industrial Pharmacy Section, A. PH. A. Academy of Pharmaceutical Sciences, New York City meeting, November 1965.

TABLE I.—FACTORS FOR A 1:1 ELECTROLYTE TO BE USED IN THE HELMHOLTZ-SMOLUCHOWSKI FORMULA IN PLACE OF THE 4π FACTOR

KCl Concn., % w/v	Specific Conductance, μmhos./cm.	κa [a]	ZP, mv. 0	25	50	70
		a, Particle Radius = 1 μ

[a] κa represents the ratio between the radius of the particle and the extension of the electrical double layer.

DISCUSSION

However, when the electrical double layer is extended, *i.e.*, in suspensions which contain little or no electrolyte, then the factor approaches Henry's 6π value (11). It is also well to point out that the concentration of ions (charge density) in the electrical double layer bears an inverse relationship to the size of the double layer itself.

The use of the Helmholtz-Smoluchowski formula is further complicated by the fact that the viscosity term in Eq. 1 exerts a more pronounced effect upon ZP than does the dielectric constant. For example, in calculating the ZP for particles dispersed in 50% syrup (sucrose in water) where the viscosity of the suspending vehicle at 25° is 0.125 poise and the dielectric constant is 64.2, the EM of the particle would have to be reduced by a factor of $^{1}/_{17}$ to give a ZP equivalent to that in water at the same temperature. The reason is that the viscosity of syrup is 14 times greater than that of water, while the ϵ of syrup is only $^{4}/_{5}$ of the value for water. With water systems thickened with a small amount of a hydrophilic colloid such as carboxymethylcellulose U.S.P. or methylcellulose U.S.P. (where the ϵ is essentially equal to that of water) the viscosity effect would be even greater. Therefore, it would seem plausible that the η term in Eq. 1, which in essence represents the shear stress between the electrical double layer and the bulk of the liquid, is only applicable to simple liquids. The use of non-Newtonian liquids and vehicles with viscosities greater than several centipoise units will seriously limit the usefulness of the basic Helmholtz-Smoluchowski expression.

EM is equal to the particle velocity per unit field strength and is expressed in μ/sec./v./cm. Particle velocity is determined microscopically by multiplying the divisions traveled per μ per eyepiece division and dividing the result by the time traveled in seconds. If a circular tube-type electrophoresis cell is employed, then the circle of zero endosmotic flow is situated at a depth which is 14.7% of the tube diameter. Since the over-all flow of the suspending liquid is zero at this point, the net motion is that of the particles themselves.[1] EM can be calculated from either the effective length of the electrophoresis cell, *l*, in cm.

[1] The electrophoresis cell of the apparatus is so designed as to make this critical depth coincide with the counting line on the eyepiece of the stereoscopic microscope.

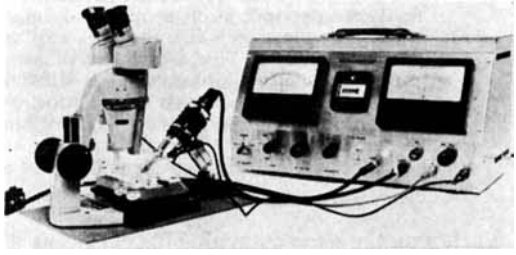

Fig. 1.—The instrument for measuring electrophoretic mobility of drug particles in suspension. Detailed instruction for its operation and calibration are provided with the equipment.

$$\text{EM} = \frac{v \cdot l}{E} \qquad \text{(Eq. 3)}$$

or from the cross-sectional area of the cell, *q*, in cm.^{2},

$$\text{EM} = \frac{v \cdot q \cdot L}{I} \qquad \text{(Eq. 4)}$$

where *v* equals particle velocity in μ/sec., *E* is the applied voltage in practical volts, *L* is the specific conductance of the cell, and *I* is the current flow through the cell in amperes. In the authors' work both Eqs. 3 and 4 were used to calculate EM.

APPARATUS

A new device[2] measures the microelectrophoretic mobility of particles in aqueous suspension. The term "Zeta-Meter" is a misnomer since the instrument neither measures nor determines directly the ZP or effective surface charge of dispersed particles. The equipment is shown in Fig. 1.

The apparatus offers the following advantages.

(*a*) Availability of a ready-to-use complete research system for determining the EM values of colloids and small dispersed particles in essentially aqueous suspension.[3]

(*b*) Since the anode chamber of the Zeta-Meter electrophoresis cell is closed and the cathode chamber is open, when electric current passes through

[2] Zeta-Meter. Marketed by Zeta-Meter, Inc., New York, N. Y.

[3] The authors are unable to comment about the capability of the instrument with respect to its use in connection with essentially nonaqueous systems because of their lack of familiarity with this particular field of study.

systems with a high concentration of electrolyte, appreciable amounts of oxygen can be produced at the anode, due to electrolysis. Such gas formation will interfere with the performance of the cell by inducing liquid movement and false particle migration. The use of a readily oxidizable molybdenum anode, which forms a tight film of oxide on its surface, prevents gaseous imbalance from creating a condition of liquid flow in the cell. A platinum strip cathode, at which hydrogen is evolved, does not induce false migration as the gas passes freely into the atmosphere. However, at low electrolyte concentrations, electrolysis is not a problem and a pair of platinum electrodes can be used. The solid molybdenum-platinum electrodes, which are provided with the unit, are more convenient than a solid-liquid, copper-saturate copper sulfate coupling, with porous plaster of paris plugs which have been previously employed to prevent gasification (12).

(*c*) The use of a stereoscopic microscope of sufficient magnification (120 to 180×) with bounced-beam illumination permits indirect viewing of colloids below 1 μ by reflected light emanating from the particle's surface. The technique is commonly referred to as the "dark-field effect." Effective view of particles extends from 0.05 to 0.02 μ. However, the lower limit of view depends upon particle shape.

(*d*) The cylindrical, tube-type plastic electrophoresis cell utilized offers several obvious advantages over the conventional Briggs flat thin-glass cell which for years has been considered a standard for EM measurement (13). The over-all depth of a Briggs cell (0.6 to 1.0 mm.) limits its ability to handle particle flocs greater than 0.1 mm. Such suspensions can be measured quite easily with the Zeta-Meter cell. In addition, the rugged construction of the plastic cell is in sharp contrast to the fragility of the glass Briggs cell.

(*e*) A new automatic sample-transfer device, also available with the basic unit, is shown in Fig. 2. This device rapidly clears the cell reintroducing fresh sample between measurements, and thereby eliminates the problem of particle drift due to the convection currents by maintaining a condition of isothermality in the cell. The problem of particle drift and thermal overturn is especially acute in flocculated or partially flocculated systems where EM is extremely slow and electrolyte concentration is high. In addition, the use of this auxiliary equipment permits an increase in the number of EM measurements that can be made with the basic unit, thereby enabling the equipment to be used as an EM or ZP titrimeter for particle adsorption and desorption study.

(*f*) In addition to these basic features, the electrophoresis cell can function as a conductivity cell once it is calibrated in the usual manner with a standard potassium chloride solution. Specific conductance values thus obtained are of sufficient accuracy and can be determined during the course of an EM measurement.

However, Schmut (14) lists several disadvantages for the apparatus in a paper concerning ZP applications in the paper industry. The most serious drawback he found is its sensitivity to vibration. The problem is especially acute when the electrophoresis cell is connected to the automatic sample-transfer device. Nevertheless, the condition can be alleviated somewhat by the use of coarse nylon screens in the inlet and outlet tubes leading to the cell. The screen apparently disrupts eddy currents that are set in motion by the oscillation of the automatic pinch-clamp.

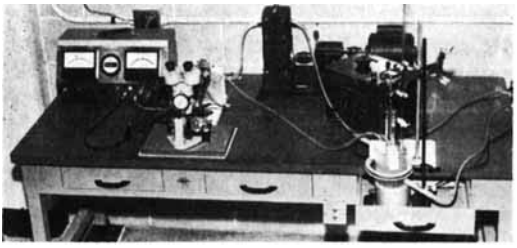

Fig. 2.—Instrumentation required to perform EM or ZP titrations, including the automatic sample-transfer device, Beckman model G pH-meter, and Zeta-Meter.

The authors have found that poor reproducibility of experimental results and meaningless EM values can be attributed to the limitation of the ZP theory to explain the significance of such data rather than instrument failure itself. Furthermore, problems of particle settling during measurement and false migration in difficult systems can be greatly diminished by the use of the automatic sample-transfer device.

STUDIES WITH PURIFIED SILICA

Purified silica[4] was selected as a model dispersed system for study. Such studies are important both as a prerequisite for work with more difficult pharmaceutical systems and to enable the investigator to become more familiar with the equipment and techniques involved in EM measurement. The material consists of high-purity, microcrystalline silica containing 99.9% silicon dioxide. Silica approaches an ideal solid for study since the material is relatively inert, suspensions of it are essentially neutral, and complications associated with surface ion-exchange are negligible (15). An additional advantage is that the material is easily wetted and simple aqueous dispersions can be conveniently prepared with low-shear equipment.

Dispersing Silica with Surfactants.—With a standard 0.01% suspension of purified silica in fresh nitrogen-sparged distilled water, a series of dispersion curves were developed with three typical surface-active agents (more commonly referred to as surfactants). They included an anionic surfactant (dioctyl sodium sulfosuccinate N.F.), a cationic surfactant (benzalkonium chloride U.S.P.), and a nonionic surfactant (polysorbate 80 U.S.P.). Surfactants are primarily used as wetting agents for hydrophobic particles, which act in this capacity by lowering the interfacial tension between suspensoid and vehicle. They can, however, also function as dispersing agents, *e.g.*, by being adsorbed on the surface of silica particles. Adsorption of a negatively charged, polymeric anionic surfactant increases the negative ZP of dispersed suspensoid particles, while conversely, adsorption of a positively charged,

[4] Purified crystalline silica was supplied by the Pennsylvania Glass Sand Corp. under the trademark 5-μ Min-U-Sil; 98% of this material has a diameter less than 5 μ. The surface area of the sample is 20,600 cm.^{2}/Gm. with an average particle size of 1.1 μ.

cationic specie reduces the existing negative ZP on silica particles. Addition of more cationic surfactant eventually produces particles that are positively charged. Since in both instances these agents are ionic in nature, there are enough dissociated counterions in the bulk liquid to induce adsorption.

Adsorption curves showing the influence of an anionic surfactant (dioctyl sodium sulfosuccinate N.F.) and a cationic surfactant (benzalkonium chloride U.S.P.) on the ZP of a 0.01% purified silica dispersion are given in Fig. 3. ZP of the suspensoid apparently increases linearly as increasing amounts of dispersant (surfactant) are added to the system. A point of maximum particle dispersion is reached which corresponds to the point of maximum ZP, either negative or positive depending upon the surfactant under study. In an adsorption process (which will be briefly discussed later) this also corresponds to the formation of a monolayer of adsorbed surfactant. Further addition of surfactant beyond this critical point produces no additional change in ZP which is reflected in no further adsorption of dispersant. The region of maximum ZP for these dispersants is also apparently very close to the critical micelle concentration (CMC) of the surfactants themselves.[5] Since the shapes of interfacial tension curves for determining the CMC of surfactants are also quite similar to the dispersion curves shown in Fig. 3, and since both parameters are manifestations of a more basic adsorption process, it is conceivable that a ZP technique, such as the one described above, can also be used to determine the CMC of surfactants.

With nonionic surfactants (Fig. 4), since the polymer supplies no appreciable ionic species to induce adsorption, the addition of an electrolyte, such as potassium chloride, is required. In essence, the presence of an electrolyte alone is all that is required to disperse silica particles. The addition of a nonionic surfactant merely decreases the concentration of electrolyte required for dispersion. However, the presence of a nonionic surfactant such as polysorbate 80 U.S.P. also apparently decreases the ZP required for complete dispersion and thus interferes with the establishment of a strong electrical double layer, probably through steric hindrance of adsorbed, bulky, surfactant molecules. Therefore, nonionic surfactants are probably less efficient dispersing agents for silica and other suspensoids than are their ionic counterparts.

Influence of Various Polyvalent Anions on Purified Silica Dispersions.—As was previously pointed out, electrolytes alone can be used to disperse silica particles in suspension. A series of dispersion curves, in which the addition of various sodium salts (chloride, sulfate, citrate, and pyrophosphate) were used to disperse a standard 0.01% silica suspension, are shown in Fig. 5. The salts show an increasing order of dispersing efficiency as polyvalent anions. On a molar basis, approximately 3 times more citrate ion, approximately 6.6 times more sulfate ion, and 10.6 times more chloride ion is required to achieve the same degree of dispersion as with the quadrivalent pyrophosphate ion.

The magnitude of the ZP of dispersed silica particles is also increased when polyvalent ions are used to aid dispersion. In all cases, however, the addition of excess electrolyte well beyond the point of maximum dispersion causes a reduction in ZP which has been described as the "bulk stress effect" (17). The phenomenon is probably caused by the collapse of the electrical double layer by the proximity of large numbers of counterions in the vicinity of the particle. With particles that are coated with adsorbed colloids or polyelectrolytes, bulk stress may induce a "salting out" of colloid, which alone is sufficient to decrease ZP.

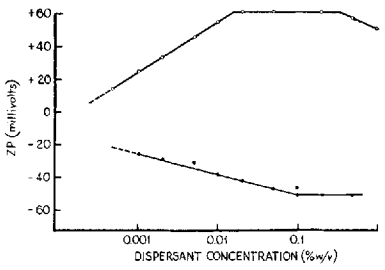

Fig. 3.—The influence of two ionic surfactants on the ZP of a 0.01% purified silica suspension. Key: top curve, benzalkonium chloride U.S.P. (cationic type); bottom curve, dioctyl sodium sulfosuccinate N.F. (anionic type).

Quantitative treatment of the efficiency with which polyvalent electrolytes disperse silica is complicated by the ionization, in solution, of the various polyprotic acids (sulfuric, citric, and pyrophosphoric) which produce these salts. No attempt was made in this study to work at a constant pH value, nor was there any attempt to consider the contribution of lower valence anions in the dispersion process.

In addition to their ability to increase the efficiency of particle dispersion, the size and type of both anions and cations are also important in the flocculation of suspended particles (18).

Dispersion as an Adsorption Process.—Another basic study of silica was concerned with determining the amount of dispersant required for maximum dispersion. Dispersion curves were constructed for a series of concentrated silica suspensions. Sodium hexametaphosphate was selected as a dispersing agent.[6] Increasing amounts of the dispersant were added to each suspension in order to determine, graphically, the amount of reagent required to reach the point of maximum ZP. This particular value is associated with the adsorption of a monolayer of dispersant on the silica particles. The amount of dispersant required in the bulk liquid to initiate adsorption was readily determined by preparing a very dilute 0.001% silica suspension. Since the concentration of silica was extremely small (10 p.p.m.) EM measurements were made directly on the suspension. In determining the EM values for the more concentrated silica slurries (5, 10, 20, and 50%), after a calculated amount of dispersant was added during each step in the construction of the dispersion curve, a sample of the slurry was filtered through a medium porosity, cellulose nitrate-membrane filter to obtain a clear filtrate of equilibrated bulk liquid. A small amount of concentrated residue was added to permit maximum visibility of silica particles for measurement. Samples prepared

[5] Determined experimentally by the surface tension method (16).

[6] The sodium hexametaphosphate used in this study was a sample supplied by the Olin Mathieson Chemical Corp. under the product designation Sodium Polyphos Ground.

in this manner gave EM values that were representative of the concentrated slurry from which they were prepared. In this manner, a series of dispersion curves were constructed for highly concentrated slurries of silica which could not be measured in the electrophoresis cell directly. The resulting dispersion curves are presented in Fig. 6.

The relationship between the amount of dispersant adsorbed and its concentration in the suspending vehicle may be represented by the adsorption equation of Langmuir (19), which is based upon a supposition that dispersion is fundamentally an adsorption process. A plot of concentration of dispersant per ZP *versus* concentration of dispersant yields a straight line whose slope is equal to some conversion constant multiplied by the Langmuir factor β/α and an intercept equal to $1/\alpha$. The Langmuir equation differs from other adsorption isotherms in that adsorption approaches a finite limit (the point of maximum ZP) as the concentration of dispersant added is increased. However, beyond the point of maximum dispersion no further adsorption takes place (Figs. 3–6). The relative constancy in ZP beyond the point of maximum dispersion is further proof that these particular dispersions conform to a Langmuir adsorption process.

In Fig. 6, the average amount of sodium hexametaphosphate adsorbed per gram of silica was found to be 0.655 mg./Gm. and the amount of dispersant in the bulk liquid required to initiate adsorption was 0.052 mg./ml. Since sodium hexametaphosphate is a water-soluble, glassy, condensed polymeric phosphate of indefinite composition, no attempt was made to determine the surface area of dispersant for monolayer adsorption. Nevertheless, the amount of dispersant required for complete disper-

sion for any given slurry concentration of silica can be calculated according to the method of Riddick (20) from the two values reported above.

Attempts to determine the amount of an anionic or cationic surfactant required to completely disperse silica or any other suspensoid, are complicated by the fact that a portion of surfactant added to such systems usually is involved in micelle formation, which apparently is a competitive physical phenomenon.

APPLICATION OF ZETA POTENTIAL IN PHARMACEUTICAL PRODUCT DEVELOPMENT

The following three examples were chosen to illustrate how ZP can be used to develop pharmaceutically stable, flocculated suspensions.

Influence of Electrolyte in Altering ZP.—A formulation for a parenteral suspension of an adrenocorticoid was developed empirically without the use of the apparatus. The system consisted of 4% micronized steroid suspended in an aqueous vehicle composed of a wetting agent (polysorbate 80 U.S.P.) to disperse the drug, a preservative (benzyl alcohol), an electrolyte (sodium chloride) to adjust tonicity, and a small concentration of an adjuvant polymer (polyethylene glycol 4000 U.S.P.) to provide a pharmaceutically stable, "noncaking"

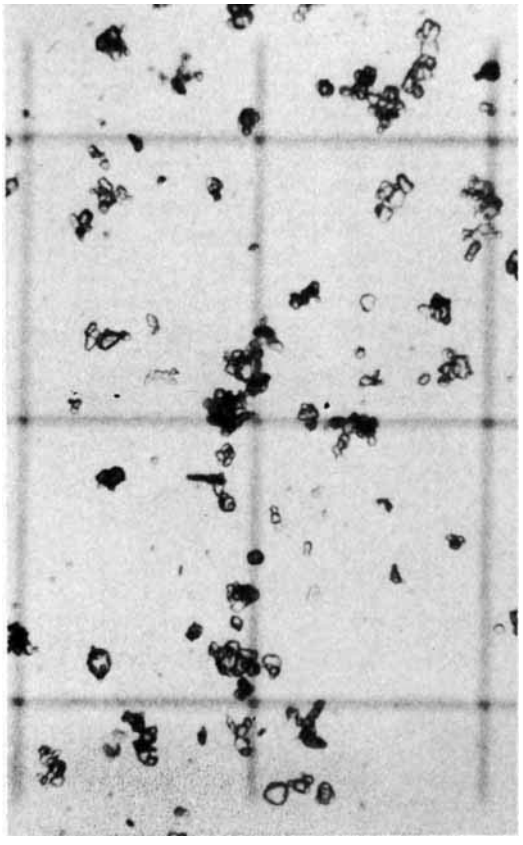

Fig. 9.—Photomicrograph of a deflocculated suspension prior to the addition of a critical concentration of a nonelectrolyte. The width of each scale division equals 96 μ.

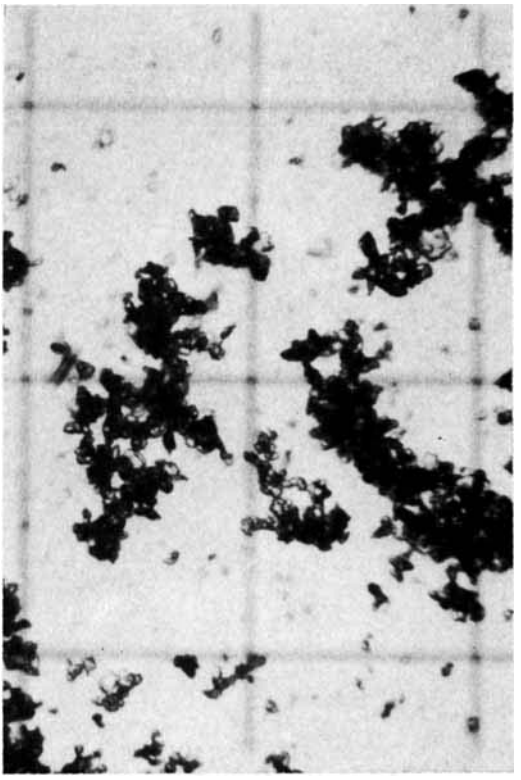

Fig. 10.—Photomicrograph of a partially flocculated suspension after the addition of the nonelectrolyte. The width of each scale division equals 96 μ.

suspension. It was assumed that "stable floc" formation was brought about by the presence of a critical amount of nonionic surfactant acting in combination with the polymer and electrolyte. In succeeding batches of the formula, the degree of overflocculation increased resulting in a suspension with poor drainage characteristics. The basic suspension was examined with the apparatus in order to determine the agent or agents actually responsible for flocculation.

A series of desorption curves were run using a $^1/_{50}$ dilution of the 4% suspension in additional suspending vehicle. Further dilutions ($^1/_2$, $^1/_4$, $^1/_8$, $^1/_{16}$, etc.) were made by replacing half of the total volume in each step with an equal volume of either distilled water or a series of different partial vehicles. The partial vehicles consisted of the complete vehicle formula minus one of the components, such as sodium chloride or polysorbate 80. The results are summarized graphically in Fig. 7.

Suspensions diluted with partial vehicles that contained sodium chloride did not deflocculate. These systems were all fully flocculated and maintained a zero ZP throughout the range of dilution. Dilution with water produced a smooth deflocculation or desorption curve after the third dilution step. Dilution of the suspension with a salt-free vehicle containing all vehicle components minus sodium chloride also produced a desorption curve. In this system, deflocculation was also initiated after the third dilution step when the salt concentration was

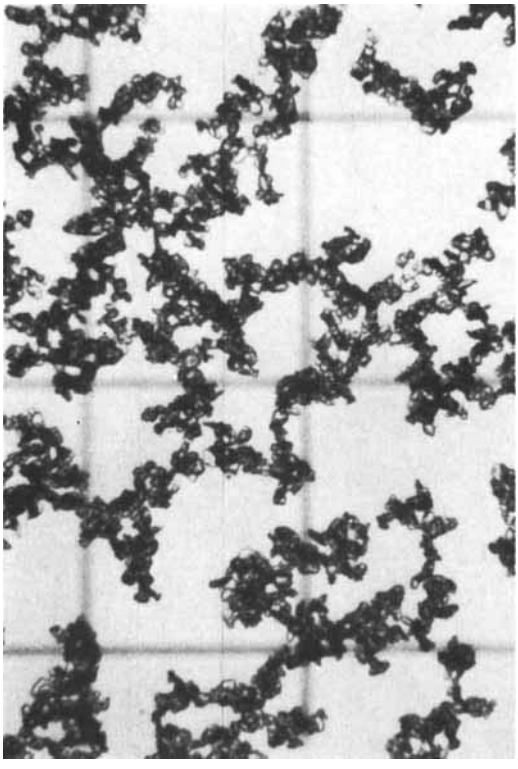

Fig. 11.—Photomicrograph of the suspension completely flocculated with the required concentration of McIlvaine buffer. The width of each scale division equals 96 μ.

reduced below 0.106%. However, the sigmoidal shape of the deflocculation curve in the region between 0.016 and 0.013% sodium chloride was apparently the result of a differential desorption.

In differential desorption, as the concentration of electrolyte and surfactant polymer is reduced, some suspensoid particles may begin to develop their own integral electrical double layer, a manifestation of which is the increase in ZP while other particles remain either partially or fully flocculated. The difference in the rate of desorption between smaller ions and larger polymer molecules apparently produces this effect.

In analyzing the desorption curves in Fig. 7, it is clear that the presence of a small concentration of electrolyte provided the necessary driving force to produce particle flocculation. However, it is not readily apparent in this study of desorption whether this is accomplished by destroying the integrity of the particles coated with adsorbed surfactant-polymer through a salting out process with electrolyte, or forcing interparticle bridging with polymer-surfactant and electrolyte. In any case, reducing the concentration of electrolyte in the formula improved drainage and the physical stability of the over-all suspension. These results also showed that an excess of salt was not required to produce "stable floc" formation.

Flocculation in the Absence of an Electrolyte.—In another example, primary flocculation was initiated in the absence of an electrolyte. Nonionic surfactants, such as polysorbate 80, acting in combination with certain other nonelectrolytes at a critical ratio of surfactant to nonelectrolyte, have the ability to produce partially or fully flocculated suspensions. However, with respect to ZP, since these systems are hydrophobic drug particles, some source of ions is required in the environment of the particle to establish a surface charge and/or electrical double layer. Therefore calculated ZP values of minus 10, 20, or 30 mv. have little or no practical significance for systems composed of neutral drug particles, nonelectrolytes, and nonionic surfactants. However, with the introduction of electrolyte, a degree of stability with respect to the ZP of the suspensoid is realized and a trend toward either deflocculation or flocculation can be ascertained.

Figure 8 shows complete adsorption and desorption curves for a drug suspension that was partially flocculated with a combination of a nonionic surfactant and a nonelectrolyte. "Stable-floc" formation was initiated with the addition of 0.03 ml. of 0.5 *M* McIlvaine buffer and completed when a total of 40 or 50 ml. of the same buffer had been added. Photomicrographs of suspensions are presented in Figs. 9–11, respectively, that show (*a*) the condition of deflocculation before the critical concentration of nonelectrolyte was added, (*b*) partial flocculation after the addition of the nonelectrolyte, and (*c*) complete flocculation when the buffer was added. The addition of electrolyte to the system in the absence of the required nonelectrolyte produces a dispersed or deflocculated system. Visual and photomicro-

scopic inspection of these three suspensions were used to confirm the authors' findings with the apparatus.

Therefore, a physically stable suspension of the drug was developed using a calculated amount of buffer to maintain pH control and insure complete floc formation.

Flocculation with Anti-D Sera Using Purified Silica.—The final example is drawn from experiences with a biological application in determining the flocculating efficiency of several anti-D sera, available as diagnostic reagents for Rh blood typing. It was felt that a suitable product could be developed with the proper ZP for agglutination testing. Purified silica was chosen as a substitute for red blood cells (RBC's) because of the difficulties involved in working with blood dispersions (21).

Approximately 500 ml. of a 0.01% purified silica dispersion in 0.45% sodium chloride solution was prepared. The ZP of such a system (approximately −30 mv.) is comparable to the value for human blood dispersions in saline solution (22). Increments of a $^1/_{100}$ dilution of anti-D serum in 0.45% sodium chloride solution were added to each purified silica dispersion. The EM of the system was determined after each addition of reagent. After a total of 0.02% serum reagent had been added, undiluted portions of serum were used to complete each ZP titration.

The results of this study are presented in Fig. 12. The flocculating efficiency of the improved formula *A* was found to be greater than a control system *B* or the original formula *C*. Recommendations for product improvement were made on the basis of a previous study of the original formula *C*. The amount of anti-D serum required to obtain complete flocculation was based upon an extrapolation of linear portions of each test curve to the isoelectric point (zero ZP). The length of the concentration-induction period before flocculation began was also related to the efficiency of the diagnostic reagent. The ranking of the three anti-D sera according to flocculating efficiency for purified silica correlated very well with results of blood-test agglutination with human RBC's.

Method for the Direct Measurement of Acetylsalicylic Acid in Human Blood

By V. F. COTTY and H. M. EDERMA

A procedure was developed for directly determining acetylsalicylic acid in human blood specimens. The method instantly stops enzymatic hydrolysis, removes salicylic acid and conjugates of salicylic acid by reaction with ceric ammonium nitrate, automatically hydrolyzes acetylsalicylic acid, and determines the resulting salicylic acid fluorometrically. It sensitively measures acetylsalicylic acid in the presence of salicylic acid, salicylamide, salicyluric acid and salicylic acid ether glucuronide (*O*-carboxyphenyl glucuronide).

SEVERAL recent publications have reported acetylsalicylic acid (ASA) concentrations in the blood of humans following the ingestion of ASA-containing proprietary preparations (1–3). In each case, ASA was calculated as the difference between the level of salicylic acid (SA) in the hydrolyzed and unhydrolyzed serum (1) or in the blood extracts (2, 3). "Difference" procedures can be characterized by

scopic inspection of these three suspensions were used to confirm the authors' findings with the apparatus.

Therefore, a physically stable suspension of the drug was developed using a calculated amount of buffer to maintain pH control and insure complete floc formation.

Flocculation with Anti-D Sera Using Purified Silica.—The final example is drawn from experiences with a biological application in determining the flocculating efficiency of several anti-D sera, available as diagnostic reagents for Rh blood typing. It was felt that a suitable product could be developed with the proper ZP for agglutination testing. Purified silica was chosen as a substitute for red blood cells (RBC's) because of the difficulties involved in working with blood dispersions (21).

Approximately 500 ml. of a 0.01% purified silica dispersion in 0.45% sodium chloride solution was prepared. The ZP of such a system (approximately −30 mv.) is comparable to the value for human blood dispersions in saline solution (22). Increments of a $^1/_{100}$ dilution of anti-D serum in 0.45% sodium chloride solution were added to each purified silica dispersion. The EM of the system was determined after each addition of reagent. After a total of 0.02% serum reagent had been added, undiluted portions of serum were used to complete each ZP titration.

The results of this study are presented in Fig. 12. The flocculating efficiency of the improved formula *A* was found to be greater than a control system *B* or the original formula *C*. Recommendations for product improvement were made on the basis of a previous study of the original formula *C*. The amount of anti-D serum required to obtain complete flocculation was based upon an extrapolation of linear portions of each test curve to the isoelectric point (zero ZP). The length of the concentration-induction period before flocculation began was also related to the efficiency of the diagnostic reagent. The ranking of the three anti-D sera according to flocculating efficiency for purified silica correlated very well with results of blood-test agglutination with human RBC's.

[a] ASA and related compounds were added to whole pooled human blood and ASA was then determined. Concentrations in mcg/ml.

accumulated errors which may become particularly serious when a small difference exists between large analytical values. Thus, it is difficult to measure low concentrations of ASA in the presence of relatively high concentrations of SA by these methods. A second problem is that the difference method may not distinguish between ASA and conjugates of SA. The purpose of the present communication is to present a semiautomated direct procedure for the determination of ASA in human blood which is not interfered with by SA, salicylamide, salicyluric acid, or salicylic acid ether glucuronide (*O*-carboxyphenyl glucuronide).

EXPERIMENTAL

Determination of ASA.—Blood specimens are initially inactivated and extracted as described by Cotty *et al.* (3) in the following manner. Five milliliters of whole blood, immediately upon withdrawal, are measured into a bottle containing 0.5 ml. of 6 *N* HCl and 50 ml. of ethylene dichloride (EDC). The bottle is capped with a polyethylene snap cap and then immediately shaken vigorously by hand until the blood becomes a brown color. The bottle is then shaken on a mechanical shaker for 10 min. The EDC is separated from the precipitated blood by filtering through dry filter paper (Whatman No. 42). The EDC extract is placed in a bottle containing 0.1 ml. of an aqueous solution of 40% ceric ammonium nitrate and 5.9 ml. of distilled water. The bottle is then capped and shaken on a mechanical shaker for 1 hr. The EDC is separated from the aqueous layer in a separator and filtered through a dry Whatman No. 42 filter paper. Thirty milliliters of the filtered EDC is transferred to a bottle containing 4 ml. of 1% $NaHCO_3$. This bottle is capped and shaken vigorously on a mechanical shaker for 10 min. Upon separation, the aqueous layer is transferred into a polystyrene sample cup which is placed in the sampler of a system[1] consisting of a special salicylate manifold, proportioning pump, heating bath, fluorometer, and recorder. (See Fig. 1.) As it traverses this system, the sample is mixed

20	6.8	0.44	38	6.3	1.24	39	7.9	0.66	40
40				4.6	1.28	38	4.8	0.27	40
60				1.9	1.40	39	2.7	0.17	40

[a] Each subject ingested 2 tablets of proprietory buffered ASA (10 gr.) after the initial (blank) blood specimen was drawn. Other specimens were drawn for analysis at the time intervals indicated. The results of two studies employing the difference method and one the direct procedure are shown in the table.

with air and 1 N NaOH in a double mixing coil. The sample then passes through a heating bath at 37.5° where aspirin hydrolysis is completed. The analytical sample is then mixed with 5 N NaOH and passed through the fluorometer flow cell. The range selector of the fluorometer is set at 30X with a No. 4 light shield slit and interference filters of 385 and 405 mμ. The results are recorded on a linear recorder. A reagent baseline is established at about 15% transmission with a 1% $NaHCO_3$ solution in the place of the sample. The sampler is set at 60 samples per hour and samples are placed in alternate holes on the turntable. Ethylene dichloride (EDC) used for the extractions was specially prepared by the Fisher Scientific Corp., Fairlawn, N. J. Ceric Ammonium Nitrate was manufactured by the G. F. Smith Co., Columbus, Ohio. Pure salicyluric acid (4) and salicylic acid ether glucuronide (*O*-carboxyphenyl glucuronide) (5, 6) were synthesized.[2] These compounds yielded satisfactory elemental analyses and produced single spots when subjected to thin-layer chromatography. Salicylamide and aspirin were U.S.P., and all other chemicals were of reagent grade. Standard curves are prepared by adding 1 to 10 mcg. of aspirin per ml. of freshly drawn blood and then carrying out the procedure as described above. ASA concentrations are plotted against peak heights.

Results.—Table I lists the amount of ASA found when analyses were performed upon blood to which known amounts of ASA had been added. The addition of related substances (salicylic acid, salicylamide, salicyluric acid, and salicylic acid ether glucuronide) does not affect precision because the discrepancies between added and found amounts of ASA are small and not increased over those obtained when ASA alone is present.

A practical comparison of the difference and direct methods was made in the following manner. Data collected from two absorption studies in which the difference method (3) was used were compared with a study in which the direct method was employed.

Each subject received two tablets (total 10 gr. ASA) of proprietary aspirin[3] and blood specimens were collected immediately before and at 10, 20, 40, and 60 min. after administration.

One study employing the "difference" method measured ASA blood levels at 10 and 20 min. has been reported previously (3). The second measured ASA blood levels at 20, 40, and 60 min. The single study employing the direct procedure measured ASA levels at 10, 20, 40, and 60 min. Thirty-eight to 40 persons were employed in each study. In most cases the subjects were the same for all studies. The analytical data of all studies are plotted in Fig. 2. The arithmetic means and standard errors are tabulated in Table II. Note the general agreement between results obtained with the two different analytical procedures. There are no significant differences between corresponding values.

DISCUSSION

Previous attempts to develop chemical procedures for the direct determination of ASA have been frustrated by its lack of a suitable characteristic group which easily reacts with appropriate reagents. The present methodology makes use of this situation, for it employs a reagent, ceric ammonium nitrate, which reacts with compounds possessing the phenolic or aliphatic hydroxyl group, as do the metabolites of ASA. The use of this reagent resulted from a screening of a number of reagents which were known to react with phenols. The formation of complexes with phenols and their subsequent oxidation by ceric salts has been described by Duke and Smith (8) and Sharma and Mehrotra (7). Thus, acetylation "protects" the phenolic group in ASA and this substance remains in solution in the organic solvent.

The high sensitivity and specificity of the procedure described above should make it a useful tool in investigations into the nature of the pharmacological responses produced by the ingestion of ASA as well as other salicylates. Much present day research on salicylates involves the relative roles of ASA and SA in the analgesic, antipyretic, and anti-inflammatory responses to salicylate therapy. These can be tested more reliably with the use of the procedure described above.

SUMMARY

A direct, semiautomated method for the determination of ASA in human blood has been described which is sensitive, reproducible, and specific. Results obtained during absorption studies of ASA in which this method was employed yielded results similar to those obtained in studies employing a "difference" method.

Some Factors Affecting the Release of a Water-Soluble Drug from a Compressed Hydrophilic Matrix

By HERBERT LAPIDUS* and NICHOLAS G. LORDI

A number of factors controlling the rate of drug release from a hydrophilic matrix were investigated. The release of chlorpheniramine maleate from a hydrated methylcellulose matrix was found to be controlled largely by drug diffusivity rather than dissolution of polymer and water penetrability. The release pattern obtained appears to follow the theoretical relationships previously proposed for solid drugs dispersed in solid matrices.

THIS STUDY has been undertaken in an effort to quantitatively describe the mechanism of drug release from a prolonged action tablet previously patented (1), more recently described in the literature (2), and currently providing the basis for several pharmaceuticals. This tablet utilizes a hydrophilic polymer as a matrix in order to inhibit the release of water-soluble and slightly water-soluble active ingredients so as to afford continuous release of said medication.

The release pattern obtained from such a tablet, when measured under idealized conditions, appears to follow the theoretical relationships proposed by Higuchi in his equation dealing with the rate of release of solid drugs suspended in ointment bases (3) and subsequently applied to solid drugs dispersed in solid matrices (4). The equation describing drug release from the single face of a tablet is

$$Q = \left[\frac{D\epsilon C_s}{\tau}(2A - \epsilon C_s)t\right]^{1/2} \qquad \text{(Eq. 1)}$$

where Q is the amount of drug released per unit surface after time, t, D is the diffusion coefficient of the drug in the release medium, ϵ is the porosity of the tablet, τ is the tortuosity of the tablet, C_s is the solubility of the drug in the release medium, and A is the concentration of the drug in the tablet.

Desai *et al.* (5) have recently reported an experimental study of factors influencing drug release from tableted insoluble plastic matrices to which Eq. 1 was applied. This report deals with release from a matrix that reacts with the release medium, a case which was excluded in the derivation of Eq. 1.

EXPERIMENTAL

The tablets used in this study were prepared by mixing chlorpheniramine maleate U.S.P. with a hydroxypropyl methylcellulose ether[1] and granulating with U.S.P. ethanol. The granulation was dried and screened through a 20 mesh sieve. A 7/16 in. flat face tablet was made from this granulation using a Carver press at a force of 3000 lb. Each granulation was assayed by dispersing it in water to effect solution of the drug and measuring the absorbance of the resulting solution at 262 mμ.

Chlorpheniramine maleate was selected as an example of a soluble drug whose ultraviolet absorption characteristics enabled its measurement without interference from other components of the tablet. The methylcellulose was selected as an example of a polymer whose effectiveness in delaying drug release had been demonstrated both *in vivo* and *in vitro* (1). It rapidly hydrated on contact with water, yet was not readily water dispersible.

The tablet was forced into a cylindrical tube composed of a fluorocarbon polymer[2] which had been machined so that a precise fit was obtained. Consequently, drug release could be measured from a single face of the tablet. No water was observed to penetrate between the tablet and the walls of the cylinder, thus eliminating the need to embed the tablet in wax as has previously been required with glass (5).

In order to obtain an accurate picture of the initial stages of drug release, a modification of the continuous flow technique described by Sjogren and Ervik (6) was utilized. A sketch of the apparatus is shown in Fig. 1.

The tablet in its holder was placed into a specially designed flow cell so that a constant flow of solvent could be maintained past the tablet face with no undue turbulence. The total volume of fluid circulating through the apparatus was 155 ml. The entire flow cell was immersed in a water bath so as to maintain the temperature at 37°. The flow of solvent through the cell was accomplished by means of a model T-8 Sigma-Motor pump set at a speed of 75 ml./min. A continuous flow cell, Beckman No. 92522, was positioned in a Beckman DK-2 recording spectrophotometer. The instrument was operated at the required fixed wavelength (262 mμ for all release media studied) and absorbance recorded as a function of time, usually for a period of 115 min. An absorbance value of 1.00 measured under these conditions was equivalent to the release of 10.3 mg. of drug in pure water.

Figure 2 shows the absorbance-time curve characterizing the release of chlorpheniramine maleate in pure water using a 300-mg. tablet containing 50 mg. of drug. This result was duplicated on numerous occasions to within ±1% deviation. The lag time in the apparatus at 75 ml./min. was 1.1 min. At lower flow rates an oscillation in the absorbance curve (the dotted line in Fig. 2), whose amplitude increased with diminishing flow rate, was observed during the first 15 min. of the experiment. The oscillation was effectively eliminated at 75 ml./min. flow rate.

In some experiments drug release from the whole tablet was measured, using the U.S.P. disintegration test apparatus (7) and a large beaker in place of the specially designed flow cell. A single tablet was confined in one of the tubes of the apparatus by a coarse wire mesh screen so that the tablet would not float to the surface. The release pattern was found to be independent of the rate of flow of solvent main-

tained through the spectrophotometer. The total volume of solvent was 1 L.

RESULTS AND DISCUSSION

Figure 3 shows plots of amount of drug released as a function of $\sqrt{t}$ demonstrating the apparent application of Eq. 1, which predicts a linear relationship, to this system. These data refer to 300-mg. tablets containing between 25 and 150 mg. of chlorpheniramine maleate, the remainder of the tablet being polymer. Furthermore, Fig. 4 indicates that a plot of the slopes of these lines (determined by a least mean squares fitting of the data) as a function of the dose of drug in the tablet is also linear up to 100 mg.

This is in agreement with a further extension of Higuchi's theory (4) which considers the effect the dissolution of the active material may have on the release rate. In this case the leaching type of release mechanism depends not only on diffusion outward but also on the change in porosity due to the elimination of this material from the tablet matrix. Equation 1 can be modified by introducing a linear relation between drug concentration and porosity, assuming that the initial porosity of the matrix is negligible. Therefore,

$$\frac{Wr}{t^{1/2}} = W_0\left(\frac{S}{V}\right)\sqrt{\frac{DKC_s}{\tau}(2 - KC_s)} \quad \text{(Eq. 2)}$$

should quantitatively describe Fig. 4. Here Wr is the amount of drug released in time, t, W_0 is the dose, S is the effective diffusional area, V is the effective volume of the matrix, and K is introduced to convert A ($= W_0/V$) to its corresponding volume fraction.

If one visualized water penetration as a front moving into the tablet, hydrating the polymer matrix, and dissolving the active material, which then diffuses out through this hydrated matrix, the application of Eq. 1 to this system would appear to be valid. Since the polymer swells on hydration, V in Eq. 2 is considerably greater than the volume of the tablet. Furthermore, it was noted that the face of the hydrated polymer film formed at the surface of the tablet was not planar but slightly convex. A slight lateral extension of the film was also observed, making S in Eq. 2 greater than the area of the tablet face. However, no significant change in diffusional area was evident once the film formed. Generally, this required less than 3 min. In an experiment in which the tablet (containing 50 mg. of drug) was depressed 0.15 mm. in its holder, $Wr/\sqrt{t}$ was found to be 12% less than the value observed when the tablet was flush with the surface of the holder. This indicated the magnitude of the area change owing to lateral extension, although a change in the effective diffusional path length may also be involved.

If Eq. 2 was applied to an insoluble matrix, K would be the specific volume of the drug. However, K must be interpreted as the fraction of hydrated polymer volume replaced by a unit weight of drug. Thus, K equals the product of the specific volume of the drug and the ratio of the volume of the hydrated to unhydrated matrix. Consequently, the replacement of polymer by an insoluble as well as a soluble diluent should result in an increase in the rate of drug release (contrary to the case of an inert matrix). The $Wr/\sqrt{t}$ values observed for 300-mg. tablets containing 50 mg. of chlorpheniramine maleate and 75 mg. of diluent were 33.2 and 24.6% greater than that observed in the absence of the diluent for lactose and tricalcium phosphate, respectively.

The tortuosity must also be a function of the extent of hydration and type of gel structure formed as water penetrates the matrix. This factor would also be influenced by air entrapped in the matrix as well as the presence of diluent. The deviation from linearity observed in Fig. 4 at high drug doses (>100 mg.) could be explained by an effective decrease in tortuosity resulting in increased drug release.

Equation 1 was derived assuming that $A \gg \epsilon C_s$. In the case of chlorpheniramine maleate, $C_s > A$. In order for Eq. 2 to apply, ϵ must be $\lesssim 0.1$. This requires that the free volume of solvent (that available to dissolve drug) be less than 10% of the volume of the hydrated matrix. If $\epsilon C_s \gtrsim A$, then the following equation would apply (4):

$$\frac{Wr}{t^{1/2}} = 2W_0\left(\frac{S}{V}\right)\sqrt{\frac{D}{\tau}} \quad \text{(Eq. 3)}$$

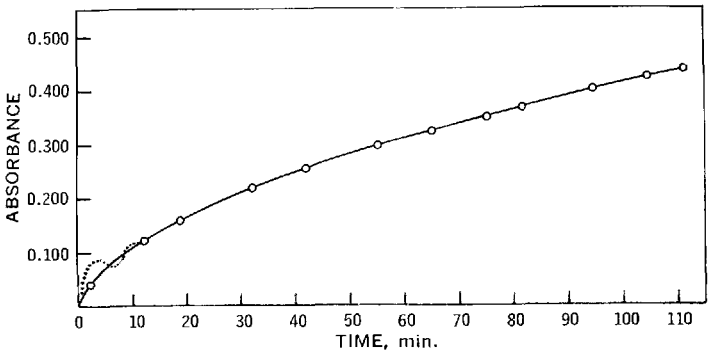

Fig. 2.—Absorbance *vs.* time curve characterizing the release of chlorpheniramine maleate and the effect of flow rates on the actual spectrophotometric recording. Key: ——, 75 ml./min.; . . . . ., 18 ml./min.

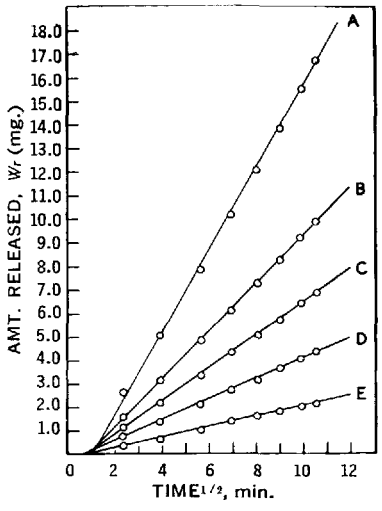

Fig. 3.—Drug release as a function of the square root of time for tablets with varying concentrations of chlorpheniramine maleate. Key: A, 150 mg. per tablet; B, 100 mg. per tablet; C, 75 mg. per tablet; D, 50 mg. per tablet; E, 25 mg. per tablet.

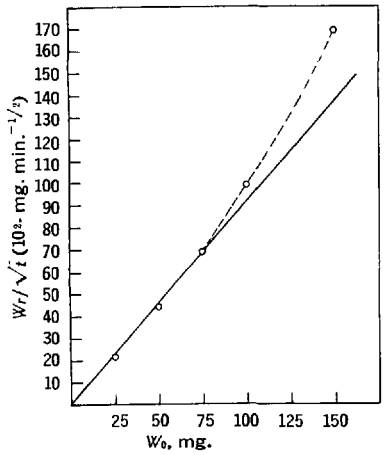

Fig. 4.—Plot of the slopes of the lines represented in Fig. 3 as a function of the dose of drug in the tablet.

In this case, the solvent penetrating the matrix is assumed to completely dissolve the drug on contact. This does not appear to be the case in the specific system reported here.

The term $S/V\tau^{1/2}$ in Eqs. 2 and 3 should measure the effect of the polymer and that of any other parameter which alters the hydration of the polymer in controlling drug release from tablets consisting of only drug and polymer. This presumes no significant complexation between the drug and polymer. The effect of changes in the ionic composition of the solvent should be largely reflected in this term.

Table I lists $Wr/\sqrt{t}$ values obtained in experiments in which the pH or salt content of the solution was varied. In all cases listed, excellent linearity of $Wr/\sqrt{t}$ plots was observed. A specific proton effect was noted. The results indicate that release rates in gastric and intestinal juices will be significantly different if pH is the only factor influencing release. This is consistent with the observed reduction in viscosity of methylcellulose solutions at pH values < 3 (8). This can be attributed to a reduction in hydration owing to protonation of ether linkages. In effect, the tortuosity of the hydrated film is decreased. The decrease in slope observed at pH 7.5 is probably the result of a decrease in the effective solubility of chlorpheniramine maleate owing to a decrease in dissociation.

On the other hand, electrolytes apparently increase the tortuosity of the hydrated film. Since ions reduce the activity of water, hydration of the matrix should be reduced, resulting in a decreased drug release rate. However, when the concentration of sodium sulfate and magnesium sulfate was raised to 0.2 *M*, a very sharp rise in drug release was encountered. This apparent inconsistency may be explained by considering that when the salt content is increased beyond a certain point, the activity of the water becomes so greatly reduced as to prevent uniform hydration of the gum. This then results in a massive discontinuity in the gel structure. In fact, upon removal of the tablet holder from the solvent, a noticeable elongation of the tablet was observed at the 0.2 *M* concentration. It no longer had a flat surface exposed but looked like an inverted "gum drop" with a greatly enlarged surface. Another factor that may be important is that the gel point of the methylcellulose is reduced to less than 37° in these solutions. The effect was not observed when release was measured at 25°.

Table I.—Effect of pH and Salt Concentration on $Wr/\sqrt{t}$ Values Obtained for Tablets Containing 50 mg. Chlorpheniramine Maleate

Solvent	Ionic Strength	pH	$Wr/\sqrt{t}$ 10^2 mg. min.$^{-1/2}$
0.15 *M* sodium acetate			
0.015 *M* boric acid	0.15	7.5	38.6
Water	0	≈5.5	45.5
0.015 *M* sodium acetate			
0.06 *M* acetic acid	0.015	5.2	45.1
0.001 *N* hydrochloric acid	0.001	3.0	47.6

0.30 *M* sodium chloride	0.30	...	38.6
0.60 *M* sodium chloride	0.60	...	36.0
0.10 *M* sodium sulfate	0.30	...	40.9
0.15 *M* sodium sulfate	0.45	...	37.5
0.175 *M* sodium sulfate	0.525	...	41.6
0.10 *M* magnesium sulfate	0.40	...	44.4
0.15 *M* magnesium sulfate	0.60	...	41.0

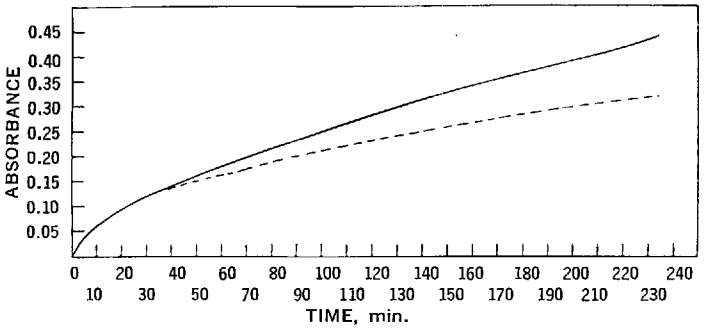

Fig. 5.—Absorbance *vs.* time curve showing release of chlorpheniramine maleate from a whole tablet. The dotted line represents the release pattern that would be necessary in order to maintain linearity if plotted against the square root of time.

Besides diffusion through a hydrated matrix, two other processes could be rate determining in affecting drug release from a compressed hydrophilic matrix. These are the rate of penetration of water through the hydrated layer and convective transport of hydrated polymer away from the tablet. Christenson and Dale (1) have suggested that hydration of the surface of the tablet results in a relatively water impermeable barrier. Drug release is achieved as the barrier is worn away. Fresh surface of the tablet is subsequently exposed, and the barrier is renewed. The tablet is described as having slowly disintegrated rather than dissolved.

Fatt and Goldstick (9) have recently presented a theoretical treatment of water transport in swelling membranes which should apply to a hydrophilic polymer matrix. They have shown that the mass of water absorbed by a thick slab of material should be a function of $\sqrt{t}$, assuming an average transport coefficient. The relative hydration and, consequently, the effective volume of the hydrated film diminish with increasing depth of penetration of the water front. If water penetration was the rate-determining step, then the transport coefficient characterizing the water-matrix system rather than the diffusivity of the drug would be the crucial parameter. The effect of electrolytes, pH, and diluents would be explainable in terms of alteration in the permeability of the swollen matrix to water.

The derivation of Eq. 1 presumes a uniform matrix through which diffusion takes place. If the rate of hydration of the matrix is slow compared to the dissolution of solid drug embedded in the matrix, then drug release would involve a leaching mechanism described by Eq. 1. If the rate of hydration is rapid, as was the case for the hydroxypropyl methylcellulose ether, then dissolution would only occur in a matrix in which hydration was effectively complete. Although the hydrated portion of the matrix through which the drug is diffusing may not be completely uniform, the results enable us to assume uniformity, at least for the time during which release was measured. This was nominally 2 hr. When release rates were observed for a period of 5 hr., the linear relationship described by Eq. 1 continued to apply. An estimate was obtained of the mass of the unhydrated tablet involved in the diffusional process. In the case of a 300-mg. tablet containing 50 mg. of chlorpheniramine maleate, 4.7 mg. of drug was released in water in 115 min. At that time, the tablet was removed from the solution and the hydrated matrix scraped from the face of the holder and assayed for drug which amounted to 2.6 mg. The total, 7.2 mg., indicated that 7.2/50 or about 14.4% of the mass of the tablet had been involved at this point. At the end of 5 hr. only 7.0 mg. of drug had been released.

That convective transport was not the rate-controlling step was confirmed by measurements of release patterns from whole tablets as shown in Fig. 5. Examination of the tablet at the end of a run in which 86% of the dose had been released showed a thick hydrated layer surrounding a small unswollen core. The figure shows that $Wr/\sqrt{t}$ was only constant during the early stages of release. Since Eq. 2 only applies to release from a plane surface, it is difficult to assess the actual factors contributing to the release in this case. Convective transport may still play a role as it must when the concentration of polymer in the tablet is significantly lowered by the addition of diluents. However, the existence of an intact hydrated layer establishes that diffusion is the most important factor contributing to the rate in this system.

The relative contribution of convective transport, water penetrability, and drug diffusivity to drug release from a hydrophilic matrix can only be assessed by independent measurement of the permeability of the hydrated polymer to water and drug in conjunction with a study of release patterns measured under the conditions described in this report. The experimental techniques, while not accurately reflecting *in vivo* conditions, do provide a reproducible means of evaluating different polymer–drug combinations. It should be anticipated that different systems in which the water solubility of the polymer or the drug may be altered would provide additional information to further clarify the mechanism of drug release.

The data reported here are only preliminary. Results of experiments in progress will be reported later.

4,6-Disubstituted Quinolines and Decahydroquinolines

By ARVIN P. SHROFF*, HATIF JALEEL†, and F. M. MILLER

This paper describes the synthesis of some 4,6-disubstituted quinolines and decahydroquinolines.

IN CONNECTION with a general study of the chemistry of Iboga alkaloids, it was of interest to synthesize some quinolines and decahydroquinolines. A modified Doebner-Miller synthesis (1) on *p*-aminobenzoic acid with methyl vinyl ketone gave the expected 4-methylquinoline-6-carboxylic acid (I). Oxidation of the 4-methyl group using a variety of oxidizing agents did not proceed in satisfactory yields. It was, therefore, converted to the styryl base (II) and oxidized with potassium permanganate (2) to give quinoline-4,6-dicarboxylic acid (III) in 76% yield. Hydrogenation of III gave a mixture of the *dl-cis* and *dl-trans* isomers of decahydroquinoline-4,6-dicarboxylic acids (IV). These were separated by virtue of the fact that the *dl-trans* isomer of the ethyl ester (V*b*) forms a solid hydrochloride more readily than the *dl-cis* isomer. The ratio of *dl-cis* to *dl-trans* was 1:4. Varying the conditions and/or the catalyst failed to increase the yield of the *dl-cis* isomer. In one experiment the *dl-cis* isomer (V*a*), obtained as an oil, was heated on an oil bath (3), and the reaction was followed by observing the change in the infrared spectrum. The appearance of the lactam carbonyl peak at 5.96 μ with retention of absorption due to the ester group (Fig. 1) suggested that the reaction proceeded to form VI as shown in Scheme I. Under similar conditions the *dl-trans* isomer (V*b*), as the free base, failed to react.

The low yield of the *dl-cis* isomer and the failure to obtain the lactam (VI) in a pure state precluded further studies in this area.

EXPERIMENTAL[1]

4 - Methylquinoline - 6 - carboxylic Acid.—A mixture of 42.9 Gm. (0.315 mole) of *p*-aminobenzoic acid, 135.1 Gm. of (0.5 mole) $FeCl_3 \cdot 6H_2O$, 10 Gm. of zinc chloride (anhydrous), and 250 ml. of ethyl alcohol was heated with stirring at 60–65°. To this mixture was added 17.5 Gm. (0.25 mole) of methyl vinyl ketone over a 2-hr. period. The mixture was allowed to reflux for an additional 2 hr. and left overnight at room temperature. Excess ethyl alcohol was removed under vacuum, and the residue was treated with 300 ml. of 20% sodium hydroxide solution. The mixture was filtered, and the filtrate was acidified with glacial acetic acid to pH 5. The light brown precipitate was washed with water and alcohol. Recrystallization from absolute alcohol gave 32 Gm. (54.1%) of 4-methylquinoline-6-carboxylic acid, m.p. 280–282°. $\lambda_{max.}^{KBr}$ 5.87 μ; 6.3 and 6.4 μ.

Anal.—Calcd. for $C_{11}H_9NO_2$: C, 70.58; H, 4.85; N, 7.48. Found: C, 71.00; H, 5.36; N, 7.16.

4-Styrylquinoline-6-carboxylic Acid.—A mixture of 14.0 Gm. of 4-methylquinoline-6-carboxylic acid, 78.7 Gm. of benzaldehyde, and 6.6 Gm. of anhydrous zinc chloride was heated on an oil bath for 5 hr. at a temperature of 180–190°. The reaction mixture was cooled and poured into 300 ml. of 25% sulfuric acid. Ethyl ether (1 L.) was added to the mixture and the styryl quinoline sulfate was filtered off. The precipitate was washed successively with 25% sulfuric acid, alcohol, and ether to give 18.6 Gm. of the salt. Recrystallization from absolute alcohol gave yellow crystals, m.p. 250–252°. The styryl sulfate (18.6 Gm.) was treated with 15% sodium hydroxide solution and filtered. The filtrate was acidified with glacial acetic acid and the buff-colored precipitate was filtered. Recrystallization from absolute alcohol gave 13.4 Gm. (65%) of 4-styrylquinoline-6-carboxylic acid, m.p. 292–293°.

Anal.—Calcd. for $C_{18}H_{13}NO_2$: C, 78.53; H, 4.76; N, 5.09. Found: C, 78.35; H, 5.07; N, 5.27.

Quinoline - 4,6 - dicarboxylic Acid.—To a mixture of 10.0 Gm. of 4-styrylquinoline-6-carboxylic acid in 250 ml. of 50% aqueous pyridine was added 14.0 Gm. of potassium permanganate over a period of 2 hr. The mixture was maintained at 0° throughout the addition. Stirring was continued for 2 hr., and the mixture was allowed to come to room temperature. It was allowed to stand overnight, and then 20 ml. of 20% potassium hydroxide solution was added. The solution was then treated with sodium bisulfate until there was a complete change

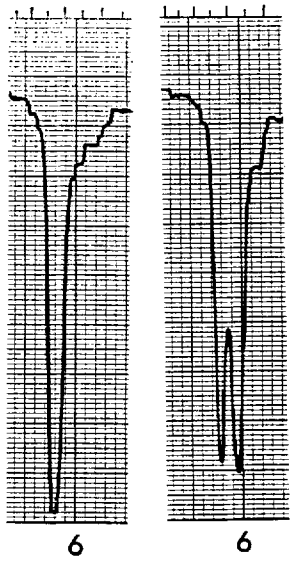

Fig. 1.—Infrared spectrum of *cis*-diethyl decahydroquinoline-4,6-dicarboxylate (V*a*) (left) and the cyclized lactam (VI).

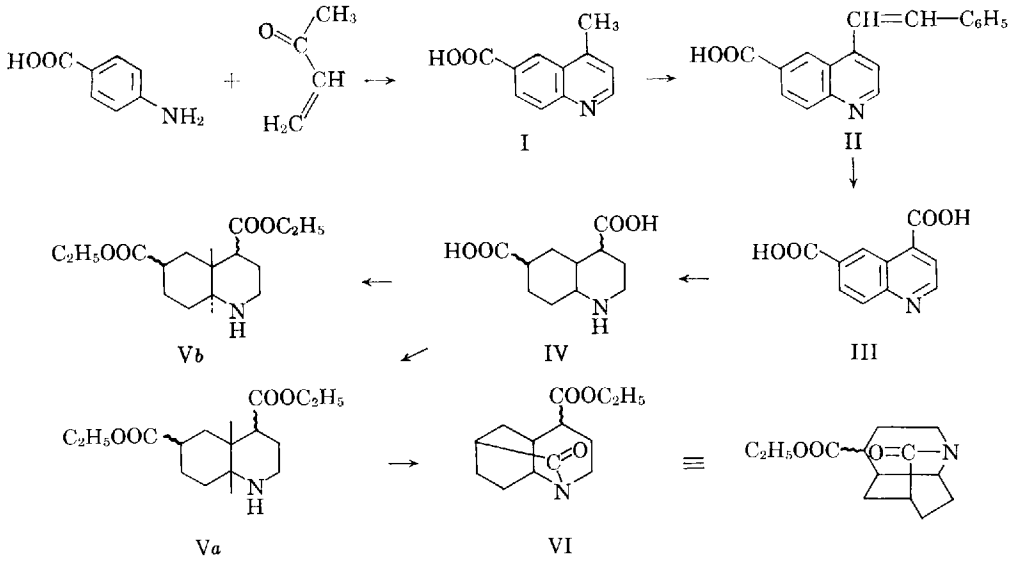
[1] All melting points were taken on a Fisher-Johns melting point apparatus and are uncorrected. The infrared and ultraviolet spectra were determined on a Perkin-Elmer Infracord spectrophotometer and a Beckman DB spectrophotometer, respectively. Elemental analyses were performed by Weiler and Strauss, Oxford, England.



Scheme I

in the color of the solution. It was filtered, and the filtrate was acidified with concentrated hydrochloric acid to pH 5. The precipitate was washed successively with water, alcohol, and then dried to give 6.0 Gm. (76%) of quinoline-4,6-dicarboxylic acid. Recrystallization from alcohol–acetonitrile gave an analytically pure sample, m.p. >300°.

Anal.—Calcd. for $C_{11}H_7NO_4$: C, 60.83; H, 3.25; N, 6.45. Found: C, 60.29; H, 3.45; N, 6.68.

Decahydroquinoline - 4,6 - dicarboxylic Acid Hydrochloride.—Quinoline-4,6-dicarboxylic acid (3.7 Gm.) was treated with 20 ml. each of water, HCl, and acetic acid, and 500 mg. platinum dioxide. The mixture was hydrogenated at 60° for a period of 36 hr. The catalyst was removed by filtration, and the filtrate was evaporated under vacuum to give white crystals of decahydroquinoline-4,6-dicarboxylic acid hydrochloride. Recrystallization from acetonitrile gave an analytically pure sample, m.p. 280–285°. The yield was 4.0 Gm. (90%) λ_{max}^{KBr} 5.85.

Anal.—Calcd. for $C_{11}H_{18}ClNO_4$: C, 50.09; H, 6.87; N, 5.31. Found: C, 50.83; H, 7.30; N, 5.16.

Diethyl Decahydroquinoline-4,6-dicarboxylate Hydrochloride.—Decahydroquinoline - 4,6 - dicarboxylic acid (2.7 Gm.) was added to a mixture of 15 ml. of alcohol, 20 ml. of benzene, and 2.5 ml. of concentrated sulfuric acid. It was refluxed for 20 hr., and the water formed was continuously removed. Excess solvent was removed under vacuum and the residue was treated with ammonium hydroxide until neutral to litmus and extracted with benzene–ether. The extracts were dried over sodium sulfate. Anhydrous hydrogen chloride was passed through the solution, and the solvent was removed leaving an oily residue. Addition of ether to this oily residue gave 2.6 Gm. (80%) of *dl-trans*-decahydroquinoline-4,6-dicarboxylic acid diethylester hydrochloride, m.p. 154–156°. The *dl-cis* isomer remains as an oil.

Anal.—Calcd. for $C_{15}H_{26}ClNO_4$: C, 56.32; H, 8.19; N, 4.37. Found: C, 56.31; H, 8.36; N, 3.81.

Cyclization of dl-cis-Diethyl Decahydroquinoline-4,6-dicarboxylate to VI.—The free ester of the *cis*-isomer was obtained by dissolving the above oil in 1.0 ml. of 5% sodium hydroxide and extracting with 10 ml. of ethyl acetate. The organic layer was washed with water, dried, and evaporated. The diethyl ester, obtained as an oil, was cyclized by heating in a distillation flask to 190–200°. The reaction was followed by observing the change in the infrared spectrum in the lactam region. After 15–20 min. the flask was cooled and the residue was chromatographed on neutral alumina. Elution with benzene gave the desired lactam VI. $\lambda_{max.}^{CHCl_3}$ 5.96 μ.

Effect of Drugs and Catecholamines on Rat Diaphragm Carbohydrate Metabolism

By LEON L. GERSHBEIN

By the method of paired hemidiaphragms, the mean differences in oxygen and glucose uptake and glycogen content were evaluated for a variety of drugs. Incubation was carried out in a phosphate-saline medium containing 120 mg. per cent glucose. Glycogen was depressed by quinidine sulfate (1.00 mg.), quinine·HCl (1.00 mg.), cinchophen (0.50 mg.), colchicine (0.75 mg.), bishydroxycoumarin (0.25 mg.), dimethyl sulfoxide (1.00 mg.), diphenylhydantoin (0.75 mg.), chlorcyclizine·HCl (0.50 mg.), chlorpromazine·HCl (0.50 mg.), and yohimbine·HCl (1.00 mg.). Glucose utilization was inhibited by the last three agents as well as by tubocurarine chloride (0.50 mg.), picrotoxin (1.00 mg.), atropine sulfate (1.00 mg.), mephenesin carbamate (0.50 mg.), and promethazine·HCl (0.50 mg.). More physiologically significant data resulted with potassium estrone sulfate (10 mcg.) which markedly inhibited glucose utilization and with testosterone (0.52 μm.) and its derivatives, norethandrolone and methandrostenolone, both at 0.33 μm., which depressed glycogen but had little effect on glucose uptake except for testosterone as such. Of the catecholamines, epinephrine at 10 mcg. depressed Q_{O_2}, glycogen, and glucose utilization, the effect persisting at 0.10 mcg. or lower as was also the case with norephinephrine. The latter at 50 mcg. promoted glycogenolysis. Adrenochrome and *dl*-metanephrine·HCl likewise affected glucose uptake at dosages of 10 or 50 mcg., but very high levels of the *O*-methylamine were required for a glycogenolytic response.

ALTHOUGH the isolated rat diaphragm has been used in conjunction with insulin, epinephrine, and several sterols in rather classical muscle metabolic researches, it has been little applied to broader classes of drugs. More recently, findings have been advanced for sulfhydryl compounds (1), thyroid hormones (2), thalidomide (3), and disulfiram (4). This report presents hemidiaphragm oxygen uptake, glucose utilization, and glycogen data for a variety of drugs, therapeutic sterols, and catecholamine derivatives and metabolites screened up to very high levels. The effect of these agents as such or by preincubation on glycogen turnover in the presence of insulin was not ascertained.

EXPERIMENTAL

The drugs were obtained from general commercial sources, mainly Nutritional Biochemicals Corp.[1] The medium of Stadie and Zapp (5) was employed in the incubation of hemidiaphragms, the composition being: 0.04 *M* Na_2HPO_4, 0.005 *M* $MgCl_2 \cdot 5H_2O$, and 0.08 *M* NaCl, pH 6.8–7.0; the glucose content was 120 mg. %.

Male Holtzman rats weighing 135–160 Gm. were starved for 24 hr., sacrificed by swift decapitation, incised, and the hemidiaphragms removed and immediately placed in chilled saline. The tissues were trimmed, blotted between filter paper, weighed, and introduced into the Warburg flasks, one hemidiaphragm being incubated with 1.0 ml. double-strength Stadie and Zapp medium and 1.0 ml. saline as such (control) and its mate, with medium and 1.0 ml. saline–drug solution (treatment). In some instances, as with cinchophen, solution was effected with aqueous NaOH and the mixture then diluted with saline to the desired concentration. A few drugs of low solubility were employed as fine suspensions. With acetylsalicylic acid and the sterols, solutions were prepared in propylene glycol, the desired dosage being delivered in a volume of 0.20 ml.; the respective flasks contained 1.0 ml. of double-strength phosphate–glucose medium, 0.80 ml. of saline, and 0.20 ml. of either glycol or the solution (6). Flasks containing the media but without tissues were also included in each run. The system was gassed with pure oxygen and incubated at 37° for 1 hr., after which time the hemidiaphragms were removed and rinsed 3 times with saline, filter paper blotting being applied between washings. The tissues were digested with alkali and glycogen precipitated and determined by the anthrone reagent (7, 8). The supernatant fluid, after removal of the hemidiaphragm, was deproteinized and analyzed for glucose by the Somogyi method (9, 10). A more detailed description of the pertinent procedures has been advanced earlier (11).

RESULTS

Mean differences in Q_{O_2}, glucose uptake, and glycogen content for hemidiaphragms incubated with drugs, testosterone derivatives, KES, epinephrine, norepinephrine, metanephrine, adrenochrome, and 4-hydroxy-3-methoxymandelic acid together with the requisite Fisher *t* values are presented in Table I. In the calculations involving the bulk data, differences in excess of $\bar{R} \pm 2.5\ R$, where $\bar{R}$ is the average range, were excluded (12). The mean differences were not statistically significant with the following, the values denoting the highest levels screened: acetylsalicylic acid (0.30), acetylcholine (1.00), barbituric acid (0.050), chloral hydrate (0.50), chlorpheniramine maleate (0.50), cyclizine·HCl (0.50), ergotamine tartrate (0.25), sodium heparin (1.00), meperidine (1.00), meprobamate (0.50), meprobamate metabolite (0.50), morphine sulfate (1.00), ouabain (0.50), pentylenetetrazol (1.00), picrotoxin (1.00), pilocarpine·HCl (0.50), procaine·HCl (1.00), reserpine (0.25), strophanthidin (0.25), strychnine sulfate (1.00), and veratrine

Received March 4, 1966, from the Biochemical Research Laboratories, Northwest Institute for Medical Research, Chicago.

Accepted for publication May 4, 1966.

[1] The following originated from the firms as specified: cyclizine·HCl and chlorcyclizine·HCl (Burroughs Wellcome); meprobamate and its metabolite, 2-methyl-2-β-hydroxypropyl-1,3-propanediol dicarbamate (Wallace); dimethyl sulfoxide (DMSO, Baker); phenylbutazone (Butazolidin, Geigy); MER-25 (ethamoxytriphetol, Merrell); norethanedrolone (17α-ethyl-19-nortestosterone, Nilevar Searle); methandrostenolone (1-dehydro-17α-methyltestosterone, Dianabol, Ciba); sodium heparin of 150 U.S.P. units/mg. and epinephrine (Wilson); pentylenetetrazol (Bilhuber, Knoll); mephenesin carbamate (ester of 3-*o*-toloxy-1,2-propanediol, Squibb); potassium estrone sulfate (KES, Penick); chlorpheniramine maleate (Hexagon); and diphenylhydantoin (Dilantin, Parke Davis Co.).

sulfate (1.00). Acetylsalicylic acid was tested both as a suspension and in propylene glycol mixture.

DISCUSSION

At the concentrations investigated, decreases in diaphragm respiration occurred in the presence of digitoxin, strophanthidin, and phenylbutazone. Of the mean differences, glucose utilization was decreased with promethazine·HCl, picrotoxin, atropine sulfate, and tubocurarine chloride. Chlorpromazine·HCl at 0.50 mg. depressed both muscle glycogen and glucose uptake but when the dosage was lowered to 0.050 mg., only the effect on glucose utilization persisted. Glycogen was depressed on incubation with the higher concentrations of cinchophen (0.50 mg.) as well as with yohimbine·HCl (1.00 mg.), colchicine (0.75 mg.), diphenylhydantoin (1.00 mg.), quinidine sulfate (1.00 mg.), and quinine·HCl (1.00 mg.), the latter two being ineffective at 0.10 mg.; glucose utilization except for yohimbine·HCl was not affected. Glycogen content was decreased but to a small extent with DMSO (1.00 mg.) and MER-25 (0.50 mg.), the last drug also depressing the Q_{O_2}; neither displayed an effect at 0.10 mg.

Both meprobamate and its metabolic product did not significantly alter any of the mean differences. However, mephenesin carbamate (0.50 mg.) depressed glucose utilization as was also observed with ethyl carbamate screened up to 1.00 mg.; Q_{O_2} was decreased in the presence of the former agent. Perhaps at the high levels, carbamate contributes to the diminished glucose uptake and that other structural attributes of the meprobamate molecule might negate the effect. It might be pointed out that the disulfiram metabolite, diethyldithiocarbamate, like the parent compound, was without action on the isolated diaphragm (4).

Regarding the sterols, KES, an interesting water-soluble conjugate of estrone, markedly depressed glucose uptake to the exclusion of any effect on Q_{O_2} and glycogen content at levels down to 10 mcg. (0.027 μm.). Testosterone introduced as a propylene glycol solution elicited inhibitory effects on the three mean differences at 0.15 mg. or 0.52 μm., but the derivatives, norethandrolone and methandrostenolone, each at 0.10 mg. or 0.33 μm., decreased Q_{O_2} and glycogen and produced no effect on glucose uptake. In fact, although not statistically significant, the latter values tended toward increased hexose utilization. In earlier published accounts, rat diaphragm glycogenesis in the presence of insulin and glucose was shown to be reduced by various sterols and the estrogen, stilbestrol (13, 14), and the inhibitory action did not obtain when hemidiaphragms were preincubated with some of these sterols (15). Desoxycorticosterone and an extract of the adrenal cortex were without action on glycogen synthesis in the presence of insulin (16).

The effect of epinephrine on the isolated rat diaphragm has been described by several workers, glucose uptake and glycogen turnover being decreased; the amine antagonizes the action of insulin on glycogenesis (7, 15–18). According to Reisser (16), the substance antagonizing insulin is not epinephrine as such but an oxidized derivative. In the present study, the effects of *dl*-metanephrine·HCl, adrenochrome, and 4-hydroxy-3-methoxymandelic acid (VMA) were ascertained, epinephrine and norepinephrine being included for purposes of comparison under these conditions. Epinephrine at 10 mcg. depressed the glycogen content and glucose utilization was greatly inhibited at dosages below 0.10 mcg. as was also noted with norepinephrine. The latter at 50 mcg. caused a decrease in glycogen. In this regard, both muscle and liver glycogenolysis in the rat is very marked with epinephrine, whereas norepinephrine possesses low activity relative to muscle glycogen but promotes hepatic glycogenolysis (19, 20). Metanephrine·HCl depressed glucose utilization at levels down to 50 mcg., but its glycogenolytic action was noted at higher concentrations (0.50 mg.). The *O*-methylated derivative, like normetanephrine, plays an important role in catecholamine metabolism in the rat and human, and an *O*-methyl transferase system is implicated (21–25). Adrenochrome, the pigment from epinephrine oxidation was similar to the latter amine in causing depressions in both glucose uptake and muscle glycogen at 0.50 mg.; glycogenolysis was definite but of low statistical significance ($p < 0.05$) at 10 mcg. The more stable semicarbazone at a level comparable to the last one (15 mcg.), although markedly inhibiting glucose uptake, was without effect on the glycogen content. However, controls, such as other semicarbazone types or semicarbazide alone, were not instituted, nor were higher concentrations of this derivative screened. The urinary catecholamine metabolite, VMA, was without action on the diaphragm even at a dosage of 1.00 mg.

The data with the above drugs are of great pharmacological interest. Except for the sterols and catecholamines, one is impressed with their relative refractoriness by the metabolic criteria, and where effects could be discerned, these invariably lacked physiological significance in view of the tremendous dosages screened. In contrast to the diaphragm findings, an increase in glucose uptake occurs with rat cerebral cortical slices under the agency of morphine (25); negative data were also obtained earlier with somewhat lower dosages of acetylcholine (16) and with excessive levels of choline (11).

Evidence for the Presence of an Atropine-Degrading Enzyme in Goat Serum

By RONALD G. MILLER, VERNA L. WALKER, GILBERT C. SCHMIDT, and HARRY C. SHIRKEY

Pooled rabbit serum containing atropinesterase, pooled rabbit serum lacking atropinesterase, and pooled goat serum were tested for their effect on some pharmacological parameters of atropine and related compounds. Pooled goat serum was found to contain a previously undescribed enzymatic activity on certain of the effects of these compounds. These activities were compared to those of the rabbit sera. White male mice were used as the test animal.

A SURVEY OF the literature reveals no reference to any protective mechanism of the goat against atropine. Even in the folklore of ancient medicine, where there was widespread belief in the therapeutic powers of different parts of the goat's body, no indication of natural resistance of the goat to atropine, atropine-containing plants, or any atropine-related compounds is found (1).

Metabolic degradation of atropine has been studied in several species, including the mouse (2–4), rat, kitten, guinea pig (5), dog (6), and rabbit. The most extensive studies have been performed on rabbits, where a genetically inherited enzyme, atropinesterase, has been credited with the ability to impart resistance to the pharmacological effects of administered atropine in those rabbits containing the enzyme. Atropinesterase from rabbit serum has recently been purified and characterized by Margolis and Feigelson (7).

This paper presents evidence for the existence of a hitherto unreported atropine-degrading enzyme, present in pooled goat serum, which differs from atropinesterase in that it has no esterase activity.

MATERIALS AND METHODS

Chemicals.—Atropine sulfate (Merck and Co.), hyoscyamine sulfate (Nutritional Biochemicals), tropic acid (Nutritional Biochemicals), and tropine (K & K Laboratories) were all commercial products. Tropine was purified by vacuum distillation in this laboratory.

Sera.—Sterile pooled rabbit serum, no preservative, was obtained from Courtland Laboratories and Baltimore Biological Laboratories. Sterile, pooled, goat serum, no preservative, was obtained from Colorado Serum Co.

Eye Assay.—A modification of the method of Pulewka (8) was used. White, male, Swiss mice were used as the test animal. Initial pupil diameter, under the direct light of an 18-w. microscope maintained 10 cm. from the mouse eye, was obtained using an American Optical binocular microscope fitted with an ocular scale. Animals then received an intraperitoneal injection of 0.5 ml. of serum, followed by 0.2 ml. of atropine or hyoscyamine solution by the same route. Each animal received a total dose of 2 mcg. of the desired alkaloid, with stated exceptions. Pupil diameter was followed at 5-min. intervals until a maximum dilation was obtained. Maximum pupil diameter increase, in arbitrary units, was calculated, and the data subjected to a t test (9) for significance. Control animals received 0.5 ml. of water, followed by 0.2 ml. of alkaloidal solution.

Median Lethal Dose Determinations.—White, male, Swiss mice, 11–12 Gm. in weight, were randomized into five groups of 10 mice each. Each group was subjected to a different dose level, the per cent kills obtained for each group, and the results analyzed by probit analysis after the method of De Beer (10).

Toxicity Studies.—Mice in the test group received 0.8 ml. of serum, followed immediately by 0.2 ml. of the alkaloidal solution, containing a dose of alkaloid at the LD_{50} level. The control group received 0.8 ml. of water, followed immediately by 0.2 ml. of the alkaloidal solution. The total number of kills was obtained for each group, and the results tested for significance, using the χ^2 method of Batson (11). All injections were intraperitoneal.

Esterase Activity.—Warburg respirometer analyses were run on 2.5-ml. reaction mixtures, 0.04 M in phosphate, 0.04 M in bicarbonate, containing 1% of atropine free base and 20% serum, at an initial pH of 7.8. Carbon dioxide production, indicating the hydrolysis of atropine to tropic acid and tropine, was used as the criterion for esterase activity (12).

RESULTS AND DISCUSSION

In a preliminary attempt to compare the effect of esterase-containing and esterase-deficient rabbit serum, and goat serum, on the pharmacological action of atropine, the authors employed two parameters: mydriatic response and gross toxicity.

The presence or absence of esterase activity was determined by Warburg studies. Substantial carbon dioxide production was observed in the case of Courtland rabbit serum, but not with Baltimore rabbit serum or goat serum. On this basis, Courtland serum was judged to contain atropinesterase, and the latter two sera were classified as lacking the enzyme.

LD_{50} studies (Table I) show the relative toxicities of atropine and its components. Atropine, the racemate, and hyoscyamine, the levorotatory isomer, were found to be nearly equal in toxicity, atropine being somewhat more toxic. These results are in agreement with Buckett's observation (13) that, in white mice, the two isomers possess equal

Received April 28, 1966, from the Children's Hospital, Birmingham, Ala.; the Department of Biological Chemistry, School of Medicine, University of Cincinnati, Cincinnati, Ohio; and the Division of Pharmacology, Department of Pediatrics, School of Medicine, University of Alabama Medical Center, Birmingham.

Accepted for publication June 1, 1966.

This investigation was supported by research grant GM-13844 (formerly GM-08447), from the National Institutes of Health, U. S. Public Health Service, Bethesda, Md.

Abstracted in part from a thesis submitted by Ronald G. Miller to the Graduate School, University of Cincinnati, Cincinnati, Ohio, in partial fulfilment of Doctor of Philosophy degree requirements.

Presented to the Medicinal Chemistry Section, A.PH.A. Academy of Pharmaceutical Sciences, Dallas meeting, April 1966.

TABLE I.—MEDIAN LETHAL DOSES FOR THE COMPOUNDS STUDIED[a]

Compd.	LD_{50}, mg./Kg.	95% Confidence Limits of LD_{50}
Atropine sulfate	180	164–198 mg./Kg.
Hyoscyamine sulfate	210	181–244 mg./Kg.
Tropine sulfate	550	490–616 mg./Kg.
Tropic acid (sodium salt)	Nontoxic[b]	...

[a] Median lethal dose and confidence limits were determined by the method of De Beer (10). [b] No deaths were observed at maximum dosages of 1500 mg./Kg.

TABLE II.—PROTECTION OF SERA AGAINST THE LETHALITY OF ATROPINE SULFATE

Serum	Effect	$\chi^{2,a}$
Goat	Protection	16.16
Esterase positive rabbit	Protection	13.00
Esterase negative rabbit	Protection	5.12

[a] Critical values for χ^2: 5% = 3.84, 1% = 6.64, 0.1% = 10.83.

potencies at toxic levels. The authors observed that, upon standing in the laboratory, solutions of hyoscyamine appear to change in toxicity. A solution of hyoscyamine was followed for several hours using a polarimeter, without change in optical rotation. Therefore, racemization does not seem to be a possible explanation for the sometimes markedly different responses that were obtained from hyoscyamine.

Tropine was found to be about one-third as toxic as atropine, and tropic acid was found to be nontoxic. Therefore, the hydrolysis of atropine by those animals containing atropinesterase could serve as a protective mechanism against the lethality of atropine.

Hydrogen-ion concentration was not a factor in the toxicity of the injected drug. Atropine sulfate and hyoscyamine sulfate solutions have a pH of 5.5, and intraperitoneal injections of dilute solutions of sulfuric acid of the same pH caused no deaths or apparent discomforts in injected mice. Tropine solutions were too basic to be used as such, and were adjusted to pH 7.0 with dilute sulfuric acid. Tropic acid, in the acid form, is only very slightly soluble in water. This compound was administered as the sodium salt, pH 7.0, to solubilize enough of the tropic acid anion to permit toxicity studies.

When dose-response curves were run for mydriatic activity, the curves for hyoscyamine and atropine were indistinguishable from one another. Subjection of the data to a t test disclosed no significant difference in the mydriatic action of atropine and hyoscyamine in male, white mice. These findings are in disagreement with Buckett's (13) observation that the levorotatory isomer is 29 times as mydriatically potent as the dextrorotatory isomer. Although Buckett also used the mouse as the test animal, he employed subcutaneous or intravenous injections, while this laboratory employed the intraperitoneal route.

All three sera tested were found to protect against the lethality of atropine (Table II). Since esterase activity was present in only the Courtland serum, it is obvious that protection, while it may be a partial function of atropinesterase in Courtland serum, cannot be a function of esterase activity in the other sera.

Tropine, the alcohol portion of the ester, exhibited lesser toxicity than the parent compound. Goat serum and esterase-lacking rabbit serum were found to protect significantly against its toxicity (Table III). Since there are no ester links in this alkaloid, additional evidence is afforded that protection is due to something other than an esterase. There is an implied association, even in sera that contain atropinesterase, of protective action and ability to degrade or alter the tropine moiety.

The toxic effects of hyoscyamine were unmitigated by all three sera, hence, the protection is stereospecific and involves the dextrorotatory isomer (Table IV). This finding the authors regard as most significant. Atropinesterase is claimed to be specific for the levorotatory isomer (14), and if protection had been a function of hydrolysis, it would have been observed in the case of the pure substrate. This finding also eliminates the possibility that protection is due to serum binding of the administered drug. If this were the mechanism, the enzyme would have bound the natural substrate, the levorotatory isomer, just as much if not more so, as the racemic mixture of isomers.

Alteration of mydriasis showed both rabbit sera to significantly decrease the amount of mydriasis caused by an injected dose of atropine (Table V), again pointing to some activity other than enzymatic hydrolysis. Goat serum had no effect on mydriatic activity.

TABLE III.—PROTECTION OF SERA AGAINST THE LETHALITY OF TROPINE SULFATE

Serum	Effect	$\chi^{2,a}$
Goat	Protection	5.72
Esterase positive rabbit	Not run	...
Esterase negative rabbit	Protection	6.37

[a] Critical values for χ^2: 5% = 3.84, 1% = 6.64.

TABLE IV.—PROTECTION OF SERA AGAINST THE LETHALITY OF HYOSCYAMINE SULFATE

Serum	Effect	$\chi^{2,a}$
Goat	None	1.41
Esterase positive rabbit	None	0.06
Esterase negative rabbit	None	...

[a] Critical values of χ^2: 50% = 0.455, 5% = 3.84.

TABLE V.—PROTECTION OF SERA AGAINST THE MYDRIATIC ACTION OF ATROPINE SULFATE

Serum	Effect	t-Test[a]
Goat	None	1.1
Esterase positive rabbit	Protects	8.02
Esterase negative rabbit	Protects	5.67

[a] $t_{(20)}$ = 3.85 at 0.1%; $t_{(20)}$ = 1.73 at 10%.

CONCLUSION

These studies indicate that the protection rendered by these sera against the pharmacological effects of atropine cannot be ascribed to atropinesterase, or any other esterase. The protection against mydriasis, exhibited by the esterase-lacking rabbit serum, together with the observation that goat serum is ineffective under the same conditions, implies further that the mechanism of protection is of a different nature in the two sera. The evidence indicates that goat serum is specific for the dextrorotatory isomer of atropine, metabolizing it to a compound that is less toxic, but of equal mydriatic activity for the mouse. The rabbit sera data indicate an activity not involving the ester linkage, but metabolizing the compound to a substance of both lesser toxicity and lesser mydriatic activity for the mouse. The data further suggest that decreases in toxicity, with all sera tested, are very likely associated with alterations of the tropine moiety.

Freezing Point Curve of Dimethyl Sulfoxide–Water Solutions

By RUTH N. HAVEMEYER*

The apparent freezing points have been determined for solutions of dimethyl sulfoxide and water. Several of the samples exhibited increasing viscosity as they were cooled and, at their solidification points, formed amorphous glasses rather than crystalline solids. It is proposed that these glasses form because of a modified lattice structure built of dimethyl sulfoxide and water molecules. The eutectic composition occurs in the region of 0.3 *M* dimethyl sulfoxide.

DIMETHYL SULFOXIDE (DMSO) has been used for many years as a solvent and a reaction medium. It will dissolve many inorganic salts and most classes of organic compounds. As a reaction medium it has been found to increase greatly the rates of many reactions beyond what would be expected (1). It also possesses a number of other unusual properties: a high dielectric constant for an aprotic solvent (2), miscibility with most organic solvents, a high heat of mixing with water (3), and a volume contraction when mixed with water (3). DMSO has also found use as a preservative and freezing medium for biological tissues (4). It has been found in this laboratory that DMSO will greatly lower the freezing point of water. This paper reports on the cryoscopic properties of DMSO–water solutions.

EXPERIMENTAL

Two sets of equipment were employed—one for those samples freezing above −40° and one for those freezing below. For the higher freezing solutions, the apparatus used for measuring the temperature was a copper-constantin thermocouple connected to a Westronics strip chart recorder. The recorder has a working range of −40° to +180° (or −1.46 to +8.24 mv.), with an accuracy of ±0.5°. The cooling chamber was a Dewar flask (12.3 cm. i.d.) containing the dry ice–glycol ether[1] cooling fluid (temperature about −75°).[2] About 2 ml. of a DMSO-water solution was placed in a 7.5 × 1 cm. glass test tube. The thermometric probe was threaded through a cork stopper in the test tube and positioned in the center of the liquid. This assembly was immersed in the cooling bath intermittently, to avoid supercooling, until the contents of the test tube had frozen. The assembly was then suspended from a clamp and allowed to warm at room temperature until the transition from solid to liquid was complete. The freezing point (melting point) of the mixture was taken as the point of inflection on the time-temperature curve.

For those samples with a freezing point below −40°, the equipment used was the Linde BF-3 biological freezer. This is a controlled rate freezer that uses liquid nitrogen as the cooling medium. A differential copper-constantin thermocouple probe is used to monitor the temperature difference between the sample and the cooling chamber. This temperature difference produces a millivolt signal, which is balanced against the controller voltage set to the desired temperature differential. As a result of the continuous comparison of these two voltages, liquid nitrogen is fed into the freezing chamber as needed, through a solenoid valve that is actuated by the controller. Thus, the freezing rate is established and maintained. After the conclusion of a particular freezing operation the sample vials are removed, the

CONCLUSION

These studies indicate that the protection rendered by these sera against the pharmacological effects of atropine cannot be ascribed to atropinesterase, or any other esterase. The protection against mydriasis, exhibited by the esterase-lacking rabbit serum, together with the observation that goat serum is ineffective under the same conditions, implies further that the mechanism of protection is of a different nature in the two sera. The evidence indicates that goat serum is specific for the dextrorotatory isomer of atropine, metabolizing it to a compound that is less toxic, but of equal mydriatic activity for the mouse. The rabbit sera data indicate an activity not involving the ester linkage, but metabolizing the compound to a substance of both lesser toxicity and lesser mydriatic activity for the mouse. The data further suggest that decreases in toxicity, with all sera tested, are very likely associated with alterations of the tropine moiety.

Freezing Point Curve of Dimethyl Sulfoxide–Water Solutions

By RUTH N. HAVEMEYER*

The apparent freezing points have been determined for solutions of dimethyl sulfoxide and water. Several of the samples exhibited increasing viscosity as they were cooled and, at their solidification points, formed amorphous glasses rather than crystalline solids. It is proposed that these glasses form because of a modified lattice structure built of dimethyl sulfoxide and water molecules. The eutectic composition occurs in the region of 0.3 *M* dimethyl sulfoxide.

DIMETHYL SULFOXIDE (DMSO) has been used for many years as a solvent and a reaction medium. It will dissolve many inorganic salts and most classes of organic compounds. As a reaction medium it has been found to increase greatly the rates of many reactions beyond what would be expected (1). It also possesses a number of other unusual properties: a high dielectric constant for an aprotic solvent (2), miscibility with most organic solvents, a high heat of mixing with water (3), and a volume contraction when mixed with water (3). DMSO has also found use as a preservative and freezing medium for biological tissues (4). It has been found in this laboratory that DMSO will greatly lower the freezing point of water. This paper reports on the cryoscopic properties of DMSO–water solutions.

EXPERIMENTAL

Two sets of equipment were employed—one for those samples freezing above −40° and one for those freezing below. For the higher freezing solutions, the apparatus used for measuring the temperature was a copper-constantin thermocouple connected to a Westronics strip chart recorder. The recorder has a working range of −40° to +180° (or −1.46 to +8.24 mv.), with an accuracy of ±0.5°. The cooling chamber was a Dewar flask (12.3 cm. i.d.) containing the dry ice–glycol ether[1] cooling fluid (temperature about −75°).[2] About 2 ml. of a DMSO-water solution was placed in a 7.5 × 1 cm. glass test tube. The thermometric probe was threaded through a cork stopper in the test tube and positioned in the center of the liquid. This assembly was immersed in the cooling bath intermittently, to avoid supercooling, until the contents of the test tube had frozen. The assembly was then suspended from a clamp and allowed to warm at room temperature until the transition from solid to liquid was complete. The freezing point (melting point) of the mixture was taken as the point of inflection on the time-temperature curve.

For those samples with a freezing point below −40°, the equipment used was the Linde BF-3 biological freezer. This is a controlled rate freezer that uses liquid nitrogen as the cooling medium. A differential copper-constantin thermocouple probe is used to monitor the temperature difference between the sample and the cooling chamber. This temperature difference produces a millivolt signal, which is balanced against the controller voltage set to the desired temperature differential. As a result of the continuous comparison of these two voltages, liquid nitrogen is fed into the freezing chamber as needed, through a solenoid valve that is actuated by the controller. Thus, the freezing rate is established and maintained. After the conclusion of a particular freezing operation the sample vials are removed, the

[a] These mixtures form glassy, amorphous solids.

chamber is reclosed, and a separate warming cycle brings the chamber to room temperature.

Using the Linde freezer 8 ml. of sample solution was placed in a 3-dr. Kimble glass vial, and one leg of the thermocouple probe was immersed in the sample and held in place with a cork stopper. The monitored sample and auxiliary samples were positioned in a carrier and placed in the freezing chamber, and the chamber was tightly sealed. The desired freezing rate was set with the control potentiometers, and the freezing cycle was begun. The time-temperature curves were obtained with a Sargent model SR recorder. Since the temperature region of interest was in the negative millivolt range, the thermocouple leads to the recorder were reversed. This gave a theoretical operating range of +1.45 to −5.38 mv. or about +35° to about −190°. The recorder voltage was calibrated with a Brown-Honeywell potentiometer; the thermocouple-recorder response was checked with chemicals of known freezing points—deionized water, chromatographic grade chloroform, and freshly distilled trichlorofluoromethane.[3] The accuracy of the calibration was about ±2°.

The data obtained by both experimental methods for deionized water, DMSO (pharmaceutical grade, Crown Zellerbach), and mixtures of these two are shown in Fig. 1 and Table I.

RESULTS

The method used for the higher-freezing mixtures did not utilize a controlled rate of freezing or thawing. Nonetheless, there were well-defined inflection points in the time-temperature curves (Fig. 2) to indicate the freezing points (or melting points). The same values were obtained on duplicate samples.

For those solutions with a freezing point below −40°, the samples either would not freeze (0.2, 0.3, 0.4 *M* DMSO) in the dry ice–glycol ether bath, or else showed only poorly defined inflection points (0.15 and 0.5 *M* DMSO). At first, an attempt was made to freeze these samples by intermittent immersion in liquid nitrogen, rather than in the dry ice–glycol ether bath, but the results were unsatisfactory. Stirring the samples with a wire loop and scratching the inner surface of the test tube during cooling were also tried in an attempt to induce crystallization. These methods had no effect. However, it was observed that the 0.2, 0.3, and 0.4 *M* DMSO solutions exhibited a range of viscosity, from glycerin-like liquid to glassy solid, during cooling. The need for a controlled freezing rate was evident, and the equipment employed hereafter was the Linde biological freezer.

Using the Linde freezer, the samples of 0.15 and 0.5 *M* DMSO showed well-defined plateau regions (Fig. 3) even when cooled at the fastest rate—about 5°/min. Samples of 0.2, 0.3, and 0.4 *M* DMSO did not give any indication of their freezing points even when cooled at the slowest rate of about 0.9°/min. However, if these samples were kept in the chamber to the operational limit of the unit, they did solidify as glasses.

These latter three concentrations of DMSO were then re-examined qualitatively. Three or four unmonitored vials were used for each run, in addition to the sample monitored with the thermocouple, so that a vial could be removed from the chamber at different times during the freezing cycle for gross observation. In this way the several stages of viscosity could be seen—slightly viscous, very viscous but flowable, nonflowing but deformable soft glass, nondeformable glass. The dotted lines in Fig. 1 indicate the temperature ranges of increased viscosity. The freezing point of each of these three samples was taken as the temperature at which the surface of the sample could not be indented when pressed with a thin wooden stick. Below this temperature the sample would suddenly show craze or shatter lines. In none of these samples were crystals seen by gross observation.

DISCUSSION

The DMSO–water eutectic forms in the region of 0.3 *M* DMSO (Fig. 1). It is in this same region that

[3] Marketed as Freon-11 by E. I. du Pont de Nemours, Inc., Wilmington, Del.

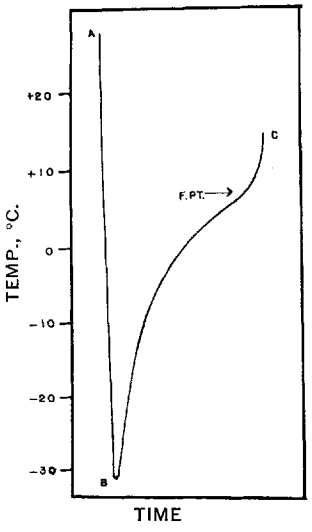

Fig. 2.—Typical freezing point (or melting point) curve of high freezing mixtures. Key: A–B, heat being removed from system; B–C, heat being added to system.

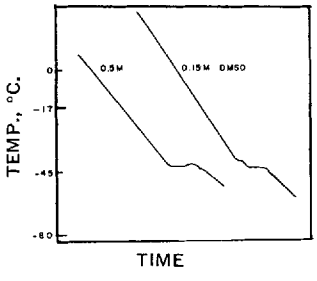

Fig. 3.—Freezing point curves of some lower freezing mixtures.

viscosity and heat of mixing of DMSO–water solutions have maximum values, and there is considerable volume contraction on mixing (3, 5). A 0.33 *M* quantity of DMSO corresponds to a ratio of 2 moles of water to 1 mole of DMSO. It has been proposed that a 2:1 complex does form between water and DMSO through hydrogen bonding and that this is stronger between water and DMSO than between two water molecules (1, 6). It would be expected that a compound with a definite composition would exhibit a maximum, rather than a minimum, in a freezing point curve. It may be that this does occur in this system but that the method of measurement and observation is not sufficiently sensitive to determine it, or supercooling occurs too rapidly to be avoided. The temperature of such a maximum, if it does exist, cannot be estimated. For this reason it is not sketched in on Fig. 1.

In Fig. 3, the "double shoulder" seen in the freezing point curve for 0.15 *M* DMSO was reproducible. These shoulders may be indicative of the beginning of solidification and the transition to the solid solution phase, respectively.

Many organic compounds are known to form glasses rather than crystalline solids when cooled. Among the best known of these are the glycols. For propylene glycol, dipropylene glycol, 2,5-hexane diol, and others Curme and Johnston (7) describe the freezing points as "sets to a glass below −50." The reasons for the formation of this "fourth state of matter" have been discussed for many years. The two major theories are the crystallite and network theories, but the latter seems to have gained wider acceptance (8). According to it, a three-dimensional network develops from a random distribution of loosely linked molecules or particles in space. Because of the haphazard arrangement in the lattice, the forces between units are not of equal strength. As a result, when heat is added to the system the lattice does not collapse all at once at a definite temperature, as in a crystal, but loses its coherence in stages as first the weaker and then the stronger bonds are ruptured (9). Conversely, as heat is removed from the system, the rigidity of the lattice takes place slowly, as evidenced by the stages of increased viscosity, until the amorphous solid is formed. Therefore, a glass has a softening region rather than a sharp melting point; it shows a region of increased viscosity, rather than a well-defined freezing point.

One of the rules of Zachariesan's network theory was that the network formed is built of polyhedra and at least three corners of each polyhedron must be shared. Therefore, the central atom of each polyhedron must have a coordination number of three or more. However, Weyl and Marboe (10) are insistent that they can see no justification for assuming that a tetrahedral structure is essential for glass formation.

It seems reasonable to explain the behavior of the DMSO–water solutions on the basis of a modified lattice theory. If there is definite compound formation between water and DMSO at a ratio of 2:1, then a structure could be formed of subunits of two water molecules tightly bound to one DMSO molecule, with each such subunit more loosely bound to the next subunit. Hence, the over-all structure would be held together by bonds of varying strength or force. At concentrations of water and DMSO other than 2:1, the system would consist of a variety of structural subunits—long and short chains and/or groups of oddly shaped units. Because of the lack of order of the structure and the complexity of the system, crystallization would not occur at the freezing point, but a glass-like solid would form instead.

Those systems that do not crystallize when cooled generally do exhibit temperature-dependent viscosity, and the viscosity reaches a maximum just above the solidification point. If temperature-dependent viscosity is due to asymmetries in the structure of the melt, then this would seem to confirm the existence of a modified lattice structure for DMSO–water solutions.

Assay of Methenamine Mandelate and Its Pharmaceutical Dosage Forms by Direct Cerimetric Titration

By LESTER CHAFETZ and CHARLES A. GAGLIA, JR.

Avoidance of bisulfate ion and control of acidity permit the direct cerimetric titration of the mandelic acid moiety of methenamine mandelate to a sharp instrumental or indicator end point. Separation and titration procedures for the drug in its dosage forms are described. The procedures compare favorably in speed and selectivity with the U.S.P. assays. The scope and limitations of the analytical reaction are defined.

METHENAMINE mandelate[1] and its tablet and oral suspension dosage forms are recognized in U.S.P. XVII (1) in the urinary antibacterial category. The drug is unique among official salts in that its biological activity derives from both ions. The U.S.P. monograph provides 96% minimum assay values for methenamine mandelate by a procedure selective for methenamine and for mandelic acid by titration with alkali. The net reaction in the U.S.P. mandelic acid assay may be represented:

$$(CH_2)_6N_4H^+ + OH^- = (CH_2)_6N_4 + HOH$$

where the actual acid titrated is the conjugate acid of methenamine; thus the mandelic acid content is inferred rather than determined.

Titration of methenamine mandelate preparations with alkali does not discriminate between methenamine conjugate acid and other organic acids. Difficulty in distinguishing mandelic acid from other organic acids generated during exaggerated stability studies of experimental methenamine mandelate formulations led to the study of conditions for the selective titration of mandelic acid reported here.

Mandelic acid is quantitatively and selectively oxidized by ceric salts according to the equation:

$$C_6H_5CHOHCO_2H + 2Ce(IV) \rightarrow C_6H_5CHO + CO_2 + 2H^+ + 2Ce(III)$$

Helmstaedter (2) applied the Verma and Paul (3) cerimetric titration of mandelic acid to methenamine mandelate. The procedure requires heating mandelic acid with excess ceric sulfate in sulfuric acid solution at reflux and back-titration with a standard reductant. Under these severe conditions the ceric reagent functions as a powerful and general oxidant and formaldehyde liberated from methamine is oxidized also (2). Mathur and Rao (4) reported a residual titration procedure at room temperature with ceric sulfate using visible light catalysis. Chafetz (5) found that ceric oxidation is general for arylglycolic acids and described procedures for their quantitative estimation by ultraviolet spectrometry of the carbonyl reaction product. Because spectrophotometry requires use of a reference standard and the residual titration methods are time consuming and are lacking in selectivity, conditions for the direct titration of mandelic acid in methenamine mandelate and its pharmaceutical dosage forms were investigated.

Received April 25, 1966, from the Pharmaceutical Research and Development Laboratories, Warner-Lambert Research Institute, Morris Plains, N. J. 07950.

Accepted for publication June 8, 1966.

Presented to the Section on Drug Standards, Analysis and Control, A.PH.A. Academy of Pharmaceutical Sciences, Dallas meeting, April 1966.

[1] Marketed as Mandelamine by Warner-Chilcott Laboratories, Division of Warner-Lambert Pharmaceutical Co., Inc.

Kinetic studies of the Ce(IV) oxidation of mandelic acid (6, 7) showed specific retardation of the reaction rate by bisulfate and hydrogen ions. Using ceric ammonium nitrate in dilute nitric acid, it was found that the oxidation rate of mandelic acid was sufficiently rapid to afford direct titration to an instrumental or color end point. This is the first report to our knowledge of a direct titration of mandelic acid with ceric ion in aqueous system.

EXPERIMENTAL

Titrant.—An approximate 0.05 *N* solution (2.45%) of ceric ammonium nitrate in *N* nitric acid was employed. The titrant was filtered through paper and standardized against primary standard grade ferrous ethylenediammonium sulfate (G. F. Smith Co.), using about 400 mg. of the ferrous salt, accurately weighed, in 100 ml. of distilled water. One drop of nitroferroin indicator solution was used, prepared by dissolving 150 mg. of 5-nitro-1,10-phenanthroline in 15 ml. of freshly made 1.4% aqueous ferrous sulfate. The color change, pink to colorless, coincided with the potentiometric end point in mandelic acid titrations.

Other Reagents and Supplies.—Chemicals used in the study were the best available commercial grades, used without further purification. These included mandelic acid, benzilic acid, phenylacetic acid, atropine sulfate, homatropine hydrobromide, and methenamine mandelate. Methenamine mandelate dosage forms described in this report were samples of regular production lots of Warner-Chilcott Laboratories. Dowex 1-X2 (50–100 mesh), a strong-base anion exchange resin, and a 5% potassium nitrate solution in 0.05 *N* nitric acid were employed in the tablet assay procedures.

Potentiometric titrations were carried out using various commercial platinum billet indicator and saturated calomel reference electrodes with a Sargent model D automatic titrator (used at the "slow" speed) or a Beckman zeromatic pH meter.

Preliminary Observations.—Oxidation of mandelic acid with 0.1 *N* ceric sulfate (U.S.P. XVII, p. 1082) was found to be too slow to afford direct titration at room temperature, even when the benzaldehyde is extracted into a hydrocarbon solvent phase, an expedient suggested by previous work (5). Direct titration proceeded smoothly using a nitric acid system and a sample solution about neutral in pH. Use of *N* nitric acid for the sample as well as titrant led to a severe fall off in reaction rate. Induction of the oxidation can be readily discerned by the increasingly strong odor of benzaldehyde which develops during the titration, a much more selective identity test for mandelic acid than that given in U.S.P.

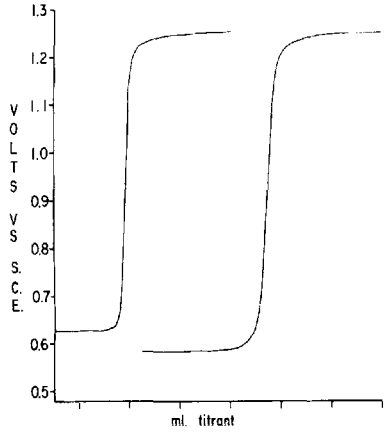

Fig. 1.—Typical titration curves using the recording titrator for methenamine mandelate (left) and mandelic acid by direct cerimetric titration.

Procedure for Mandelic Acid or Methenamine Mandelate U.S.P.—Dissolve approximately 45 mg. mandelic acid or 90 mg. methenamine mandelate, accurately weighed, in 25–50 ml. of water, and titrate the magnetically stirred solution with standard 0.05 *N* ceric ammonium nitrate in *N* nitric acid to the redox indicator or potentiometric end point. The milliequivalent weight of mandelic acid is 76.08 mg.; of methenamine mandelate, 146.17 mg.

$$\text{mg. } C_8H_8O_3 \text{ or } C_6H_{12}N_4 \cdot C_8H_8O_3 = \text{ml.} \times N \times \text{meq. wt.}$$

Assay of Methenamine Mandelate Oral Suspension U.S.P.—Transfer an accurately weighed sample of methenamine mandelate oral suspension, equivalent to about 275 mg. of methenamine mandelate, to a 250-ml. separator. Add 35 ml. of heptane and exactly 100.0 ml. of distilled water. Shake vigorously and allow the layers to separate. Filter about 50 ml. of the aqueous phase through paper, and transfer exactly 25.0 ml. to a 100-ml. beaker. Add 1 drop of nitroferroin indicator solution, and titrate with standard 0.05 *N* ceric reagent from a 25-ml. buret.

$$\text{methenamine mandelate, mg./5 ml.} = \text{ml.} \times N \times 146.17 \text{ mg.} \times 100/25 \times 5 \times \text{density/Gm. sample}$$

Assay of Methenamine Mandelate Tablets U.S.P.—Determine the average weight of 10 tablets and pulverize them. Transfer a portion of the powdered tablets, equivalent to about 1000 mg. of methenamine mandelate, accurately weighed, to a 100-ml. volumetric flask. Add about 60 ml. of distilled water, and shake the mixture mechanically for 10 min. Dilute to the mark with water, mix, and filter through paper. Transfer exactly 5.0 ml. of filtrate to a 5–10 mm. i.d. ion exchange column containing about 1 Gm. of ion exchange resin[2] in the hydroxide cycle. (Prepare the column by equilibrating the resin with about 5 ml. of *N* sodium hydroxide for 10 min., then transferring it to the column and washing with distilled water until the effluent is neutral.) Allow the liquid to drain to the top of the resin bed, then wash the column with about 10 ml. of water, allowing the effluent to drain at the rate of 1–2 ml./min. Stop the flow when the wash level reaches the top of the resin bed, place a 150-ml. beaker as receiving vessel, and elute the mandelic acid with about 50 ml. of 5% potassium nitrate in 0.05 *N* nitric acid at a rate of about 3 ml./min. After collecting about 50 ml., add 1 drop of nitroferroin indicator, and titrate with 0.05 *N* ceric titrant.

$$\text{methenamine mandelate, mg./tablet} = \text{ml.} \times N \times 146.17 \times 100/5 \times \text{mg. av. tablet wt./mg. sample wt.}$$

It may be noted that the procedure may readily be adapted to single unit assay.

Titration of Related Compounds.—Benzilic acid, phenylacetic acid, homatropine hydrobromide, and atropine sulfate were titrated as described above for mandelic acid, using approximately 0.3 mmole of each compound. The ester alkaloids were titrated before and after alkaline saponification.

[2] Marketed as Dowex 1-X2 by the Dow Chemical Co., Midland, Mich.

RESULTS AND DISCUSSION

Potentiometric Data.—Typical titration curves obtained on mandelic acid and methenamine mandelate using an automatic recording titrator are shown in Fig. 1. The oxidation potential of the reaction, Ce(IV) + e = Ce(III), was calculated as +1.464 v. from the titration curve. Half-cell potentials for irreversible oxidation of mandelic acid, methenamine mandelate, and nitroferroin were calculated to be +0.868, +0.832, and +1.044 v., respectively.

Assay of Mandelic Acid and Methenamine Mandelate.—Titrations proceeded smoothly with mandelic acid or its methenamine salt, with no apparent interference from the methenamine. Data found are presented in Table I.

Methenamine Mandelate Oral Suspension.—Samples of suspension in which the vegetable oil vehicle has become rancid cannot be accurately assayed by the U.S.P. method, for titration with alkali does not discriminate between methenamine conjugate acid and fatty acids. The cerimetric method could be successfully applied to assay of methenamine mandelate in rancid vegetable oil without separation of the drug using the potentiometric

Table I.—Cerimetric Titration of Methenamine Mandelate[a]

Trial	mg. Weighed	mg. Found	% Found

Table II.—Replicate Assays of Methenamine Mandelate Oral Suspension

Trial	*1*	*2*	*3*	*4*	*5*	*6*
mg./5 ml. (250 mg. declared)	254.5	257.0	255.0	257.5	256.5	255.0

method by the simple expedient of immersing the electrode tips in the aqueous layer; however, use of the color indicator was preferred because of its simplicity. Observation of the indicator color change in one formulation with a pink color was difficult, for it required discerning a change from pink to colorless in the aqueous layer in the presence of a pink organic layer. Typical results obtained by the extraction procedure using the redox indicator are presented in Table II.

Methenamine Mandelate Tablets.—The ion exchange resin isolation procedure prescribed was employed to circumvent slight interference from sucrose, used as an excipient in the tablet coating. The sugar was slowly oxidized by the titrant. Triplicate assays of methenamine mandelate tablets declaring 500 mg. provided results of 491, 490, and 493 mg./tablet, using a composite sample.

Titration of Related Compounds.—Ceric oxidation of arylglycolic acids appears to be a general reaction (5) which may be represented:

$$\mathrm{Ar{-}\underset{\displaystyle R}{\underset{|}{C}}HOHCO_2H + 2Ce(IV) \rightarrow ArCOR + CO_2 + 2H^+ + 2Ce\,(III)}$$

In this reaction, Ar = aromatic or heteroaromatic, and R = H, an aromatic or alicyclic group. Wholly aliphatic glycolic acid derivatives do not oxidize with the same stoichiometry (6).

Benzilic acid, where Ar = R = C_6H_5—, can be titrated as readily as mandelic acid. Duplicate titrations of benzilic acid provided values 100.1% of theory.

Phenylacetic acid, $C_6H_5CH_2CO_2H$, which may be considered in this discussion a desoxymandelic acid, does not consume titrant. Atropine, the tropine ester of tropic acid, $C_6H_5CH(CH_2OH)CO_2H$, homologous to mandelic acid, did not consume titrant before or after saponification.

The titration could be applied to homatropine hydrobromide, the mandelic acid homolog of atropine, after saponification, but the only indication of reaction in the intact ester was a slight benzaldehyde odor. The saponified ester titrated readily to a value 100.3% of theory.

Interferences.—Although oxidations with ceric salts are selective for mandelic acid and other arylglycolic acids, they are by no means specific. The products obtained depend on reaction conditions employed. Although no interference by methenamine was encountered in the titrations described here, heating methenamine mandelate with excess ceric sulfate results in oxidation of the formaldehyde liberated from methenamine to formic acid (2) as well as oxidation of the mandelic acid to benzaldehyde. In general, some type of separation procedure is necessary for determination of methenamine mandelate in the presence of reducing agents or in colored solutions where the indicator method of end point detection is used.

SUMMARY AND CONCLUSIONS

Mandelic acid is quantitatively and selectively oxidized by ceric salts to benzaldehyde, carbon dioxide, and hydrogen ion. Although residual titration procedures employing excess oxidant have been described, no direct titration has been reported previously. The specific rate retarding effect of bisulfate ion, present in the conventional ceric sulfate titrant, is eliminated by using ceric ammonium nitrate in nitric acid as titrant. This affords a sufficiently rapid reaction rate to permit direct titration to a sharp indicator or instrumental end point, obviates one standard solution, and saves time. The benzaldehyde odor produced during the titration serves as a confirmatory identity test for mandelic acid.

Application of the titration in conjunction with appropriate separation procedures is described for assay of methenamine mandelate and its official preparations. The proposed assays compare favorably with the U.S.P. procedures.

The scope and limitations of the reaction are defined.

Nuclear Magnetic Resonance Spectra of Amines III. Identification of *N*-Substituted Amino Acids

By W. E. THOMPSON, R. J. WARREN, I. B. EISDORFER, and J. E. ZAREMBO

Spectra of *N*-substituted amino acids examined in alkaline deuterium oxide and in trifluoroacetic acid show chemical shifts and first-order spin-spin splitting patterns that are useful for identification of *N*-methyl, *N*-methylene, *N*-phenyl, and other groups attached to the nitrogen of an amino acid.

STRUCTURE-SPECTRA correlations of amino acids have been a favorite research subject for many years now, so it is not surprising that considerable work has been done correlating amino acid structures with NMR spectra. Among the more interesting studies that have been reported in this field are the correlation of NMR spectra with L- and *m*-structures of cystine (1), and a study of the effect of optical activity of amino acids on their NMR spectra (2). There have also been a significant number of comprehensive analyses of specific amino acid spectra using NMR (3–6). The spectra reported in this paper were needed for the identification of amino acid side chains on a drug metabolite. The authors are following the technique initiated by Silverstein (7, 8), using the simplest compounds available to illustrate the NMR spectrum due to a particular functional group.

The authors have examined NMR spectra of glycine and *N*-substituted glycine in alkaline D_2O and in trifluoroacetic acid as solvents to illustrate the spectral effects of conversion of *N*-substituted amino acid anions into cations.

EXPERIMENTAL

All spectra were obtained with a Varian model A-60 NMR spectrometer using Varian sample tubes. One normal KOD in deuterium oxide was used as the solvent for anion spectra and trifluoroacetic acid as solvent for cation spectra. The probe temperature was 38°. The concentration of amino acid was 50 mg./ml. The sample of glycine was A grade (Calbiochem) purchased from the California Corp. for Biochemical Research. The *N*-substituted glycines were used as purchased from the K & K Laboratories, Inc., Plainview, N. Y.

RESULTS AND DISCUSSION

Figures 1–4 show the effect of conversion of the anions to cations on the NMR spectra of *N*-substituted glycines. The first-order splitting pattern of the methylene or methyl(s) in the cations is related to the number of protons on the nitrogen (9). The number of lines in a multiplet is one more than the number of protons on the nitrogen (cation), a quartet for a primary amine ion, $-NH_3^+$ (Fig. 1, B), a triplet for a secondary amine ion, $=NH_2^+$ (Fig. 2, B) and a doublet for a tertiary amine ion, $\equiv NH^+$ (Fig. 3, B).

The spectrum for *N*-phenylglycine as anion (Fig. 4, A) shows a complex AB_2X_2 pattern for the phenyl protons in the δ = 6.6–7.6 p.p.m. region. When converted to the cation (Fig. 4, B) the AB_2X_2 pattern collapses into a single peak at 7.6 p.p.m. A possible cause of this signal coalescence was postulated in a previous note (10).

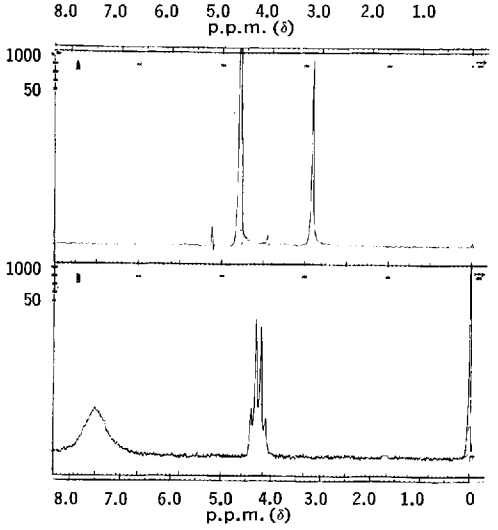

Fig. 1.—NMR spectra for glycine. Key: A, 1 *N* KOD in D_2O as solvent; B, CF_3COOH as solvent.

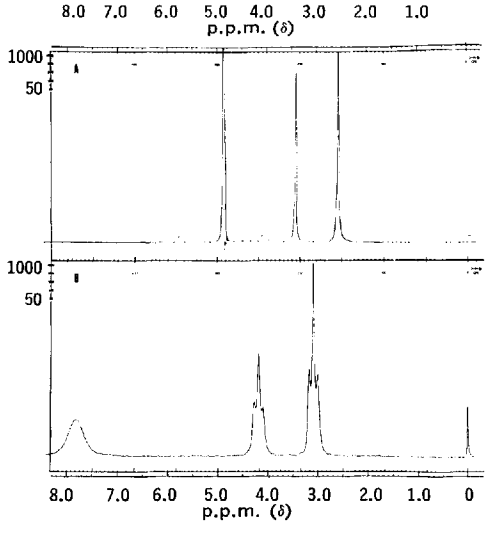

Fig. 2.—NMR spectra for sarcosine (*N*-methylglycine). Key: A, 1 *N* KOD in D_2O as solvent; B, CF_3COOH as solvent.

Received March 31, 1966, from Smith Kline & French Laboratories, Philadelphia, Pa. 19101.
Accepted for publication May 23, 1966.
The authors acknowledge the assistance of MRS. Eleanor Cherry in obtaining the spectra presented here.

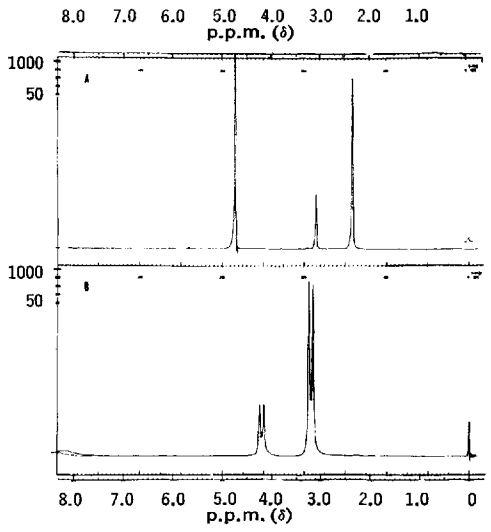

Fig. 3.—NMR spectra for *N,N*-dimethylglycine. Key: A, 1 *N* KOD in D_2O as solvent; B, CF_3COOH as solvent.

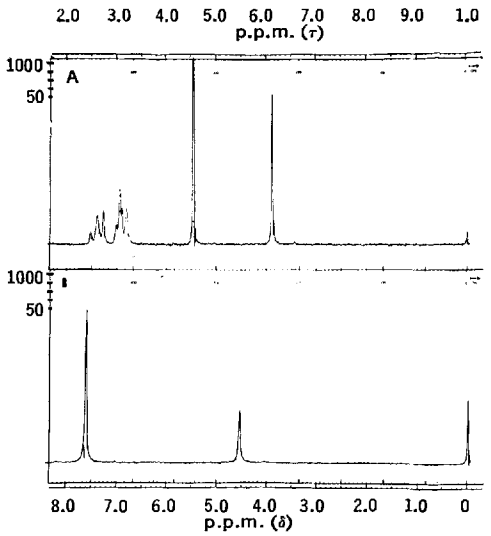

Fig. 4.—NMR spectra for *N*-phenylglycine. Key: A, 1 *N* KOD in D_2O as solvent; B, CF_3COOH as solvent.

TABLE I.—NMR CHEMICAL SHIFTS FOR *N*-SUBSTITUTED GLYCINES

Compd.	Chemical Shifts as Anion in 1 *N* KOD/D_2O	Chemical Shifts as Cation in CF_3COOH
Glycine	$D_2NCH_2COO^-$	$NH_3{}^+CH_2COOH$
	3.18	4.25
	s	*q*
Sarcosine	$CH_3NDCH_2COO^-$	$CH_3NH_2{}^+CH_2COOH$
	2.57 3.40	3.07 4.17
	s *s*	*t* *t*
N,N-Dimethylglycine	$(CH_3)_2NCH_2COO^-$	$(CH_3)_2NH^+CH_2COOH$
	2.35 3.02	3.22 4.23
	s *s*	*d* *d*
N-Phenylglycine	$C_6H_5NDCH_2COO^-$	$C_6H_5NH_2{}^+CH_2COOH$
	6.6–7.6 3.82	7.60 4.53
	AB_2X_2 *s*	*s* *s*

The methylene absorption at 4.53 p.p.m. in Fig. 4, B, remains a single peak in trifluoroacetic acid since this acid is not strong enough to protonate the nitrogen irreversibly. The rapid exchange of protons prevents observation of spin-spin splitting in this solvent at 38°.

Chemical shift data for these *N*-substituted glycines are listed in Table I.

Numbers below hydrogen attached to carbon are chemical shift values in parts per million downfield relative to 3-(trimethylsilyl)-1-propanesulfonate ion for D_2O solutions and relative to tetramethyl silane for trifluoroacetic acid solutions. The abbreviations for splitting patterns are: *s* = single peak, *d* = doublet, *t* = triplet, *q* = quartet, and AB_2X_2 = 5 proton pattern of up to 110 lines.

The spin-spin splitting constant for the doublets, triplets, and quartet was 5 c.p.s.

The chemical shifts for all nonexchangeable protons are downfield on conversion of the anion to cation. These changes in magnetic shielding range from 0.5 p.p.m. downfield for the methyl in sarcosine to 1.21 p.p.m. downfield for the methylene in *N,N*-dimethylglycine. The shielding values for nonexchangeable protons in CF_3COOH solutions seem more consistent than the shielding values in KOH–D_2O. The values for sarcosine in water indicate considerable solvent interaction.

CONCLUSIONS

The spectral changes for an *N*-substituted amino acid observed between alkaline D_2O and CF_3COOH as solvents are useful for locating *N*-methyl, *N*-methylene, *N*-phenyl, and other adjacent structures attached to the nitrogen of an amino acid.

Modified Medium Containing Phosphomolybdic Acid Useful in the Identification of Specific Yeast-Like Fungi

By JOSEPH E. GRAY

A medium containing phosphomolybdic acid is described which permits growth and differentiation between closely related yeast-like fungi. When properly formulated and packaged, the vials of medium can be stored at room temperature for 6 months or more without loss of stability or effectiveness.

CANDIDA ALBICANS is the most frequent isolate from mycotic vaginitis infections and is considered by many clinicians to be the only pathogenic *Candida* species. However, studies by Haley (1), Kearns and Gray (2), Jillson and Lyle (3), Hurley and Morris (4), and De Sousa and Van Uden (5) have shown that yeast species other than *C. albicans* can initiate or complicate this infection. Taubert and Smith (6) have reported a significant number of cases where a clinical diagnosis of vaginal candidiasis was made and from which *C. albicans* was not cultured.

Various laboratory media have been developed to aid in the identification of *C. albicans*. However, these media are less precise in their ability to distinguish between *Candida* species other than *C. albicans*. Biological methods described by Lodder and Kreger-Van Rij (7), Wickerham (8, 9), and Martin *et al.* (10) are definitive but time consuming. It would appear that a selective medium able to rapidly differentiate between closely related yeast-like fungi would be of value in the diagnosis of mycotic vaginitis.

The use of a medium containing phosphomolybdic acid for *C. albicans* differentiation was first described by MacLaren and Armen (11) in 1958. The cultures were identified by their macrocolony pigmentation and an extracellular reaction seen in the medium.

This original medium had deficiencies which were reported by Holland and Kunz (12), who found a variation in the colony pigmentation obtained within *C. albicans* strains. In unpublished studies in this laboratory it was found that the medium often showed closely related *Candida* species with similar colony pigmentation, a result which hindered positive identification.

The modification described in this report results in a formulation that significantly improves the differentiation of yeast-like fungi encountered in cases of mycotic vaginitis. The distinct colony pigmentation or growth characteristics obtained with the various species, on this medium, makes possible a relatively rapid identification.

PROCEDURE

Essentially the medium consists of two portions: the basal medium and the stock solutions. These are prepared and sterilized before use.

Materials.—Agar (Difco), sucrose (Difco), proteose peptone (Difco), phosphomolybdic acid (20 $MoO_3 \cdot 2\ H_3PO_4 \cdot 48\ H_2O$, Merck), polysorbate 21 (polyoxyethylene sorbitan monolaurate)[1] yeast nitrogen base (Difco), and neomycin sulfate.

Basal Medium.—Distilled water is added to 1.5 Gm. of agar to give a total volume of 75 ml. in a 300-ml. flask. This size flask allows the medium to be properly agitated during formulation. The agar is dissolved by heating in water then auto-

TABLE I.—STOCK SOLUTIONS

Ingredient	Concn. w/v	Amt./75 ml. Basal Medium
Sucrose	40%	10 ml.
Proteose peptone	10%	10 ml.
Phosphomolybdic acid	1.66%	5 ml.
Polyoxyethylene sorbitan monolaurate	11.4%	1 ml.
Yeast nitrogen base	6.7%	3 ml.
Neomycin sulfate	7 mg. neomycin base/ml.	3.8 ml.
	Total vol.	107.8 ml.

TABLE II.—COLONY COLOR AND GROWTH CHARACTERISTICS

Organism	Results
C. albicans	A distinctive olive colony—the reverse of the colony is also olive.
C. tropicalis	A deep blue or blue-green colony—the reverse is also blue. Blue pigment is usually present in the medium.
C. guilliermondi	A brown or dark gray colony with a definite white border.
C. krusei	A small dull white colony.
Torulopsis glabrata	A small, flat, white shiny colony that may be hard to distinguish from *C. krusei*.
C. albicans var. stell.	A small light tan colony.
C. parakrusei	A dull brown slow growing colony, larger and more irregular than the smooth *C. albicans* colony.
Saccharomyces cerevisiae	A bright blue colony, lighter in color and larger than *C. tropicalis*.
Cryptococcus neoformans	A white raised moist colony, larger than *T. glabrata*. Later may show mucoid growth with a tan cast.
Rhodotorula sp.	A pink to pinkish - brown yeast-like colony.

Received May 2, 1966, from the Research and Development Department, Norwich Pharmacal Co., Norwich, N. Y.
Accepted for publication May 23, 1966.
The author is indebted to Mrs. June Horton and Mr. Ralph Bush for their technical assistance and to Mr. Peter Alotta, Pharmaceutical Research Division, for supplying the packaging data and material.

TABLE III.—MOST FREQUENTLY ISOLATED SPECIES FROM MYCOTIC VAGINITIS INFECTIONS, RESULTS OF CULTURE ON TEST MEDIUM

Organism	Strains Tested, Total No.	Typical Reactions, No.	Atypical Reactions, No.	Explanation
C. albicans	171	162	9	2 = Olive green colony 3 = Light tan colony 1 = Poor growth 3 = No growth
T. glabrata	17	16	1	= No growth
C. tropicalis	8	8		
C. krusei	7	5	2	= No growth
C. guilliermondi	5	3	2	= No growth
C. parakrusei	2	1	1	= Olive white colony
Totals	210	195	15	

claved at 120° for 15 min. The flask is cooled to 50° in a water bath; if necessary the volume is readjusted to 75 ml. with sterile distilled water. The requisite amounts of stock solution are then added.

Stock Solutions.—All solutions are prepared using distilled water and are sterilized by Millipore filtration using type HA filter pads.

The stock solutions must be added to the basal medium in the order shown (Table I). After the addition of the phosphomolybdic acid, the flask is shaken vigorously to insure homogeneity of the heavy precipitate that results. The addition of polyoxyethylene sorbitan monolaurate reduces foam formation and permits the medium to be tubed satisfactorily. It is not necessary to adjust the pH of the basal medium before sterilizing. The pH of the complete medium is about 5.3.

Packaging.—Sufficient medium is slanted in clear glass vials to permit visual examination of colony growth. A screw cap with a moisture proof liner is necessary for storage. The vials can then be stored at room temperature for periods of 6 months or more without loss of sensitivity.

Inoculation.—The medium can be inoculated with a sterile cotton swab or a sterile loop. Better results are obtained with a light inoculum. Mixed yeast infections are more readily detected when discrete colonies develop. Often the presence of excess body exudate may hinder colony growth. If necessary, streak plates on Sabouraud's dextrose agar can be made, then discrete colonies can be transferred to the medium for growth and identification.

RESULTS AND DISCUSSION

Table II shows the colony pigmentation and growth characteristics for those yeast or yeast-like fungi most frequently isolated from mycotic vaginitis infections. These species samples were individually identified by the biological methods mentioned previously (7–10). In addition, some species are listed that appear infrequently in vaginitis infections: *Saccharomyces cerevisiae, Cryptococcus Neoformans, and Rhodotorula species* (2, 5, 13). For purposes of comparison, duplicate cultures representing the various species were obtained from the American Type Culture Collection.

Table III lists the clinical isolates, the number of each species studied, and the results obtained on the test medium. The majority of cultures showed characteristics similar to those described in Table II for the particular species. Of the 15 cultures considered atypical, eight failed to grow on the test medium while showing good growth on Sabouraud's medium.

In a separate experiment, a number of strains were inoculated on freshly prepared media, and media stored at room temperature for 6 months. There was no difference between the two lots of media.

Although the medium described in this report is concerned with the differentiation of fungi associated with mycotic vaginitis, it has also been tested for possible use in the isolation and identification of dermatophytic organisms. With the exception of *Trichophyton rubrum*, most dermatophytes grow rapidly on the medium, but there is no color differential as seen with the yeast-like fungi.

The concentration of phosphomolybdic acid is critical for the production of specific pigments among the closely related *Candida* species. Neomycin sulfate is not necessary for the development of the differential characteristics but does inhibit the utilization of phosphomolybdic acid by bacterial contaminants often found in clinical samples. Those bacteria that do succeed in growing usually show a low, moist blue, confluent streak of growth easily distinguished from that of *C. tropicalis*. To date, no bacterial species that grows similar to *C. albicans* on the medium has been encountered in the clinical samples from cases of mycotic vaginitis.

Detection of Trace Amounts of Lysergic Acid Diethylamide in Sugar Cubes

By CZESLAWA RADECKA and ISHWAR C. NIGAM

A method for the detection of trace amounts of lysergic acid diethylamide in sugar cubes is described. The free base is extracted from aqueous sodium bicarbonate solution with methylene chloride and hydrogenated with Adam's catalyst. The product is examined by gas chromatography and its identity confirmed by thin-layer chromatography of the eluate which yields two characteristic spots—one blue, the other yellow—on spraying with *p*-dimethylaminobenzaldehyde. The yellow spot exhibits strong blue fluorescence when viewed under ultraviolet light prior to application of the reagent.

THE NEED for sensitive procedures to detect lysergic acid diethylamide (LSD) in narcotic seizures was illustrated in a previous communication from this laboratory (1). The recent discovery of the illegal sale of sugar cubes impregnated with the psychotomimetic drug focused anew the authors' attention on existing analytical methodologies and prompted them to develop an additional microphysicochemical technique for its detection and identification. Exploratory experiments aimed at direct application of gas chromatography to the analysis of LSD were unsuccessful. Due to low volatility, the compound could not be recovered even when using columns of low packing ratio and operating at high column temperatures. Consideration was, therefore, given to hydrogenation of the drug prior to gas chromatography as a means of eliminating its unsaturation (C_9-C_{10} bond) and thereby increasing its stability.

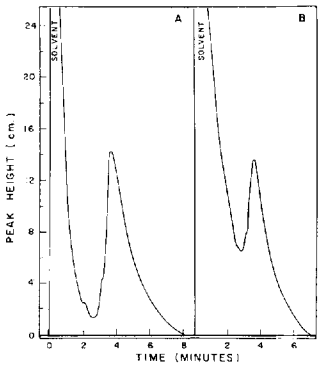

Fig. 1.—Gas chromatograms of hydrogenated LSD. Key: A, reference sample; B, sugar cube extract (exhibit J568). Column temperature: 270°; injector temperature: 290°; nitrogen flow: 22 ml./min.; sample volume: 1 μl.

TABLE I.—THIN-LAYER CHROMATOGRAPHY OF HYDROGENATED LSD

Sample	Spot	Chromatographic Data: Color Observed: Under U.V. Light	After Spraying	*Rf* Value	Relative *Rf* Value[a]
Hydrogenated LSD	1	Blue fluorescence	Faint yellow	0.81	1.04
	2	...	Blue	0.78	1.00
Gas chromatographic eluate, 3–4 min.	1	Blue fluorescence	Faint yellow	0.81	1.04
	2	...	Blue	0.78	1.00
Hydrogenated LSD soln. stored for 2 wk.	1	Blue fluorescence	Faint yellow	0.81	1.04
	2	...	Blue	0.78	1.00
	3	...	Blue	0.54	0.69

[a] Reference: spot 2.

The present communication describes the successful application of this approach to the detection of the psychotomimetic drug in sugar cubes and provides additional identity tests based on thin-layer chromatography of the effluent gas chromatographic peak.

EXPERIMENTAL

Materials

Lysergic Acid Diethylamide Tartrate.—LSD 25 (courtesy Sandoz Ltd., Dorval, Quebec, Canada).

Sugar Cubes.—(*a*) Specimens seized by officers of the Royal Canadian Mounted Police (exhibit J568) and (*b*) specimens prepared by impregnation with aqueous solutions containing 1 mg. of LSD/ml., and drying in a stream of warm air (50°) for about 5 min.

Methods

Extraction of LSD.—The drug was isolated in accordance with the following procedure (2). The sugar cube was dissolved in 10 ml. of distilled water, 0.5 Gm. of sodium bicarbonate was added, and the free base was extracted with four 5-ml. portions of methylene chloride. The lower layer was withdrawn through a piece of cotton wool placed in the stem of the separator, care being taken to minimize exposure of the isolate to light and heat. The extract was evaporated to dryness in a gentle stream of nitrogen.

Hydrogenation of LSD.—The sample (reference compound or material extracted from a sugar cube) was dissolved in 1 ml. of methanol and hydrogenated at atmospheric pressure for 3 hr. using 10 mg. of Adam's catalyst. After filtration, the solution was gently concentrated to 0.1 ml. in a slow stream of nitrogen.

Gas Chromatography.—An Aerograph Hi-Fi,

Received February 23, 1966, from the Research Laboratories, Food and Drug Directorate, Department of National Health and Welfare, Ottawa, Ontario, Canada.
Accepted for publication April 12, 1966.
The authors are indebted to Dr. Leo Levi for his interest in this study.

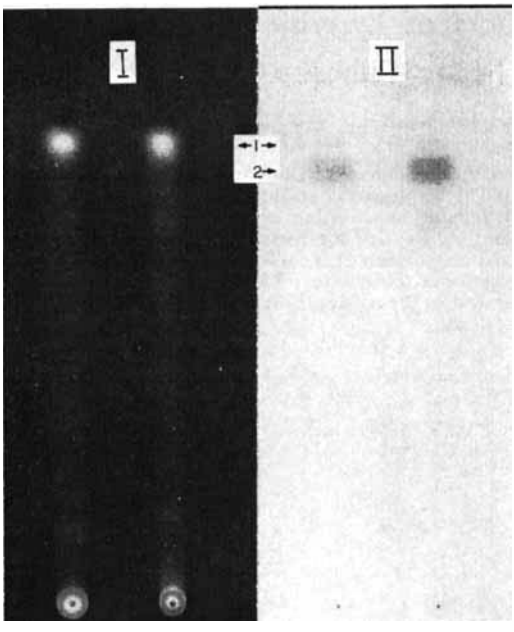

Fig. 2.—Thin-layer chromatograms of hydrogenated LSD. Key: I, observed under U.V. light; II, observed after spraying with *p*-dimethylaminobenzaldehyde; A, reference sample: product from hydrogenation of 1.8 mg. LSD in 0.1 ml. methanol. Volume applied: 2 μl.; B, sugar cube (exhibit J568). Product from hydrogenation of sugar cube extract in 0.05 ml. of methanol. Volume applied: 4 μl.

model A-600-C, equipped with hydrogen flame ionization detector, was employed. A glass tube was inserted into the injection port to minimize degradation of the sample at the metal surface of the preheater. The column, a stainless steel tube (5 ft. × 1/8 in.) was packed with micro glass beads (60 mesh) coated with 0.2% of silicone rubber SE-30. By means of a stream splitter, eluates were collected in capillaries packed lightly with methanol moistened glass wool.

Thin-Layer Chromatography.—*Thin-Layer Plates.*—Glass plates (20 × 20 cm.) coated with aluminum oxide G (Merck). Layer thickness 250 μ.

Solvent System.—Chloroform–ethanol (96:4) (3).

Detection.—Following migration of the solvent front (15 cm.), plates were observed under ultraviolet light (3660 Å.) and subsequently sprayed with a solution of *p*-dimethylaminobenzaldehyde (2 Gm.) in concentrated HCl (20 ml.) and ethanol (80 ml.) (4).

RESULTS AND DISCUSSION

The product obtained by catalytic hydrogenation of LSD could easily be subjected to gas chromatography. A main peak (retention time: 3.6 min.) and two slight shoulders (retention times: 3.1 and 2.1 min., respectively) were observed (Fig. 1). In order to obtain more reproducible retention time data, ergonovine maleate hydrogenated in accordance with the procedure described was used as internal reference. Relative retention time of hydrogenated LSD: 1.64.

Thin-layer chromatographic analysis of the effluent emerging between 3 and 4 min. served to confirm the gas chromatographic identification. The thin-layer chromatogram of hydrogenated LSD exhibited a blue fluorescent spot when viewed under ultraviolet light. After spraying with the reagent, this spot acquired a yellow coloration, while another intense blue spot appeared at a slightly lower R_f value (Table I and Fig. 2). These same spots were observed when the gas chromatographic eluate was similarly examined. Solutions which had been kept for several days showed a number of additional but faint spots, among which one at R_f 0.54 was most prominent.

The thin-layer chromatographic technique was found to be superior to the gas chromatographic technique in that it allowed the characterization of LSD concentrates which failed to produce gas chromatographic peaks. Thus, when a sugar cube impregnated with 50 mcg. of LSD was processed as described, only a shoulder appeared on the descending portion of the solvent peak in the gas chromatogram at 3.6 min., while the corresponding eluate yielded a convincing thin-layer chromatogram.

REVIEWS

Advances In Chromatography. Vol. 1. Edited by J. CALVIN GIDDINGS and ROY A. KELLER. Marcel Dekker, Inc., New York, N. Y., 1965. 395 pp. Price $14.50.

Volume I of "Advances in Chromatography" is the first of a projected series which is directed toward the separation of the "hard core" of advances of chromatography from the mass of supporting data from which that core is established. It is comprised of ten chapters, six devoted to gas chromatography and four to general chromatography, each prepared by experts drawn from both academic and industrial backgrounds in England, Switzerland, and Yugoslavia as well as the United States.

The stated intent of the Editors is to present not the customary review, but rather critical surveys which will enable the reader who cannot keep up with the explosive growth in the field to maintain an over-all view of the progress in chromatography. As so frequently happens in a compilation of this type, there is a marked difference in the extent to which the individual authors attain this objective.

The single chapter of the volume relating directly to pharmaceutical chemistry (Qualitative and Quantitative Aspects of the Separation of Steroids, by E. C. Horning and W. J. A. Vandenheuvel) thoroughly fulfills the promise of its title. This is one of five chapters which succeeds in maintaining the balance of depth and breadth of coverage needed to achieve the goal of the Editors. Of the other five chapters, two are rigorous theoretical presentations of quite narrow topics, while a third covers a broad field at a rather elementary level. The remaining two fall between these.

Column partition chromatography is not discussed in this volume (nor in Volume II of the series, the contents of which are presented), although the chapter "Ion Exchange Chromatography," by F. Helfferich, alludes to a partition chromatography which differs from Martin and Synge's concept of the term.

A very interesting contrast in emphasis is found in two chapters. In "Separation of Steroids" a single sentence notes that separation of steroids became practical only after decreasing the amount of liquid phase; the chapter "Lightly Loaded Columns," by B. L. Karger and W. D. Cooke, is entirely devoted to the effects of this decrease. The two chapters thus complement each other.

In addition to the chapters mentioned above, the volume includes: "Chromatography and Electrophoresis on Paper and Thin Layers: A Teachers Guide," by Ivor Smith. "The Stationary Phase in Paper Chromatography," by G. H. Stewart. "The Techniques of Laminar Chromatography," by E. V. Truter. "Capillary Columns: Trials, Tribulations, and Triumphs," by D. H. Desty. "Gas Chromatographic Characterization of Organic Substances in the Retention Index System," by E. Sz. Kováts. "Inorganic Gas Chromatography," by R. S. Juvet, Jr. and F. Zado. "Interactions of the Solute with the Liquid Phase," by D. E. Martire and L. Z. Pollara.

This volume will be a worthwhile addition to the library of the pharmaceutical chemist.

Catalytic Hydrogenation: Techniques and Applications in Organic Synthesis. By ROBERT L. AUGUSTINE. Marcel Dekker, Inc., 95 Madison Ave., New York, N. Y., 1965. xii + 188 pp. 15.5 × 23 cm. Price: $8.75.

Periodically there becomes available a book which the chemist interested in preparative aspects of organic chemistry finds exceedingly useful. This is such a book.

The book presents descriptions, with illustrations, of the various types of apparatus available for carrying out hydrogenations as well as more detailed operating instructions for the more commonly used pieces of equipment. A chapter is devoted to the catalyst, reaction conditions, and the effects of variables such as temperature and pressure on the course of a hydrogenation. The catalysts which are discussed are those used most often in catalytic hydrogenation procedures and include nickel, platinum, palladium, ruthenium, copper–chromium oxide, and rhenium. Specific directions for preparing a number of these catalysts are given in an appendix.

In following chapters, there are presented general procedures for hydrogenation and hydrogenolysis of functional groups. Examples of virtually all functional groups and heterocycles capable of undergoing hydrogenation or hydrogenolysis are included. Such aspects as choice of catalyst, limitations of a given catalyst, and problems likely to be encountered in the hydrogenation of these functional groups are discussed. The stereochemical implications of hydrogenation reactions are discussed where pertinent, although rather briefly in some instances.

The literature pertaining to catalytic hydrogenations is vast and many procedures having preparative utility appear in papers which do not deal specifically with catalytic hydrogenation and for this reason may often be overlooked. However, the references used by the author are well chosen to illustrate the points being made and provide the reader with a source of more detailed information.

The text is well written, concise, and easy to read. Boldface type is used to make the recommended procedures for hydrogenation or hydrogenolysis of the common functional groups stand out. The author index is conveniently arranged so that both the page on which the work is cited and the page on which the full reference citation appears are given.

The book should be a particularly useful and ready source of information on preparative applica-

REVIEWS

Advances In Chromatography. Vol. 1. Edited by J. CALVIN GIDDINGS and ROY A. KELLER. Marcel Dekker, Inc., New York, N. Y., 1965. 395 pp. Price $14.50.

Volume I of "Advances in Chromatography" is the first of a projected series which is directed toward the separation of the "hard core" of advances of chromatography from the mass of supporting data from which that core is established. It is comprised of ten chapters, six devoted to gas chromatography and four to general chromatography, each prepared by experts drawn from both academic and industrial backgrounds in England, Switzerland, and Yugoslavia as well as the United States.

The stated intent of the Editors is to present not the customary review, but rather critical surveys which will enable the reader who cannot keep up with the explosive growth in the field to maintain an over-all view of the progress in chromatography. As so frequently happens in a compilation of this type, there is a marked difference in the extent to which the individual authors attain this objective.

The single chapter of the volume relating directly to pharmaceutical chemistry (Qualitative and Quantitative Aspects of the Separation of Steroids, by E. C. Horning and W. J. A. Vandenheuvel) thoroughly fulfills the promise of its title. This is one of five chapters which succeeds in maintaining the balance of depth and breadth of coverage needed to achieve the goal of the Editors. Of the other five chapters, two are rigorous theoretical presentations of quite narrow topics, while a third covers a broad field at a rather elementary level. The remaining two fall between these.

Column partition chromatography is not discussed in this volume (nor in Volume II of the series, the contents of which are presented), although the chapter "Ion Exchange Chromatography," by F. Helfferich, alludes to a partition chromatography which differs from Martin and Synge's concept of the term.

A very interesting contrast in emphasis is found in two chapters. In "Separation of Steroids" a single sentence notes that separation of steroids became practical only after decreasing the amount of liquid phase; the chapter "Lightly Loaded Columns," by B. L. Karger and W. D. Cooke, is entirely devoted to the effects of this decrease. The two chapters thus complement each other.

In addition to the chapters mentioned above, the volume includes: "Chromatography and Electrophoresis on Paper and Thin Layers: A Teachers Guide," by Ivor Smith. "The Stationary Phase in Paper Chromatography," by G. H. Stewart. "The Techniques of Laminar Chromatography," by E. V. Truter. "Capillary Columns: Trials, Tribulations, and Triumphs," by D. H. Desty. "Gas Chromatographic Characterization of Organic Substances in the Retention Index System," by E. Sz. Kováts. "Inorganic Gas Chromatography," by R. S. Juvet, Jr. and F. Zado. "Interactions of the Solute with the Liquid Phase," by D. E. Martire and L. Z. Pollara.

Sulfonation and Related Reactions. By E. E. GILBERT. Interscience Publishers, Inc., 605 3rd Ave., New York, N. Y., 1965. xi + 529 pp. 15.5 × 23.5 cm. Price $16.50.

It has been twenty-five years since the classic treatise on tetracovalent sulfur, by C. M. Suter, was completed. Since that time a great deal of research on the synthesis of organic derivatives of sulfur trioxide has taken place, but no summary volume has appeared until now. This book is an effort to bridge that gap. The author has, however, been selective, with emphasis on sulfonic acids, sulfonic esters, and sulfamates, and on chemistry described mainly since 1941. Even so, a total of 2656 references are included.

The book is designed principally as an aid to the practicing laboratory chemist, so that emphasis is on experimental conditions, rather than theoretical aspects of sulfonation and related reactions. Chapter one describes the nature of useful sulfonating reagents. Chapter two is especially good, covering much of the recent work on sulfonation with selective reagents, such as dioxane–sulfur trioxide and pyridine–sulfur trioxide, reagents which were only beginning to be used twenty-five years ago. Chapters three, four, and five describe sulfonation by indirect processes, such as addition of bisulfite to unsaturated systems, oxidation of sulfides, or by sulfomethylation. Chapter six is devoted to sulfation, the formation of organic sulfate esters, and chapter seven to sulfamation, or nitrogen sulfonation. The final chapter, eight, deals with the methods and conditions for the elimination of sulfonic acid groups from organic molecules, the desulfonation reaction.

Sulfonic acids, amides, and esters have long been used to alter the solubility and stability of known biologically active compounds. They are also frequent intermediates in the preparation of new compounds of potential pharmaceutical interest. In recent years sulfate esters have been shown to occur more commonly in biological systems than had been previously supposed, suggesting that sulfonation will have an increased interest to workers in the biological chemical field. Hence this book should prove useful to medicinal chemists.

The book is relatively free of errors, considering the enormous number of structural formulas. Only one missing double bond (p. 213) was detected by this reviewer! I was somewhat disappointed in the rather cursory coverage of sulfonation of heterocycles in twelve pages (pp. 92–104). The data are presented chiefly in tables, which provide references to work on specific systems and give fairly good coverage. The author has warned that he will be selective, however, and has chosen the areas of broadest interest for more extended coverage. The volume deserves its place on the library shelf.

Stereochemical Factors and Receptor Interactions Associated with Narcotic Analgesics

By PHILIP S. PORTOGHESE

STEREOCHEMICAL studies on narcotic analgesics can be considered an outgrowth of earlier chemical investigations which were concerned primarily with the elucidation of structural moieties necessary for analgesic activity. During this period, which spans about 50 years, considerable attention had been focused on the design and synthesis of analgesics. The role of steric factors, however, was not well understood and was largely unexplored.

The major advances in configurational and conformational analysis which occurred approximately 15 years ago set the stage for various stereochemical studies on narcotic analgesics which were soon to follow. These studies have drawn attention to the importance of steric factors in analgesia and have provided greater insight into the nature of the analgesic–receptor interaction.

This review is organized into three main sections: (*a*) absolute configurational studies, (*b*) conformational factors, and (*c*) concepts on analgesic–receptor interactions. No attempt has been made to give an exhaustive coverage of the chemical and pharmacological literature on this subject, but rather, discussion has been restricted to key developments and recent research related to the steric aspects of analgetically active compounds.

ABSOLUTE CONFIGURATIONAL STUDIES

One of the best approaches to delineating the steric requirements for analgesia involves the correlation of enantiomeric potency with absolute spatial geometry. In most cases one enantiomer possesses greater analgesic activity than its mirror image form. Since the lipid solubility and dissociation constant of enantiomeric bases are identical, differences in distribution are minimized and the variation in analgesic activity may be ascribed more confidently to events at the receptor level. The difference in potency between enantiomorphs is very likely due to the asymmetric topography of the receptors. In such a dissymmetric environment, (+)- and (−)-antipodes behave differently. Thus, one enantiomer may be more potent by virtue of its greater affinity and/or intrinsic activity (1, 2).

Inasmuch as optical rotation of structurally diverse compounds possessing a common asymmetric center is not necessarily indicative of absolute stereochemistry, correlations of optical rotation with analgesic activity are devoid of

Received from the Department of Pharmaceutical Chemistry, College of Pharmacy, University of Minnesota, Minneapolis. 55455.

any meaning other than being an expression of differences in the stereoselectivity of analgesic receptors for (+)- and (−)-enantiomers. In order to correlate molecular spatial geometry with analgesic potency, the configuration of the enantiomers must be established. Most of the methods employed for this purpose have involved chemically relating one of the optical antipodes to a compound of known configuration. The analgesics which have received greatest attention are those which possess an asymmetric center in common with methadone and with isomethadone.

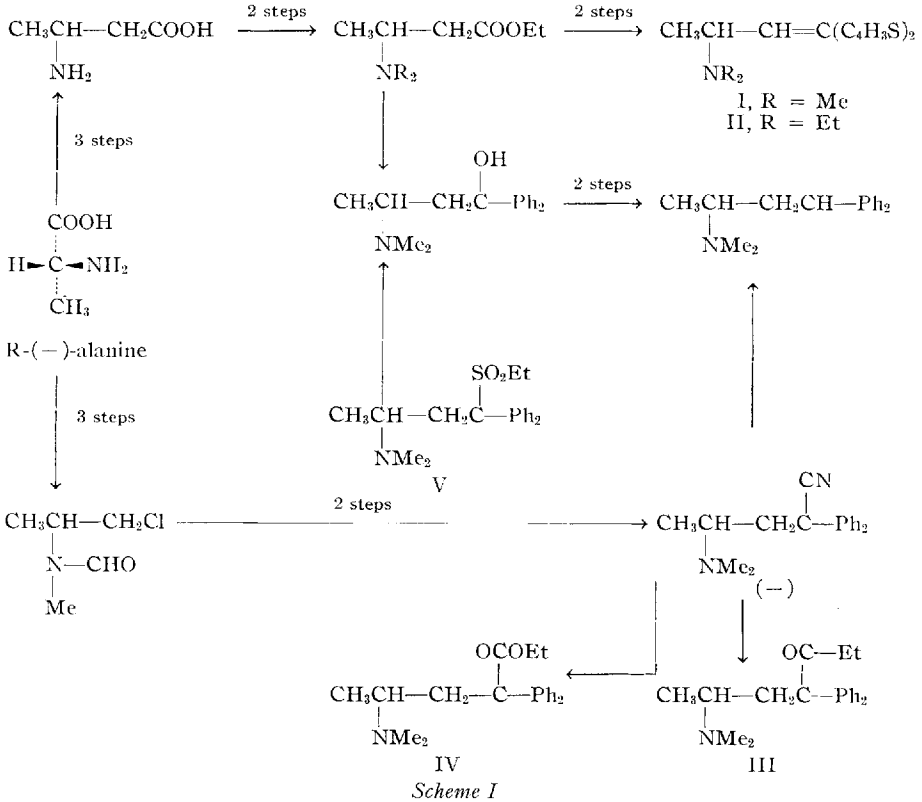
Structures Possessing an Asymmetric Center in Common with Methadone.—The first reported investigation on the configuration of synthetic narcotic analgesics of the methadone type was carried out by Beckett and Casy (3) who related the (+)-thiambutenes (I and II: *Scheme I*) (4) and the (−)-enantiomers of methadone (III: *Scheme I*) (5–8) and analogous structures (IV and V: *Scheme I*) (8, 9) to R(−)-alanine by the route outlined in *Scheme I*. The key reaction in this sequence was the transformation of R-alanine to β-aminobutyric acid *via* the Wolf rearrangement. Since this reaction was generally known to proceed with retention of configuration, the butyric acid intermediate was assumed to be stereochemically related to its precursor. Aminobutyric acid was then converted in several steps to (+)-thiambutene (I: *Scheme I*) and its diethyl homolog (II: *Scheme I*). The configuration of (−)-methadone (III: *Scheme I*) was established by converting the (−)-nitrile, which is a precursor of III: *Scheme I*, to 1,1-diphenyl-3-dimethylaminobutane derived from R-alanine. Since all of these stereochemical interrelationships were based on the assumption that the Wolf rearrangement had proceeded in the usual way, the configuration of III: *Scheme I* was subsequently confirmed unequivocally by converting R-alanine to the (−)-nitrile without involving the asymmetric center in question. The (−)-nitrile was also transformed to the (−)-carbethoxy analog of methadone (IV: *Scheme I*). The (−)-sulfone analog (V: *Scheme I*) was hydrolyzed to the same aminobutanol derivative which was derived from R-alanine.

From molecular rotation studies (−)-phenadoxone (Table III, *2*) (10) was also determined to be configurationally related to R-(−)-methadone.

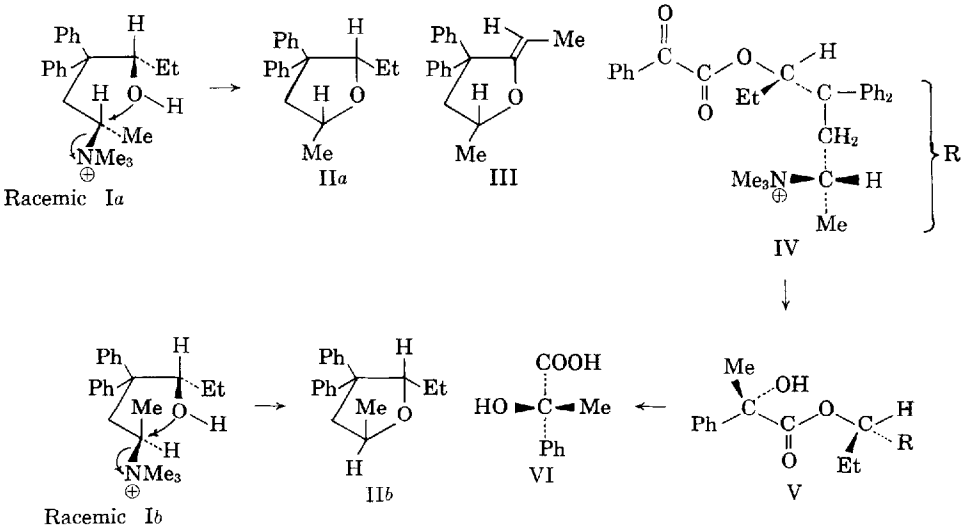
It has been pointed out by Beckett and Casy (11) that the (+)-enantiomers of I and II: *Scheme I* and the (−)-enantiomers of III, V: *Scheme I* and Table III, *2*, are all more active and configurationally related to R-alanine. Equally significant, however, is the fact that the more active enantiomer of IV: *Scheme I* is in the (S)- rather than in the (R)-series.

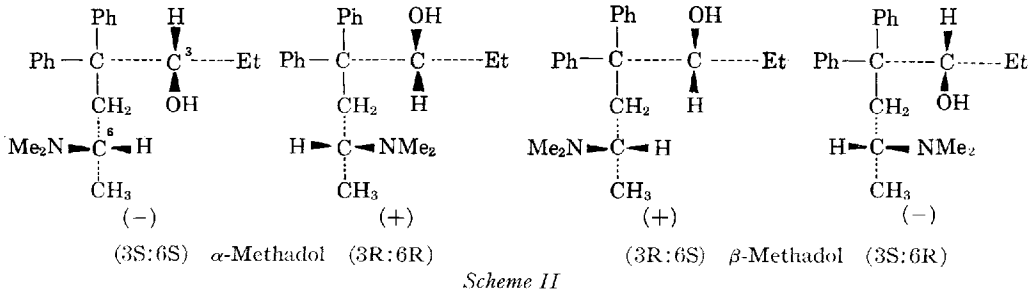
Pohland (8) and Eddy (12) have described the synthesis of optically active diastereomers of methadol (Table I, *1*) and acetylmethadol (Table I, *2*). Catalytic hydrogenation of methadone afforded only α-methadol (Table I, *α-1*), whereas sodium and propanol reduction yielded a mixture of diastereomers in which the β-isomer (Table I, *β-1*) predominated. The absolute stereochemistry at C-6 is now known because the diastereomers were derived from enantiomers of methadone, whose configuration (3) was subsequently determined. The stereochemistry of the C-3 hydroxyl group had not been reported, however. The absolute stereochemistry of the methadols is of particular interest because of the inversion of configurational selectivity[1] of analgesic receptors which occurs on transforming methadone to α-methadol (Table I). Interestingly, no such inversion occurs in the case of Table I, *β-1*. Upon acetylation of Table I, *α-1*, to form Table I, *α-2*, the potency ratio becomes inverted, so that the (6R)-series is once again more active. Portoghese and Williams (13) have investigated the stereochemistry of the methadols and have assigned the configuration at C-3 as designated in *Scheme II*. These assignments were based on the ability of racemic α- and β-methadol methiodide (I*a* and I*b*: *Scheme II*, respectively) to undergo stereospecific ring closure to isomeric tetrahydrofurans II*a* and II*b*: *Scheme II*. It was found that catalytic hydrogenation of the ethylidene compound (III: *Scheme II*) gave rise to II*a*: *Scheme II* as the preponderant isomer. Molecular models indicated that adsorption by the catalyst would occur on the less hindered top face of III: *Scheme II* to afford the *cis* isomer (II*a*: *Scheme II*). Since ring closure occurs with inversion at the C-6 center of I, the relative stereochemistry of the α- and β-isomers was deduced. Inasmuch as the configuration at C-6 is known (3), the absolute stereochemistry at C-3, therefore, was established. Additional proof was obtained from the dissociation constants of α- and β-methadol. The α-isomer was found to be a stronger base. This indicated less steric hindrance of the α-compound to intramolecular hydrogen bond formation be-

[1] The term "selectivity" rather than "specificity" is employed throughout. The former signifies that pharmacological activity is found predominantly in one isomer, though not exclusively, while the latter implies that activity resides in only one isomer. This definition is adapted from Eliel, E. L., "Stereochemistry of Carbon Compounds," McGraw-Hill Book Co., Inc., New York, N. Y., 1962, p. 436.



Scheme I





Scheme II

tween the protonated amine function and the oxygen atom of the hydroxyl group (14). Molecular models of α-methadol show that it is less hindered in the internally bonded form than is the β-isomer. Asymmetric induction studies utilizing Prelog's rule confirmed the above stereochemical assignment. Thus, treatment of (3S:6S)-methadol benzoylformate methiodide (IV: *Scheme II*) with methylmagnesium iodide gave the atrolactate ester (V: *Scheme II*) which on basic hydrolysis afforded S-atrolactic acid (VI: *Scheme II*) in 8% optical purity. A knowledge of the stereochemistry of the methadols made possible the complete configurational assignment of the acetate esters (Table I, *2*) and other related compounds. (See also Table III.)

The configuration of several basic anilide analgesics (15, 16), which have an asymmetric center in common with methadone, has been investigated by Portoghese and co-workers (17, 18). The (−)-enantiomers of these compounds were related to R-alanine by the route outlined in *Scheme III*. The (+)-diamine (V: *Scheme III*) was converted to the (−)-antipodes of I through IV: *Scheme III*. The stereochemistry of (+)-V: *Scheme III*, was determined by transforming it to (−)-VI: *Scheme III*, whose configuration was established by synthesis from R-alanine. Significantly, the more

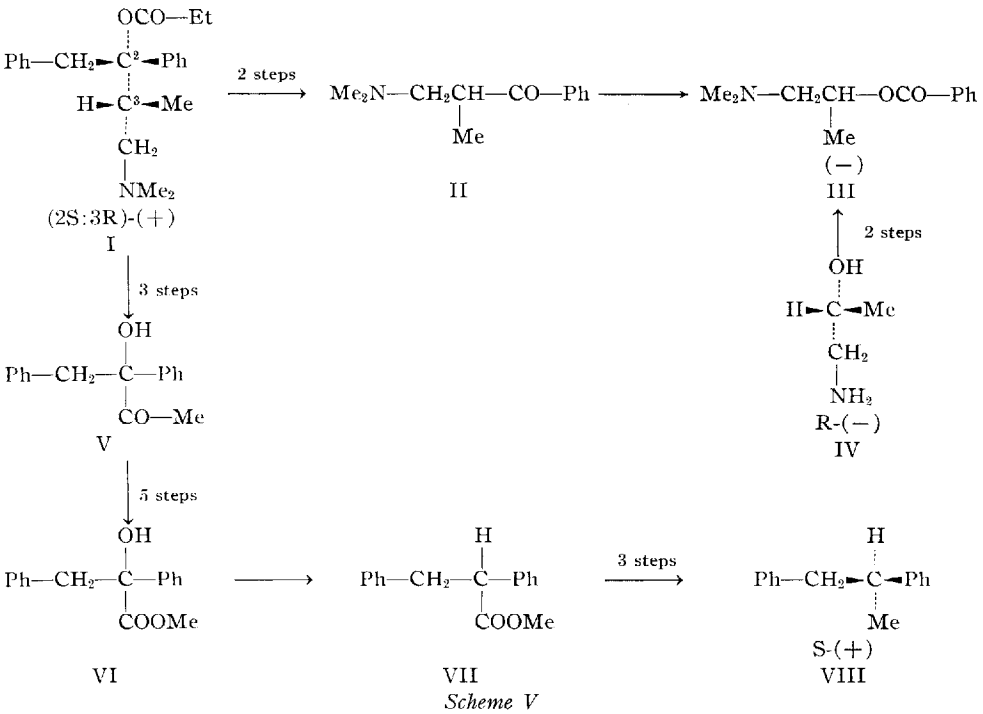
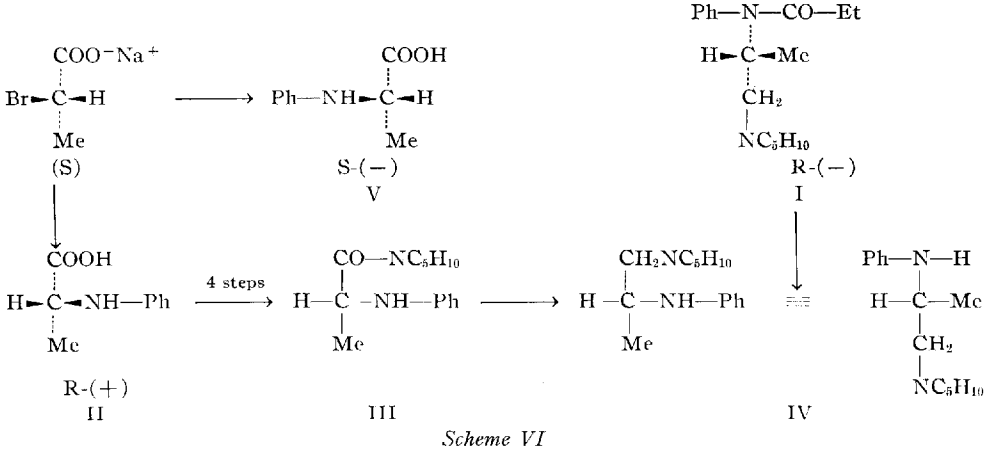


Scheme V



Scheme VI

active (+)-enantiomers of the aforementioned compounds are related to S-alanine (Table III) and hence possess a configuration opposite to that of the active antipodes of methadone. Moreover, the stereoselectivity of the receptors decreases (enantiomeric potency ratio approaches unity) as the length of the aralkyl chain is increased. This phenomenon is discussed further in a subsequent section (Table XII).

Structures Possessing an Asymmetric Center in Common with Isomethadone. — Most of the analgesic activity of isomethadone has been found to reside in the (−)-enantiomer (I: *Scheme IV*) (19). The absolute stereochemistry of this compound was elucidated by Beckett *et al.* (20) by the pathway outlined in *Scheme IV*. R(−)-α-Methyl-β-alanine (II: *Scheme IV*) was transformed to (+)-III: *Scheme IV*, which was also derived from the (−)-isomethadone precursor, (+)-IV: *Scheme IV*. This establishes the stereochemical relationship between II: *Scheme IV* and (−)-isomethadone (I: *Scheme IV*) whose configuration is designated as S-isomethadone.

May and Eddy (19) have reduced the carbonyl group of optically active isomethadone to produce isomeric isomethadols. Reduction with lithium aluminum hydride proceeded stereospecifically to give the α-isomer (Table II, *α-1*). Treatment with sodium in propanol

afforded a mixture of Table II, *α-1* and *β-1*, with the latter as the predominant isomer. The analgesic activity of these optical isomers and their stereochemical relationship to (+)- and (−)-isomethadone are shown in Table II. All of the enantiomers in the α- and β-series, which are related to R-isomethadone, have a low order of activity. With isomers derived from S-isomethadone, however, Table II, (+)-*β-1*, is much more potent than Table II, (−)-*α-1*. The reverse is true for the acetate esters, in that Table II, (+)-*α-2*, is more active than Table II, (−)-*β-2*. It can be noted that there is an inversion in the enantiomeric potency ratio of the type seen in the α-methadol compounds (Table I), although in this case, a large diminution of analgesic potency and of stereoselectivity is observed.

(+)-Propoxyphene (I: *Scheme V*) is the only one of four optical isomers which has significant analgesic activity (21). Sullivan, Beck, and Pohland (22) have determined its absolute stereochemistry as (2S:3R) *via* an elegant series of transformations (*Scheme V*). Establishment of the configuration at C-3 was accomplished by converting I to the Mannich base (II: *Scheme V*) and then carrying out a Baeyer-Villiger oxidation to give the (−)-ester (III: *Scheme V*). The identical ester was prepared from R(−)-propanolamine (IV: *Scheme V*). Since the oxidation is known to proceed with retention of configuration, the C-3 center was designated as being in the R-series. Casy and Myers (23) subsequently have confirmed this configurational assignment by a route which did not involve the C-3 asymmetric center. Elucidation of the stereochemistry at C-2 was carried out by transforming (+)-propoxyphene to S(+)-1,2-diphenylpropane (VIII: *Scheme V*). The reaction sequence involved the degradation of I: *Scheme V*, to the methyl ketone (V) which was subsequently converted to VIII *via* intermediates VI and VII. The assignment of the stereochemistry at C-2 is based upon the fact that the steric course of hydrogenolysis of a benzylic hydroxyl group proceeds with high retention of configuration.

Phenampromide (I: racemic *Scheme VI*) (24), a basic anilide analgesic which can be considered structurally related to isomethadone and propoxyphene, has been resolved and the (−)-enantiomer found to be four times more active than the (+)-isomer. The configuration of I was determined by Portoghese (25) to be related to R-(+)-*N*-phenylalanine (II: *Scheme VI*). The absolute stereochemistry of II: *Scheme VI* was established (26) by studying the steric course of the interaction of aniline with S-2-bromopropionate. When the reaction was carried out in pure or 4 *M* aniline the (+)-amino acid (II: *Scheme VI*) was produced, whereas in a 0.1 *M* aniline solution the (−)-enantiomer (V) was formed. According to the established mechanism (27) of displacement reactions on sodium 2-bromopropionate, the former reaction should take place with net inversion and the latter with net retention of configuration. Since the inverted product (II: *Scheme VI*) is derived from S-2-bromopropionate, II: *Scheme VI*, therefore, possesses the R-configuration. The optically pure amino acid (II: *Scheme VI*), obtained by deracemization, was transformed to the amide (III) and this was reduced to the diamine (IV). The identical diamine was derived from the hydrolysis of (−)-phenampromide (I: *Scheme VI*). It should be pointed out that the more active enantiomers, R-phenampromide, S-isomethadone, and (2S:3R)-propoxyphene, are all stereochemically related at their common asymmetric center (Table IV). This may mean that the aforementioned analgesics are interacting with common receptors, although

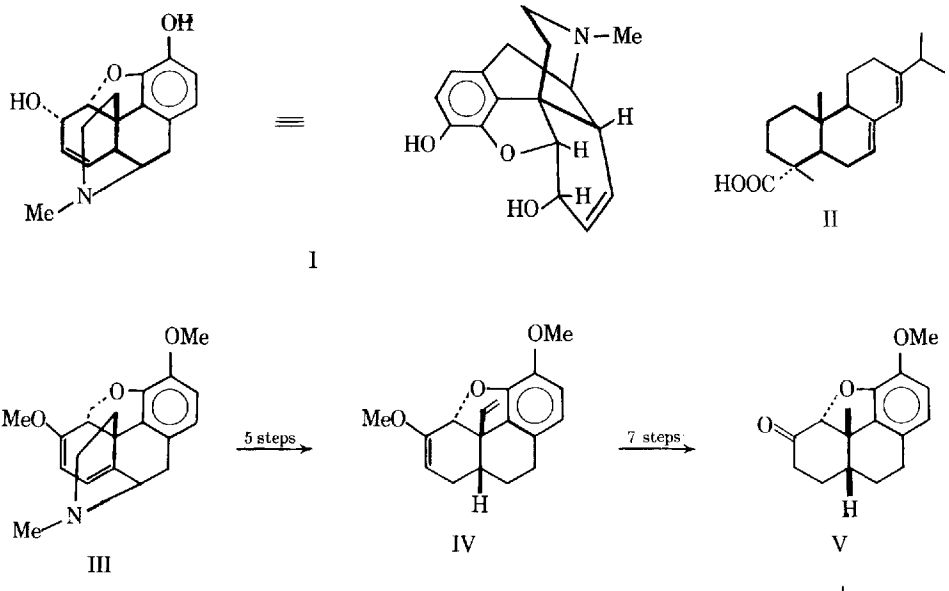


Scheme VII

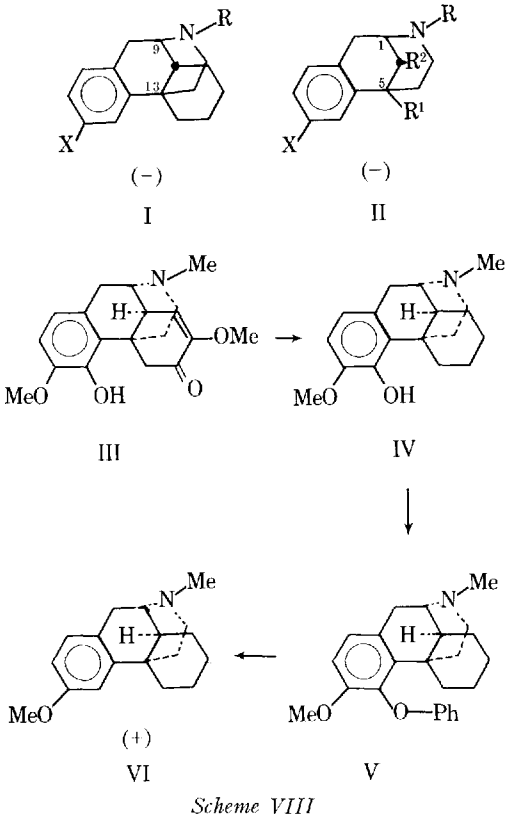
it is also possible that such stereochemical equivalence may be entirely fortuitous.

The relationship between configuration and analgesic activity of compounds having an asymmetric center in common with methadone and with isomethadone are summarized in Tables III and IV, respectively. The data compiled in Table III show an apparent lack of consistency, inasmuch as the more active enantiomers are not all configurationally related. The constitution of the R group appears to play a key role in determining the configurational selectivity of analgesic receptors. Such changes in stereoselectivity recently have been interpreted as being reflective of differing modes of analgesic–receptor interactions (28). (See under *Concepts on Analgesic-Receptor Interactions.*) A much more consistent correlation is shown in Table IV where the more active enantiomers, with one possible exception (Table IV, *2*), are all stereochemically related at a common asymmetric center.

Morphine and Related Structures.—The absolute configuration of (−)-morphine (I: *Scheme VII*) was determined by Jeger and collaborators (29) who converted thebaine (III: *Scheme VII*) to a degradation product (VII) of abietic acid (II) of known absolute stereochemistry (30). The route which was employed is outlined in *Scheme VII*. Hydrogenation of III, followed by exhaustive methylation and degradation, gave the vinyl intermediate (IV). This was transformed, in a series of reactions, to the tetracyclic ketone (V), which was then converted to intermediate (VI). Ozonization of VI afforded the (−)-diacid (VII) which was identical to that obtained from II. MacKay and Hodgkins (31) have come to the same conclusion by means of X-ray crystallography.

It has been determined that unnatural (+)-morphine is inactive as an analgesic (32). Similarly, the activity of optically active morphinans (I: *Scheme VIII*) and benzomorphans (II: *Scheme VIII*) has been found to reside principally in the (−)-enantiomers (33). This strongly suggested that the (−)-isomers of these compounds are configurationally related to (−)-morphine. Chemical evidence in the morphinan series for such a relationship was obtained by degradation of I: *Scheme VIII* (R = Me, X = OH), to VII: *Scheme VII via* a scheme (34) which is similar to the procedure employed in establishing the configuration of morphine. Sawa *et al.* (35) have also related sinomenine (III: *Scheme VIII*), which is enantiomeric to (−)-morphine at the C-9 and C-13 asymmetric centers, to (+)-3-methoxy-*N*-methylmorphinan (VI: *Scheme VIII*). Clemmensen reduction of III: *Scheme VIII*, afforded IV. This compound was converted to

the phenyl ether (V) and subsequently reduced to VI. In accord with the above stereochemical assignment, Beckett (36) has reported that silica gel which has been pretreated with levorphanol (I: *Scheme VIII;* R = Me, X = OH) has greater adsorptive capacity for (−)-morphine than silica gel that has been treated with the corresponding (+)-morphinan.

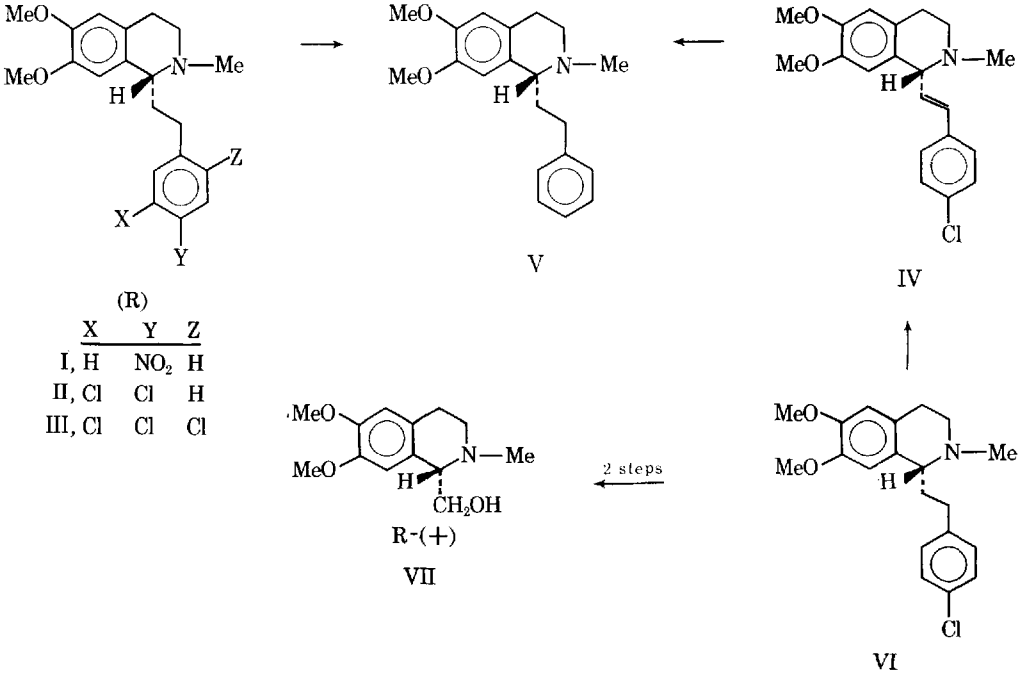


Scheme VIII

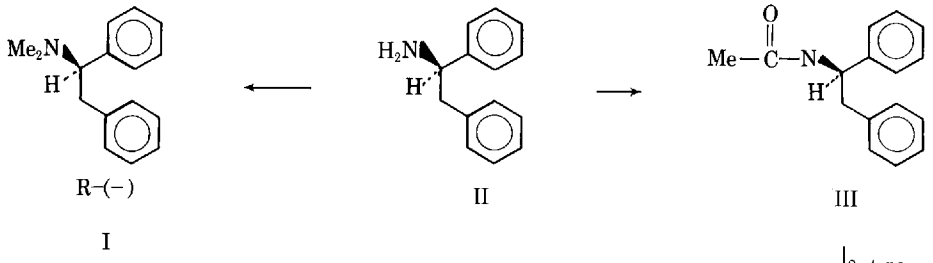
No direct chemical proof of the absolute configuration of benzomorphan derivatives (II: *Scheme VIII*) is available. Beckett (36) has furnished evidence, from stereoselective adsorption studies on silica gel, which suggests that II: *Scheme VIII* (R = R^1 = R^2 = Me, X = OH), is configurationally related to I: *Scheme VIII* (R = Me, X = OH), and hence to (−)-morphine (I: *Scheme VII*). The optical rotatory dispersion (ORD) characteristics of the above compounds have been studied (37), and it has been found that the free bases and salts all exhibit Cotton effects of the same sign. This provides strong evidence that the C-1 and C-5 centers in (−)-II: *Scheme VIII*, are identical to the C-9 and C-13 centers of (−)-morphine.

Miscellaneous Structures.—These compounds are grouped together under this classification because they have no obvious common centers of asymmetry and/or do not bear close structural resemblance to the previously discussed analgesics.

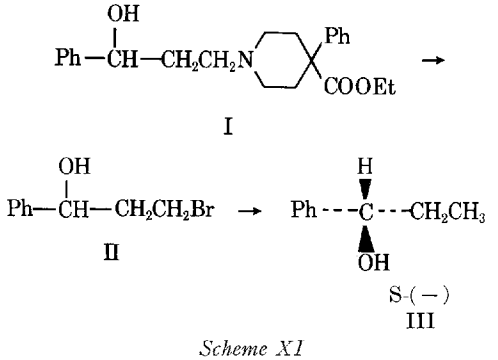
The phenethyltetrahydroquinolines (*Scheme IX*) represent a relatively new class of analgesics having activity in the range of codeine (38). These compounds have been resolved (38, 39)



Scheme IX



Scheme X



Scheme XI

and activity found to reside mainly in one antipode. The absolute stereochemistry of these analgesics has recently been determined by Rheiner and Brossi (39) (*Scheme IX*). The (−)-enantiomers, II and IV: *Scheme IX*, and the (+)-antipode (III) were all converted to the same product (V) by reductive dehalogenation. Reduction of the (−)-nitro compound (I) to the amine followed by deamination also afforded V. Since IV previously (40) had been related to R-(+)-calycotomine (VII) *via* VI, compounds I through IV possess the R-configuration. All of the analgesically more active enantiomers are in the R-series.

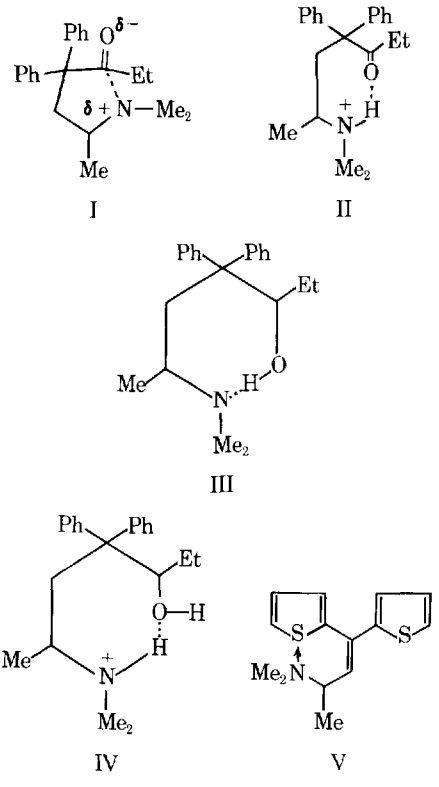
The (−)-enantiomer of *N,N*-dimethyl-1,2-diphenethylamine (I: *Scheme X*) has been reported (41) to be approximately half as active as morphine, while the (+)-antipode is virtually inactive. Nakazaki *et al.* (42) have determined the stereochemistry of I: *Scheme X*, by the procedure shown in *Scheme X*. The amide (III: *Scheme X*), which was derived from the precursor (II) of I, was subjected to exhaustive ozonolysis. The ozonolysis product ultimately was converted to R-aspartic acid (IV). It has been noted (42) that there is a stereochemical resemblance between I and the C-9 asymmetric center of (−)-morphine.

Mazur (43) has resolved the highly potent analgesic, phenoproperidine (I: *Scheme XI*) and found the (−)-isomer to be 4 times more potent than its enantiomer. This suggests that the *N*-aralkyl group is contributing to the pharmacological effect by interacting with a dissymmetric portion of the receptor surface. The configuration of the (−)-isomer was determined by dealkylating with cyanogen bromide to yield the aralkyl bromide (II: *Scheme XI*) and then reducing to the (−)-enantiomer of 1-phenylpropanol (III: *Scheme XI*), whose stereochemistry is known to be in the S-series.

CONFORMATIONAL FACTORS

The relationship between conformational preference and analgesic activity is difficult to assess because differences in conformation *in vivo* can be brought about only by structural variation of the molecule. Since the physical and chemical properties of such compounds may be different enough so that their distribution characteristics are not identical, a knowledge of the relative concentrations of analgesics in the biophase would be needed before differences in potency could be attributed to phenomena related to drug–receptor complex formation. In view of this major drawback, a small difference in potency between diastereomeric compounds, for example, may be difficult to interpret. In spite of the above pitfalls, such correlations appear to be of value, if not for elucidating the optimal conformational requirements for analgesia, then most certainly for determining which conformational species are active.

Open-Chain Analgesics.—It has been postulated (11, 44) that open-chain analgesics such as methadone form ring-like conformations, thereby approximating the over-all geometry



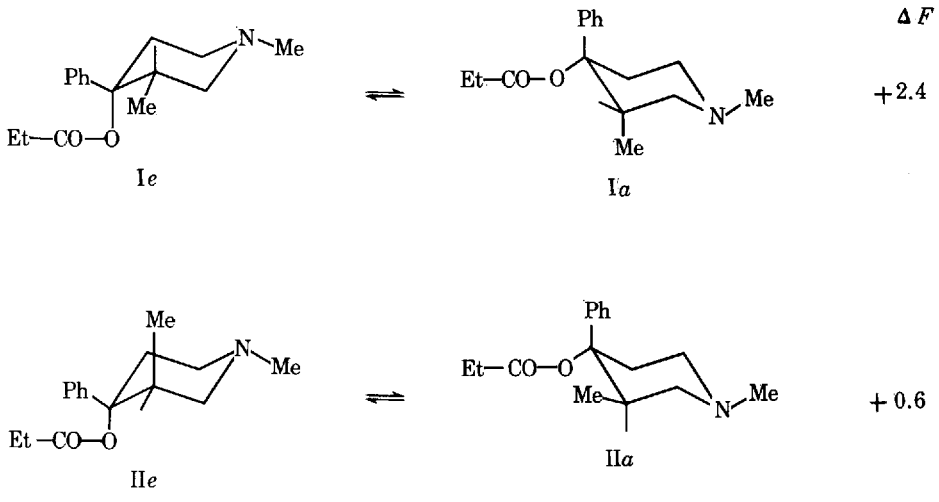
of the piperidine moiety in morphine. Subsequent investigation led Beckett (45) to conclude that such a quasi ring conformation (I) occurs by virtue of an interaction of the basic nitrogen with the carbonyl carbon atom. It has recently been reported by Smith (46) that the NMR spectrum of methadone hydrochloride in chloroform shows magnetically nonequivalent *N*-methyl groups. This has been interpreted as being caused by the molecular asymmetry inherent in the methadone molecule and by intramolecular association between the protonated amine function and the carbonyl oxygen (II). An infrared study of methadol diastereomers has indicated that both the α- and β-isomers (III) are internally hydrogen bonded (13). The protonated forms also are intramolecularly hydrogen-bonded as represented by IV. The α-isomer has been determined to form a stronger hydrogen bond than its diastereomer. (See under *Structures Possessing an Asymmetric Center in Common with Methadone.*) Gero (44) has postulated that thiambutene exists in a conformation (V) which allows intramolecular association between the basic nitrogen and the sulfur atom in the thiophene ring.

Cyclic Analgesics. Cyclic analgesics are restricted to far fewer possible conformations than are open-chain compounds. Moreover, in compounds containing the piperidine ring, the position of equilibria between flip conformational species can be estimated by assuming that the nonbonded interactions are similar to those in cyclohexane.

Among the simplest diastereomeric phenylpiperidine analgesics of known stereochemistry (47–49) are α- and β-prodine (I and II: *Scheme XII*, respectively) (50, 51). β-Prodine is approximately 7 times more potent than the α-isomer. A similar relationship holds for the *N*-phenethyl analogs (52). Estimates of the relative amounts of conformational isomers (I and II: *Scheme XII*) in solution can be obtained if it is assumed that the nonbonded interactions in the solvated free base and cyclohexane are similar. This is a valid assumption in view of the recent report (53) that hydrogen–solvated electron pair and hydrogen–hydrogen interactions differ by only a small factor. It is also reasonably assumed that the *N*-methyl group exists primarily in the equatorial orientation (54) in both flip conformations. The free energy differences between axial- and equatorial-phenyl species have been calculated from average values[2] obtained from the literature (55). It should be emphasized that the ΔF values are approximations, and that small differences ($\Delta\Delta F$) between diastereomers cannot meaningfully be assessed by this method. The ΔF for the conformational equilibrium of the α-isomer (I: *Scheme XII*) has been calculated to be +2.4 Kcal./mole, while that of the β-compound has been estimated to be +0.6 Kcal./mole. This means that the equilibrium for α-prodine is about 98% in the direction of Ie: *Scheme XII*, and that the β-isomer contains approximately 75% of IIe: *Scheme XII*.

Beckett and Casy (11) have postulated that II: *Scheme XII*, is more active than I: *Scheme XII* by virtue of its greater ability to adopt the axial conformation (IIa: *Scheme XII*) which would be similar to the orientation of the phenylpiperidine moiety in morphine (I: *Scheme VII*). Ziering and co-workers (51) have noted, however, that there is little relationship between stereochemistry and analgesic activity, since other 3-substituted compounds in the prodine series (Table V) do not display parallel activity. The α- and β-isomers of the 3-ethyl compound have about equal activity, and in the 3-allyl analog the α- is more active than the β-isomer. The conformational equilibria of the ethyl and allyl compounds should be comparable to that

[2] The average values employed for ΔF/interaction (in Kcal./mole) are as follows: OCO-Et:H, 0.4; Ph:H, 1.4; Me:H and Me: solvated *N*, 0.9; Me:Me, 3.7; Me:OCO-Et, 2.2.



Scheme XII

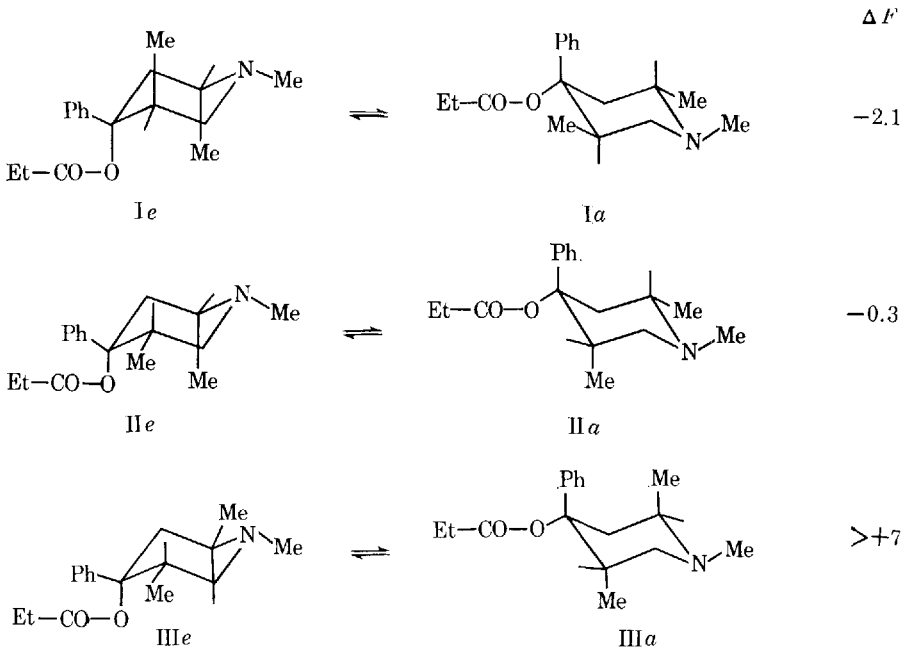
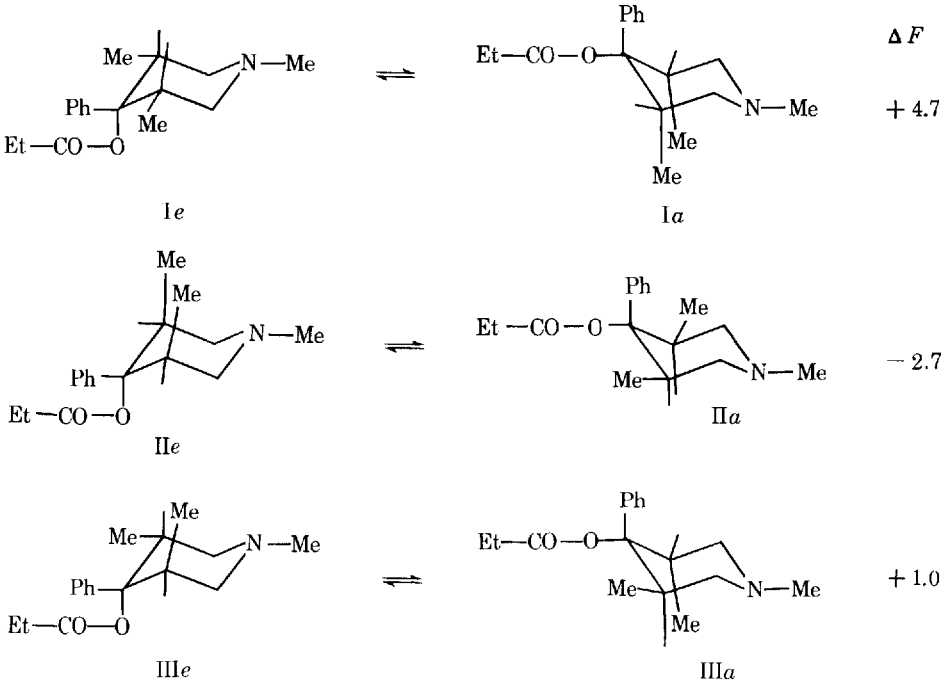
of the 3-methyl diastereomers (I and II: *Scheme XII*), inasmuch as the steric bulk (55) of these groups do not differ substantially. It seems that studies on the distribution and metabolism of these compounds are warranted in order to determine whether the differences in the α/β potency ratio are reflective primarily of events at the receptor level or rather due mainly to concentration differences in the brain. If it is found that differences in activity are related to drug–receptor phenomena, this could also mean that the 3-substituent, rather than the orientation of the phenyl group, exerts a primary influence on drug–receptor association. In any case, it is apparent that an answer to the question of the importance of conformational factors remains highly speculative and awaits experimental clarification.

Nazarov and co-workers (56) have prepared three of the four possible racemates of 1,2,5-trimethyl-4-phenyl-4-propionoxypiperidine. The complete stereochemical assignment of these diastereomeric racemates has been reported (57) to be as illustrated in *Scheme XIII*. [In *Schemes XIII* and *XIV*, ΔF values (Kcal./mole) are approximations only. See *Footnote 2* for information on the calculation of these values.] The γ-isomer (III: *Scheme XIII*), which is known as promedol, exceeds the potency of morphine by about threefold, while the β-racemate (II) is about twice as effective as promedol. The most active compound is the α-isomer (I) which has twice the potency of the β-compound. Calculation of the free energy differences between conformational isomers gives an approximation of the positions of the equilibria. Thus, with the α-, β-, and γ-isomers, the values are −2.1, −0.3, and >+7 Kcal./mole, respectively. This indicates that Ia and IIa: *Scheme XIII* are present to the extent of about 97 and 62%, respectively, while IIIa is virtually absent. It appears therefore that I and II: *Scheme XIII* are exerting their action in both flip conformations and that promedol is acting in the equatorial conformation (IIIe: *Scheme XIII*). The positions of the conformational equilibria correlate with the relative analgesic potency of the diastereomers in that increasing axial character parallels analgesic activity. This is consistent with the ideas expressed by Beckett and Casy (11) in connection with the prodines (I and II: *Scheme XII*), although alternate possibilities for the above correlation, which have already been discussed in relation to the prodines, also should be considered.

The three theoretically possible diastereomers of 1,3,5-trimethyl-4-propionoxy-4-phenylpiperidine (*Scheme XIV*) have been prepared by Sorokin (58). The γ-racemate (III: *Scheme*



Scheme XIII

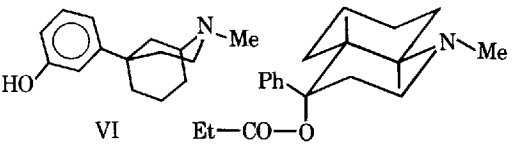


Scheme XIV

XIV) has activity comparable to promedol (III: *Scheme XIII*), whereas the α- and β-isomers are inactive. Conformational analysis indicates no parallelism between potency and the relative amounts of axial-phenyl species in equilibrium with the equatorial form, as has been observed for the prodines (*Scheme XII*) and promedols (*Scheme XIII*). Thus, the inactive β-isomer has a calculated ΔF of −2.7 Kcal./mole, which means that approximately 99% is present as the axial-phenyl conformation (II*a*: *Scheme XIV*). The α-diastereomer, which is also inactive,

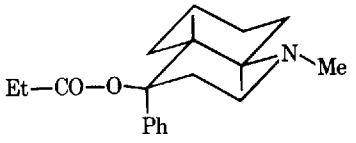
has a value of +4.7 Kcal./mole, which suggests that virtually all of it exists as Ie. On the other hand, the highly potent γ-racemate has a conformational free energy difference (+1 Kcal./mole), which is between the values calculated for I and II: *Scheme XIV*, corresponding to about 15% of IIIa. The preceding analysis suggests that the inactivity of the α- and β-diastereomers (I and II) is related to the 3,5-diequatorial methyl groups which are present in the more stable conformations (Ie and IIa). The active γ-diastereomer (III) is incapable of disposing both the 3- and 5-methyl groups in a similar orientation when in a chair conformation. If the inactivity of I and II are reflective of phenomena at the receptor level, this may be caused by steric hindrance of the 3,5-diequatorial methyl groups to analgesic–receptor association (59).

Although it cannot be stated unequivocally that variation in potency among diastereomeric structures is a direct consequence of the analgesic–receptor interaction, it has been suggested by conformational analysis of flexible phenylpiperidine diastereomers (*Schemes XII–XIV*) that both equatorial- and axial-phenyl conformations have the ability to produce high analgesic activity when other groups on the piperidine ring do not prevent drug–receptor association. Molecules having structural features which prevent conformational inversion can furnish further insight into the nature of the pharmacophoric species. It is well known, for example, that morphine (I: *Scheme VII*), morphinans (I: *Scheme VIII*), and benzomorphans (II: *Scheme VIII*) are all conformationally homogeneous by virtue of the methylene bridge which connects the axial aromatic group to the piperidine ring. The equatorial counterpart to the above compounds is found in the azabicyclononane derivative (VI) (60). The trimethylene bridge prevents conformational inversion and therefore precludes the presence of an axial aromatic ring. This compound has activity comparable to the phenolic benzomorphan structure (II: *Scheme VIII*; R = R^1 = R^2 = Me, X = OH). In a recent study, Smissman and Steinman (61) have prepared two isomeric decahydroquinoline analogs (VII and VIII) of the prodine type analgesics. The *trans* ring juncture in these structures prevents inversion of the piperidine moiety and, thereby, ensures conformational homogeneity. Since both the equatorial (VII) and axial (VIII) isomers were equally potent, it was concluded that no definite conformational requirements of the aromatic ring are necessary for analgesic activity. This is inconsistent with



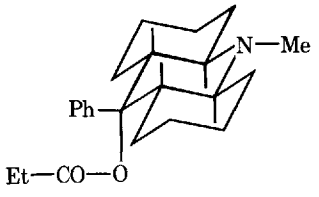
VI

VII



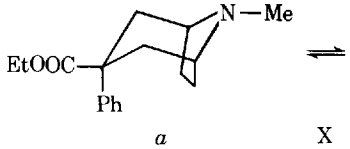
VIII

Beckett's hypothesis (11) which states that analgesics containing an axially oriented aromatic ring should be more potent than those possessing the equatorial conformation. The perhydroacridine analog (IX) was also prepared (62) and found to be inactive. This has been attributed to steric hindrance of the carbocyclic moieties attached to both sides of the piperidine ring, and is consistent with the results obtained from conformational analysis of I and II: *Scheme XIV*.

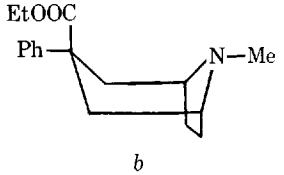


IX

The tropane analog (X) of meperidine was prepared by Bell and Archer (63) and found to be slightly more potent than meperidine (XI). Although inversion of the piperidine moiety cannot occur because of the restriction imposed by the ethylene bridge, spectral evidence (63, 64) suggests that there is a substantial amount of the boat conformation (X*b*) present. This is to be expected in view of the severe diaxial interactions between the phenyl group and the



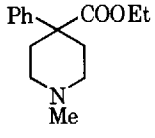
a X



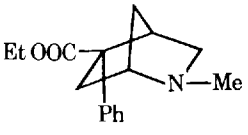
b

ethylene bridge when in the chair conformation (X*a*). Unequivocal evidence demonstrating that

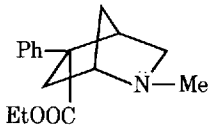
a boat conformation is active has been provided by Portoghese and co-workers (65), who have synthesized and tested bicycloheptane analogs (XII and XIII) of meperidine. In these diastereomers, the piperidine ring is rigidly held in a boat conformation by the C-7 methylene group. The *endo*-phenyl compound (XII), which is about 6 times more potent than the corresponding *exo*-isomer (XIII), is about twice as active as meperidine (XI). The difference in activity between isomers may be due in part to distribution since XIII is a stronger base than XII and hence would not be expected to reach the site of action in the same concentration as its isomer.



XI



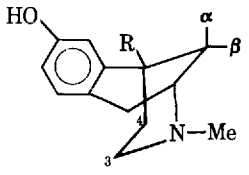
XII



XIII

From all the available data it appears that the conformational requirements for most of the 4-phenylpiperidine type analgesics are minimal. It is rather paradoxical that in certain cases high optical selectivity of the analgesic receptors is observed, whereas a variety of compounds in different conformations are capable of producing analgesia. This paradox can be resolved if it is assumed that differing modes of analgesic–receptor binding (28) occur. (See under *Concepts on Analgesic–Receptor Interactions.*)

In the preceding discussion the possibility was considered that disposition of groups other than the aromatic ring could also influence analgesic activity. Thus, the activity of prodine-type diastereomers (*Schemes XII–XIV*) could depend in part on the orientation of alkyl groups attached to the piperidine ring. In order to limit the number of variables, it would be informative to examine the effect of a configurational change at a single asymmetric center in analgesics whose geometry is largely restricted to a single conformation. Inasmuch as such compounds are epimeric rather than enantiomeric, it should be mentioned that the observed differences in activity between epimers cannot unequivocally be attributed to events at the receptor level when differences in potency are small. Much of the work on compounds which fall into this category has been carried out by May and co-workers (66–70), who have prepared a variety of epimeric benzomorphans. The conclusions derived from these correlations cannot be extrapolated to the prodines, however, because the modes of interaction of the benzomorphans and the former compounds are most probably different. (See under *Concepts on Analgesic–Receptor Interactions.*) The data presented in Table VI show that compounds in the β-series are consistently more potent than the corresponding α-isomers. Furthermore, it appears that when R = R′ = propyl, the α-compound shows a large decrease in potency while the β-epimer exhibits a relatively small decrease. It can be seen from the three-dimensional representation (XIV) of these isomers



XIV

that the α-series possesses an equatorial C-9 alkyl group, whereas the isomeric β-series has

this group oriented in the axial conformation. This suggests that when the C-9 substituent is in the equatorial conformation and beyond a certain size, it may adversely affect drug–receptor association. An equatorial C-9 group would be expected to have little effect on analgesic activity if association with a receptor involved contact only with the C-3,4 hydrocarbon moiety and aromatic ring. Since this is not the case, it appears as if other portions of the molecule are also involved in the receptor interaction. A somewhat related situation exists in certain highly potent analgesics derived from Diels-Alder adducts of thebaine (XV) (71, 72). The —CRR'OH group, which is on the top face of the molecule, can enhance analgesic activity by a factor of up to 7800 times the potency of morphine. Moreover, it has been reported that when the carbinol group is asymmetric (XV; R = Me, R′ = Pr, X = OMe), the activity of one of the isomers is about 90 times that of morphine and approximately 130 times more potent than its epimer. This remarkable difference in potency is probably related, in some way, to the ability of CRR'OH in one of the epimers to enhance receptor binding when in a preferred conformation.

CONCEPTS ON ANALGESIC–RECEPTOR INTERACTIONS

Since isolation and visualization of narcotic analgesic receptors presently is not possible, the medicinal chemist is naturally dependent on the relationship between molecular structure and analgesic activity in order to obtain some insight into the nature and dimensions of such receptors.

The process of determining the pharmacophoric groups necessary for analgesic action evolved slowly and can be traced back to Whalen (73), who in 1902, proposed that the properties of morphine (I: *Scheme VII*) were due to the phenanthrene skeleton. This idea prevailed (74) until 1939, when Eisleb and Schaumann (75) discovered that meperidine (XI) possessed substantial analgesic activity. The structural relationship between morphine and meperidine was realized and it was postulated (76) that the 4-phenylpiperidine moiety was necessary for analgesic activity. With the advent of the methadones (Table X, series 1 and 2) (77), Schaumann (78) modified and generalized his hypothesis by suggesting the structural requirements to be an aromatic ring attached to a quaternary carbon atom two carbons removed from a tertiary amine function. The requirements for analgesic activity, however, were once again outmoded with the appearance of the thiambutenes (Table X, series 5) (4, 79). Gero (44) attempted to rationalize the activity of the thiambutenes and methadones by postulating that these open-chain analgesics formed pseudo-ring conformations.

Beckett and Casy (11) sought to elucidate the receptor requirements for analgesic activity through stereochemical studies of the methadones and thiambutenes. The fact that the more active enantiomers of some of these structures were found to be configurationally related, supported the idea that "fit" at an analgesic receptor is important for activity. A receptor surface was formulated whose dimensions were complementary to certain elements of the phenylpiperidine moiety in morphine. Hence, it was postulated that an analgesic receptor possessed a flat surface, a cavity, and an anionic site which were envisaged to accommodate an aromatic ring, a hydrocarbon moiety, and a protonated basic nitrogen, respectively. These features were depicted as being in a particular sequence, the active enantiomers being capable of three-point contact while the inactive or less active enantiomers were capable of presenting only two of the three essential groups for orientation at the receptor surface. According to this concept, specific orientations of the various pharmacophoric groups in an analgesic molecule are required in order that they may conform to the above receptor dimensions. It was suggested that meperidine and the prodines (*Scheme XII*) were able to associate with this receptor with greater facility when in the axial-phenyl conformation and that the methadones interact by assuming a cyclic conformation. Subsequent studies on the dissociation constants of methadone-type compounds led Beckett (45) to conclude that methadone and related compounds form ring-like conformations by virtue of an interaction of the basic nitrogen with the carbonyl carbon atom. It was concluded (80) from correlations of analgesic activity with the widths of the basic groups, that the anionic site has a width of 7.5–8.5 Å.[3]

[3] This is based on the assumption that the distribution and metabolism of the methadones containing different basic groups are approximately the same. If this is indeed found to be the case by determining the concentration of these compounds in the brain, then their correlation would receive much stronger support.

TABLE VII.—SOME POTENT ANALGESICS OF DIVERSE CONSTITUTION

As more compounds were synthesized and found to possess analgesic activity, it soon became evident that the requirements which were summarized by Braenden, Eddy, and Halbach (60) in 1955 were once again violated (81). It is now known, for example, that there may be as many as five atoms between the aromatic ring and basic nitrogen and still have compounds which are at least as potent as meperidine. Some structurally diverse analgesics, to list only a few, are compiled in Table VII. Other radical departures recently have been reported (86). It is apparent that this presents quite a perplexing problem. Can all of these structures fit a receptor surface having dimensions which have been postulated (11) to be complementary to portions of the morphine molecule while still maintaining high activity? It seems quite probable that this is not the case. Other aspects of the relationship between structure and analgesic activity which are not adequately explained by the Beckett hypothesis are found in Table III, where it can be seen that there is no consistent correlation between the configuration of the more active enantiomers and analgesic activity. It is obvious that the constitution of the R moiety has an important bearing on the configurational selectivity of the receptors. Still another puzzling phenomenon was the ability of identical *N*-substituents to either enhance or diminish analgesic activity when attached to different analgesiophores.[4] For example, replacing the *N*-methyl group in meperidine by the cinnamyl substituent enhances activity by thirty to forty-fold while an identical change in morphine causes a loss of potency (see Table VIII). Along these same lines, it is well known that replacement of the *N*-methyl in morphine by an allyl group results in a compound which has low activity in rodents and morphine antagonist properties. Significantly, similar replacement in meperidine (Table VIII) or in methadone-type analgesics (Table X) results neither in a drastic diminution of potency nor in a compound which has antagonistic properties (87).

Quite recently, Portoghese (28) has introduced a new concept on the mode of interaction of narcotic analgesics with receptors in order to explain all of the above phenomena. It has been postulated that complex formation of different narcotic analgesics with receptors may, in many cases, involve differing modes of interaction rather than a single type of drug–receptor interaction involving binding to the same sites on the receptors. The possibility of induced fit as a factor contributing to receptor binding of diverse analgesics was also recognized (2, 28). Within the framework of this concept the possible modes of interaction were outlined as follows.

Case 1.—Interaction of different analgesics with a single species of receptors; (*a*) identical interaction; (*b*) differing interaction.

Case 2.—Interaction of different analgesics with two or more species of receptors common to the different analgesics; (*a*) identical partitioning on the receptors by different analgesics, (*b*) dissimilar partitioning on the receptors by different analgesics.

Case 3.—Interaction of different analgesics with two or more species of receptors not common to the different analgesics.

Different molecules may interact with identical sites [Case 1(*a*)] or with different sites [Case 1(*b*)] on the same receptor species. Case 1(*b*) is schematically illustrated in Fig. 1. The molecule outlined by the solid line depicts one position of binding, while the dashed line denotes a second position. It is assumed that the steric environment presented to different molecules in different binding positions are not identical.

The second case is symbolized by the following equations:

$$\begin{aligned} A + \alpha + \beta &\rightleftharpoons (A\alpha) + (A\beta) \\ B + \alpha + \beta &\rightleftharpoons (B\alpha) + (B\beta) \end{aligned}$$

Different analgesics (A and B) and species of receptors (α and β) common to A and B may interact so that the ratios, $(A\alpha):(A\beta)$ and $(B\alpha):$

[4] Analgesiophore is defined as the analgesic molecule less the substituent on the basic nitrogen.

(Bβ), are similar [Case 2(*a*)] or different [Case 2(*b*)].

The third possibility is illustrated by the equations below. In this case α and β are not common to A and B. If different receptor species

$$A + \alpha + \beta \rightleftharpoons (A\alpha)$$
$$B + \alpha + \beta \rightleftharpoons (B\beta)$$

have dissimilar steric requirements in Cases 2(*b*) and 3, then this would be manifested by a difference in the stereoselectivity of the receptors for analgesics A and B.

Combinations of the above cases may also exist, thus creating a much more complex situation. It is probable that Cases 1 and 2 may be the most prevalent types of interaction.

This concept is capable of explaining the lack of correlation between configuration and analgesic activity (Table III). If, for example, methadone (Table III, *1*) and α-methadol (Table III, *5*) are interacting with different patterns of sites on a single species of receptors [Case 1(*b*)] then the steric requirements for the analgesic molecules may not be identical. The fact that the more active enantiomers of the above compounds possess the opposite configuration supports the contention that at least a portion of these analgesic molecules are in different physicochemical environments on the receptors. Figure 2 illustrates schematically how R-methadone and (3S:6S)-methadol, with opposite configuration at C-6, may interact with analgesic receptors. Dipoles conceivably can be sites which are hydrogen bonding donors (X) or acceptors (Y). Interaction of methadone with an analgesic

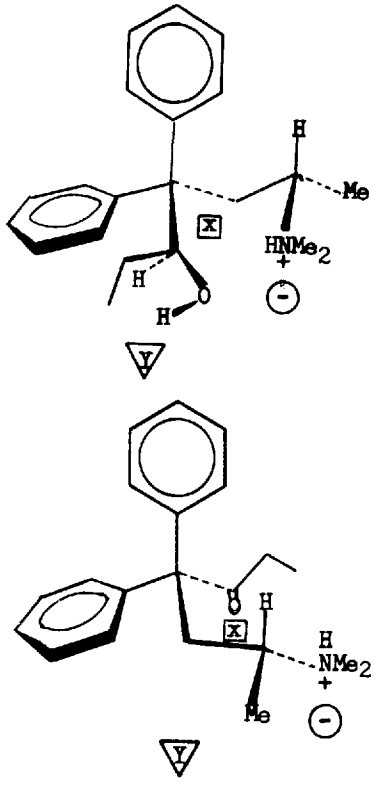

Fig. 2.—One possible mechanism whereby different polar groups in analgesic molecules may cause inversion in the configurational selectivity of analgesic receptors. Hydrogen bonding proton donor and acceptor dipoles are noted by X in square and Y in triangle, respectively. The anionic site is represented by ⊖. Top: (3S:6S)-methadol; bottom: R-methadone.

receptor may involve hydrogen bonding of the ketonic carbonyl group by X, whereas with α-methadol, OH...Y could occur. According to the above interpretation, alteration of a polar group in an analgesic molecule may afford a compound which can interact with dipolar sites and hydrophobic areas that differ from those involved in the binding of the unaltered structure. An alternate explanation can be found in Case 2(*b*). In this case, methadone and α-methadol would interact in different ratios with two or more species of receptors having dissimilar steric requirements. This too could bring about an inversion in configurational selectivity if the steric requirements of the different receptor species common to both analgesics are dissimilar.

The well-known ability of the basic group to influence analgesic activity has been utilized as a means of detecting similarities or differences in the mode of binding to receptors (28, 88). If the mode of interaction between various analgesics and receptors is similar [Cases 1(*a*) and 2(*a*)], then the *N*-substituent should be positioned in a similar physicochemical environment on the receptors and, therefore, contribute to the analgesic effect quantitatively in the same way. Thus, if identical changes of the *N*-substituent in two or more series of compounds produce parallel changes in potency, the mode of binding of the different analgesiophores should be similar. Conversely, dissimilar modes of interaction [Cases 1(*b*), 2(*b*), and 3] should produce nonparallel changes in potency. This is exemplified in Table VIII where parallel relationships can be seen between the meperidines (series 1) and the acyloxy analogs (series 2 and 3). Parallelism is also exhibited among the compounds in the morphine (series 4), morphinan (series 5), and benzomorphan (series 6) series. Comparison of the former (series 1, 2, and 3) with the latter (series 4, 5, and 6), however, shows that there is no parallelism. The correlations in Table VIII indicate that the analgesiophores in series 1, 2, and 3 are binding to receptors by similar modes and that an analogous situation exists among the latter series. On the other hand, lack of parallelism between the phenylpiperidines and structures related to morphine suggested that the binding mode of identically substituted compounds in the former series is different from those in the latter.

If identically *N*-substituted compounds in two different series are interacting with receptors in a similar manner, then the quantitative contribution to the analgesic effect by various substituents should produce, under steady-state conditions, proportionate variations of activity in both series. Such a proportionality is reflective of a linear free energy relationship. The slope of such a regression should be near unity, since identical basic groups are expected to contribute to the pharma-

Y., for providing this information. [g] Average value. [h] Mice were employed as test animals. [i] Calculated from *Reference 15*. [j] Animal species not revealed. [k] Administered intraperitoneally.

cological effect by the same mechanism. The above quantitative relationship is, of course, dependent on the assumption that identical changes in substituents on two different analgesiophores will affect the distribution of the compounds in a similar fashion. This assumption is quite reasonable in view of the successful application of substituent constants for predicting drug availability at the site of action (89). When the mode of binding is not similar, a nonparallel relationship should be obtained which may be characterized by point scattering and the absence of a regression.

It is important to point out that a regression cannot be properly constructed unless the pharmacological data have well-defined confidence limits and are derived from a single source. The analgesic data of Janssen and Eddy (90) appeared to fulfill these requirements. The regressions obtained from these data are shown graphically (Fig. 3) and in Table IX. The high correlation coefficients (r) corroborate the postulate that parallelism in activity is indicative of similar modes of binding and that this concept (28, 87) is of utility in distinguishing between similar [Cases 1(*a*) and 2(*a*)] and different modes [Cases 1(*b*),

2(*b*), or 3] of drug–receptor interactions. Although series 3, 4, and 5 (Table VIII) also display parallelism, these data cannot be quantitated because the activities were obtained from different literature sources.

It was discussed earlier that inversion of configurational selectivity is indicative of differences in the mode of interaction between analgesic molecules and receptors. Further support for this proposal was obtained by qualitatively assessing whether parallelism exists between different series of open-chain compounds (Table X) whose *N*-substituents were varied in the same way. Because these data were obtained from a variety of sources, only substantial changes in potency were interpreted as being meaningful.

Qualitative inspection suggests that series 1, 2, 3, and 5 exhibit a roughly parallel variation of analgesic activity. This has been interpreted as being reflective of similar modes of interaction with receptors [Cases 1(*a*) or 2(*a*)] and is consistent with the fact that, among the series containing an asymmetric center (series 2, 3, and 5) the more active enantiomers are configurationally related to R-alanine (Table III). Since series 4 and 6 (Table X) show little correlation with series 2, 3, and 5, the mode of interaction of compounds in the former series is probably different from those in the latter. Significantly, the more active enantiomers (series 4 and 6) possess the S-configuration. In the above case, dissimilar binding modes are characterized by both inversion in the stereoselectivity of the receptors and by nonparallel variations in activity. It is important to realize that an identical stereochemical relationship between more active enantiomers does not necessarily imply that analgesic molecules are interacting with receptors in a similar fashion, since this may be coincidental. A more rigorous procedure would, in addition, involve the correlative procedures discussed above. For example, the more active enantiomers of the carbethoxy analog of methadone (series 4; R = R^1 = Me) and the basic anilide compounds (series 6; R = Me, R^1 = benzyl) possess identical configuration but variation of the *N*-substituent does not appear to affect analgesic activity in the same way. This is suggestive of different binding modes despite the fact that the more active optical isomers have the same configuration.

Similar analysis on phenolic and nonphenolic morphinans (I: *Scheme VIII*) and benzomorphans (II: *Scheme VIII*) has also been carried out by the substituent variation method (28). The phenolic compounds show an enhancement of activity on replacing an *N*-methyl with a phenethyl group, while the nonphenolic structures exhibit a decrease in activity when an identical change is made (81). This suggests that the phenolic and nonphenolic compounds are binding to analgesic receptors by different modes. Lack of correlation with other series is also seen among the tetrahydroisioquinoline analgesics (*Scheme IX*), where it has been reported (91) that replacement of the *N*-methyl group by a variety of substituents causes a loss of activity. The pyrrolidine analgesics (Table XI) exhibit a pattern of activities on substituent variation, which is unlike its close relative, the prodines (92). Nonparallelism is also found in the highly potent benzimidazole analgesics (XVI) (93) where variation of the basic group causes changes in activity unlike those seen in other types of analgesic compounds. All of the above phenomena can be rationalized in terms of differing modes of drug–receptor binding. These possibilities include Cases 1(*b*), 2(*b*), and 3, which were described earlier.

It has also been mentioned (28) that differing modes of interaction were likewise possible among compounds in a single series. In such a case, the binding mode of an analgesiophore would be modified when the basic group is changed. One criterion for detecting transitions in the mode of binding is a large change in enantiomeric potency ratio. It has been shown (18) recently that as the number of methylenes in the *N*-aralkyl group of the basic anilide analgesics (Table XII) is increased from one to three, the enantiomeric potency ratio approaches unity. These marked

changes in potency ratio, which were observed on increasing the chain length, represent a decrease in the stereoselectivity of the receptors which is attributed to differing modes of analgesic–receptor binding [possibilities are Cases 1(*b*), 2(*b*), or 3].

Archer (94, 95) has reported a significant observation regarding the effect of stereochemistry on analgesic antagonist activity. The *cis* and *trans* 5,9-dimethyl (XVII) and the *cis*-5-ethyl-9-methyl (XVIII) compounds all show antagonism against narcotic analgesics, while *trans* XVIII is a meperidine antagonist but does not antagonize morphine. This suggests that the mode of interaction of *trans* XVIII differs from that of the other dimethallyl benzomorphans and provides support that more than one receptor species (Cases 2 or 3) may be involved in analgesic action.

It is conceivable that the great variability in the physical dependence associated with various narcotic analgesics could be related to differing modes of interaction. May (66, 70) has shown that analgesic activity can be separated from physical dependence by merely altering the 5,9-dialkyl substituents in *N*-methylbenzomorphans. Moreover, the stereochemistry of the 5,9-dialkyl substituents appears to affect, in certain cases, this separation. For example, the *cis* 5-propyl-9-methyl benzomorphan (Table VI) exhibits no physical dependence capacity, whereas the corresponding *trans* isomer shows high physical dependence capacity (70).

XVIII, R = Et

CONCLUDING REMARKS

Modification of the pain threshold by strong analgesics is a complex phenomenon which is not well understood. The large variety of structurally unrelated compounds which possess morphine-like activity attests to the complexity of this phenomenon. The structural diversity of compounds having high analgesic potency may be due to a combination of factors. Induced fit (2, 28, 94, 96) and differing modes of analgesic-receptor association (2, 28) have been discussed as possible contributing causes for the apparent overall lack of consistency in the relationship between structure and activity. For this reason the topographical characteristics of analgesic receptors remain obscure. The problem of delineating the geometry of analgesic receptors and ideally, elucidating the chemical components which comprise such entities, will challenge the best efforts of the medicinal chemist for years to come.

Pharmacology and Mechanism of Action of Cryptenamine

By BHAGAVAN S. JANDHYALA* and JOSEPH P. BUCKLEY

Cryptenamine, an alkaloidal preparation from *Veratrum viride*, was investigated for hypotensive activity. Simultaneous bilateral denervation of the carotid sinus-body complex and bilateral vagotomy abolished the effects of cryptenamine. Adrenalectomy or pretreatment of the animals with *N,N*-di-isopropyl-*N'*-isoamyl-*N'*-diethylaminoethylurea (P-286), bretylium, reserpine, or α methyldopa abolished or markedly inhibited the hypotensive effects of cryptenamine, whereas guanethidine, which does not induce depletion of catecholamines from the adrenal medulla, failed to block the hypotensive effects of cryptenamine. Central depressor effects of cryptenamine were not abolished either in dog cross-circulation preparations or in the perfused lateral ventricle preparation of the cat. Although cryptenamine induced a depressor response in the body of the recipient following the administration of the drug into the carotid inflow to the recipient's head in the cross-circulation experiment, these responses were essentially abolished by bilateral denervation of carotid sinus-body complex. Cryptenamine potentiated epinephrine-induced depressor responses in the dog and isoproterenol-induced relaxation of both the cat nictitating membrane and the vasculature of the isolated denervated hind limb of the dog. Pronethalol decreased the duration of the hypotensive activity of cryptenamine. The data suggest that sensitization of β adrenergic receptors, a possible increased release of epinephrine from the adrenal medulla, and stimulation of carotid reflex mechanism contribute to the over-all hypotension induced by cryptenamine.

THE DETERRENT to the wider use of the veratrum alkaloids in therapy is the narrow range between their therapeutic and emetic doses. Cryptenamine, an alkaloidal preparation prepared from *Veratrum viride* by a nonaqueous benzene triethylamine extraction procedure, has been reported to have a ratio of emetic to effective hypotensive dose superior to that of other veratrum preparations (1, 2). Finnerty (2) reported that in humans the divergence between the hypotensive and emetic doses of cryptenamine was apparent on intravenous administration. McCall and his colleagues (3) studied the effects of cryptenamine on cerebral circulation and cerebral oxygen consumption in patients with toxemia of pregnancy and reported that cryptenamine induced fewer side effects than other veratrum preparations. The satisfactory ambulatory treatment of hypertension has been reported (4). Abreu *et al.* (5), however, failed to demonstrate any superiority of cryptenamine over protoveratrine A in comparing ratio of emetic to hypotensive dose in dogs.

The pharmacological advantages of cryptenamine have been attributed to the presence of amorphous hypotensive ester alkaloids reportedly lost by hydrolysis during alternative ammonia benzene extraction procedures (1). The present investigation was mainly concerned with the study of the hypotensive activity of cryptenamine and possible mechanism of action.

METHODS

Effects of Cryptenamine on Blood Pressure and Heart Rate of Anesthetized Dogs.—Mongrel dogs of either sex were anesthetized with sodium pentobarbital, 35 mg./Kg., i.v., and the blood pressure recorded from a cannulated femoral artery *via* a Statham pressure transducer onto a Grass polygraph. Heart rate was computed from blood pressure recordings. The intensity and duration of the hypotensive effects of control doses of cryptenamine, 5 mcg./Kg., were determined for each preparation. After arterial pressure returned to normal baseline, the animals were treated with one of the following: atropine sulfate, 1 mg./Kg.; *N,N* - di - isopropyl - *N'* - isoamyl - *N'* - diethylaminoethylurea (P-286), 10 mg./Kg.; bretylium tosylate, 10 mg./Kg.; or pronethalol, 10 mg./Kg.; and 5 mcg./Kg. of cryptenamine repeated within 10 min. All compounds were administered into a cannulated femoral vein. In several additional

This investigation was supported by research grant HE-03475 from the National Heart Institute, U.S. Public Health Service, Bethesda, Md.
The authors express their appreciation to Mr. George J. Grega and Miss Marie L. Steenberg for their technical assistance.
Cryptenamine was kindly supplied by Neisler Laboratories, Decatur, Ill.
* Present address: Department of Pharmacology, U. S. Vitamin and Pharmaceutical Corp., Yonkers, N. Y.

experiments, the animals were debuffered by denervation of the carotid sinus-body complex and bilateral vagotomy or bilateral adrenalectomy performed.

Effects of Cryptenamine on Dogs Pretreated with Reserpine, Guanethidine, or α Methyldopa.—In order to study the role of catecholamines on the mechanism of cryptenamine activity, dogs were pretreated with one of the following: reserpine phosphate, 1 mg./Kg., i.m., 24 hr. prior to the experiment; α methyldopa, 200 mg./Kg., 6 hr. prior to the experiment; or guanethidine, 10 mg./Kg., i.p., 12 hr. prior to the experiment. The animals then were anesthetized with sodium pentobarbital administered by slow intravenous infusion. Blood pressure and heart rate were recorded, and cryptenamine, 5 mcg./Kg., was administered intravenously. Several of these experimental animals were also pretreated with atropine sulfate, 1 mg./Kg., i.v., prior to the administration of cryptenamine.

Effects of Cryptenamine on Epinephrine-Induced Depressor Responses on Blood Pressure of Dogs.—Small doses of epinephrine may produce depressor responses by stimulation of β adrenergic receptors. This property of epinephrine was utilized in the following experiment to study the effects of cryptenamine on β adrenergic receptors.

Mongrel dogs were anesthetized with sodium pentobarbital, 35 mg./Kg., i.v., and prepared for the recording of blood pressure as previously described and mean blood pressure recorded on a Grass polygraph. Four doses of *l*-epinephrine bitartrate, 0.025, 0.05, 0.10, and 0.15 mcg./Kg., were administered intravenously. Cryptenamine, 5 mcg./Kg., i.v., was then administered and the doses of epinephrine repeated 30 min. later.

Effects of Cryptenamine on β Adrenergic Receptors in the Cat Nictitating Membrane.—Effects of cryptenamine on β adrenergic receptors in the cat nictitating membrane were studied using the procedure described by Gyorgy *et al.* (6). Cats were anesthetized with sodium pentobarbital, 35 mg./Kg., i.p. A femoral artery was cannulated for recording of blood pressure as previously described. Preganglionic superior cervical sympathetic nerve was isolated and stimulated at a frequency of 6 c.p.s., 0.2 msec. duration, and 1–3 v., thereby producing a state of continuous contraction of the nictitating membrane without damage to either nerve or muscle. Under these conditions, relaxation of the membrane was elicited with the administration of 5 to 20 mcg./Kg. of isoproterenol, i.v. Cryptenamine, 5 mcg./Kg., was then administered and the same dose of isoproterenol repeated. Both the blood pressure and the activity of the nictitating membrane were recorded on a Grass polygraph.

Effects of Cryptenamine on Isoproterenol-Induced Relaxation in the Denervated Perfused Hind Limb of the Dog.—Mongrel dogs of either sex were anesthetized with sodium pentobarbital, 35 mg./Kg., i.v., and a femoral artery was cannulated for the recording of blood pressure. One hind limb was denervated by severing the femoral and sciatic nerve trunks, and vascularly isolated by clamping the muscles with a 21-gauge stainless steel wire placed under the femoral artery and vein and ligated with a Schiffrin wire tightener. The distal segment of the femoral artery of the isolated limb was cannulated and perfused with the blood drawn from the central segment of the same artery. A sigmamotor pump was utilized to perfuse the leg at a constant rate of flow. Perfusion pressure was measured between the pump and isolated limb by means of a Statham pressure transducer. The changes in perfusion could be related to the changes in the vascular resistance, since blood flow to the limb remained relatively constant.

In order to study the effects of cryptenamine on β adrenergic receptors, four different doses of isoproterenol, 1, 2, 5, and 10 mcg., were administered intra-arterially into the limb followed by cryptenamine, 5 mcg./Kg., i.v. After a 30-min. stabilization period, the doses of isoproterenol were repeated.

Effects of Cryptenamine in the Dog Cross-Circulation Preparation.—Recipient dogs were anesthetized with sodium pentobarbital, 35 mg./Kg., i.v., and prepared for the recording of blood pressure as previously described. The neck musculature was removed utilizing electrocautery to expose the vertebral column from C-2 to C-5. A dorsal laminectomy was performed between C-3 and C-4; the vertebral venous sinuses and vertebral arteries were occluded utilizing 21-gauge stainless steel wire, as described by Bickerton and Buckley (7). Donor dog was similarly anesthetized and prepared for the recording of blood pressure. Circulation was established between the right common carotid artery of the donor and the head of the recipient *via* the recipient's two common carotid arteries and from the two jugular veins of the recipient's head to the right jugular vein of the donor animal. This resulted in a neurally intact, vascularly isolated recipient's head preparation. Circulatory leakage between the recipient's head and the trunk was determined utilizing ^{131}I (radio-iodinated serum albumin) administered into the recipient's carotid inflow. In several of these preparations, the carotid sinus-body complex of the recipient was denervated. Cryptenamine, 5 mcg./Kg., was administered into the arterial inflow of the recipient's head.

Effects of Intraventricular Administration of Cryptenamine on Blood Pressure of Cats.—The method of administration of compounds into the cerebrolateral ventricle, as described by Feldberg (8) and Bhattacharya and Feldberg (9), was utilized in these experiments. Cats were anesthetized with sodium pentobarbital, 35 mg./Kg., i.p., and prepared for the recording of blood pressure on an Offner dynograph as described earlier. A 22-gauge unbeveled needle, 34 mm. in length, employed as a cannula, was stereotaxically implanted in the left cerebrolateral ventricle and secured firmly to the skull with dental cement. The cisterna magna was exposed and the dura carefully cut allowing the cerebrospinal fluid to escape. Then, the lateral ventricle was perfused with artificial cerebrospinal fluid (NaCl, 8.1 Gm.; KCl, 0.25 Gm.; $CaCl_2$, 0.14 Gm.; $MgCl_2$, 0.11 Gm.; NaH_2PO_4, 0.081 Gm.; $NaHCO_3$, 0.07 Gm.; urea, 0.13 Gm., and dextrose, 0.61 Gm.; glass distilled water, 1000 ml.) maintained at 38°. The rate of perfusion was kept constant at 0.1 ml./min., utilizing a Phipps Bird constant-infusion pump.

Lateral ventricles were perfused 60 to 90 min. prior to the administration of cryptenamine. Doses of cryptenamine ranging from 1 to 10 mcg. were administered into the ventricles utilizing a Baltimore microinjection unit.

TABLE I.—EFFECTS OF CRYPTENAMINE, 5 mcg./Kg., i.v., ON BLOOD PRESSURE AND HEART RATE OF DOGS PRETREATED WITH SEVERAL PHARMACOLOGICAL AGENTS

Pretreatment	Dose, mg./Kg.	Animals, No.	Prior to Pretreatment: Mean % Decrease in Blood Pressure	Prior to Pretreatment: Mean % Decrease in Heart Rate	Prior to Pretreatment: Mean Duration, min. Fig. 1.—Effect of cryptenamine (5 mcg./Kg., i.v.) on blood pressure of dogs pretreated with certain pharmacological agents. Key: A, shorter duration compared with control responses; B, duration less than 10 min.

RESULTS

Effects of Cryptenamine on Blood Pressure and Heart Rate of Anesthetized Dogs.—Single doses of cryptenamine, 5 mcg./Kg., produced marked bradycardia and hypotension, persisting for 2 to 3 hr. A return of the bilateral carotid occlusion response was taken as an index for the recovery of the animals from the effects of cryptenamine. Tachyphylaxis was not observed when the second dose of cryptenamine was administered after return of this reflex.

Pretreatment of the animals with atropine sulfate partially blocked the bradycardia and the depressor effect. When cryptenamine was administered after adrenalectomy or pretreatment with P-286 or bretylium, the onset of action was delayed and only a moderate decrease in blood pressure occurred for a relatively short period of time. Pretreatment with either bretylium or P-286 produced complete blockade of the effects of cryptenamine in atropinized dogs. The cryptenamine depressor effect was blocked in three of six atropine-treated adrenalectomized animals, and the duration of activity was significantly reduced in the other animals. Pretreatment with pronethalol or pronethalol plus atropine sulfate decreased the duration of the hypotensive effects of cryptenamine. Bilateral vagotomy or bilateral denervation of the carotid sinus-body complex by itself was not sufficient to completely block the effects of cryptenamine; however, the effects were abolished by complete debuffering (Table I, Fig. 1).

Effects of Cryptenamine on Dogs Pretreated with Reserpine, Guanethidine, or α Methyldopa.—Pretreatment of the animals with either reserpine or α methyldopa significantly reduced the intensity and duration of the hypotensive activity of cryptenamine. Pretreatment with the above compounds followed by atropinization completely eliminated the depressor activity of cryptenamine. Guanethidine plus atropine abolished the effects of cryptenamine on heart rate but failed to reduce markedly the hypotensive activity of cryptenamine (Table I).

Effects of Cryptenamine on Epinephrine-Induced Depressor Responses on Blood Pressure of Dogs.—Depressor responses of epinephrine increased with the doses in the dosage range utilized. After cryptenamine, the depressor responses produced by each dose of epinephrine were potentiated suggesting a sensitization of β adrenergic receptors by cryptenamine (Table II).

Effects of Cryptenamine on β Adrenergic Receptors in the Cat Nictitating Membrane Preparation.—Isoproterenol induced a transient relaxation

of the electrically contracted nictitating membrane, and administration of cryptenamine did not alter the state of the contraction of the membrane. However, following cryptenamine, the administration of isoproterenol produced a biphasic response consisting of an initial relaxation of the membrane approximately equal to the control responses followed by a secondary relaxing effect of greater intensity and duration of action, suggesting a potentiation of the isoproterenol response on the nictitating membrane. When isoproterenol was administered following a return of the cat's blood pressure to precryptenamine levels, the effects on the nictitating membrane were similar to control responses both in intensity and duration (Table III).

Effects of Cryptenamine on Isoproterenol-Induced Relaxation in the Denervated Perfused Hind Limb of the Dog.—Administration of isoproterenol intra-arterially into the denervated perfused hind limb produced a decrease in perfusion pressure. The decrease in vascular resistance as indicated by a decrease in perfusion pressure was proportional with the dose of isoproterenol in that there was a linear relationship between the decrease in perfusion pressure and log dose of the β adrenergic stimulant. Doses of isoproterenol were repeated 20 to 30 min. after the administration of cryptenamine, and the decrease in perfusion pressure originally produced by each dose was significantly potentiated, approximately 25 to 30%. On graphical representation, the log-dose response relationship shifted to the left indicating the potentiation facilitated by cryptenamine on isoproterenol-induced relaxation of the vasculature of the limb (Table IV, Fig. 2).

Effects of Cryptenamine in Dog Cross-Circulation Preparation.—The administration of cryptenamine into the carotid inflow of the recipient's head produced a significant decrease in blood pressure in the recipient's trunk followed by a decrease in the donor blood pressure (N = 4). When the animals were debuffered by denervation of the carotid sinus-body complex, administration of cryptenamine into the head produced a pressor response in the body of the recipient followed by a depressor response in the donor (Table V).

Effects of Intraventricular Administration of Cryptenamine on Blood Pressure of Cats.—Doses ranging from 1 to 10 mcg. of cryptenamine were administered into the perfused lateral ventricle of cats. The lower doses (1–2 mcg.) produced a pressor response, and higher doses (3–10 mcg.) had no effect on blood pressure of the cat. Depressor responses were not observed following the administration of cryptenamine (Table VI).

DISCUSSION

Veratrum alkaloids have been reported to sensitize certain afferent receptors in left ventricles sending impulses *via* the vagus to the central nervous system resulting in hypotension and bradycardia (10). Cryptenamine appears to resemble other veratrum derivatives in this respect. It was necessary to perform bilateral vagotomy as well as bilateral denervation of the carotid sinus-body complex to abolish the effects of cryptenamine on blood pressure and heart rate, suggesting that cryptenamine induced reflex hypotension and bradycardia by affecting afferent receptors at the carotid sinus-body area and in the myocardium. Central hypotensive effects of cryptenamine were not demonstrated either in cross-circulation preparations or in perfused lateral ventricle preparations of the cat. The depressor effects observed in the recipient's trunk following the administration of cryptenamine into the arterial inflow of the head in the dog cross-circulation preparations were most likely due to the effects of cryptenamine on baro- or chemo-receptors in the carotid sinus-body complex. These effects were abolished in the debuffered preparations, and pressor effects resulted in the recipient's trunk.

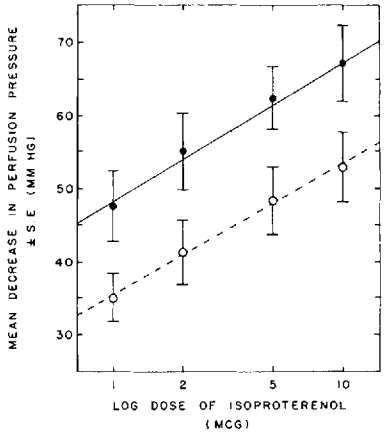

Fig. 2.—Effect of cryptenamine on isoproterenol responses in denervated perfused hind limb of dog. Crytenamine, 5 mcg./Kg. Key: ○, before; ●, after.

The efferent pathways in this reflex are still open to question. None of the pharmacological agents (atropine, pronethalol, bretylium, and P-286) when administered alone, could block the cryptenamine effects in dogs even though they all produced marked alterations in the responses, suggesting the complexity of various mechanisms involved in this reflex. The efferent parasympathetic pathways were blocked by atropinization in order to study the nature of other efferent pathways.

P-286 has been reported to block catecholamine release from the adrenal medulla induced by splanchnic stimulation (11). Pretreatment of the animals with P-286 and atropine sulfate completely abolished the effects of cryptenamine on blood pressure and heart rate. If P-286 is as specific in blocking the adrenal glands as has been reported, a combination of adrenalectomy and atropinization would be expected to produce similar effects. The data obtained in the current study do not totally disagree with this possibility, in that adrenalectomy produced marked inhibition of cryptenamine activity in atropinized animals. Since the adrenal medulla contains large concentrations of catecholamines especially epinephrine, it is quite probable that cryptenamine may reflexly release epinephrine from the adrenal medulla. The possible role of catecholamines in the hypotensive mechanisms of cryptenamine was further confirmed using animals

TABLE VI.—EFFECTS OF INTRAVENTRICULAR ADMINISTRATION OF CRYPTENAMINE ON BLOOD PRESSURE OF CATS

Sex	Wt., Kg.	Dose, mcg.	Control Blood Pressure, mm. Hg	Change, %	Duration, min.
F	2.6	1	110/60	+33.7	160
M	2.3	2	190/110	+ 7.8	150
M	2.3	3	190/110	0.0	...
M	3.4	5	190/125	0.0	...
M	3.4	10	190/125	0.0	...

pretreated with reserpine or α methyldopa. Depletion of catecholamines with reserpine or α methyldopa (12) facilitated blockade of the effects of cryptenamine in atropinized animals, whereas guanethidine which does not induce depletion of catecholamines from the adrenal medulla (13) could not block the cryptenamine effects in animals pretreated with atropine sulfate. Therefore, it appears that nonparasympathetic efferent pathways involved in the reflex hypotension produced by cryptenamine may exert their action through the release of catecholamines from the adrenal medulla.

Since the effects of epinephrine are predominantly on α receptors (14), a sensitization of β receptors could mask any pressor effect that might result from epinephrine. The data obtained indicate a sensitization of β adrenergic receptors following the administration of cryptenamine.

It is apparent that there are many mechanisms in the complex phenomena of cryptenamine-induced hypotension. The results of this investigation which included the ability of P-286, reserpine, α methyldopa, and adrenalectomy to inhibit the effects of cryptenamine suggest a role of catecholamines and the adrenal medulla. The reduction of the cryptenamine effects by pronethalol, potentiation of the isoproterenol effects in the cat nictitating membrane and isolated perfused hind limb of the dog, and potentiation of the epinephrine-induced depressor responses in the dog indicate a role of the β adrenergic receptors and suggest that cryptenamine sensitizes the β adrenergic receptors to circulating epinephrine.

Formation of Acetylcodeine from Aspirin and Codeine

By A. L. JACOBS, A. E. DILATUSH, S. WEINSTEIN, and J. J. WINDHEUSER

A reaction is discussed which leads to the formation of acetylcodeine from aspirin and codeine. It is noted that the generally published methods of analysis will not differentiate between the two alkaloids. A method of separating and assaying the individual compounds is described. Furthermore, the dependence of the interaction on water is discussed.

Although an abundance of products are marketed which contain combinations of aspirin, phenacetin, caffeine, and codeine, little has been published as to the stability and reactivity of these systems. Studies (1, 2) have been conducted on the stability of aspirin *per se*, but little attention has been given to its effect on other compounds.

During the development of a capsule product containing aspirin, phenacetin, caffeine, itobarbital, and codeine phosphate,[1] thin-layer chromatography indicated the presence of an unknown product in some samples after aging. The present communication deals with an investigation of this reaction and indicates that under certain conditions acetylcodeine forms. The acetylcodeine which results from this interaction of aspirin and codeine cannot be detected by the normal analytical methods employed for the determination of codeine. A partition column separation technique of codeine from acetylcodeine is described.

RESULTS AND DISCUSSION

Isolation and Identification of the Reaction Product.—Based upon the possible reactants, it was speculated that an interaction might occur between aspirin and codeine (Scheme I).

Although the mechanism of the reaction has not been investigated, it might proceed by a classical transesterification or might be facilitated by an

pretreated with reserpine or α methyldopa. Depletion of catecholamines with reserpine or α methyldopa (12) facilitated blockade of the effects of cryptenamine in atropinized animals, whereas guanethidine which does not induce depletion of catecholamines from the adrenal medulla (13) could not block the cryptenamine effects in animals pretreated with atropine sulfate. Therefore, it appears that nonparasympathetic efferent pathways involved in the reflex hypotension produced by cryptenamine may exert their action through the release of catecholamines from the adrenal medulla.

Since the effects of epinephrine are predominantly on α receptors (14), a sensitization of β receptors could mask any pressor effect that might result from epinephrine. The data obtained indicate a sensitization of β adrenergic receptors following the administration of cryptenamine.

It is apparent that there are many mechanisms in the complex phenomena of cryptenamine-induced hypotension. The results of this investigation which included the ability of P-286, reserpine, α methyldopa, and adrenalectomy to inhibit the effects of cryptenamine suggest a role of catecholamines and the adrenal medulla. The reduction of the cryptenamine effects by pronethalol, potentiation of the isoproterenol effects in the cat nictitating membrane and isolated perfused hind limb of the dog, and potentiation of the epinephrine-induced depressor responses in the dog indicate a role of the β adrenergic receptors and suggest that cryptenamine sensitizes the β adrenergic receptors to circulating epinephrine.

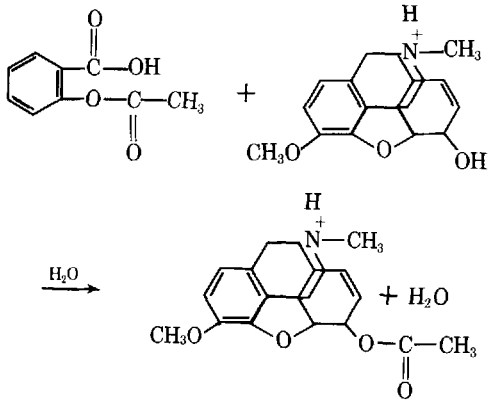
RESULTS AND DISCUSSION

Isolation and Identification of the Reaction Product.—Based upon the possible reactants, it was speculated that an interaction might occur between aspirin and codeine (Scheme I).

Although the mechanism of the reaction has not been investigated, it might proceed by a classical transesterification or might be facilitated by an



Scheme I

anhydride as reported by Higuchi *et al.* (3) for a number of systems.

Mixtures of aspirin and codeine phosphate were placed into ampuls and water was added. The samples were sealed and heated at 60° for periods up to 4 weeks. At the end of regular time intervals the samples were fractionated using a thin-layer preparative chromatographic method. Aside from the aspirin, codeine, and salicylic acid, a new product was isolated. The isolation was carried out by scraping the silica gel from the plate in the area where the spot was evident and subsequent extraction with chloroform. The chloroform was evaporated to dryness leaving a white crystalline residue. The material was analyzed and compared with known acetylcodeine with the following findings.

Acetylcodeine, m.p. 131.5–132.5°; unknown m.p. 129.0–130°.

Anal.[2]—Calcd. for C, 70.4; H, 6.8; N, 4.1; O, 18.8. Found: C, 69.1; H, 6.7; N, 4.3; O, 18.6.

A mixed melting point (1:1) was 129.0°–131.0°. The ultraviolet and infrared spectra of the known and unknown were found to be identical. The R_f values of acetylcodeine, the unknown compound found in the aspirin–codeine mixture, and the unknown compound in the analgesic combination were identical in the systems described under *Experimental*. From these data one may conclude that this degradation product is acetylcodeine. A somewhat similar reaction was reported by Troup and Mitchner (4) involving the acetylation of phenylephrine.

Analysis of Mixtures Containing Codeine and Acetylcodeine.—As previously mentioned, it was noted during initial work on the analgesic combination that although a spot, now known to be acetylcodeine, appeared on the thin-layer chromatograms, no apparent loss of codeine was detected. The analytical technique used was a modification of the method proposed by Heuermann and Levine (5) for the separation of APC plus codeine mixtures. Ultraviolet measurements of the codeine fraction did not indicate any loss of the alkaloid, nor was any change apparent when the codeine fraction was titrated under nonaqueous conditions with perchloric acid. It is evident from Fig. 1, which shows the spectra of codeine and acetylcodeine, that the two are of the same order of magnitude. It is readily apparent that the *a* 1%, 1 cm. at 286 mμ of the compounds in chloroform are essentially identical (codeine = 55; acetylcodeine = 44), and, therefore, an ultraviolet method without prior separation would not be suitable for quantitative analysis.

The acetylation of codeine does not alter the basicity of the tertiary nitrogen and consequently does not affect the nonaqueous titration values.

Codeine and acetylcodeine can be separated by partition chromatography using a Celite support with the nonmobile phase being a 4% citrate buffer system at pH 3.5. At this pH the codeine is held on the column and the acetylcodeine is eluted with chloroform. The codeine can then be eluted with ammonia-saturated chloroform. Figure 2 is a typical chromatogram showing this separation of the products. Recovery of the acetylcodeine and codeine was shown to be quantitative.

From this it is evident that when assaying for codeine in an APC mixture according to the method of Heuermann and Levine (5), the codeine fraction should be passed through the citrate column to assay for acetylcodeine, after determining the presence of this degradation product by thin-layer chromatography.

Dependence of the Reaction on Water.—In order to ascertain the effect of moisture on the rate of the reaction, aspirin and codeine phosphate were mixed in the ratio of 100:15 w/w and placed into ampuls. Varying amounts of water were added and the ampuls sealed. A control sample was included to which no moisture was added. All ampuls were placed into a constant-temperature oven at 60° and heated for periods of time up to 22 days. At intervals, ampuls were withdrawn and assayed for aspirin, salicylic acid, codeine, and acetylcodeine.

The findings are shown graphically in Fig. 3. The data indicate that, as expected, the reaction is dependent on water in the lower moisture regions, but, however, at the higher levels the increase in the rate shows less of a dependency. This can most probably be attributed to the effect of the reverse

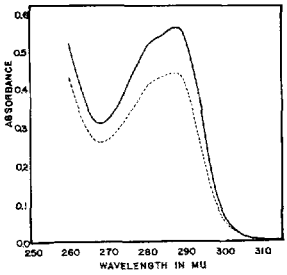


Fig. 1.—Ultraviolet spectra of codeine and acetylcodeine in chloroform. Key: ——, codeine; - - - - - -, acetylcodeine.

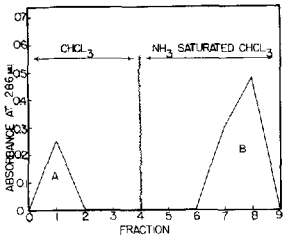

Fig. 2.—A typical chromatogram showing the separation of acetylcodeine (A) from codeine (B) by partition chromatography.

[2] The cooperation of Mr. Urs Stoeckli in performing the elemental analysis is gratefully acknowledged.

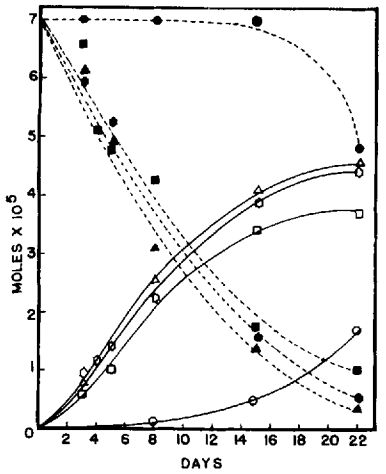

Fig. 3.—A composite representation of the degradation of codeine and formation of acetylcodeine under varying moisture conditions at 60°. Key: ●, < 0.1% moisture, codeine; ○, acetylcodeine; ■, 0.5% moisture codeine, □, acetylcodeine; ▲, 1.0% moisture, codeine; △, acetylcodeine; ⬢, 2.0% moisture, codeine; ⬡, acetylcodeine.

reaction which becomes more evident at the higher moisture concentrations.

It must be pointed out that the evaluation of such a heterogeneous system does not lend itself to a detailed kinetic analysis, but the results do indicate that moisture is essential for the reaction to proceed.

Analysis of commercial samples of the capsule product[1] stored at room temperature for 32 months indicated no evidence of acetylcodeine formation. These capsules were prepared in such a manner that the total moisture present was less than 0.2%. This bears out the findings with the simple aspirin–codeine mixture that at low moisture levels the reaction proceeds slowly even at elevated temperatures.

It should also be pointed out that based upon the work of Buckett *et al.* (6) the apparent activity and toxicity is not altered by the acetylation.

EXPERIMENTAL

Reagents

All chemicals used for the preparation of samples and analytical work were of U.S.P. or reagent grade, except for the acetylcodeine. The acetylcodeine was obtained as the hydrochloride (Merck), converted to the base, extracted with chloroform, and obtained in crystalline form by evaporation of the solvent, m.p. 131.5°–132.5°.

Analytical Procedures

Thin-Layer Chromatography.—*Plates.*—A 0.25-mm. layer of Silica Gel G (E. Merck, Darmstadt) was applied to the plates. The plates were air-dried for 10 min. and then heated in an oven for 45 min. at 120°. The plates were then stored in a desiccator until used.

Solvent System.—(*a*) Chloroform–acetone–diethylamine, 5:4:1 (7). (*b*) Chloroform–methanol, 10:1.

Spray Reagent.—One milliliter of 37% formaldehyde dissolved in 30 ml. of sulfuric acid (8).

Procedure and R_f Values.—Spot the equivalent of 100 mcg. of the alkaloid bases and develop over 10 cm. Dry the plate and spray with the reagent. Both codeine and acetylcodeine appear as purple spots. For nondestructive spraying, use distilled water to locate the compounds.

	Solvent	
R_f Values	(*a*)	(*b*)
Acetylcodeine	0.7	0.95
Codeine	0.4	0.60
Unknown[3]	0.7	0.95

Codeine Phosphate.—The nonaqueous titration as prescribed in the U.S.P. XVII was used to assay the codeine phosphate.

Aspirin.—(In mixture containing aspirin and codeine 100:15 w/w.) Place approximately 25 mg. of the mixture into a separator containing 30 ml. of chloroform and 10 ml. of 0.2 *N* sulfuric acid. Shake. Withdraw the organic layer and place into a 100-ml. volumetric flask. Repeat the extraction twice and bring the organic solution to volume with chloroform. Determine the absorbance of the solution at 280 mμ and compare with a known aspirin solution at the same wavelength.

Salicylic Acid.—Determined by the method of Levine (9).

Acetylcodeine and Codeine in Degraded Samples.—Adjust a 4% aqueous solution of citric acid monohydrate U.S.P. to pH 3.5 with 1 *N* sodium hydroxide. Mix 4.5 ml. of this solution with 7.5 Gm. of acid-washed Celite 545 (Johns-Manville Corp.) and pack into a 200 × 25 mm. chromatography tube previously plugged with glass wool. Top the Celite layer with a pledget of glass wool.

Add a 150-mg. sample of aspirin–codeine to a separator containing 10 ml. of 1 *N* sodium bicarbonate and 30 ml. of chloroform. After shaking, transfer the organic phase to the prepared column. Set a 100-ml. volumetric flask as a receiver beneath the column. Perform two additional chloroform extractions of the sodium bicarbonate layer adding each, in turn, to the column. Add sufficient water-saturated chloroform to the column to bring the eluate to 100 ml. This fraction contains the degradation product (acetylcodeine).

Elute the column with ammonia-saturated chloroform into a 100-ml. volumetric flask. This fraction contains the codeine. Read each fraction on a spectrophotometer at 286 mμ and compare with a standard.

Solubility of the Xanthines, Antipyrine, and Several Derivatives in Syrup Vehicles

By ANTHONY N. PARUTA and BHOGILAL B. SHETH

The solubilities of the xanthine drugs, antipyrine, aminopyrine, and 4-aminoantipyrine in sucrose solutions of varying concentration have been determined. The effect of "additive" concentration, sucrose, upon the solubility of subject materials is rather dramatic, either increases or decreases in solubility being noted. The path or rate of change of solubility with increasing sucrose concentration are seen in some cases to be of a complex functionality and may indicate a combination of mechanisms. Since the dielectric constants of these sucrose vehicles were also known, the solubility as a function of the dielectric constant is also considered.

SYRUP VEHICLES still find wide use in the pharmaceutical field in liquid preparations, and in a continued effort (1) to study the characteristics of these dissolution media, this study was undertaken. The primary objective of this study was to determine if a given solute would have the same magnitude of solubility in water and simple syrup. If the solubilities were found to differ, it was felt important to determine the rate of change of solubility with sucrose concentration. Thus, syrup vehicles at concentrations intermediate to simple syrup were also tested. The solubilities of the xanthines, antipyrine, aminopyrine (4-dimethyl aminoantipyrine), and 4-aminoantipyrine in syrup vehicles at various concentration levels up to saturation have been determined.

Since it was known that the dielectric constants of sucrose solutions (1) decreased with increasing concentration, this was felt to be another parameter in which solubility could be expressed. It is implied that the usefulness of the dielectric constant resides in the expression of polarity of a given dissolution media. The dielectric constants of sucrose solutions have been determined previously (1), by other workers (2, 3), and have been repeated in this study. One main purpose of studying dielectric constants of saturated solutions of solutes was to observe if the magnitude of solubility could be correlated with the change in dielectric constant of the syrup vehicle used.

These sucrose solutions can also be considered as media in which the activity of water has been decreased by the additive, sucrose, and this may also effect the magnitude of solubility. It is possible that both decreased and increased solubility can occur and the operative mechanism being decreased dielectric constant, decreased activity, or a combination of these. It is obvious that as the sucrose concentration is increased, the water concentration is decreased; however, it is the author's view that these vehicles are *per se* dissolution media. The dependence of increased or decreased solubility probably resides in the nature of the solute and the solvent system. Whereas increased solubility had been noted in a previous study (1), both increased and decreased solubility have been found in this study.

Previous work (4–7) had indicated that the asymptotic portion of the solubility curve would have to be extended past the dielectric constant value for pure water in order to achieve decreased solubility. The results of this study show that significant solubility decreases can occur with a solvent system having dielectric constant values less than pure water.

EXPERIMENTAL

Materials.—Caffeine U.S.P. (Nepera Chemical Co.), theophylline U.S.P. (Matheson, Coleman and Bell, 7094 Tx 450), theobromine alkaloid N.F. (Penick NBT 4092), antipyrine N.F. (Penick NBT 3710), aminopyrine N.F. (Penick NBT 2376), and 4-aminoantipyrine (Eastman-Kodak white label—6902). These materials were used directly as received from the manufacturer.

Equipment.—Constant-temperature bath, Bausch & Lomb spectronic 505, WTW Multidekameter DK-06, Bantam demineralizer, BD-1, with mixed resin bed.

Solubility Determinations.—Solubility determinations were made as described previously (4–7). Equilibration time was found to be 72 hr. and all determinations made at 25° ± 0.1°. Some difficulty was encountered in pipeting samples of simple syrup due to high viscosity and these samples show a somewhat larger variation since 1-ml. samples were used in contrast to 5-ml. samples for all other syrup vehicles. After appropriate dilutions, all samples were assayed spectrophotometrically.

Dielectric Constant Determinations.—Dielectric constant determinations were done at 25° on a WTW Multidekameter, DK-06. A calibration curve was prepared from absolute ethanol and water. One advantage of this instrument is that the cali-

TABLE I.—SUMMARY OF THE AVERAGE SOLUBILITY AND THE SOLUBILITY RANGE OF THE VARIOUS SOLUTES STUDIED IN WATER AND SYRUP VEHICLES

Solvent	Av. Solubility, mg./ml.					
	Antipyrine	4-Amino-antipyrine	Amino-pyrine	Caffeine	Theophylline	Theobromine
Water	670 ± 15	410 ± 10	48 ± 3	21 ± 1	8.0 ± 0.3	0.56 ± 0.02
7.5% w/w sucrose	605 ± 20	390 ± 10	42 ± 2	...	8.2 ± 0.3	...
18.5% w/w sucrose	500 ± 20	340 ± 10	36 ± 2	19 ± 1	8.3 ± 0.2	0.66 ± 0.05
31.5% w/w sucrose	380 ± 20	305 ± 10	30 ± 2	17 ± 1	8.3 ± 0.3	0.70 ± 0.03
41.5% w/w sucrose	...	250 ± 10	24 ± 2	...	8.2 ± 0.3	...
46% w/w sucrose	280 ± 20	205 ± 15	19 ± 2	14 ± 1	7.9 ± 0.3	0.70 ± 0.03
63.5% w/w sucrose	185 ± 20	140 ± 20	16 ± 2	10 ± 1	6.2 ± 0.5	0.83 ± 0.03

TABLE II.—SUMMARY OF THE AVERAGE SOLUBILITY RATIOS, $\frac{\text{SOLUBILITY IN SYRUP}}{\text{SOLUBILITY IN WATER}}$, FOR THE VARIOUS SOLUTES STUDIED

Solute	Av. Solubility Ratio, $\frac{\text{mg./ml. Syrup}}{\text{mg./ml. Water}}$
Caffeine	0.48
Theophylline	0.83
Theobromine	1.40
Antipyrine	0.28
Aminopyrine	0.32
4-Aminoantipyrine	0.38

bration curve is linear and although minor day to day variations are noted, the calibration curves are virtually a family of parallel lines. The error in the measurement of dielectric constants is ±0.3 dielectric constant units. Deionized water was used throughout this study as distilled water seemed to cause slight aberrations in the calibration curves, possibly due to ionic contaminants.

RESULTS AND DISCUSSION

The solubilities of the solutes under consideration in this study in water and the various syrup vehicles used are given in Table I. The average value given expresses the average of at least six determinations and in some cases, *i.e.*, theophylline and theobromine, 8–12 determinations were made. The range of the determined solubility in mg./ml. is also shown in this table for the lowest and highest solubility noted over the number of runs made.

The average solubility ratios, the solubility in mg./ml. of simple syrup/solubility in mg./ml. of water, for the solutes studied are given in Table II. In all cases, significant changes in the magnitude of solubility were noted in going from water to simple syrup.

The solubility of caffeine in mg./ml. *versus* either sucrose concentration or dielectric constants is given in Fig. 1. For caffeine it is observed that the solubility decreases dramatically, the magnitude of solubility being about 0.5 in syrup relative to pure water. The path or rate of change in solubility is a smooth nonlinear function when plotted *versus* sucrose concentration; however, approximate linearity is observed on a dielectric constant basis. The rate of change for this parameter is about 0.55 mg./dielectric constant unit. The representation of data on a dielectric constant basis simply "squeezes in" the x-axis, and the solubility curve retains the approximate shape noted on the concentration basis.

In the case of aminopyrine and antipyrine it is also observed that the solubilities decrease dramatically with either increasing sucrose concentration or decreasing dielectric constant. The data have been plotted and are shown in Figs. 2 and 3. Both solubility curves are essentially smooth nonlinear functions, and the ratio of the solubility in syrup relative to water for aminopyrine and antipyrine are 0.32 and 0.28, respectively.

The solubility of 4-aminoantipyrine in the syrup vehicles studied is given in Fig. 4. Again, the experimental solubilities are plotted in mg./ml. of solution for both increasing sucrose concentration and decreasing dielectric constants. In this case, it is observed that an essentially sigmoidal solubility curve is obtained, and a significant change in the solubility occurs. The ratio of the solubility in syrup relative to water for this solute was found to be about 0.38.

The effect of substituents, solubility ratios, and magnitudes of solubility will be discussed later in this communication with respect to the antipyrine derivatives.

In the case of theobromine, an increase in solubility is found with increasing sucrose concentration or decreasing dielectric constants. The ex-

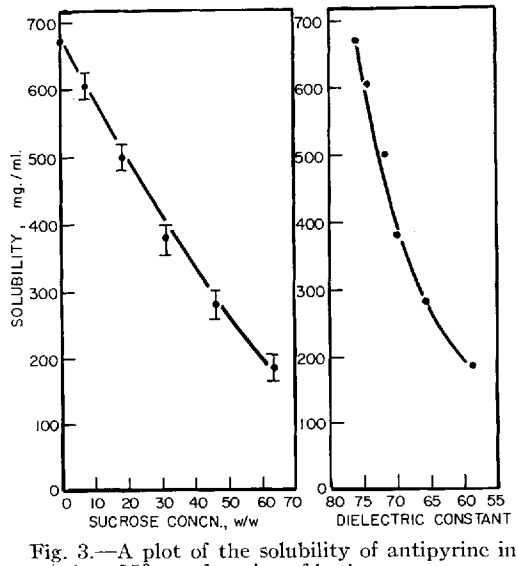

Fig. 3.—A plot of the solubility of antipyrine in mg./ml. at 25° as a function of both sucrose concentration and dielectric constants.

perimental data obtained were plotted in the usual fashion and are shown in Fig. 5. In this case, the solubility ratio has a value greater than unity, the solubility in syrup relative to water having a value of about 1.4. However, as noted in the case of 4-aminoantipyrine, the path of change is essentially sigmoidal but opposite in direction.

The solubility of theophylline presented in the usual fashion is given in Fig. 6. The solubility curve goes through a maxima and the equilibrium solubility in simple syrup finally fell to a lower value than the solubility in pure water. The solubility in simple syrup relative to water had a value of about 0.8. The maximum solubility at about 20–30% w/w sucrose represents about an 8% increase in solubility.

Mechanistically, it is felt that the additive decreases the activity of water by causing a statistically reduced number of hydrogen bonding sites which would ordinarily be available to the solute in the absence of the additive. It would seem then that any additive capable of interferring with, reducing

the number, or tying up hydrogen bonding sites disturbs or shifts the equilibrium to the left, thereby decreasing the magnitude of solubility.

However, increased solubility was also found in this study, and this may be due to the decreased polarity of the syrup vehicles as measured by the dielectric constant. It is probable that a combination of mechanisms are operative. From this study, and others presently underway, it would seem that the nature of the solubility curve for a given solute in syrup vehicles depends strongly upon the original magnitude of solubility in pure water.

On the dielectric constant basis, maximum solubility is seen to occur in the dielectric constant range of 70–75. Some data (8) were available in which the solubility of theophylline had been studied in alkylamine solutions. Although the authors, Leuallan and Osol, were apparently determining the "complex" formation of theophylline and amines and solubilization therefrom, their data have been reanalyzed to apply the dielectric constant concept. The data have been replotted and shown in Fig. 7.

In the presence of monomethylamine, a maxima appears in the solubility curve at about 1.8 Gm. moles amine/L. of water. In this case and in other solubility curves presented for the amines, it has been assumed that the dielectric constant variation is linear with respect to the weight/weight composition notation. In other words, the decrease in dielectric constant from pure water to any amine concentration is proportional to the weight of the added amine. For monomethylamine, the peak solubility occurs at a dielectric constant value of about 75 which agrees with the span of 70–75 noted in the syrup vehicles. In the case of monoethyl and monopropylamines, also shown in Fig. 7, peak solubility occurs at dielectric constant values of about 71 and 68, respectively. These values concur with the range of 70–75 found in syrup vehicles. It should also be noted that the peak dielectric constants in these amine systems decrease with increasing size of the *n*-alkyl substitution.

The above data have been summarized in Table III using dielectric constant values from the literature (9). The approximate correlation of peak solubility dielectric constants for some of the amine–theophylline systems and theophylline–syrup systems is considered to be fair. The remaining theophylline–amine systems were also analyzed; however, no conclusion could be drawn from the data within the above context. Furthermore, it may be instructive to note, that both the amine and sucrose can be considered as "additives" having an approximately common effect on the solubility of theophylline. It is also rather surprising that irrespective of the possible formation of a more soluble "amine compound" or just simply adding sucrose, the peak solubility dielectric constants are to a fair degree correlatable.

Table III.—Summary of the Peak Solubility Dielectric Constants Found for Several Theophylline–Amine Systems[a]

Amine	ϵ^b Amine	Dielectric Constant Range	Peak Solubility Dielectric Constant
Monomethylamine	9.4	78.5–69.7	74.6
Monoethylamine	7.9	77.0–69.6	71.2
Monopropylamine	~5.0	75.5–62.5	68.0

[a] Data from *Reference 8*. [b] *Reference 9*.

DIELECTRIC CONSTANTS

After sample withdrawal for those solutes, the saturated solutions were tested in the dekameter at 25°, by a circulating water bath, relative to their dielectric constant values.

It had been hoped that, as the concentration of a given solute would increase or decrease, the dielectric constant of that sample would increase or decrease proportionally relative to the dielectric constant value of the syrup vehicle. In other words, the 10 mg./ml. of caffeine in simple syrup should affect the dielectric constant of simple syrup to a lesser extent than the 19 mg./ml. of caffeine in the 20% w/w syrup vehicle. This was not found to be the case in general, and no apparent conclusion could be observed from these data. The dielectric constants of the saturated solutions did, however, follow the shape of the solubility curve, but there was no general pattern in incremental increases or decreases relative to the syrup vehicles themselves. It should be noted that these determinations are over a relatively short dielectric constant span and overlapping small incremental changes with the error involved and day-to-day calibration variation are too close to delincate any patterns of change.

There was a notable exception to the above, that being the case of the highly water-soluble antipyrine, and this is shown in Fig. 8. In this figure the solubility curve and the Δ-dielectric constant curve for the saturated solutions (difference between the dielectric constant of saturated solution and the syrup vehicle) cross each other and are approximately mirror images. In this case then, as the solubility of antipyrine decreases in the syrup vehicles going to simple syrup there is proportionately less effect on the dielectric constant of the syrup vehicle itself. The very high solubility of antipyrine relative to the other solutes studied is probably the main factor in this type of analysis.

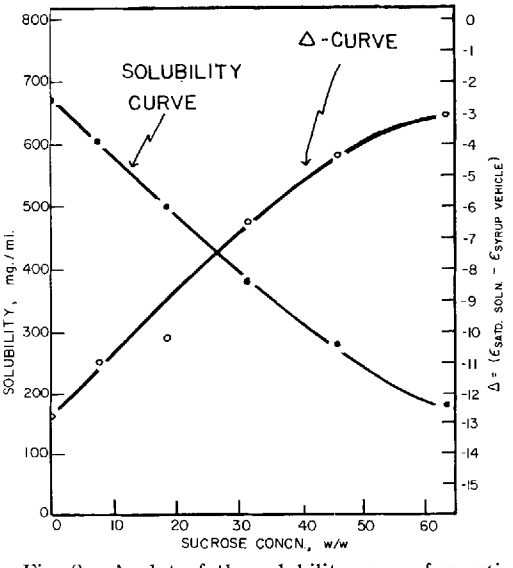

Fig. 8.—A plot of the solubility curve for antipyrine in syrup vehicles and the dielectric constant difference (Δ-curve) between saturated solutions of antipyrine and the syrup vehicles used.

PREDICTION OF SOLUBILITY CHANGE

The data on antipyrine and its derivatives may be considered from an alternate approach. Antipyrine and two derivatives, the 4-amino and 4-dimethyl amino, were studied in order to find the effect of substituent groups relative to solubility effects. In Table IV, the average determined solubility in water and simple syrup is listed. By allowing the solubility of the aminopyrine in water and simple syrup to be represented by unity, the ratios of solubility of the other solutes in the same solvent system were calculated. As can be seen from the table, these ratios are fairly constant irrespective of the solvent system. By taking the difference between the solubility in water and the solubility in syrup a delta value (Δ) is obtained. If the Δ value is divided by the original solubility, the percentage decrease in solubility can be calculated. These values are shown in the final column of this table. The percentage decrease is also seen to be fairly constant. It would seem that the derivative effects for these solutes are relatively constant and predictive solubility is a possibility, at least for the range and systems studied.

In other words, in so far as the approximate rule is valid, only the solubility of antipyrine in syrup need be determined; and the solubility of the derivatives in syrup can be approximately calculated from the ratios in pure water.

Although this type of analysis could be done for antipyrine and its derivatives, the xanthines could not be viewed in the same fashion since the solubility curves obtained were more complex and they are essentially positional isomers, with caffeine containing an extra methyl group in the 1-position.

This study is the first in a series of investigations of the solubility of various solutes in syrup vehicles and has shown that both decreases and increases in solubility are possible with this additive. Furthermore, it seems that the path in syrup vehicles in certain systems has a complex functionality. It must be pointed out that this work deals only with one highly water soluble material, *i.e.*, sucrose, and conclusions attendant to this must be viewed for the

TABLE IV.—SUMMARY OF THE SOLUBILITIES AND SOLUBILITY RATIOS OF ANTIPYRINE AND SEVERAL DERIVATIVES IN WATER AND SIMPLE SYRUP

Substance	Solubility, mg./ml.		Solubility Ratio		Δ mg./ml.	% Decrease = Δ/Soly. in Water
	Water	Simple Syrup	Water	Syrup		
Antipyrine	670	185	14.0	11.6	485	72
4-Aminoantipyrine	411	141	8.6	8.8	270	66
4-Dimethylamino-antipyrine	48	16	1	1	32	67

range and the system studied. It would be interesting to note the effect of additives, especially other sugar moieties, upon the solubility of various solutes.

Whether the dielectric concept, or activity concept mechanisms, or a combination of these are strictly involved cannot be completely delineated in this work. Although the fair correlation given for theophylline has some basis in dielectric constants, no sweeping involvement of dielectric constants for all their systems is apparent. In addition, the observations made may eventually show a very strong solute nature and solvent system dependence. Studies attendant to these points are being carried out in these laboratories and will be the subject of future communications.

Solubilizing Properties of Bile Salt Solutions II

Effect of Inorganic Electrolyte, Lipids, and a Mixed Bile Salt System on Solubilization of Glutethimide, Griseofulvin, and Hexestrol

By THEODORE R. BATES*, MILO GIBALDI†, and JOSEPH L. KANIG

Studies of the influence of inorganic electrolyte on the solubilization of griseofulvin, glutethimide, and hexestrol in four individual bile salt solutions at 37° showed that sodium chloride had little effect on the solubility of the former two drugs but significantly increased the solubility of hexestrol. Based on these findings the possible location of the drug molecules within the micelle is considered. A mixed bile salt system was found to possess a significantly lower critical micelle concentration (CMC) than any of the individual bile salts previously studied. However, the affinities of this mixed micellar system for the drugs were comparable with those obtained with individual bile salts. The addition of lipids to the mixed bile salt system resulted in a decrease in hexestrol solubility but had little effect on griseofulvin and glutethimide solubility. The biological implications of the results obtained in the present communication are explored, and a mechanism for the role of dietary lipids and bile salts in the absorption of drugs is proposed.

BORGSTRÖM (1) has proposed a theory for the fate of ingested triglycerides prior to absorption. According to this theory, the breakdown products of pancreatic lipolysis (*i.e.*, 1- and 2-monoglycerides and fatty acids) are solubilized by bile salt micelles, present in the upper segment of the small intestine, prior to their absorption across the intestinal mucosa. In connection with this theory of fat absorption, several *in vitro* investigations have appeared in the literature demonstrating the marked micellar solubilizing properties of conjugated bile salts for fatty acids and monoglycerides (2–5). There has also been *in vivo* and *in vitro* evidence that the intestinal mucosa is capable of uptaking fatty acids and monoglycerides from a mixed micellar solution composed of these substances and conjugated bile salts (6–8).

In a previous communication (9) the effects of bile salt concentration and type, and temperature on the micellar solubilizing properties of bile salt solutions for the relatively water-insoluble drugs, griseofulvin, glutethimide, and hexestrol were reported. This report proposed that bile salts play a role in the dissolution step of the intestinal absorption mechanism for water-insoluble drugs.

In the present communication the results of findings on the influence of a mixed bile salt system, inorganic electrolyte concentration, and pancreatic lipolytic products and bile components on the degree of micellar solubilization of griseofulvin, glutethimide, and hexestrol are presented.

Solubilizing Properties of Bile Salt Solutions II

Effect of Inorganic Electrolyte, Lipids, and a Mixed Bile Salt System on Solubilization of Glutethimide, Griseofulvin, and Hexestrol

By THEODORE R. BATES*, MILO GIBALDI†, and JOSEPH L. KANIG

Studies of the influence of inorganic electrolyte on the solubilization of griseofulvin, glutethimide, and hexestrol in four individual bile salt solutions at 37° showed that sodium chloride had little effect on the solubility of the former two drugs but significantly increased the solubility of hexestrol. Based on these findings the possible location of the drug molecules within the micelle is considered. A mixed bile salt system was found to possess a significantly lower critical micelle concentration (CMC) than any of the individual bile salts previously studied. However, the affinities of this mixed micellar system for the drugs were comparable with those obtained with individual bile salts. The addition of lipids to the mixed bile salt system resulted in a decrease in hexestrol solubility but had little effect on griseofulvin and glutethimide solubility. The biological implications of the results obtained in the present communication are explored, and a mechanism for the role of dietary lipids and bile salts in the absorption of drugs is proposed.

BORGSTRÖM (1) has proposed a theory for the fate of ingested triglycerides prior to absorption. According to this theory, the breakdown products of pancreatic lipolysis (*i.e.*, 1- and 2-monoglycerides and fatty acids) are solubilized by bile salt micelles, present in the upper segment of the small intestine, prior to their absorption across the intestinal mucosa. In connection with this theory of fat absorption, several *in vitro* investigations have appeared in the literature demonstrating the marked micellar solubilizing properties of conjugated bile salts for fatty acids and monoglycerides (2–5). There has also been *in vivo* and *in vitro* evidence that the intestinal mucosa is capable of uptaking fatty acids and monoglycerides from a mixed micellar solution composed of these substances and conjugated bile salts (6–8).

In a previous communication (9) the effects of bile salt concentration and type, and temperature on the micellar solubilizing properties of bile salt solutions for the relatively water-insoluble drugs, griseofulvin, glutethimide, and hexestrol were reported. This report proposed that bile salts play a role in the dissolution step of the intestinal absorption mechanism for water-insoluble drugs.

In the present communication the results of findings on the influence of a mixed bile salt system, inorganic electrolyte concentration, and pancreatic lipolytic products and bile components on the degree of micellar solubilization of griseofulvin, glutethimide, and hexestrol are presented.

EXPERIMENTAL

Materials.—Hexestrol,[1] griseofulvin,[2] and glutethimide[3] were used as received. The pure bile salts, sodium cholate,[4] sodium desoxycholate,[4] sodium taurocholate,[5] sodium glycochenodesoxycholate,[6] sodium glycodesoxycholate,[6] sodium taurochenodesoxycholate,[6] and sodium taurodesoxycholate[6] were dried *in vacuo* for 36 hr. prior to use. The first four bile salts were used individually to study the effect of inorganic electrolyte concentration on the degree of micellar solubilization of the three drugs, whereas, the latter six conjugated bile salts, representing those found in the human intestinal bile content, were used as a mixture to examine their influence on solubilization, alone and in the presence of lipid additives.

Reagent grade (Fisher Scientific Co.) sodium chloride, anhydrous sodium phosphate, and sodium biphosphate were used as received.

The lipid additives chosen for this study were those which are normal components of human bile or the end products resulting from the enzymatic action of pancreatic lipase during the process of digestion of ingested dietary triglycerides. The former compounds are represented by cholesterol,[7] and lecithin,[7] and the latter by lauric acid,[8] myristic acid,[8] palmitic acid,[8] 1-monolaurin,[9] 1-monomyristin,[9] and 1-monostearin.[9]

Effect of Inorganic Electrolyte on Solubilization.—Solutions of 0.04 *M* sodium cholate, sodium desoxycholate, sodium glycocholate, and sodium taurocholate were prepared and adjusted to 0.06, 0.08, or 0.16 *M* total sodium ion concentration by the addition of sodium chloride.

Effect of a Simulated Intestinal Bile Salt Mixture on Solubilization.—A stock bile salt solution, reported to approximate the human intestinal bile content (10) was prepared. It contained, per liter of final solution: sodium glycocholate, 0.030 mole; sodium glycochenodesoxycholate, 0.030 mole; sodium glycodesoxycholate, 0.015 mole; sodium taurocholate, 0.010 mole; sodium taurochenodesoxycholate, 0.010 mole; sodium taurodesoxycholate, 0.005 mole; and sodium chloride, 0.05 mole. The final stock solution was thus 0.1 *M* with respect to total bile salt concentration and 0.15 *M* with respect to sodium ion concentration. This solution was kept refrigerated when not in use.

A pH 6.4 phosphate buffer solution was prepared by mixing the following solutions in appropriate volumes to give the desired pH. A 0.3 *M* NaH_2PO_4 solution and a 0.15 *M* Na_2HPO_4 solution were mixed in a ratio of 55 parts of the former solution to 45 parts of the latter solution. The resulting solution was thus 0.3 *M* with respect to sodium ion concentration. This stock buffer solution was diluted 1:1 (v/v) with distilled water immediately before use.

The concentration of the simulated intestinal bile salt mixture was varied from 0–0.06 *M* by volumetrically mixing the 0.1 *M* stock solution with the appropriate volume of diluted pH 6.4 buffer. The pH of a 0.06 *M* solution prepared in this manner was approximately 6.48.

Preliminary experiments with this mixture showed that it supported the growth of bacteria under the conditions posed by the solubility experiments. Therefore, all solutions containing this mixture were sterilized by means of Millipore filtration (0.45 μ pore size) in the presence of ultraviolet light. Solutions sterilized in this manner showed no evidence of bacterial growth during the time required for the samples to reach equilibrium.

Effect of Lipid Additives on Solubilization.—In these experiments the simulated bile salt mixture (0.04 *M*), adjusted to the pH (about 6.4), and total sodium ion concentration (0.15 *M*) of the intestinal contents was employed. Predetermined amounts of the lipid additives were rotated for 1 to 2 hr., at 37°, in measured quantities of the bile salt mixture until solution was effected. The resulting clear solutions were then subjected to sterile filtration, and an excess quantity of drug added. These solutions were rotated at 37° until equilibrium was established.

The lipid additives, and the concentration in which they were employed are as follows: (*a*) 1-monolaurin, 0.40%; (*b*) 1-monomyristin, 0.20%; (*c*) 1-monostearin,[10] about 0.025%; (*d*) lauric acid, 0.40%; (*e*) myristic acid, 0.20%; (*f*) palmitic acid,[10] about 0.05%; (*g*) lecithin, 0.20%; (*h*) cholesterol,[10] about 0.025%.

The percentages of lipid additives selected were such that the mixed bile salt micelles were nearly saturated with these compounds. This condition is quite similar to *in vivo* conditions during fat digestion where the bile salt micelles are saturated with the digestive products (*i.e.*, fatty acids and monoglycerides).

A concentration of 0.04 *M* bile salt approximates the molarity of total bile salts present in the small intestine within 30 min. after the administration of a test meal containing corn oil (10).

Equilibration.—In each of the above experiments an excess amount of drug was added to bile salt solution contained in suitably sealed tubes. For those experiments in which the simulated intestinal bile salt mixture was employed, the drug was added under sterile conditions. The tubes were then placed in a shaker-incubator[11] and equilibrated for periods usually not less than 1 week's duration. Equilibrium was determined by repetitive sampling.

Assay Procedure.—The procedure employed for sampling and determining the amount of solubilized drug has been previously reported (9). Sodium chloride and all of the lipid additives, with the exception of lecithin, had no effect on the Beer's law curves for

the three drugs, in the concentrations present in the solutions subjected to spectrophotometric analysis. In the case of lecithin, which does absorb, a blank solution containing the same concentration of lecithin and simulated intestinal bile salt mixture as the sample being analyzed was employed.

RESULTS AND DISCUSSION

Effect of Inorganic Electrolyte on the Degree of Solubilization.—The effects of total sodium ion concentration on the solubility of griseofulvin, hexestrol, and glutethimide in 0.04 *M* concentrations of the four individual bile salts at 37° are presented in Table I. As can be seen from this table, the solubility of griseofulvin and glutethimide, in all of the individual bile salts, is essentially constant over the entire sodium ion concentration range (0.04–0.16 *M*) studied. However, the solubility of hexestrol significantly increased with increasing total sodium ion concentration, in each of the bile salt solutions examined. Sodium chloride, in itself, has no solubilizing potential. For example, the solubility of each of the drugs in water and 0.16 *M* sodium chloride solution, respectively, at 37°, are: griseofulvin (1.4 mg./100 ml., 0.7 mg./100 ml.), glutethimide (1.20 mg./ml., 1.08 mg./ml.), and hexestrol (1.0 mg./100 ml., 0.8 mg./100 ml.).

According to the theory proposed for micellar solubilization by typical ionic surfactants, inorganic electrolytes function to shrink effectively the double layer surrounding the like-charged polar head groups of the surfactant molecules comprising the micelle. As a result, the electrical repulsions existing between adjacent charged surfactant molecules are reduced and the surfactant molecules are able to approach one another more closely in the micelle. This condition would, in effect, allow more surfactant molecules to enter the micelle with the result that the size of the micelle and therefore the volume of the hydrocarbon center of the micelle would increase. As a consequence of the increased volume, the solubility of a material which is solubilized by a mechanism involving incorporation into this region of the micelle (*i.e.*, nonspecific solubilization) should be enhanced. The enhancement noted in the solubilization of hexestrol, in the four individual bile salts, upon the addition of sodium chloride, is consistent with this theory (Table I). This suggests that hexestrol is solubilized by a "nonspecific" mechanism. A concomitant effect of inorganic electrolytes is to increase the degree of packing of the surfactant molecules in the micelle and thereby effectively reduce the volume in the palisade layers of the micelle. Consequently, the solubility of a compound which is solubilized by a mechanism involving incorporation into the palisade layers of the micelle (*i.e.*, specific solubilization) would either remain the same as in the absence of added electrolyte or decrease, depending on the concentration of electrolyte added to the surfactant system. The data given in Table I showing the effect of total sodium ion concentration on the solubility of griseofulvin and glutethimide in the four individual bile salts are consistent with the premise that these solubilizate molecules are solubilized by a mechanism in which they are more closely associated with the palisade layers of the bile salt micelle. This hypothesis, however, is not in agreement with tentative conclusions based solely on relative saturation ratio data (9, 11, 12).

Effect of a Simulated Intestinal Bile Salt Mixture on Solubilization.—The solubilization curves for griseofulvin, hexestrol, and glutethimide, in varying concentrations of the simulated intestinal bile salt mixture, at 37° are shown in Figs. 1–3, respectively. The CMC values for this mixture as determined from the solubilization of griseofulvin and hexestrol at 37° are 0.004 and 0.003 *M*, respectively. These values are in excellent agreement with that determined by Hofmann from the solubilization of azobenzene (5). This investigator obtained, under the same experimental conditions of pH, temperature, and total sodium ion concentration, a CMC value of 0.0035 *M* for this simulated intestinal mixture.

The CMC values obtained for the conjugated bile salt mixture are considerably lower than those previously obtained for the individual, conjugated bile salts, sodium glycocholate and sodium taurocholate at 37° (9). The lower CMC can be attributed to the effect of sodium ion concentration, the presence of more than one surfactant in the system, and the pH on the process of micelle formation. Inorganic electrolytes have been shown to

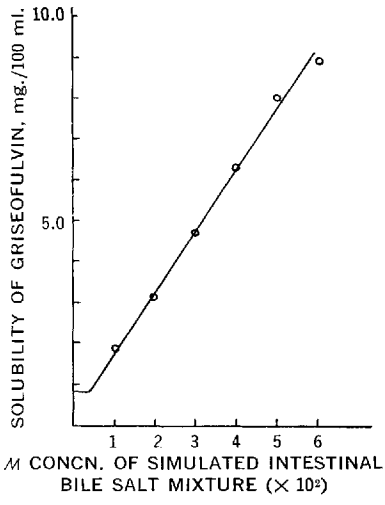

Fig. 1.—Solubility of griseofulvin as a function of simulated intestinal bile salt mixture concentration at 37°.

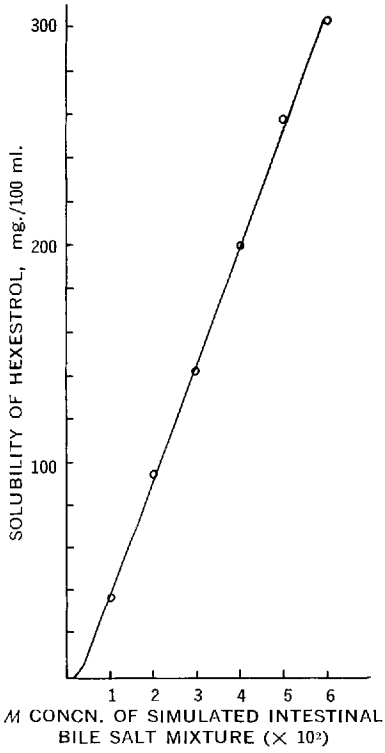

Fig. 2.—Solubility of hexestrol as a function of simulated intestinal bile salt mixture concentration at 37°.

decrease the CMC of ionic surfactants by decreasing the repulsive forces existing between adjacent charged surfactant molecules in the micelle (11, 12). The effect of mixtures of ionic surfactants on the CMC has a twofold effect (11, 12). First, at low concentrations the surfactants that have the lesser tendency to form micelles act as though they were salts to lower the CMC of the other surfactants. Second, at higher concentrations, the surfactants that have the lesser tendency to form micelles become important constituents of the micelle because they themselves are solubilized (12). The presence of these surfactants within the palisade layers of the micelle acts to stabilize the resulting mixed micelle through the formation of intermolecular van der Waal and hydrogen bonding. This stabilization also results in a decrease in the CMC. Normally, the effect of reducing the CMC is to increase micellar solubilization since at a given concentration of surfactant the number of micelles available are increased.

In the case of ionic surfactants the extent of ionization will be influenced by pH. The pH of an aqueous solution of the six conjugated bile salts, in water, is approximately 7.2. Since they are anionic in nature a decrease in the pH to 6.4 will significantly reduce the extent of ionization of some of the bile salts. In the micelle, those bile salts which are least ionized act to screen the repulsive forces between the bile salts which are ionized to a greater extent at this pH. The charge density on the micelle is also reduced. Thus, the over-all effect of pH is to increase the stability of the resultant mixed micelle and thereby lower the CMC.

The saturation ratios for griseofulvin, hexestrol, and glutethimide are included in Table II. For

griseofulvin, a comparison of the saturation ratios of all of the bile salts listed in Table II shows that at 37° the simulated intestinal mixture has the lowest saturation ratio, even though its CMC is the lowest. For hexestrol the simulated intestinal mixture has a saturation ratio lower than that for the conjugated bile salts, sodium taurocholate and sodium glycocholate, even though its CMC is considerably lower. In the case of glutethimide, the presence of the mixed bile salt system had little effect on the maximum solubilizing power (*i.e.*, saturation ratio).

As noted, the presence of more than one surfactant in the system should result in a decrease in the CMC of the system. As a result of the lowering of the CMC, solubilization should begin at a concentration lower than that for a system containing one surfactant. The results of this investigation are consistent with this theory. In addition, as predicted by theory, the amount of hexestrol solubilized at any one simulated intestinal bile salt mixture concentration is higher than that at the same concentration of sodium taurocholate or sodium glycocholate (Fig. 4). However, the increased degree of solubilization based on individual solubilities at a particular surfactant concentration should not be construed as indicating that the simulated intestinal bile salt mixture is a more efficient solubilizer than is sodium taurocholate or sodium glycocholate. As may be noted in Table II the saturation ratio, for hexestrol, obtained with the simulated intestinal bile salt mixture is significantly lower than that obtained with either conjugated bile salt, both of which are components of the mixture. This is indicative of a reduced affinity of the micelle for the solubilizate molecules. The same situation exists in the case of griseofulvin (Table II).

The formation of a mixed surfactant micelle is usually accompanied by a closer degree of packing of the surfactant molecules in the micelle. It is quite possible that this increased packing reduces the maximum solubilizing ability (*i.e.*, saturation ratio) of the simulated intestinal mixture as compared to a system containing one surfactant. The inclusion of surfactant molecules within the palisade layer of the micelle may preclude the effective penetration of solubilizate molecules.

Effect of Lipid Additives on Solubilization at 37°.—The effects of saturated fatty acids, 1-monoglycerides, lecithin, and cholesterol on the solubilization of griseofulvin, glutethimide, and hexestrol in 0.04 *M* simulated intestinal bile salt mixture at 37° are manifest in the data presented in Table III.

Nonpolar additives which are solubilized in the hydrocarbon center of the micelle would, according to theory, "swell" the micelle and effectively increase the volume available in the palisade layers of the micelle for the solubilizate molecules. Consequently, the solubility of a material normally solubilized by a "specific" process, should be enhanced. Whereas solubilizate molecules, normally solubilized by a "nonspecific" mechanism, should show a decrease in solubility upon the addition of nonpolar additives to the system. This results from a competition existing between the solubilizate and nonpolar additive for the space available in the hydrocarbon center of the micelle.

Amphiphilic additives (*i.e.*, compounds which are believed to be solubilized by a "specific" mechanism) act on the surfactant molecules comprising the micelle in a manner similar to inorganic electrolytes and would therefore essentially have the same effect on the solubility of solubilizate molecules. The nature of the effect would depend on the region of the micelle in which the solubilizate molecule normally resides (*i.e.*, specific or nonspecific solubilization).

All of the lipids listed in Table III, with the exception of lecithin and 1-monolaurin, have been shown to function as nonpolar additives in a system containing one bile salt at 37° (2–4). The decrease in the solubility of hexestrol in their presence can therefore be attributed to a competition between hexestrol and the nonpolar additives for the space available in the hydrocarbon center of the micelle. Although lecithin and 1-monolaurin have been reported to function as amphiphiles in a system containing a single bile salt (4, 5), it is conceivable that in a mixed surfactant system they are functioning as nonpolar additives. In the case of glutethimide and griseofulvin the addition of these lipids to the simulated intestinal bile salt system had little or no effect on the solubility of the drugs. However, a sufficient quantity of nonelectrolytes were present in the system such that they nearly saturated the mixed bile salt micelles. Under these saturated

TABLE III.—EFFECT OF LIPID ADDITIVES ON THE SOLUBILIZATION OF GRISEOFULVIN, HEXESTROL, AND GLUTETHIMIDE IN 0.04 *M* SIMULATED INTESTINAL BILE SALT MIXTURE (SIM) AT 37° (pH 6.4 [Na^+] TOTAL 0.15 *M*)

conditions it is highly probable that these nonpolar, lipid compounds, which are normally solubilized by a nonspecific mechanism, also penetrate into the palisade layers of the micelle. If such penetration occurs then competition with the griseofulvin and glutethimide solubilizate molecules would be expected. As a result, the increase in the solubility of these solubilizates which would normally occur in the presence of nonpolar additives, is counterbalanced by the decrease in solubility resulting from the competition between the solubilizate molecules and the nonpolar additives. It is conceivable that the solubilities of griseofulvin and glutethimide reported in Table III represent the net effect of these two opposing factors.

BIOLOGICAL IMPLICATIONS

The significantly high micellar phase to nonmicellar phase (*i.e.*, pH 6.4 buffer) partition coefficients found at 37° for hexestrol, griseofulvin, and glutethimide, (*viz.*, 2.69×10^5, 1.03×10^4, and 1.2×10^3, respectively) indicates that these relatively water-insoluble drugs are preferentially partitioned to the simulated intestinal bile salt micelle, in agreement with the theory proposed for the physical state of the pancreatic lipolytic products during fat digestion and absorption. Based on this similarity, it is quite reasonable to predict that bile salts play a role in the intestinal absorption of water-insoluble drugs.

The absorption and serum levels of griseofulvin have been shown to be enhanced, in humans, when the drug was administered in conjunction with high fat meals (13). A similar effect was observed in rats when griseofulvin was administered in corn oil (14). The present studies conducted to examine the influence of fatty acids, 1-monoglycerides, lecithin, and cholesterol have shown that these lipid substances have no critical effect on the solubilization of griseofulvin and glutethimide, but a decreasing effect on hexestrol solubility. Even though the solubility of hexestrol decreased in the presence of added lipid, its solubility is still significantly higher than that in the absence of bile salts and lipids (*i.e.*, 132–182 times its solubility in pH 6.4 buffer).

The present findings suggest a mechanism to explain the reported enhancement of drug absorption following the administration of a high fat meal. It is well known that triglycerides and other fatty material stimulate the flow of bile into the small intestine. The elevated bile salt concentration then serves to solubilize the drug to a degree far greater than its water solubility. From the limited observations with three different drug molecules it would appear that the concurrent solubilization of fatty material does not preclude significant solubilization of the drug molecules. The increased solubility results in an increased rate of dissolution (15) and, in turn, an increased absorption rate for any compound which manifests a dissolution rate-limited absorption process.

Comparison of Different Photobeam Arrangements for Measuring Spontaneous Activity of Mice

By NATHAN WATZMAN, HERBERT BARRY, III, WILLIAM J. KINNARD, JR., and JOSEPH P. BUCKLEY

Effects of chlorpromazine (1, 2, 4, 8 mg./Kg., p.o.) and aggregation (one or five animals) were tested on activity of mice in a circular photocell activity cage. The use of two right-angle (crisscross) beams yielded a better delineation of low drug doses than the use of three parallel beams. Fewer counts were recorded from the middle of three parallel beams than from the same beam in the crisscross arrangement, suggesting that the tendency of rodents to stay near the periphery was enhanced when the audible clicks of the counter were generated by interruptions of the peripheral beams. Both beam arrangements showed higher counts for aggregated than single animals and also showed a significant dose-aggregation interaction, with chlorpromazine decreasing activity of aggregated more than single animals. The findings indicate certain optimal conditions for testing the effects of chlorpromazine on activity.

THE PHOTOCELL activity cage summates, on digital counters, light beam interruptions due to animals in motion. This instrument has been used extensively in the preliminary evaluation of potential psychotropic agents, for measuring their ability to alter the normal spontaneous locomotor activity of small animals. Variations of this apparatus, used for testing drug effects, have included a rectangular single-beam cage (1), and a circular arena with two beams (2) or six beams (3, 4) activating a single counter. Investigation of the conditions which maximize the sensitivity and reliability of this measuring instrument may contribute scientific knowledge about the interactions of experimental variables with drug effects and also may be of practical use in evaluating compounds.

The present paper reports on the use of a photocell activity cage with a separate counter recording from each of several beams. Thus, it is possible to compare different arrangements of beams recording the activity of the same animals simultaneously. The principal objective of this study was to determine whether photocell beams in different locations show significant differences in the magnitude of drug effects that are recorded. Studies with the six-beam photocell activity cage (3, 4) gave evidence that chlorpromazine (CPZ) may have a greater effect on activity of animals tested in aggregations of five rather than singly; the present study provided a test of this drug–aggregation interaction in the independent-beam photocell activity cage.

Received April 4, 1966, from the Department of Pharmacology, School of Pharmacy, University of Pittsburgh, Pittsburgh, Pa. 15213.

Accepted for publication June 13, 1966.

Presented to the Pharmacology and Biochemistry Section, A.PH.A. Academy of PharmaceuticalSc iences, Dallas meeting, April 1966.

EXPERIMENTAL

Subjects.—The subjects were 360 male, Swiss-Webster albino mice (Taconic Farms, New York, N. Y.).

Apparatus.—Spontaneous locomotor activity was measured by the photocell cage available from Aidiation Electronics, Alexander, Va. This unit is a circular arena 13 in. in diameter and physically similar to the six-beam Actophotometer (Metro Industries, New York, N. Y.). The counters, which produce an audible clicking sound, are mounted on the front of the apparatus, near the base of beam D, shown in Fig. 1. Spontaneous activity can be measured by a single beam, or a combination of any two or three beams operating simultaneously. Also, the positions of any of the light sources may be changed so that a parallel or right-angle (crisscross) arrangement of the beams may be utilized. The experimental room was sound attenuated.

Experimental Design.—The animals were divided into two groups, one tested with two beams in a crisscross arrangement (Fig. 1, left), the other with three beams in a parallel arrangement (Fig. 1, right). Each group was subdivided into five subgroups which were given one of four dosages of CPZ (1, 2, 4, 8 mg./Kg. orally) or saline placebo (0.9%, 0.1 ml./10 Gm. body weight). These groups were further subdivided into two test aggregation conditions: singly or in groups of five. Thus, the experiment comprised a complete factorial design with every combination of two beam arrangements, five dosage levels (including placebo), and two aggregation conditions; the design was repeated 6 times. The animals were given a 60-min. test session in the photocell cage in a dark environment, beginning 60 min. after drug administration.

Statistical Treatment of Data.—The number of activity counts for the first 30-min. period were punched on IBM cards, then converted into square roots, and evaluated by the BMDO2V analysis of variance program on the IBM 7090 computer. In accordance with prior findings (3, 4), the use of the square root transformation, for the first 0.5 hr.

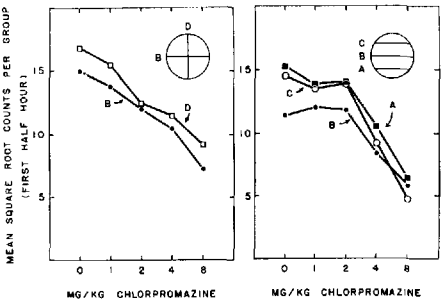

Fig. 1.—Effects of CPZ and beam arrangement on spontaneous activity recorded from each separate beam in the crisscross and parallel arrangements.

of the session, yielded a minimally skewed distribution of scores, with stable performance and large drug effects. For testing the dosage conditions (0, 1, 2, 4, 8 mg./Kg.), and interactions between dosage conditions and any other variables, the statistical significance test was based on the linear orthogonal polynomials, with 1 degree of freedom (5, 6), as used in the prior papers by Watzman *et al.* (3, 4). This test for linear trend assumes a progressive dose-response relationship.

RESULTS

Figure 1 shows the effects of the different dose conditions on activity recorded by each beam, separately for the crisscross and parallel beam arrangements. Different activity counts were recorded on beam B, depending on whether it was one of two crisscross beams or the middle one of three parallel beams. The analysis of variance, comparing this one beam in the different arrangements, shows a statistically significant over-all difference, with higher counts in the crisscross arrangement ($F = 10.1$, d.f. $= 1, 95$, $p < .01$).

A comparison between different beams simultaneously recording the activity of the mice also reveals some highly significant differences. The left graph of Fig. 1 shows a consistent difference between the two crisscross beams, with higher activity recorded on beam D ($F = 25.5$, d.f. $= 1, 50$, $p < .001$). This over-all difference was due to a highly significant interaction between beams and aggregation ($F = 17.5$, d.f. $= 1, 50$, $p < .001$), with beam D recording higher activity levels than beam B for the aggregated but not for the singly tested mice. No significant interaction was found between these two beams and the dosage conditions.

With the parallel arrangement, as shown in the right graph of Fig. 1, the two peripheral beams did not differ significantly from each other, but the middle beam produced lower activity counts, in spite of the fact that it covers the longest span. The quadratic term in the analysis of variance, which provides a comparison between the middle and peripheral beams, shows a significant over-all difference ($F = 20.8$, d.f. $= 1, 100$, $p < .001$). The greater drug decrement for the peripheral beams, which registered substantially higher activity counts than the middle beam for the groups given placebo and the lower doses but not for the groups given the higher doses, resulted in a significant interaction of beams with dosage conditions ($F = 8.35$, d.f. $= 1, 100$, $p < .01$). No significant interaction was found between these three beams and aggregations.

For testing the effects of drug doses and aggregation on activity, the two crisscross or three parallel beams were averaged together. For both arrangements (Fig. 2), the difference among dosage conditions was highly significant, with a similar order of magnitude ($F = 58.1$, d.f. $= 1, 45$, $p < .001$ for the crisscross arrangement; $F = 62.1$, d.f. $= 1, 45$, $p < .001$ for the parallel arrangement). However, an important difference may be seen in the pattern of drug effect. The crisscross arrangement shows a progressive decrease in activity with increasing doses, including a clear delineation between placebo and the lowest doses, but the parallel arrangement shows no consistent decrease in activity with the two lower doses. An analysis of variance limited to the placebo and lower two doses showed a significant dose–response relationship for the crisscross arrangement ($F = 10.9$, d.f. $= 1, 25$, $p < .01$) but not for the parallel arrangement ($F < 1$, d.f. $= 1, 25$).

Figure 2 also shows that higher activity counts were recorded with aggregated than single animals; this aggregation effect was greater with the crisscross arrangement ($F = 86.2$, d.f. $= 1, 45$, $p < .001$) than with the parallel arrangement ($F = 20.6$, d.f. $= 1, 45$, $p < .001$). With both beam arrangements, the drug produced a greater activity decrement in aggregated than single animals, as shown by a significant linear trend for the interaction between dosage and aggregation ($F = 8.76$, d.f. $= 1, 45$, $p < .01$ for the crisscross arrangement; $F = 6.64$, d.f. $= 1, 45$, $p < .05$ for the parallel arrangement).

DISCUSSION AND CONCLUSIONS

The natural tendency of rodents to stay near the periphery of the arena is indicated by the lower number of counts on the middle beam than on the peripheral beams in the parallel arrangement. Figure 1 shows that a significantly larger number of counts, with a superior delineation of small CPZ doses, was recorded from the same location (beam B) when it was one of two crisscross rather than one of three parallel beams. The different locations in which the animals activated the clicking noise of the counters thus produced a significant difference in locomotor behavior, with the crisscross and parallel arrangements. Mice have been shown to behave

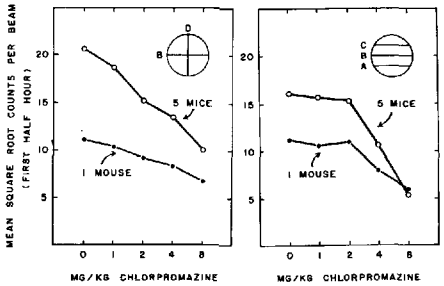

Fig. 2.—Effects of CPZ and aggregation on spontaneous activity; the separate beam recordings in the crisscross and parallel arrangements are pooled together.

so as to elicit noises of low intensity and pitch, comparable to the clicking sound of the counters (7). The present results indicate that the greater coverage of the peripheral portion of the arena, with the parallel beams, enhanced the natural tendency to stay near the periphery, and thus reduced the number of counts on the middle beam. With the crisscross arrangement, the more uniform coverage of all quadrants of the arena by the noise-producing beams apparently elicited a more consistent pattern of activity and dose–response relationship.

The higher counts produced by beam D than beam B, for the aggregated animals tested in the crisscross arrangement, indicates that the aggregated animals tended to clump together near the periphery, either near the counters (at the base of beam D) or away from them, thus activating beam D more often than beam B. The lack of any difference between the two peripheral beams (A and C), in the parallel arrangement, indicates that there was no consistent tendency either to approach or avoid the counters. A further comparison of the parallel beams also shows that the peripheral beams recorded higher counts than the middle beam for the animals under placebo and the low CPZ doses, but not for those under the highest dose. Apparently, the high doses of CPZ reduced the tendency to stay at the periphery of the arena.

With both beam arrangements there was a large dose–aggregation interaction, with CPZ producing a greater depression in activity of grouped than single mice. This indicates a greater tranquilizing effect of this compound in the stimulating social situation, in agreement with prior findings (3, 4). In the photocell activity cage with six crosscross beams recording on a single counter, the less consistent dose–aggregation interaction (4) may be due to failure of the single counter to record fully the high rate of beam interruptions during the intense activity of grouped animals in the placebo condition.

The six-beam Actophotometer is closely similar in dimensions and appearance to the independent beam instrument used in the present study. The counter which recorded activity in the six-beam unit was placed in a separate room and was inaudible to the animals. Apparently this condition of silence does not necessarily improve the delineation of drug effects; the present crisscross arrangement compares favorably with the six-beam unit in detecting the effects of low doses of CPZ. However, a separate experiment, with all other conditions equalized, would be necessary to test the effect of the audible counter clicks on spontaneous activity.

The superiority of the crisscross arrangement in detecting effects of small doses of CPZ, plus the greater drug effect with the peripheral than middle beam in the parallel arrangement, suggest that the most sensitive measure of effect of CPZ would be with an arrangement of two pairs of peripheral beams at right angles to each other, forming a tic-tac-toe pattern. The optimal conditions should probably include the use of animals in aggregations of five rather than singly as well as a separate counter for each beam.

Distribution of Quaternary Ammonium Salts Between Chloroform and Water

By JOHN A. BILES, FOTIOS M. PLAKOGIANNIS, BEVERLY J. WONG, and PAULA M. BILES

The apparent partition coefficients, $K_{app.}$, of some alkylsulfate salts of six quaternary ammonium compounds and one tertiary amine are reported. The $K_{app.}$ of the corresponding bisulfate salts were determined by extrapolation. Some comparisons of molecular structures to the $K_{app.}$ are discussed. A method of analysis of the quaternary cations in the presence of long chain anions is reported. The relationship of longer crystal spacings of the sodium salts of alkylsulfates to the molecular weight is shown.

IN PREVIOUS communications (1, 2) it was reported that the partition of organic salts or complexes was determined by the molecular weight of the organic ions, the branching effect of the aliphatic amine cations, and the nature of the organic solvent system used. The authors showed that partitioning into the organic layer from the aqueous layer could be increased by the addition of proton donor molecules.

workers (3–7) have discussed the results of their studies concerning the intestinal absorption of quaternary ammonium compounds. It was shown that the poor absorption of quaternary ammonium compounds was attributable to the formation of nonabsorbable complexes with mucin (3). Later Levine reported that, although intestinal mucus can form nonabsorbable complexes with quaternary ammonium compounds, removal of the mucus by washing the intestine resulted in a decrease rather than an increase in the absorption of these ions (4). This led to Levine's study of the absorption of a mixture of quaternary ammonium compound and a phosphatido-peptide fraction (PPF). In two separate reports Levine reported that a mixture of PPF and either benzomethamine or *d*-tubocurarine caused more efficient absorption of either quaternary ammonium compound (5, 6). Cavallito and O'Dell reported that the administration of certain sterol acids improved the oral responses to a quaternary hypotensive agent (8). Schanker has suggested that organic ions might penetrate the gastrointestinal-blood barrier by the diffusion of the ions through the barrier in the form of a less polar complex formed with some material normally present in the lumen. He also suggested that the absorption might occur by a specialized transport process analogous to those which transport certain inorganic cations (9).

These data indicate that it is possible that a cation–anion complex is formed which may facilitate the absorption of the quaternary ammonium compound. Therefore, a program was initiated to determine to what extent the presence of anions in aqueous solution containing quaternary ammonium compounds would become more soluble in lipoid solvents and determine to what extent, if any, these salts or complexes would affect the rate of intestinal absorption of the quaternary ammonium compound. The initial communication deals with the *in vitro* study of the partitioning of the alkylsulfate salts of quaternary ammonium compounds between chloroform and water. The *in vivo* studies will be the subject of a future communication.

EXPERIMENTAL

Reagents.—The sodium alkylsulfates were furnished by E. I. DuPont Co. Additional batches were synthesized. Benzomethamine was furnished by Squibb, oxyphenonium bromide by Ciba, methantheline bromide and propantheline bromide by Searle, isopropamide by Smith Kline & French, tridihexethyl iodide by Lederle, and 2-PAM chloride by A. Kondritzer. Homatropine HBr was purchased from Mallinckrodt Chemical Works. Chloroform U.S.P. and distilled water were used as partitioning solvents.

A cationic resin,[1] was cleaned and charged by first treating the resin with 5 *M* HCl and then washing repeatedly with distilled water to remove all traces of excess HCl. The resin was stored in distilled water.

Synthesis.—The sodium alkylsulfates were synthesized by refluxing the aliphatic alcohol (Matheson, Coleman and Bell) with a moderate excess of concentrated sulfuric acid. After refluxing and cooling, the oil was neutralized with sodium bicarbonate. Excess sodium chloride was added to precipitate the sodium alkylsulfate salt (10). The salt was recrystallized several times from alcohol–ether solutions. The degree of purity of the alkylsulfates was followed using X-ray powder diffraction. Carbon and hydrogen analyses were performed.

Preparation of Solutions.—Stock solutions of each of the sodium alkylsulfates were prepared by dissolving enough of the salt in distilled water to make a 0.0005 *M* solution. Also 0.0005 *M* concentrations of each of the quaternary ammonium compounds and homatropine hydrobromide were prepared by dissolving the required amount of solute in sufficient distilled water. The tropaeolin 00 stock solution was prepared as previously described (1).

Determination of the Apparent Partition Coefficients ($K_{app.}$).—The procedures previously described were modified (1, 2). It was concluded from initial studies that association of the cations and anions in aqueous solutions was very low when using very dilute concentrations. Initial studies also indicated the salt existed as ion–ion paired monomers in the organic phase (1). Therefore, a log–log plot of the concentrations of the salt in the chloroform *versus* the concentrations of the ions in the aqueous phase would yield a slope of 2 with the y intercept being equal to $pK_{app.}$

In applying these previous observations, equivalent concentrations of a specific sodium alkylsulfate and quaternary ammonium compound or homatropine were added to 4-oz. amber bottles and enough distilled water added to bring to 40 ml. (considered to be 40 Gm.). The concentrations of each solute were either 1.5, 2.5, 3.5, or 4.5 μm./40 Gm. To the 40 Gm. of aqueous solution was added 40 Gm. of chloroform. All stoppered bottles were shaken for at least 30 min. in an Eberbach horizontal shaker. Following the shaking, the liquids were separated by decantation or by using separators. Blank solutions were also prepared.

Analyses.—Dilute aqueous solutions of the quaternary ammonium compounds and homatropine were used to prepare standard curves. An appropriate amount, usually 0.5 to 1.0 μm., of each solute was mixed with 25 ml. of a saturated solution of tropaeolin 00. The mixed solution was shaken with aliquots of chloroform for extraction. A total of 50 ml. of the chloroform extracts was collected in a 50-ml. volumetric flask. No change in the standard curve was obtained if a slurry of the standard solution of the organic cationic agent and resin was filtered and then treated with tropaeolin 00 and extracted with chloroform.

The procedure for assay of the quaternary ammonium compounds and homatropine in the presence of equivalent concentrations of alkylsulfate was

[1] Marketed as Dowex by the Dow Chemical Co., Midland, Mich.

TABLE I.—TWO LONGER CRYSTAL SPACINGS OF THE SODIUM SALTS OF ALKYLSULFATES

Alkylsulfate	d_2	d_3
Octyl	14.97 Å.	9.86 Å.
Nonyl	16.30	10.75
Decyl	17.59	11.61
Undecyl	19.07	12.46
Dodecyl	20.21	13.32
Tetradecyl	22.50	14.79

modified because the anion interfered with the extraction of the "dyesalt" of the cation and tropaeolin 00. For successful analysis of the cation, enough solution containing approximately 1 μm. of cation was added to a 150-ml. beaker. The resin was then added to remove the anion. After standing for a short period of time, the solution was filtered into a 125-ml. separator. The resin collected in the funnel above the flask was washed with several small portions of distilled water. When washing was complete, 25 ml. of the saturated solution of tropaeolin 00 was added to the filtrate and the quaternary ammonium "dyesalt" was extracted with aliquots of chloroform. The chloroform extract was collected in a 50-ml. volumetric flask. All chloroform solutions were read at 425 mμ using a Beckman DU spectrophotometer.

Temperature Variation Studies.—The apparent partition coefficients of the quaternary ammonium alkylsulfates were determined at various temperatures ranging from 4° to 45°.

RESULTS AND DISCUSSION

Powder Diffraction Data.—The purification of the sodium salts of the alkylsulfates was followed by the change in the X-ray powder diffraction patterns.[2] Copper K-α radiation source was used. In general, it was found that the differences in peaks of diffraction became consistent as the alkylsulfates became pure. The d distances in angstroms for the second and third peaks are recorded in Table I and plotted in Fig. 1. The spacings obtained in these laboratories were not in complete agreement with those reported by Boyd *et al.* (11). It was also noted that distinctly different lines for the even-numbered and odd-numbered carbon atom chains were not observed as found with the fatty acids (12). This is illustrated in Fig. 1.

Apparent Partition Coefficients ($K_{app.}$).—Benzomethamine chloride was subjected to a detailed analysis since the studies of the intestinal absorption of this compound have been rather extensive (3). Both the homologous series of fatty acid salts and the alkylsulfates were studied. The fatty acids of molecular weight greater than decanoic acid were studied. The 0.0005 M solutions were prepared by adjusting the pH of the aqueous solution to 7.4 with NaOH to insure complete dissociation of the acid. It was found that partitioning did not occur with any of the fatty acid ions studied even when three or more equivalents of anion were mixed with one equivalent of cation. These observations can perhaps be explained by assuming that the partition constant of the fatty acid (even considering the almost total dissociation of acid) between chloroform and water is very large so that the fatty acid partitions in favor of the ion-ion pair of the fatty acid–ion and quaternary ammonium compound (13).

The 0.0005 M solutions of the sodium alkylsulfate salts were also used to study their effect on the partition of benzomethamine between chloroform and

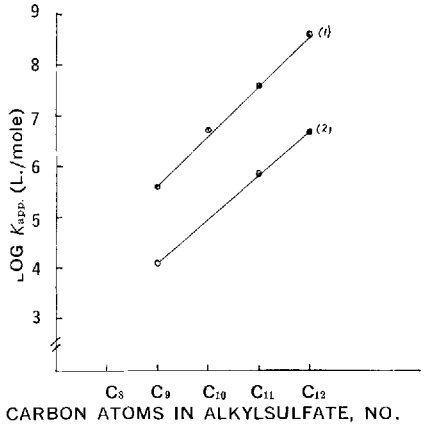

Fig. 3.—The apparent partition coefficients of alkylsulfates of propantheline (*1*) and methantheline (*2*) between chloroform and water.

water. The highest concentration of alkylsulfate used in the study was less than the concentration at which dimerization of anion has been observed (14). The sodium salts of nonyl-, decyl-, undecyl-, and dodecylsulfate were each used to determine their effect on the partition of benzomethamine. The log chloroformic concentration of benzomethamine was plotted against the log aqueous concentration of benzomethamine. The data obtained are plotted in Fig. 2.

The results for benzomethamine shown in Fig. 2 indicate that there was no apparent change in association over the 1.5–4.5 μM/40 Gm. concentration range studied. The slope for each anion varied from 1.70 to 1.89 as shown by the first entry in Table II. The slope would theoretically be 2.00 if dissociation of ions was complete in the aqueous phase and the complex existed as an ion-ion paired monomer in the chloroform. Similar studies were done using other organic cationic agents. The slopes of each cation–anion studied were calculated. The values are recorded in Table II.

The $pK_{app.}$ for the various alkylsulfates and the quaternary ammonium compounds and homatropine were determined. Since the extent of dissociation in the aqueous phase and the association in the chloroformic phase was similar for the various quaternary ammonium compounds listed in Table II, it was decided that the $pK_{app.}$ could be determined for the alkylsulfates of methantheline bromide, propantheline bromide, and tridihexethyl iodide using but one concentration, namely 2.5 μm. of quaternary ammonium ion and 2.5 μm. of alkylsulfate. The $pK_{app.}$ for all values listed in Table III were calculated from the 2.5 μM concentrations. In calculating the $pK_{app.}$ it was assumed that the slope would ideally be two, that is, that the ions were completely dissociated in the aqueous and that the ions existed as paired monomers in the chloroform. Thus, calculations were made using Eq. 1

$$pK_{app.} + 2 \log \text{concn.}_{aq.} = \log \text{concn.}_{CHCl_3} \quad \text{(Eq. 1)}$$

The calculated values are listed in Table III.

Partition studies were also performed using 2-pyridinealdoxime methiodide (2-PAM). However, the partitioning using sodium laurylsulfate was too low to determine any apparent partition coefficient. The data from Table III are plotted in Figs. 3 and 4. The data for methantheline and propantheline are plotted separately to compare more readily the two structurally similar compounds. When the linear plots in Figs. 3 and 4 are extended through the ordinate, one may posssibly conclude the intercepts to be the apparent partition constants for the acid sulfate (bisulfate) salts. These possible apparent partition constants may also be calculated knowing the change in the $pK_{app.}$ per carbon atom of the alkylsulfate. This change represents the slope of the line in Figs. 3 and 4. The information is recorded in Table IV.

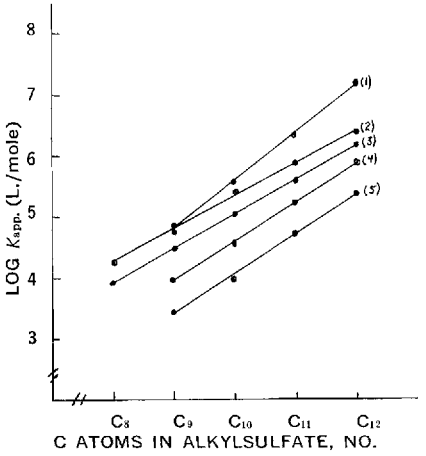

Fig. 4.—The apparent partition coefficients of alkylsulfates of tridihexethyl (*1*), oxyphenonium (*2*), isopropamide (*3*), benzomethamine (*4*), and homatropine (*5*) between chloroform and water.

Fig. 5.—Structures of quaternary ammonium compounds and one amine.

The $pK_{app.}$ values for the bisulfate salts were not determined because the ordinate intercept values were too small. Also the concentrations were too low in aqueous solutions for accurate determination.

The structures of the organic cationic agents listed in Table IV are illustrated in Fig. 5. When the data in Table IV are related to the structures given in Fig. 5, limited conclusions may be drawn. Some of the conclusions are made with the assumption that halide ions in the concentration present do not alter the apparent partition coefficient of the alkylsulfates. There is evidence that bromides and iodides in particular affect the distribution of organic cations between aqueous and organic solvents (7, 15, 16). A comparison of the partition studies of methantheline and propantheline bromides indicates that the $K_{app.}$ increases (*i.e.*, lipoid solubility increases) as the molecular weight increases. However, the change in $pK_{app.}$ per carbon atom change in the alkylsulfates is not the same for the two compounds. No conclusions can be drawn with respect to the $pK_{app.}$ of the alkylsulfates of tridihexethyl, benzomethamine, isopropamide, and oxyphenonium and their molecular structures. A comparison of tridihexethyl and oxyphenonium does indicate that an ester linkage and methyl group alter the $pK_{app.}$ considerably. A comparison of the structures of benzomethamine and oxphenonium does indicate that the degree of aromaticity and ester or amide alters the $pK_{app.}$ to a large extent. A comparison of the changes in structures of isopropamide and benzomethamine indicates that changes in functional groups alter the $pK_{app.}$ to a significant extent.

The apparent partition coefficients for the alkylsulfate salts of benzomethamine, tridihexethyl, and isopropamide were determined at various temperatures to determine to what extent, if any, iceberg structuring (17) around the nonpolar portion of the organic cation and anion occurred in aqueous solution. Studies were run at 4°, 23°, 32°, and 45°. No significant differences in $pK_{app.}$ values could be detected over this range of temperature. This was surprising; however, the solubility of water in chloroform may have contributed to a canceling effect. Nevertheless, it was of interest to find that significant differences occurred with one experimental study of benzomethamine and sodium laurylsulfate, but could not be duplicated with other batches of laurylsulfate. Carbon, hydrogen analysis indicated a quite small amount of adulteration of the one batch of sodium laurylsulfate. The adulterant present was not identified.

A useful analytical assay for quaternary ammonium compounds using the "dyesalt" method of analysis was developed when the aqueous solutions contained alkylsulfates. It was noted that very small amounts of the alkylsulfate would interfere with the extraction of the "dyesalt" even when huge amounts (relatively speaking) of the anionic dye was used. This indicated that the stability constant of the quaternary ammonium alkylsulfate was significantly high when compared to the tropaeolin 00 salt of the quaternary ammonium salt.

The intestinal absorption of the alkylsulfate salts of the various quaternary ammonium compounds illustrated in Fig. 5 is now being studied and will be the subject of a future communication.

Requirements for the Growth of *Aspergillus versicolor* on Atropine Sulfate

By GILBERT C. SCHMIDT, HOWARD W. WALKER*, FRANK R. ROEGNER†, and CARL G. FISCHER‡

Three strains of *Aspergillus versicolor* were isolated from soil, obtained in pure culture, and grown with atropine sulfate as the sole source of carbon and nitrogen. Optimum growth was obtained at 25°, when cultures were aerated by continual shaking, and were buffered to pH 5.5 with 0.2 to 0.4 *M* phosphate. Optimal media contained 1.25 per cent atropine sulfate and were supplemented with vitamins and minerals. Growth rate was inhibited by higher substrate levels. Peak growth was attained in 5 days, following a 2-day lag period.

ALTHOUGH atropine is toxic for many microorganisms, microbial growth often is observed in aqueous solutions of the alkaloid. Little is known of the contaminating organisms, of other organisms capable of utilizing this alkaloid, or of the degradative pathways that are involved.

An organism that utilized atropine, hyoscyamine, scopolamine, tropine, or tropionone as sole carbon and nitrogen sources was first reported by Bucherer (1), who classified it as *Corynebacterium belladonnae* (Nov. spec.). Eighteen years later, phenylacetic acid and tropic acid were isolated from the growth medium, and the presence of atropinesterase was reported (2). In the interim, Kaczkowski (3) had reported that *Arthrobacter terregens* produced tropine, nortropine, tropic acid, and atropic acid, when grown with atropine as the sole source of carbon and nitrogen. Niemer (2) also isolated atropic acid during his studies with *C. belladonnae*, but only traces were obtained. He reasoned that atropic acid arose by dehydration during isolation and was an artifact rather than a metabolite of atropine.

Using complete disappearance from the growth medium as the criterion for degradation, Kedzia and co-workers (4) surveyed 744 strains for ability to degrade atropine. Fifty-four strains, one of which was an *Aspergillus*, degraded the alkaloid. In all instances, ability to degrade atropine was an unstable property that was reacquired when the organism was subcultured 7 to 15 times in a meat broth medium that contained atropine.

From a soil sample, the authors have isolated pure cultures of three strains of *Aspergillus* that utilize atropine as a sole source of carbon and nitrogen. The authors intend to use these strains in studies of atropine metabolism and as a source of atropine-degrading enzymes. This report describes the identification of the three strains and the establishment of optimal growth conditions for that strain which grew most rapidly in aqueous solutions of atropine sulfate.

MATERIALS AND METHODS

Isolation of Aspergillus Strains.—Harary's method (5) for obtaining nicotinic acid-dependent organisms was modified by using atropine sulfate, rather than nicotinic acid, as the sole source of carbon and nitrogen. Three strains of *Aspergillus*, a *Penicillium* strain, and one *Sclerotium* species initially grew together in atropine solutions. Standard mycological methods (6) were used to obtain the five organisms in pure culture. The ability of each to grow in atropine solutions was then tested, and only the three *Aspergilli* utilized atropine sulfate as a sole carbon and nitrogen source. These three strains were stored on sterile soil and were repeatedly subcultured on atropine-agar slants before use.

Identification of the Organisms.—For identification of organisms, cultural and morphological characteristics, determined by standard mycological methods (6), were compared with published data (7). Mycophil agar, Czapek's agar, and Czapek's agar containing 20% sucrose[1] were used routinely. Descriptions are based on observations of colonies arising from hyphal transfers, following examination of the colonies at weekly intervals for 2 months.

Measurement of Growth.—For the measurement of growth, distilled water suspensions of spores, diluted to contain 30 mcg. of nitrogen/ml., were used for inoculation. Spore suspensions were prepared from 15-day-old second transfers on

[1] Czapek's agar is available from Difco, Detroit, Mich. Mycophil agar is available from Baltimore Biological Laboratories, Baltimore, Md.

agar slants that contained 1.5% agar, 1% atropine sulfate, and 0.025% $MgSO_4 \cdot 7H_2O$. Triplicate sets of conical flasks, each containing 20 ml. of the appropriate medium, were inoculated with 0.2 ml. aliquots of the standard spore suspension. With stated exceptions, the inoculated flasks were incubated at room temperature as stationary cultures.

At appropriate times, mats were filtered individually through previously dried and tared 8-ml. Pyrex crucibles, having fine porosity disks. Mats were washed with water until free of atropine, dried at 105° to constant weight, and progress curves were obtained by plotting mat weight as a function of duration of incubation. Each point on the progress curves was the average of at least three mat weights.

Maximum growth was read directly from the progress curves. Progress curves were extrapolated to the abscissa to estimate the time that growth was initiated. The lag phase was assumed to be that interval between inoculation and the initiation of growth. Rate of growth was determined from the slope of that tangent to the curve which passed through the time of growth initiation.

Stock Solutions and Buffers.—Reagent grade chemicals were used to prepare all solutions. Vitamin and alkaloid solutions were sterilized by filtration through a Morton bacterial filter, having an ultrafine fritted disk. All other solutions were sterilized by autoclaving for 15 min. at 15 lb. pressure.

Minerals, vitamins, and atropine as concentrated, sterile, stock solutions were added to previously sterilized buffer solutions. Phosphate buffers were used in all experiments and were 0.2 *M* final concentration, with stated exceptions.

For supplementation with $MgSO_4$, a final concentration of 0.025% of the hydrated salt was used routinely. When complete mineral supplements were used, 1 ml. of stock solution was added to each 100 ml. of culture medium. Each milliliter of the mineral stock solution contained 2 mg. of $FeCl_3 \cdot 6H_2O$, 2 mg. of $ZnSO_4 \cdot 7H_2O$, 2 mg. of $MnSO_4 \cdot H_2O$, and 40 mg. of $MgSO_4 \cdot 7H_2O$. These salts were selected to avoid the introduction of extraneous carbon and nitrogen sources and did not support growth in the absence of atropine or similar carbon and nitrogen source.

One milliliter of stock vitamin solution, which was added to each 100 ml. of medium when vitamins were used, containing 0.4 mcg. of biotin and cyanocobalamin, 40 mcg. of niacin, and 80 mcg. each of riboflavin, thiamine HCl, pyridoxine HCl, and calcium pantothenate. This concentration of vitamins did not support growth in the absence of atropine or other carbon and nitrogen source.

With stated exceptions, a final concentration of 1% atropine sulfate was used routinely. The alkaloid was sterilized as a 25% aqueous solution and an appropriate amount was added to previously sterilized buffer immediately before use.

RESULTS AND DISCUSSION

Identification of Organisms.—Cultural and morphological characteristics indicated that the three strains capable of utilizing atropine as a sole source of carbon and nitrogen were all strains of *A. versicolor*, differing in details of color, texture, and pigment formation.[2] Two of the three strains were green spored, one was rough textured, and the other was smooth textured. The third strain was an unstable, asporogenous variant that represented about 2% of the total population and quickly "reverted" to one or the other of the more stable forms. Except for data concerned with identification and descriptions, results reported here were obtained with the strain that grew most rapidly on media containing atropine as the sole source of carbon and nitrogen.[2]

Growth on Czapek's agar was very slow, colonies were 25–30 mm. in diameter after 4 weeks, sporulation was delayed, and no hulle cells were produced. The colony was flat, with few radial folds, having some floccose growth in the folds or in the center of the colony. The color changed during growth from an initial white, to light gray, through shades of yellow, orange, and green to a final, dark gray green or olive green. In some variants, the different colors appeared in definite zones, while in others there were irregular patches. Droplets of pink exudate appeared in younger colonies, particularly those with a maroon reverse. The reverse was usually maroon, but it was yellow in some strains. Relatively few well-developed conidial heads occurred, but there were many conidial chains borne on mycelial branches without vesicles.

Growth on Czapek's agar with 20% sucrose was somewhat more rapid than on Czapek's agar. Colonies were 35–45 mm. in diameter after 4 weeks, there was more abundant sporulation, and hulle cells were produced. The colony was flat, with a slightly raised center of floccose mycelium. Conidial heads were almost hemispherical, becoming radiate upon longer incubation. Color of the colony was extremely variable, with different shades of gray, green, yellow, orange, and occasionally brick red. Color occurred in definite, concentric zones or with some variant types in irregularly shaped patches. When the brick-red color occurred, the vesicles and sterigmata usually had the same color as the mycelium. Hulle cells of the *A. nidulans* type were produced abundantly throughout the mycelium, and in pale yellow clusters resembling perithecia.

Growth on Mycophil agar at pH 7.0 was very rapid, and sporulation occurred after only a few days' incubation at room temperature. After 4 weeks, colonies were 45–55 mm. in diameter. Small differences in colony color, colony texture, and degree of sporulation were much more apparent on Mycophil agar than on the other media. The colony types varied from relatively smooth and flat colonies, to raised colonies with considerable radial folding, to types having predominantly flocculose growth. Color ranged through pale green, to yellow green, to the darker shades of green, depending on age of the colony. Hulle cells were abundant throughout the mycelium, but were most abundant in clusters that appeared near the outer edges of the colony. These yellow clusters resembled irregularly shaped perithecia,

[2] Three apparently identical cultures of each type organism were examined and cataloged by Dr. C. W. Hesseltine and Dr. J. J. Ellis of A. R. S. Culture Collection, Peoria, Ill. The nine cultures were assigned A. R. S. numbers A-12232, A-12233, A-12234 (asporogenous variant), A-12235, A-12236, A-12237 (rough-textured variant), A-12238, A-12239, and A-12240 (smooth-textured variant). The organism used in the establishment of optimal growth conditions was A 12238.

TABLE I.—COMPARISON OF MORPHOLOGICAL CHARACTERISTICS[a] OF ONE ATROPINE-DEPENDENT STRAIN[b] WITH PUBLISHED DATA[c] FOR *A. versicolor*

Characteristic	*A. versicolor*	Atropine-Dependent Strain
Heads	Hemispherical to radiate. Up to 100–125 μ diam.	Hemispherical to radiate. 88–111 μ diam. Some chains of conidia borne on mycelial branches without vesicles.
Conidiophores	5–10 μ diam. Smooth	2.7–4.6 μ diam. Smooth
Vesicles	15–20 μ diam.	8.9–13.1 μ diam.
Primary sterigmata	8–9 × 3 μ	4.2–10.7 × 1.8–3.2 μ
Secondary sterigmata	5–10 × 2–2.5 μ	3–7.7 × 2.1–3 μ
Conidia	Globose, echinulate, 2.5–3 μ. Occasionally 3.5–4 μ	Globose, echinulate, 3.0–4.5 μ
Hulle cells	Up to 25 μ diam. *A. nidulans* type	Globose, thick-walled, 12.5–19.6 μ diam.
Perithecia or sclerotia	Absent	Absent. Clusters. Hulle cells resembling perithecia are present.

but contained only hulle cells with no evidence of asci or ascospores.

A comparison of the morphological characteristics of the green-spored, smooth-textured, atropine-dependent variant with published descriptions of *A. versicolor* (7) is shown in Table I. From the data, it was concluded that the strain, used to establish optimal growth conditions, is a variant of *A. versicolor*[3] capable of utilizing atropine as a sole source of carbon and nitrogen.

Effects of Hydrogen Ion Concentration on Growth.—Maximal and prolific growth was observed when the test organism was grown on dextrose and ammonium sulfate buffered to pH 6.5 for 5 to 7 days. In contrast, after 20 days' incubation in atropine sulfate solutions, growth of the organism was scanty. On the assumption that a change in substrate might be accompanied by a shift in the pH optimum, the effects of pH on growth rate and maximum growth were studied in an attempt to obtain better growth on atropine.

Stationary cultures were grown in liquid media buffered to different hydrogen ion levels in the pH range 5.0–8.0, flasks were processed for mat weight at 3-day intervals from 1 through 3 weeks, and average mat weights were determined for each pH at each incubation time. Progress curves were plotted, and maximum growth and growth rate were determined from the curves for each pH level. The effects of pH on growth rate and on growth maximum are shown in Table II.

Peak growth and rate of growth were maximal at pH 6.0, and rapidly declined within 0.5 pH unit on either side of the optimum. Maximum growth approximated that earlier seen in stationary cultures on glucose–ammonium sulfate at pH 6.5, but rate of growth on the atropine medium was much less than on the simple carbon and nitrogen source. This difference in growth rates caused the authors to consider vitamin and mineral supplementation.

Effects of Vitamin and Mineral Supplements.—Preliminary experiments disclosed a shift in the pH optimum to pH 5.5, increased growth, and increased growth rate in supplemented media. These observations were confirmed by studying the effects of supplements at both pH 5.5 and pH 6.0.

TABLE II.—EFFECT OF pH ON MAXIMUM GROWTH AND GROWTH RATE[a]

Initial pH	Max. Growth, mg. Mat Wt.	Growth Rate, mg. Mat/Day
5.0	24.6	4.3
5.5	41.0	6.0
6.0	55.0	8.4
6.5	40.2	4.5
7.0	31.9	3.5
7.5	30.9	3.0
8.0	21.8	2.0

[a] Growth of atropine-utilizing *A. versicolor* at room temperature, in stationary cultures, 0.2 *M* phosphate buffers, 1% atropine sulfate supplemented with 0.025% magnesium sulfate. Data taken from individual growth curves, as described in text.

Growth at both hydrogen ion levels, in solutions of atropine supplemented with magnesium, minerals, vitamins, and vitamins plus minerals was measured over 3 weeks, in the manner previously described. Throughout this period, growth on mineral, vitamin, and vitamin-mineral controls was insignificant (2–3 mg.). From the individual growth curves, maximum mat weights and growth rates were determined for each of the eight test media, and are shown in Table III.

Significant increases in maximum mat weight and the growth rate were observed in media supplemented with minerals or vitamins plus minerals. These increases were accompanied by a shift in the pH optimum from 6.0 to 5.5. Lysis was much more rapid at the higher hydrogen ion level, as is apparent from the two progress curves shown in Fig. 1. In formulating the "optimal" medium, vitamins were arbitrarily included, although their addition did not produce growth increases significantly greater than those produced by mineral supplements alone.

Effects of Temperature on Growth.—In early experiments, cultures were incubated at 25° because this temperature is recommended (8) for the growth of *A. versicolor* on simple carbon and

[3] The authors are indebted to Dr. C. W. Hesseltine and Dr. J. J. Ellis, A. R. S. Type Culture Investigations, Peoria, Ill., for their assistance and for confirming the identification of organisms used in this study.

TABLE III.—EFFECT OF SUPPLEMENTS ON MAXIMUM GROWTH AND GROWTH RATE AT pH 5.5 AND pH 6.0[a]

Supplement Added	Max. Growth, mg. Mat Wt. pH 5.5	pH 6.0	Growth Rate, mg. Mat/Day pH 5.5	pH 6.0
Magnesium sulfate	40.1	48.8	6.4	8.0
Minerals	56.3	45.9	9.5	7.8
Vitamins	21.6	11.1	1.9	1.6
Vitamins plus minerals	59.4	56.0	10.0	8.0

[a] Growth in stationary cultures, room temperature, 0.2 *M* phosphate buffers, 1% atropine sulfate solution, supplemented as indicated and as described in the text. Growth rates and maximum growth were determined from individual growth curves.

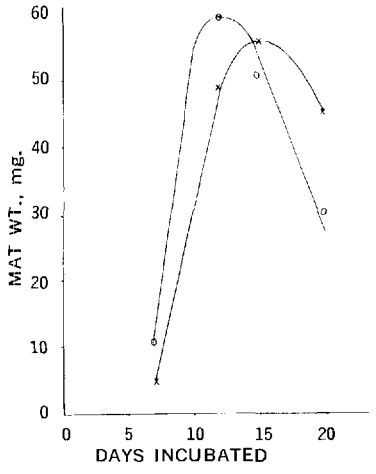

Fig. 1.—Growth of *A. versicolor* on optimal media adjusted to pH 5.5 and pH 6.0. Growth in stationary culture at 25°, 0.2 *M* phosphate buffers, 1% atropine sulfate supplemented with both minerals and vitamins. Key: O, pH 5.5; and ×, pH 6.0.

nitrogen sources. Since atropine is a complex carbon and nitrogen source, temperature effects on growth of the atropine-dependent strain were studied.

Using stationary cultures and optimal media adjusted to pH 5.5, growth curves were plotted for incubations at 0°, 8°, 20°, 25°, 30°, and 36°. Maximum mat weights, determined from the individual growth curves, were then plotted as a function of incubation temperature, as shown in Fig. 2.

It is apparent from the curve that there was a sharp temperature optimum at 25°, as reported for *A. versicolor* grown on simple carbon and nitrogen sources. Thus, the change from simple carbon and nitrogen sources to atropine did not affect the optimum incubation temperature.

Effects of Aeration.—Because fungi usually require good aeration for maximum growth, the effect of aeration by shaking was investigated. Two sets of flasks, one set incubated without shaking and the other shaken continuously on a rotary shaker, were incubated under otherwise identical conditions. At 2-day intervals or less, flasks were removed from each set in quadruplicate and were processed for mat weights. The results obtained at different time intervals, for shaken and stationary cultures, are compared in Table IV.

Aeration caused a striking increase in both growth rate and maximum mat weight, the lag phase was reduced from 6 days to 2 days, and maximum mat weights were 50% higher in shaken cultures. These conditions appeared to be nearly optimal because total mat weights, and the incubation period required, were almost identical with those observed in early experiments in which simple carbon and nitrogen sources were supplied for the organism.

Effect of Phosphate Concentration.—Because the *Aspergilli* usually grow best at phosphate levels between 0.01 and 0.05 *M*, the possible toxic effects of the phosphate concentrations used in development of the optimal medium were considered.

Cultures were grown 4 days, with continuous shaking at pH 5.5 and 25°, on media that were optimal except for varying phosphate concentrations. Four flasks for each of the following phosphate concentrations were employed: 0.00, 0.01, 0.02, 0.05, 0.10, 0.20, 0.30, and 0.40 *M*. Average mat weight was plotted as a function of phosphate concentration, as shown in Fig. 3.

Growth on atropine was very slight at phosphate levels below 0.15 *M* and increased with increasing phosphate, through the highest phosphate concentration tested. Since incubation time was constant and had not reached the optimum, maximum mat weights would not necessarily follow the same pat-

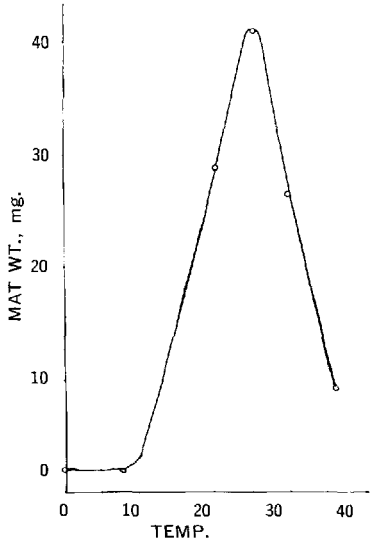

Fig. 2.—Effect of temperature on growth of *A. versicolor*. Growth on optimal medium, stationary cultures, pH 5.5. Maximum mat weight obtained from individual growth curves.

TABLE IV.—COMPARATIVE GROWTH OF *A. versicolor* IN SHAKEN AND STATIONARY CULTURES[a]

Incubation Time, Days	Max. Mat Wt., mg. Shaken Cultures	Max. Mat Wt., mg. Stationary Cultures
0	1.2	1.3
2	12.0	2.5
4	39.5	4.8
6	65.0	20.2
7	82.6	30.0
8	79.0	48.7
10	51.7	55.0

[a] Growth on optimal medium at pH 5.5, 0.2 *M* phosphate buffers. Each point is the average of 4 individually determined mat weights.

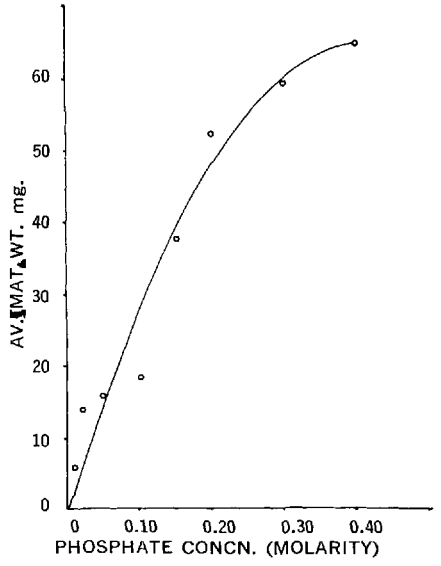

Fig. 3.—Effect of phosphate concentration on growth of *A. versicolor*. Growth for 4 days, continuous shaking, pH 5.5, on media that were optimal except for variations in phosphate levels. Each point is the average of four mat weights.

tern. In more prolonged incubations, the relative rates of growth and lysis would have an important influence on observed mat weights. Lysis was especially apparent in cultures grown in 0.3 and 0.4 *M* phosphate.

In contrast to the growth of *A. versicolor* on simple carbon and nitrogen sources, phosphate requirements are unusually high when atropine is the sole carbon and nitrogen source. This observation is unexplained, but may be associated with the complexity of the substrate, or with increased requirements for nucleic acid synthesis. More extensive studies would be required to clarify this point.

Growth as a Function of Alkaloid Concentration.—Unequivocal proof of atropine utilization by the strain of *A. versicolor* used in these experiments was obtained by relating growth to concentration of the alkaloid, in the absence of other sources of carbon and nitrogen.

Atropine concentrations were varied from 0.06 to 2.0%, using stationary cultures and otherwise optimal media and conditions. To obtain growth rate directly from mat weight, cultures were incubated for 12 days, at which time growth was submaximal and was increasing linearly with time. Growth rates, obtained by averaging triplicate mat weights at each atropine level, were plotted as a function of alkaloid concentration, as shown in Fig. 4.

There was a linear increase in growth rate throughout the concentration range 0–0.5% atropine, a maximum at 1.25%, and a sharp decrease beyond this point. In the absence of other carbon and nitrogen sources, the linear relationship between growth rate and atropine level confirms the ability of this strain of *A. versicolor* to utilize atropine as a sole carbon and nitrogen source. That growth rate is inhibited by high substrate levels is indicated by the existence of a maximum.

SUMMARY AND CONCLUSIONS

Three soil fungi, capable of utilizing atropine as a sole source of carbon and nitrogen, were obtained in pure culture, identified, and the identifications then independently confirmed. Although cultural and morphological characteristics differed somewhat from published data, all three were identified as strains of *A. versicolor*, differing in details of color, texture and pigment formation. These differences were far more apparent on the Mycophil agar used than on other media.

Optimal growth conditions, when atropine sulfate was the sole source of carbon and nitrogen, were determined for that strain which initially grew most rapidly in solutions of atropine supplemented with magnesium. For maximal growth, supplementation with vitamins and minerals was required, although the omission of vitamins had little effect. Using the supplemented medium, the organism grew best at 25° and pH 5.5. Aeration during growth greatly increased growth and decreased the induction period. Phosphate requirements were unusually high, good growth occurring at 0.2–0.4 *M* phosphate, but essentially none occurring below these levels.

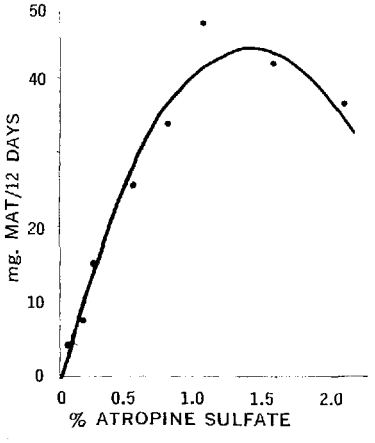

Fig. 4.—Growth of *A. versicolor* as a function of atropine concentration. Optimal media, pH 5.5, 0.2 *M* phosphate, stationary cultures. Each point is the average of three individually determined mat weights.

The need for high phosphate concentrations was not explained. Growth was optimal at an atropine concentration of 1.25% and was inhibited by higher concentrations of alkaloid.

The details of atropine utilization are being studied and will be reported at a later date, but there is evidence that an atropinesterase is involved. There is also evidence that growth requirements are quite specific for atropine, hyoscyamine, or their hydrolysis products.

Analysis of Steroids in Mixtures Using the Kinetics of Blue Tetrazolium Reduction

By DAVID E. GUTTMAN

The rate of formation of formazan resulting from the base-catalyzed reduction of blue tetrazolium by certain steroids was studied spectrophotometrically. With cortisone and hydrocortisone, the reaction rate exhibited a first-order dependency on steroid concentration. The rate constant for cortisone-containing systems was significantly larger than that found for hydrocortisone systems. Studies with cortisone acetate showed that hydrolysis of the ester was prerequisite to reaction with the tetrazolium salt. Differences in rates of color development were used to analyze mixtures of cortisone and hydrocortisone and of cortisone and cortisone acetate.

A WIDELY USED colorimetric method for the determination of the purity of corticosteroids and the potency of dosage forms containing such steroids is based on the formation of a colored formazan resulting from the base-catalyzed reduction of blue tetrazolium by the α-ketol side chain of the steroid molecule. The method consists of determining, after a specified time period, the intensity of color in a test preparation and comparing it with that produced under similar conditions in a standard preparation of the steroid under consideration. There have been a number of published studies of the rates of color formation in systems containing reducing steroids and blue tetrazolium and it has been observed that closely related steroids can exhibit significant differences in their rates of reaction with the tetrazolium salt. For example, Chen, Wheeler, and Tewell (1) presented data which suggested that color generation in cortisone-containing systems was much more rapid than in systems containing hydrocortisone. Meyer and Lindberg (6), in their extensive study, showed that the position and configuration of certain keto- and hydroxy-groups in the steroid molecule influenced reducing characteristics. Recknagel and Litteria (7) also demonstrated differences in reaction rate by their determination of the optimum incubation times for maximum color development for various steroids; *i.e.*, 30 min. for cortisone and 11-deoxycorticosterone as contrasted to 50 min. for corticosterone and hydrocortisone. Similarly, Izzo, Keutmann, and Burton (3) reported that reducing steroids with an 11-keto group developed maximum color faster than those with an 11-hydroxyl group. Martin and Salvador (5) found that acetylation of the 21-hydroxyl group decreased reaction rate relative to the parent alcohol, while Johnson, King, and Vickers (4) reported that with hydrocortisone hemisuccinate, and triamcinolone, color development was unusually slow compared to other steroids.

It has not been generally recognized that, under the conditions usually employed in the assay procedure where the steroid is present at a much lower concentration than that of the catalyst and the tetrazolium reagent, the rate of appearance of formazan exhibits a first-order dependency on the steroid concentration. This behavior is of potential analytical utility because of the lack of direct methods for analyzing mixtures of closely related steroids and because certain steroids which might be found or combined in mixtures do exhibit differences in the rate of this reaction. The present study was conducted to test the feasibility of utilizing such differences as the basis for analytical methods for the determination of steroids in mixtures. Toward this end, this laboratory has studied, under closely

The author thanks Mrs. Gail W. Saloman for competent technical assistance in this study.

The need for high phosphate concentrations was not explained. Growth was optimal at an atropine concentration of 1.25% and was inhibited by higher concentrations of alkaloid.

The details of atropine utilization are being studied and will be reported at a later date, but there is evidence that an atropinesterase is involved. There is also evidence that growth requirements are quite specific for atropine, hyoscyamine, or their hydrolysis products.

Analysis of Steroids in Mixtures Using the Kinetics of Blue Tetrazolium Reduction

By DAVID E. GUTTMAN

The rate of formation of formazan resulting from the base-catalyzed reduction of blue tetrazolium by certain steroids was studied spectrophotometrically. With cortisone and hydrocortisone, the reaction rate exhibited a first-order dependency on steroid concentration. The rate constant for cortisone-containing systems was significantly larger than that found for hydrocortisone systems. Studies with cortisone acetate showed that hydrolysis of the ester was prerequisite to reaction with the tetrazolium salt. Differences in rates of color development were used to analyze mixtures of cortisone and hydrocortisone and of cortisone and cortisone acetate.

A WIDELY USED colorimetric method for the determination of the purity of corticosteroids and the potency of dosage forms containing such steroids is based on the formation of a colored formazan resulting from the base-catalyzed reduction of blue tetrazolium by the α-ketol side chain of the steroid molecule. The method consists of determining, after a specified time period, the intensity of color in a test preparation and comparing it with that produced under similar conditions in a standard preparation of the steroid under consideration. There have been a number of published studies of the rates of color formation in systems containing reducing steroids and blue tetrazolium and it has been observed that closely related steroids can exhibit significant differences in their rates of reaction with the tetrazolium salt. For example, Chen, Wheeler, and Tewell (1) presented data which suggested that color generation in cortisone-containing systems was much more rapid than in systems containing hydrocortisone. Meyer and Lindberg (6), in their extensive study, showed that the position and configuration of certain keto- and hydroxy-groups in the steroid molecule influenced reducing characteristics. Recknagel and Litteria (7) also demonstrated differences in reaction rate by their determination of the optimum incubation times for maximum color development for various steroids; *i.e.*, 30 min. for cortisone and 11-deoxycorticosterone as contrasted to 50 min. for corticosterone and hydrocortisone. Similarly, Izzo, Keutmann, and Burton (3) reported that reducing steroids with an 11-keto group developed maximum color faster than those with an 11-hydroxyl group. Martin and Salvador (5) found that acetylation of the 21-hydroxyl group decreased reaction rate relative to the parent alcohol, while Johnson, King, and Vickers (4) reported that with hydrocortisone hemisuccinate, and triamcinolone, color development was unusually slow compared to other steroids.

It has not been generally recognized that, under the conditions usually employed in the assay procedure where the steroid is present at a much lower concentration than that of the catalyst and the tetrazolium reagent, the rate of appearance of formazan exhibits a first-order dependency on the steroid concentration. This behavior is of potential analytical utility because of the lack of direct methods for analyzing mixtures of closely related steroids and because certain steroids which might be found or combined in mixtures do exhibit differences in the rate of this reaction. The present study was conducted to test the feasibility of utilizing such differences as the basis for analytical methods for the determination of steroids in mixtures. Toward this end, this laboratory has studied, under closely

Accepted for publication June 28, 1966.
The author thanks Mrs. Gail W. Saloman for competent technical assistance in this study.

controlled conditions, the kinetics of the reaction of cortisone, hydrocortisone, and cortisone acetate with blue tetrazolium and has taken advantage of rate differences to analyze mixtures of cortisone and hydrocortisone, and of cortisone and cortisone acetate. The method of proportional equations, suggested by Garmon and Reilley (2), was used for this purpose and was found to yield reasonably accurate estimations of steroid concentration and to offer a rather convenient approach to what would normally be a difficult analytical problem.

PROCEDURE

Stock solutions of the steroids[1] were prepared in absolute alcohol at a concentration of 10 mcg./ml. Binary mixtures of two steroids were prepared by mixing aliquots of two solutions.

Cortisone–Hydrocortisone Systems.—Absorbance-time plots were obtained with a Beckman DB spectrophotometer and a Beckman linear-log recorder equipped with an event marker. The spectrophotometer was set at a wavelength of 525 mμ. A recorder speed of 1 in./min. was used. The cell compartment was maintained at constant temperature by the circulation of water at 24° ± 0.1° with a P.M. Tamson, N.V. constant-temperature circulating bath.

Twenty milliliters of steroid solution was placed in a 50-ml. glass-stoppered conical flask. Twenty milliliters of absolute alcohol was placed in a similar flask to serve as a blank. One milliliter of a 0.5% solution of blue tetrazolium in absolute alcohol was added to each flask. The recorder was started and 1 ml. of a 1% solution of tetramethylammonium hydroxide in absolute alcohol (prepared from a 10% solution in water) was added to each flask simultaneously and with mixing. The time of addition of base was marked on the recorder chart with the event marker. The solutions were placed in cells which were stoppered and placed in the cell compartment.

Cortisone–Cortisone Acetate Systems.—Absorbance-time plots for cortisone acetate-containing systems were obtained in the manner previously described. For the analysis of mixtures of these two steroids, a somewhat different procedure was used. Here, 20-ml. aliquots of steroid solution were pipeted into each of two glass-stoppered test tubes. Corresponding blank tubes were prepared to contain 20 ml. of absolute alcohol. One milliliter of the 0.5% solution of blue tetrazolium was added to each tube. The tubes were placed in a constant-temperature bath at 25° ± 0.1° and allowed to attain temperature equilibrium. One milliliter of the 1% solution of tetramethylammonium hydroxide was added to each tube, and the time of addition was taken as zero time. Exactly 8 min. after the addition of base, one steroid tube and a corresponding blank were quenched by the addition of 1 ml. of glacial acetic acid. Exactly 20 min. after the addition of base, the remaining steroid tube and its corresponding blank were similarly treated. Absorbance values at 525 mμ were determined for each steroid solution using the corresponding blank solution as the reference blank. Standard solutions of pure cortisone and pure cortisone acetate were treated in an identical manner.

Cortisone Acetate Ophthalmic Suspensions.—Two samples of commercially available cortisone acetate ophthalmic suspension were assayed by the kinetic method. The samples were obtained from a local pharmacy. One sample, according to the pharmacist "has been on the shelf for years." The other "was just received from the supplier." These will be designated as "aged suspension" and "fresh suspension," respectively. One milliliter of suspension was placed in a 50-ml. separator and diluted with 5 ml. of distilled water. The steroid was extracted with three 20-ml. portions of chloroform. The chloroform extracts were drained through a cotton plug into a 100-ml. volumetric flask. Chloroform was added to volume. Five-milliliter aliquots of the chloroform solution were placed in each of two 50-ml. glass-stoppered, conical flasks and the chloroform was evaporated using gentle heat. The residue in each flask was dissolved in 20 ml. of absolute alcohol. The analysis was conducted as previously described.

RESULTS AND DISCUSSION

Cortisone–Hydrocortisone Systems.—The time course for formazan appearance, as reflected by increase in absorbance at 525 mμ, is illustrated for each of the steroids in Fig. 1. It is apparent from this figure that formazan production occurred much more rapidly from cortisone-containing systems than from corresponding systems containing hydrocortisone. The semilog plot of Fig. 2 emphasizes this rate difference and illustrates that, under the conditions employed, the rate of appearance of formazan followed first-order kinetics. Here, the logarithm of the function $(A_\infty - A_t)$ is plotted as a function of time, where A_∞ is the asymptotic absorbance and A_t is the absorbance at a particular time. In each case, excellent linearity was observed over at least three half-lives. The pseudo first-order rate constant for cortisone was calculated to be 18×10^{-2} min.$^{-1}$ while that for hydrocortisone was 5.1×10^{-2} min.$^{-1}$. Treatment of the data by the Guggenheim method, which does not rely on an infinity value for absorbance, yielded the same rate constants.

For the analysis of the two steroids in combination, the method of Garmon and Reilley (2), that of proportional equations, was employed. In a reacting mixture containing both steroids, a common product, the formazan, is produced by two simultaneously occurring first-order processes. The absorbance at 525 mμ, which is specific for the product, is thus established at any time by:

$$A = aC(1 - e^{-k_c t}) + aH(1 - e^{-k_h t}) \qquad \text{(Eq. 1)}$$

where

A = absorbance at 525 mμ,
C = initial concentration of cortisone,
a = absorptivity of formazan at 525 mμ,
k_c = first-order rate constant for cortisone,
H = initial concentration of hydrocortisone,
k_h = first-order rate constant for hydrocortisone.

Measurement of two absorbance values at two

[1] The steroids were obtained from commercial sources and were of U.S.P. or N.F. quality.

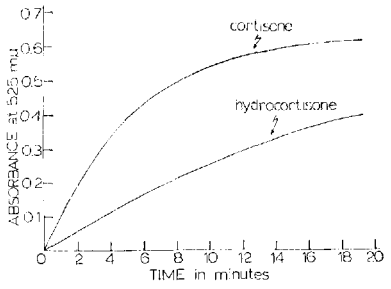

Fig. 1.—A plot illustrating the rate of reaction of cortisone and hydrocortisone with blue tetrazolium.

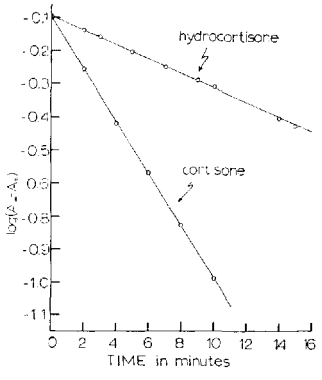

Fig. 2.—A plot illustrating the pseudo first-order appearance of formazan in the reaction of blue tetrazolium with cortisone and hydrocortisone.

times, a shorter time, t, and a longer time, t', allows the formulation of two equations which can be solved simultaneously to yield values for C and H, *i.e.*,

$$A = K_cC + K_hH \qquad \text{(Eq. 2)}$$

$$A' = K'_cC + K'_hH \qquad \text{(Eq. 3)}$$

where

A = absorbance value after the shorter reaction time, t,
A' = absorbance value after the longer reaction time, t',
$K_c = a\,(1 - e^{-k_c t})$; $K'_c = a\,(1 - e^{-k_c t'})$
$K_h = a\,(1 - e^{-k_h t})$; $K'_h = a\,(1 - e^{-k_h t'})$

Although the constants K_c, K'_c, K_h, K'_h can be calculated from a knowledge of rate constant, time, and absorptivity, it is more convenient to determine them directly from absorbance values, at the appropriate reaction times, exhibited by standard preparations of the pure steroids. Thus,

$$K_c = A_c/C_s;\quad K'_c = A'_c/C_s;$$
$$K_h = A_h/H_s;\quad K'_h = A'_h/H_s$$

where

C_s = concentration of the standard solution of cortisone,
H_s = concentration of the standard solution of hydrocortisone,

A_c and A'_c are the absorbances exhibited by the standard preparation of cortisone at times t and t', respectively.

A_h and A'_h are the absorbances exhibited by the standard preparation of hydrocortisone at times t and t', respectively.

Appropriate substitution into Eqs. 1 and 2 and solution of the simultaneous equations for C and H yields:

$$\frac{C}{C_s} = \frac{A - \frac{A_h}{A'_h}A'}{A_c - \frac{A_h}{A'_h}A'_c} \qquad \text{(Eq. 4)}$$

$$\frac{H}{H_s} = \frac{A - \frac{A_c}{A'_c}A'}{A_h - \frac{A_c}{A'_c}A'_h} \qquad \text{(Eq. 5)}$$

For the analysis of mixtures of these two steroids, the longer reaction time was chosen to be 20 min. A shorter reaction time of 5 min. was found to be optimum on the basis of the graphical approach to time selection which was recommended by Garmon and Reilley (2). Absorbance values at these reaction times were read directly from absorbance *versus* time plots which were obtained with mixtures and with standard solutions of the steroids. Results which illustrate the precision and accuracy obtained in the determinations are presented in Table I.

Cortisone–Cortisone Acetate Systems.—Absorbance-time plots obtained with cortisone acetate at a number of different concentrations of base are presented in Fig. 3. A cortisone curve is presented here for comparative purposes. It is apparent from these curves that the rate of reduction of the tetrazolium salt did not exhibit a first-order dependency on the concentration of the steroid ester.

Sample	Label Claim, mg./ml.	Cortisone Acetate Found,[a] mg./ml.	Cortisone Found[a]
"Aged" suspension	5	5.25	0
"Fresh" suspension	5	4.90	0

[a] Average of 3 determinations.

The curves are sigmoidal in shape and a lag-time in the appearance of formazan is observed. It is also seen that as the concentration of catalyst was decreased, the lag-time increased, and the sigmoidal shape of the curve was emphasized. The observed behavior indicates that here production of formazan was the result of a series of consecutive reactions. A logical assumption is that hydrolysis of the ester was prerequisite to a reaction resulting in the generation of formazan, *i.e.*,

$$\text{cortisone acetate} \xrightarrow[OH^-]{k_1} \text{cortisone} + \text{acetate}$$

$$\text{cortisone} + \text{blue tetrazolium} \xrightarrow[OH^-]{k_2} \text{formazan}$$

If the steroid is present in limiting concentration, k_1 and k_2 are pseudo first-order rate constants and the time course for increase in absorbance would be given by:

$$A = aE\left[1 + \frac{1}{k_1 - k_2}(k_2 e^{-k_1 t} - k_1 e^{-k_2 t})\right] \quad \text{(Eq. 6)}$$

where E = initial concentration of cortisone acetate.

The validity of this model was checked by calculating the value of k_1 by iteration based on a knowledge of k_2, a, E, and absorbance values at particular times. The value, in systems prepared from the 1% solution of tetramethylammonium hydroxide, was determined to be 12×10^{-2} min.$^{-1}$. The solid line of Fig. 3, corresponding to the condition of 1% base, represents observed behavior while the circles represent points predicted from the calculated rate constants.

Although the kinetics of formazan generation in reaction systems containing the cortisone ester is complex, absorbance at constant reaction time is directly proportional to the initial concentration of ester, and the method of proportional equations can, therefore, be used to analyze mixtures of cortisone and cortisone acetate. The derivation and nature of the equations used in this case are essentially identical to those discussed in the case of cortisone and hydrocortisone. Analysis of binary mixtures of cortisone and cortisone acetate were carried out and the results are shown in Table II. Here reaction times of 8 and 20 min. were found to be appropriate.

The method was also applied to aged and fresh samples of commercially available cortisone acetate ophthalmic suspension with the anticipation that the aged preparation might exhibit a detectable concentration of free alcohol. Results are shown in Table III. It was found that the cortisone acetate content in both preparations was consistent with the label claim and that negligible free alcohol was present. The low solubility of the steroid in the aqueous vehicle is probably responsible for the long-term stability of the product.

In applying this differential kinetic method to the analysis of dosage forms or to extracts from biological systems, the same types of interferences that are well recognized in the application of the conventionally used tetrazolium assay of steroids should be anticipated. Thus, for example, the presence in a sample of a nonsteroidal reducing agent, acids, or alkali would be expected to interfere and would necessitate a preliminary treatment by which steroidal components are separated from the interfering substances. In this method, as with other analytical procedures based on reaction kinetics, careful control of temperature and of the concentrations of catalyst and reagent was necessary for reproducible results.

Absorption, Disposition, and Excretion of ^{3}H-Mineral Oil in Rats

By A. G. EBERT*, C. R. SCHLEIFER, and S. M. HESS

The fate in rats of ^{3}H-mineral oil was studied after both oral and i.p. administrations. Five hours following a single oral dose of 0.66 ml. of ^{3}H-mineral oil/Kg. about 1.5 per cent of the dose had been absorbed unchanged, and an additional 1.5 per cent of the dose was found in the carcasses as ^{3}H-nonmineral oil substances. The ^{3}H-mineral oil concentration in the carcasses decreased at first rapidly to 0.3 per cent within 2 days post-treatment, and much more slowly, thereafter, to 0.1 per cent of the amount administered by day 21. The absorption and excretion of mineral oil after chronic administration orally was similar to the absorption and excretion after a single dose. The physiologic disposition of the drug, 5 hr. after an oral dose, indicated that the liver, fat, kidney, brain, spleen, and carcass contained ^{3}H-mineral oil. After the i.p. administration of labeled mineral oil, it was excreted very slowly; 11 per cent was found in the feces during the first 8 days post-treatment; only trace quantities were found in the urine. The identity of the mineral oil following oral administration that had been isolated from tissues and excreta was made on the basis of thin-layer chromatography of tissue extracts. The similarity of the physical properties of the extracts of animals that had received mineral oil, i.p. or p.o., supported the view that it was mineral oil that had passed through the walls of the gut. The nonmineral oil nature of the substances containing ^{3}H after the administration of ^{3}H-water indicated that other substances were not mimicking ^{3}H-mineral oil in the assay. ^{3}H-mineral oil was shown to have exchanged ^{3}H with other substances. Metabolism of ^{3}H-mineral oil to more polar substances may also have occurred. The incorporation in the oil of dioctyl sodium sulfosuccinate, an emulsifying agent, tended to increase the amount of ^{3}H-mineral oil absorbed.

MINERAL OIL, liquid petrolatum U.S.P., is a mixture of thousands of compounds (1); it has been employed for over 50 years as a lubricant laxative. Despite its widespread and often chronic use, little is known of the physiologic disposition of this compound. Several reports have been published which have dealt with this problem, but the lack of a suitable assay and the indefinite composition of the mineral oil employed in the various studies made such studies difficult to evaluate, especially quantitatively (2–7). A comprehensive bibliography on this subject has been recently prepared (8). From the work of Stetten (5) and Bernhard and Scheitlin (6) it appeared that 5 to 25% of the administered doses to rats had been absorbed. This report contains data on the absorption, distribution, and excretion of mineral oil by rats that had received an oral or intraperitoneal dose of tritiated mineral oil, randomly labeled.

METHODS

Tritiated mineral oil (^{3}H-MO) which met the standards for liquid petrolatum U.S.P., except for the presence of radioactivity, specific activity 1.52 mc./ml., was administered to Sprague-Dawley and Holtzman rats of either sex at a dose of 0.66 ml./Kg., an amount equivalent to the recommended human dose. In studies of the fate of mineral oil after chronic administration, nonlabeled mineral oil was administered for 31 consecutive days at a dose of 0.66 ml./Kg. Tritiated mineral oil was given as the final dose on the 32nd day, and the animals were sacrificed at intervals thereafter. The effect on absorption of the oil of adding a wetting agent, dioctyl sodium sulfosuccinate, was studied. Radioactivity was measured in the alimentary tracts, carcasses, feces, and urines 24 hr. after the oral administration of tritiated mineral oil containing 1.7 or 8.3 mg./ml. of dioctyl sodium sulfosuccinate.

To study the excretion of the oil rats were placed in metabolism cages where food and water were provided *ad libitum*. Urine and feces were collected daily and stored at −15° until assayed.

In the distribution studies rats were anesthetized with ether and killed by exsanguination at suitable intervals following drug administration. After the hair had been removed with an electric clipper, the alimentary tract was exposed by a midline incision, carefully isolated, and ligated a few millimeters from the oral and anal ends. The tract and the remainder of the rat, defined as carcass, were separately weighed and homogenized with 4 vol. of toluene. In several studies visceral organs were removed for individual assays.

For the assays of radioactivity in the treated animals, tissues, as well as feces, were extracted with toluene 3 times. The residue of each sample, after toluene extraction, was extracted once with *p*-dioxane. Radioactivity that had been extracted from the tissues or excreta was measured in a liquid scintillation spectrometer after portions of the ex-

Accepted for publication May 31, 1966.
The authors are indebted to Dr. I. M. Whittemore and Dr. B. A. Fries, California Research Corp., for preparing the tritiated mineral oil and to Mr. C. Chinn, Biochemical Pharmacology Laboratory, Squibb Institute for Medical Research, for his help in some of the technical aspects of this study.
*Present address: Administrative Center, International Minerals and Chemical Corp., Skokie, Ill.

tracts had been added to toluene or dioxane scintillation solutions.[1] Radioactivity that could not be extracted from the feces or tissues was measured by combusting portions of the extracted residue by the oxygen flask technique of Kelly *et al.* (10). Radioactivity in urine was measured by counting an aliquot of the urine in the dioxane scintillation solution directly.

This technique made it possible to extract in excess of 98% of the radioactive material from control tissues and from feces to which ^{3}H-mineral oil had been added or from tissues and feces of treated rats.

The presence of ^{3}H-mineral oil in the extracts of the tissues and feces of the treated rats was demonstrated by the use of thin-layer chromatography. The extracts were evaporated at temperatures <45° under reduced pressure to small volumes, usually less than 5 ml. Measured portions were applied to thin-layer chromatography plates of Silica Gel G 250 μ thick. The 30 × 20 cm. plates were activated before use by heating at 120° for 30 min. After activation, the plates were fully developed with Baker's reagent grade benzene to remove interfering impurities (11). The plates were dried at 100° for 5 min. and then spotted. They were developed in hexane–diethyl ether–glacial acetic acid (90:10:1 by volume) (12). ^{3}H-mineral oil was assayed after the plates had been developed by scraping small areas of the chromatogram into vials, adding a toluene or dioxane scintillation mixture, and measuring the radioactivity in a liquid scintillation spectrometer. Under these conditions ^{3}H-mineral oil could be detected on the chromatographic plate at a level of 5×10^{-3} mcg. at R_f 0.90 ± 0.02. The developed plates were visualized when necessary by spraying with 50% aqueous sulfuric acid followed by heating at 100° for 15 min. More polar substances remained at the origin or moved more slowly than mineral oil; they did not, however, separate into discrete areas, but remained as a long smear well separated from the ^{3}H-mineral oil. The quantitative nature of the recoveries was determined by applying appropriate standards to each of the plates before it was developed. Included among the standards were ^{3}H-mineral oil and extracts of control tissues to which ^{3}H-mineral oil had been added at the time the extract was applied to the chromatographic plate.

The lability of the ^{3}H label of the mineral oil was demonstrated by shaking 0.1 ml. of ^{3}H-mineral oil with 1 ml. of aqueous 0.01 *N* HCl. The water layer was carefully separated from the oil and washed 3 times with equal volumes of hexane. The water was vaporized at 95° and atmospheric pressure and condensed on a cold finger chilled with solid CO_2 and acetone. The condensate contained 0.1% of the radioactivity that had been present in the ^{3}H-mineral oil.

In another experiment 80 mg. of ^{3}H-mineral oil was dissolved in 1.0 or 100 ml. of propionic acid. The solutions were allowed to stand at room temperature for 18 hr.; they were then made alkaline by the addition of sodium hydroxide, 1.7 ml. to the first solution, and 17.0 ml. to a 10-ml. aliquot of the second. The alkalinized mixtures were extracted repetitively with heptane until the heptane washes were free of radioactivity. The tritium in the aqueous layers was measured by the use of Bray's solution (9). The aqueous layer of the 1-ml. solution contained 0.89% of the radioactivity, whereas the aqueous layer of the 100-ml. solution contained 3.76%.

Whether other substances accepted ^{3}H and mimicked the chromatographic characteristics of ^{3}H-mineral oil was investigated by administering orally to rats 0.5 ml. of ^{3}H-water with a specific activity of 340 μc./ml., the same dose of radioactivity that had been administered to the rats that had received ^{3}H-mineral oil. The tissues of these animals were subjected to the extraction and chromatographic separation described above for mineral oil.

RESULTS

After the administration of ^{3}H-mineral oil to rats, 85% of the radioactivity extracted from the tissues by toluene proved to have been ^{3}H-mineral oil. Most of the remaining 15% was present in unidentified, more polar substances that remained near the origin of the chromatogram. Of the material extracted with dioxane about 8% proved to have been ^{3}H-mineral oil on the basis of its chromatographic characteristics, the remaining 92% comprised unidentified, more polar substances.

Toluene and dioxane extracts of the carcasses of rats that had been dosed 24 hr. earlier with ^{3}H-water contained 0.3 and 40.9% of the radioactivity, respectively. After the extracts had been concentrated and chromatographed, however, no evidence of substances with the characteristics of ^{3}H-mineral oil was found in any of the tissues; in the carcass, *e.g.*, this was $<5 \times 10^{-4}$ mcg./Gm. based on the specific activity of ^{3}H-mineral oil.

The dispositions of ^{3}H-mineral oil and of tritium-containing substances other than mineral oil in rats that had received 0.66 ml. of tritiated drug/Kg. orally, either acutely or after chronic administration, are illustrated in Fig. 1. It is apparent that more than 80% of the total dose had not been absorbed before it was excreted in the feces. The highest concentration of mineral oil that had been absorbed by the rats at any time was 13.8 mcg./Gm. (1.6% of the dose); this was found 5 hr. after administration. Twenty-four hours after the dosing, the small amount of ^{3}H-mineral oil remaining in the rats was still largely in the alimentary tract, about 4.5% of the quantity administered; the carcass at that time contained about 0.6%, or 5.2 mcg. of mineral oil/Gm. of tissue. These levels continued to fall steadily, 48 hr. after the administration the levels of ^{3}H-mineral oil in the gastrointestinal tract and in the carcass had dropped to 0.7 and 0.3% of the dose, respectively.

Figure 1 shows that rats treated daily for 31 days with unlabeled mineral oil prior to the terminal dose of ^{3}H-mineral oil gave no evidence of facilitated absorption. The concentrations of ^{3}H-mineral oil found in the alimentary tracts and in the remainders of the animals were similar whether the rats had received the drug acutely or chronically.

[1] The toluene scintillation solution contained 4 Gm. of PPO, 0.05 Gm. of POPOP in 1 L. of toluene. The dioxane scintillation solution of Bray (9) contained 4 Gm. of PPO, 0.2 Gm. of POPOP, 60 Gm. of naphthalene, 20 ml. of ethylene glycol, 100 ml. of absolute methanol diluted to 1 L. with *p*-dioxane.

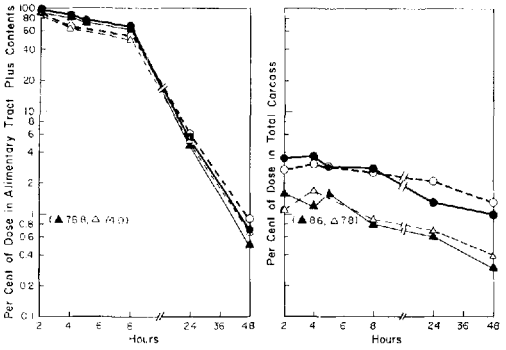

Fig. 1.—Disposition of radioactivity in alimentary tracts plus contents or in the carcasses of acutely or chronically dosed rats following an oral dose of tritiated mineral oil 0.66 ml./Kg. Each point represents the data from two animals in all the acute experiments except 24 hr. at which time five animals were assayed; three animals were assayed for each point in the chronic experiments. The difference between total ^3H and the ^3H-MO represents the radioactivity contained in substances other than ^3H-mineral oil. The figures in parentheses represent 1% of the dose expressed as mcg. of mineral oil/Gm. of tissue. Key: ●, total ^3H, acute; ○, chronic; ▲, ^3H-MO, acute; △, chronic.

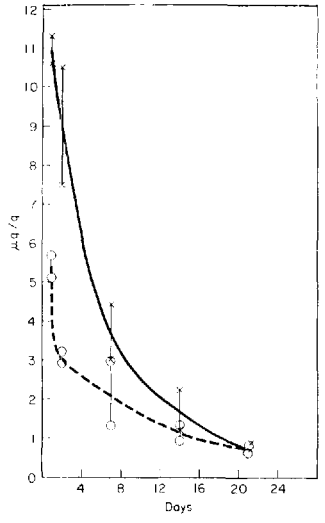

Fig. 2.—Long-term retention of ^3H-mineral oil in the carcasses of rats following a single oral dose of 0.66 ml./Kg. The curves have been drawn through the means obtained at each interval. Each mean was based on two animals as shown. Key: ———, total ^3H-substances; – – – –, ^3H-MO.

That the ^3H in the mineral oil exchanged with other substances in the rat accounted for the difference between the values of radioactivity in the ^3H-mineral oil and total radioactivity. The possiblity could not be ruled out that metabolism of ^3H-mineral oil may have contributed to the non-mineral oil substances that contained ^3H. In the alimentary tract the ratio of radioactivity of ^3H-mineral oil to the radioactivity of other substances was about 10:1 during the period when most of the drug was still in the animal; it had dropped to about 8:1 at 24 hr. and to 3:1 at 48 hr. post-treatment.

In the carcass, however, the evidence for metabolism of the oil or for exchange of ^3H from the ^3H-mineral oil to other substances was more apparent. At 24 and 48 hr. post-treatment the ratios of the radioactivity in ^3H-mineral oil to the radioactivity of other substances were 1:2 and 1:3, respectively.

The long-term retention of mineral oil in the carcasses of rats is summarized in Fig. 2. The initial

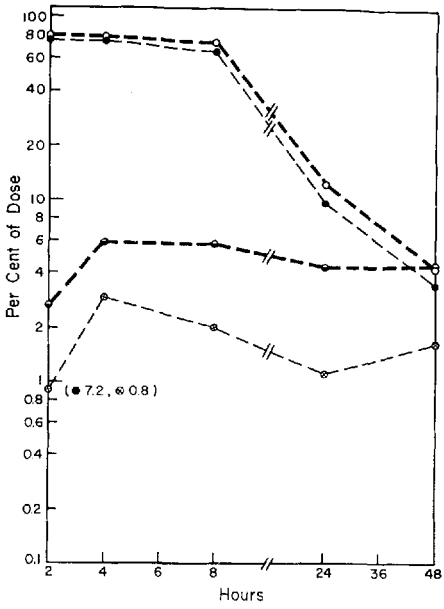

Fig. 3.—Disposition of radioactivity in the alimentary tracts plus contents or in the carcasses of rats chronically treated orally with mineral oil at various periods after the administration of a final dose of 0.066 ml. of ^3H-mineral oil. (See text for details.) Each point represents an assay of a single animal. The figures in parentheses represent 1% of the dose expressed as mcg. of mineral oil per Gm. of tissue. Key: ○, total ^3H, alimentary tracts plus contents; ◒, total ^3H, carcass; ●, ^3H-MO, alimentary tract plus content; ×, ^3H-MO, carcass.

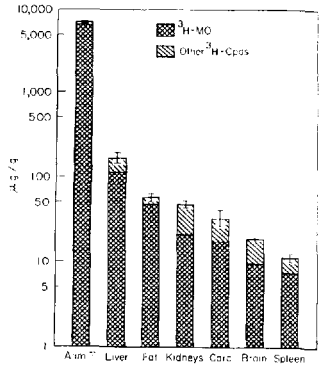

Fig. 4.—Disposition of radioactivity 5 hr. after oral administration to rats of tritiated mineral oil 0.66 ml./Kg. Height of each bar indicates the mean concentration per Gm. of tissue. Bars indicate the range of the actual values (n = 2).

sharp drop in the concentration of mineral oil may have been due to the elimination of absorbed mineral oil in the bile and also to the effects of exchange of ^3H. The slope of the curve of ^3H-mineral oil changed sharply by day 2, and, thereafter, it reflected a much slower elimination of the mineral oil. The convergence of the curve denoting the total radioactivity with the curve for ^3H-mineral oil attested to the slower rate of exchange or other change in the ^3H-mineral oil components after day 2. This was reasonably anticipated since all the ^3H atoms in the mineral oil were not equally active; those that were most active would exchange with H more rapidly than the rest. Significant concentrations of the mineral oil, 0.7 mcg./Gm. (0.1% of the amount administered), were detected in the carcasses 21 days after the single oral dose.

Evidence that the amount of mineral oil absorbed was dependent on the dose given was obtained in a chronic experiment in which rats received orally 0.066 ml. of ^3H-mineral oil/Kg., one-tenth of the usual dose. This experiment was carried out by administering orally 0.66 ml. daily of unlabeled mineral oil/Kg. for 31 consecutive days. On the 32nd day the animals received orally one-tenth the usual dose, 0.066 ml. of ^3H-mineral oil/Kg.; they were sacrificed at intervals after the final dose. The results of this experiment (Fig. 3) indicated that the carcasses of the rats that had received the smaller dose contained about 1% (0.8 mcg./Gm.) of the ^3H-mineral oil that had been administered 24 hr. earlier, whereas the carcasses of the rats that had received the normal dose contained after a comparable interval 0.7% (5.5 mcg./Gm.) of the amount administered. These data seemed to offer preliminary evidence that the passage of mineral oil through the gut wall resulted from diffusion. Clearly, additional animals would need to be tested before a firm conclusion could be reached.

The physiologic disposition in various organs and in fat 5 hr. after a single oral dose of 0.66 ml. of ^3H-mineral oil/Kg. is summarized in Fig. 4. The livers contained relatively high concentrations of the mineral oil at that time, 110 mcg./Gm., 0.5% of the dose. The concentrations in the fat, kidneys, brains, and spleens were relatively low; they ranged from 50 to 8 mcg./Gm. It was calculated that these organs contained a total of less than 0.2% of the dose. The remainder of the carcasses[2] contained 17.5 mcg./Gm., or 1.6% of the dose.

As was indicated earlier, the major portion of the dose, 75%, still remained in the alimentary tracts 5 hr. after dosing. Very little alteration in the ^3H-mineral oil occurred during that period. Of the radioactivity in the alimentary tracts, only 5% was found in substances other than mineral oil. In the carcass of the rat, however, the concentration of ^3H-nonmineral oil substances was somewhat higher. This may have been due to metabolism of the oil, to the preferential absorption of substances other than mineral oil that had been labeled with ^3H, by exchange in the gut, or to the increased opportunity for exchange after absorption of the mineral oil.

[2] The carcass in Fig. 4 represented the remainder of the animal after the other organs and tissues discussed above had been removed.

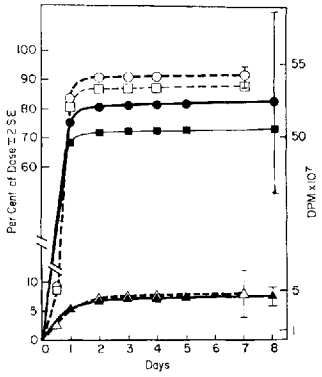

Fig. 5.—Cumulative excretion of radioactivity by rats orally dosed with tritiated mineral oil 0.66 ml./Kg. Each point in the chronic experiment represents the mean for two animals. Each point in the acute experiment represents the mean for four animals, except days 1 and 2, at which times 11 and six animals, respectively, were used. The difference between total ^3H and ^3H-mineral oil represents DPM of substances other than mineral oil, which contained ^3H, expressed as per cent of the administered dose. Only trace quantities of mineral oil were found in the urine, 0.3–2.5 × 10^{-3}% of the dose in the first 24 hr. after administration. Key: ▲, total ^3H in urine, acute; △, in urine, chronic; ●, in feces, acute; ○, in feces, chronic; ■, ^3H-MO in feces, acute; □, in feces, chronic.

The cumulative excretion of radioactivity following oral administration of the drug is illustrated in Fig. 5. The major portion of the drug was excreted during the 24-hr. period after the dose had been administered. About 80% of the dose was recovered in the feces of acutely dosed rats during the first 2 days after treatment. Levels of radioactivity recovered in the feces of chronically treated animals were slightly, but not significantly higher, than the values for acutely treated animals. Two standard errors about each point were calculated. Typical values are given about the points at days 7 and 8. As with the radioactivity in the alimentary tract over 90% of the ^3H in feces was in the form of mineral oil.

Seven to 8% of the radioactivity administered was excreted in urine during the week following drug administration. Samples collected for an additional week contained an additional 1 to 2% of the dose. Several urine samples were exhaustively extracted with toluene; the toluene extracts were carefully concentrated and portions of the concentrate were chromatographed. In five separate experiments less than 2% of the radioactivity in the urine excreted during the first day after dosing was extractable by toluene; the amount of ^3H-mineral oil in the urine varied between 0.3 and 2.5 mcg./day (0.3–2.5 × 10^{-3}% of the dose).

The fate of mineral oil administered i.p. was studied, not only to provide information about the disposition of the oil after this route of administration, but also to learn if any difference could be detected between the original ^3H-mineral oil and the ^3H-mineral oil isolated from the tissues of the body after the drug had passed through the walls of the gut.

The results of this experiment (Table I and Fig. 6)

TABLE I.—CONCENTRATION OF ^{3}H-MINERAL OIL AND NONMINERAL OIL SUBSTANCES CONTAINING ^{3}H IN THE TISSUES OF RATS AFTER THE ADMINISTRATION OF ^{3}H-MINERAL OIL[a]

	mcg./Gm.			
	Oral		I.p.	
Tissue	^{3}H-Mineral Oil	^{3}H-Nonmineral Oil Substances	^{3}H-Mineral Oil	^{3}H-Nonmineral Oil Substances
Liver	21.7	19.3	432.5	31.2
Kidney	3.3	6.2	174.9	70.8
Brain	3.4	2.7	6.5	2.9
Fat	21.4	4.0	20,235.2	<1.0

[a] Rats received 0.66 ml. of ^{3}H-mineral oil/Kg. orally (n = 2) or i.p. (n = 3). Twenty-four hours later they were sacrificed and the tissues assayed as described in the text. The specific activity of the nonmineral oil substances was assumed to have been the same as that of ^{3}H mineral oil.

revealed that the mineral oil isolated after an i.p. injection exhibited the same characteristics in the extraction and assay as that isolated after oral administration; this provided additional evidence that mineral oil had been absorbed from the gut.

It may be seen from Table I that the concentrations of labeled material in the brain were relatively unaffected by the route of administration. It is also apparent that after oral administration the nonmineral oil fractions of the total radioactivity, found in the respective tissues, were greater than after i.p. administration.

The excretion of mineral oil after an i.p. injection was found to have been relatively slow. Only 11% of the dose of radioactivity was excreted in the feces during 8 days post-treatment (Fig. 6). About 95% of the radioactivity in the feces was ^{3}H-mineral oil. The chronic i.p. administration of mineral oil did not alter the pattern of excretion exhibited after a single acute i.p. dose. Because of the relatively wide variation from animal to animal there was no significant difference in the quantities excreted in the feces following a single acute injection or following chronic i.p. administration of the drug.

The urine excreted during the first 8 days post-treatment contained 8% of the total radioactivity injected. During the first 24 hr. after i.p. dosing 0.4 mcg. of ^{3}H-mineral oil was excreted in the urine (0.3×10^{-3}% of the dose).

The influence of an emulsifying agent on the absorption and disposition of mineral oil was tested by treating rats with ^{3}H-mineral oil containing 1.7 or 8.3 mg. of dioctyl sodium sulfosuccinate/ml. The results of this experiment are summarized in Fig. 7. Total radioactivity excreted in the urine and feces, which accounted for the major portion of the dose, was not significantly altered from control values by the addition of dioctyl sodium sulfosuccinate to the mineral oil. When one considered only the relatively small fraction of the dose that had been absorbed, however, the levels of ^{3}H-mineral oil in the carcasses were found to have been higher in both groups that had received mineral oil containing the emulsifying agent.

In terms of total radioactivity in the carcasses both preparations containing the additive seemed better absorbed than the oil alone. The increased quantities of ^{3}H-mineral oil and of ^{3}H-nonmineral oil substances found in the carcasses amounted to a total of 0.7% of the dose, a barely significant increase. In terms of ^{3}H-mineral oil in the carcasses, the presence of the additive produced concentra-

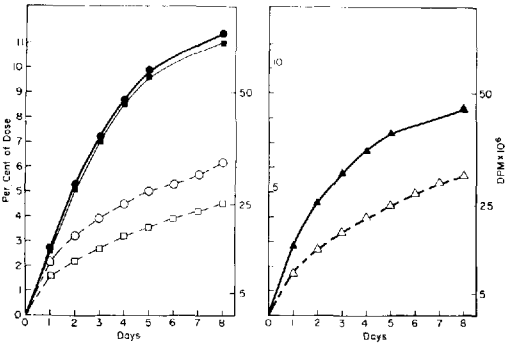

Fig. 6.—Cumulative excretion of radioactivity by rats intraperitoneally dosed with tritiated mineral oil, 0.66 ml./Kg. Each point represents the mean of three to five animals. A trace of mineral oil was found in the urine, 3.0×10^{-4}% of the amount administered in the first 24 hr. after dosing. Key: ▲, total ^{3}H in urine, acute; △, in urine, chronic; ●, in feces, acute; ○, in feces, chronic; ■, ^{3}H-MO in feces, acute; □, in feces, chronic.

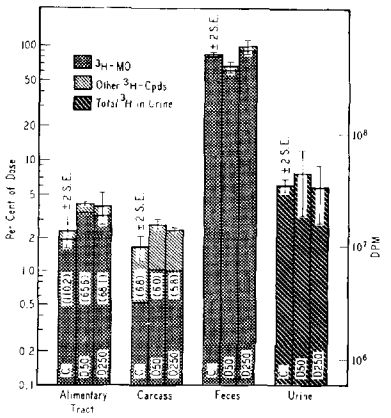

Fig. 7.—Disposition of radioactivity in rats 24 hr. after oral administration of ^{3}H-MO (C) or tritiated mineral oil containing dioctyl sodium sulfosuccinate, 1.7 mg./ml. (D50) or 8.3 mg./ml. (D250). Height of each bar indicates the mean percentage of the dose recovered. In control animals the means ±2 S.E. are listed (n = 3). In experimental animals, the mean, and the value for each animal are given (n = 2). The figures in parentheses represent 1% of the dose expressed as mcg. of mineral oil per Gm. of tissue.

tions that were almost 2 times higher than those found in the control group—6.1 and 5.8 mcg./Gm. in the groups that had received the low and high dose of the emulsifying agent, respectively, and 3.4 mcg./Gm. in the control group.

DISCUSSION

Although the literature contains reports on the disposition of mineral oil in animals (2, 5, 6), in all of the studies, doses far in excess of those normally employed by patients were given. Administration of high levels of oil was often required in such studies because of the poor specificity and low sensitivity of the methods of assay available. With the availability of a radioactive product it was possible to administer the oil at dosage levels equivalent to those recommended for humans and to assay tissues and excreta with a sensitivity previously unattainable.

Following oral administration approximately half of the radioactivity in the carcasses was shown to have been ^{3}H-mineral oil. The remaining half was ^{3}H-containing substances other than mineral oil which had been formed by the exchange of ^{3}H which had been shown to occur *in vitro*. These nonmineral oil substances might have been absorbed after undergoing an exchange reaction with the mineral oil in the gut, or they might have been formed after absorption. It is also possible that some polar metabolites of ^{3}H-mineral oil may have been included in the radioactive nonmineral oil fraction. That some ^{3}H in the ^{3}H-mineral oil exchanged rapidly was demonstrated *in vitro* by mixing the oil with a dilute aqueous acid solution or by allowing the mineral oil to mix with propionic acid overnight and measuring the ^{3}H content of the aqueous layer after separating the oil. The metabolic alteration of the mixture of saturated hydrocarbons that constituted ^{3}H-mineral oil was not demonstrated by any of the procedures described in this report, yet such a change cannot be ruled out. In any case, the specific activity of the ^{3}H-mineral oil was reduced by the amount of radioactivity found in the nonmineral oil fraction. Since efforts to determine the specific activity of the ^{3}H-mineral oil after it had been absorbed were uniformly unsuccessful because of the low concentrations present, the values of the ^{3}H-mineral oil reported in these experiments have been based on the original specific activity. These data represent, therefore, a minimum concentration of ^{3}H-mineral oil.

If the entire exchange reaction had occurred only after the absorption of ^{3}H-mineral oil, the quantity of oil that had been absorbed would be calculated on the basis of the sum of the radioactivity of the unchanged ^{3}H-mineral oil, the radioactivity of the nonmineral oil substances, the radioactivity found in the urine, and the radioactivity excreted in the bile. It has been calculated that in such a condition the concentration of ^{3}H-mineral oil reported here to have been 17.5 mcg./Gm. in the carcasses (1.6% of the dose) 5 hr. after an oral dose (Fig. 4) would have been increased to not more than 42.5 mcg./Gm. (4% of the dose) by the concentration of nonmineral oil substances containing the tritium in the carcass and by the contribution of radioactivity found in the urine (Fig. 5).

It is likely, however, that the actual value of ^{3}H-mineral oil in the carcasses lies well below the higher figure for a number of the following reasons. Exchange had been demonstrated in the lumen of the gut (Fig. 4). The ready absorption of ^{3}H-nonmineral oil substances had been demonstrated after the administration of ^{3}H-water. The i.p. administration of ^{3}H-mineral oil to rats produced relatively large quantities of ^{3}H-mineral oil in the organs; nevertheless, in comparison with results after oral administration, the concentrations of ^{3}H-nonmineral oil substances were rather low. This suggested that much of the ^{3}H-nonmineral oil substances found in the organs of the rat after the oral dose arose by a reaction that had occurred in the gut prior to absorption.

The failure of the concentration of ^{3}H-mineral oil in the brain to reflect the large amount present in the carcasses after i.p. administration may have been due, to some extent, to an immobility of the oil after it had been injected.

The kidney was able to excrete only trace quantities of mineral oil. This was demonstrated whether the drug had been given orally or i.p. Mineral oil was clearly demonstrated in homogenates of kidneys after either route of administration.

That the excretion of mineral oil after it had been absorbed by the rat was slow is apparent on examination of Fig. 6. The major portion of the dose remained in the animal 8 days following i.p. administration. At that time only 6–10% of the dose had been excreted. It is likely that one route of excretion of mineral oil is in the bile. The relatively slow rate of excretion by this route may have been due in part to the immobility of the oil after it had been deposited in the tissues, a suggestion consistent with that proposed for explaining the low concentrations found in the brains after i.p. administration; or it may have been due in part to the inability of the biliary system to collect it.

The mechanism of the absorption of mineral oil remains unknown. Frazer and Stewart (13) demonstrated that if mineral oil were emulsified with oleic acid and cholesterol to form particles not greater than 0.5 μ in diameter, absorption of large amounts of the oil would occur. These authors commented also that in the absence of emulsification negligible absorption of mineral oil had been noted. The data in this report substantiate the first observation; the presence of an emulsifying agent increased the absorption of mineral oil. With respect to the second observation, these data, contrary to those of Frazer and Stewart (13), indicate that a small but significant amount of mineral oil had been absorbed in the absence of an exogenous emulsifying agent.

The levels of radioactivity in the carcasses of rats chronically treated with ^{3}H-mineral oil were similar to those found after an acute dose. This evidence suggests that chronic administration did not alter the ability of rats to absorb or to excrete mineral oil.

At the dosage level employed in these studies only a mild laxative action was observed. In the chronic studies this effect disappeared 1 or 2 days after initiating the treatment.

The high levels of radioactivity excreted in the feces of the orally dosed rats reflected the poor absorption and the rapid elimination of ^{3}H-mineral oil.

Enzyme Inhibitors XIV

Syntheses of Some 9-(*m*-Substituted Benzyl)-6-substituted Purines and Their Evaluation as Inhibitors of Adenosine Deaminase

By HOWARD J. SCHAEFFER and R. N. JOHNSON

Recent studies have shown that 9-(*p*-bromoacetamidobenzyl)adenine is an irreversible inhibitor of adenosine deaminase. In order to study the effect of isomers on the inhibition of adenosine deaminase, a variety of reversible inhibitors of adenosine deaminase have been synthesized which are 9-(*m*-substituted benzyl)-6-substituted purines. In addition, it was found that 9-(*m*-bromoacetamidobenzyl)adenine is an irreversible inhibitor of adenosine deaminase, but the rate of irreversible inactivation by the *meta* derivative was lower than that by the corresponding *para* isomer. This decreased rate of irreversible inhibition by 9-(*m*-bromoacetamidobenzyl)-adenine may be rationalized by assuming that in the reversible E...I complex the alkylating group is not positioned as near a nucleophilic group on the enzyme as it is in the case of the corresponding *para* isomer or that the *meta* derivative alkylates a different amino acid on the enzyme than does 9-(*p*-bromoacetamidobenzyl)adenine.

In a recent study, it was found that 9-(*p*-bromoacetamidobenzyl)adenine was an irreversible inhibitor of adenosine deaminase, whereas iodoacetamide was not an irreversible inhibitor of this enzyme (1, 2). Kinetic analysis of the data indicated that the irreversible inhibition of adenosine deaminase by 9-(*p*-bromoacetamidobenzyl)adenine occurred only after the inhibitor had reversibly complexed with the enzyme. In this complex, then, the bromoacetamido moiety of the inhibitor is held near a nucleophilic group on the enzyme, and a reaction related to a neighboring-group reaction occurs with the formation of a covalent bond. Such inhibitors, which Baker has called active-site-directed irreversible inhibitors (3), should be quite specific in their irreversible inactivation of an enzyme. For example, when a comparison is made of isomers of some potential irreversible inhibitors, the environment on the enzyme in which the alkylating or acylating group of the inhibitor is held in the reversible E...I complex (enzyme–inhibitor) could be quite different. Thus, it is possible that the reactive group of one isomer could be held near an appropriate nucleophilic group on the enzyme, whereas the reactive group of an isomeric inhibitor could be held in the reversible E...I complex in such a position that it cannot form a covalent bond with the enzyme. In an attempt to determine the specificity of 9-(*p*-bromoacetamidobenzyl)adenine for adenosine deaminase, it was decided to investigate the possible reversible and irreversible inhibition of adenosine deaminase by some 9-(*m*-substituted benzyl)-6-substituted purines.

S. Public Health Service, Bethesda, Md., and by grant T-337 from the American Cancer Society.

DISCUSSION

Chemistry.—Previous studies have shown that adenosine deaminase (calf intestinal mucosa) has a hydrophobic region to which the 9-alkyl group of some 9-alkyladenines can bind (4). Furthermore, it has been found that some 9-(*p*-substituted benzyl)-6-substituted purines were capable of inhibiting

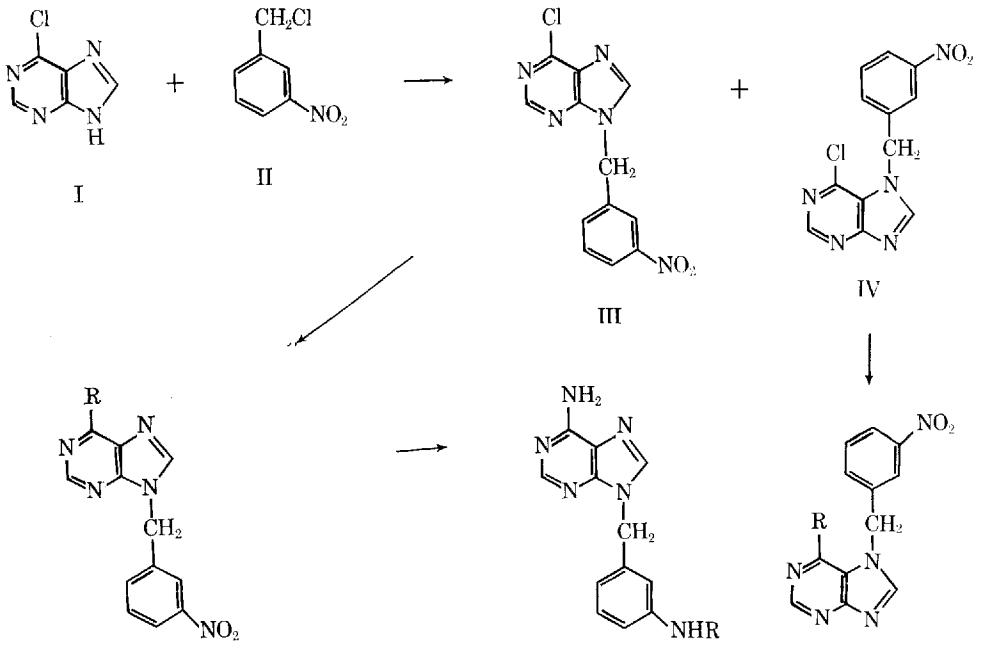
adenosine deaminase (1, 2). In order to study the effect on inhibition of this enzyme by other 9-(substituted benzyl)-6-substituted purines, the preparation of some purines which contained at the 9-position a *meta*-substituted benzyl group was undertaken. The key compound for such a study is 9-(*m*-nitrobenzyl)-6-chloropurine, since this compound could be caused to undergo nucleophilic displacement at the 6-position to give a variety of products. In addition, the nitro group of appropriate inhibitors could be reduced to an amino group which could be converted into a potential alkylating or acylating group, such as a bromoacetamido or phenoxycarbonylamino group.

The general method which was employed for the synthesis of these compounds is a modification of a method that has previously been employed (5) and is outlined in Scheme I. Condensation of 6-chloropurine (I) with *m*-nitrobenzyl chloride (II) gave a mixture of 9- and 7-(*m*-nitrobenzyl)-6-chloropurines (III and IV) which was separated by chromatography on alumina. When III was allowed to react with ammonia, methylamine, dimethylamine, 1 *N* hydrochloric acid, or thiourea, the corresponding 6-substituted derivatives (V–IX) were obtained in good yields. Catalytic hydrogenation of V gave the corresponding *m*-aminobenzyl derivative (X) which on reaction with bromoacetic anhydride, phenyl chloroformate, and acetic anhydride gave XI, XII, and XIII, respectively. The assignment of structure to XI, XII, and XIII is based on the observation that N^6-acylation of adenine compounds shifts the ultraviolet maxima to longer wavelengths (6). Thus, it has been found (6) that *N*, $O^{3'}$-diacetyl deoxyadenylic 5′-acid exhibited an ultraviolet maximum at 273 mμ at pH 8, whereas XI, XII, and XIII exhibited ultraviolet maxima either at shorter wavelengths than X or at essentially the same wavelength as X.

In addition, it was found that when 7-(*m*-nitrobenzyl)-6-chloropurine (IV) was allowed to react with 20% methanolic ammonia, a mixture of the 6-amino and 6-methoxy derivatives (XIV and XV) was obtained. This unusual formation of a 6-methoxy derivative from the reaction of methanolic ammonia with a 7-substituted-6-chloropurine has been observed previously (7). However, treatment of IV with liquid ammonia at 65° gave, in moderate yield, 7-(*m*-nitrobenzyl)adenine (XIV). When IV was allowed to react with aqueous formic acid, a good yield of XVI was obtained.

Finally, the fact that III and IV, and therefore the compounds which were prepared from them, are the 9- and 7-substituted purine isomers, respectively, was established in the following manner. A 9-substituted adenine has a unique ultraviolet spectrum which allows it to be distinguished from a 1-,3-, or 7-substituted adenine (8, 9). Similarly, by ultraviolet spectroscopy a 1-substituted adenine may be distinguished from a 3-,7-, or 9-substituted



Scheme I

adenine. However, a 3- and a 7-substituted adenine have similar ultraviolet spectra but may be distinguished by their differences in pKa′ values (9).

A new alkylated adenine (XVII) was prepared by allowing adenine to react with *m*-nitrobenzyl chloride in the absence of an acid acceptor. In a similar alkylation of adenine with benzyl bromide, it was found that 3-benzyladenine was formed (10). A comparison of the ultraviolet spectra and pKa′ data of these isomerically alkylated adenines with certain known compounds is given in Table I. From this table, it can be seen that V corresponds to the 9-substituted isomer, XIV corresponds to the 7-substituted isomer, and that XVII corresponds to the 3-substituted isomer. These data constitute another example that the alkylation of 6-chloropurine in the presence of an acid acceptor produces a mixture of the 9- and 7-substituted-6-chloropurines (2, 5, 7).

TABLE I.—ULTRAVIOLET AND pKa′ DATA OF SOME SUBSTITUTED ADENINES

Compd. (Adenine Derivative)	—H⁺— $\lambda_{max.}$ mμ	—H⁺— $\epsilon \times 10^{-3}$	—OH⁻— $\lambda_{max.}$ mμ	—OH⁻— $\epsilon \times 10^{-3}$	pKa′
1-Methyl[a]	259	11.7	270	14.4	
3-Methyl[a]	274	17.0	273	13.3	5.3[a,b]
3-(*m*-Nitrobenzyl) (XVII)	274	23.0	272	19.6	5.7[c]
7-Methyl[a]	272	15.0	270	10.5	3.6[a,b]
7-(*m*-Nitrobenzyl) (XIV)	270	19.5	267	16.6	3.6[c]
9-Methyl[a]	260	14.2	260	14.7	
9-(*m*-Nitrobenzyl) (V)	261	23.3	262	23.0	

[a] These data were taken from *Reference 9*. [b] Determined titrimetrically in 50% DMF in H_2O. [c] Determined spectrophotometrically in 4% DMF in H_2O.

EXPERIMENTAL[1]

9- and 7-(m-Nitrobenzyl)-6-chloropurine (III and IV).—A mixture of 1.53 Gm. (9.95 mmoles) of I, 1.80 Gm. (10.5 mmoles) of II, and 1.46 Gm. (10.5 mmoles) of anhydrous potassium carbonate in 20 ml. of dimethylformamide was stirred for 20 hr. at room temperature. The reaction mixture was poured into 150 ml. of ice cold water, which caused the precipitation of a yellow solid. This material was collected by filtration. A chloroform solution of the crude material was chromatographed on a column of neutral alumina (48.0 Gm). 9-(*m*-Nitrobenzyl)-6-chloropurine (III) was eluted with chloroform (180 ml.); yield, 1.97 Gm. (68.6%), m.p. 135°. The 9-isomer was recrystallized from methanol and gave 1.36 Gm. (47.5%) of the pure material, m.p. 141–142°. $\lambda_{max.}$ in mμ ($\epsilon \times 10^{-4}$): pH 1, 265 (1.66); pH 7, 265 (1.73); pH 13, 265 (1.67). ν in cm.$^{-1}$ (KBr): 1580 and 1550 (C=N and C=C); 1520 and 1340 (NO_2).

Anal.[2]—Calcd. for $C_{12}H_8ClN_5O_2$: C, 49.74; H, 2.78; N, 24.18. Found: C, 49.52; H, 2.81; N, 24.34.

7-(m-Nitrobenzyl)-6-chloropurine (IV).—This was eluted from the alumina column with chloroform containing 1% methanol (150 ml.). After removal of the solvent *in vacuo*, 529 mg. of the 7-substituted product was obtained; yield, 18.4%. The analytical sample was obtained by two recrystallizations of the crude material from ethanol. It melted at 191–192°. $\lambda_{max.}$ in mμ ($\epsilon \times 10^{-4}$): pH, 1, 267 (1.53); pH 7, 267 (1.53); pH 13, 267 (1.53). ν in cm.$^{-1}$ (KBr): 1600 and 1570 (sh) (C=N and C=C); 1530 and 1350 (NO_2).

Anal.—Calcd. for $C_{12}H_8ClN_5O_2$: C, 49.74; H, 2.78; N, 24.18. Found: C, 49.42; H, 2.88; N, 24.00.

9-(m-Nitrobenzyl)adenine (V).—A mixture of 1.00 (3.46 mmoles) of III and 50 ml. of 20% methanolic ammonia was heated in a steel bomb at 90° ± 2° for 20 hr. The white solid was collected by filtration, washed with water, and dried. One recrystallization of the crude material from methyl cellosolve gave 716 mg. (76.5%) of the pure product (V), m.p. 276–278° dec. $\lambda_{max.}$ in mμ ($\epsilon \times 10^{-4}$): pH 1, 261 (2.33); pH 7, 262 (2.30); pH 13, 262 (2.30). ν in cm.$^{-1}$ (KBr): 3320, 3150, and 1660 (NH); 1590 and 1570 (C=N and C=C); 1530 and 1350 (NO_2).

Anal.—Calcd. for $C_{12}H_{10}N_6O_2$: C, 53.33; H, 3.73; N, 31.10. Found: C, 53.13; H, 3.83; N, 30.94.

9-(m-Nitrobenzyl)-6-methylaminopurine (VI).—A solution of 145 mg. (0.50 mmole) of III in 5 ml. of ethanol and 8 ml. of aqueous methylamine (40%) was heated in a steel bomb at 98° ± 3° for 23 hr. The yellow product which precipitated was collected by filtration and washed with water. Addition of 20 ml. of water to the filtrate caused the precipitation of an additional amount of purine. Total yield, 101 mg. (71.1%). Two recrystallizations of the crude product from 1-propanol gave the analytical sample (VI); yield, 75 mg. (53%), m.p. 210–212°. $\lambda_{max.}$ in mμ ($\epsilon \times 10^{-4}$): pH 1, 265 (2.68); pH 7, 268 (2.55); pH 13, 268 (2.49). ν in cm.$^{-1}$ (KBr): 3300 (NH); 1635 and 1570 (C=N and C=C); 1520 and 1340 (NO_2).

Anal.—Calcd. for $C_{13}H_{12}N_6O_2$: C, 54.92; H, 4.26; N, 29.57. Found: C, 55.03; H, 4.40; N, 29.73.

9-(m-Nitrobenzyl)-6-dimethylaminopurine (VII).—A solution of 96 mg. (0.33 mmole) of III in 5 ml. of ethanol and 5 ml. of aqueous dimethylamine (25%) was heated in a steel bomb at 96° ± 1° for 16 hr. The yellow solid which precipitated from the reaction mixture was collected by filtration and washed with water. To the filtrate was added an additional 20 ml. of water which caused the precipitation of a second crop of product. Total yield, 86 mg. (88%). One recrystallization of the crude material from ethanol–water gave the pure product (VII); yield, 64 mg. (65%), m.p. 156–157°. $\lambda_{max.}$ in mμ ($\epsilon \times 10^{-4}$): pH 1, 269 (2.55); pH 7, 275 (2.51); pH 13, 275 (2.47). ν in cm.$^{-1}$ (KBr): 1590 and 1560 (sh) (C=N and C=C); 1520 and 1340 (NO_2).

Anal.—Calcd. for $C_{14}H_{14}N_6O_2$: C, 56.36; H, 4.73; N, 28.18. Found: C, 56.10; H, 4.90; N, 28.01.

[1] The infrared spectra were determined on a Perkin-Elmer model 137 spectrophotometer; the ultraviolet spectra were determined on a Perkin-Elmer model 4000 A spectrophotometer; the enzyme studies were done on a Gilford instrument, model 2000 spectrophotometer. The melting points, unless otherwise noted, were taken in open capillary tubes on a Mel-Temp apparatus and are corrected. All analytical samples exhibited only one spot on thin-layer chromatography.

[2] The analyses reported in this paper were performed by Galbraith Microanalytical Laboratories, Knoxville, Tenn.

9-(m-Nitrobenzyl)-6-hydroxypurine (VIII).—A solution of III (873 mg.; 3.08 mmoles) in 90 ml. of 1 *N* hydrochloric acid was refluxed for 1 hr. Evaporation of the volatile materials *in vacuo* and two recrystallizations of the crude material from ethanol gave the pure product (VIII); yield, 587 mg. (72.5%), m.p. 271–271.5°. $\lambda_{max.}$ in mμ ($\epsilon \times 10^{-4}$): pH 1, 252 (1.72); pH 7, 251 (1.85); pH 13, 257 (1.92). ν in cm.$^{-1}$ (KBr): 3500 (OH); 2800–2300 (acidic hydrogen); 1690 (C=O); 1590 and 1550 (sh) (C=N and C=C); 1530 and 1340 (NO_2).

Anal.—Calcd. for $C_{12}H_9N_5O_3$: C, 53.13; H, 3.34; N, 25.83. Found: C, 53.12; H, 3.31; N, 25.63.

9-(m-Nitrobenzyl)-6-mercaptopurine (IX).—A mixture of 146 mg. (0.504 mmole) of III, 41 mg. (0.54 mmole) of thiourea in 3.0 ml. of 1-propanol was refluxed for 0.75 hr. The product which precipitated from the reaction mixture was collected by filtration and dried; yield, 140 mg. The analytical sample was obtained by dissolving the purine in aqueous sodium hydroxide and precipitating it by addition of 5% aqueous hydrochloric acid; yield, 126 mg. (81.3%), m.p. 294–294.5° dec. $\lambda_{max.}$ in mμ ($\epsilon \times 10^{-4}$): 0.1 *N* HCl/15% DMSO 325 (2.45); H_2O/15% DMSO 322 (2.20); 0.1 *N* NaOH/15% DMSO 314 (2.26). ν in cm.$^{-1}$ (KBr): 2800–2650 (acidic hydrogen); 1590 and 1570 (sh) (C=N and C=C): 1530 and 1340 (NO_2).

Anal.—Calcd. for $C_{12}H_9N_5O_2S$: C, 50.18; H, 3.16; N, 24.39. Found: C, 50.35; H, 3.30; N, 24.32.

9-(m-Aminobenzyl)adenine (X).—A solution of 210 mg. (0.778 mmole) of V in 50 ml. of acetic acid containing 66 mg. of 5% palladium-on-charcoal catalyst was hydrogenated for 1.75 hr. under an initial pressure of 60 p.s.i. The catalyst was removed by filtration and the filtrate was evaporated *in vacuo*. An ethanolic solution of the residual solid was heated with decolorizing carbon, filtered, and allowed to crystallize. The product was collected by filtration and after drying gave 111 mg. (59.7%) of the desired product (X), m.p. 230–231°. $\lambda_{max.}$ in mμ ($\epsilon \times 10^{-4}$): pH 1, 259 (1.53); pH 7, 262 (1.65); pH 13, 262 (1.66). ν in cm.$^{-1}$ (KBr): 3300, 3150, and 1660 (NH); 1600 and 1550 (sh) (C=N and C=C).

Anal.—Calcd. for $C_{12}H_{12}N_6$: C, 59.99; H, 5.04; N, 34.98. Found: C, 59.73; H, 4.83; N, 34.76.

9-(m-Bromoacetamidobenzyl)adenine (XI).—To a cold solution of 200 mg. (0.832 mmole) of X in 5 ml. of tetrahydrofuran and 0.8 ml. of 10% aqueous acetic acid was added a solution of 351 mg. (1.97 mmoles) of bromoacetic anhydride in 2 ml. of tetrahydrofuran. The solution was stirred for 1.5 hr. at 0°, then for 0.5 hr. at room temperature. After filtration, 15 ml. of chloroform was added to the filtrate to cause precipitation of the crude product which was collected by filtration; yield, 271 mg. (81.5%). Two precipitations from tetrahydrofuran–hexane gave 118 mg. (39.4%) of the analytical sample (XI), which did not melt below 400°. $\lambda_{max.}$ in mμ ($\epsilon \times 10^{-4}$): 0.1 *N* HCl/10% EtOH, 257 (2.28); H_2O/10% EtOH, 259 (2.30); 0.1 *N* NaOH/10% EtOH, 259 (2.24). ν in cm.$^{-1}$ (KBr): 3310, 3160 (NH); 1700 (amide I); 1655 (NH) and 1530 (amide II); 1590 and 1570 (C=N and C=C).

Anal.—Calcd. for $C_{14}H_{13}BrN_6O$: C, 46.55; H, 3.62; Br, 22.12; N, 23.26. Found: C, 46.57; H, 3.81; Br, 21.91; N, 23.52.

9 - (m - Phenoxycarbonylaminobenzyl)adenine (XII).—To a solution of 95 mg. (0.40 mmole) of X and 50 mg. (0.50 mmole) of triethylamine in 25 ml. of *p*-dioxane was added 62 mg. (0.40 mmole) of phenyl chloroformate. The mixture was stirred at room temperature for 45 min., filtered, and the filtrate evaporated *in vacuo* at room temperature. One recrystallization of the crude material from methanol–water gave 60 mg. (42%) of pure material (XII), decomposition point about 310°. $\lambda_{max.}$ in mμ ($\epsilon \times 10^{-4}$): 0.1 *N* HCl/10% EtOH, 239 (2.08); 259 (1.58); H_2O/10% EtOH, 240 (2.04); 259 (1.58); 0.1 *N* NaOH/10% EtOH 239 (2.54); 259 (1.70). ν in cm.$^{-1}$ (KBr): 3310 and 3140 (NH); 1700 (C=O and NH); 1530 (amide II); 1610, 1590, and 1570 (C=N and C=C); 1200 (C—O—C, ester).

Anal.—Calcd. for $C_{19}H_{16}N_6O_2$: C, 63.32; H, 4.48; N, 23.32. Found: C, 63.17; H, 4.74; N, 23.51.

9-(m-Acetamidobenzyl)adenine (XIII).—To a cold solution of 150 mg. (0.652 mmole) of X in 5 ml. of tetrahydrofuran and 0.60 ml. of 10% aqueous acetic acid was added 154 mg. (1.51 mmoles) of acetic anhydride in 2 ml. of tetrahydrofuran over a period of 7 min. The solution was stirred at 0° for 2 hr., and the resulting precipitate was collected by filtration to give 108 mg. (58.6%) of product melting at 234–238°. Recrystallization from ethanol–water gave 77 mg. (42%) of the analytical sample (XIII), m.p. 237–239°. $\lambda_{max.}$ in mμ ($\epsilon \times 10^{-4}$): 0.1 *N* HCl/10% EtOH, 255 (1.84); H_2O/10% EtOH, 254 (1.90); 0.1 *N* NaOH/10% EtOH, 254 (1.99). ν in cm.$^{-1}$ (KBr): 3340, 3180 (NH); 1670 (amide I); 1650 (sh) (NH) and 1540 (amide II); 1600 and 1570 (C=N and C=C).

Anal.—Calcd. for $C_{14}H_{14}N_6O$: C, 59.56; H, 5.00; N, 29.77. Found: C, 59.67; H, 5.01; N, 29.95.

7-(m-Nitrobenzyl)adenine (XIV) and 7-(m-Nitrobenzyl)-6-methoxypurine (XV).—A mixture of 0.29 Gm. (1.0 mmole) of IV and 21 ml. of 20% methanolic ammonia was heated in a steel bomb at 106° ± 3° for 3 hr. The solution was filtered to give 36 mg. (13%) of the 6-methoxypurine derivative (XV), m.p. 192–193.5°. One recrystallization from water gave 23 mg. (8%) of the analytical material, m.p. 195–196°. $\lambda_{max.}$ in mμ ($\epsilon \times 10^{-4}$): pH 1, 260 (1.66); pH 7, 261 (1.49); pH 13, 262 (1.45). ν in cm.$^{-1}$ (KBr): 1610 and 1550 (C=N and C=C); 1520 and 1350 (NO_2); 1250 and 1070 (=C—O—CH_3).

Anal.—Calcd. for $C_{13}H_{11}N_5O_3$: C, 54.73; H, 3.89; N, 24.55. Found: C, 55.00; H, 4.03; N, 24.75.

Evaporation of the methanolic ammonia solution from which the 6-methoxypurine was obtained, produced a yellow solid which was extracted with hot methanol[3] (2 × 1 ml.). The residue (57 mg., 21%) which did not dissolve melted at 254–259°.

One recrystallization from methanol gave 35 mg. (13%) of the pure 7-(*m*-nitrobenzyl)adenine (XIV), m.p. 265–267° dec. $\lambda_{max.}$ in mμ ($\epsilon \times 10^{-4}$): pH 1, 270 (1.95); pH 7, 268 (1.67); pH 13, 267 (1.66). ν in cm.$^{-1}$ (KBr): 3380, 3150, and 1660

[3] By thin-layer chromatography, this extract was shown to be a mixture of 7-(*m*-nitrobenzyl)-6-methoxypurine and 7-(*m*-nitrobenzyl)adenine. Since the desired 6-aminopurine was prepared by an alternate method, no attempts were made to further separate this mixture.

(NH); 1600 and 1540 (C=N and C=C); 1520 and 1340 (NO_2).

Anal.—Calcd. for $C_{12}H_{10}N_6O_2$: C, 53.33; H, 3.73; N, 31.10. Found: C, 53.26; H, 3.90; N, 30.90.

7-(m-Nitrobenzyl)adenine (XIV).—A mixture of 290 mg. (1.00 mmole) of IV in about 20 ml. of liquid ammonia was heated in a steel bomb at 65° ± 5° for 19 hr. After evaporation of the ammonia, the crude product was recrystallized from water; yield, 169 mg. (62.6%), m.p. 255–259° dec. An additional recrystallization from methanol gave 130 mg. (48.1%) of the pure product (XIV), m.p. 264–265° dec. ν in cm.$^{-1}$ (KBr): 3390, 3150, and 1660 (NH); 1600 and 1540 (C=N and C=C); 1520 and 1340 (NO_2).

7-(m-Nitrobenzyl)-6-hydroxypurine (XVI).—A solution of 205 mg. (0.710 mmole) of IV in 10 ml. of 88% aqueous formic acid was heated under reflux for 20 min. The yellow solution was evaporated *in vacuo*, and the residue was recrystallized from water to yield 142 mg. (73.2%) of the product, m.p. 254–256°. An additional recrystallization from water gave the analytical sample, 110 mg. (56.7%), m.p. 255–256°. $\lambda_{max.}$ in mμ ($\epsilon \times 10^{-4}$): pH 1, 257 (1.48); pH 7, 260 (1.62); pH 13, 265 (1.63). ν in cm.$^{-1}$ (KBr): 1690 (C=O); 1630 and 1580 (C=N and C=C); 1530 and 1340 (NO_2).

Anal.—Calcd. for $C_{12}H_9N_5O_3$: C, 53.13; H, 3.34; N, 25.83. Found: C, 53.11; H, 3.35; N, 26.07.

7-(m-Nitrobenzyl)-6-hydroxypurine (XVI).—Dry hydrogen chloride was passed into a solution of 3.2 mg. (0.011 mmole) of XV in 1.5 ml. of methanol. The solution was evaporated *in vacuo*, and the residue recrystallized from water to give 2.6 mg. (72%) of the hydroxypurine (XVI), m.p. 255–255.5°. $\lambda_{max.}$: pH 1, 257; pH 7, 260; pH 13, 265. ν in cm.$^{-1}$ (KBr): 1690 (C=O); 1630 (sh) and 1580 (C=N and C=C); 1530 and 1340 (NO_2). This sample was identical with a sample prepared by the previous procedure.

3-(m-Nitrobenzyl)adenine Hydrochloride (XVII).—A mixture of 6.33 Gm. (37.0 mmoles) of adenine dihydrate and 19.0 (111 mmoles) of II in 100 ml. of *N,N*-dimethylacetamide was heated at 115° for 20 hr. The solution was evaporated *in vacuo* to a yellow solid which was triturated with water and then with ethanol. The residue, 9.16 Gm. (80.5%), m.p. 264–267° dec., was recrystallized from water to give 6.79 Gm. (59.5%) of the analytical material, m.p. 264–266° dec. $\lambda_{max.}$ in mμ ($\epsilon \times 10^{-4}$): 0.1 *N* HCl/4% EtOH, 274 (2.30); H_2O/4% EtOH, 272 (1.82); 0.1 *N* NaOH/4% EtOH, 272 (1.96). ν in cm.$^{-1}$ (KBr): 3090 (NH); 1670 (C=NH^+); 1610, 1580, and 1520 (C=C and C=N); 1540 and 1350 (NO_2).

Anal.—Calcd. for $C_{12}H_{11}ClN_6O_2$: C, 46.98; H, 3.62; Cl, 11.56; N, 27.40. Found: C, 46.86; H, 3.64; Cl, 11.45; N, 27.26.

CHEMICAL REACTIVITY OF THE ALKYLATING AGENTS

These experiments were performed by a modification of a procedure described in the literature (11–13). Equal volumes (10 ml.) of the following preheated (37°) solutions were mixed: (*a*) 5% 4-(*p*-nitrobenzyl)pyridine in 2-methoxyethanol, (*b*) 0.05 *M* phthalate buffer (pH 4.2) in water, and then (*c*) 0.81 m*M* solution of the alkylating agent in 2-methoxyethanol.

The reaction mixture was incubated at 37° and at appropriate time intervals, a 3-ml. aliquot was removed and cooled briefly in an ice bath. Then 1 ml. of triethylamine was added to generate the colored quinoid-like free base, and the absorbance was immediately determined at 573 mμ against a blank which had been treated in an identical manner and contained all of the reagents except the alkylating agent. A comparison of the initial rates of reaction is given in Fig. 2.

REAGENTS AND ASSAY PROCEDURE

Adenosine and adenosine deaminase (type I) from calf intestinal mucosa were purchased from the Sigma Chemical Co. The assay procedure for the reversible inhibitors has been described by Kaplan (14). The measurements of the rates of the enzymic reactions were performed at 25° in 0.05 *M* phosphate buffer at pH 7.6. The stock solutions of the enzyme, substrate, and inhibitors were prepared in 0.05 *M* phosphate buffer at pH 7.6. Those inhibitors which were only slightly soluble in phosphate buffer were dissolved in phosphate buffer containing 10% dimethylsulfoxide. The addition of dimethylsulfoxide caused a slight decrease in the initial rate of the enzyme reaction. Consequently, in those experiments where it was necessary to employ dimethylsulfoxide to dissolve the inhibitor in phosphate buffer, the stock solutions of enzyme, substrate, and inhibitors were all prepared in phosphate buffer containing 10% dimethylsulfoxide. In this way, a constant 10% concentration of dimethylsulfoxide is maintained during the determination of the velocities of the enzymic reactions. In order to determine that the dimethylsulfoxide did not cause variation in the index of inhibition, the following experiment was performed. For an inhibitor which was readily soluble, the index of inhibition was determined in one set of experiments where all reagents were dissolved in 0.05 *M* phosphate buffer and in another set of experiments where the enzyme, substrate, and inhibitor were dissolved in 0.05 *M* phosphate buffer containing 10% dimethylsulfoxide. In this way, it was found that the index of inhibition did not vary in the two different determinations.

The method employed to study the irreversible inactivation at 37° of adenosine deaminase has been described previously (2) and is a modification of a published procedure (15).

RESULTS AND DISCUSSION

The results of the enzymic evaluation of these compounds are given in Table II. For those compounds which were substituted at the 9-position of the purine nucleus by a *m*-nitrobenzyl group, it was found that the 6-amino and 6-methylamino analogs (V and VI) were significantly inhibitory; the 6-amino compound (V) being approximately three times more effective than the 6-methylamino derivative (VI). Those compounds which were substituted at the 6-position of the purine nucleus by a chloro, dimethylamino, hydroxy, or mercapto group (III, VII, VIII, or IX) when tested at 0.12 m*M* concentration were either noninhibitory or at

XVII	NH_2	H	0.10 ± 0.01	1.5 ± 0.2[d]	

[a] None of these compounds served as substrates of adenosine deaminase. [b] The concentration of adenosine in all experiments was 0.066 m*M*. In no experiment of reversible inhibition did the concentration of inhibitor exceed 0.12 m*M*. In that case where a higher concentration is shown for 50% inhibition, the value was obtained by extrapolation of a plot of V_0/V *vs.* I, where V_0 = initial velocity of the uninhibited reaction, V = initial velocity of the inhibited reaction at various inhibitor concentrations, and I = the various concentrations of inhibitors. $[I/S]_{0.5}$ = the ratio of the m*M* concentration of the inhibitor for 50% inhibition to the m*M* concentration of the substrate. [c] Average deviation. [d] Data taken from *Reference 2*.

best, very weakly inhibitory relative to the corresponding adenine derivative (V). Thus, it would appear that the 6-amino group of V makes a contribution, either directly or indirectly through the purine nucleus, to the binding of the inhibitor to adenosine deaminase. In addition, when the 7-substituted isomers (IV, XIV, XV, and XVI) were evaluated as inhibitors of adenosine deaminase at 0.12 m*M* concentrations, they were essentially noninhibitory or at best, very weakly inhibitory relative to V. In the case of XIV, one could rationalize this result by assuming that the enzyme has little bulk tolerance for a group at the 7-position of the purine nucleus of an inhibitor or that an important binding group at the 9-position of the inhibitor is absent. Similar results have been obtained earlier (7).

With regard to the *meta* substituent on the 9-benzyl group of the 6-aminopurines, it was found that the reversible inhibitory power of the compounds decreases in the following order: $-NO_2$ (V)> $-NHCOOC_6H_5$(XII)> $-NHCOCH_2Br$ (XI)> $-NHCOCH_3$(XIII)≥ H (XVII)> NH_2(X). It was observed by the double reciprocal plot method (16) that XI is a competitive inhibitor of adenosine deaminase with a K_i of 3.6×10^{-5} *M*. This order of decreasing inhibition is different from that obtained with the corresponding *para* derivatives (2). As one example, the $[I/S]_{0.5}$ for the *m*-nitro derivative (V) is 0.3, whereas the $[I/S]_{0.5}$ of 9-(*p*-nitrobenzyl)adenine is 3.6 (2). Thus, of the adenine derivatives prepared in the *meta* series, the *m*-nitro derivative (V) is the most potent reversible inhibitor of adenosine deaminase whereas in the corresponding 9-(*p*-substituted benzyl)adenines, the *p*-nitro derivative is the weakest reversible inhibitor of the series. The reasons for the differences in the order of reversible inhibition in the two series is not yet clear. Further studies on this problem are planned and will be the subject of a future paper.

Finally, when the two potential irreversible inhibitors (XI and XII) were incubated with adenosine deaminase, it was found that the *m*-phenoxycarbonylamino derivative (XII) did not cause irreversible inactivation of the enzyme whereas the *m*-bromoacetamido derivative (XI) irreversibly inhibited the enzyme but at a rate which was very low relative to 9-(*p*-bromoacetamidobenzyl)adenine. It was found, however, that both XI and 9-(*p*-bromoacetamidobenzyl)adenine were capable of causing more than 90% irreversible inhibition of adenosine deaminase. The inactivation of the enzyme by these compounds was not reversed by dialysis. A comparison of the apparent first-order loss of enzyme activity caused by XI and 9-(*p*-bromoacetamidobenzyl)adenine is given in Fig. 1. Because the reaction of XI with adenosine deaminase is slow, these enzyme inactivation experiments have larger experimental errors than in the case of 9-(*p*-bromoacetamidobenzyl)adenine. Since the irreversible inhibitors have limited solubility in phosphate buffer, the reactions were performed in phosphate buffer containing 10% dimethylsulfoxide but even with the addition of dimethylsulfoxide, a concentration of 0.20 m*M* was near the upper range of solubility of XI. However, an examination of Fig. 1 reveals that XI irreversibly inhibited adenosine deaminase at concentrations of 0.10 and 0.20 m*M* at a much lower rate than did 9-(*p*-bromoacetamidobenzyl)adenine at a concentration of 0.03 m*M*. This significant difference in the rate of irreversible inactivation of the enzyme is not caused by a lack of chemical reactivity of the *meta* isomer since the

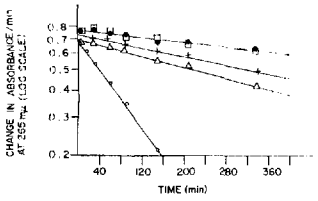

Fig. 1.—Irreversible inactivation of adenosine deaminase. Key: ●, enzyme control; □, iodoacetamide (1.0 mM); +, 9-*m*-bromoacetamidobenzyladenine (0.10 mM); △, 9-*m*-bromoacetamidobenzyladenine (0.20 mM); ○, 9-*p*-bromoacetamidobenzyladenine (0.030 mM).

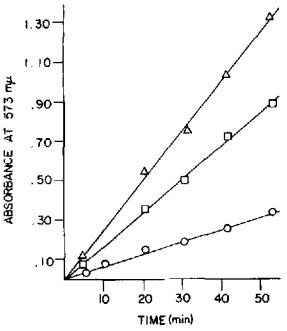

Fig. 2.—Comparative chemical reactivities of some alkylating agents with 4-(*p*-nitrobenzyl)-pyridine at pH 4.2. Key: ○, iodoacetamide (0.27 mM); □, 9-(*p*-bromoacetamidobenzyl)adenine (0.27 mM); △, 9-(*m*-bromoacetamidobenzyl)-adenine (0.27 mM).

meta isomer (XI) is actually more reactive than the *para* isomer when 4-(*p*-nitrobenzyl)pyridine (11–13) was used as the nucleophilic reagent (Fig. 2). In addition, the differences in the rates of irreversible inactivation of adenosine deaminase by XI and 9-(*p*-bromoacetamidobenzyl)adenine cannot be explained by the suggestion that XI is rapidly destroyed by the phosphate buffer solution. This suggestion was excluded when it was found that less than 10% of the alkylating ability of XI is lost during a 4-hr. incubation of XI with phosphate buffer containing 10% dimethylsulfoxide at 37°. Because iodoacetamide does not significantly irreversibly inhibit adenosine deaminase even at concentration of 1.6 mM, the authors believe that the irreversible inactivation which is caused by XI occurs mainly through a reversible E . . . I complex and not significantly by a random biomolecular process. In addition, XIII did not cause an irreversible inactivation of the enzyme. Thus, the irreversible inactivation of the enzyme by XI appears to be specifically related to its alkylating ability through an E . . . I complex.

When a comparison of the irreversible inactivation of the enzyme is made on the basis of the amount of the enzyme in the reversible E . . . I complex, it is found that 9-(*p*-bromoacetamidobenzyl)adenine is still much more reactive than the corresponding *meta* derivative (XI). Baker (17) has derived Eq. 1 for the calculation of the fraction of the total enzyme that is in the E . . . I complex.

$$[E\ldots I] = \frac{[E_t]}{\frac{K_i}{[I]} + 1} \qquad \text{(Eq. 1)}$$

In the case where a 0.10 mM solution of XI is incubated with the enzyme, the amount of the total enzyme (E_t) in the reversible E . . . I complex is 0.73 E_t, and the half-life of the inactivation is > 600 min. When a 0.030 mM solution of 9-(*p*-bromoacetamidobenzyl)adenine is employed under identical conditions with identical total enzyme concentration, the amount of the total enzyme in the reversible E . . . I complex is 0.70 E_t, and the half-life for the inactivation is 94 min. Thus, even when the concentration of the reversible E . . . I complex for the two inhibitors is nearly equal, the rate of inactivation by the *meta* derivative is much lower than that of the *para* isomer. The authors believe that these results offer evidence that in the initial reversible E . . . I complex between XI and adenosine deaminase, the alkylating agent of XI is not positioned as close to a nucleophilic group on the enzyme as occurs when 9-(*p*-bromoacetamidobenzyl)adenine is employed; consequently, the rate of alkylation by XI in the E . . . I complex is lower. However, it is possible that when the alkylating group is in the *meta* position of 9-benzyladenine as in XI, it is alkylating a different amino acid of the enzyme than when the alkylating group is in the *para* position of 9-benzyladenine. Further studies are necessary to differentiate these two suggestions.

Analysis of Selected Pharmaceuticals by Quantitative Thin-Layer Chromatography

By J. C. MORRISON* and J. M. ORR

Thin-layer chromatography was employed to separate the components of 14 selected commercial pharmaceutical mixtures in tablet and capsule form. The components included the amphetamines, certain barbiturates, and several related compounds. A recording photoelectric densitometer with an electronic integrator was utilized to scan and estimate quantitatively the various constituents which were rendered visible by specific reagents. Silica Gel G was the adsorbent used and a dioxane–benzene–25 per cent ammonia mixture (40:40:10 v/v) was found to be a suitable developing solvent for separating the mixtures examined. Most of the drugs studied could be estimated with an experimental error of approximately 5 per cent when applied in concentrations of 25 to 100 mcg.

MULTICOMPONENT tablets and capsules provide two of the most convenient forms for the oral administration of drugs since they are easily mass produced and provide a compact accurate dose in a convenient form. For this reason they constitute the method of administration for over 75% of all drugs prescribed.

The widespread use of these dosage forms has given rise to problems in pharmaceutical analysis. In many cases the concentration of an incorporated drug is extremely small—a milligram or less—and rapid techniques of semimicro analysis must be devised for its assay. As the formulation of the preparation becomes more complex the greater are the assay problems introduced since the components must be separated and estimated individually. For the purpose of quality control, three or more components may have to be isolated and assayed in the product.

Since its introduction by Stahl in 1956 (1) the technique of thin-layer chromatography has been used extensively in many fields. In the past 3 years, however, it has been applied increasingly to pharmaceutical analysis because of its rapidity and the high degree of resolution achieved. Under specified conditions the technique lends itself to quantitative interpretation and can be used for analytical control and toxicological investigations. Direct elution techniques from the adsorbent may be used provided no extracted contaminants interfere with the assay, although colorimetric reagents can be employed to ensure that only specific chemicals are estimated (2). Since there is a correlation between the amount of drug applied to a plate and the area of the developed spot, drugs have been estimated by careful measurement of spot area (3). By this method Morrison and Chatten estimated antihistamines in drug mixtures and measured the spot areas involved manually (4).

The present work was undertaken to develop the technique of densitometric measurement, a method in which spot area is calculated electronically. This method of area measurement is simple to operate and compares favorably with gravimetric or spectrophotometric techniques. Furthermore, in using a photoelectric device, the process of measurement is rapid and convenient. Such an instrument allows analytical procedures to become automated when their reliability has been established and these procedures can then be carried out by semiskilled operators. By employing specific reagents to render the drug or drugs visible on the chromatoplate, the technique nullifies the effect of any impurities present in the adsorbent and ensures that only the drug is estimated. The need for elution or extraction of the drug is thus eliminated (5–7).

The authors report the application of such a technique to pharmaceutical preparations available in Canada and suggest possible sources of error in the method.

EXPERIMENTAL

Materials and Apparatus.—Glass plates (200 × 200 mm.) in glass developing tanks lined with solvent saturated filter paper.

Preparation of the Plates.—The plates were coated with a layer of adsorbent 250 mμ thick according to the method of Stahl (1). The slurry was prepared by mixing 30 Gm. of Silica Gel G with 60 ml. of 25% 1,2-dimethoxyethane in distilled water. This resulted in a smooth even film of adsorbent which was not liable to flake or crack.

Chemicals.—All chemicals and reagents used were analytical reagent grade. The chemical purity of the standards was checked by observing their melting points and comparing them with the literature. As further proof of purity, each standard produced only one spot on chromatographic examination. The drugs used in this investigation were acetylsalicylic acid, salicylic acid, phenacetin, amphetamine sulfate,

methamphetamine hydrochloride, theophylline, caffeine, ephedrine, phenobarbital, amobarbital, butabarbital, pentobarbital, carbromal, meprobamate, and prochlorperazine maleate.

Developing Solvent.—The developing solvent used in all cases was dioxane–benzene–25% ammonia (40:50:10 v/v).

Spray Reagents.—The compositions of the seven spray reagents used in this investigation are listed in Table I.

Application of Drugs and Development of Chromatogram.—The samples for analysis were applied in ethanolic solution approximately 1 in. from the edge of the plate. Self-filling lambda pipets cali-

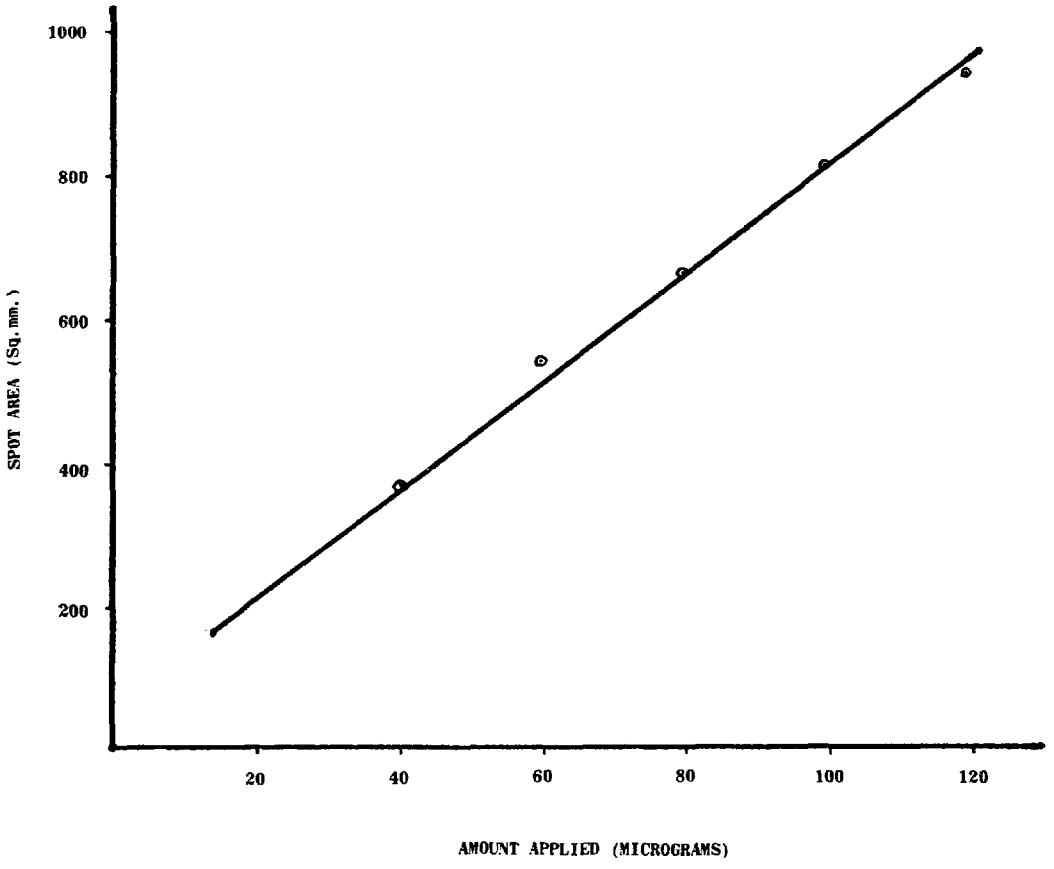

Fig. 2.—Relationship between spot area and spot weight for phenobarbital.

brated to deliver accurately known volumes were used for application, and the spot area was 6–8 mm. in diameter. The plates were developed through a distance of 15 cm., dried at room temperature for 15 min., oven dried for 20 min. at 110°, and sprayed with the appropriate reagent. Reference standards for each drug mixture were applied on the same plate and in concentrations commensurate with the drugs in the sample.

Measurement of Spot Area.—A photovolt densicord (model 542) was used to obtain quantitative results from the developed chromatograms which were positioned directly under the scanning head at a height of approximately 6 mm. The response control selected for the instrument varied with the chemical reagent used to render the drugs visible. The resulting graph plotted by the instrument was rendered quantitative by the densicord electronic integrator which calculated the area under the curve. Results were calculated with reference to the appropriate standard.

Preparation of Standard Curves.—To establish the relationship between spot area and concentration, amphetamine, phenobarbital, and acetylsalicylic acid were spotted in various concentrations in their respective detectable ranges. Following development, the chromatograms were scanned and the integrated areas found for each concentration.

Assay of Simulated Drug Mixtures.—To check the reliability of the method ethanolic solutions of several drugs in concentrations approximating those of various commercial preparations were spotted on plates and developed. The chromatograms were then scanned with the densitometer and compared with relative standards.

Assay of Commercial Preparations.—Each of the preparations was treated individually due to differences in the concentrations of the constituents. The amount of drug applied to the chromatogram varied from one product to another, but this was necessary to ensure that the spot would contain the minimum assayable quantity of the drug. The general procedure for tablets consisted in crushing several weighed tablets in a mortar and dissolving a weighed portion in approximately 15 ml. of ethanol. After shaking for 20 min., the solution was filtered, rinsed with two portions of ethanol, and made up to volume. Assay limits were established by running a series of chromatograms containing several concentrations of the drugs. The appropriate standards were applied to the plate to ensure a total of 10 assays for each constituent. Standards and samples were spotted alternately on the plate to facilitate assay and nullify any variation in the silica gel layer. After development, the plates were sprayed with the appropriate reagent to de-

velop visible spots. R_f values were recorded and the chromatograms scanned by the densitometer.

RESULTS

Relationship Between Spot Area and Concentration.—By preparing a series of known standards it was possible to demonstrate a linear relationship between spot area and spot content and to reproduce this correlation within certain parameters (Figs. 1–3). This relationship was established for amphetamine sulfate in concentration ranges between 5 and 25 mcg. and for phenobarbital and acetylsalicylic acid in concentrations between 40 and 120 mcg. and between 50 and 250 mcg., respectively. The slight variation in the slopes of the lines can be attributed to several factors such as the intensity of stray light

on the photocell, the detection spray used, and variations in layer thickness (8). The results are shown in Table II.

Results for Simulated Drug Mixtures and Commercial Preparations.—The percentage recoveries obtained from the drug mixtures simulating existing commercial preparations are shown in Table III, and the recoveries from the commercial preparations are shown in Table IV which includes the labeled strength of each preparation and the mean recovery from 10 assays on each preparation. The R_f values and the minimum and maximum assayable quantities are included for each preparation together with the staining reagent used to render the drugs visible.

DISCUSSION

From the results obtained in this study it is suggested that the technique of densitometric measurement is sufficiently accurate for routine pharmaceutical analysis and can be applied to pharmaceutical dosage forms. The average error involved was found to be about 5%, a figure which is similar to that reported in related fields (9–11).

Several experimental factors were found to be critical in obtaining consistent and accurate results. Since the area of the spot can increase during development from 25 to 100%, the size of the initial spot application should be as small and as uniform as possible. An applied spot of 6–8 mm. was found to be satisfactory. Spots which are not uniformly

applied may occupy different areas, and this difference with its consequent error will be registered by the photocell. Similarly, variations in the layer thickness of the silica gel can cause alterations in the light reflected by the background, and this error can be recorded by the densitometer since it is designed to produce results which are based on the difference in photoelectric intensity between the visible spot and the background of the plate. For this reason it is essential to use spray reagents which produce stains specific for individual drugs and which do not color the background to any appreciable extent, otherwise the contrast between spot and background will be diminished. If a satisfactory spray reagent cannot be developed, it is doubtful whether the method could be used for quantitative work.

In using thin-layer densitometry it was essential that the drugs being assayed separated sharply and distinctly as any degree of spot overlap renders area measurement techniques liable to error. To some extent it was found possible to counteract the effects of overlap by spraying the plate with a stain which rendered only a particular drug visible for purposes of assay. Alternatively, two or more plates could be used, one of which was treated to allow estimation of one fraction of the drug mixture while the other plate was developed to estimate any additional components.

The minimum quantity of a drug necessary for detection on a thin-layer plate appeared to depend on the specificity of the spray reagent used to produce the necessary color, and it was observed that these chemical stains varied in their relative sensitivities of detection. For example, with the exception of phenobarbital, the barbiturates did not appear distinctly after charring with sulfuric acid, but when a 2% mercuric sulfate spray was used followed by 0.1% sodium molybdate in concentrated sulfuric acid both amobarbital and butabarbital appeared as distinct brown spots on a gray background and could be assayed satisfactorily. Consequently, the minimum assayable quantity for these drugs using the acid-molybdate spray was 40 mcg. as opposed to 50 mcg. with the sulfuric acid spray. Thus, it was found necessary to vary the amount of solution applied to a plate in such a way that the amount of drug being estimated contained the minimum detectable quantity. For example, in preparation *I* the tablets have a ratio of amphetamine to meprobamate of 1–80 and the amounts of solution applied to the plate in the assay of this preparation must be varied to allow the accurate estimation of each drug.

Due to the very low solubility of prochlorperazine maleate in the extracting solvents the agitation time during its extraction was increased from 30 to 60 min. to ensure its complete removal from the tablet. Solubility was also a factor in the assay of preparation *11* when it was found that the theophylline in the tablets has such a low solubility and was so slowly soluble that quantitative estimation by this method proved unreliable.

Triple-sulfa tablets U.S.P. were included in this study to demonstrate the application of the densitometric technique to systems where distinct stains exist or can easily be found. Using the method reported by Wehrli (12) for the qualitative separation of these sulfonamides, it was found that quantitative evaluation of the tablets could be readily carried out by this method.

It is suggested that if a sensitive spray reagent exists and the correct experimental conditions are observed regarding the parameters of the assay, the densitometric method could be applied in various fields of pharmaceutical analysis to yield quantitative results.

SUMMARY

A thin-layer chromatographic technique using Silica Gel G as the adsorbent has been devised for the separation and analysis of 14 selected pharmaceuticals which included amphetamines, barbiturates, and related compounds. It was demonstrated that a linear relationship exists between spot area and spot content. Quantitative evaluation was achieved without elution from the adsorbent by using a photoelectric densitometer coupled to an electronic integrator which computed the spot areas. The experimental error was found to be approximately 5%. The technique gave quantitative results when the drugs were applied to the plates within certain concentrations. These concentrations varied with individual drugs but were in the range of 25 to 100 mcg. generally. Dioxane–benzene–25% ammonia (40:50:10 v/v) was found satisfactory for resolving the selected pharmaceuticals into their respective components. Results were obtained more rapidly and with greater convenience than by planimetry or visual area measurement. Several experimental factors which influence quantitative recovery are discussed. The technique could be applied routinely in microanalysis and has specific application to pharmaceuticals.

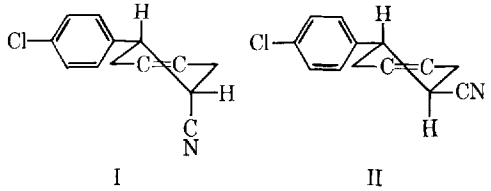
Characterization of Epoxides of *cis*- and *trans*-4-(*p*-Chlorophenyl)-5-cyanocyclohexene from NMR Spectra of Derivatives

By DAVID B. ROLL* and ALAIN C. HUITRIC

The epoxidation of *cis*-4-(*p*-chlorophenyl)-5-cyanocyclohexene with *m*-chloroperbenzoic acid in diethyl ether yielded *trans*-4-(*p*-chlorophenyl)-*trans*-5-cyano-1,2-epoxycyclohexane as the only product. Epoxidation of *trans*-4-(*p*-chlorophenyl)-5-cyanocyclohexene with *m*-chloroperbenzoic acid yielded *cis*-4-(*p*-chlorophenyl)-*trans*-5-cyano-1,2-epoxycyclohexane and *trans*-4-(*p*-chlorophenyl)-*cis*-5-cyano-1,2-epoxycyclohexane in ratio of about 7 to 3, respectively, when carried out in ether but in ratio of about 1 to 1 in 1,2-dichloroethane. The epoxides were characterized from the NMR spectra of the derived diols, mono-, and diacetates by taking advantage of the difference between the spatial 1,3-diaxial deshielding effects of hydroxyl and acetoxy groups.

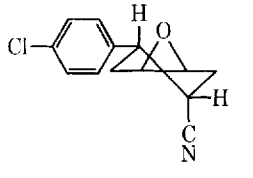
IN THE course of the synthesis of certain agents of possible medicinal interest it was necessary to characterize the epoxidation products of *cis*- and *trans*-4-(*p*-chlorophenyl)-5-cyanocyclohexene, compounds I and II, respectively. Compounds I and II were prepared by the Diels-Alder condensation of butadiene with *cis*- and *trans*-*p*-chloro-β-cyanostyrene (1), respectively. Epoxidation of I with *m*-chloroperbenzoic acid in diethyl ether yielded a single product, while epoxidation of II yielded two products in ratio of about 7 to 3 when carried out in ether but in ratio of 1 to 1 when carried out in 1,2-dichloroethane. The epoxidation of I was not carried out in 1,2-dichloroethane. Analysis was done by gas chromatography. These epoxides have been characterized from the nuclear magnetic resonance spectra of some of their derivatives by taking advantage of the long-range 1,3-diaxial deshielding effects of the hydroxyl and acetoxy functional groups.



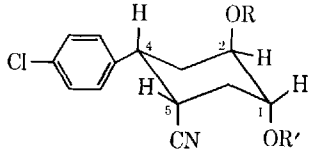
I II

CONFIGURATIONAL ASSIGNMENT OF EPOXIDE DERIVED FROM I

Assignment of configuration of the single epoxide obtained from I was not possible from its NMR spectrum. The epoxide was characterized as the isomer with the epoxy group *trans* to the cyano group, compound IV, from the NMR spectra of the diol (V), the monoacetate (VI), and the diacetate (VII) derived from it. It is interesting to note that of the two possible epoxides only IV was obtained in detectable quantity. From consideration of steric factors it is not surprising that the rate of formation of IV should be faster than that of the isomer with the epoxy group *cis* to the cyano group.



IV



V, R = R′ = H
VI, R = H, R′ = Ac
VII, R = R′ = Ac

The relevant portions of the spectra of V, VI, and VII, measured in pyridine, are given in Fig. 1, A, B, and C, respectively. Analysis of the spectra shows that in pyridine all three derivatives exist predominantly in the chair conformation with the aromatic ring in equatorial orientation.

Spectrum A indicates the equatorial orientation for H-1, H-2, and H-5, and the axial orientation for H-4. The equatorial orientation is established for H-1 at τ 5.65 and H-2 at 5.46 from their narrow signals, half-height width of 6 to 7 c.p.s. The axial orientation is established for H-4 from the sextet at τ 6.23. The sextet indicates a coupling constant of about 13 c.p.s. between H-4 and axial H-3 with additional minor coupling of about 3.5 c.p.s. with equatorial H-3 and H-5. The signal of H-5 at τ 6.73 is partially overlapped with the signal of axial H-3, but the approximate width of the signal indicates that H-5 has the equatorial orientation. The signal centered at τ 7.05, which appears as a main triplet with separation of 13 c.p.s., plus additional minor splitting, is attributed to axial H-3. The main splitting of about 13 c.p.s. results from geminal

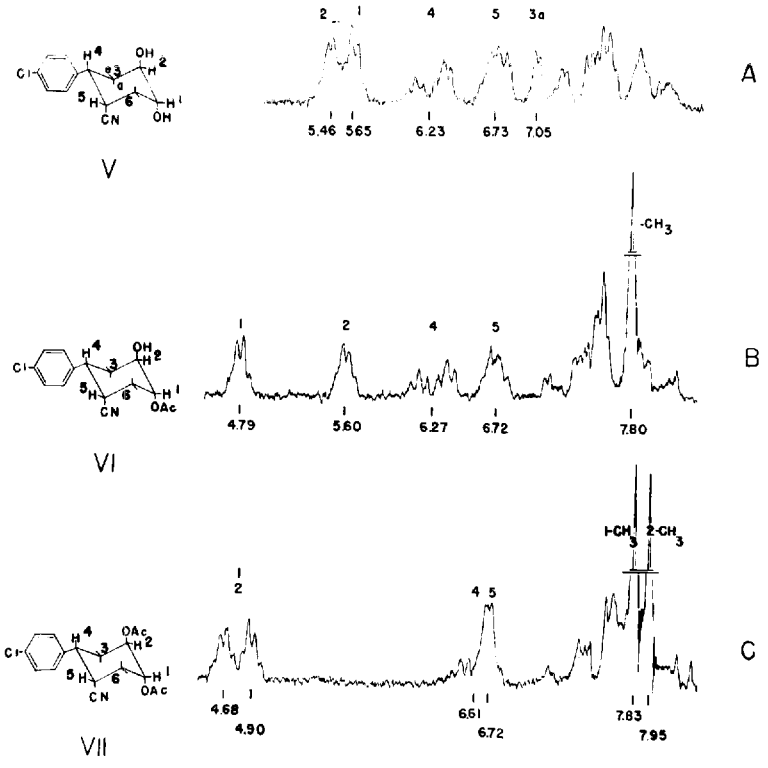

Fig. 1.—NMR spectra of *trans*-2-hydroxy-*cis*-4-(*p*-chlorophenyl)-*cis*-5-cyanocyclohexanol (A), the corresponding 1-acetate (B), and the corresponding 1,2-diacetate (C) at 60 mc. in pyridine at 37°; chemical shifts in τ units; TMS internal reference.

coupling with equatorial H-3 and vicinal coupling with axial H-4. The minor splitting results from coupling with equatorial H-2. The downfield shift of axial H-3 results from long-range deshielding by the axial hydroxyl and cyano groups on C-1 and C-5, respectively. Differentiation of the signals of H-1 and H-2 was done by spin-spin decoupling. Irradiation at τ 5.46 caused the sextet of axial H-3 at τ 7.05 to collapse into a sharp triplet with separations of 13 c.p.s., while irradiation at 5.65 caused no change in this signal.

The given chair conformation is established as the predominant structure of VI from spectrum B in a similar way. The narrow signals of half-height width of about 7 c.p.s. for H-1 at τ 4.79 and H-2 at τ 5.60 indicate the equatorial orientation of these two protons. The axial orientation is established for H-4 from its sextet at τ 6.27 with apparent coupling of 13 c.p.s. with axial H-3 and about 3.5 c.p.s. with equatorial H-3 and H-5. The half-height width of about 8 c.p.s. for the signal of H-5 at τ 6.72 indicates the equatorial orientation of H-5.

In a similar way the narrow signals of half-height width of about 6 to 7 c.p.s. for H-1 and H-2 at τ 4.68 and 4.90, and H-5 at τ 6.72 in spectrum C establish the equatorial orientation of these three protons, and, therefore, also establish the given chair conformation of VII in pyridine. Signals of H-1 and H-2 cannot be differentiated with certainty. The signal of H-4 is partially overlapped by the signal of H-5, but its chemical shift is approximated as 6.61. The acetoxy methyl groups are magnetically nonequivalent. Assignment was made by comparison with spectrum B of VI. The downfield shift of the group on C-1 is attributed to the long-range deshielding effect of the axial cyano group.

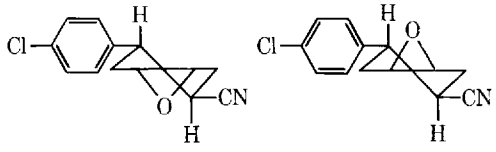
Having established the conformations of V, VI, and VII, the assignment of the configuration of the parent epoxide was possible from the chemical shifts of H-4 of the three derivatives by taking advantage of the spatial 1,3-diaxial deshielding effect of a hydroxyl group on ring hydrogens (2–4) and of the larger deshielding effect of a hydroxyl group compared to the corresponding acetoxy group (3, 4). The chemical shifts of H-4 of the diol V and the monoacetate VI are almost identical, τ 6.23 and 6.27, respectively; but the signal of H-4 appears at about τ 6.61 in the spectrum of the diacetate (VII), about 20 to 23 c.p.s. upfield from that of the monoacetate or diol. This establishes that axial H-4 is deshielded by an axial hydroxyl group on C-2 in the monoacetate (VI) as well as in the diol (V) and in turn establishes that the parent epoxide has the epoxy group *trans* to the cyano group (IV). The established structures of the derivatives indicate that the epoxide opening occurred *via* a transition state with the aromatic group essentially equatorial. A transition state with the aromatic group axial would yield a diol which would differ from structure V by having the *trans* diequatorial hydroxyl groups. The two possible isomeric epoxides would yield identical diaxial diols and diacetates but different monoacetates *via* the transition state with the aromatic group equatorial. If the product of epoxidation had been the *cis*-epoxide, the chemical shift of H-4 should have been almost identical in the mono- and diacetate but significantly different in the monoacetate compared to the diol.

Hydrogenation of I and II yielded *cis*-2-(*p*-chlorophenyl)-1-cyanocyclohexane (III) and *trans*-2-(*p*-chlorophenyl)-1-cyanocyclohexane (VIII), respectively. The NMR spectrum of III measured in

pyridine clearly establishes the *cis* configuration. The signal of H-2 appears as a broad multiplet of about 23 c.p.s. width at τ 7.33. The width of the signal indicates that H-2 has an axial orientation. The signal of H-1 gives a much narrower peak of half-height width of about 7 c.p.s. at τ 6.92, indicating that H-1 has the equatorial orientation. In the spectrum of the *trans* isomer there is overlapping of the broad signals of axial H-2 and H-1 when measured in carbon tetrachloride. The spectrum of VIII was not obtained in pyridine.

CONFIGURATIONAL ASSIGNMENT OF EPOXIDES DERIVED FROM II

The NMR spectra of the two epoxides (IX and X) obtained from II did not provide unequivocal characterization of the two isomers.



IX X

The major component of the epoxidation reaction of II in ether was converted to the diol, monoacetate, and diacetate derivatives, compounds XI, XII, and XIII, respectively, but the spectra of these three derivatives did not allow an unambiguous application of the method used for characterization of epoxide (IV) because of overlapping of signals of H-4 and H-5. In order to obtain reliable chemical shifts for H-4 the three corresponding derivatives deuterated at C-5 were prepared. The deuterium exchange on the cyano-bearing carbon was accomplished by refluxing II in methanol-*d* in the presence of sodium methoxide. Some isomerization occurred during the deuterium exchange process and pure deuterated II was obtained by recrystallization from absolute ethanol. Deuterated II was epoxidized in ether and the major component was converted to the diol, monoacetate, and diacetate derivatives, compounds XI*d*, XII*d*, and XIII*d*, respectively. The pertinent portions of the NMR spectra of the deuterated derivatives measured in pyridine are given in Fig. 2. The effect of deuteration on C-5 is demonstrated by the portions of the spectra of the corresponding nondeuterated compounds shown above the signal of H-4 in each spectrum. In the spectra of the nondeuterated compounds there is partial overlap of the signals of H-4 and H-5. Replacement of H-5 with deuterium also simplifies the signal of H-4 which is now coupled only with the two protons on C-3.

The three spectra show that in pyridine all three derivatives exist predominantly in the chair conformation with the aromatic ring in equatorial orientation. The spectra also establish that the epoxide from which they were derived has the epoxy group *trans* to the cyano group, structure IX.

Spectrum D establishes the equatorial orientation of H-1 and H-2 in XI*d* from their overlapping signals at τ 5.65 which give a narrow peak of half-height width of about 6 to 7 c.p.s. The axial orientation of H-4 is established from the quartet at τ 6.42. The quartet gives apparent coupling constants of 12.0 c.p.s. between H-4 and axial H-3 and about 3.5 to 4 c.p.s. between H-4 and equatorial H-3. The spectrum is consistent with the conformation shown in Fig. 2.

The given conformation of XII*d* is established in the same fashion from the narrow signals (half-height width of 6 to 7 c.p.s.) of H-1, at τ 5.74 and H-2 at τ 4.73 which establish the equatorial orientation of H-1 and H-2, and from the quartet of H-4 at τ 6.74 ($J_{43a} \simeq 12$ c.p.s. and $J_{43e} \simeq 4$ c.p.s.) which established the axial orientation of H-4.

In the spectrum of the diacetate (XIII*d*), spectrum F, the signals of H-1 and H-2 are overlapping to give a narrow signal at τ 4.87. The half-height width of the combined signals is about 7 c.p.s. indicating that H-1 and H-2 have the equatorial orientation. Any significant contribution of the other chair conformation with H-1 and H-2 axial would give wider signals for H-1 and H-2. In this spectrum the signal of II-4 appears as a symmetrical triplet with separation of 8.2 c.p.s. instead of the expected quartet. The important thing to note is that the width of the signal of 16.4 c.p.s. is about identical to the width of the signals of H-4 in spectra D and E. A deceptively simple spectrum, giving a triplet instead of the expected quartet, will occur for the signal of H-4 if averaging of coupling constants J_{43a} and J_{43e} results due to strong coupling effects (5–7). Averaging of coupling constants due to strong coupling effects will become operative when the difference between the chemical shifts of the axial and equatorial protons on C-3 approaches, or become smaller than, the geminal coupling constant between the two protons on C-3. In the limit where the chemical shifts of axial and equatorial H-3 are equal the signal of H-4 will yield a symmetrical triplet with separations equal to $(J_{43a} + J_{43e})/2$ (7). Complications due to strong coupling effects do not cause any change in the width of the signal. Inspection of the upper field portion of spectrum F and comparison with spectra D and E indicates that similar chemical shifts of the two protons on C-3 probably prevails in XIII*d*. In compounds XI*d* and XII*d* the deshielding effect of the C-1 axial OH will cause a downfield shift of the signal of axial H-3 of more than 50 c.p.s. when measured in pyridine at 60 mc. (2). The signal of axial H-3 will, therefore, be downfield from that of equatorial H-3 in XI*d* and XII*d*. This is also indicated to be the case from the up-field portions of spectra D and E. Since the 1,3-diaxial deshielding effect of the acetoxy group is about 20 cycles less than that of the OH group, nearly identical chemical shifts of axial and equatorial H-3 is not unexpected and provides a logical explanation for the observed triplet of H-4. The width of the signal definitely establishes the axial orientation of H-4.

Having established the conformations of XI*d*, XII*d*, and XIII*d*, the configuration of the parent epoxide was possible from the chemical shifts of H-4 in the three derivatives. The chemical shift of H-4 is almost the same in the mono- and diacetate but it is from 19 to 24 cycles to lower field in the diol. This establishes that the acetoxy group is *cis* to axial H-4 in the monoacetate and in turn establishes the configuration of its parent epoxide as the isomer with the epoxy group *trans* to the cyano group, structure IX. The two epoxides obtained from peracid

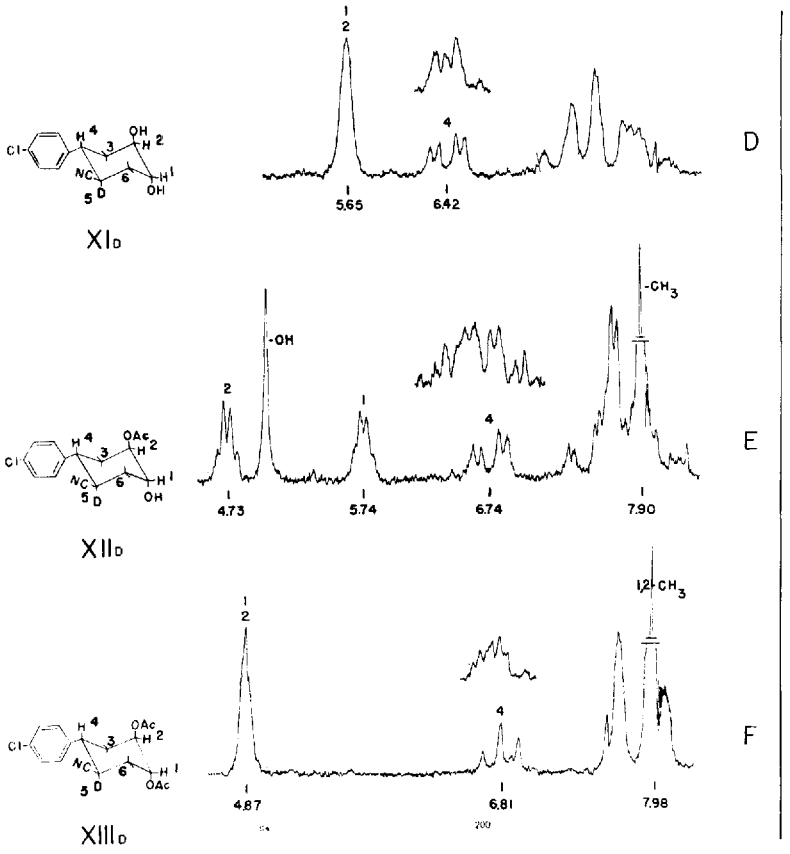


Fig. 2.—NMR spectra of *trans*-2-hydroxy-*cis*-4-(*p*-chlorophenyl)-*trans*-5-cyanocyclohexanol-5-*d* (D), the corresponding 2-acetate (E), and 1,2-diacetate (F); portions of the spectra of the corresponding nondeuterated compounds are shown above signals of H-4; all at 60 mc. in pyridine at 37°; chemical shifts in τ units; TMS internal reference.

oxidation of II yield the same diol (XI) on acid catalyzed hydrolysis. The major product of the epoxidation reaction in ether is, therefore, characterized as structure IX and the minor product has structure X.

cis-2-(*p*-Chlorophenyl)-1-aminomethylcyclohexane (XIV) and the *trans* isomer (XV) were prepared by lithium aluminum hydride reduction of the corresponding cyano compounds (III and VIII). The NMR spectra of these compounds were not very informative. The hydrobromide salts of the two amines elicited strong CNS excitation in mice when injected i.p., but there was little observable difference in potency between the two isomers.

EXPERIMENTAL

Melting points were determined on a Kofler micro hot stage. The NMR spectra were determined with a Varian A-60 spectrometer. Spectra were taken in pyridine, unless otherwise indicated in a concentration of about 150 mg./0.5 ml. with tetramethylsilane as internal reference.

cis-4-(p-Chlorophenyl)-5-cyanocyclohexene (I).—In a typical synthesis 20 Gm. (0.122 mole) of *cis*-*p*-chloro-β-cyanostyrene (1), about 80 ml. of condensed butadiene, 20 ml. of toluene, and a trace of hydroquinone were heated with shaking under a nitrogen atmosphere in a stainless steel bomb for 16 days at a temperature of 138°. Analysis of the reaction mixture by gas chromatography on a 10-ft. column of 20% silicon QF-1 on acid-washed Chromosorb W at 185° showed a ratio of unchanged styrene to product I of about 2 to 1. The dark crude material was passed on a column of 0.05–0.2 mm. silica gel using benzene as solvent, resulting in the removal of much colored material. After removal of the benzene the residue was washed repeatedly with hot isopropyl alcohol. This treatment resulted in the extraction of the product and unreacted styrene from a considerable amount of rubbery polymeric material which was left behind. The isopropyl alcohol was removed and product I was separated from the unchanged styrene by numerous recrystallizations from hexane. Because of the distinctive crystal structure of I the purification could be speeded up by preliminary mechanical separation of crystals. The separation was also accomplished by column chromatography on 0.05–0.2 mm. silica gel using petroleum ether–benzene mixtures as solvent. Final recrystallization was from isopropyl alcohol–benzene mixture, m.p. 48–49°.

Anal.—Calcd. for $C_{13}H_{12}ClN$: C, 71.72; H, 5.56. Found: C, 71.47; H, 5.70.

trans-4-(p-Chlorophenyl)-5-cyanocyclohexene (II).—Compound II was prepared by the same method as I, except that the reaction time was 9 days, the temperature 130°, and the preliminary chromatography was not used in the purification procedure. There was some unchanged styrene present. The product was obtained in 44% yield by recrystallization from hexane. The final crystallization was from a mixture of isopropyl alcohol and benzene, m.p. 132.5–134°.

Anal.—Calcd. for $C_{13}H_{12}ClN$: C, 71.72; H, 5.56; N, 6.44. Found: C, 72.28; H, 5.43; N, 6.45.

cis- and trans-2-(p-Chlorophenyl)-1-cyanocyclohexane (III and VIII).—These compounds were obtained by low pressure catalytic hydrogenation of I and II, respectively, using 10% Pd on carbon in absolute ethanol. The yields were quantitative. An analytical sample of III recrystallized from hexane melted at 103.5–104.5°, whereas VIII recrystallized from the same solvent melted at 107–108°.

Anal.—Calcd. for $C_{13}H_{14}ClN$: C, 71.07; H, 6.42; N, 6.38. Found: (III) C, 71.29; H, 6.41; N, 6.65. (VIII) C, 71.04; H, 6.47; N, 6.20.

trans-4-(p-Chlorophenyl)-trans-5-cyano-1,2-epoxycyclohexane (IV), cis-4-(p-Chlorophenyl)-trans-5-cyano-1,2-epoxycyclohexane (IX), and trans-4-(p-Chlorophenyl)-cis-5-cyano-1,2-epoxycyclohexane (X).—In a typical synthesis, 3.27 Gm. (0.015 mole) of alkene and 7.68 Gm. of 85% *m*-chloroperbenzoic acid (0.38 mole) were dissolved in about 100 ml. of diethyl ether and allowed to stand at room temperature in the dark for 4 days. The reaction mixture was then washed twice with cold 10% sodium hydroxide. The ether solution was washed with water until the washings no longer were basic to litmus and dried with Drierite. The yield of crude product IV was 89%, which when crystallized from benzene–hexane mixture, melted at 109–110.5°. The yield of the mixture of epoxides (IX and X) from epoxidation of II was 86%. These were in a ratio of approximately 7 to 3 as determined by gas chromatography on a 10-ft. column of 20% silicon QF-1 on acid-washed Chromosorb W at 235°. When II was epoxidized in a similar manner as above, but with 1,2-dichloroethane as the solvent, the ratio of the two epoxides was about 1 to 1. Column chromatography of the mixture of epoxides on 0.05–0.2 mm. silica gel using mixtures of purified benzene and petroleum ether, followed by mixtures of benzene and diethyl ether resulted in the separation of substantial quantities of pure IX and only small quantities of X, still somewhat contaminated with IX, as well as a number of fractions with varying ratios of IX and X. Small amounts of pure X could be obtained by crystallizing fractions rich in X from absolute ethanol. The analytical samples of IX and X, when recrystallized from a mixture of benzene–hexane, melted at 128.5–129° and 148–150°, respectively.

Anal.—Calcd. for $C_{13}H_{12}ClNO$: C, 66.81; H, 5.18. Found: (IV) C, 67.12; H, 5.47. (IX) C, 66.94; H, 5.13. (X) C, 66.93; H, 5.21.

trans-2-Hydroxy-cis-4-(p-chlorophenyl)-cis-5-cyanocyclohexyl Acetate (VI) and trans-2-Acetoxy-cis-4-(p-chlorophenyl)-trans-5-cyanocyclohexanol (XII).—In the synthesis of VI, 1 Gm. (0.0043 mole) of IV was dissolved in 6 ml. of glacial acetic acid and refluxed for 14 hr. The solution was added to 100 ml. of cold water, extracted 3 times with ether, the ether washed with 5% NaOH, and dried over Drierite. After drying, the residue was recrystallized from benzene–hexane mixture yielding 645 mg. (51%) of VI which melted at 149–151°. The rest of the material did not crystallize and was shown by comparison of NMR spectra to be a mixture of the monoacetate (VI) and the diacetate (VII). In the synthesis of XII, to avoid the possible formation of diacetate (XIII), 0.75 Gm. (0.0032 mole) of IX was dissolved in 5 ml. of glacial acetic acid containing 10% w/v of potassium acetate and allowed to stand at room temperature for 24 hr. The reaction mixture was worked up in the same manner as the synthesis of VI above. Crystallization from benzene–hexane mixture yielded 685 mg. (73%) of XI, m.p. 148.5–150°.

Anal.—Calcd. for $C_{15}H_{16}ClNO_3$: C, 61.33; H, 5.49. Found: (VI) C, 61.08; H, 5.65. (XII) C, 61.19; H, 5.77.

trans-2-Hydroxy-cis-4-(p-chlorophenyl)-cis-5-cyanocyclohexanol (V) and trans-2-Hydroxy-cis-4-(p-chlorophenyl)-trans-5-cyanocyclohexanol (XI).—In the synthesis of V, 300 mg. (0.0013 mole) of IV was dissolved in 3 ml. of purified dioxane and 1.5 ml. of distilled water and a drop of concentrated sulfuric acid added. In the case of XI the same procedure was followed except either epoxide IX or a mixture of epoxides IX and X was used, since the glycol (XI) is the product of the hydrolysis of either IX or X. The reaction mixture was allowed to stand at room temperature for 24 hr., suspended in 20 ml. of water, extracted with ether, the ether dried with Drierite, and the solvent removed. The yields of unpurified crystalline product from typical syntheses of V and XI were 232 mg. (71%) and 245 mg. (75%), respectively. Recrystallization of both from benzene–acetone mixture yielded pure V, m.p. 189–190.5°, and pure XI, m.p. 175.5–177°.

Anal.—Calcd. for $C_{13}H_{14}ClNO_2$: C, 62.03; H, 5.61; N, 5.56. Found: (V) C, 62.26; H, 5.76. (XI) C, 61.71; H, 5.62; N, 5.31.

trans-2-Acetoxy-cis-4-(p-chlorophenyl)-cis-5-cyanocyclohexyl Acetate (VII) and trans-2-Acetoxy-cis-4-(p-chlorophenyl)-trans-5-cyanocyclohexyl Acetate (XIII).—The monoacetate VI or XII was placed in 2 ml. each of pyridine and acetic anhydride and allowed to stand at room temperature for 24 hr. The reaction mixture was dissolved in ether and extracted with cold 5% HCl and the ether layer dried over Drierite. In the case of VII, after removal of solvent, the yield of crude product was quantitative. Recrystallization from benzene–hexane mixture yielded pure VII, m.p. 127–128.5°. In the case of XIII, recrystallization from benzene gave a crystalline material melting at 58–61°. The NMR spectrum of this material indicated the presence of a considerable amount of benzene. Heating under vacuum at 80° resulted in removal of the benzene. On solidification, XIII melted over a wide range, 82–106°. The analysis was correct and the NMR spectrum consistent with the expected product.

Anal.—Calcd. for $C_{17}H_{18}ClNO_4$: C, 61.08; H, 5.40. Found: (VII) C, 61.35; H, 5.48. (XIII) C, 61.26; H, 5.16.

cis-2-(p-Chlorophenyl)-1-aminomethylcyclohexane Hydrobromide (XIV) and trans-2-(p-Chlorophenyl)-1-aminomethylcyclohexane Hydrobromide (XV).—A slurry of compound III in ether was added to an excess of $LiAlH_4$ in ether at a rate that maintained a gentle refluxing. The reaction mixture was allowed to stir at room temperature for 1 hr. after the addition was completed. The excess $LiAlH_4$ was destroyed by dropwise addition of ice water. Aqueous 5% NaOH was then added to increase the water layer, the mixture extracted with ether, and the ether solution dried with Drierite. Removal of the solvent gave a quantitative yield of the crude amine, the infrared spectrum of which

showed no —C≡N absorption. The crude amine was dissolved in *n*-hexane and HBr gas bubbled into the solution. The yield of the salt was quantitative. Recrystallization from absolute ethanol yielded pure XIV, m.p. 290–292°.

In the synthesis of XV tetrahydrofuran was used as solvent. Due to low solubility, compound VIII was added as a slurry to an excess of $LiAlH_4$ in tetrahydrofuran. The rest of the reaction and work-up was the same as in the synthesis of XIV above. The yield was quantitative for both the free amine and the salt. Pure XV melted at 237–239° when crystallized from absolute ethanol–benzene mixture.

Anal.—Calcd. for $C_{13}H_{19}BrClN$: C, 51.25; H, 6.29; N, 4.60. Found: (XIV) C, 51.46; H, 6.31; N, 4.44. (XV) C, 51.49; H, 6.24; N, 4.45.

Deuteration on C-5 of II, IX–XIII.—Deuterium exchange on C-5 of II was carried out by refluxing 1.5 Gm. of II in 15 ml. of CH_3OD in the presence of 1 Gm. of sodium methoxide. After cooling, 10 ml. of deuterium oxide was added; the resulting suspension was extracted with anhydrous ether and the ether solution dried with Drierite. After removal of the ether, the NMR spectrum of the product indicated that a considerable amount of isomerization of II to I had occurred during the exchange. Deuterated II was obtained by recrystallization from ethanol. Compound II deuterated at C-5 was submitted to the same sequence of reactions as II in order to obtain compounds IX–XIII deuterated at C-5.

Hypoiodite Oxidation of 3α-Bromo and 3α-Chloro-2β-hydroxy-5α-androstan-17-one

By R. E. COUNSELL and G. W. ADELSTEIN

Hypoiodite oxidation of 3α-bromo and 3α-chloro-2β-hydroxy-5α-androstan-17-one gave the expected 2β,19-oxide along with lesser amounts of 16-iodinated, 19-hydroxylated, and 19-acetoxylated products. The product composition as well as the yield of each product was found to vary considerably even when the reaction was performed under presumably identical conditions. The structures were assigned on the basis of chemical and spectroscopic evidence. The NMR and other spectroscopic properties of the epimeric 16α- and 16β-iodinated derivatives of 3α-bromo-2β,19-oxido-5α-androstan-17-one are discussed.

INTEREST in 19-substituted steroids as potential anabolic agents led to the investigation of the hypoiodite oxidation of 2β-hydroxyandrostanes as a means of introducing functional groups at the C-19 position (1). During the course of these studies it was noted that a number of minor by-products were formed in addition to the expected oxidation product. This report involves a study of this reaction and structural elucidation of the by-products.

DISCUSSION

The conversion of 2β-hydroxysteroids to 19-functionalized products has been accomplished by: (*a*) oxidation with lead tetraacetate alone (2, 3) or in the presence of iodine (hypoiodite) (4) and (*b*) photolysis of nitrite esters (3, 5). In each case, an alkoxy radical (A) is generated which can interact with the proximal angular methyl group. In the hypoiodite reaction, a furan (B) or an iodofuran (C) can form depending on the mechanism of ring closure. (Scheme I).[1] Although compounds of type C have not been isolated, the characterization of the corresponding hydroxy and acetoxy derivatives among the reaction products has suggested the intermediacy of such an iodinated precursor.

In these studies, hypoiodite oxidation of 3α-bromo-2β-hydroxy-5α-androstan-17-one (I) in refluxing carbon tetrachloride afforded a 36% yield of 3α-bromo-2β,19-oxido-5α-androstan-17-one (III) after chromatography.[2] In addition to this expected product, three other crystalline products were isolated. Two of these products preceded the major product on chromatography and were characterized as the 16β- and 16α-iodinated derivatives (IV and V). These epimers were obtained in 1.4 and 1.2% yield, respectively. The third product, obtained in 10% yield, followed the major product on chromatography and was identified as the hemiacetal (VI).

Hypoiodite Oxidation of 3α-Bromo and 3α-Chloro-2β-hydroxy-5α-androstan-17-one

By R. E. COUNSELL and G. W. ADELSTEIN

Hypoiodite oxidation of 3α-bromo and 3α-chloro-2β-hydroxy-5α-androstan-17-one gave the expected 2β,19-oxide along with lesser amounts of 16-iodinated, 19-hydroxylated, and 19-acetoxylated products. The product composition as well as the yield of each product was found to vary considerably even when the reaction was performed under presumably identical conditions. The structures were assigned on the basis of chemical and spectroscopic evidence. The NMR and other spectroscopic properties of the epimeric 16α- and 16β-iodinated derivatives of 3α-bromo-2β,19-oxido-5α-androstan-17-one are discussed.

INTEREST in 19-substituted steroids as potential anabolic agents led to the investigation of the hypoiodite oxidation of 2β-hydroxyandrostanes as a means of introducing functional groups at the C-19 position (1). During the course of these studies it was noted that a number of minor by-products were formed in addition to the expected oxidation product. This report involves a study of this reaction and structural elucidation of the by-products.

DISCUSSION

The conversion of 2β-hydroxysteroids to 19-functionalized products has been accomplished by: (*a*) oxidation with lead tetraacetate alone (2, 3) or in the presence of iodine (hypoiodite) (4) and (*b*) photolysis of nitrite esters (3, 5). In each case, an alkoxy radical (A) is generated which can interact with the proximal angular methyl group. In the hypoiodite reaction, a furan (B) or an iodofuran (C) can form depending on the mechanism of ring closure. (Scheme I).[1] Although compounds of type C have not been isolated, the characterization of the corresponding hydroxy and acetoxy derivatives among the reaction products has suggested the intermediacy of such an iodinated precursor.

In these studies, hypoiodite oxidation of 3α-bromo-2β-hydroxy-5α-androstan-17-one (I) in refluxing carbon tetrachloride afforded a 36% yield of 3α-bromo-2β,19-oxido-5α-androstan-17-one (III) after chromatography.[2] In addition to this expected product, three other crystalline products were isolated. Two of these products preceded the major product on chromatography and were characterized as the 16β- and 16α-iodinated derivatives (IV and V). These epimers were obtained in 1.4 and 1.2% yield, respectively. The third product, obtained in 10% yield, followed the major product on chromatography and was identified as the hemiacetal (VI).

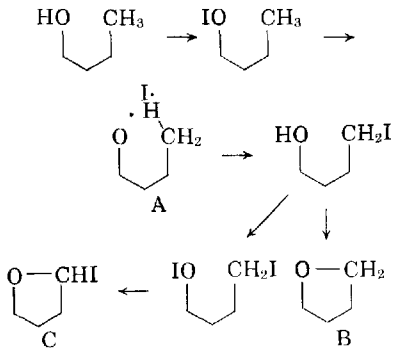
[1] The mechanisms involved in the hypoiodite reaction have been excellently reviewed by Heusler, K., and Kalvoda, J., *Angew. Chem. Intern. Ed.*, **3**, 525(1964).
[2] This product has been isolated in yields as high as 53% under presumably the same conditions (1).



Scheme I

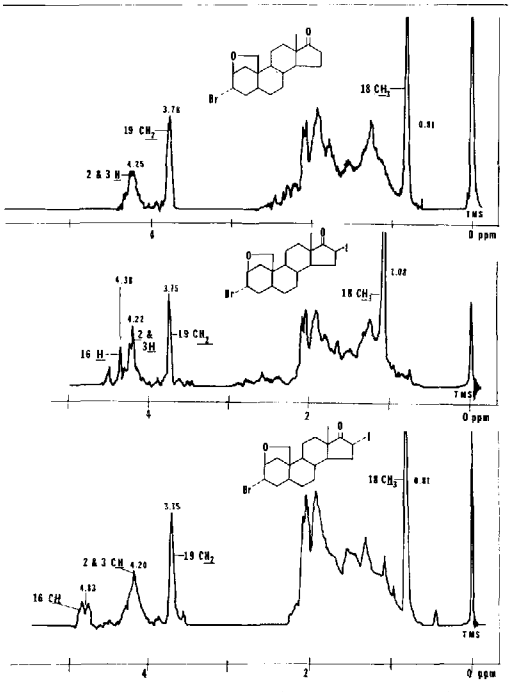


Fig. 1.—NMR spectra of unsubstituted ketone (III) (top) and the epimeric 16β-(IV) (middle), and 16α-iodoketones (V) (bottom).

The hypoiodite oxidation of I was repeated several times under presumably identical conditions using purified reagents and chromatographically pure halohydrins and each time the yield of products and the product composition were found to vary. The 16α-iodo product (V) was isolated in subsequent experiments, but none of the 16β-epimer could be separated. Moreover, in one experiment trituration of the crude reaction product with methanol afforded a high-melting product in 5.5% yield which was subsequently identified as the 19-acetoxy derivative (VII). In this instance none of the corresponding 19-hydroxylated product (VI) could be distinguished after chromatography. In still another experiment, VII was isolated in 5% yield after chromatography of the crude product which would tend to indicate that this ester is not hydrolyzed during chromatography. No explanation can be offered at this time for the variations in product yield and composition.

The structural assignments for the epimeric iodoketones (IV and V) were based on chemical evidence as well as spectral and elemental analysis. The 16α-epimer (V) was synthesized by first converting III to its enol acetate (IX) followed by iodination with iodine and mercuric acetate as described by Mueller and Johns (6). No 16β-isomer (IV) was isolated in this experiment.

The NMR spectra revealed distinct differences between the epimeric iodoketones (see Fig. 1). One epimer displayed a profound downfield shift of 14.5 c.p.s. for the C-18 methyl resonance when compared to the unsubstituted ketone (III). Cross and Beard (7) have noted a similar deshielding of the C-18 methyl protons by 16β-methyl substituted steroids. Moreover, the C-18 methyl resonance is shifted downfield by 19 c.p.s. in 11β-bromo-12-ketosteroids and is essentially unaffected in 11α-bromo-12-ketosteroids (8). On the basis of these findings as well as others indicating that introduction of a new 1:3 nonbonded diaxial interaction with an angular methyl group leads to a noticeable downfield shift in the angular methyl proton frequency (9), the iodine atom in IV was assigned as 16β and that in V is 16α. These assignments also agree with the observed chemical shifts for the 16 proton in each case. The latter appeared as an overlapping doublet at 261 c.p.s. in IV and at 290 c.p.s. in V. Thus, if observations made for steroidal α-haloketones (10) hold for 16-halo-17-ketosteroids, such chemical shifts would indicate that the 16α-hydrogen in IV is pseudoequatorial while the 16β-hydrogen in V is pseudoaxial. A study of the NMR spectra of more readily available 16-iodo-17-ketosteroids is currently in progress.

Although very few studies have been concerned with the ultraviolet absorption of α-iodoketones, Djerassi and co-workers (11) have established that absorption in the 260 mμ region is due to the iodine atom which masks the π-π* absorption band in the 300 mμ region corresponding to the carbonyl

group. They noted, however, that a bathochromic shift of the maximum was apparent for the axially oriented α-iodo-ketosteroids and suggested that this red shift could be used as a spectral criterion for assigning an axial orientation to substituted α-iodocyclohexanones. Ultraviolet analysis of IV and V showed maxima at 275 and 285 mμ, respectively (see Fig. 2). Such results would suggest a pseudoaxial orientation for the iodine atom in V if the above criterion apply. Such an interpretation is contrary to that drawn from the NMR spectra. An attempt to resolve some of these disparities is currently in progress in our laboratories.

In the α-halocyclohexanone series, Jones (12) and Corey (13) were able to distinguish between an axial and equatorial halogen atom by the small or large shift in the carbonyl frequency. In the case reported here, however, no conclusion regarding the conformations of the 16 halogens could be made on the basis of the infrared spectra. Both iodoketones (IV and V) showed carbonyl maxima at 1725 cm.$^{-1}$, the same as for the noniodinated product (III). A similar observation was made by Mueller and Johns in the estrone series (6). These results emphasize the hazards in attempting to translate relationships established in the cyclohexanone series to substituted cyclopentanones.

The structure of VI was readily determined from chemical and spectral evidence. The NMR showed a singlet at 318 c.p.s. which shifted to 390 c.p.s. upon acetylation. This is the expected region for a hemiacetal acetate proton (4, 14) and the downfield shift of 72 c.p.s. corresponds to that observed upon acetylation of secondary alcohols (8). The hemiacetal was readily oxidized with Jones reagent (15) to the corresponding lactone which lacked a proton in the 300–400 c.p.s. region. The configuration of the 19-hydroxyl group remains to be established.

Similar results were obtained upon hypoiodite oxidation of the chlorohydrin (II). The major product was the expected 2β,19-oxide (X) but the corresponding 16α-iodinated (XI) and 19-acetoxylated (XII) derivatives were isolated in low yield by chromatography. Although this reaction has been carried out several times, no 16β-iodinated product has been isolated. (Scheme II.)

EXPERIMENTAL[3]

Hypoiodite Oxidation of 3α-Bromo-2β-hydroxy-5α-androstan-17-one (I).—A mixture of I (21.1 Gm.), lead tetraacetate (78.5 Gm.), and iodine (29.6 Gm.) in carbon tetrachloride (2.15 L.) was stirred under reflux for 8 hr. The reaction mixture was allowed to stand at room temperature for 3 hr. and filtered. The filter cake was washed with methylene chloride until no longer pink. The filtrate was washed with 10% sodium thiosulfate solution (2 × 200 ml.) and water (200 ml.), the layers separated, and the organic phase dried over anhydrous sodium sulfate. Evaporation of the solvent left an orange oil which was dissolved in benzene and adsorbed onto a column of silicic acid (500 Gm.). The column was eluted with benzene, followed by benzene containing increasing concentrations of ethyl acetate. The benzene–ethyl acetate (19:1) eluates afforded two distinct crystalline products. The first product was established to be 3α-bromo-16β-iodo-2β,19-oxido-5α-androstan-17-one (IV, 0.26 Gm.), m.p. 196–198° (from methanol); $\gamma_{max.}$ 1725, 1228, and 1018 cm.$^{-1}$; $\lambda_{max.}$ 275 mμ, log ϵ 2.72; NMR: 63.5 (C-18 methyl), 224 (C-19 proton), 251 (C-2 and C-3 protons, multiplet), and 261 c.p.s. (C-16 proton, overlapping doublet $J_{AX} + J_{BX} = 17$).

Anal.—Calcd. for $C_{19}H_{26}BrIO_2$: C, 46.26; H, 5.31. Found: C, 46.42; H, 5.43.

The other product was characterized as the epimer, 3α-bromo-16α-iodo-2β,19-oxido-5α-androstan-17-one (V, 0.3 Gm.), m.p. 210–212° (from methanol); $\gamma_{max.}$ 1725, 1232, and 645 cm.$^{-1}$; $\lambda_{max.}$ 285 mμ, log ϵ 2.73; NMR: 50 (C-18 methyl), 225 (C-19 proton), 252 (C-2 and C-3 protons, multiplet), and 290 c.p.s. (C-16 proton, overlapping doublet $J_{AX} + J_{BX} = 8$).

Anal.—Calcd. for $C_{19}H_{26}BrIO_2$: C, 46.26; H, 5.31; Br, 16.20; I, 25.73. Found: C, 46.27; H, 5.27; Br, 16.35; I, 25.73.

Further elution with benzene–ethyl acetate (9:1) furnished 3α-bromo-2β,19-oxido-5α-androstan-17-one (III, 7.6 Gm.), m.p. 130–132° (from methanol),

[3] The melting points were taken on a Fisher-Johns apparatus and are corrected. Elemental analyses were performed by Spang Microanalytical Laboratories, Ann Arbor, Mich. Infrared spectra were taken in KBr disks with a Perkin-Elmer 337 spectrophotometer. Ultraviolet spectra were recorded on a Beckman DK2A spectrophotometer in 95% ethanol. The NMR spectra were obtained in $CDCl_3$ with a Varian A-60 spectrometer using tetramethylsilane as the internal standard. The lead tetraacetate used in the experiments was obtained from Arapahoe Chemicals, Inc., and recrystallized from benzene prior to use. The silicic acid used in the column chromatography was Baker and Adamson reagent grade.

undepressed by admixture with an authentic sample (1). Elution with benzene–ethyl acetate (1:1) gave 3α-bromo-19-hydroxy-2β,19-oxido-5α-androstan-17-one (VI, 2.1 Gm.), m.p. 168–170° (from methanol–water); $\gamma_{max.}$ 3440, 1715, and 1012 cm.$^{-1}$; NMR: 52 (C-18 methyl), 249–269 (C-2 and C-3 protons, multiplet), and 318 c.p.s. (C-19 proton).[4]

Anal.—Calcd. for $C_{19}H_{27}BrO_3$: C, 59.53; H, 7.10; Br, 20.85. Found: C, 59.61; H, 7.21; Br, 20.92.

19-Acetoxy-3α-bromo-2β,19-oxido-5α-androstan-17-one (VII).—A solution of VI (10 mg.) in acetic anhydride (0.5 ml.) and pyridine (0.5 ml.) was allowed to stand at room temperature for 23 hr. The solution was added slowly to cold water and the product collected by filtration. Recrystallization from methanol afforded pure VII, m.p. 235–237°; $\gamma_{max.}$ 1725, 1219, 1016, and 1009 cm.$^{-1}$; NMR: 50 (C-18 methyl), 130 (acetate methyl), 259–265 (C-2 and C-3 protons, multiplet), and 390 c.p.s. (C-19 proton).

Anal.—Calcd. for $C_{21}H_{29}BrO_4$: C, 59.30; H, 6.87. Found: C, 59.13; H, 6.86.

3α-Bromo-2β,19-oxido-19-oxo-5α-androstan-17-one (VIII).—The hemiacetal (VI, 14 mg.) was dissolved in acetone (2 ml.) and the solution cooled to 0°. An 8 *N* chromic acid solution (15) (0.1 ml.) was added and the mixture stirred for several minutes. The excess oxidant was decomposed with a few drops of isopropyl alcohol. The solution was diluted with water and the crystalline product collected by filtration. The crude product (12 mg.), m.p. 192–194°, was recrystallized from methanol to afford an analytical sample, m.p. 198–200°; $[\alpha]_D^{25}$ + 92°; $\gamma_{max.}$ 1750, 1725, and 715 cm.$^{-1}$; NMR: 57 (C-18 methyl), 275–287 (C-2 proton multiplet), 257–268 c.p.s. (C-3 proton, multiplet).

Anal.—Calcd. for $C_{19}H_{25}BrO_3$: C, 59.85; H, 6.61. Found: C, 59.88; H, 6.56.

3α-Bromo-2β,19-oxido-5α-androst-16-en-17-ol Acetate (IX).—A solution of III (0.5 Gm.) and *p*-toluene sulfonic acid (75 mg.) in isopropenyl acetate (10 ml.) was slowly distilled for 4 hr. and 5 ml. of distillate collected. Another portion of isopropenyl acetate (10 ml.) was added along with sodium bicarbonate (0.5 Gm.). The solvent was removed by distillation and the remaining traces removed *in vacuo*. The residue was extracted with ether which was subsequently washed with an ice-cold saturated salt solution and dried over anhydrous sodium sulfate. The solvent was removed *in vacuo* and the brown residue recrystallized from methanol. This afforded pure IX (0.1 Gm.), m.p. 150–151°.

Anal.—Calcd. for $C_{21}H_{29}BrO_3$: C, 61.61; H, 7.14. Found: C, 61.51; H, 7.20.

Iodination of IX.—A solution of IX (55 mg.) and mercuric acetate (9 mg.) in acetic acid (3 ml.) was cooled in an ice bath. A solution of iodine (50 mg.) in acetic acid (3 ml.) was added dropwise with stirring. The iodine was decolorized after adding a few drops, but then the color persisted. The brown solution was poured into water, and the precipitate collected by filtration. The crude product was washed with 10% sodium thiosulfate solution, water, and air dried. Recrystallization from methanol gave V (20 mg.), m.p. 205–207°, undepressed by admixture with the product isolated above.

Hypoiodite Oxidation of 3α-Chloro-2β-hydroxy-5α-androstan-17-one (II).—Oxidation of II (3.3 Gm.) with lead tetraacetate (13.6 Gm.) and iodine (5.2 Gm.) in refluxing carbon tetrachloride (340 ml.) was carried out as described above. The resulting orange oil was adsorbed onto a column of silicic acid (100 Gm.) and eluted with benzene. This was followed by benzene containing increasing concentrations of ethyl acetate. Fractions obtained by elution with benzene–ethyl acetate (19:1) gave 3α-chloro-16α-iodo-2β,19-oxido-5α-androstan-17-one (0.1 Gm.), m.p. 197–200° dec. Recrystallization from methanol afforded pure XI, m.p. 212–214° dec.; $\gamma_{max.}$ 1725, 1235, and 643 cm.$^{-1}$; NMR: 50 (18-methyl), 224 and 227 (C-19 protons, inner peaks of unresolved quartet), 240–265 (C-2 and C-3 protons), and 283–300 c.p.s. (16β-proton).

Anal.—Calcd. for $C_{19}H_{26}ClIO_2$: C, 50.85; H, 5.84. Found: C, 50.97; H, 5.94.

Further elution with benzene–ethyl acetate (9:1) gave a crude crystalline product (1.7 Gm.), m.p. 120–128°. Recrystallization from methanol gave a high-melting compound (0.2 Gm.), m.p. 235–236°. Recrystallization of this product from methanol gave a pure sample characterized as 19-acetoxy-3α-chloro-2β,19-oxido-5α-androstan-17-one (XII), m.p. 243–244°; $\gamma_{max.}$ 1735, 1710, and 1235 cm.$^{-1}$; NMR: 49 (C-18 methyl), 128 (acetate methyl), 252–257 (C-2 and C-3 protons) and 384 c.p.s. (C-19 proton).

Anal.—Calcd. for $C_{21}H_{29}ClO_4$: C, 66.21; H, 7.67. Found: C, 66.00; H, 7.64.

Concentration of the mother liquor afforded a crystalline product (0.4 Gm.) shown to be identical with authentic 3α-chloro-2β,19-oxido-5α-androstan-17-one (X)[5] described previously (1).

[4] In another experiment involving hypoiodite oxidation of 36.3 Gm. of I, trituration of the crude reaction product with methanol afforded a crystalline product (1.7 Gm.) which upon recrystallization from methanol was found to be the hemiacetal acetate (VII), identical with that obtained by acetylation of VI.

[5] In another experiment, oxidation of II (3.7 Gm.) gave X (1.9 Gm.) and XII (0.2 Gm.), but no XI could be isolated.

Quantitative Determination of Ethinyl Estradiol by Gas Chromatography, and a Comparison of Gas Chromatographic and U.S.P. Procedures

By O. D. BOUGHTON, RHYS BRYANT, W. J. LUDWIG, and D. L. TIMMA

Ethinyl estradiol was extracted from other tablet or granulation excipients by a modified U.S.P. procedure. It was then quantitatively determined by gas chromatography of its trimethylsilyl ether. Estrone was used as an internal standard. A comparison of this gas chromatographic method with the U.S.P. method indicated that, in general, the precision of the U.S.P. method was superior to that of the gas chromatographic method.

THE ACCURATE analytical determination of estrogenic and progestational substances is of interest to all pharmaceutical manufacturers, especially those concerned with the now well-established oral contraceptives. Analysis of the progestational agent is usually much easier than analysis of the estrogen, because of the necessity for a larger amount of the former in tablets.

The authors' main interest has been in the analysis of the estrogen ethinyl estradiol. The accepted standard method for assay of this material has been that of the U.S.P. XVII (1). This method is time-consuming and is nonspecific in that it may be used for any estrogen characterized by a phenolic steroidal A ring (2).

Subsequently, alternative methods using gas chromatography have been applied to the problem. Schulz (3) reported the estimation of ethinyl estradiol-3-methyl ether in the presence of other steroids by gas chromatography. More recently, Talmage, Penner, and Geller (4) reported a gas chromatographic technique for determination of ethinyl estradiol in sesame oil solutions and solid dosage forms. The ethinyl estradiol appears to have been uncontaminated with other steroids and was estimated as its acetate.

A quantitative gas chromatographic method for determination of ethinyl estradiol in which the active ingredient is ethinyl estradiol alone, or ethinyl estradiol plus 17β-hydroxy-6α-methyl-17-(1-propynyl)-androst-4-en-3-one (dimethisterone) has been developed.

A comparison of the gas chromatographic method *versus* the U.S.P. method to gain insight into the precision of the two methods has also been made. (No comparison of the two methods has been made until now, although Talmage, Penner, and Geller stated (4), with no supporting data, that the U.S.P. method was no more accurate than $\pm 10\%$.)

The method of Talmage *et al.* depends on initial preparation of the 3-acetate of ethinyl estradiol, and subsequent gas chromatography of this compound. In attempting to apply this method to the problems reported here, two distinct disadvantages in the method were discovered. Preparation of the acetate involves the use of acetic anhydride which must subsequently be removed by evaporation at an elevated temperature. Even under the conditions stated in the original paper (evaporation under nitrogen on the steam bath) (4), this step is time consuming and introduces a possible source of error. Second, the authors wished to analyze for at least 50% less ethinyl estradiol than Talmage, Penner, and Geller had analyzed, and for our purposes the acetate-derivative did not give sufficient response on the chromatograph.

In this method the ethinyl estradiol, after extraction, is converted to its trimethylsilyl ether and chromatographed. Advantages of the use of the trimethylsilyl ether are that it is readily prepared, quantitatively, at room temperature, and is sufficiently volatile to give an excellent chromatographic response. (Quantities of ethinyl estradiol as low as 1 mcg. after trimethylsilylation are readily detectable.) Details of the procedure are presented under *Experimental.*

The comparison of the gas chromatographic and U.S.P. methods of analysis took the form of two experiments. In experiment *A*, the authors took a small amount of granulation and further homogenized it using a mortar and pestle. It was then assayed 10 times by both U.S.P. (1) and gas chromatographic (GLC) methods. In experiment *B* the authors allowed conditions to approach those usually found in analysis of a production batch, when the possibility of a certain amount of inhomogeneity cannot be ruled out. Both tablets and granulations were

Received March 14, 1966, from Mead Johnson Research Center, Mead Johnson and Co., Evansville, Ind. 47721.
Accepted for publication June 1, 1966.
The authors thank Mrs. Nancy Wagoner for technical assistance and Mr. M. C. Schwartz for statistical analyses.

analyzed 10 times by each method. The results of these experiments were then analyzed statistically in order to obtain the comparisons required.

GAS CHROMATOGRAPHIC METHOD

Experimental

Apparatus.—Gas chromatograph, F and M model 609, with flame ionization detector. Aerograph model 471 digital integrator.

Column.—Stainless steel column (6 ft. × 1/4 in.) packed with 3.8% SE-30 on Anakrom ABS, 60/70 mesh. The liquid phase was deposited by the filtration technique (5) from a 2% solution of SE-30 in methylene chloride. The column was "no flow" preconditioned (no carrier gas flowing) for 0.5 hr. at 325°. The carrier gas used was nitrogen.

Chromatography Conditions.—Column temperature, 260°; injection port temperature, 285°; detector temperature, 265°; hydrogen flow, 7; air flow, 7; nitrogen flow, 9 (these flows may vary according to the instrument); attenuation, 800×.

Standard Ethinyl Estradiol Solution.—*Solution A*.—A 100.0-mg. quantity of reference standard ethinyl estradiol U.S.P. was dissolved in 100 ml. absolute ethanol.

Solution B.—A 10.0-ml. quantity of solution *A* was diluted to 100 ml. with absolute ethanol. (The ethanolic solutions are stable and require no special precautions.)

Solution C.—A 5.0-ml. quantity of solution *B* was diluted to 100 ml. with chloroform. Twenty milliliters of standard solution *C* contained 0.1 mg. of ethinyl estradiol. Solution *C* was prepared fresh daily.

Internal Standard (Estrone) Solution.—*Solution A*.—A 150.0-mg. quantity of estrone U.S.P. was dissolved in 100 ml. absolute ethanol.

Solution B.—A 5.0-ml. quantity of solution *A* was diluted to 100 ml. with absolute ethanol. (The ethanol solutions are stable and require no special precautions.)

Solution C.—A 10.0-ml. quantity of solution *B* was diluted to 100 ml. with chloroform. Ten milliliters of solution *C* contained 0.075 mg. estrone. Solution *C* was prepared fresh daily.

Etherification Reagents.—In a screw-cap vial was placed a mixture[1] of anhydrous pyridine[2] (4.5 ml.), hexamethyldisilazane[3] (1.5 ml.), and anhydrous trimethylchlorosilane[3] (0.5 ml.). No purification of reagents was necessary. The tube was capped tightly and the contents mixed thoroughly. It is essential to exclude atmospheric or other moisture, which destroys the reagent. The etherification reagent was prepared fresh daily.

Extraction Procedure.—An amount of tablet or granulation equivalent to 0.1 mg. of ethinyl estradiol was placed in a 125-ml. separator containing sulfuric acid (30 ml., 1 *N*), and the suspension extracted with chloroform (3 × 20 ml.). After filtration through a small quantity of cotton, the combined chloroform solution was evaporated to low bulk (about 5 ml.). Petroleum ether (25 ml., b.p. 30–60°) was added to the hot solution. It was cooled to room temperature and transferred to a 125-ml. separator with the aid of several small portions of petroleum ether. The solution was extracted with 10% aqueous sodium hydroxide (3 × 10 ml.). The extract was acidified with dilute sulfuric acid (6 ml., 1:1 v/v) and cooled. The acid solution was extracted with chloroform (2 × 20 ml.), which was passed through a column (10 × 1.2 cm.) of anhydrous sodium sulfate. The column was rinsed with chloroform (1 × 10 ml.). All column eluates were combined, 10.0 ml. of internal standard solution (estrone) was added, and the solution was evaporated to dryness. Chloroform (1–2 ml.) was added to the hot residue. The resulting solution, after cooling, was transferred to a 1-dr. screw-cap vial and evaporated to dryness under a gentle air stream. It was finally dried at 80° for 5 min. *in vacuo*.

Etherification Step.—To the cooled ethinyl estradiol extract in the vial was added 10 drops (0.1 ml.) of etherification reagent. The vial was tightly stoppered and the contents thoroughly mixed. After 30–60 min. excess reagent was evaporated with a gentle air stream (about 15 min.). (The reaction time was varied from 15 min. to 60 min. with no effect. The reaction is obviously complete in less than 15 min. A lapse-time of 30–60 min. was chosen arbitrarily to allow simultaneous assay of a number of samples.) Immediately prior to chromatography, chloroform (10 drops) was added and the resulting solution mixed thoroughly. This solution (5–6 μl.) was injected into the chromatograph. Duplicate injections of each sample are to be preferred.

Standard.—A standard was carried through the procedure with each set of samples. Twenty milliliters of standard ethinyl estradiol solution was shaken with dilute sulfuric acid (30 ml., 1 *N*). The chloroform solution was drained through cotton, and the sulfuric acid extracted with chloroform (2 × 20 ml.). The combined chloroform solution was then treated as for the samples.

Calculation.—The peaks due to estrone and ethinyl estradiol have retention times of approximately 4.5 min. and 7 min., respectively. The ratio (R) of the peak areas is given by:

$$R = \frac{\text{area of ethinyl estradiol peak}}{\text{area of estrone peak}}$$

For tablets containing 0.1 mg. ethinyl estradiol:

$$\text{mg. of ethinyl estradiol} = \frac{R \text{ for sample}}{R \text{ for standard}} \times 0.100$$

For granulations containing 0.04% ethinyl estradiol:

$$\%\ \text{ethinyl estradiol} = \frac{R \text{ for sample}}{R \text{ for standard}} \times 0.0400$$

RESULTS

Reproducibility of the Etherification Step.—Four aliquots of a standard solution of ethinyl estradiol, after addition of estrone, were etherified and each aliquot chromatographed in duplicate.

[1] This mixture is available commercially from Applied Science Laboratories, Inc.

[2] Analytical reagent grade pyridine supplied by Mallinckrodt was used. It was dried with molecular sieve, type 4A.

[3] Hexamethyldisilazane and trimethylchlorosilane were obtained from Peninsular Chemresearch, Inc.

Std. 4	1.720	

TABLE II.—STANDARD THROUGH EXTRACTION PROCEDURE[a]

	R	Av. R	% Recovery
Sample 1	1.710	1.685	99.4
Sample 1	1.660		
Sample 2	1.690	1.710	101
Sample 2	1.730		
Sample 3	1.720	1.670	98.5
Sample 3	1.620		
Sample 4	1.695	1.730	102
Sample 4	1.765		
Sample 5	1.670	1.680	99.1
Sample 5	1.690		

Av. recovery = 100%, $\sigma = \pm 1.5$

[a] All samples were aliquots of the same standard ethinyl estradiol solution.

Table I incorporates the results. The average R value was 1.695, $\sigma = \pm 0.014$.

Reproducibility of the Extraction.—This was checked (*a*) by taking a known quantity of ethinyl estradiol through the extraction procedure; (*b*) by adding a known quantity of ethinyl estradiol to the tablet placebo (containing all excipients including dimethisterone, but without the ethinyl estradiol) and taking this through the procedure; and (*c*) by taking the placebo through the procedure, and then adding a known quantity of ethinyl estradiol. The samples were then etherified and chromatographed in the normal manner. The results were compared with the average R value (1.695), obtained by chromatography of the standards which had not been taken through the method, to give the percentage recovery. (See Tables II–IV.)

Reproducibility of the Method.—Table V summarizes the results obtained when 4 separate aliquots of the same granulation (containing only ethinyl estradiol as active ingredient) were taken completely through the method. The average percentage of ethinyl estradiol was 0.0404, $\sigma = \pm 0.0025$.

Table VI gives similar results for 5 aliquots of another granulation, which contained both ethinyl estradiol and dimethisterone. In this case, the percentage of ethinyl estradiol was found to be 0.0412, $\sigma = \pm 0.0018$.

General Applicability.— Some results of the applicability of the method to tablets and granulations are included in Table VII (EE = formulations containing ethinyl estradiol; MEE = formulations containing both dimethisterone and ethinyl estradiol).

COMPARISON OF THE METHODS

Experiment *A*

Samples.—Two granulations were used, one containing ethinyl estradiol as sole active ingredient (EE granulation); the other containing both dimethisterone and ethinyl estradiol (DMEE granulation).

Preparation of Samples.—A small sample (11 Gm.) of the EE granulation was finely ground in a mortar. (The sample size was restricted in order to ensure as high a degree of homogeneity as

possible.) All 10 assays by the U.S.P. method and all 10 assays by the gas chromatographic method were done on this 11-Gm. sample.

An 11-Gm. sample of DMEE granulation was treated similarly, and all 20 assays performed on it.

Method of Assay.—*a.*—The U.S.P. method was carried out by a single operator experienced with the method using 0.500 Gm. of sample for each assay. Not more than four assays (two EE and two DMEE) were undertaken on the same day.

b.—The gas chromatographic method was performed by a single operator experienced with the method using 0.250 Gm. of sample for each assay. Again, not more than four assays were done on a single day.

Results.—The results obtained in experiment *A* are shown in Table VIII. (Theoretically, granulations should contain 0.040% ethinyl estradiol.)

Statistical Analysis.—The results of the statistical calculations are included in Table IX.

Experiment *B*

Samples.—Four samples were used: 1, EE granulation; 2, DMEE granulation; 3, EE tablets; and 4, DMEE tablets.

Preparation of Samples.—*a.*—From the batch of EE tablets, 200 tablets were retained as the stock of tablets. From this stock each day, 20 tablets were taken and pulverized in a mortar; 0.500 Gm. of this sample was used for the U.S.P. method, and 0.250 Gm. of the sample was used for the gas chromatographic method. A separate lot of 20 tablets was used each day, and 0.500 and 0.250-Gm. samples removed from it.

A stock of DMEE tablets was treated in exactly the same way.

b. Granulations.—From the batch of EE granulation, 160 Gm. was removed. It was passed through a sample splitter to give 2 × 80-Gm. portions. Each 80-Gm. portion was passed separately through the sample splitter to yield 4 × 40-Gm. portions. Each 40-Gm. portion was similarly split, and so on, with each subsequent 20-Gm. and 10-Gm. portion until 32 × 5-Gm. portions were obtained. Of these 32 × 5-Gm. portions, 10 × 5 Gm. were used for the current experiment.

Each day one of the 5-Gm. portions was taken and again pulverized using a mortar and pestle; 0.500 Gm. was taken for the U.S.P. assay, and 0.250 Gm. was taken for the gas chromatographic assay.

The DMEE granulation was treated in the same way.

Method of Assay.—The U.S.P. method was performed by a single operator experienced with the method. Each day for a total of 10 days, one each of the EE tablet, DMEE tablet, EE granulation, and DMEE granulation was assayed.

The gas chromatographic method was performed by a single experienced operator. Each day, for a total of 10 days, one each of the EE and DMEE tablets, and EE and DMEE granulations was assayed.

Results.—The results obtained in experiment *B* are summarized in Table X. Granulations are quoted as percentages; tablets as mg./tablet. (Theoretical content of granulations is 0.040%; and of tablets 0.100 mg.)

Statistical Analysis.—The average values obtained and the variance (σ^2) and standard deviations (σ) of the methods are reported in Tables XI (for granulations) and XII (for tablets).

DISCUSSION

The Gas Chromatographic Method.—Dimethisterone had a retention time of 12 min. and in no way interfered with the other steroid peaks. It was therefore unnecessary to extract the ethinyl estradiol completely from dimethisterone, as is required by the U.S.P. XVII procedure.

The use of a short column of sodium sulfate helped to remove any trace of acid which might be occluded in the chloroform and subsequently interfere with the etherification step.

Comparison of the Methods.—In all cases, the standard deviation (as per cent) is lower for the U.S.P. method than for the gas chromatographic method. While it is also obvious that the average value obtained differs between the methods, statistically (using the *t* test) only in the case of the DMEE granulation (experiment *A*) is this significant. Also, only in the case of the DMEE granulation (experiment *B*), and possibly the EE granulation (experiment *B*), can any significance be attached to the difference in variances (*F* test).

SUMMARY

The Gas Chromatographic Method.—Ethinyl estradiol was extracted into chloroform from an acid suspension and separated from dimethisterone by alkaline extraction. With estrone as an internal standard, the ethinyl estradiol was converted to its trimethylsilyl ether and this was chromatographed on a SE-30 column.

Evaluation of the results contained in Table VII shows that, based on an expected value of 0.0400% ethinyl estradiol, the average value found was 0.039%, σ = ±0.002. Based on an expected value of 0.100 mg./250 mg. tablet, the average found value was 0.098 mg., σ = ±0.002.

The Comparison of Methods.—Under the conditions of our comparisons, the U.S.P. method in all cases showed a standard deviation lower than that of the gas chromatographic method. The over-all average standard deviation for the U.S.P. method was ±5.5% and for the GLC method ±8.6%. Although the U.S.P. method would appear to give a better precision, in most cases the difference in variances is not statistically significant.

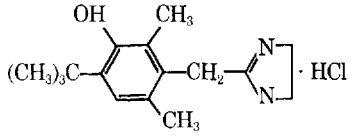
Qualitative and Quantitative Tests for Oxymetazoline Hydrochloride

Provisional, unofficial monographs are developed by the Drug Standards Laboratory, in cooperation with the manufacturers of the drug concerned, for publication in the *Journal of Pharmaceutical Sciences*. The ready availability of this information affords discriminating medical and pharmaceutical practitioners with an added basis for confidence in the quality of new drug products generally, and of those covered by the monographs particularly. Such monographs will appear on drugs representing new chemical entities for which suitable identity tests and assay procedures are not available in the published literature. The purity and assay limits reported for the drugs and their dosage forms are based on observations made on samples representative of commercial production and are considered to be reasonable within expected analytical and manufacturing variation.

6-TERT-BUTYL-3-(2-IMIDAZOLIN-2-YLMETHYL)-2,4-DIMETHYL-PHENOL HYDROCHLORIDE; $C_{16}H_{24}N_2O \cdot HCl$; mol. wt. 296.84. The structural formula of oxymetazoline hydrochloride may be represented as



Physical Properties.—Oxymetazoline hydrochloride occurs as a white to nearly white, fine crystalline powder, m.p. about 300° dec., U.S.P. class I. It is soluble in water, freely soluble in alcohol, and insoluble in ether and in chloroform.

Identity Tests.—Dissolve about 2 mg. of oxymetazoline hydrochloride in 1 ml. of water, add 0.5 ml. of sodium nitroprusside solution (1 in 100), 2 drops of sodium hydroxide solution (15 in 100), mix, and allow to stand 10 min. Add 1 ml. of sodium bicarbonate solution (5 in 100) and allow to stand 10 min.: a violet color is produced.

A 1 in 20,000 solution of oxymetazoline hydrochloride in water exhibits an ultraviolet maximum at about 279 mμ [absorptivity (a) about 6.0] and a minimum at about 252 mμ. The spectrum is shown in Fig. 1.

The infrared spectrum of a 0.5% dispersion of oxymetazoline hydrochloride in potassium bromide, in a disk of about 0.82 mm. thickness, is shown in Fig. 2.

Dissolve about 50 mg. of oxymetazoline hydrochloride in 3 ml. of water, add ammonia T.S. until basic, and filter. Acidify the filtrate with diluted nitric acid and add 1 ml. of silver nitrate T.S.: a white precipitate forms, which is insoluble in diluted nitric acid, but soluble in ammonia T.S. (presence of chloride).

Purity Tests.—Dry about 1 Gm. of oxymetazoline hydrochloride, accurately weighed, at 105° to con-

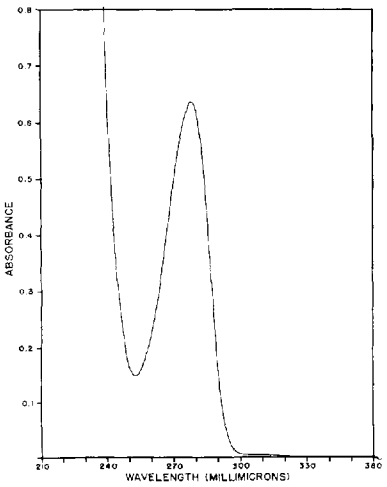


Fig. 1.—Ultraviolet absorption spectrum of oxymetazoline hydrochloride in water (100 mcg./ml.); Beckman model DK-2A spectrophotometer.

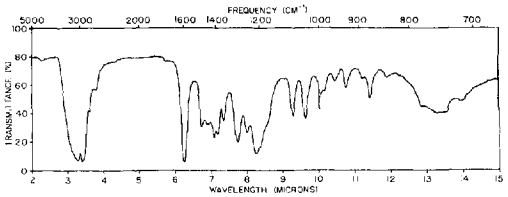

Fig. 2.—Infrared spectrum of oxymetazoline hydrochloride in potassium bromide disk (0.5%); Perkin-Elmer model 21 spectrophotometer, sodium chloride prism.

Received March 3, 1966, from the Drug Standards Laboratory, AMERICAN PHARMACEUTICAL ASSOCIATION FOUNDATION, Washington, D. C. 20037.

Accepted for publication June 10, 1966.

The Schering Corp., Bloomfield, N. J., has cooperated by furnishing samples and data to aid in the development and preparation of this monograph.

stant weight (about 3 hr.): it loses not more than 0.5% of its weight.

Char about 1 Gm. of oxymetazoline hydrochloride, accurately weighed, cool the residue, add 1 ml. of sulfuric acid, heat cautiously until evolution of sulfur trioxide ceases, ignite, cool, and weigh: the residue does not exceed 0.1%. Retain the residue for the heavy metals test.

Dissolve the sulfated ash obtained from 1 Gm. of oxymetazoline hydrochloride in a small volume of hot nitric acid and evaporate to dryness on a steam bath. Dissolve the residue in 2 ml. of diluted acetic acid, dilute to 25 ml. with water, and determine the heavy metals content of this solution by the U.S.P. heavy metals test, method I: the heavy metals limit for oxymetazoline hydrochloride is 10 p.p.m.

Assay.—Transfer about 500 mg. of oxymetazoline hydrochloride, accurately weighed, to a tall-form 200-ml. beaker and dissolve in 50 ml. of glacial acetic acid. Add 10 ml. of mercuric acetate T.S. and titrate potentiometrically with 0.1 *N* acetous perchloric acid. Alternatively, add 2 drops of crystal violet T.S. and titrate to an emerald-green end point.[1] Each milliliter of 0.1 *N* perchloric acid is equivalent to 29.68 mg. of $C_{16}H_{24}N_2O.HCl$. The amount of oxymetazoline hydrochloride found is not less than 98.5% and not more than 101.5%.

DOSAGE FORMS OF OXYMETAZOLINE HYDROCHLORIDE

Oxymetazoline Hydrochloride Nasal Solution

Identity Tests.—Transfer 2 ml. of oxymetazoline hydrochloride nasal solution to a test tube containing 2 ml. of alcohol, add 0.5 ml. of sodium nitroprusside solution (1 in 100), 2 drops of sodium hydroxide solution (15 in 100), mix, and allow to stand 10 min. Add 1 ml. of sodium bicarbonate solution (5 in 100), adjust the pH to about 8 with diluted hydrochloric acid, and allow to stand 10 min.: a violet color is produced.

Assay.—Transfer to a separator an accurately measured volume of oxymetazoline hydrochloride nasal solution equivalent to 5 mg. of oxymetazoline hydrochloride. Add 25 ml. of saturated sodium borate solution and extract with four 25-ml. portions of chloroform, combining the extracts in a 250-ml. separator. Extract the chloroform phase with two 20-ml. portions of 0.5 *N* hydrochloric acid, combine the acid extracts in a 100-ml. volumetric flask, dilute with the acid to volume, and mix. Concomitantly determine the absorbance of this solution and of a standard solution of oxymetazoline hydrochloride, in the same medium, at a concentration of about 50 mcg./ml., in 1-cm. cells, at the maximum at about 279 mμ, with a suitable spectrophotometer, using 0.5 *N* hydrochloric acid as the blank. Calculate the quantity, in mg., of $C_{16}H_{24}N_2O \cdot HCl$ in each ml. of the nasal solution taken, by the formula $0.1 \times (C/V) \times (A_u/A_s)$, in which C is the exact concentration of the standard solution, in mcg./ml., V is the volume, in ml., of the nasal solution taken, A_u is the absorbance of the sample solution, and A_s is the absorbance of the oxymetazoline hydrochloride standard solution. The amount of oxymetazoline hydrochloride found is not less than 95.0% and not more than 115.0% of the labeled amount.

DISCUSSION

U.S.P. and N.F. terminology for solubility, melting range, reagents, etc., has been used wherever feasible.

Oxymetazoline hydrochloride,[2] synthesized by Fruhstorfer and Mueller-Calgan (1), is a nasal decongestant for the treatment of a wide variety of allergic and infectious disorders, including rhinitis, nasopharyngitis, and sinusitis.

Identity Tests.—The absorbance maximum for oxymetazoline hydrochloride in water or acid solution is about 279 mμ. A bathochromic displacement, typical for phenols, is noted by an absorbance maximum at about 302 mμ in 0.5 *N* NaOH with a calculated absorptivity of about 15.3.

Quantitative Methods.—The potentiometric nonaqueous titration for oxymetazoline hydrochloride was conducted using glass *versus* calomel electrodes. The calomel electrode was modified by replacing the aqueous potassium chloride salt bridge with 0.02 *N* lithium chloride in glacial acetic acid. The indicator end point is sharp and corresponds to a 100–150-mv. break in the potentiometric titration curve obtained under identical conditions. An average value of 99.9 ± 0.4%[3] was obtained for oxymetazoline hydrochloride by this titrimetric method.

Analysis of commercial oxymetazoline hydrochloride nasal solution by the spectrophotometric method gave an average value of 110.7 ± 0.9%[3] of the labeled amount. The suitability of the procedure was verified by the quantitative recovery of a standard oxymetazoline hydrochloride solution carried through the extractive steps as included for the nasal solution.

Compressed Coated Tablets II

Influence of Size Distribution of Coating Granulation on Weight Uniformity of Tablets

By LEON LACHMAN, HANNA D. SYLWESTROWICZ, and PETER P. SPEISER*

Compressed coated tablets were prepared on a Manesty machine from four granulations of the same formulation, each having a granule of different size as its major component. The effect of granulation size on the weight variability of tablets was determined. The coating granulation sizes which give minimum and maximum weight variability are illustrated and are shown to be reproducible. The relationship that exists between weight variation and core centration is discussed.

IT IS EVIDENT from the numerous compressed coated tablets on the market today that the principle of coating tablets by compression has met wide acceptance in the pharmaceutical industry.

Literature reports (1–9) appearing on the subject of dry coating are concerned with (*a*) the physical properties required for core and coating granulation to give suitable compressed coated tablets, (*b*) coating and core formulations adequate for use in compression coating, (*c*) formulations concerned with disguising a bitter taste, eliminating discoloration, and improving the stability of an active ingredient, (*d*) formulations for imparting sustained-action properties to a drug, and (*e*) forming enteric-coated tablets. However, studies relative to the factors influencing the quality of the compressed coated tablets appear to be lacking. Accordingly, investigations along these lines were initiated in our laboratories. An initial report (10) from these studies was concerned with the factors influencing core centration and methods of evaluating same.

In this report, it will be shown that coating granulation size influences the weight variability of compressed coated tablets prepared on the Manesty Dry Cota machine. The relationship that exists between the weight variation results and the core centration data presented in an earlier report is discussed. The utility of these evaluation techniques to determine the coating granulation size for a particular formula compressed coated tablet to give optimal centration and weight uniformity is illustrated.

EXPERIMENTAL

The Manesty Dry Cota shown in Fig. 1 basically consists of two rotary tablet presses coupled by a single drive shaft and a special transfer device in such a manner that core tablets can be compressed and coated in one continuous cycle.

Core Granulation.—The formula and procedure of preparation of this core granulation have been described in a previous study (10). The formula is as follows:

Material and Formula	
Lactose U.S.P.	10.000 Kg.
Wheat starch	2.750
Aerosil compositum[1]	0.750
Gelatin U.S.P.	0.250
Stearic acid, spray dried	0.625
Charcoal	0.125
Talcum U.S.P.	0.500
Purified water	*q.s.*

The sieve analysis for a representative sample of this formulation is given in Table I.

Coating Granulation.—The formula and procedure of preparation of this coating granulation have been described in an earlier report (10). The formula is as follows:

Material and Formula	
Lactose U.S.P.	16.000 Kg.
Aerosil compositum	1.500
Gelatin U.S.P.	0.500
Wheat starch	2.500
Arrowroot starch	2.500
Talcum U.S.P.	1.000
Stearic acid, spray dried	1.000
Purified water	*q.s.*

The above granulation was fractionated through screens to give four granulations of different size

[1] Composed of 85% colloidal silica and 15% hydrolyzed starch.

Fig. 1.—Photograph illustrating the Manesty Dry-Cota machine.

distribution, each one having a different size granule as its major component. The sieve analyses for these four granulations are presented in Table II. In an earlier study concerned with core centration, granulation fraction 12 was numbered 8, and granulation fraction 20 was numbered 35.

Preparation of Compressed Coated Tablets on Manesty Dry Cota.—The compressed coated tablets were prepared on the Manesty Dry Cota model 350 at a rate of 18,000 tablets/hr. The cores weighed 150 mg., were 7 mm. in diameter (0.276 in.), and had a radius of curvature of 13 mm. The coated tablets weighed 400 mg., were 10 mm. in diameter (0.394 in.), and had a radius of curvature of 18 mm.

Influence of Coating Granulation Size Distribution on Weight Uniformity.—By varying the size distribution of the coating granulation and maintaining the size of the core granulation constant, the influence of coating granulation on tablet weight uniformity was investigated. Tablets were compressed for 1 hr. with each of the four granulations. The Manesty machine was regulated for tablet weight uniformity at the start of the hour's run. Then 100 tablets were collected initially and every 10 min. thereafter during the hour without adjusting the machine. This resulted in a collection of seven samples of 100 tablets each for each of the four granulations. This experiment was repeated one-half year later to determine the reproducibility of the data. In the first experiment, 15 tablets were taken at random from each of the seven samples of 100 tablets; and for the second experiment, 10 tablets were taken at random from each of the second set of seven samples of 100 tablets. The tablets in each of these subsamples were weighed individually on an analytical balance and the weights analyzed statistically. Therefore, the set of data from the first experiment consisted of 28 samples of 15 tablets, and the set of data from the second experiment consisted of 28 samples of 10 tablets.

Table I.—Sieve Analysis of Core Granulation

Sieve No.	On Screen, %
8	60.5
12	34.5
20	4.0
30	0.5
50	0.5

Statistical Analysis of Data.—For the samples of tablets taken at the seven time periods for the four granulations in each experiment, the means and standard deviations of tablet weights were computed. The sample means at the various time periods will be hereafter called "time-means."

To permit a comparison of the variabilities "between time-means" and the variabilities "within time-means" of the tablets produced from the four coating granulations, a simple manner of rating these variabilities is provided.

An *Index of Variability* was calculated to describe the variations that exist "between time-means," and an *average variance* for 1 hr. of machine operation was used to describe the variability which exists "within time-means." Both measures of variability are based on an analysis of variance on individual tablet weights of each granulation. The indices are provided by "between time-means" variance components, and the average variances are provided by residual terms of analysis of variance (Table V). The homogeneity of sample variances (seven time samples of two experiments = 14 variances for each granulation) was checked by Bartlett's test (11).

RESULTS AND DISCUSSION

It should be noted that the estimations of tablet weight variability prepared from the four different granulation fractions of the same formulation was based on data obtained from compressed coated tablets. The variance of coated tablets equals the variance of core plus the variance of coating plus twice the covariance of core and coating expressed as follows:

$$V_t = V_c + V_{ct} + 2\,Cov_{c \times ct} \qquad \text{(Eq. 1)}$$

where V_t = variance of coated tablets; V_c = variance of core; V_{ct} = variance of coating; and $Cov_{c \times ct}$ = covariance of core and coating.

A preliminary study on 50 core tablets prepared from the core granulation used for all the compressed coated tablets in the first experiment indicated that

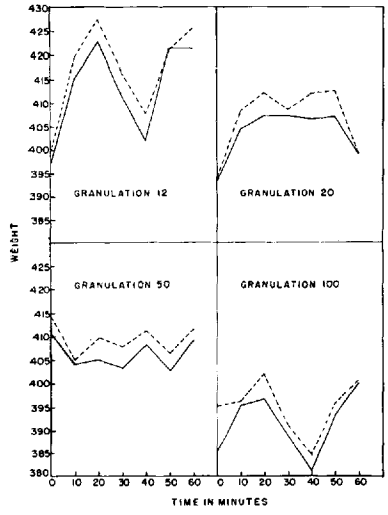

Fig. 2.—Means of tablet weights at 10-min. intervals for 1 hr. tablet press operation. Key: ————, experiment I; ----------, experiment II.

the variance of core (V_c) is very small relative to the variance of coated tablets (V_t). The absolute value of covariance of core and coating ($Cov_{c \times ct}$) is at most the square root of the product of variance of core (V_c) and variance of coating (V_{ct}) (Eq. 2)

$$| Cov_{c \times ct} | \leq \sqrt{V_c}\,\sqrt{V_{ct}} \qquad \text{(Eq. 2)}$$

and is small relative to the variance of the coated tablets (V_t).

From Eq. 1, it can be seen that if V_c and $Cov_{c \times ct}$ are small, the difference, $V_t - V_{ct}$, is necessarily very small.

Therefore, in this study, core variance corrections were not made, and the analysis was performed on the assumption that variance of coating equals variance of coated tablets ($V_{ct} = V_t$). This assumption is further justified by the fact that the authors are more interested in relative values of the four granulations "estimates of variances" than in their absolute values.

The computed means and standard deviations for each sample of 10 or 15 tablets of the two experiments are summarized in Tables III and IV.

To depict more clearly the variability of the tablet weights for the two experiments over the 60-min. time period of the compression operation, the means and standard deviations are plotted in Figs. 2 and 3, respectively. It is interesting to note that each

Average variances[d] (Within time-means provided by residual)	$V_{12} = 17$			$V_{20} = 6$			$V_{50} = 16$			$V_{100} = 79$		

[a] Significant at $p = <0.001$. [b] Significant at $p = 0.01$. [c] "Between experiments" mean squares are not tested for significance since they reflect initial adjustment of tablet press. "Interaction" mean squares are not significant for granulations 12, 50, and 100, indicating that time variation of means does not differ significantly from experiment to experiment, *e.g.*, these time patterns are systematic. "Interaction" mean squares for granulation 20 are significant. However, the "between time-means" mean square is much larger than the "interaction" mean square so that although the time pattern does differ between experiments, the common part of the pattern is much greater than the difference between experiments (Fig. 2, granulation 20). The variances of 12 samples for granulation 100 are not homogeneous across an hour run. However, the samples with heterogeneous variances were included in the analysis of variance so that the variability "within time-means" is measured by the average variance for the whole run of the machine. The ratio of "between time-means" mean square and "residual" mean square is sufficiently large so that the significance of the former is not in doubt.

granulation has a typical pattern of variability for time-means and a different pattern for standard deviations which was similar for both experiments, even though they were performed about 6 months apart. It is evident from the plots in Fig. 2 that granulation 12 shows the greatest scatter of mean tablet weights over the time period of compression and granulation 50 the least. However, the standard deviation of the mean tablet weights is the smallest for granulation 20 and largest for granulation 100 as seen from the plots in Fig. 3.

The results obtained from Bartlett's test showed that for granulation 12 and 50, the zero time variances differ significantly (are heterogeneous) when compared with the remaining 12 samples' variances from 10 to 60 min. Granulation 20 showed homogeneous variances for the mean weights of the 0- to 60-min. samples. Granulation 100, however, showed heterogeneous variances for the mean tablet weights for the 0-, 10-, and 20-min. samples as compared with the other time periods. As a result of these findings, the zero time data were eliminated from further analysis since it was felt that the tablet press was not yet standardized at the zero time sampling. Although the 10- and 20-min. samples of granulation 100 exhibited heterogeneous variances, they were retained for the analysis of variance. The justification for this is given with Table V which shows the analysis of variance and the calculations of indices (I), as well as average variances (V) for each granulation.

It was found that granulation 12 had an $I = 53$, granulation 20 an $I = 19$, granulation 50 an $I = 6$, and granulation 100 an $I = 42$. The higher the index, the larger the variability of the tablet weight time-means during the 1-hr. compression period. The granulations exhibit the following order of increase of variability of time-means over the 1 hr. duration of tablet manufacture: $50 < 20 < 100 < 12$. It is interesting to note that the granulations of the medium particle size range show the smallest indices. The average variances for the four granulations are $V_{12} = 17$, $V_{20} = 6$, $V_{50} = 16$, and $V_{100} = 79$. It is evident from these data that the following increasing order of variability exists within the mean tablet weights for the four granulations: $20 < 50 < 12 < 100$. The average variances for the four granulations demonstrate that granulation 100 exhibits the worst variability.

Comparison of Weight Uniformity and Core Centration Data.—In order to permit this evaluation, the tablets used in this study and in a previous one on core centration (10) were from the same batch. When the results obtained in this study are compared with the core centration data, it is found that the tablets prepared from coating granulation fraction 20 also exhibited optimal core centration.

SUMMARY

The influence of coating granulation size distribution of the same formulation on the weight variability of compressed coated tablets prepared on a Manesty machine was studied, and simple measures of tablet weight variability were presented. The following summarizes the findings.

1. The size distribution of the coating granulation substantially affects the weight uniformity of the compressed coated tablets.

2. For each granulation, there is a pattern of time variation of means which is systematic for the experiments.

3. Granulations 12 and 100 cause the largest variability in tablet weight means during the 1-hr. period of tablet press operation. In addition, granulation 100 has the largest variability of all the granulations when scatter of tablet weight within a sample of 10 or 15 tablets is taken under consideration.

4. Granulations 20 and 50 cause small scatter of means of tablet weights; and in addition, granulation 20 shows particularly low variability of tablet weights within samples of 10 or 15 tablets.

Lined and Unlined Rubber Stoppers for Multiple-Dose Vial Solutions II

Effect of Teflon Lining on Preservative Sorption and Leaching of Extractives

By LEON LACHMAN, WAYNE A. PAULI, PRAVIN B. SHETH, and MIRIAM PAGLIERY

This report demonstrates the protective action of Teflon linings on the sorption and leaching characteristics of polyurethan and natural rubber stoppers. This lining was effective in essentially eliminating extractives from appearing in water, 50 per cent polyethylene glycol 300, 50 per cent *N,N*-dimethylacetamide, 10 per cent ethanol, and 2 per cent benzyl alcohol when these solvents were in contact with the closures for 6 hr. at 115°. Sorption of the preservative, *p*-chloro-β-phenylethyl alcohol, from aqueous solution was effectively retarded by the Teflon lining on the stoppers. Reduced protection against sorption and leaching was found when Teflon lined closures, which previously underwent multiple puncture with a 20-gauge hypodermic needle, were used.

WITHIN recent years, the influence of rubber closures on the contents of multiple-dose vial solutions has received considerable attention (1, 2). It has been shown that both leaching of rubber extractives from rubber closures into solution and sorption of materials from solution by rubber stoppers can be detrimental to multiple-dose injectable preparations. Since many of the materials extracted from closures are reactive chemicals, they could cause stability (3–5) or toxicity and pyrogenicity (6, 7) problems with the vial contents, as well as interfere with assay methods (2), making it difficult or impossible to quantitatively identify active ingredients. The loss of antibacterial preservatives from multiple-dose vials resulting from sorption into rubber closures and/or reaction with rubber extractives is recognized as a serious problem. Since these agents are added to multiple-dose injectable preparations to insure bacteriostasis for the life of the product, any significant loss of the antimicrobial agent from solution can seriously undermine sterility maintenance of the product. Various attempts have been made to retard sorption of materials from vial solutions and to reduce the amount of extractives leached from closures into solutions. Certain rubber stopper manufacturers have attempted to eliminate these incompatibilities between vial solutions and closures by application of a lacquer lining to the inner surface of their closures. This lining appears to be essentially noneffective in retarding both sorption and leaching effects (8). A recent report from these laboratories (9) contains an evaluation of the protective action of an epoxy lining on rubber stoppers of varying composition. Although this lining was found to afford partial protection against leaching, no protective action against sorption was observed.

This study was initiated to determine the extent of protection afforded by Teflon linings, described by Hopkins (10), on polyurethan and natural rubber stoppers against sorption and leaching. The sorption characteristics of the lined and unlined elastomer closures were tested

Lined and Unlined Rubber Stoppers for Multiple-Dose Vial Solutions II

Effect of Teflon Lining on Preservative Sorption and Leaching of Extractives

By LEON LACHMAN, WAYNE A. PAULI, PRAVIN B. SHETH, and MIRIAM PAGLIERY

This report demonstrates the protective action of Teflon linings on the sorption and leaching characteristics of polyurethan and natural rubber stoppers. This lining was effective in essentially eliminating extractives from appearing in water, 50 per cent polyethylene glycol 300, 50 per cent *N,N*-dimethylacetamide, 10 per cent ethanol, and 2 per cent benzyl alcohol when these solvents were in contact with the closures for 6 hr. at 115°. Sorption of the preservative, *p*-chloro-β-phenylethyl alcohol, from aqueous solution was effectively retarded by the Teflon lining on the stoppers. Reduced protection against sorption and leaching was found when Teflon lined closures, which previously underwent multiple puncture with a 20-gauge hypodermic needle, were used.

WITHIN recent years, the influence of rubber closures on the contents of multiple-dose vial solutions has received considerable attention (1, 2). It has been shown that both leaching of rubber extractives from rubber closures into solution and sorption of materials from solution by rubber stoppers can be detrimental to multiple-dose injectable preparations. Since many of the materials extracted from closures are reactive chemicals, they could cause stability (3–5) or toxicity and pyrogenicity (6, 7) problems with the vial contents, as well as interfere with assay methods (2), making it difficult or impossible to quantitatively identify active ingredients. The loss of antibacterial preservatives from multiple-dose vials resulting from sorption into rubber closures and/or reaction with rubber extractives is recognized as a serious problem. Since these agents are added to multiple-dose injectable preparations to insure bacteriostasis for the life of the product, any significant loss of the antimicrobial agent from solution can seriously undermine sterility maintenance of the product. Various attempts have been made to retard sorption of materials from vial solutions and to reduce the amount of extractives leached from closures into solutions. Certain rubber stopper manufacturers have attempted to eliminate these incompatibilities between vial solutions and closures by application of a lacquer lining to the inner surface of their closures. This lining appears to be essentially noneffective in retarding both sorption and leaching effects (8). A recent report from these laboratories (9) contains an evaluation of the protective action of an epoxy lining on rubber stoppers of varying composition. Although this lining was found to afford partial protection against leaching, no protective action against sorption was observed.

This study was initiated to determine the extent of protection afforded by Teflon linings, described by Hopkins (10), on polyurethan and natural rubber stoppers against sorption and leaching. The sorption characteristics of the lined and unlined elastomer closures were tested

with an aqueous buffered solution of the preservative, *p*-chloro-β-phenylethyl alcohol, stored in multiple-dose vials. The leaching tendencies of water, 10% ethanol, 50% polyethylene glycol 300, 50% *N,N*-dimethylacetamide, and 2% benzyl alcohol on the closures were evaluated. Identification of the extractives leached from the stoppers was attempted.

EXPERIMENTAL

Materials.—*p* - Chloro - β - phenylethyl alcohol (Ciba), b.p. 80–83°, at 1.07 mm.; thiazole-type accelerator, thiuram-type accelerator, dithiocarbamate reaction product, urethan monomer glycol-amine curing agent, and an organo-metallic catalyst were supplied by the rubber manufacturer.

Polyethylene glycol 300 (Union Carbide); *N,N*-dimethylacetamide (E. I. du Pont); benzyl alcohol, reagent grade (Fisher Scientific Co.), double distilled at Ciba; 0.275 *M* citric acid–sodium phosphate buffer of pH 4.0; polyurethan and natural rubber stoppers Teflon lined and unlined, 13 mm. (West Co.); U.S.P. type 1, 10-ml. clear ampuls and vials (Kimble Glass Co.); three-piece aluminum caps for vials (West Co.), No. 13-30 were also utilized.

Equipment.—Beckman model DB recording spectrophotometer, Beckman model G pH meter, and microdistillation apparatus, as previously described in an earlier report (2), were employed.

Preparation of Ampuls, Vials, and Stoppers.—These units were washed and dried in accordance with the procedures described in a previous publication from this laboratory (1).

Sorption of Preservative from Solution.—To evaluate the effectiveness of Teflon lining against preservative sorption, lined and unlined closures of the same basic rubber formulations were used. The preservative solution used in the evaluation, 0.3% *p*-chloro-β-phenylethyl alcohol was prepared on a weight to volume basis with water for injection buffered to a pH of 4.0. Before being filled into 10-ml. clear glass ampuls and vials, the preservative solution was filtered through a medium porosity sintered-glass filter. Ampul closure was accomplished by the customary pull sealing technique with an oxygen-gas flame. The vials containing the preservative solution were then divided into four equal parts and stoppered with Teflon lined and unlined polyurethan and natural rubber stoppers. The stoppered vials were sealed with three-piece aluminum caps using a Fermpress hand crimper. The ampuls and vials containing the preservative solution were then placed into constant-temperature cabinets regulated at 25, 50, and 60 ± 1.5°. Half of the vials were stored upright and half inverted; and at designated time intervals, samples were withdrawn and evaluated for residual preservative content.

To investigate the effect of multiple puncture of lined closures on preservative sorption, Teflon lined natural rubber stoppers were punctured 5 times with a 20-gauge hypodermic needle. Ten-milliliter clear vials containing the 0.3% buffered preservative solution were stoppered using these closures and then capped as described previously. Half of the vials were stored upright and half inverted at the same conditions employed for the other vials.

Sealed 10-ml. clear ampuls of the preservative solution served as controls at the various storage conditions.

Rubber Closure Extractives.—To determine the effectiveness of the Teflon lining on the two different closures against leaching of unreacted materials and reaction products into the vial solution, several solvents commonly found in parenteral formulations were employed. These solvents, including water, 10% ethanol, 50% polyethylene glycol 300, 50% *N,N*-dimethylacetamide, and 2% benzyl alcohol, were filled into 10-ml. clear glass vials and stoppered with the unlined and Teflon lined polyurethan and natural rubber closures. Multipunctured Teflon lined natural rubber stoppers were also employed to evaluate the possible loss of protection resulting from the multiple perforations in the Teflon film. The stoppered vials were then sealed with three-piece aluminum caps again using the hand crimper described previously. After autoclaving the vials in an inverted position at 115° (10 p.s.i.) for 6 hr., the solutions in the vials were scanned spectrophotometrically to obtain ultraviolet absorption curves of the rubber extractives.

Identification of Extractives.—For the various organic additives and their possible reaction products of the two rubber compositions used in this study, saturated solutions were prepared in the five solvent systems and scanned spectrophotometrically to obtain their characteristic ultraviolet absorption spectra. This made possible a qualitative identification of the materials extracted from the polyurethan and natural rubber closures.

Analytical Method.—The assay method employed for *p*-chloro-β-phenylethyl alcohol has been described in an earlier publication from these laboratories (1).

RESULTS AND DISCUSSION

The protective action of a Teflon lining on polyurethan and natural rubber stoppers against sorption of the preservative, *p*-chloro-β-phenylethyl alcohol, from solution and leaching of extractives from the stoppers by several solvents was investigated. The composition and per cent rubber content of these stoppers are presented in Table I.

Sorption Studies.—The sorption tendencies of Teflon lined, multipunctured Teflon lined, and unlined rubber stoppers were evaluated with vial solutions of *p*-chloro-β-phenylethyl alcohol buffered to a pH of 4.0. The protective action of the Teflon lin-

ing on natural rubber closures against sorption of the preservative from solution can readily be seen from the data in Table II. At all temperature conditions throughout the 12-week period, no decrease in preservative content is noted for any of the vials with lined closures. The observed loss of *p*-chloro-β-phenylethyl alcohol from vials with plain closures appears to level off at around the 8-week period. This plateau could indicate the presence of an equilibrium condition. It is interesting to note that only for the unlined closures do vial solutions stored in an inverted position show greater loss of preservative content than those stored upright.

To evaluate the effectiveness of the Teflon lining after the stopper was punctured several times by a hypodermic needle, Teflon lined natural rubber closures were punctured 5 times with a 20-gauge hypodermic needle and employed as closures for vials containing the preservative solution. These vials were stored at the same conditions and for the same time period as the other group. Results show that even when perforated several times by a hypodermic needle, the Teflon lining still affords some protection against sorption when compared with loss of preservative for the unlined closures.

The data in Table III summarize the sorption tendencies of lined and unlined polyurethan closures for *p*-chloro-β-phenylethyl alcohol at the various temperature conditions. Excellent protection was afforded by the Teflon lining against sorption at all storage conditions throughout the 12-week evaluation. Again, only for the unlined closures do the vial solutions stored in an inverted position show a greater loss of preservative than those stored upright.

Since there was no diminution of preservative concentration in the ampul solutions, the loss in the vial solutions stoppered with natural and polyurethan closures must be attributed to closures.

Although no physical changes in the natural rubber closures were noted at the various elevated temperature conditions employed, both the lined and unlined polyurethan closures deformed markedly at these same temperatures. In fact, the unlined closures were so badly deformed that the loss data of preservative in the vials could be due to loss around the closure and out to the atmosphere in addition to that sorbed by the closure.

Leaching of Extractives.—Several solvents commonly used in injectable formulations were employed to evaluate the leaching of extractives from

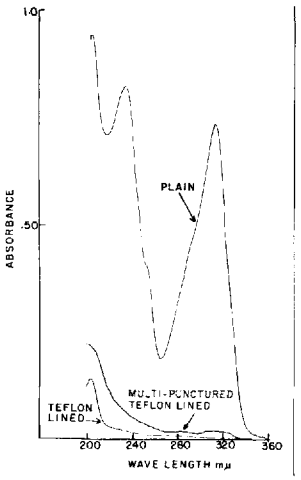

Fig. 1. — Ultraviolet absorption curve of leached extractives. Rubber, natural; solvent, water; storage condition, 6 hr. at 115°, vial inverted.

Teflon lined and unlined stoppers when used on multiple-dose vials. Table IV lists the ultraviolet maxima and corresponding absorbances representing extractives from the polyurethan and natural rubber closures appearing in the various solvents. It can readily be seen that for each of the rubber compositions employed and in each of the solvent systems, the Teflon lining afforded considerable protection against leaching of extractables from the closures as evidenced by the extremely low absorbance values obtained when lined closures were used. Considerable protection against leaching was also provided using the multipunctured Teflon lined closures. Representative ultraviolet absorption spectra for the extractives found in the vial solutions containing water and stoppered with lined, multipunctured lined, and unlined natural rubber stoppers are given in Fig. 1.

It is interesting to note from the data in Table IV that of the five solvents investigated with the lined closures, only 50% polyethylene glycol 300 appeared to be successful in leaching out a significant amount of extractives from both polyurethan and natural rubber. To explore whether decomposition of the polyethylene glycol 300, when exposed to the extreme conditions of the evaluation, gave degradation products which also showed ultraviolet absorption, samples of this solvent were sealed in clear glass ampuls and heated for the same period at the same temperature as the vials. The ultraviolet absorption spectra of the 50% polyethylene glycol 300 solution heated in ampuls and an untreated control are given in Fig. 2. The appearance of an absorption peak at approximately 250 mμ for the heated glycol solution indicates that the decomposition of the glycol most likely contributes to the relatively high absorbance values found with this solvent from vials using Teflon lined closures.

Identification of Extractives.—Materials of the rubber compositions studied, which would tend to give absorption in the ultraviolet region, were obtained from the rubber stopper manufacturer and ultraviolet absorption spectra taken in the solvents studied. This information was employed to aid in the identification of the extractives leached from the polyurethan and natural rubber stoppers. The absorption data for these various ingredients are summarized in Table V. With this information, positive identification of each of the various extractables was made possible.

For the natural rubber stoppers, the material responsible for the absorption at 308–326 mμ and 228–230 mμ is believed to be the thiazole-type accelerator. The solvent decomposition products and/or the dithiocarbamate reaction product could account for the absorption at 248 mμ in 50% polyethylene glycol 300. In the case of the polyurethan closures, the absorption at 270–280 mμ can be ascribed primarily to the organo-metallic catalyst employed with the possibility of minor contribution from the urethan monomer. The observed peak found for 50% polyethylene glycol 300 of approximately 250 mμ can be attributed to solvent decomposition and not to extractives from the rubber. Even though slight ultraviolet absorption was observed for the glycol-amine curing agent, the absorption spectra of this agent in the various solvent systems employed were rather diffuse with no definable maxima.

SUMMARY

Teflon lined and unlined polyurethan and natural rubber closures were evaluated for their sorption and leaching characteristics. Multiple-dose vials containing an aqueous buffered solution of the preservative, *p*-chloro-β-phenylethyl alcohol, were stoppered with the lined and unlined rubber closures for the sorption studies. Several solvents commonly used in injectable formulations were employed to evaluate the leaching of extractives from the lined and unlined closures when used on multiple-dose vials. The solvents used were water, 10% ethanol, 2% benzyl alcohol, 50% *N,N*-dimethylacetamide, and 50% polyethylene glycol 300. The following results were obtained.

1. The Teflon lining was found to afford excellent protection against sorption of the preservative into either the polyurethan or natural rubber stoppers.
2. The lining was found to be effective in preventing the leaching of extractives from the rubber closures by the various solvents employed.
3. The extractives leached by the different sol

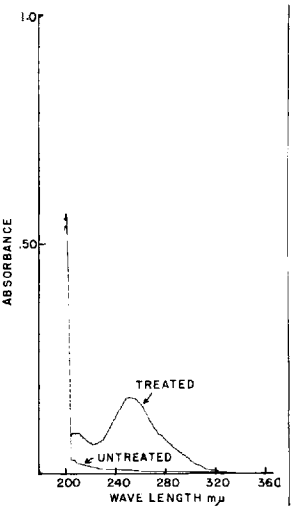

Fig. 2. — Ultraviolet absorption spectra of a 50% polyethylene glycol 300 solution after autoclaving in sealed ampuls for 6 hr. at 115°, 10 p.s.i., and an untreated control.

vents from both the unlined polyurethan and natural rubber closures were qualitatively identified.

4. Teflon lined natural rubber stoppers, which were perforated several times by a hypodermic needle, still afforded some protection against sorption and considerable protection against leaching.

Notes

Phosphorus-Nitrogen Compounds V. Some Guanidine and 2-Aminopyrimidine Derivatives

By LINDLEY A. CATES and NOEL M. FERGUSON

Five amidino(thio)phosphoramidates and six 2-pyrimidyl(thio)phosphoramidates were prepared for screening in four cancer test systems. Three of these derivatives were also tested against *Plasmodium berghei*. None of the compounds exhibited significant antineoplastic or antimalarial activity.

THE SYNTHESIS of phosphoramidopyrimidines was undertaken to further ascertain the effect of phosphorus bonding on the cytotoxic properties of heterocyclic amines. The preparation of similar pyridine-containing compounds was described in an earlier report in this series (1).

The rationale for antineoplastic activity by these derivatives originates from an hypothesis concerning the mechanism of action of cyclophosphamide. According to this theory, cyclophosphamide exists as an inactive transport form *in vivo* until the P-N bond is cleaved by the enzymatic action of phosphamidases or phosphatases to yield the alkylating ethylenimmonium ion (2). Thus, replacement of the bis(2-chloroethyl)amino group by an aminopyrimidine moiety might give rise to an antimetabolic activity of a more specific nature than would be realized by administration of the parent compound. More recent evidence (3), however, suggests that the conversion of cyclophosphamide *in vivo* into a cytostatically effective activation product is the result of a metabolic process dependent on the presence of oxygen and not the result of simple hydrolysis. At this time it can be stated that no direct proof of the postulated biochemical transformations of cyclophosphamide and related congeners is available.

Since guanidine and some of its derivatives are known to possess antiprotozoal properties (4) three of the amidino(thio)phosphoramidate intermedi-

vents from both the unlined polyurethan and natural rubber closures were qualitatively identified.

4. Teflon lined natural rubber stoppers, which were perforated several times by a hypodermic needle, still afforded some protection against sorption and considerable protection against leaching.

Notes

Phosphorus-Nitrogen Compounds V. Some Guanidine and 2-Aminopyrimidine Derivatives

By LINDLEY A. CATES and NOEL M. FERGUSON

Five amidino(thio)phosphoramidates and six 2-pyrimidyl(thio)phosphoramidates were prepared for screening in four cancer test systems. Three of these derivatives were also tested against *Plasmodium berghei*. None of the compounds exhibited significant antineoplastic or antimalarial activity.

THE SYNTHESIS of phosphoramidopyrimidines was undertaken to further ascertain the effect of phosphorus bonding on the cytotoxic properties of heterocyclic amines. The preparation of similar pyridine-containing compounds was described in an earlier report in this series (1).

The rationale for antineoplastic activity by these derivatives originates from an hypothesis concerning the mechanism of action of cyclophosphamide. According to this theory, cyclophosphamide exists as an inactive transport form *in vivo* until the P-N bond is cleaved by the enzymatic action of phosphamidases or phosphatases to yield the alkylating ethylenimmonium ion (2). Thus, replacement of the bis(2-chloroethyl)amino group by an aminopyrimidine moiety might give rise to an antimetabolic activity of a more specific nature than would be realized by administration of the parent compound. More recent evidence (3), however, suggests that the conversion of cyclophosphamide *in vivo* into a cytostatically effective activation product is the result of a metabolic process dependent on the presence of oxygen and not the result of simple hydrolysis. At this time it can be stated that no direct proof of the postulated biochemical transformations of cyclophosphamide and related congeners is available.

Since guanidine and some of its derivatives are known to possess antiprotozoal properties (4) three of the amidino(thio)phosphoramidate intermedi-

[a] All melting points were determined on a Fisher-Johns apparatus and are uncorrected. [b] Elemental analyses were run on a Fisher CHN analyzer.

ates, which contain the guanidino moiety, were incidentally tested for antimalarial activity.

The pyrimidine derivatives were prepared by two different methods: phosphorylation and condensation. Two of the products were synthesized by direct acylation using diphenyl phosphorochloridate, whereas several attempts at phosphorylation of halo- and hydroxy-substituted pyrimidines employing alkyl and aryl phosphorochloridates proved unsuccessful. This failure is attributed to the relatively high pK_b values of these pyrimidines. A recent report (5) indicates that halo-substituted 2-aminopyrimidines will, however, yield phosphoramidic dichlorides and phosphorimidic trichlorides

when the more reactive phosphorus pentachloride is employed.

As an alternate route pyrimidine synthetic methods involving double condensation between cyanoacetic, malonic and β-keto esters and substituted guanidines were employed. The amidinophosphoramidates and amidinophosphoramidothionates required in these condensations were obtained by the reaction between phosphorochloridates or phosphorochloridothionates and guanidine. The latter reactant was prepared *in situ* using guanidine hydrochloride and alcoholic potassium hydroxide. The synthesis of amidinophosphoramidates is somewhat controversial in that Shvachkin and Prokof'ev (6) reported that the preparation of diphenylphosphorylguanidine from phosphoryl chloride, phenol, and guanidine (7) could not be duplicated, and they synthesized the product using diphenylphosphorochloridate and guanidine. This procedure was also reported by Cramer and Vollmar (8), as well as an alternate method involving the treatment of guanidine hydrochloride in aqueous sodium hydroxide with diphenylphosphorochloridate in benzene. The guanidine hydrochloride–alcoholic potassium hydroxide process reported in this paper is considered to be a convenient and economical method for the synthesis of phosphoryl(thio)guanidines. Of the guanidine derivatives prepared, the ethyl and *n*-propyl amidinophosphoramidothionates were selected for pyrimidine condensation.

EXPERIMENTAL

Chemistry

Amidinophosphoramidates and Amidinophosphoramidothionates (Table I).—A solution of potassium hydroxide (0.2 mole) in 100 ml. of absolute ethanol was added in portions to guanidine HCl (0.2 mole) in 100 ml. of absolute ethanol at 0° with stirring. This temperature was maintained and the appropriate phosphorochloridate or phosphorochloridothionate (0.1 mole) was introduced dropwise with stirring. The reaction mixture was allowed to remain overnight and then spin evaporated over a steam bath to yield a white mass or oil. The residue was dissolved in hot benzene and ether was added to precipitate guanidine hydrochloride. The filtrate was again spin evaporated to yield a white mass or oil. Compounds I, II, and III were isolated by crystallizing from hot benzene. Compounds IV and V were obtained in pure form by washing an ethereal solution of the residue with 10% sodium hydroxide solution and water, drying over anhydrous calcium sulfate, and concentrating the ether filtrate. Known compound VI was purified according to a previously described method (6). All products were white crystalline solids.

2-Pyrimidylphosphoramidates (Table II).—A mixture of 2-aminopyrimidine or 2-amino-4,6-dimethylpyrimidine (0.2 mole) and diphenyl phosphorochloridate (0.1 mole) in 500 ml. of reagent dioxane was refluxed for 0.5 hr. and allowed to remain overnight. The reaction mixture was spin evaporated to yield a brown mass which was washed with petroleum ether and water and the residue dissolved in hot ethanol. After treating with activated charcoal, clouding with water, and cooling, the product formed as a white crystalline solid.

2-Pyrimidylphosphoramidothionates (Table II.)—The appropriate amidinophosphoramidothionate (0.05 mole) was refluxed for 1 hr. with sodium (0.25 mole), which was previously reacted with 300 ml. of absolute ethanol, and the reaction mixture was allowed to set overnight. A fivefold excess of diethyl malonate, ethyl cyanoacetate, or ethyl acetoacetate was added, the mixture refluxed for 2 hr., and allowed to remain overnight. The reaction mixture was concentrated by spin evaporation and any precipitate dissolved by addition of the least amount of water. Following filtration the solution was adjusted to pH 8 using 5% hydrochloric acid and a Corning pH meter. The resulting precipitate was collected and crystallized from ethanol–water.

Infrared Spectra

All starting materials and products were examined by means of a Beckman IR-8 spectrophotometer using a Nujol mull. The new guanidine derivatives showed the following characteristic absorptions, ν in cm.$^{-1}$: 3200 (NH), 1020–1060 (POCalkyl), and 1240 (P=O in compounds III and V). Some of the principal absorptions given by the pyrimidine derivatives were, ν in the cm.$^{-1}$: 1520–1580 (C=C, C=N in all compounds), 1240 (P=O in compounds VII and VIII), 1080–1090 and 1200 (POC aryl in compounds VII and VIII), 1020–1055 (POC alkyl in compounds IX–XII), and 3350 (NH_2 in compound XI). The lack of a free amino group (except, of course, in compound XI) indicates the correctness of the proposed structures, eliminating an alternative course of the condensations. No assignment of P–N absorption was attempted since this band, usually designated around 715 cm.$^{-1}$, falls in the skeletal structure absorption range. Derkach (9) reported the infrared spectra of some related phosphoramidates and assigned the 893–910 cm.$^{-1}$ range to P–N. This assignment may not be correct since a similar strong peak was noted in the compounds reported here but only in the case of the phenyl esters. The reliability of assigning P–N absorption in the region of 715 cm.$^{-1}$ has also been questioned by Bellamy (10) and Thomas (11).

Screening Data

Samples of the new compounds were submitted for antitumor testing against sarcoma 180, Lewis lung carcinoma, lymphoid leukemia L-1210, and KB cell culture.[1] Results of that testing which have been completed indicate that only compound I has a per cent T/C (ratio of tumor weight of test animals to control animals; expressed as per cent) of less than 50 when screened against sarcoma 180 and that at a dose of 500 mg./Kg. The most toxic member of the series was compound V which gave no survivors at a dose of 100 mg./Kg. The pyrimidine derivatives exhibited relatively low acute toxicities having lethal doses in excess of 250 mg./Kg. Five mice were infected with a lethal dose of *Plasmodium berghei* 3 days prior to administration of compounds I, III, and V in doses of 40, 160, and 640 mg./Kg.[2] At the higher dose level compound III (most active) extended the survival time by only 35%. Compounds I and III showed low acute toxicities and the relatively high toxicity of compound V was confirmed in these tests.

Tracer and Radioactivation Studies on Tartar Emetic Impurities

By A. ALIAN, YEHIA M. DESSOUKY*, and R. SHABANA

The problem of contamination of tartar emetic with arsenic and lead was examined using the radioactive isotopes, ^{76}As and ^{209}Pb. Neutron activation and radiochemical separation methods have been applied for the determination of arsenic and lead concentrations throughout the different stages of tartar emetic synthesis. It has been shown that, while most of arsenic is eliminated during the synthesis process, the major portion of lead remains in the final product. It was also found that the two impurities can be eliminated by successive washing of the starting materials with 0.2 *M* nitric acid and water. Tartar emetic synthesized from purified starting materials conforms to the requirements in pharmacopeias.

ONE OF THE most important problems of the pharmaceutical industry is the production of synthetic drugs in a suitably pure condition. The classical methods of tracing impurities are either misleading, tedious, or inaccurate. Antimony potassium tartrate (tartar emetic) is the most commonly employed drug in the treatment of bilharziasis, schistosomiasis, leishmaniasis, filariasis, ascariasis, and other tropical diseases (1). It is one of the early drugs found to be active against trypanosomes (2). The drug is widely used in Africa, Asia, and Latin America because of the simplicity and easiness of its synthesis and acceptance among patients and physicians. It is still the drug of choice in the treatment of bilharziasis in Egypt as well as other countries where infections occur (3). Cases of toxicity and inconvenience of intravenous injection of this drug are reported, however, and have been attributed, at least partly to the presence of toxic impurities such as arsenic and lead (3, 4).

Most pharmacopeias in which tartar emetic is mentioned require certain specifications for arsenic and lead limits for the sake of its medical safety. These limits vary in the case of arsenic to not more than 200 p.p.m. in the U.S.P. (5), 10 p.p.m. in the E. P. (6), 8 p.p.m. in the B.P. (7), and in case of lead to not more than 10 p.p.m. in the E.P. and 5 p.p.m. in the B.P.

The quantitative determination of the two metals, particularly arsenic, at such low concentrations in the presence of antimony cannot be performed with accuracy by the conventional analytical methods (8–11). The utilization of radioactive isotopes in solving some production problems and in working up technical operations in the pharmaceutical industry has found its way only recently (12). Some studies have been published on the manufacture of pure tartar emetic (3, 13), but none of the authors have made use of radioactive isotope techniques.

The purpose of the present paper was to find an economical method to eliminate arsenic and lead and to produce tartar emetic in pure form. For tracing these two metals, the radioactive isotopes, ^{76}As and ^{209}Pb, have been used, while their concentrations in the starting materials and in the final products have been determined by a neutron radioactivation procedure.

EXPERIMENTAL

Materials.—Unless otherwise stated, all chemicals employed were analytical grade reagents. The radioactive isotopes ^{76}As and ^{209}Pb were prepared by irradiating spectrographically pure arsenic trioxide and lead. Arsenic trioxide was then dissolved in dilute hydrochloric acid, while lead was dissolved in dilute nitric acid. Standard and carrier solutions of arsenic and lead were prepared by dissolving inactive arsenic trioxide and lead in a similar manner.

Apparatus.—The instruments used were an EKCO scintillation assembly for counting the γ radiation of ^{76}As and a Philips counting instrument with an end window G.M. tube for measuring ^{209}Pb β-radiations.

Irradiations.—Samples to be irradiated were wrapped in thin aluminum sheets and were enclosed in aluminum cans which were then irradiated at a flux of about 1.3×10^{13} neutrons/cm.^{2}/sec. in the U.A.-RR-1, 2 MW reactor. For the radioactivation analysis of arsenic and lead, every sample was placed together with the standards in one can and exposures were of about 5 hr. duration.

Procedure.—All experiments on the study of arsenic and lead uptake were performed in 100-ml. conical flasks. For evaluating arsenic uptake on

7[b]	163	4.9
8	203	6.0
9[b]	203	7.5
10	1000	19.2

[a] The values given are the average of four experiments. [b] Cooled in refrigerator.

tartar emetic, in the coarse of its synthesis, the following procedure was followed: 1.5 Gm. of antimony trioxide, 1.8 Gm. of acid potassium tartrate, both in a finely powdered form, were thoroughly mixed with a few drops of distilled water and a known amount of arsenic containing its radioactive isotope. The paste was left for 24 hr., boiled with 12 ml. of distilled water for 15 min., filtered while hot, and the clear filtrate was left to crystallize at room temperature or in a refrigerator. The crystals of tartar emetic thus obtained, after being filtered off and washed with ice cold water, were dried. The arsenic content of the filtrate and crystals were determined by measuring the radioactivity of ^{76}As. In some other series of experiments a mixture of antimony trioxide, acid potassium tartrate, and arsenic was refluxed with 12 ml. of distilled water for 1 hr., filtered while hot, and the procedure was completed as mentioned before. The study of tartar emetic purification from arsenic by recrystallization was carried out as follows: 3 Gm. of tartar emetic was dissolved in 10 ml. of hot distilled water to which was added a known amount of arsenic. The mixture was then cooled, and tartar emetic was examined for its arsenic content as in the above two series.

The lead contamination of tartar emetic was investigated by refluxing the reaction mixture to which is added a known amount of lead, and in the same manner as in the case of arsenic. The purification of tartar emetic from lead was studied also as in the case of arsenic. Lead which is added in the above two cases, however, was prepared by mixing a known volume of lead solution in nitric acid with 0.5 ml. of concentrated hydrochloric acid. Lead chloride thus precipitated was washed once with ice cold water before being used in the experiment.

The purification of antimony trioxide (Sb_2O_3) was studied by stirring 5 Gm. of crude Sb_2O_3 with different washing solutions. The Sb_2O_3 was then filtered off and examined for the arsenic and lead content.

Radioactivation analysis of arsenic and lead was done by methods similar to those published in the literature (14, 15) except for some modifications to fit with the given samples. For arsenic, a double distillation process was necessary to separate it from antimony, while the preliminary separation of lead from antimony was done by extraction (16).

Radiochemical Purity.—This was checked by measuring the spectra (arsenic) or from the decay curves (lead) of the corresponding radioactive species.

RESULTS AND DISCUSSION

Arsenic and Lead Uptake on Tartar Emetic During Its Synthesis.—The experimental results of arsenic uptake on tartar emetic throughout the process of its synthesis (Table I) show that this uptake increases with the increase of its amount

TABLE IV.—VARIATION OF LEAD UPTAKE ON TARTAR EMETIC WITH THE CONDITION OF EXPERIMENT[a]

Condition of Expt.	Original Lead Added, p.p.m.	Lead Uptake on Tartar Emetic Crystals, p.p.m.
Cooled at room temp.	~200	~ 132
Cooled in refrigerator	~200	~ 138

0.2 *M* nitric acid	450	60	...	1

[a] The values given are the average of two or three experiments.

originally present in the reaction mixture. The uptake, however, is always less than 1%. It is clear, also, that when tartar emetic is left to crystallize gradually at room temperature, the arsenic uptake on the crystals is less than in case of enhancing crystallization by cooling the solution. The addition of some complexing agents such as ethylenediaminetetraacetic acid (EDTA) and 8-hydroxyquinoline to the reaction mixture increases the arsenic contamination of tartar emetic. The contamination, however, is the same for the synthesis of the drug by the two methods, *i.e.*, with or without refluxing the reaction mixture.

The uptake of lead, on the other hand, was found to be about 60% of its amount originally added to the reaction mixture (Table II).

Purification of Tartar Emetic by Crystallization.—Table III presents the experimental results of the recrystallization of tartar emetic in the presence of different amounts of arsenic. It is evident that the uptake of arsenic is about 2–3% of its original amount. Cooling the solution increases the arsenic contamination. The percentage uptake, however, is higher than in the case of tartar emetic synthesis. This is most probably due to the uptake of some arsenic onto the unreacted residue.

In some separate experiments, it has been found that the addition of a little amount of hydrochloric acid decreases the arsenic uptake onto the crystals.

The uptake of lead is given in Table IV. It is clear that, while most arsenic can be removed from tartar emetic by recrystallization, the major part of lead remains in the crystals.

The preliminary investigation has shown that the two impurities are mainly present in antimony trioxide, hence, the authors' efforts were directed toward the study of its purification. Water and other washing solutions have been tried for eliminating arsenic and lead from antimony trioxide. The results are presented in Table V.

Washing antimony trioxide with water and 0.2 *M* nitric acid is evidently sufficient to eradicate the arsenic and lead impurities, while losses are negligible. Moreover, this is simpler than eliminating arsenic as arsine using reducing amalgam or complexing lead by a chelating agent (13). Acid potassium tartrate containing arsenic and lead can be sufficiently purified by washing in a similar manner.

RECOMMENDED PROCEDURE AND CONCLUSION

The foregoing data show the different possibilities of eliminating arsenic and lead impurities from tartar emetic. In light of the above discussion, the recommended procedure for the synthesis of highly pure tartar emetic is summarized as follows.

Antimony trioxide is washed once with 0.2 *M* nitric acid and then twice with water. The volume in liters of nitric acid and of water must be fivefold the weight in kilograms of antimony trioxide. Every washing should be followed by filtering the slurry produced. Antimony trioxide is then thoroughly mixed with the calculated amount of similarly washed acid potassium tartrate to obtain a homogeneous paste, and left for 24 hr. The paste is then boiled for 15 min. with distilled water, filtered while hot, and the filtrate is left to cool. The crystals of tartar emetic thus obtained are washed with cold water and then dried. This procedure, while retaining a better yield, is more economic. The product obtained is almost free from arsenic and lead.

Desoxycholic Acid Enhancement of Orally Administered Reserpine

By MARVIN H. MALONE, HOWARD I. HOCHMAN*, and KARL A. NIEFORTH

Quantities of 1:2, 1:4, 1:8, 1:16, and 1:32 molar amounts of reserpine : desoxycholic acid were dissolved in alcohol and/or chloroform, chilled to −5°, and solvents removed under reduced pressure. When administered orally to mice, the presence of desoxycholic acid hastened blepharoptotic activity and increased blepharoptotic potency of reserpine. Maximum enhancement was observed with 1:16 reserpine–desoxycholic acid where 1 mg. of reserpine as the combination was equivalent to 3.8–2.5 mg. of reserpine base using observations 2 and 24 hr. after dosage, respectively. An equivalent physical mixture prepared by trituration was significantly more potent than reserpine base but much less potent than the prepared combination. Desoxycholic acid alone was without blepharoptotic activity.

THE ENHANCED absorption of various medicinal agents upon concomitant administration with desoxycholic acid may be attributed to its ability to reduce interfacial tension and/or to form inclusion or clathrate compounds. Previous work concerning this increased absorption usually has been restricted to the effect of desoxycholic acid on the absorption of the fat-soluble vitamins and closely related analogs where the effect was thought to be due to the surface action of desoxycholic acid. This report is concerned with an increase in the blepharoptotic activity of reserpine when given in intimate combination with desoxycholic acid.

The general role of bile salts in absorption, the ability of desoxycholic acid to form inclusion compounds (choleic acids), and the relative inefficiency of reserpine absorption prompted this study of the effects of combining reserpine and this acid prior to oral administration. Evidence of an interaction between reserpine and desoxycholic acid was reported by Lach and Pauli (1) after the completion of the work reported here. The interaction was demonstrated by an increase in the solubility of reserpine in hydroalcoholic solutions of desoxycholic acid. Simple interfacial effects of desoxycholic acid were not thought to be the sole contributing factor for this increased solubility, and it was suggested that the interaction might result from a combination of micellar solubilization and inclusion formation.

EXPERIMENTAL

Preparation of Reserpine–Desoxycholic Acid Combinations.—The usual method for the formation of desoxycholic acid inclusion compounds (dissolving both desoxycholic acid and the guest component in ethanol and allowing the inclusion compound to crystallize) was not used in this instance due to the poor solubility of reserpine in anhydrous alcohol.

Method A.—The calculated quantity of purified desoxycholic acid (Nutritional Biochemicals Corp., lot 2185) was dissolved in 5 ml. of commercial grade absolute ethanol in a 20-ml. round-bottom flask. The desired amount of reserpine (C grade, Calbiochem, lot 502858) was added and dissolved with slight warming. The flask and its contents were chilled in an ice–salt bath to −5° and the solvent removed under reduced pressure and trapped in a cold finger cooled with a dry ice–acetone bath. The contents of the flask were protected from light as completely as possible. The residues were dried for 12 hr. in a vacuum to remove the last trace of alcohol.

Method B.—This method was essentially the same as above except that 5 ml. of chloroform was used to dissolve the reserpine, and this solution was added to the desoxycholic acid dissolved in 10 ml. of absolute alcohol. The resultant solution was then treated as described under *Method A*.

Method C.—A physical mixture of desoxycholic acid and reserpine was prepared by intimately triturating the two dry powders without previous dissolution in any solvent. Table I summarizes the physical properties of all the test mixtures.

Blepharoptotic Assay.—White mice were obtained from E. G. Steinhilber, Oshkosh, Wis., and maintained in this laboratory on Purina laboratory chow and water *ad libitum* for at least 4 days prior to test. All animals were taken off food 10 hr. prior to dosing and placed back on food after recording the +6 hr. observations. Free access to water was allowed throughout the entire test period. The mice were dosed orally using precision grade syringes and cut-off, blunted, polished 20-gauge hypodermic needles. A constant dosage volume of 30 ml./Kg. was maintained for all injections using 0.25% aqueous agar as the dosing vehicle. Test drugs and combinations were suspended by trituration. All test solution suspensions were coded and the animals dosed in a random test pattern using a 3 × 3 assay format with further randomization between the two sexes of mice and the two dosing technicians. Prior to ptotic scoring, each mouse was manually aroused and placed on a screen facing the scorer at the scorer's eye level. Ptosis for each eye was rated following the scale used by Rubin *et al.* (2): 4 = complete, 3 = 3/4, 2 = 1/2, 1 = 1/4 closure of the eyelids. Nonptotic responses were scored as 0. All scores of 4 were checked to insure that the lid was not encrusted shut by eye secretions. The individual metameter was the sum of the ptotic scores for both eyes so that the graded test response could vary from 0–8 per animal.

RESULTS AND DISCUSSION

As shown in Table II, eight balanced log dose-response blepharoptotic assays were conducted assaying reserpine (in combination with desoxycholic acid) against reserpine base as a standard. For the assay calculations the reserpine content of

[a] Range of figures within parentheses indicate the calculated 95% confidence limits for the potency. [b] Significant departure from parallelism (P = 0.01–0.05) in 3 × 3 assay; best graphical estimate of potency = 2.49 × reserpine base. [c] Recovery was sufficient so that neither statistical nor graphical estimates of potency could be determined with validity.

the combinations was handled using the "exact" ratios shown in Table I, although the approximate molar ratios are used in this text to identify the various combinations. Doses of 3, 6, and 12 mg./Kg. were used for the reserpine standard (C grade, Calbiochem, lot 502858) and for the reserpine of the 1:2, 1:4, and 1:8 reserpine–desoxycholic acid combinations. Doses of 1.5, 3, and 6 mg./Kg. and 0.75, 1.5, and 3 mg./Kg. were used for the reserpine of the 1:16 and 1:32 combinations, respectively. Where enhancement of the reserpine-like activity did not allow 3 × 3 calculations, a 2 × 2 assay was calculated matching two dosages of the standard with two doses of the combination in the same linear portion of the dose-response curve. Significant departure from parallelism was noted in only one calculation. The statistical treatment for the 3 × 3 (120 mice, 20 animals/dosage level) and 2 × 2 (80 mice) assays involved analysis of variance, factorial analysis, and calculation of potency and its 95% confidence limits using the techniques of Bliss and Calhoun (3). An average λ value (s/b) of 0.27 was obtained for the 32 valid assay calculations reported in Table II, which value agrees well with a λ of 0.29 reported earlier for this assay technique (4) using a different mouse stock, reserpine acetate as the standard, and water as the dosage vehicle.

As shown in Fig. 1, the 1:2 to 1:16 reserpine–desoxycholic acid combinations show a progressive increase in the apparent potency of reserpine with the 1:16 reserpine–desoxycholic acid combination

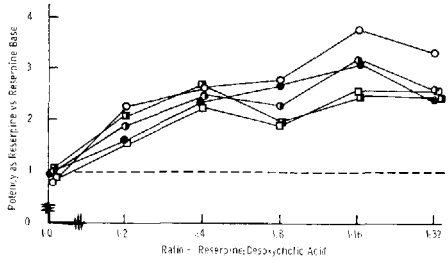

Fig. 1.—Variation of ptotic potency of reserpine when administered orally in the form of various molar ratio coprecipitates with desoxycholic acid. Key: ○, +2 hr.; ◑, +4 hr.; ●, +6 hr.; □, +10 hr.; ◧, +24 hr.

producing the maximum enhancement of activity. The decrease in activity shown by the 1:32 combination would appear to indicate that the maximum attainable activity (1:16) has been physically diluted by excess desoxycholic acid.

As illustrated in Fig. 2, the potency of 1:0 reserpine–desoxycholic acid does not significantly deviate from the theoretical value of 1.0, while maximum distortion of the apparent potency of the 1:2–1:32 combinations was apparent at +2 hr. after oral administration. This appears to indicate that desoxycholic acid increases the speed of absorp-

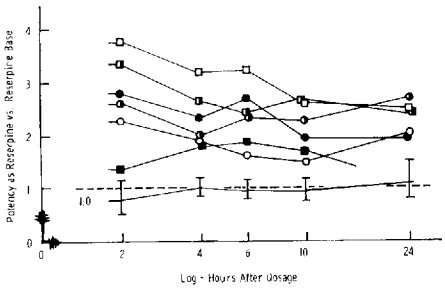

Fig. 2.—Variation with time of the oral potencies of various reserpine–desoxycholic acid molar coprecipitates as compared to reserpine base as a standard. Key: □, 1:16; ◨, 1:32; ●, 1:8; ◑, 1:4; ○, 1:2; ■, 1 + 16; I, 1:0.

tion of reserpine as well as increasing the potency. Considering the 95% confidence limits of potency reported in Table II, reserpine administered as the 1:16 combination behaves equivalent to at least 1.8 mg. of reserpine base (+24 hr.) and possibly equivalent to as much as 5.0 mg. of reserpine (+2 hr.).

A molar equivalent physical mixture of reserpine and desoxycholic acid (1 + 16) produced a slower onset of the period of maximum enhancement (+4–6 hr.), and the potencies were significantly less ($P \leq 0.001$) than those reported for the 1:16 intimate combination. In all cases where calculation was possible, the 1 + 16 mixture was significantly more potent than reserpine base alone (observed P: 0.025–0.05 at +2 hr. and ≤ 0.001 at +4, 6, and 10 hr.).

While there is debate as to whether palpebral ptosis is a peripheral or central manifestation of reserpine-like activity (4–6), this characteristic symptom does indicate absorption of reserpine from the gastrointestinal tract. Coprecipitates of reserpine and desoxycholic acid both increase the potency of reserpine and produce a more rapid onset of reserpine-like activity when administered orally. No attempt has been made here to define the exact physical/chemical nature of the reserpine–desoxycholic acid combination.

Utilization of Hydrophilic Gums for the Control of Drug Release from Tablet Formulations I. Disintegration and Dissolution Behavior

By H. E. HUBER, L. B. DALE*, and G. L. CHRISTENSON

Tablet formulations and data to illustrate rate of drug dissolution and tablet volume decay during *in vitro* disintegration tests are presented. It was found that tablets prepared by compression of hydrophilic gums, excipients, and drug in specified ratios result in prolonged release of drug. Assay of simulated gastric and intestinal fluids from *in vitro* tests show the drug to be released at essentially a uniform rate after an initial hydration phase. The mechanism of prolonged release is proposed as a combination of drug diffusion from, and attrition of, a dynamically changing gel barrier at the tablet periphery.

ORAL CONTROLLED release dosage forms have been recognized as a therapeutically significant advance in dosage form design, whereby a more uniform and prolonged tissue concentration of drug substance may be achieved. The methods used for obtaining prolonged action have been reviewed by Ballard and Nelson (1) and Parrott (2) and various systems are described, whereby an initial therapeutic dose is released followed by a continual release of additional drug substance over a prolonged period of time.

In 1962, a system was developed by The Wm. S. Merrell Co. (3) describing a novel approach for the control of drug substance release rate from tablet formulations. The method described involves mixing a medicinal agent or agents with certain nondigestible, hydrophilic gums and compressing the mixture into tablets. When such a tablet is exposed to water or digestive fluids, a rapid release of drug substance from the dosage form to the dissolution medium is initially observed. However, hydration and gelation of gum at the tablet–liquid interface also occurs to form a viscous gel barrier. The remaining drug substance is then released at a much slower rate that apparently depends on diffusion from and/or attrition of the gel barrier. The nature of the phenomenon is illustrated by Fig. 1, which shows, in cross section, the appearance of such a tablet after exposure to solvent. It can be seen that the intact tablet core is surrounded by a gel barrier layer of significant size.

The present communication is concerned with studies that were conducted to obtain preliminary

information on the dissolution and disintegration behavior of such tablets and the influence of formulation variables on their behavior.

EXPERIMENTAL

Influence of Gum Content on Disintegration Behavior.—Six batches of tablets containing nicotinic acid and hydroxypropylmethylcellulose 4000 cps. in the ratio of 10:1, 2:1, 1:1, 1:4, and 1:16 were prepared as follows. The powders were mixed and 1% zinc stearate added as lubricant. The mixes were compressed on a $^3/_8$-in. standard cup punch to yield tablets weighing approximately 250 mg. each. Six tablets from each batch were placed in the basket of a U.S.P. modified Stoll-Gershberg apparatus. The basket was lowered into an 800-ml. beaker containing 600 ml. of simulated gastric fluid maintained at 37° ± 0.5° and the apparatus operated in the manner prescribed by the U.S.P. At the end of 1 hr. the basket was transferred to an 800-ml. beaker containing 600 ml. of simulated intestinal fluid, and the operation was continued until disintegration was complete. The time required for complete disintegration was noted.

In Vitro Drug Release Characteristics.—The *in vitro* release characteristics of two formulations were investigated.

Formula *1*	Per Tablet, mg.
Doxylamine succinate	20
Pheniramine maleate	20
Pyrilamine maleate	20
Sodium carboxymethylcellulose	640
Magnesium trisilicate	40
Stearic acid	10

The sodium carboxymethylcellulose was slugged, granulated, and mixed with the remaining powders. Magnesium trisilicate was added to act as an absorbant for the eutectic formed by the antihistamines. The mixture was compressed into $^7/_{16}$-in. tablets at 750 mg. each and a Stokes (Monsanto) hardness of approximately 16 Kg. These antihistamine tablets[1] were placed in the Stoll-Gershberg apparatus and treated as described, except that simulated intestinal fluids were changed at the end of each 2-hr. period. At various time intervals, aliquots of fluid were withdrawn, treated with sodium hydroxide solution, and extracted with 3 vol. of ether. The combined ether extracts were re-extracted with 0.1 *N* HCl and assayed spectrophotometrically for pyrilamine content. Tablets from two different batches were subjected to this study. Three determinations were made on each batch.

[1] Marketed as Tridecamine tablets, by National Drug Co., Division of Richardson-Merrell, Inc., Philadelphia, Pa.

Formula *2*	Per Tablet, mg.
Quinidine sulfate	300
Hydroxypropylmethylcellulose	150
Magnesium stearate	9

The powders were granulated with water and the granulation was ground to a coarse powder. Lubricant was added and the mix was compressed on $^7/_{16}$-in. punches to yield tablets weighing approximately 459 mg. each and a Pfizer hardness of approximately 12 Kg.

Five of these tablets were individually subjected to the release test described for antihistamine tablets. Here, however, the baskets were transferred to fresh solution at the end of each hour. An aliquot of each solution was pipeted into a volumetric flask and made to volume with 0.1 *N* HCl. The solutions were filtered and assayed spectrophotometrically for quinidine sulfate content.

Volume Decay of Tablets.—In order to demonstrate the change in volume during disintegration, quinidine sulfate tablets (disk shaped) were measured, prior to disintegration, with an Ames micrometer gauge. They were disintegrated as previously described for 1, 2, 3, 4, and 5-hr., respectively, removed from the fluids, allowed to dry, and again measured. Tablet volumes were calculated from the formula $\pi r^2 h$. A displacement method for volume determination was also done to verify the micrometer procedure. Volumes were in close agreement with the micrometer procedure.

RESULTS

Influence of Gum Content on Disintegration Behavior.—Tablets made with hydroxypropylmethylcellulose and nicotinic acid had disintegration times proportional to the per cent gum. As the gum content was increased, the disintegration time was extended. The results are given in Table I.

In Vitro Drug Release Characteristics.—Drug substance release patterns from the antihistamine tablets and quinidine sulfate tablets are shown in Figs. 2 and 3. It can be seen that in both cases, an initial rapid release of drug substance occurred. For example, approximately 26% of the pyrilamine content was released from the antihistamine formulation in 1 hr., while approximately 32% of the quinidine sulfate was released in the same time period. After the initial rapid release phase, a much slower constant rate of release occurred until about the 7th hour. It was observed at this time that the tablets were completely hydrated and proceeded to dissolve.

Volume Decay of Tablets.—Tablet volume decay data, obtained for quinidine sulfate tablets, are shown in Fig. 4. An initial rapid decay is noted during the initial period of tablet hydration in gastric fluid followed by an interim change in rate of decay when transferred to intestinal fluid. Linear decay of the dry tablet core takes place

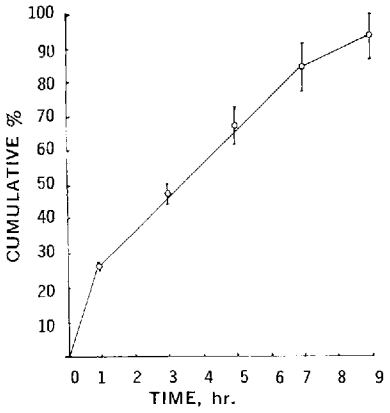

Fig. 2.—*In vitro* dissolution rate for antihistamine tablets. Average and standard deviation of cumulative per cent drug released for six baskets of six tablets.

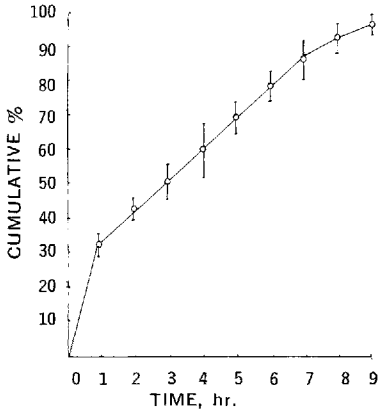

Fig. 3.—*In vitro* dissolution rate for quinidine sulfate tablets. Average and standard deviation of cumulative per cent drug released for five individual tablets.

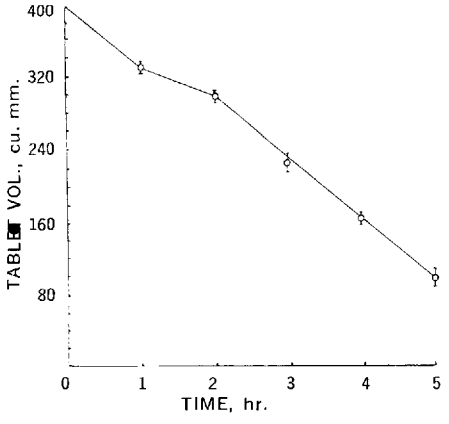

Fig. 4.—*In vitro* volume decay for quinidine sulfate tablets. Average and standard deviations for each of five baskets of six tablets run 1, 2, 3, 4, and 5 hr., respectively.

over the remaining time period until hydration is complete at approximately 7 hr. The 5-hr. sample was the last point at which a large enough dry core was available for accurate measurement.

DISCUSSION

The studies which have been described do not permit a complete elucidation of the exact mechanism involved in this approach to control of drug substance release from tablet formulations. However, the data do support the theory that hydration and gelation of the gum at the tablet–liquid interface constitute an important step in the mechanism. The existence of a gel barrier would be expected to retard drug substance release by limiting the exposure of solid drug to the dissolution liquid. Attrition of and/or diffusion from the gel barrier with concomitant formation of fresh gel could explain the constancy of release rate observed over a considerable time period.

As illustrated by the experiments with the nicotinic acid formulations, the percentage of gum in the formulation has a marked influence on the disintegration and dissolution behavior of the tablet. It should be recognized, however, that this behavior will differ, in quantitative terms, with different drugs and different gums. It has been the author's experience that the most useful gums are those which hydrate readily and rapidly at body temperature. Two examples are sodium carboxymethylcellulose and hydroxypropylmethylcellulose. The antihistamine and quinidine formulations illustrate the type of behavior observed when these gums are used. The dissolution rate patterns here are especially interesting in that a constant rate of release occurred over a considerable time period. This is in contrast to many other systems designed for controlled release where it has been found that release rate decreases as the drug substance content in the dosage form reservoir decreases.

Although no direct correlations between *in vitro* and *in vivo* behaviors of specific formulations have been attempted, it is interesting to note that Halpin (4) in his clinical investigation of the antihistamine formulation reported that the clinical response extended over a 12-hr. period. He also reported a rapid onset of activity. His observations were confirmed by Hansel (5), who reported an antihistaminic effect lasting for 12 hr. Jones *et al.* (6) using an intradermal wheal test, found that the preparation suppressed wheal size for a 12- to 14-hr. period.

The approach that has been described appears to offer attractive possibilities for sustaining the release of drug substances administered orally. The availability of many different gums, the utilization of other excipients, and the application of techniques such as multiple compression of tablets offer the possibility of varying qualitative and quantitative aspects of release rate patterns over a wide range.

Effect of Glyceryl Trinitrate on Extracellular Fluid Space of Aortic Strips

By O. J. LORENZETTI*, ARTHUR TYE, and JOHN W. NELSON

Extracellular fluid space (ECF) was determined in untreated rabbit aortic tissue and in tissue exposed to 0.1 per cent glyceryl trinitrate. The ECF space determinations were made in tissues bathed in a normal Krebs solution, calcium-free Krebs solution, magnesium-free Krebs solution, and calcium–magnesium-free Krebs solutions. The glyceryl trinitrate increased the ECF space in all solutions except the magnesium-free solution.

THE INCREASING importance of the concentration and distribution of ions in tissue during the state of contraction and relaxation necessitates the determination of distribution of tissue water (1, 2). Of importance in studying some effects of glyceryl trinitrate on smooth muscle relaxation was the determination of the extracellular fluid space (ECF).

The direct methods used to determine the distribution of water between extracellular and intracellular compartments are based on the measurement of the volume of distribution of an impermeable solute molecule, *e.g.*, urea, mannitol, inulin, and radio-iodinated serum albumin. Although these substances penetrate the tissue at various rates dependent on their molecular size, the use of any one substance will give an estimate of the relative distribution of the water in the extracellular fluid space.

For the authors' measurements the ECF space was determined by use of inulin, using the anthrone color reaction for spectrophotometric analysis of the inulin concentration (3). The anthrone color reaction is highly sensitive for determinations of small quantities of inulin, as low as 5 mcg./ml. of solution.

The purpose of this paper is to provide data on the measurement of the ECF space of the rabbit aorta exposed to various ionic media, before and after treatment with glyceryl trinitrate.

MATERIALS AND METHODS

Male albino rabbits weighing 2–3 Kg. were killed by a blow to the back of the neck. The thorax and abdomen were opened, and the descending aorta from the arch extending down 9 cm. was isolated from surrounding tissue. The thoracic aorta was mounted directly onto a glass rod and kept moist with Krebs–bicarbonate solution at room temperature.

The aortic strips were cut by rotating the rod against a fixed scalpel blade according to the method described by Furchgott (4). All of the aortic strips conformed to the following dimensions: 2.0 ± 0.55 mm. wide, 2.0 ± 0.3 cm. long, and 450 ±50 μ thick as noted under a microscope. Throughout this procedure the tissue was kept moist with Krebs–bicarbonate solution and gassed with 95% oxygen and 5% carbon dioxide.

The isolated aortic tissue was placed individually into 12-ml. weighing bottles containing 5 ml. of 1.0% w/v inulin in modified Krebs solution. Inulin was substituted for glucose in all Krebs solutions. Three solutions with various concentrations of electrolytes were employed in addition to the normal Krebs solution. The composition of these modified solutions is shown in Table I. The osmotic concentration of the solutions was between 314.5 and 317.5 milliosmoles. The ionic strength ranged from 0.168 to 0.174. The pH was adjusted to 7.36 ± 0.08. Some aortic muscle strips were exposed to 0.1% glyceryl trinitrate and were called treated strips.

TABLE I.—COMPOSITION OF BATH MEDIA FOR AORTIC STRIPS IN mmoles/L.[a]

	Krebs-HCO_3	Calcium-Free	Magnesium-Free	Calcium and Magnesium-Free
NaCl	118.5	120.0	120.0	128.0
KCl	4.8	4.8	4.8	4.8
$CaCl_2 \cdot 2H_2O$	1.9	...	1.9	...
KH_2PO_4	1.2	1.2	1.2	1.2
NaH_2PO_4	...	...	1.2	...
$MgSO_4 \cdot 7H_2O$	1.2	1.2	...	...
$NaHCO_3$	25.0	25.0	25.0	25.0
Dextrose	10.0	10.0	10.0	10.0

[a] Ionic strength, 0.168 to 0.174; osmolarity, 314.5 to 317.5; pH, 7.28 to 7.44.

Both treated and untreated aortic strips were allowed to equilibrate for 12 hr. The tissue was then removed, blotted, and placed in 5 ml. of distilled water contained in another weighing bottle. At the end of a 12-hr. period in the distilled water, the tissue was removed from its container, was blotted, and was weighed. The tissue was then carefully homogenized in 2 ml. of distilled water using a 10-ml. hand homogenizer. The homogenate was centrifuged at 6000 r.p.m.'s for 5 min., and the supernatant was decanted and analyzed for inulin as described below.

Inulin Assay.—Two samples of the distilled water–inulin solution were removed, placed in 22 × 175-mm. Pyrex test tubes, and cooled in a cold water bath to 8 ± 1° for 10 min. Then 2 ml. of freshly prepared anthrone reagent was added directly to the solution in the test tube and mixed by swirling. The anthrone reagent consisted of 0.02% w/v anthrone and 0.1% w/v thiourea (to prevent oxidation of the active enol tautomer of anthrone) in 96% sulfuric acid. The anthrone reagent was precooled to 8 ± 1°. Then the samples were immediately heated for 6 min. at 90 ± 3° on a water bath. The tubes were cooled for 5 min. in an ice bath to 8° and were allowed to come to room temperature. The resulting turquoise-green solutions were read on a Beckman spectrophotometer at 620 mμ within 20 min.

of their removal from the water bath, against a distilled water–tissue blank. The blanks gave a reading of 0.97 ± 0.04% ECF per wet weight of tissue, as determined on 20 tissue blanks taken at random. The inulin concentration was read from a standard curve, constructed from determinations on inulin in distilled water. The inulin space is equivalent to the extracellular fluid space and was expressed as the mg. of inulin per 100 mg. of aortic tissue, wet weight, divided by the mg. $ml.^{-1}$ of inulin in the

ECF times 100 to give per cent ECF per wet weight of tissue (5).

In the tissues exposed to 0.1% glyceryl trinitrate, it was found that the nitrates interfered with the assay. The solutions obtained from tissue treated with glyceryl trinitrate were passed through an anion exchange resin,[1] contained in a 3-cm. (i.d.) × 30-cm. column. The resulting glyceryl trinitrate-free solution was then assayed for inulin as described.

RESULTS

The rate of permeability indicated by a plot of the per cent of extracellular fluid space per 100 mg. tissue wet weight *versus* time (Figs. 1–4) shows that

[1] Marketed as Amberlite IR-45 by Mallinckrodt, St. Louis, Mo.

saturation of the inulin spaces occurs in approximately 4 hr.

The results for the normal Krebs solution in Fig. 1 show that the presence of glyceryl trinitrate increases the permeability of the cell membrane in the tissue as represented by the increase in ECF. The increase was significant from the first to the fourth hour. The values obtained were high relative to those reported in the literature by the use of other methods. It was not intended that the measurement would be an exact value of the extracellular fluid space since the incomplete penetration of inulin into the connective tissue has not been considered. Nichols and co-workers have shown that the ECF space measurements obtained with chloride are better estimations, since chloride penetrates much more rapidly than inulin (6).

The muscle exposed to glyceryl trinitrate in a calcium-free medium also shows a significant increase in the extracellular fluid (Fig. 2). The results indicate that absence of calcium does not affect the increased ECF space induced by the presence of glyceryl trinitrate.

The magnesium-free Krebs media produced an inhibition of the ability of glyceryl trinitrate to increase the ECF space of the smooth muscle over most of the 4-hr. period (Fig. 3). The Krebs media without calcium or magnesium showed no change in the ECF space for the first 2 hr., then a significant increase in ECF in the last 2 hr. as seen in the unmodified Krebs medium (Fig. 4).

The approximately $\pm 5\%$ of the calculated mean in the ECF space determination reflects some variability among the multiple samples. That may be attributed to an actual section-to-section variation within the aorta, with respect to the inulin space or endogenous carbohydrates.

DISCUSSION

Although the velocity of inulin distribution is not affected by incubation of the muscle with glyceryl trinitrate, the apparent volume of distribution of inulin is increased. This indicates an increased permeability of the tissue in the presence of nitrate and nitrite. The increased permeability was not observed in the absence of magnesium with calcium present.

In all the bathing solutions, an early rapid phase and a late slow phase was noted before equilibrium was attained. This could be attributed to different water compartments, but recent studies have indicated that there are more than the two classic water compartments (7) indicated in this study. Possibly, the phases noted could be characteristic of the tissue investigated, indicative of latent penetration of inulin into more complex extracellular structures as suggested by Page (8) for heart muscle.

Saturation of the inulin space occurred in 3 to 4 hr. in these studies. Even after this prolonged time, nitrates and nitrites can still exert an effect on the cell membrane (9).

SUMMARY

Glyceryl trinitrate increases the extracellular fluid space of rabbit aortic tissue in normal Krebs and calcium–magnesium-free Krebs solutions. Only the magnesium-free Krebs solution failed to produce an elevation of the extracellular space of aortic tissue after treatment with glyceryl trinitrate.

Interactions of Surfactants with Lipoproteins

By H. TAKRURI and B. ECANOW

The interactions of benzalkonium chloride and sodium lauryl sulfate with α- and β-serum lipoproteins have been studied. Both fractions, below their isoelectric points, form insoluble complexes with the anionic surfactant. At higher concentrations of the surfactant the insoluble complexes are resolubilized completely. Above the isoelectric point, the lipoprotein fractions exhibit the same phenomenon with benzalkonium chloride. The charge and the hydrophilic nature of the macromolecules are the major factors in these interactions. The formation of insoluble complexes and the resolubilization of these complexes are modified considerably by the addition of urea to the systems.

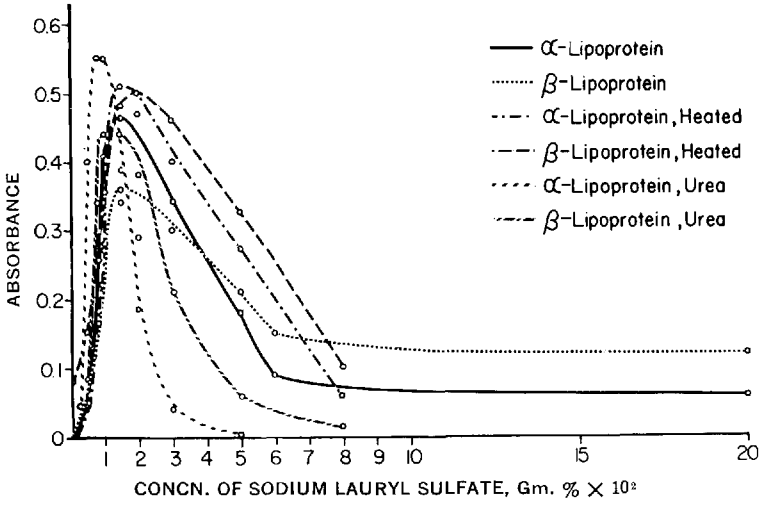

Fig. 1.—Turbidity of various lipoprotein systems as a function of the concentration of sodium lauryl sulfate.

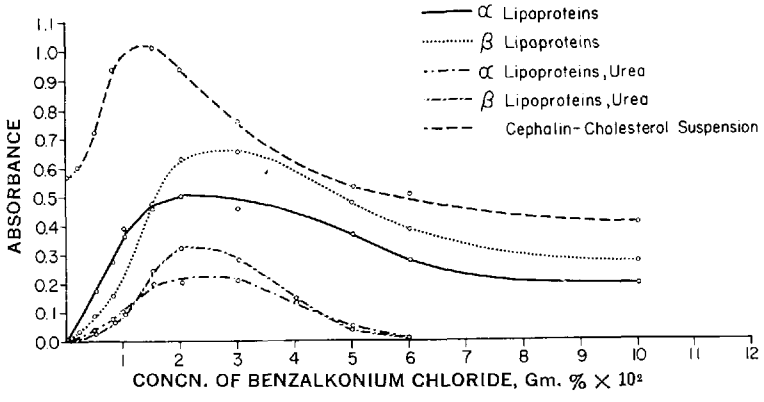

Fig. 2.—Turbidity of various lipoprotein systems as a function of the concentration of benzalkonium chloride.

The lipoproteins have been studied recently in connection with their possible role in the pathogenesis of atherosclerosis and other diseases. Certain subfractions of β lipoprotein were found to be definitely linked to plaque formation (4, 5). The effects of nonionic surfactants on lipoproteins were studied *in vivo* and *in vitro* (6–8). The effects of ionic surfactants on the electrophoretic mobility of these fractions were also studied (1). β Lipoproteins have the property of forming several complexes, soluble and insoluble, with heparin and other polysaccharide sulfates. These interactions depend on several factors, including pH, ionic strength, and metal ions. These interactions are utilized in the separation and characterization of β lipoproteins. Cornwell and Kruger (3) reviewed these interactions in detail.

This paper is a report on a study of the interactions of an anionic and a cationic surfactant with α and β lipoproteins carrying charges opposite to that of the surfactant. The influence of urea on these interactions was also studied.

EXPERIMENTAL

Reagents

Human α lipoprotein, fraction IV-1 (Nutritional Biochemical Corp.), human β lipoprotein, fraction III-0 (Nutritional Biochemical Corp.), bovine α lipoprotein fraction IV-1 (Pentex), cephalin-cholesterol reagent (Wilson), sodium lauryl sulfate (Fisher), benzalkonium chloride solution, 17% (Winthrop Laboratories).

Procedure

Interaction with Sodium Lauryl Sulfate.—A stock solution of 1% sodium lauryl sulfate in distilled water was prepared. Dilutions were made of this stock solution by adding a specified volume to 200-ml. portions of 0.04 *M* sodium chloride solution. One milliliter of 0.1 *N* hydrochloric acid was added to each solution to give a uniform pH of all the solutions. The solutions of the lipoproteins were prepared by dissolving 250 mg. of human β lipoprotein or bovine α lipoprotein in 50 ml. of 0.04 *M* saline. These solutions were dialyzed for 4 hr. at room temperature against a large volume of 0.04 *M* saline. After dialysis, 1.5 ml. of 0.1 *N* HCl was added to each solution and each was made up to 60 ml.

Three milliliters of the lipoprotein solution were added to 22 ml. of the various dilute solutions of sodium lauryl sulfate. This gives a concentration of 50 mg. % of the lipoprotein. This concentration was found to be the optimum concentration for

the determination of turbidity. After the surfactant–lipoprotein solutions were vigorously shaken, they were left to stand for 30–60 min. before the measurements were performed. The interaction was instantaneous and the only observation that required time was the sedimentation of the floccules. The turbidity was measured in a Coleman junior spectrophotometer. The measurements were performed at 450 mμ. The choice of this wavelength was arbitrary. In the study of urea-containing systems, the lipoprotein solutions were subjected to the action of 6 *M* urea for 1 hr. before they were added to the surfactant solutions.

Interactions with Benzalkonium Chloride.—Human lipoprotein fractions, 125 mg. of each, were dissolved in 50 ml. of 0.04 *M* saline, dialyzed for 4 hr. at room temperature against 0.04 *M* saline, and then diluted to 250 ml. with the same solvent. The pH was adjusted to 7.5 ∓ 0.2 with 0.1 *N* NaOH. Twenty milliliters was measured out in 1-oz. bottles and specified volumes of benzalkonium chloride stock solutions (0.1, 1, and 10%) were added to the individual bottles to give the desired concentration of the surfactant. In studying the effect of urea, the lipoprotein solutions were subjected to the action of 3 *M* urea for 36 hr. before adding the surfactant.

The interaction of cephalin–cholesterol reagent and benzalkonium chloride was also studied. This reagent is employed as a liver-function test. The mechanism of the test was reviewed by Bauer (2).

RESULTS

Figure 1 shows the turbidity of the various lipoprotein–sodium lauryl sulfate systems as a function of the concentration of the surfactant. The curves show that α lipoprotein complexes are solubilized at a lower concentration than β lipoprotein complexes. Also they show the negligible effect of heating the lipoproteins solutions for 4 hr. at 60° and the significant effect produced by urea.

Figure 2 shows the turbidity of various lipoprotein–benzalkonium chloride systems and the system benzalkonium chloride–cephalin–cholesterol. The turbidity curves resemble in shape those obtained with sodium lauryl sulfate.

DISCUSSION AND SUMMARY

The plasma concentration of most lipids, including cholesterol, glycerides, and phospholipids, has been studied extensively in relation to many diseases and pathological conditions. But the fact remains that practically all these lipids are found in blood as lipoproteins. The physical-chemical properties of these colloids are very important in determining their behavior and interactions in the body regardless of the total concentration of a particular component, *e.g.*, cholesterol or phospholipids. α and β lipoproteins differ considerably in their colloidal properties. The main difference could be expressed in terms of their hydrophilic nature.

The results of this study show that negatively charged lipoproteins, both α and β, are precipitated and then resolubilized by cationic surfactants. Positively charged lipoproteins are, on the other hand, precipitated and resolubilized by anionic surfactants. The interaction does not require di- or polyvalent metal ions and the insoluble complexes are not dissociated at very high ionic strength (up to 20% NaCl). These results are in contrast to the interactions of polysaccharide sulfates with lipoproteins. The results show that the more hydrophilic α fraction is solubilized at a lower concentration than the β fraction. Heating the lipoproteins causes a slight modification of these interactions. Urea produces a major change in these interactions. The concentration at which no observable turbidity is attained is considerably lowered in the presence of urea. The effect is related to the action of urea on the lipoprotein structure, the water structure, and the critical micelle concentration of the surfactant. The pH profiles of the lipoprotein–surfactant systems as a function of the concentration of the surfactant throw a light on the mechanism of these interactions. This aspect will be the subject of a future communication.

Chromatographic Study of the Alkaloids of *Aquilegia formosa*

By G. H. CONSTANTINE, JR., M. R. VITEK, K. SHETH, P. CATALFOMO, and L. A. SCIUCHETTI

Chromatographic investigation of alkaloid fraction from the roots of *Aquilegia formosa* Fisch. (*Ranunculaceae*) revealed the presence of five alkaloidal spots. Two of them were identified as magnoflorine and berberine. A thin-layer chromatographic procedure was developed which effectively separated berberine, palmatine, and jatrorrhizine.

A PHYTOCHEMICAL investigation of plants considered to be of medicinal value by certain Indian tribes of the Northwest, particularly those of the Warm Springs Reservation, Ore., revealed the presence of alkaloids in the roots of *Aquilegia formosa* Fisch.

An ethnobotanical survey conducted by French (1) noted that numerous species of *Aquilegia* have been widely used by the Indians of North America for a host of medicinal purposes. The reputed medicinal uses include diuretic and analgesic activity, treatment of diarrhea or smallpox, a stimulating tea, etc. Species of *Aquilegia* were employed not only as medicines but also as perfumes (2), and were used in certain magical rites. Hitchcock *et al.* (3) indicate that there are approximately 70 species of *Aquilegia* native to the north temperate zones. They are commonly referred to as "columbines," and many are available as horticultural varieties.

A comparative paper chromatographic screen of 10 horticultural varieties of *Aquilegia* was conducted by Winek *et al.* (4). Their screen did not include *A. formosa*. From the entire group, three alkaloids were established—magnoflorine, berberine, and aquileginine. Chromatography also revealed other alkaloids, but their identities were not established. The presence of palmatine remained equivocal because the solvent systems used did not separate this alkaloid from berberine. An investigation of *A. hybrida* by this same group (5) revealed eight alkaloids in this species. Three of the isolated alkaloids were identified as berberine, magnoflorine, and aquileginine. The others remain unknown.

Since preliminary studies indicated alkaloids in *A. formosa*, and readily available quantities could be collected in the wild, the present study was undertaken. The objectives of this investigation were to identify the alkaloids in this species and to develop a thin-layer chromatographic procedure to identify the alkaloids encountered.

EXPERIMENTAL

Collection and Extraction.—*A. formosa* was collected at the flowering stage during the month of May in Benton County, Ore. The roots were separated, cleaned, and dried in a forced-air dryer at 48° for 5 days. The dried roots were ground to a coarse powder in an Abbé mill. A 2.36-Kg. quantity of this material was continuously extracted with alcohol in a Soxhlet extractor until the extractive gave a negative test with Mayer's reagent. The extract was concentrated to a syrupy residue in a flash evaporator at 40° under reduced pressure. The residue (approximately 600 Gm.) was stored in a refrigerator while portions of it were investigated chromatographically.

Separation of Alkaloidal Fraction.—A 200-Gm. portion of the extract was dissolved in a solution containing 100 ml. of 2% hydrochloric acid and 500 ml. of distilled water. A 2% solution of ammonium reineckate was then added until precipitation ceased (approximately 400 ml.). The mixture was refrigerated for 6 hr., the liquid decanted, and the residue dried *in vacuo*. The dried residue was then taken up in warm acetone (250 ml.), and an equal volume of distilled water was added. To this mixture was added 430 ml. of 0.6% silver sulfate to precipitate silver reineckate (6). The mixture was filtered and the filtrate saved. The precipitate was washed with several portions of 50% acetone (total 500 ml.) and the washings added to the original filtrate. The filtrate was then concentrated to a thick syrup in a flash evaporator.

Chromatographic Procedures.—The initial separation and identification procedures utilized were modified techniques of Winek *et al.* (5). The concentrate described previously was adsorbed onto 28.0 Gm. of activated alumina[1] and pulverized to a fine powder with a mortar and pestle. Ten grams of this mixture was placed atop an activated alumina column (35 × 150 mm.). The column was then developed successively with benzene, chloroform, several varying chloroform–methanol mixtures, and finally methanol alone (Table I, AB). Each fraction was concentrated to approximately 10 ml. in a flash evaporator and subjected to analysis using paper chromatography. The extracts were spotted on Whatman No. 2 filter paper and developed with the upper phase of *n*-butanol–acetic acid–water (BAW 5:1:4) using the ascending technique, or *n*-propanol–ammonium hydroxide–water (PAW 2:1:1) employing the descending technique. The spots were revealed by examining the sheets under ultraviolet light and by spraying them with Dragendorff's reagent (7). The results obtained in this manner were not completely satisfactory, and subsequent analyses were conducted with thin-layer chromatography (TLC). TLC plates of Silica Gel G[2] were prepared according to standard techniques. Several recommended solvent systems for alkaloids (8) were tried. Effective separation of alkaloidal constituents was not realized. The combination of systems finally utilized were BAW (4:1:5) upper phase, BAW (4:1:1), and PAW (2:1:1). The spots were located as previously de-

scribed. The results are summarized in Table I, AB. The U.V. fluorescence was noted only for those compounds which gave orange spots with Dragendorff's reagent.

Presence of Magnoflorine and Berberine.—Winek *et al.* (4, 5) reported the presence of magnoflorine and berberine in several *Aquilegia* species. Based on preliminary chromatography, it appeared that these alkaloids were also present in *A. formosa*. A portion of column fraction 5 (Table I, AB) was spotted heavily in three different channels on Silica Gel G TLC plates. Authentic magnoflorine[3] was spotted

[3] The authors are grateful to Professor J. L. Beal, School of Pharmacy, Ohio State University, Columbus, for authentic samples of magnoflorine, berberine, palmatine, and jatrorrhizine.

TABLE II.—RESULTS OF CO-SPOTTING EXPERIMENTS

Solvent	R_f Values					
	Eluate	Eluate + Magnoflorine Chloride	Magnoflorine Chloride	Eluate	Eluate + Berberine Chloride	Berberine Chloride
BAW (4:1:5)	0.22	0.22	0.22	0.36	0.35	0.36
PAW (2:1:1)	0.64	0.63	0.64	0.70	0.72	0.72

in a fourth channel. The plates were developed in BAW (4:1:5). The three zones possessing blue fluorescence and corresponding to magnoflorine (R_f 0.23) were removed from the plate by means of a zone extractor and eluted with 10 ml. of hot methanol. The solution was reduced to a small volume (approximately 0.1 ml.) and divided into two portions. A chromatoplate was prepared containing the one portion of eluate and magnoflorine spotted individually and one spot containing the other portion of the eluate plus magnoflorine. The plates were developed in PAW (2:1:1). Examination of the plate under U.V. light or spraying with Dragendorff's reagent (blue fluorescence under U.V., orange spot with Dragendorff's reagent) revealed that the eluate and the co-spot of eluate plus magnoflorine gave only one zone which had an identical R_f value to that of reference magnoflorine. Similarly, fraction 5 was chromatographed in PAW (2:1:1). The blue fluorescent zones corresponding to known magnoflorine (R_f 0.65) were extracted and eluted with hot methanol and the co-spotting experiment was run using BAW (4:1:5). Comparable results were obtained.

The presence of berberine was established in an identical manner. In this instance, column fraction 7 was used since visual inspection of preliminary chromatograms indicated higher concentration of the suspected berberine in this fraction. Yellow fluorescent zones corresponding to reference berberine [R_f 0.39 and 0.75 for chromatoplates developed in BAW (4:1:5) and PAW (2:1:1), respectively] were extracted and eluted with methanol. Concentrated eluates were co-chromatographed with berberine in a manner similar to that for magnoflorine. The results of these experiments are summarized in Table II.

TLC plates of fractions 5 and 7 were prepared and developed in BAW (4:1:1). Solutions of reference magnoflorine and berberine chlorides were spotted singly and in combination with extracts 5 and 7, and these were compared to plates of extracts without additions. Detection of spots was carried out as before. The procedure revealed the presence of both alkaloids.

Other Alkaloids.—Preliminary paper chromatography revealed the presence of other alkaloids in fractions 5 and 7. When these fractions were chromatographed in the TLC system, additional spots were noted (Table I). These spots were not identified, but co-chromatography experiments using the three solvent systems described earlier indicated that they were not palmatine or jatrorrhizine.

DISCUSSION

Winek *et al.* (4, 5) reported the presence of alkaloids in 10 species of *Aquilegia* which, however, did not include *A. formosa*. On the basis of chromatography, particularly TLC, the presence of at least five well-defined alkaloids has been demonstrated. Consistent with the results of Winek *et al.* (4, 5), *A. formosa* also contained magnoflorine as the principal alkaloid and berberine as one of the minor alkaloids. Since the majority of the conventional solvent systems (8) failed to provide effective separation of these alkaloids (perhaps because of their quaternary nature), two systems—namely, BAW (4:1:5, acidic) and PAW (2:1:1, alkaline)—were used during co-spotting experiments. In all instances, the alkaloidal mixture along with an authentic sample of either magnoflorine or berberine was run in one system and the subsequent co-chromatography was run in the other. Thus, the eluted spot and the authentic sample were subjected to an entirely new environment. In every case there was no separation of the co-spot.

Berberine and palmatine could not be distinguished by TLC employing BAW (4:1:5). However, BAW (4:1:1) separated these two closely related alkaloids cleanly. Co-chromatography using the combination of three TLC systems (Table I, AB) eliminated the presence of palmatine in *A. formosa*. In a similar manner, the presence of jatrorrhizine in the alkaloid mixture was also eliminated. It will be necessary to isolate adequate quantities of the other alkaloidal substances in order to establish their identity.

Determination of *In Vitro* Release Rates of Sustained-Action Preparations by Paper Chromatography and Electrophoresis

By H. SCHRIFTMAN

Determination of *in vitro* release rates of experimental formulations requires multiple analyses by conventional methods. A general procedure is presented for determining *in vitro* release patterns using paper chromatography and electrophoresis techniques which eliminates the tedious manipulations involved with the evaluation of such formulations by conventional methods. Application of these chromatographic and electrophoretic procedures to a preparation containing phenylpropanolamine HCl, dextromethorphan HBr, and chlorpheniramine maleate is described. The procedures compare favorably in accuracy and speed with the conventional techniques. A scheme for the rapid evaluation of several experimental sustained-action formulations using the above techniques is suggested.

DRUGS that have been in general use for a long time are now becoming available in sustained-action formulations containing other active compounds. In handling the assay of these preparations, the customary methods, *i.e.*, ultraviolet spectroscopy and colorimetry, become laborious and unwieldy because additional filtering and extraction steps are generally necessary for their successful application. In addition, the difficulties are magnified by the need to assay many samples in order to determine the *in vitro* release patterns. The assays and release studies of these multicomponent preparations are considerably simplified by paper chromatographic and electrophoretic procedures. In general, separations of the various compounds are accomplished through ascending and descending paper partition chromatography by selection of appropriate solvent systems or by paper electrophoresis with selected pH buffer systems. The papergrams are sprayed with an appropriate color developing reagent and assayed quantitatively by photoelectric densitometry. These techniques have been described previously for conventional multicomponent formulations (1–3).

Application of these procedures to a sustained-action preparation containing phenylpropanolamine HCl, dextromethorphan HBr, and chlorpheniramine maleate is described. In addition, a scheme for the rapid evaluation of experimental sustained-action formulations using the above techniques is suggested.

EXPERIMENTAL

Reagents.—*n*-Butanol A.C.S., 1 *N* hydrochloric acid, absolute alcohol U.S.P., methanol A.C.S., modified Dragendorff's reagent (iodobismuthate) as described before (2, 3), ninhydrin (Fisher reagent), cadmium acetate·$2H_2O$ (Baker reagent), glacial acetic acid A.C.S., pH 4 acetate buffer (0.1 *M*), 1 *N* sodium hydroxide, petroleum ether (Fisher reagent), simulated gastric juice, and intestinal juice were employed.

Equipment.—Whatman No. 1 and 3 mm. chromatographic paper, micropipets,[1] 0.005 and 0.010 ml., photovolt densitometer, model 530 with recording and integrator attachments, pressure plate paper electrophoresis equipment, model EC-455-18 in. with power supply No. EC453 and ice water circulator No. EC322 (E. C. Apparatus Co.), rotating bottle apparatus (Smith Kline & French) as described before (4), and appropriate chromatographic containers were used.

Procedures.—Totals and release rates of a sustained-action capsule containing chlorpheniramine maleate, 4 mg., phenylpropanolamine hydrochloride, 50 mg., and dextromethorphan hydrochloride, 30 mg., are assayed as follows.

Paper Chromatography.—Powdered contents of two capsules are used directly for total assay while the residues obtained from the usual rotating bottle technique for release studies are dried and ground to a fine powder. These powders are transferred to a 25-ml. volumetric flask to which 15 ml. of absolute alcohol is added. After heating the flask on a steam bath and shaking mechanically for 15 min., the flask is cooled and diluted to mark with absolute alcohol. This mixture is well shaken and undissolved material is allowed to settle to the bottom before spotting the sample. A standard solution containing known amounts of "actives" are likewise prepared in absolute alcohol. These solutions are spotted with micropipets (0.04 ml. in 0.01-ml. increments) on Whatman No. 1 paper which was prewetted with a 1:1 mixture of butanol (saturated with 1 *N* HCl) and methanol. This moist, blotted paper is used for separating and quantitating the dextromethorphan HBr and the chlorpheniramine maleate, while another similarly prepared paper is spotted with 0.005 ml. for the assay of the phenylpropanolamine hydrochloride. A descending chromatographic technique is used with butanol saturated with 1 *N* HCl as the solvent system. An overnight migration of the solvent is sufficient for separating the chlorpheniramine maleate and dextromethorphan HBr. The air-dried chromatograms are sprayed with modified Dragendorff's reagent and the resultant orange-red spots are quantitatively evaluated and compared with a photovolt densitometer containing recording and integrating equipment (1). The other papers containing phenylpropanolamine spots are also analyzed by photoelectric densitometry after spraying with a special ninhydrin reagent (0.2% ninhydrin plus 0.5% cadmium acetate in 95% alcohol containing 2% glacial acetic acid) and heating for 10 min. at 100°. Figure 1 shows the relative migration of the active ingredients.

Paper Electrophoresis.—Again the powdered con-

Received April 25, 1966, from the Pharmaceutical Research and Development Laboratories, Warner-Lambert Research Institute, Morris Plains, N. J. 07950.

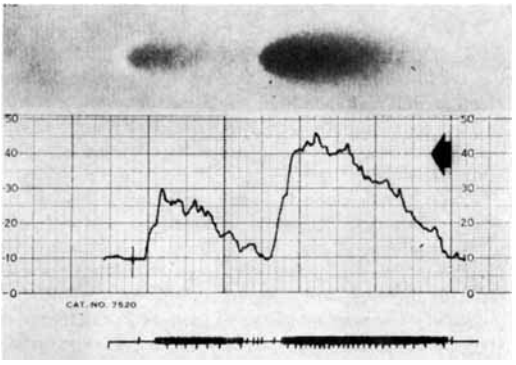

Fig. 2.—Electrophoretic separation of chlorpheniramine and dextromethorphan and their respective recorded and integrated density curves. Chlorpheniramine is the faster moving spot.

tents of two capsules and residues are dissolved and prepared as described for the paper chromatographic procedure. Whatman No. 3 mm. paper strips are prepared for electrophoresis with pH 4 acetate buffer (0.1 *M*) as described previously (1). Two strips are spotted with 0.04 ml. (in 0.01-ml. increments) of standard and sample solutions, while two other strips are spotted with 0.005 ml. of each solution. The papers are placed in an EC apparatus horizontal-type electrophoresis equipment (18 in.) for 16 hr. at 250 v. at 4° (in a walk-in refrigerator). Alternately, the migration can proceed at 600 v. for 6 hr. using salted ice water circulated by a peristaltic pump through the plates. One set of completed and dried electrophoretograms containing the 0.04-ml. spots are sprayed for the detection of the chlorpheniramine maleate and dextromethorphan HBr while the other strips are sprayed with ninhydrin reagent for phenylpropanolamine HCl as described above. Again, as described under *Paper Chromatography*, the resultant spots are analyzed and compared by photoelectric densitometry. Figures 2 and 3 show relative migration of spots as well as their typical recorded and integrated curves.

Application of Paper Chromatography and Paper Electrophoresis to Aqueous Portions of Release Studies.—It may be necessary at times (usually on initial runs) to assay the filtered aqueous portions as well as the residues from a sustained-release study in order to check out the assay and verify the release pattern. The filtered aqueous portions are placed into a 250-ml. separator and 5 ml. of 1 *N* sodium hydroxide is added. The alkaline solution is extracted with 2 × 75 ml. of petroleum ether, which is evaporated to small volume on a steam bath. Evaporation is continued to dryness at room temperature with the aid of a stream of nitrogen. The

residue is dissolved in absolute alcohol and transferred to a 25-ml. volumetric flask and brought up to mark with alcohol. The analysis of this solution is then continued *via* paper chromatography and electrophoresis as described.

RESULTS

The results listed in Table I indicate that the procedures presented here compare favorably with a conventional method involving a periodate oxidation of phenylpropanolamine hydrochloride as reported by Chafetz (5) followed by bicomponent spectral analysis of the other two ingredients, which must include corrections for interference from base materials. Thus, in addition to eliminating the tedious manipulations involved in the assay of these preparations by the conventional methods, paper chromatography and electrophoresis have dispensed with the need for correction factors which have to be determined every time a new formulation is devised. Reliance of the proposed methods are further substantiated by data contained in Table II, which compare the assays of the residues with their corresponding aqueous portions obtained from the release studies. In general, a scan of the results obtained from the respective and combined aqueous and residue contents of "actives" approaches within 2 to 3% of the theoretical 100% combined values.

DISCUSSION

The comparative ease and success of applying these procedures to a sustained-action formulation lends credence to the following proposed scheme for the rapid evaluation of these preparations. The pharmaceutical developer could semiquantitatively compare his various formulations using the above techniques, as follows.

Large sheets of Whatman No. 1 chromatographic paper or several strips of Whatman No. 3 mm. paper are prepared by spotting known quantities of the "actives" in the release pattern that is required, *i.e.*, 50% release of active No. 1, 20% release of active No. 2, and 25% of active No. 3 for 1 hr., followed by the requirements for 2, 3, 4, 5 hr., etc. The various formulations after the various hours of the release study are then subjected to procedures as described here, and their resultant spots are compared visually with the respective reference spots. This rapid surveillance could indicate which formulation (if any) approaches the desired release pattern. In this manner, many formulations could be evaluated and compared at the same time, thus saving the experimental formulator valuable time. In addition, the analyst obtains fewer samples for final and accurate quantitation; and using the methods presented here, he saves further time which frees him for the performance of other assays.

SUMMARY

Paper chromatographic and electrophoretic procedures have been successfully applied for studying the release pattern of a multicomponent sustained-action preparation.

The procedures compare favorably in accuracy and speed with the conventional techniques.

Simplicity and ease of application of these methods have led to the suggestion that several sustained-action formulations could be rapidly evaluated by the product developer.

Some Factors Affecting Inhaler Dosing

By KENNETH R. HEIMLICH and MARY C. GINKIEWICZ

Some factors affecting the dose from an inhalant dosage form have been studied. It was found that rate of dosing, but not pressure, influenced the amine dose from propylhexedrine inhalant N.F.

SOME ASPECTS of inhaler technology were discussed in this journal in 1962 by Kennon and Gulesich (1). From their work they concluded that the vapor pressure of the drug and additives in an inhalant dosage form was not the dose-determining factor. They contended that inhaler dosing is a process controlled by factors affecting the rates of volatilization, whereas, vapor pressure values represent an equilibrium situation. Recently, in answer to an inquiry from the National Aeronautics and Space Administration, the authors have substantiated the above findings and further studied the factors affecting the dose from an inhalant dosage form. The inquiry from NASA concerned the possible inclusion of propylhexedrine inhalant N.F. in the medical kit for the Apollo Space Program. Since the pressure inside the spacecraft is maintained at 5 lb./sq. in. absolute (p.s.i.a.), it was necessary to know the amount of propylhexedrine per inhalation which would emanate from the inhaler at this reduced pressure.

EXPERIMENTAL

A dosing chamber (Fig. 1) which could be operated at reduced pressures and varying flow rates was constructed. An oxygen source was attached to the inlet valve of the system and the outlet was attached to an aspirator. The chamber then was adjusted to maintain the desired pressure at a specific flow rate of oxygen. At the time of dosing, a valve which maintained an open system between the chamber and the dosing tube was closed. This caused the oxygen flow to pass through the inhaler unit carrying vapors down into the dosing tube which contained a standardized solution of sulfuric acid. The assay of the amine was done by making the solution alkaline and extracting with chloroform. The chloroform extract was titrated potentiometrically in an isopropanol–ethylene glycol solution with hydrochloric acid. Three inhalers were dosed and assayed at each condition.

RESULTS AND DISCUSSION

The results of the inhaler dosings are given in Table I.

The data indicate that reducing the pressure above the inhaler to 5 p.s.i.a. does not affect the dose delivered by the inhaler. However, the rate at which the oxygen is passed through the inhaler significantly affects the dose.

Received June 8, 1966, from the Product Development Laboratory, Menley and James Laboratories, Ltd., subsidiary of Smith Kline & French Laboratories, Philadelphia, Pa.

Accepted for publication July 6, 1966.

The authors thank Dr. E. Garrett for his helpful comments concerning this work, and Mr. Russell Lantz for constructing the dosing chamber.

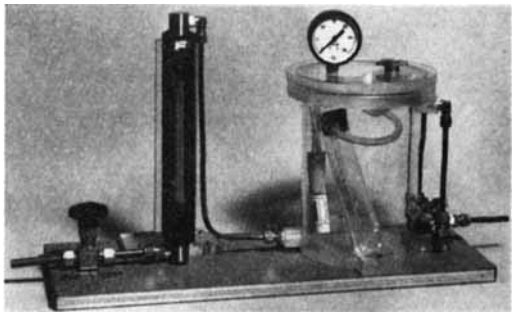

Fig. 1.—Dosing chamber for inhaler units. Chamber can be operated at varying pressures and flow rates.

TABLE I.—MILLIGRAMS OF PROPYLHEXEDRINE FROM INHALERS DOSED AT VARYING PRESSURES AND FLOW RATES

Flow Rate through Inhaler	Pressure	Propylhexedrine/L. of Oxygen passed through Inhaler, mg.
6 L./min.	5 p.s.i.a.[a]	0.39
6 L./min.	Atmospheric	0.45
1 L./min.	5 p.s.i.a.	0.71
1 L./min.	Atmospheric	0.75

[a] Pounds per square inch absolute.

The dosing of an inhaler may be considered analogous to a distillation process in that the active driving force of the system is the tendency for liquid and vapor to approach equilibrium. In the inhaler system this equilibrium is never attained. The fact that the vapor dose varied at different flow rates is direct evidence of this. If sufficient time were allowed for the passage of a constant volume of oxygen through the inhaler, the amount of drug evaporated would be independent of time since equilibration would occur. However, at a certain dosing rate of oxygen per unit time, the evaporation rate becomes dose determining. Thus, at a constant evaporation rate more drug is obtained per unit volume from a slow dosing rate than from a faster rate.

Since the change of pressure did not affect the dose, it may be assumed that the gases are behaving ideally at the pressures present in the system. Had the system been operated at higher pressures, collision with higher concentrations of molecules would have retarded the amount of amine vaporized and conceivably the dose would become pressure dependent.

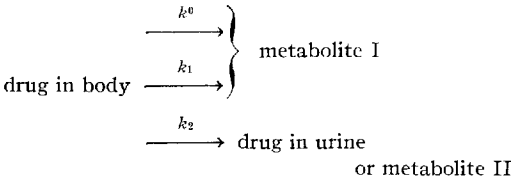
Possibility of Simultaneous Apparent Zero- and First-Order Kinetics in the *In Vivo* Formation of a Single Drug Metabolite

Sir:

The biotransformation of many drugs is describable by first-order kinetics and most of the theoretical models in pharmacokinetics have been developed on that basis (1, 2). It is now known that several important biotransformation processes have a limited capacity (3, 4) and proceed by apparent zero-order kinetics in the therapeutic dose range (4). The purpose of this communication is to propose the possibility that a single biotransformation product may be formed by a combination of simultaneously occurring apparent zero- and first-order processes.

Many biotransformation processes are known to occur in more than one tissue. For example, significant enzymic transformation of phenol to phenol sulfate has been demonstrated in human liver, adrenals, kidneys, and small intestine (5). These tissues differ in intrinsic (maximum rate per unit weight of tissue) and absolute capacity for this process. Therefore, it is likely that, at a sufficiently high drug concentration in body fluids, biotransformation in one tissue proceeds at a maximum rate while the same process in another tissue follows apparent first-order kinetics.

Such mixed kinetics in the formation of a single metabolite (metabolite I) might involve, for example, one apparent zero-order process[1] in parallel with one or more apparent first-order processes which do not reach "saturation" at any reasonable drug concentration. If the drug is also eliminated partly by renal excretion or by apparent first-order formation of another metabolite (metabolite II), the following model will apply:



where k^0 and k_1 are apparent zero- and first-order rate constants, respectively, for the formation of metabolite I, and k_2 is the apparent first-order rate constant for renal excretion of unchanged drug or for formation of metabolite II. Under these conditions, the fraction of the dose which is excreted as metabolite I will decrease with increasing dose. However, unlike the case where one of the metabolites is formed *solely* by apparent zero-order kinetics, the fraction of the dose excreted as metabolite I will approach a relatively constant value at high doses. This is so because the contribution of the apparent zero-order process to the total elimination process will become negligible at sufficiently high doses. At these high doses, the fraction of the total excreted drug which is metabolite I will approach the value $k_1/(k_1 + k_2)$ as in apparent first-order kinetics (6). The dose range where this occurs will depend on the values of k^0 and k_1.

[1] It is assumed as a matter of convenience that the capacity of this process is so low that a maximum rate is reached with very low doses.

Stereochemistry of Methadol Diastereomers

Sir:

Previous investigations (1, 2) have shown that catalytic or lithium aluminum hydride reduction of methadone (I) proceeds stereospecifically to afford α-methadol (II*a*), while sodium in propanol reduction gives rise to a mixture of diastereomers in which the β-isomer (II*b*) predominates. The stereochemistry of these isomers is of great interest because of the remarkable changes in the configurational selectivity of analgesic receptors (Table I) which takes place in the α-series. Such changes recently have been rationalized in terms of differing modes of analgesic–receptor interactions (3).

In this paper evidence is presented which leads to the complete stereochemical assignment and conformational preference of these diastereomers.

Quaternization of racemic α- and β-methadol with methyl iodide afforded the corresponding methiodides, IV*a* (4) and IV*b*, m.p. 189–191°. Pyrolysis of IV*a* and IV*b* proceeded stereospecifically to give rise to isomeric tetrahydrofuran derivatives V*a*, m.p. 90–91° (4), and V*b*, m.p. 61–63°, respectively. Catalytic hydrogenation of VI which was obtained by the method of Easton (5, 6), afforded a mixture of V*a* and V*b* in 60% yield, whose composition was estimated by NMR analysis to be in a ratio of 2 to 1. Molecular models (Stuart-Briegleb) indicate that the top face of VI is more accessible to the hydrogenation catalyst than is the side which is *cis* to the C-5 methyl group. This strongly suggests that V*a* corresponds to the *cis*-isomer and V*b* represents the *trans*-diastereomer.

In view of the stereospecificity of the ring closure to V and the reported (7) formation of optically active VI from enantiomers of methadone methiodide, it is evident that the cyclization of IV*a* and IV*b* involves inversion at the C-6 asymmetric center. The relative stereochemistry of II*a* and II*b* therefore can be designated as (3S:6S) or (3R:6R) and (3R:6S) or (3S:6R), respectively. This assignment was corroborated by determining the dissociation constants of α- and β-methadol in methanol. The pKa of II*a* is 8.15 while that of II*b* is 7.85. According to the current concepts (8) concerning the base strength of diastereomeric amino alcohols, the pKa of these diastereomers is a reflection of the difference in the ability of the protonated species of II*a* and II*b* to form intramolecular hydrogen bonds of the type illustrated by formula VII. The diastereomer which is hydrogen bonded more strongly is more highly dissociated. The fact that α-methadol (II*a*) is a stronger base therefore indicates that there is less steric hindrance to intramolecular hydrogen bond formation. Molecular models show that this is consistent with the stereochemistry proposed above for II*a* and II*b*, since it can be seen that the cyclic hydrogen bonded conjugate acid of β-methadol (VIII*b*) has both the methyl and ethyl groups on the same side of the *quasi* ring, whereas the less hindered α-isomer (VIII*a*) has these groups on opposite sides.

High resolution infrared studies of II*a* and II*b* in carbon tetrachloride show that the bases are intramolecularly hydrogen bonded in as high a concentration as 0.25 *M*, thus indicating strong association. This was substantiated by NMR analysis of the bases in deuterochloroform. The hydroxylic protons of II*a* and II*b* resonate at unusually low field (8.6 and 7.9 p.p.m., respectively) and have peak half-widths of 30 and 23 c.p.s., respectively. The fact that the hydroxy-

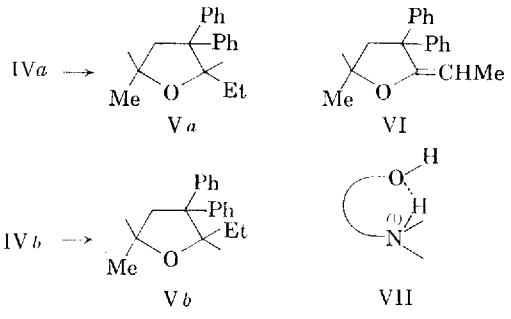

TABLE I.—ANALGESIC ACTIVITY OF METHADOLS AND ACETYLMETHADOLS (2)

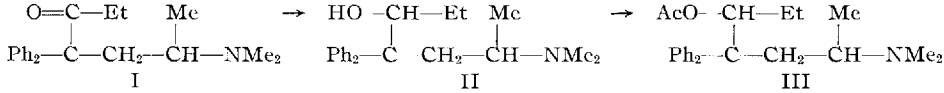

Configuration	ED_{50}[a]	Isomer	ED_{50}[a]	Isomer	ED_{50}[a]

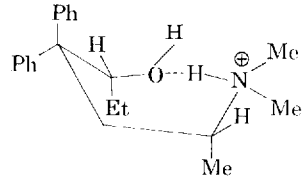
VIII *a*



VIII *b*

ylic proton resonance for II*a* is broader than that of II*b* indicates that the former free base forms stronger intramolecular hydrogen bonds than does the latter. The conformation of the bases, therefore, are very similar to the hydrogen bonded conjugate acids.

Further evidence for the stereochemistry of the methadols was obtained by application of Prelog's rule (9). Treatment of (−)-II*a* with benzoylformyl chloride produced in 95% yield the benzoylformate ester hydrochloride (IX), m.p. 195°, $[\alpha]_D^{25}$ −74.9°, which was converted to its methiodide (X), m.p. 208°, $[\alpha]_D^{25}$ −42.8° (70% yield). Reacting either IX or X with methylmagnesium iodide followed by saponification, afforded (80% over-all yield from X) S-(+)-atrolactic acid (XI), $[\alpha]_D^{25}$ +4.3° (1% in 1 *N* NaOH), corresponding to 8% optical purity (10). In accordance with Prelog's rule (9), the stereochemistry at C-3 therefore is assigned to the S-series.

Since the absolute configuration of (+)- and (−)-methadone, which are precursors of optically active α- and β-methadol (see Table I) has been determined (11), the complete absolute stereochemistry is as shown below. The (+)-α- and (−)-β-series are the mirror image forms corresponding to the projection formulas.

Carbonate Prodrugs in Formulation and Therapeutics

Sir:

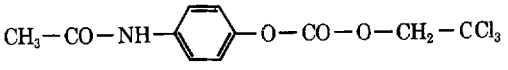
The authors have noted that numerous carbonate diesters can be made of drugs containing the hydroxy group. Often such carbonates are prodrugs, *i.e.*, new compounds having physical–chemical properties different from the parent drugs but retaining qualitatively identical pharmacologic effects and reverting to the parent drug in the body. That they are prodrugs which are hydrolyzed to the parent drugs in the body is attested to by *in vitro* cleavage studies where blood serum has been shown to be a good source of enzymes for catalyzing the hydrolysis reactions.

The principle of prodrug formation has special utility where the parent drug possesses undesirable pharmaceutical features. For example, trichloroethanol possesses interesting sedative properties; but it is a volatile liquid with an unpleasant odor and taste. As such, it is not conveniently suited for therapeutic use: but by reaction with phosgene, it can be converted into bis-trichloroethyl carbonate having a melting point of 86–87°. This previously unreported crystalline compound is virtually tasteless, has sedative properties, and can be encapsulated or tableted.

$CCl_3—CH_2—O—CO—O—CH_2—CCl_3$

bis-Trichloroethyl Carbonate

Similarly, for example, a trichloroethyl carbonate diester of acetaminophen has been made by reacting it with trichloroethyl chloroformate. It is a crystalline compound, m.p. 151–153.5°, possessing the analgetic and sedative properties of the parent drugs from which it is derived, and is also virtually free of taste.



2,2,2-Trichloroethyl-4-acetamido-phenylcarbonate

These compounds, and some related ones, are interesting new compositions of matter. With but few exceptions (quinine ethyl carbonate, alkyl erythromycin carbonates) carbonate diesters have not been utilized as therapeutic agents, and to our knowledge it has not been demonstrated, heretofore, that diester carbonates are prodrugs. Studies on their physical-chemical properties, cleavage rates, biochemistry, and pharmacology along with studies on their pharmaceutic and therapeutic utilities will be subjects of more detailed publications.

Nonexistent Compounds: Compounds of Low Stability. By W. E. DASENT. Marcel Dekker, Inc., 95 Madison Ave., New York, N. Y. 10016, 1965. ix + 182 pp. 16 × 23.5 cm. Price $8.50.

To anyone concerned with preparing or using stable compounds, the unstable ones are of interest, if only for the purpose of avoidance. And, of course, there are many shades of gray between the possible and impossible.

This little book has taken as its theme those inorganic compounds that are on the verge of stability, usually arranged in such classes that some of the members are stable and some are not. The compounds are discussed in terms of the reasons for their variations in stability.

The book opens with a chapter on various general approaches to stability, *e.g.*, valence and structure, thermodynamics, tendencies in chain and multiple bond formation. A chapter illustrating each of several types of stability then follows. The semistable compounds of nitrogen, sulfur, phosphorus, and silicon have the most representatives, but there are illustrations from almost all the elements except the electropositive metals and the two rare earth series. There is a ten page discussion of compounds of the noble gases. It is difficult to give a typical example of the types of compounds included, so varied are they. The purely ionic compounds are specifically excluded.

Explanations and discussions are well grounded theoretically and are well documented. There are extensive tabulations of energetic data. The author leans heavily on Pauling's "Nature of the Chemical Bond" as concerns valence and bond energies, and writes generally in the same spirit as Pauling.

The book is not a mere curiosity, as suggested by the facetious title. It will find its best use as a rich source of illustrative material for the principles involved in the stability of inorganic and metal-organic chemistry. Some readers will be disappointed that it contains little of direct value for the organic chemist. A book in that subject would have a larger audience, and its point of view would be much different. Of course, it would have a different author.

Remington's Pharmaceutical Sciences. XIII ed. Editor-in-Chief ERIC W. MARTIN. Mack Publishing Co., Easton, Pa., 1965. xii + 1954 pp. 21 × 29 cm. Price $23.50

In keeping with the increased emphasis on the scientific basis of pharmacy, this classic has changed its title—from "Remington's Practice of Pharmacy" to "Remington's Pharmaceutical Sciences." The basic outline of earlier editions has been followed; however, many chapters have been revised and several new chapters have been added to reflect the latest developments in analytical and manufacturing procedures. The greatest amount of new material has been in the field of physical pharmacy—four areas are covered in new individual chapters—biopharmaceutics, quantum theory, reaction kinetics, and thermodynamics. A chapter on plastics has been added to the manufacturing section and includes the more recent developments in the nature, uses, and testing of plastics used in medicine.

Drugs are discussed individually as in previous editions. The use statements might more properly be called a therapeutic summary; uses are given, of course, but also included in the discussion are action, special advantages and/or disadvantages, side effects, and cautions.

Tests and assays for official (U.S.P. and N.F.) items are no longer included, since the respective compendia may be consulted for this information.

The physical make-up of the book is excellent; type size and column width make it easy to read, and it is well indexed.

The Remington is up to date, with the changes in the N.F. and U.S.P. being reflected.

It is difficult to review a book so familiar to all pharmacists and already of proved value. The summation which appears on the title page seems most appropriate. "Remington's Pharmaceutical Sciences" is: "A treatise on the manufacturing, standardizing, and dispensing of pharmaceutical products with biological and chemical properties and tests, assays, uses, and doses; also a guide to the legal obligations of the pharmacist and the professional services rendered in helping to maintain community health. A textbook and reference guide for pharmacists, physicians, and other medical scientists."

Encyclopedia of Industrial Chemical Analysis. Vol. I, General Techniques A-E. Edited by F. D. SNELL and C. L. HILTON. Interscience Publishers, a div. of John Wiley & Sons., Inc., 605 Third Ave., New York, N. Y. 10016, 1966. xv + 763 pp. 18.5 × 26 cm. Price $35.00 per copy with subscription. $45.00 per single copy.

The structure of the chemical industry, the nature of the chemical products, and the methods and techniques of analysis have undergone radical changes in recent years. As a result, a comprehensive view of industrial analytical chemistry was felt to be a desirable undertaking. This is the first in a series of volumes to fulfill that need. Methods and techniques used throughout the world for the analysis of raw materials, intermediate, and finished products, as well as evaluation of the finished product for its intended use, will be included. The Encyclopedia will be presented in

Remington's Pharmaceutical Sciences. XIII ed. Editor-in-Chief ERIC W. MARTIN. Mack Publishing Co., Easton, Pa., 1965. xii + 1954 pp. 21 × 29 cm. Price $23.50

In keeping with the increased emphasis on the scientific basis of pharmacy, this classic has changed its title—from "Remington's Practice of Pharmacy" to "Remington's Pharmaceutical Sciences." The basic outline of earlier editions has been followed; however, many chapters have been revised and several new chapters have been added to reflect the latest developments in analytical and manufacturing procedures. The greatest amount of new material has been in the field of physical pharmacy—four areas are covered in new individual chapters—biopharmaceutics, quantum theory, reaction kinetics, and thermodynamics. A chapter on plastics has been added to the manufacturing section and includes the more recent developments in the nature, uses, and testing of plastics used in medicine.

Drugs are discussed individually as in previous editions. The use statements might more properly be called a therapeutic summary; uses are given, of course, but also included in the discussion are action, special advantages and/or disadvantages, side effects, and cautions.

Tests and assays for official (U.S.P. and N.F.) items are no longer included, since the respective compendia may be consulted for this information.

The physical make-up of the book is excellent; type size and column width make it easy to read, and it is well indexed.

The Remington is up to date, with the changes in the N.F. and U.S.P. being reflected.

It is difficult to review a book so familiar to all pharmacists and already of proved value. The summation which appears on the title page seems most appropriate. "Remington's Pharmaceutical Sciences" is: "A treatise on the manufacturing, standardizing, and dispensing of pharmaceutical products with biological and chemical properties and tests, assays, uses, and doses; also a guide to the legal obligations of the pharmacist and the professional services rendered in helping to maintain community health. A textbook and reference guide for pharmacists, physicians, and other medical scientists."

Encyclopedia of Industrial Chemical Analysis. Vol. I, General Techniques A-E. Edited by F. D. SNELL and C. L. HILTON. Interscience Publishers, a div. of John Wiley & Sons., Inc., 605 Third Ave., New York, N. Y. 10016, 1966. xv + 763 pp. 18.5 × 26 cm. Price $35.00 per copy with subscription. $45.00 per single copy.

The structure of the chemical industry, the nature of the chemical products, and the methods and techniques of analysis have undergone radical changes in recent years. As a result, a comprehensive view of industrial analytical chemistry was felt to be a desirable undertaking. This is the first in a series of volumes to fulfill that need. Methods and techniques used throughout the world for the analysis of raw materials, intermediate, and finished products, as well as evaluation of the finished product for its intended use, will be included. The Encyclopedia will be presented in

but each chapter begins with an excellent table of contents. The binding of the book is fairly good; the print is readable; and the quality of the paper is good.

The book is addressed to research workers and graduate students, and it will be highly useful as a reference to organic chemists, biochemists, physical organic chemists, analytical chemists, and (to a lesser extent) to physical pharmacists. It is recommended for the research library, with the hope that the entire set of "Chemistry of Functional Groups" will be of the same quality.

Nonexistent Compounds: Compounds of Low Stability. By W. E. DASENT. Marcel Dekker, Inc., 95 Madison Ave., New York, N. Y. 10016, 1965. ix + 182 pp. 16 × 23.5 cm. Price $8.50.

To anyone concerned with preparing or using stable compounds, the unstable ones are of interest, if only for the purpose of avoidance. And, of course, there are many shades of gray between the possible and impossible.

This little book has taken as its theme those inorganic compounds that are on the verge of stability, usually arranged in such classes that some of the members are stable and some are not. The compounds are discussed in terms of the reasons for their variations in stability.

The book opens with a chapter on various general approaches to stability, *e.g.*, valence and structure, thermodynamics, tendencies in chain and multiple bond formation. A chapter illustrating each of several types of stability then follows. The semistable compounds of nitrogen, sulfur, phosphorus, and silicon have the most representatives, but there are illustrations from almost all the elements except the electropositive metals and the two rare earth series. There is a ten page discussion of compounds of the noble gases. It is difficult to give a typical example of the types of compounds included, so varied are they. The purely ionic compounds are specifically excluded.

Explanations and discussions are well grounded theoretically and are well documented. There are extensive tabulations of energetic data. The author leans heavily on Pauling's "Nature of the Chemical Bond" as concerns valence and bond energies, and writes generally in the same spirit as Pauling.

The book is not a mere curiosity, as suggested by the facetious title. It will find its best use as a rich source of illustrative material for the principles involved in the stability of inorganic and metal-organic chemistry. Some readers will be disappointed that it contains little of direct value for the organic chemist. A book in that subject would have a larger audience, and its point of view would be much different. Of course, it would have a different author.

The Encyclopedia will be presented in

two parts—General Techniques and Analysis of Specific Materials. General techniques is considered as an introduction to the main work. In three volumes, general methodology applicable to a large number of products will be covered and step-by-step procedures using typical equipment are included. A few of the many items which appear in this first volume (A–E) are: absorption and emission spectroscopy, acid–base titrations, chromatography, coulometry and coulometric titrations, electrical methods of analysis, and evaluation of analytical data.

Journal of Macromolecular Chemistry. Vol. 1, No. 1, January 1966. Edited by GEORGE E. HAM. Marcel Dekker, Inc., 95 Madison Ave., New York, N. Y., 10016, 1966. 196 pp. 15 × 22.5 cm. Price $35.00 per year (4 issues).

This is the first issue of this new journal which is to be published quarterly. It is the first new journal in the polymer field in the United States in the last 25 years. The editorial board is representative of the U. S., Canada, Japan, Italy, Germany, England, France, and Switzerland with members from both industry and education. A sample of the contents of the first issue is provided by four arbitrarily picked papers from the twelve included: (*a*) Interpretation of the Microstructure of Polyisoprene and Polybutadiene Obtained in Anionic Polymerization; (*b*) Molecular Structure and Configuration of Polymers: NMR Spectra of Poly-(Alkylene Oxide) Terminal Groups; (*c*) Sequence Reversibility in the Copolymerization Process; and (*d*) Particle Flocculation During Emulsion Film Formation.

Techniques Utilized in the Evaluation of Psychotropic Drugs on Animal Activity

By WILLIAM J. KINNARD, JR., and NATHAN WATZMAN

CONTENTS

INTRODUCTION

THE EVALUATION of chemical compounds for potential psychotropic activity involves their sequential evaluation in a battery of pharmacologic tests. This screening protocol serves to eliminate toxic or inactive compounds and at the same time allows for the stepwise formation of a profile of pharmacodynamic and toxicological information. The sensitivity of this entire program is heavily dependent upon the initial screening tests involving measurements of animal activity. It is ironic that, of all of the procedures that comprise a screening program, these are the most critical, yet the least standardized, most highly individualized, and most vulnerable to environmental factors. It is therefore, important that careful thought and organization of test criteria precede actual laboratory work. The investigator should determine the optimum set of experimental conditions for his laboratory, since external influences on drug responses will vary from one laboratory to another. It is the purpose of this paper to acquaint the reader with the problems of evaluating animal activity, the advantages and limitations of present-day test apparatus and procedures, the parametric variables which may alter drug response, and the design and statistical techniques which may increase the efficiency of this type of experimentation.

OBSERVATIONAL TECHNIQUES

General Considerations.—The subjective observation of drug-induced changes in the activity of laboratory animals has long been a preliminary procedure in drug testing. This initial procedure can provide information concerning general pharmacological and behavioral drug actions as well as preliminary toxicological data. These total data comprise one facet of the preclinical experimental protocol needed for any attempt on the part of the investigator to predict the clinical activity

of the drug. Two approaches can be utilized in the evaluation of potential psychotropic agents through the use of gross observational techniques (1). The first of these is the *criterion behavior* approach in which a form of abnormal human behavior is selected and its basic characteristics are determined. The next step is the induction in test animals of a form of behavior which is as nearly as possible similar to this human behavior. The search is then made for new drugs which will modify this behavior at low doses. This might be exemplified by the production of "experimental neuroses" in laboratory animals and the examination of test drugs on this behavior. The second approach is the use of *criterion drugs*. The effects of clinically established drugs are determined in animals using a wide variety of tests, and then the new compounds are studied on the most sensitive of these tests. Most laboratories actually use a composite of these procedures.

The generation of an adequate rating scale for observational procedures requires that the behavior patterns of the experimental animals be carefully examined. As the spontaneous behavior of animals is studied, the events occurring within the animal's behavior can be organized into patterns that are dependent upon the variability of these events (2). Careful examination of these behavior patterns can be made and documented to provide a basis for rating programs (3). Since these observable patterns are under the influence of innumerable internal and external factors, the emphasis on the development of a rating program must be placed upon the use of carefully controlled conditions. There are many variables that must be carefully regulated before the observational test procedure can be used efficiently. The all important variable is the test animal itself. Certainly, all of the attributes of the proper experimental design used in any pharmacologic procedure should be followed in the selection of the test animal. The health of the animals should be a primary concern, and the operations of the animal colony should ensure that a minimal stressing of the animals occurs. If female animals are to be used, the effect of the estrus cycle must be taken into consideration. The development of estrus in the cat periodically alters baseline activity of the animal, and total ovariectomy will eliminate this problem, yet allow for general behavior patterns to remain virtually unchanged (4).

Environment will play a major role in the animal's total behavioral response. As noted by Brady (5), the effects of drugs upon behavior depend upon the environmental conditions affecting the animal when the pharmacologic agent is being evaluated. The initial standardization of the observation area in regard to temperature, humidity, range area of the animal, etc., should not be altered throughout the experiment in order to prevent minute behavioral changes from occurring. Consideration must also be made of the "arousal-provoking" quality of the experimental situation (6). Irwin (7) used a soundproofed or sound attenuated room for the examination of cat behavior, whereas other investigators have used a standard laboratory room that permitted external auditory stimuli to reach the test animals. The question arises here as to whether unexpected external stimuli can be used as an indication of animal awareness. It would appear that they could contribute to a more adequate assessment of the animal's attentiveness.

The observer is an extremely important variable in the test procedure. This person must be a highly trained, observant, and patient individual. He must be fully cognizant of the animal's normal behavior and totally aware of the possible changes in behavior that a drug can produce. He must be able to recognize and record not only those events that are listed in the test program, but also any others that may occur. The training of an individual is based on experience and is very critical; it cannot be achieved by the presentation of written or oral material describing the procedure. Each of the behavioral changes must be shown to the observer through the use of control drugs, and many experimental trials must be performed to ensure adequate reproducibility of the observer's rating.

The mechanics of the rating procedure should be considered in the design of the rating sheet. Most investigators use a single sheet to note any drug effects over the experimental time period. In order to negate subjective bias of the observer, a booklet form can be used for rating (4). Each of the observational time intervals is placed on a separate page so that the observer does not see the previous rating entries. Also, to help ensure that the observer is examining each item on the list, a place can be allowed at each rating point for "no observable change." The design of the sheet or booklet may also be governed by the type of information retrieval program used by the laboratory. If the material is to be placed on punch cards for later printing, the rating sheets should also be designed so that the key punch operator may accurately transfer the information from the rating sheet to the punch card. The choice of items to be placed on any rating scale must be dependent

upon the skill of the supervisor and the observer in the determination of the animal's ongoing behavior patterns in response to the test situation. A rating scale should originally include as many items for rating as possible, based upon the general behavior of the animal and the discrete items that occur within each behavior pattern, as well as upon known changes elicited by the prototype compounds. Following use of the test scale, certain items can be eliminated from the program if the frequency of these events is found to occur at a very low level. As noted by Irwin (8), it is better to have an excess of rating points rather than a deficiency for the test scale.

There are several weaknesses present in multidimensional observation procedures. First, observers vary in their ability; this is only overcome by standardizing the rating scale and quantifying the observed behavior on the basis of an all-or-none rating of events. Second, a tendency toward subjective bias exists as well as a tendency to have an insufficient number of steps in the rating scale. This latter point would possibly cause a loss of information from the behavioral observation. Subjective bias may be overcome by the use of blind procedures for drug administration and observation, and the loss of information can be overcome by adding more rating items. This excessive subdivision does not appear to distort the data (8). Two further problems must be considered: reproducibility of procedures and data between laboratories, and the difficulty of summarizing the information developed from the test procedure (9). The difficulty in transferring the experimental method from one laboratory to another is well known. These procedures are highly individualized and dependent upon the scientist generating the scale. Extremely well-defined profiles are required to overcome this limitation. Their definition must not only be in writing but in some pictorial form as well.

Observational Procedures with Rodents.—Observational test procedures involving rodents vary greatly depending upon the specific need of the particular laboratory. Some investigators (10, 11) use little or no detail in their rodent tests, but these programs are only a minor part of a larger over-all program of drug evaluation. Janssen (12) used a protocol which involved a large number of tests in rodents and dogs; among these were an open field measure, hot and cold plate tests, a toe pinching procedure, a rotarod test, etc. The question which arises from this type of program is whether these multiple tests are necessary for the evaluation of drug effects at the early level of pharmacologic screening. Perhaps early screens should not be overly burdened, but rather allow for fewer, more definitive tests to show potential drug action. A fairly complete rating scale for mice or rats has been clearly defined by Irwin (13). His procedure for the evaluation of the general activity and acute toxicity produced by the test drug is written in a manner that allows for accurate interlaboratory replication. The paper includes a rating chart used in his laboratory, and shows drawings of the animal postures rated for the righting reflex and passivity items on the scale. Norton (2) has developed a rating scale that is more behaviorally oriented than those produced by others. Her profile for the hamster is well defined and includes five main behavior patterns: sociability, contentment, excitement, defensive hostility, and aggressive hostility. Under each of these main categories there are five subheadings which are specified items of behavior. As an example, the items of squawk, pulling, chasing, biting, and rearing are subheadings under the category of aggressive hostility. She compared the results with the hamster to those obtained from monkey and cat studies, and noted that the test animals responded differently to the individual test drugs. For example, chlorpromazine caused an increase in sociability in all animals, but caused an increase in contentment in the monkey and hamster with a decrease in contentment in the cat. It induced an increase in excitement in the cat and monkey, but a decrease in the hamster.

The depressant activity of drugs has been identified rather well for many years, and the utilization of some of these procedures may contribute to the efficiency of rating programs in psychopharmacology. Lim *et al.* (14) used a procedure to evaluate sedation in rats. Animals were housed individually in small cages and pictures taken of their posture and degree of eye closure, with the activity of the animals being measured by a photocell system. The animals were startled periodically with a mild air blast, and the changes in posture and degree of eye closure rated. The illustration of depressed postures of rats and dogs in this paper can aid in the replication of its data. Cohen and Nelson (15) rated depressive activity of rats, noting the effect of chlorpromazine and pentobarbital on the loss of spontaneous motion, response to stimuli, and the degree of ataxia. Each of these were subdivided into four or five rating items. A simple measure of motor activity that has been used to test depressants is the open field test, a procedure that can easily be incorporated into a rating

program. Furthermore, Brimblecombe (16) considered the open field test with the rat to be a valid measure of emotionality. He noted, however, that by itself it may not be accurate, but in a battery of tests it does give some indication of the drug action on the emotional behavior of the animal. In the classical test, the animals are placed at the center of a circular (17) or rectangular (18) open area which has been suitably marked off, and the number of times that an animal moves across the zone lines is recorded. In addition other rating points such as the degree of grooming and defecation can be checked simultaneously (16, 19, 20). This test can utilize individual or paired rats (19), and has been used as a measure of motor deficit, emotionality, and exploration. These behavior patterns can also be analyzed in different ways. Randrup and Munkvad (21) rated the behavior of individual rats by counting the different types of grooming that occurred as well as recording their locomotion within an area through the use of multiexposure photography. They noted that amphetamine produced a stereotyped activity which they could alter through the use of perphenazine. Bindra and Baran (22) evaluated drug-induced changes on sniffing, lying, grooming, and general activity of male hooded rats, which were individually housed in foot square boxes. Many other behavioral signs can be added and scored in this procedure. Cole and Dearnaley (23) utilized a simple rating program in the evaluation of the effects of reserpine and morphine in rats and mice. They illustrated Straub tail reactions, and also noted the effects of the test drugs on such items as the grasp reflex, piloerection, tremor, and posture. Catalepsy and palpebral ptosis have also been used as observational test items (24). Toman and Everett (25) called particular attention to unusual aspects of behavior; for example, hunching and squinting which are characteristic responses to reserpine. Lim (26) included items of morphine-like fixation of posture and pseudohypnosis in his profile for rating drug effects on rats.

One hesitates to talk about emotionality in rodents, but there are certain aspects of behavior that investigators use for its evaluation. Raitt *et al.* (27) and King (28) used a six-item program with each component rated on a 5- or 6-point scale. Rats were evaluated on their reaction to the presentation of a probe to their snout, response to a light rap on the back with a probe, resistance to capturing, resistance to handling, vocalization during stages of capture and handling, and urination and defecation during these stages. This procedure certainly allows for the assessment of drug effects on the stress induced by the observer's interaction with the test animal, but one wonders if this type of emotional rating can be correlated with clinical effects.

Sulser *et al.* (29) have utilized a different test situation in their rating of drug effects on behavior in the rat. The animals were placed on top of a box about 1 ft. high. Control animals would move about and explore their surroundings for a few minutes, then cluster together, and groom themselves, but would not leave the top of the box. Test drugs altered this response; for example, rats given a benzoquinolizine compound (RO-41284) remained motionless and isolated from each other for about 3 hr. Rats treated with amphetamine would dash about helter-skelter, while rats given RO-41284 plus desmethylimipramine would move around the edge of the box and fall off or leave the box. Votava *et al.* (30) examined the effect of experimental drugs on the central nervous system with the aid of a test involving orientation activity in the rat. The animal was placed in a small chamber and after a short interval was allowed to move into a second and larger chamber when a barrier was removed. The animal was then rated on various motor responses, such as the number of times it moved through the door, the amount of grooming, etc. Welker (31) has examined sniffing as an aspect of exploratory behavior in the albino rat. In a rather detailed paper, he noted the various aspects of this behavior and how it was altered by various stimulants and depressants.

Most rodent rating scales utilize individual animals, but the social interaction of these animals should not be overlooked. If social interaction is to be included in a rating scale, some excellent discussions (32, 33) of this behavior in rats and mice can be consulted. Silverman (34) has recently discussed the use of ethology as a means of observing animal behavior with increasing precision. He has developed a well-defined and integrated rating profile for social interaction, which includes the categories of exploration, investigating, mating, aggression, and other signs. Rats were isolated for several days and then introduced into the observation cages in pairs; only one of the test animals was treated with placebo or chlorpromazine, and a counterbalanced order of presentation was introduced into the experimental design. Chance and Silverman (35) evaluated chlorpromazine, amphetamine, and amobarbital on the latter test. It is possible that within groups of rats, different degrees of social interaction will occur. Irwin (36) reported that there was a significant negative

correlation between individual treadwheel counts and the time devoted to interactional behavior of rats; *i.e.*, animals which showed a high degree of spontaneous activity in the treadwheel did not score high in social interaction.

Certain aspects of social behavior lend themselves well to the testing of psychotropic drugs. The aggressive tendency of rodents in certain situations has been used in an attempt to duplicate clinical situations. When mice are isolated for a period of time and then placed together, an aggressive behavior, which can be rated (37–39), is produced between the two mice. An instinctive behavior that is seen in some rats is the mouse-killing reaction. Certain rats will almost immediately kill a mouse when it is introduced into the rat's cage. While many psychotropic drugs are not specific antagonists of this response, it has been noted that antidepressants will block it (40).

If animals are to be re-used in these test procedures, prior experience must be taken into consideration. Marriott and Spencer (41) examined the exploratory behavior of rats under the influence of various psychotropic drugs. Their studies, based on that of Steinberg *et al.* (42), used a Y-shaped box and noted the number of complete entries that the rat made with all four feet into one of the arms of the box. They found that chlorpromazine reduced exploratory behavior, but that meprobamate and chlordiazepoxide increased it. However, the effect of chlordiazepoxide on exploration was completely inhibited by a single previous exposure to the Y box. This fact should be taken into consideration if open field tests or other forms of exploratory behavior measurements are to be used.

The addition of many of the aforementioned behavioral signs or procedures to the standard pharmacological screening test used in observational studies may aid in the identification of potential psychotropic agents. These rating scales in their final form should be as quantitative as possible. It is relatively easy to quantify certain physiological signs within the test structure; these include such items as pupil size, cardiac and respiratory rates, and body temperature. One caution that must be noted is that the desire for exacting quantification may yield a rating scale that, through the time and effort required for its usage, drastically reduces the efficiency of the total rating program.

Observational Procedures with Cats.—A requisite for gross observational studies is that the test animal must possess a fairly stable personality for the prolonged periods of time required for laboratory study; in addition, the animals must show a sufficient range of spontaneous behavioral patterns to allow accurate studies to be made. Cats seem to fit these qualifications (43). Irwin also favors the cat as a test animal for its value in predicting drug effects in man. He noted that its sensitivity to various behavioral drug effects appears to be more like that of man than any other laboratory animal, with the ratio between doses producing behavioral and side effects in the cat being closely approximate to that of man. A disadvantage in the use of the cat is that it shows atypical effects to certain drugs; for example, it is stimulated by certain narcotic analgesics and antihistamines (44); also chlordiazepoxide produces an effect in the cat that lasts for several days. The cat, along with the dog and monkey, allows a wider range of behavior and drug personality interactions to be observed than one would see with the rat or the mouse (45).

The cat observational technique is not truly a preliminary test in that the rodent screen should be initially utilized to eliminate a large number of inactive and toxic compounds from the test series. This is necessary since the procedures involving cats require the use of colonies that become invaluable because of the time involved in establishing behavioral baselines. Drugs that are to be tested on these animals must also have some toxicological data available for the estimation of initial drug dosage. The drugs should be given orally to allow a better clinical correlation of data, although other routes have been considered (8). Drugs can be administered in capsule form to the cats who are restrained either in a box or in the arms of an assistant. The capsules are placed on the back of the tongue using a long curved forceps or hemostat, and the animal's mouth is then held shut. However, the oral route is not without its disadvantages; for example, chlorpromazine often produces vomiting in the cat (46), and thus, the animal will not receive the full dose of the drug.

As with the other species, the environment and method of observation can influence the behavior of the cat. Individual animals can be observed within (43, 47, 48) or when removed from their home cage (49). Multiple animals have been tested either as pairs of unrestrained, free-roaming cats (4) or as four cats restrained by leashes to allow only minimal overlap of animal test areas (6). The rating of individual animals allows for the notation of behavioral and physiological signs influenced by the interaction with the observer or with other aspects of the test environment, but does not allow for the evaluation of social interaction between test animals. This disadvantage

can readily be overcome by using multiple animals in the test sequence. As noted before, Irwin *et al.* (6) chose to rate multiple animals within a sound attenuated room to minimize external stimuli, while others (4) rated the animals in a regular laboratory room which allowed for the animals to react to random sounds from the external environment.

The rating scale should be developed with an intimate knowledge of normal behavior of the cat in the surroundings in which the test is to be conducted. It would appear that the test procedure and environment should generate as much behavior as possible in the test animals. The behavior patterns to be observed should be reliable and consistent within the test sequence. As an example, the authors, during the preliminary development of a cat rating program, presented to the cats a mouse within a plastic chamber. All of the cats did not respond with the typical mouse-kill pattern of behavior, even when the lid was removed from the plastic cage. This type of test then could not be used as a part of the behavioral scheme unless the cats were screened for this specific reaction. This type of selection, involving the elimination of various cats because of the lack of reactivity to certain test sequences, reduces the heterogeneity of the test sample. It would appear to be a better course to randomly select a series of healthy cats and build the test around these animals rather than to find the animals to suit the test.

Various types of rating scales have been developed for cats. Norton and deBeer (43) examined behavior patterns of individual cats and selected four main rating categories (sociability, contentment, excitement, and hostility). Sociability and hostility were categories selected to represent opposite reactions of the animals directed toward the observer, while contentment and excitement were selected to represent opposite patterns reflecting the emotional attitude of the cat in his accustomed surroundings. Each of these main headings had five subheadings of behavioral signs, and the scoring system was based on the frequency of occurrence of these signs. Using this procedure, drugs were administered orally to cats; and it was noted that chlorpromazine, among the compounds tested, reduced sociability to the least degree, but produced the greatest reduction in hostility. Sharma *et al.* (47), using the same type of rating profile, also showed a decrease in sociability with chlorpromazine and reserpine. Irwin (6, 13) used a much more comprehensive scoring system for the evaluation of drug effects. Cats were restrained on leashes so that they had approximately 1 ft. of interanimal overlap to allow some play or aggressive activity. The observer conducted the experiment for 5 hr. following drug administration. During this time the animals were rated on major changes of behavior, changes in interaction with the observer, and changes in interaction between the animals. Items rated included: time to sleep, lying down, alertness, curiosity, reactivity, locomotion, restlessness, stereotypy, grooming, vocalization, effect (playful, placid, fearful, aggressive), staggering gait, pupil size, heart rate, respiratory rate, limb weakness, relaxation of the nictitating membrane, and deep sleep. Chlorpromazine produced a diminution of play, grooming activity, fearfulness, or aggressiveness, especially in low doses. Hostile behavior was almost always suppressed, but some animals did show an increased fear or aggression after drug administration (45). Kinnard *et al.* (4) used a 32-item rating scale which included measures of social interaction, interaction with the observer, and general behavioral or physiological changes of the individual animal. Activity of the pairs of free-roaming cats was stimulated through the use of play objects and periodic presentations of catnip to the animals. Using this method, chlorpromazine or perphenazine, imipramine, pentobarbital, and *d*-amphetamine could be readily differentiated from each other. Data output from this and other multi-item rating programs tends to become voluminous, and a need for data reduction is apparent. Through the use of a computer program, adapted from one used for the clinical rating of patient symptoms, the 32 variables in the latter test were reduced to nine factors of behavior. In the past, investigators have preselected behavioral patterns and then subdivided these patterns through the use of specific animal actions, such as the subdivisions of yowling, hissing, and piloerection for aggression. Through the use of the computer program, the results of a test can be grouped into major factors based upon the intercorrelation of the responses of the animals to the experimental drugs. This type of analysis of the data may lead to a more efficient definition of the drug activity.

Rice and McColl (50) rated cat behavior using a small profile that included autonomic signs, somatomotor effects, and behavioral effects. The behavioral signs rated were howling, habit change, and hostility. Cole and Glees (51) rated the ability of cats to obtain food from a horizontal glass tube, their ability to walk along a ladder to obtain this food, and their performance in a placing reflex test involving the hind legs.

The procedures previously described have used

the normal behavior of laboratory cats as their baseline. However, it is quite conceivable that the effect of the drug on this type of behavior might not correlate with the drug's clinical activity. Investigators have attempted to induce abnormal behavior in cats and then test drugs upon this altered activity. Masserman (52) trained cats to open a box to receive a pellet of food following a light signal; after learning this event, the cat was trained to turn a switch to initiate the program. The animals were then subjected to an air blast or a mild shock which induced a motivational conflict behavior between conditioned hunger and fear. Under these conditions the animals developed startle and phobic reactions to sound and light stimuli as well as other neurotic behavioral patterns (53). Jacobsen and Skaarup (54, 55) have used this technique to study psychotropic drugs. They noted that chlorpromazine, in total doses of 0.1 to 2.0 mg. s.c., did not alter the neurotic reaction in cats, although benactyzine did. This type of response might be compared to the conditioned emotional responses (CER) used in rat behavioral techniques. Mixed results have been obtained from this procedure, and it was reported that chlorpromazine and reserpine did not alter the emotional response of the rat in this test (56). It is possible that this specific type of conflict behavior in the cat may not be a definitive test for all types of psychotropic drugs. Sacra *et al.* (57) produced a conflict behavior in cats by administering shock through the tail of a mouse whenever the cat attacked the mouse. The cat thus received a shock when it went to pick up the mouse. Following several presentations of this response, a conflict behavior pattern developed. Chlorpromazine and meprobamate were found to be effective in protecting against this type of response.

The environment and observer also play a major role in the final drug effects observed in the conflict studies. Masserman (58) noted that sedative and tranquilizing drug effects were greater when the test animals (cats or dogs in conflict behavior) were in the accustomed security of their home cages than when in a state of alert anticipation during transportation to the laboratory; the new environment, on the other hand, enhanced the stimulant effects of the test drugs. He also noted that the drug effects were dependent upon the difference in handling of each animal by different experimenters no matter how constant the research protocol was. It has been pointed out that observer reliability and consistency is extremely important and that this should be rated within the test program (59). The age of the animal used is also important. Pechtel *et al.* (60) showed that kittens, compared to older cats, adapted less well to laboratory routine and learned tasks of lever pressing and audiovisual discrimination. The young animals readily developed neurotic patterns under the stress of adaptive conflict.

Observational procedures have been used in experiments that involved different routes of drug administration or types of pretreatment. Feldberg and Sherwood (61) have analyzed the behavior of cats following the injection of test drugs into the lateral ventricle of an unanesthetized animal. Behavioral changes were not rated, but were noted in a general manner. Haley and Dasgupta (62) observed the changes caused by an intracerebral injection of LSD in conscious dogs and cats, but again no rating scale was used. Elder and Dille (63) administered LSD to singly caged cats and rated autonomic responses, spontaneous behavior, and response to types of stimuli (auditory, visual, and tactile). Various pharmacologic agents were then used in an attempt to antidote the LSD response. Sturvesant and Drill (64) analyzed the effect of mescaline on the behavior of cats. Rowe *et al.* (65) noted the behavior of reserpinized cats following monoamine oxidase inhibitors, and included photographs of the cat's behavior. Burdock *et al.* (66) analyzed the behavior of laboratory animals before and after the production of hypothalamic and midbrain lesions in the animals. Behavior of the animals can also be observed and rated in conjunction with neurophysiological recordings of brain activity (67).

Observational Procedures with Other Species.—The dog has been used by many investigators as a test animal for observational techniques, but apparently it is secondary to the cat in these procedures. Lang and Gershon (68) have used the dog in a procedure involving the intravenous administration of yohimbine to the animal. The induced behavior before and after the use of potential antagonists was then rated. The rating program presented was extremely well defined with 17 main divisions of behavior, each with a specified 3-point scale.

The monkey would appear to be the ideal test animal to use in observational techniques, especially if one considers its place on the phylogenetic scale. However, the use of the monkey, possibly because of costs and other reasons, is not so widespread as it should be in this type of pharmacologic program. Many investigators (69–75) have tested potential psychotropic drugs on monkey behavior. The viciousness of monkeys, such as the rhesus and the cynomolgus,

can be used as a tool for the evaluation of potential psychotropic agents. The animals, as in the rodent or cat studies, can be tested singly or in a procedure which involves chained pairs of monkeys to allow interaction (74). Knapp *et al.* (70) tested chlorpromazine and piperacetazine in dogs and squirrel monkeys, and noted that the drug effects may have been more discernible in the dog than in the monkey. In spite of this, the monkey should still be considered a prime test animal for observational studies since its behavioral patterns, in comparison to other laboratory animals, more closely resemble those of the human.

INSTRUMENTAL TECHNIQUES

Spontaneous Locomotor Activity.—Methods for measuring small animal activity have been used since the turn of the century. The devices were, for the most part, mechanically operated and used by psychologists to study the normal behavioral patterns of laboratory animals (76, 77). However, the search for psychoactive agents gave impetus to the need for instruments which would accurately assess the ability of these compounds to alter the normal spontaneous locomotor activity of small animals.

Activity recording units can be classified into four main groups involving four different types of activity cages: those which are immobile and record activity independently of cage movement (photocell activity cage); those which rotate about a central axis as the animal runs (treadwheel); those cages which are vertically or horizontally displaced as a result of animal movement (jiggle cage); and those which tilt on a fulcrum (tilt cage). The first type (fixed) is considered a direct recording apparatus because animal movement itself is recorded, whereas the latter three instruments are the indirect type because they basically record cage movement rather than animal movement. Since Riley and Spinks (78) reviewed the early prototypes of these instruments in 1958, this phase of the paper will emphasize the types of activity recording units developed since then.

An ideal device for measuring spontaneous activity would be one that is (*a*) sensitive to all types of motor movements, (*b*) sensitive to minor changes in animal activity, (*c*) free of positive feedback of stimuli, (*d*) free of carry-over momentum, (*e*) independent of animal weight variation, (*f*) capable of delineating between the activity of animals receiving placebo and animals treated with small doses of psychotropic compounds, (*g*) capable of recording a stable baseline of activity over short trials, (*h*) capable of simple operation and adjustment, (*i*) capable of being used with a simple direct-reading digital recorder. Needless to say, an instrument possessing all of these characteristics has yet to be developed.

The photocell activity cage has been used extensively as a drug screening device to determine the effects of psychotropic compounds on the spontaneous activity of small animals. It operates on the photocell system, in which light beam interruptions due to animals in motion are converted into electrical impulses which are transmitted to digital counters. Activity of the animal is thus reflected as a summation of light beam interruptions due to lateral movements. Many modifications of the photocell activity cage have been described in the literature and reflect the attempts of investigators to maximize its sensitivity. Dews (79) utilized a rectangular single beam unit to study psychomotor stimulants; Winter and Flataker (10) also used a single beam but reflected it twice off the sides of the cage; Kinnard and Carr (80) used a circular single beam unit to determine the activity patterns of central nervous system depressants, *e.g.*, secobarbital and meprobamate. A circular two-beam unit was utilized to study the ataractic properties of chlorpromazine and sodium pentobarbital (81). Most investigators employ horizontal beams; however, an apparatus with a single vertical light source has been used satisfactorily (82). The beam is directed from the ceiling of the unit downward onto several photocells placed below a Lucite floor. The use of a single light source precludes the possibility of variations in light intensity among the beams as in units with multiple light sources. The disadvantage is that fecal boluses may block off the operation of the vertically directed beams. Woodard (83) designed an apparatus with six photoelectric cells equally spaced around the perimeter of a circular raceway. A single light source was housed in a circular compartment in the center of the cage. This design takes advantage of the natural instinct of the rodent to confine its activity to the periphery of any confined environment; however, it places limitations on the spontaneous activity which satisfies the animal's strong instinct for exploratory behavior.

Tedeschi *et al.* (84) used another approach to the evaluation of psychoactive compounds on the motor activity of rats. They devised a photocell unit which was only large enough for a rat to rear up but precluded him from moving laterally. Rats placed in such a test situation at first elicited exaggerated behavior which progressed to complete inactivity toward the end of their

confinement. The authors suggested that drugs which reduce motor activity can be tested during the initial period of increased activity and, conversely, drugs which increase motor activity may be tested during the latter part of confinement when activity is markedly reduced. The effects of established psychoactive agents were measured in both the confined motor activity (CMA) test and the conventional photocell activity cage. Caffeine, in an oral dose of 5 mg./Kg., produced a 200% increase in activity in the CMA test; whereas, 5 to 350 mg./Kg., orally, did not increase the activity level in the conventional photocell apparatus. Similarly, tranylcypromine (5 mg./Kg. orally), a clinical antidepressant, produced a 200% increase in activity in the confined motor activity test; whereas, the chronic administration of tranylcypromine (5 mg./Kg., orally, twice a day) failed to produce any consistent or significant effects on motor activity in the conventional apparatus (85). In the CMA test, the effect of *d*-amphetamine was greatly magnified in that 0.24 mg./Kg., orally, increased activity 200%; whereas, in the conventional motor activity test, an oral dose of 5 mg./Kg. produced only a 40% increase in activity. A significant limitation of the conventional photocell activity cage was noted (86) when an oral dose of 16 mg./Kg. of *d*-amphetamine was administered to mice. This dose produced a decrease in lateral movement and induced tremors of the head and limbs analogous to the well-known clinical side effects of restlessness, irritability, and emotional disturbance. This type of activity resulted in a decrease in beam interruptions in the conventional unit, but under the CMA tests, may have been accurately registered as an increase in activity. Thus, by monitoring only one component (rearing) of spontaneous activity, Tedeschi has been able to correlate the preclinical and clinical effects of well-established stimulants and antidepressants. The CMA test was also effective for quantifying the effects of drug which decreased spontaneous activity, but the sensitivity was not significantly greater than that of the conventional photocell unit. The data suggest that it may not be necessary to measure total activity but only selected components of activity known to be affected by certain classifications of compounds. The problem is that psychotropic agents have a diffuse action on the nervous system and psychopharmacological techniques in existence today cannot, with certain exceptions, delineate the component effects of drug action.

Another novel approach to the recording of animal activity was the use of electroconductive slats placed across the floor of the test cage (87). Each slat was made of varnished Masonite and painted with silver-based conductive paint. As each animal made contact with the slats, an electronic relay activated an externally powered counter. This appears to be a satisfactory method of recording locomotor activity of small animals. It is less bulky than the photobeam units and can readily be installed to activate timers and measure areas of the test environment explored. Mitchell (88) devised another type of unit in which the lateral motion of an animal on a galvanized iron plate caused it to move slightly, inducing an electric current in a coil with a bar magnet core. The currents thus produced were then amplified electronically and recorded as activity.

More sophisticated methods of monitoring small animal activity have been developed, such as the transmission of vibrations produced by animal motion, using a piezo-electric head (89), a 30-gauge galvanized steel diaphragm (90), or a crystal phonograph cartridge (91). In most of these procedures, activity is recorded by means of a stylus recorder, resulting in records which are difficult to quantify. Alvarez-O'Bourke (91) solved the problem of quantifying such graphs by eluting each record with acetone and quantitatively evaluating it with a spectrophotometer on the principle that the amount of ink laid down by the pen is proportional to the frequency and intensity of the movements of the animal. Otis (92) designed a chamber which operated on a floor displacement principle. Normal floor vibrations which occurred during locomotion were transduced into modulated electrical signals that operated from 1 to 3 electromagnetic counters depending on the intensity of floor movements. Only downward motion was recorded, and the counter circuits were preset so that one counter will fire at the slightest movement of the animal, a second counter only if the animal's activity is moderate, and a third, only if violent activity occurs. The value of this apparatus is that it detects both the occurrence and intensity of movement, which the photocell cage is not capable of. Otis attached this device to a treadwheel so that the experimental animals would have access to either unit. Therefore, he was able to compare the effects of psychoactive compounds on activity with both devices separately and combined. The data of his studies indicated that the treadwheel failed to discriminate between intraperitoneal injections of placebo and 2.5 mg./Kg. of amphetamine, 30 mg./Kg. of imipramine, and moderate doses of other psychostimulating agents. In contrast, the floor displacement apparatus did delineate between

placebo treatment and equivalent doses of the same stimulating drugs. The over-all conclusion of this study was that the combined chamber–treadwheel combination was the most sensitive method for detecting drug effects. Knoll (93) developed an electronic device in which an animal moved over four aluminum plates, and counters registered every crossing from one plate to another. The advantage of this method is that as many as 24 mice can be tested at one time. Shillito (94) measured mouse locomotor movements by a capacitor system including six brass probes. When an animal moved past a probe, its capacitance was altered, resulting in an imbalance in the electrical circuit, which caused a dot to be recorded on a moving kymograph. The data were analyzed by merely counting the dots, and as many as four mice were tested simultaneously without causing an overlapping of marks. This device is similar to the "antenna cage" (95) in which a rat moves around a radio antenna placed in the middle of the cage; his movements change the capacity between the cage and the antenna. The latest electronic activity device[1] generates a soundwave of a frequency and level that cannot be detected by most animals. Any motion within an experimental cage into which this sound wave is directed produces disturbances in the received portion of the wave, causing the receiver to produce electrical impulses which can activate many types of recording and counting devices.

Melander (96, 97) used a photographic technique similar to Rothlin and Cerletti (98). The experimental mice were painted with a dye which emits visible light when activated by ultraviolet light. The animals were then exposed for 5 min. to panchromatic film. The resulting films afforded the investigator information on the types of movement, but they were not quantifiable.

Several modifications of the tilt-type activity cage have been described in the literature. Basically, the cage pivots on a central fulcrum, tilting in response to the weight of the animal as he moves from one part of the cage to the other. Sensing contacts (microswitches), below the platform, register the gross movement of the animal on digital counters. The apparatus is sensitive only to movement in line with the sensing contact on the platform below. Minor movements such as rearing, grooming, etc., which are not large enough to tilt the cage are not monitored. Tilt-type units have been described by Campbell (99) and Kissel (100), and the latter reported a lack of habituation to the unit probably due to the positive feedback typical of all moving-type devices. The limitation of these units is that only running activity is recorded to the exclusion of important minor movements (tremors, etc.) which may be drug induced. This limitation was overcome by Caviezel *et al.* (101), who added a closed air-Marey tambour system which recorded activity by means of a work adder. Thus, while the microswitches below the tilt platform recorded running movements, the downward displacement of the ball-bearing fulcrum set in motion the tambour membrane, and this recorded minor activity. Bastian (102) and Bourgault *et al.* (103) utilized a rectangular cage which tilted on a wide metal fulcrum, perpendicular to its axis; thus, an animal must run along the long axis of the cage in order to register a count; movement perpendicular to the long axis of the cage was not recorded. Also, minor movements were not monitored, and various types of activity were not differentiated as is true of other instruments of this class.

The jiggle cage has been used extensively to evaluate the effects of drugs on small animal activity. Earlier designs were usually of the spring-suspended type in which animal movement vertically displaced the freely swinging cage (104). Several interesting modifications of the jiggle cage have been described. Cho (105) used a 500-Gm. Toledo scale for the rat and a 500-Gm. dietetic scale for the mouse; movement of the animal vertically displaced the platform of the scale causing upward and downward deflections of a pen writing on a moving kymograph. Schallek (106) and Sandberg (107) used a unit (Williamson Development Co., West Concord, Mass.) in which the cage was suspended on a resilient cantilever beam which permits slight sideways motion of the cage in response to the animal's activity. The sideways motion is proportional to the acceleration imparted by the animal. Such motion caused a switch to close momentarily whenever the integrated accelerations reached a predetermined level. A similar apparatus was described by Chappel (108); the cage was suspended by a ball and socket joint from a spring steel or spring bronze cantilever beam. Movements of the animals were recorded by electrical counters activated by contact of the cantilever with a stationary screw. The sensitivity of the apparatus can be adjusted for body weight differences by turning the screw regulating the gap between the stationary contact and the cantilever beam. The advantage of this unit is that small movements such as

[1] Ultra-Sonic Motion Detector, Alton Electronics Co., Gainesville, Fla.

grooming, biting, gross respiration, head bobbing and swaying can be recorded, although the movement of the cage, itself, is relatively slight. A jiggle platform (Lehigh Valley Electronics, Fogelsville, Pa.) has been developed which oscillates horizontally on a set of ball bearings. Sudden movements, *e.g.*, turning, running, jumping, etc., cause the platform to move slightly, making and breaking an electrical contact. A wide range of sensitivity is accomplished by the raising or lowering of a conical pendulum into or out of a metal ring. However, this apparatus is only suitable for measuring the activity of rats or hamsters and cannot monitor mouse activity. In general, the suspended jiggle cage has several limitations. First, most of the units lack a dampening effect so that carry-over momentum generally exaggerates the amount of activity; second, it is a moving or mobile unit which may generate a small amount of positive feedback stimuli; third, the animals satiate rapidly so that accurate estimation of peak drug effect is required or else the effect will be missed; finally, the units are difficult to calibrate; attempts to maximize the sensitivity of such cages in order to pick up minor movements result in excessive residual excursions after animal activity has stopped; on the other hand, decreasing the sensitivity precludes the monitoring of minor movements. An advantage is that various types of behavioral patterns can be monitored on a pen recorder; however, such records are difficult to quantitate and are only useful for *visual* comparison of the changes in behavior elicited by various drugs.

The revolving treadwheel turns as the animals run or walk, and revolutions in either direction are recorded on counters. For a review of the early units (prior to 1958) the reader is referred to Riley and Spinks (78). Skinner (109) also reviewed the parameters of the exercise wheel in 1933. Because of the large positive feedback generated by animal movement, habituation to this unit does not occur so that it is possibly the only unit in which cross-over studies can be carried out (110). This apparatus is capable of detecting the stimulating effects of monoamine oxidase inhibitors (110) which cannot be monitored with immobile units. Irwin (110) indicated that the treadwheel can also detect doses of drugs which disorganize behavior. Because of the mobility of the apparatus, animals generally sustain their behavior over a long time interval and, therefore, it appears that the unit is of more value in the study of depressants where it is desirable to obtain stable, sustained levels of activity as a baseline. In order to study stimulants in this type of unit, Wiedemeijer *et al.* (111) limited the mice to a section of the turning wheel by fixing a partition within it causing the animals to produce a smaller baseline of spontaneous activity. Since the apparatus only measures running activity in revolutions, Royer *et al.* (112) increased the information output by attaching a tachometer–generator and recorded the output on an Esterline–Angus pen recorder.

Investigators have used both graphic and numerical recording techniques to illustrate drug-induced changes in spontaneous activity. Graphic recording illustrates types of activity (rearing, jumping, grooming, etc.), and, therefore, can indicate specific qualitative alterations on behavior; digital counters, on the other hand, reflect only quantitative changes. The tendency today is to record only quantitative changes, because it is relatively simpler and less expensive to attach some type of digital counter to the activity unit. However, this must be done with guarded caution, for each method of recording gives important information about drug effects. For instance, Tonini (113) has indicated that sedative, subhypnotic doses of barbiturates did not decrease numerical values in his actograph unit, but did alter the activity graphs (short, intense, and more frequent bursts of activity with long periods of rest between); whereas, tranquilizers, in therapeutic doses, decreased numerical values but did not alter the graphic record. Thus, both procedures should be used in the preliminary evaluation of psychoactive compounds.

Forced Motor Activity.—The neurotoxic effects of psychoactive compounds have been evaluated by "fall-time" tests which measure motor coordination of experimental animals. There are two types of "fall-time" methods: those using inclined planes, and those using rotating rods and cylinders. A discussion of the fixed incline plane procedure can be found in the paper by Riley and Spinks (78). The data are usually expressed as the average time that a group of animals can stay on or as the percentage of animals falling off within an arbitrary period of time. The first of the horizontal rod-type of instrument was the hollow screen cylinder devised by Young and Lewis (114) for testing insulin. Mice which could not hold on to the rotating cylinder fell into metal trays. It was later used in the assay of curare (115) and the measurement of sedation (116). The horizontal rod method appears to be the more popular device today because of the simplicity of construction and objectivity of measurement. It was used by Dunham and Miya (117) for detecting neurological deficits of psychotropic agents in rats and

mice; Herr (118) compared the effects of antidepressants and tranquilizers on the rotarod performance of mice; and Plotnikoff *et al.* (119), studying the effect of stimulants, was able to distinguish between amphetamine which enhanced rotarod performance and caffeine which was inactive; Kinnard and Carr (80) studied several types of depressants and suggested the combined use of the rotarod and the photocell activity cage to characterize and differentiate between various types of depressants. The objectivity of the apparatus was increased recently by an electronic circuit which automatically stops a timer when the animal falls to the compartmentalized platform beneath the rod (120).

Otis (121) assessed motor coordination by forcing animals to perform on a drum 18 in. in diameter. When an animal could not maintain his performance, he slipped to the back wall plate of his compartment, tripping a microswitch which transmitted an impulse to a digital counter. Both the number of times and the total time the wall plate was depressed were recorded.

An important factor which has been neglected in forced motor studies is the "free ride" animals will take periodically throughout the trial. A "free ride" is defined as one revolution in which the animal holds on without walking. This could result in the failure to detect minor depressive actions of drugs and neurotoxicity, because a drug might decrease motor coordination without impairing the ability of the animals to wrap themselves around the rod and ride. In one study (86) the average per cent rides for the training trials ranged from 0.2–11.1%, and the range among the placebo-treated animals was 0.0–10.5%. While 0.2% riding may be insignificant, especially at the higher speeds and longer time trials, the higher value of 11.1% may mask drug effects. The results may be affected to a greater degree when large doses of a depressant drug are administered, because the animals may have enough strength to hold on, even though the drug has affected their coordination. Per cent rides as high as 57.6% were recorded with 16 mg./Kg. of chlorpromazine, administered orally to mice. It is suggested that investigators observe animal performance carefully and take into consideration the possibility that erroneous conclusions concerning drug effects may be drawn from such data.

Parametric Influences on Drug Response.—Although the literature is filled with many papers dealing with the effect of psychotropic drugs on motor activity, very few investigators have been concerned with the various parameters which might significantly influence drug response as measured in the various devices described above. Such parametric effects may differ not only among the various classifications of compounds but from drug to drug within a single classification. Thus, by experimental manipulation of environmental factors, a drug may be made to have a stimulant effect, a depressant effect, or no effect on motor activity (122). It is, therefore, of extreme importance that investigators take into consideration the parameters which have been shown to influence drug response and utilize the combination of variables which will produce the optimum results. For instance, test and housing aggregation size, sex, illumination of the test environment, availability of food prior to the test, and route of administration can be powerful determinants of the magnitude of drug effect. Wright *et al.* (83) reported that promazine produced an immediate equal decrease in the activity of individual mice and groups of mice; whereas, pentobarbital in low doses produced a greater increase in the activity of animals tested singly than those tested in groups. Brown (123) found no differential effect of chlorpromazine on the activity of single and grouped mice, but Watzman *et al.* (124) reported that chlorpromazine had a greater depressant effect on activity of mice tested in aggregations of five than on those tested singly. This drug–aggregation interaction may indicate that chlorpromazine potentiates the tendency for grouped animals to clump together and thus register relatively low activity. When dose-response curves for test aggregations of one, five, and nine animals per test unit were compared (125), the slopes indicated that chlorpromazine produced a greater depressant effect on the larger test aggregations than on animals tested singly; furthermore, the slopes for both multiple animal groups were approximately the same so that there appeared to be no advantage in using as many as nine (126) animals per test unit. It has also been reported (125) that chlorpromazine produced a significantly greater effect on animals housed and tested under the same aggregation conditions than those housed and tested under different conditions. Since amphetamine has been shown to stimulate aggregated animals more intensely than isolated animals (127), the group situation gives evidence of accentuating both depressant and stimulating drug effects.

An experimental condition producing a powerful effect on drug response is the illumination of the test environment (125). It is well documented that the spontaneous activities of rodents (128) and rabbits (129, 130) are affected by illumination conditions. Chlorpromazine had a greater effect

on spontaneous motor activity of mice tested in the dark than in the light during the latter half, but not the first half, of a 2-hr. test (125). Under the placebo condition the decrement in activity of mice in the last hour of the trial was much steeper and decreased to a much lower level in the animals tested in the illuminated condition. Testing in the dark produced no increase in activity in the initial exploratory phase but did greatly decrease adaption during the latter part of the session. Apparently, the high curiosity and exploratory behavior in the initial part of the test was powerful enough to overcome the effects of illumination.

It has also been reported that the activity of females was consistently higher than males in the photocell activity cage, and that chlorpromazine had a significantly greater depressant effect on the spontaneous activity of females than males, during the first 0.5 hr. of the trial (125). It was thus concluded that conditions which elevate normal activity (aggregation, darkness, female sex, same housing, and test groupings) enhance the depressant effect of chlorpromazine on spontaneous activity. On the other hand, when the normal activity level is low, such as at the end of a test session in an illuminated environment, the effect of chlorpromazine is slight. The influence of these factors appears to be class-specific. For instance, while the activity response to perphenazine and chlorpromazine (phenothiazines) is influenced by the same environmental factors and in the same direction, the response to pentobarbital is not (83, 126). The response to pentobarbital was not differentially affected by test illumination, as was the response to phenothiazines; however, it did produce a consistently greater effect on fasted than satiated animals, while responses to the phenothiazine compounds were not differentially affected by the feeding condition of the animals. The authors recommended (125) that the most sensitive measure of chlorpromazine effect in the photocell activity cage could be obtained by testing an aggregation of five female mice for a period of 0.5 hr. beginning 30 min. after i.p. administration of the drug (86).

Another parameter, often neglected, which may alter response to a drug is the difference in sensitivity among the measuring units. If more than one instrument is being used, then the investigator must demonstrate equality of sensitivity (131). Failure to do so may lead to inaccurate interpretations of drug effects. Since there is a difference in sensitivity among photocell units, even from the same manufacturer (125), it is imperative that the various levels of all experimental variables be exposed to each unit in a factorial design or else all animals under all conditions should be tested in a single unit.

The location of the photocell beams is also an important determinant of drug effect on motor activity. The use of two right-angle (crisscross) beams yielded a better delineation of low doses of chlorpromazine than three parallel beams (132). However, there was a greater drug effect with the two peripheral beams than middle beam in the parallel arrangement, with no significant drug–beam interaction in the crisscross arrangement. The data suggested that the most sensitive measure of chlorpromazine effect would be with an arrangement of two pairs of peripheral beams at right angles to each other.

The importance of evaluating drugs at certain test intervals is borne out by Dews (79) in measuring the influence of certain drugs on the locomotor activity of mice with the photocell activity cage. He found that the initial part of the trial (first 15 min.) produced more reliable data than any other test interval. This is the period of exploratory hypermotility which occurs when animals are first placed into a new environment. The high reproducibility of the data during this period is probably due to the fact that the animals search to the same degree to satisfy their curiosity and, therefore, the variability of movement among the animals is small. Borsy *et al.* (133) studied several classical tranquilizers by their ability to inhibit this orientational hypermotility. This appears to be a sound approach to the evaluation of depressants because the test compounds were made to challenge a natural, unlearned reaction similar to the clinical situation for which these compounds are used. Bonta (134) reinforced this exploratory behavior by moving mice from a large rectangular cage in a dark room to a small round test cage in an illuminated room and measured spontaneous activity for the first hour only. Reserpine, azacyclonol, benactyzine, and chlorpromazine abolished this hypermotility, but meprobamate was successful only in ataxic doses. These tests are in contrast to the studies in which drug-induced hyperactivity is used as the baseline of performance (135, 136).

Otis (92) illustrated the importance of evaluating drug effects over long, as well as short, periods. He reported that deanol, phenelzine, and imipramine produced quantitative differences in spontaneous activity relative to placebo controls, depending on whether they were tested for 3 or 16 hr. The data suggested that different drugs may require different testing periods in order to achieve significance.

Irwin (137) has reported on the influence of

internal and external factors on spontaneous activity in the treadwheel; female rats were more responsive to drug effects than male animals; hyperactive animals were found to be significantly more responsive to both stimulant and depressant drugs than hypoactive animals. In the female rat, peak running activity occurred every fourth day in correlation with the estrus cycle (138). Older rats performed more intensely but with shorter spurts of activity and maximum treadwheel activity was observed in animals between 87 and 120 days (139), 175 days (140), and 300 days old (141). Jones *et al.* (142) reported that running activity in the wheel varies inversely with age and directly with experience although these relationships are not linear. Desroches (143) also found that activity in the treadwheel declined with age but reported that prior experience in the unit did not influence this decrease. The discrepancy in the literature is probably due to differences in environmental conditions, such as temperature, illumination, and sound levels of the experimental room. Ström has described extensive studies on the suitability of the treadwheel for the evaluation of substances having potential central depressant action (144).

The literature is sparse with regard to the influence of experimental conditions on rotarod performance. However, there is some evidence that manipulation of speed and rod diameter alters the magnitude of drug response. Plotnikoff *et al.* (119) studied the effect of amphetamine and other stimulants at three different speeds (11.44, 18.30, and 29.28 r.p.m.) and reported that the effect of amphetamine was smallest at the lowest speed. Watzman *et al.* (86) found that chlorpromazine produced a greater depressant effect on mice when they performed on a 2-in. diameter rod rather than on a 1 or 1.5-in. rod.

It is apparent from the foregoing discussion that environmental and experimental factors must be carefully controlled; for, as mentioned before, the effects of drug on behavior are largely a function of the situation in which they are studied.

Repeated Tests of the Same Animals.—The advisability of re-using animals in experimental situations has been controversial and was briefly discussed earlier. It is highly desirable, if possible, to give repeated tests to the same animals when evaluating the effects of psychotropic agents on behavior. Not only is it an economic advantage, but a more sensitive test is obtained because the consistency of individual performances usually found in repeated tests means a smaller variation in scores against which the effects of drug can be measured. On the other hand, the disadvantage of repeated tests on the same animals is that both drug and behavioral carry-over effects may occur from one test to the next, especially when there is a short time interval between sessions. Adler (145), utilizing the photocell activity cage, found a greater depressant effect of tetrabenazine on the motor activity of rats in the second of two tests with a 1-week intertrial period. Rushton *et al.* (146) have shown that even a single brief experience in a Y-shaped maze, lasting only 3 min., markedly modified subsequent reactions to an amphetamine–amobarbital mixture. Ross and Schnitzer (147) reported an elevation of activity level of mice 2 weeks after the animals had been tested for locomotion while under the influence of a single dose of *d*-amphetamine sulfate. The same authors later showed in a separate experiment, that the drug was not directly involved in the later elevation of activity and theorized that the animals learned to be more active due to their prior treatment of the stimulating drug. Watzman *et al.* (124) tested mice twice in the photocell activity cage, 1, 3, 7, and 14 days apart. The scores in the second test were generally lower than those of the first test, and this behavioral carry-over effect was greater for groups given a second test at intervals of 1 or 3, rather than 7 or 14 days after the first test. Even at the 7 and 14-day intervals the recovery of the original activity level was not complete. A more important finding in this experiment was that chlorpromazine produced a greater depressant effect on activity in the first 0.5 hr. of the second session than of the first session. This effect was clearly not due to accumulation of the drug from the first session because the greater drug effect was found in the second session after the 14-day interval as well as after the 1-day interval. The authors concluded that investigators must be careful when using the same animals more than once in tests of drug effects. They recommended that the sequence be counterbalanced giving placebo first to half of the animals, and the drug first to the other half. The high over-all correlation in activity between the first and second sessions showed that the use of repeated tests on the same animals can increase the sensitivity of the test of drug even though there is a difference in performance and a different magnitude of drug effect between the two sessions. Thus, the effects of the drug can be tested adequately with a greatly reduced number of animals by the use of a repeated test design.

Statistical Treatment of Activity Data.—Parametric tests of statistical significance, such as the analysis of variance and *t* tests, assume

that the frequency distribution of scores is nonskewed and that the variance among the experimental groups is approximately equal. Usually, because of the extreme variations in activity performance among small animals, it is necessary to transform the data and thus normalize the frequency distribution. If this is not done, the non-normality is likely to be accompanied by a loss of power in the F and t tests and a corresponding loss of efficiency in estimation of treatment effects (148). Furthermore, extremely high raw scores are likely to lead to a misinterpretation of relative magnitudes if they are farther from the mean than the lowest scores. Logarithmic or square root transformation of data may normalize the distribution of scores by reducing the magnitude of the high scores more than the low ones. In a recent study of the photocell activity cage (124), a comparison of the raw, square root, and logarithmic forms of experimental data indicated that the raw scores were skewed in a positive direction with extreme high scores being much farther from the mean than were the extreme low scores. The logarithmic scores were skewed in the opposite, negative direction, whereas the square root scores were skewed to the least degree (positive direction). Also, spontaneous activity appeared to be most stable when the scores were in the square root form. Irwin (110) has used square root transformation data on locomotor activity in the treadwheel, and Kissel (100) found it necessary to transform tilt cage data into logarithmic form. The skewness of a frequency distribution can be roughly estimated by comparing the relative distance of the highest score and the lowest score from the mean or median value. A more refined procedure (149) requires the estimation of the mean (M), median (Mdn) or mode, and standard deviation (S.D.). Either of three equivalent equations may be used as follows:

$$\frac{\text{M} - \text{mode}}{\text{S.D.}} = \frac{\text{M} - [\text{M} - 3(\text{M} - \text{Mdn})]}{\text{S.D.}} = \frac{3(\text{M} - \text{Mdn})}{\text{S.D.}}$$

The value of a normal frequency distribution is 0, and therefore data which are distributed in a manner approaching normality would have a value close to 0.

Because reliability and reproducibility of data are of extreme importance to scientific investigators, it is desirable to use the most sensitive measure of reliability. One statistical procedure which is extremely useful is the split-half method (150), in which stability of performance for each animal within the same session can be readily computed. For example, if the spontaneous motor activity of an animal is measured over a 2-hr. period in 15-min. segments, the performance of the even time intervals (2nd, 4th, 6th, and 8th) is correlated with the scores recorded in the odd time segments (1st, 3rd, 5th, and 7th). The resulting correlation coefficients can then be tested for statistical significance of differences by the method described by Edwards (151).

Rotarod performance of rodents treated with central nervous system depressants has been recorded as the per cent decrease in performance times (81) or the per cent of animals (118, 152, 153), falling off at a predetermined time (all-or-none method). A more consistent dose response effect was obtained for chlorpromazine when the "performance time" method of recording was used (87). The all-or-none method, in principle, does not appear to be satisfactory. If an animal scores 179 sec. under a low dose and 20 sec. under a higher dose in a 3-min. trial, a satisfactory dose response curve would be achieved under the time-response procedure; whereas, under the all-or-none method, 100% depression would be reported for both doses. There is even some question as to the suitability of the "performance time" method of recording the data. Because all trials are terminated at some point of time, the data are usually skewed with the majority of trained animals scoring at the "ceiling" or maximum time limit of the experiments with some animals scattered throughout the middle and lower part of the frequency distribution. Therefore, parametric tests of significance, such as the analysis of variance and t tests, cannot be properly applied for the reasons given above.

Since the drug effect may vary with environmental factors, it is desirable in activity experiments to study the effect of a drug over a range of conditions. This can be done efficiently by the use of the factorial design which permits broader generalizations to be drawn than a group of individual studies which are limited to a single set of conditions (154). The statistical treatment of activity data of this type can be efficiently analyzed by the analysis of variance test. It is a flexible statistical procedure which is capable of treating several levels of experimental variables simultaneously. By providing estimates of interactions between doses and the other variables of the experiment, it gives important information on parameters which govern or influence the appearance of a particular drug effect.

SUMMARY

It would appear that a total pharmacological evaluation of psychotropic drugs must include the use of at least two different animal species in an

observational program. If time and funds are available, a third species can be added. The rodent (mouse or rat) and the cat would seem to be the favored animals for this procedure with the monkey being the third species. The rodent screen should provide not only behavioral or pharmacodynamic data, but also toxicological information for the protection of animals used in subsequent studies. The rodent observational scale should include the signs characteristic of autonomic and central nervous system changes, and certain behavioral measurements obtained through the use of open field tests and the rating of signs, such as grooming, etc. More important, an additional sequence should involve the measurement of social interaction of rodents. This latter point is too often omitted from the typical observational scale. The cat can be used as a test animal once sufficient toxicological data has been obtained. It provides the stable baseline of behavior that may give a better correlation of drug effects than the data obtained from the rodent studies. The cat procedure should allow the generation of a high degree of behavior, and the rating scale should include a sufficient number of rating points so that information is not overlooked. The use of paired, free-roaming cats may be advantageous over other techniques in that their activity may be increased over caged or restrained animals. Data reduction is extremely important in these tests, and the use of certain computer programs may serve to fulfill this need. The clinical predictiveness of observational data is undoubtedly more reliable when the number of species involved in the tests is increased. The addition of the monkey to the rating procedure increases this reliability and provides some natural behavior patterns (aggression) that are not seen routinely in other test animals. Even with the additional species, preclinical predictiveness is at best difficult. To overcome this and other inadequacies, better models of behavior must be developed for the test animals. It would appear that the "experimental neuroses" developed in test animals should be re-evaluated and a new set of baselines formed. The present methods of developing conflict behavior by using adverse stimuli may not be the suitable method for attempting the differentiation of drug effects, but this would appear to be a major area for future work in observational research.

The fixed type of activity unit such as the photocell cage appears to be the preferable apparatus for monitoring small animal activity. It measures lateral motion directly and does not introduce any movement artifacts typical of the indirect type of activity cage. The indirect measuring units, such as the jiggle cage, are difficult to calibrate and the data, too often, represent frequency of cage movements rather than animal movements. The sensitivity of the direct type of activity apparatus has been vastly increased by investigators with the use of intricate electronic circuitry. Further efforts to increase sensitivity with still more complex and sophisticated instrumental design does not appear to be necessary. Present concepts of drug evaluation are based on the assumption that *total* movement must be measured in order to monitor drug effects sensitively. However, investigators (84) have accurately simulated the clinical effects of stimulants by recording only one component of behavior, while the recording of total locomotor activity failed to do so. This is not surprising in view of the fact that the primary effects of amphetamines in humans are nonlocomotor in nature (restlessness, irritability, anxiety). Similarly, depressant compounds may alter selectively only a few component behavioral patterns of total activity. Therefore, research should turn its attention toward delineating, if possible, the specific behavioral patterns affected by particular compounds or classification of compounds. If successful, the use of complex, expensive apparatus capable of recording every type and all degrees of movement would not be justified. Papers have been reviewed which indicate that the qualitative and quantitative effects of a drug are a function of the environment in which it is tested. Because such parametric influences vary from laboratory to laboratory, it is incumbent upon each investigator to determine the optimum set of experimental conditions for his laboratory.

Because of the great variability in activity between animals, proper statistical treatment of data is extremely important to the behavioral scientist. He depends to a great extent on the power of tests of statistical differences to give meaning to his data. Since parametric tests (analysis of variance, t tests) assume that frequency distributions are normal, it is imperative that investigators consider the transformation (log, square root) of raw data before applying these statistical tests.

Synthesis of ^{14}C-Labeled Isomers of Dichlorodiphenyldichloroethanes (DDD)

By R. E. COUNSELL and ROBERT E. WILLETTE

1,1-Dichloro-2-(*o*-chlorophenyl)-2-(*p*-chlorophenyl-^{14}C)ethane (*o,p'*-DDD-^{14}C), 1,1-dichloro-2-(*m*-chlorophenyl)-2-(*p*-chlorophenyl-^{14}C)ethane (*m,p'*-DDD-^{14}C), and 1,1-dichloro-2,2-bis-(*p*-chlorophenyl-^{14}C)ethane (*p, p'*-DDD-^{14}C) were synthesized by acid catalyzed condensation of chlorobenzene-^{14}C with excess 2,2-dichloro-1-(*o*-, *m*-, and *p*-chlorophenyl)ethanols. The carbinols were prepared in good yields by reverse addition of the chlorophenyl Grignard reagent to dichloroacetaldehyde. Purity was determined by thin-layer and gas chromatography. The I.R., U.V., and NMR spectra of these compounds are discussed.

INTEREST in the development of radiopharmaceuticals suitable for adrenal photoscanning prompted the present study. For this purpose, an agent that selectively concentrated in the adrenal and could be labeled with a γ-emitting radionuclide was necessary. This paper describes the synthesis of ^{14}C labeled isomers of 1,1-dichloro-2,2-bis-(chlorophenyl)ethane (DDD) to be utilized in tissue distribution studies. The synthesis of other DDD isomers and ^{125}I and ^{131}I isomers will be reported elsewhere.

Received April 25, 1966, from the Laboratory of Medicinal Chemistry, College of Pharmacy, University of Michigan, Ann Arbor.
Accepted for publication July 1, 1966.
Presented to the Medicinal Chemistry Section, A.PH.A. Academy of Pharmaceutical Sciences, Dallas meeting, April 1966.
This work was supported by grants CA-08349-01 from the National Cancer Institute, U. S. Public Health Service, Bethesda, Md., and PRA-18 from the American Cancer Society, New York, N. Y.

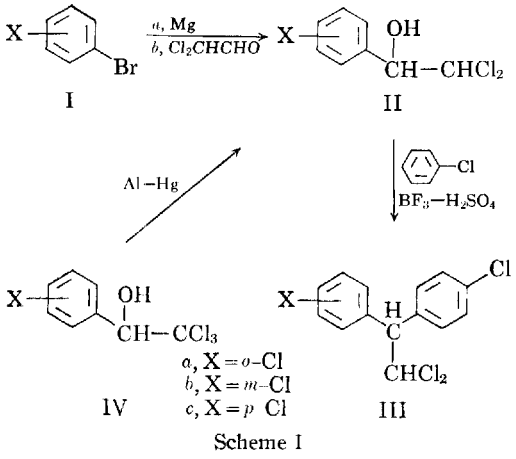

Scheme I

Isomers of DDD were chosen for this study because they have been shown to have a predilection for adrenal tissue. During an investigation of the toxicological properties of various insecticides, Nelson and Woodard (1) observed that *p,p'*-DDD (III*c*) caused extensive necrosis and atrophy of the adrenal cortex in dogs. This observation led to unsuccessful attempts to utilize this substance clinically to produce a chemical adrenalectomy (2). Cueto and Brown (3) demonstrated, however, that the adrenocorticolytic activity ascribed to *p,p'*-DDD was actually due to the *o,p'*-isomer (III*a*) which was present as a contaminant. They also showed that *o,p'*-DDD concentrated to a greater extent than *p,p'*-DDD in the adrenals of dogs.

Several reports concerning the actions of *o,p'*-DDD have appeared recently. Studies have shown it to produce tumor regression in cases of metastatic adrenal cortical carcinoma (4) and to cause remissions of symptoms in patients with Cushing's syndrome (5, 6). It was found ineffective, however, for the treatment of mammary carcinoma (7). *o,p'*-DDD has also been found to have an effect on steroid metabolism and this aspect has received considerable attention. These studies have shown it to stimulate cortisol metabolism (8), to alter the extra-adrenal metabolism of cortisol (9), and to inhibit specific enzymes (10).

Although *o,p'*-DDD has been studied to a considerable extent, Nichols *et al.* (11) indicated that the *m,p'*-isomer (III*b*) was more effective in causing regression of adrenal carcinoma with fewer side effects. Despite the interest in *o,p'*-DDD and its isomers, tissue distribution studies with labeled compounds have not been reported. The first synthesis of these labeled DDD isomers is reported here.

EXPERIMENTAL[1]

Synthesis of Isomeric 2,2-Dichloro-1-(chlorophenyl)ethanols (II).—The Grignard reagent, prepared from the appropriate bromochlorobenzene (n mole), magnesium (n mole), and ether in a three-necked flask provided with a stopcock-fitted outlet on the bottom, was added over 1 hr. to a well-stirred solution of dichloroacetaldehyde[2] (n mole) in ether (total $n \times 200$ ml.) with ice cooling under a nitrogen atmosphere. After stirring an additional 30 min. at room temperature, 6 *N* sulfuric acid or concentrated ammonium chloride solution was added and the mixture separated and extracted with ether. The combined organic layers were dried ($MgSO_4$) and the ether removed at atmospheric pressure. The residue was distilled under reduced pressure. (See Table I.)

1,1 - Dichloro - 2 - (o - chlorophenyl) - 2 - (p-chlorophenyl-^{14}C)ethane.—A mixture of 2.26 Gm. (0.01 mole) of 2,2-dichloro-1-(*o*-chlorophenyl)ethanol, 29.7 mg of chlorobenzene-^{14}C (uniformly labeled, 0.50 mc.),[3] and 530.3 mg. (total 0.005 mole) of chlorobenzene was stirred at 40° and 6 ml. of boron trifluoride-saturated sulfuric acid added dropwise over 5 min. The mixture was heated at 40° with vigorous stirring for 3 hr. and then extracted with petroleum ether (b.p. 30–40°, 3 × 25 ml.). The combined extract was washed with water (2 × 25 ml.) and dried ($MgSO_4$ and charcoal). The filtered extract was concentrated under vacuum and the residue chromatographed on a column of 35 Gm. of silicic acid, prepared and developed with benzene–hexane (1:1). The eluate was monitored with a Geiger survey meter and the radioactive fraction collected and evaporated. The oily residue was taken up in methanol and refrigerated to give,

[1] Melting points were taken on a Fisher-Johns melting point apparatus and are corrected. Elemental analyses were performed by Spang Microanalytical Laboratories, Ann Arbor, Mich. Infrared spectra were taken in KBr disks on a Perkin-Elmer 337 spectrophotometer. Ultraviolet spectra were recorded on a Beckman DK2A spectrophotometer in 95% ethanol. The NMR spectra were obtained with a Varian A-60 spectrometer in $CDCl_3$ at a concentration of 10%, with tetramethylsilane as internal reference. Thin-layer chromatograms (TLC) were run with 1 in. wide Eastman Chromagrams, type K301R with fluorescence indicator, developed with benzene, and spots detected with U.V. light and iodine vapor. Chromagrams of ^{14}C-labeled compounds were scanned with an Atomic Associates RCS-363 Radiochromatogram Scanner. Gas-liquid chromatography (GLC) was carried out with a F&M, model 400, gas chromatograph equipped with an electron-capture detector; column, 122 cm. × 3 mm. i.d. glass tube; packing, 3.8% by wt. silicone rubber SE-30 on 80–100 mesh Diatoport S, prepared according to Horning *et al.* (21); column temperature, 185°; detector temperature, 210°; flash heater, 230°; inlet pressure, 40 p.s.i.; flow rate, about 70 ml./min. Radioactivity measurements were made with an Atomic Associates FC-72A gas-flow planchet counter and Baird-Atomic 146 scaler. Silicic acid used in the column chromatography was Baker and Adamson reagent grade, dried at 105° for 1 hr. just prior to its use.

[3] Purchased from New England Nuclear Corp., Boston, Mass.

in two crops, 656 mg. (41%) of colorless needles, m.p. 75–76° [lit. m.p. 76–78° (12) and 75.5–76.5° (13)]; specific activity 99.5 μc./mmole. It showed one spot (R_f 0.67) on a TLC strip, which scanned as a homogeneous radioactive area. $\nu_{max.}$ 3070, 3050 (Ar—H); 2980, 2930 (CH); 1480, 1465 (C=C); 1100, 1051, 1029, 770 (1,2-disubstituted Ar—H); 1083, 1040, 1010, 810 (1,4-disubstituted Ar—H); 757 (CCl_2); 608; and 509 cm.$^{-1}$. $\lambda_{max.}$ 229.5 (ε 16,970) and 267.5 mμ (ε 640). The NMR spectrum showed doublets at 5.21 δ (benzylic proton) and 6.38 δ (—$CHCl_2$) with J = 8.5 c.p.s., and a single aromatic-proton peak at 7.35 δ.

1,1 - Dichloro - 2 - (m - chlorophenyl) - 2 - (p-chlorophenyl-^{14}C)ethane.—A mixture of 2.26 Gm. (0.01 mole) of 2,2-dichloro-1-(*m*-chlorophenyl)ethanol, 29.7 mg. of chlorobenzene-^{14}C (uniformly labeled, 0.50 mc.)[3] and 530.3 mg. (total 0.005 mole) of chlorobenzene was stirred at 40° and 6 ml. of boron trifluoride-saturated sulfuric acid added dropwise over 1 hr. After heating at 40° with vigorous stirring for 1 hr., 2 ml. of cyclohexane was added. After heating 2 hr. longer, the mixture was worked up as above and chromatographed with benzene–hexane (1:4). The radioactive fraction was dissolved in an equal volume of 95% ethanol and after allowing to stand in the refrigerator 3 weeks gave 490 mg. (31%), m.p. 51–52°, which was recrystallized from ethanol to give 388 mg., m.p. 53–54° [lit. m.p. 54° (14)], specific activity 89.3 μc./mmole. TLC showed one spot (R_f 0.67), which was the only radioactive area on scanning. $\nu_{max.}$ 3050 (Ar—H); 2995, 2910 (CH); 1580, 1565, 1480, 1470 (C=C); 1090, 1072, 836, 785 (1,3-disubstituted Ar—H); 1085, 1040, 1009, 808 (1,4-disubstituted Ar—H); 759 (CCl_2); 615; and 502 cm.$^{-1}$. $\lambda_{max.}$ 219 (ε 19,770), sh. 226.5 (ε 16,700), and 268.5 mμ (ε 800). The NMR spectrum showed doublets at 4.57 δ (benzylic proton) and 6.31 δ (—$CHCl_2$) with J = 8.0 c.p.s., and an aromatic peak split at 7.26 and 7.29 δ.

1,1 - Dichloro - 2,2 - bis - (p - chlorophenyl - ^{14}C)-ethane.—A mixture of 2.26 Gm. (0.01 mole) of 2,2-dichloro-1-(*p*-chlorophenyl)ethanol, 107 mg. of chlorobenzene-^{14}C (uniformly labeled, 0.50 mc.),[4] and 456 mg. (total 0.005 mole) of chlorobenzene was stirred at 40° and 6 ml. of boron trifluoride-saturated sulfuric acid added dropwise over 30 min. The reaction was conducted and worked up as described for the *meta* isomer above.

The radioactive fraction afforded from methanol 694 mg., m.p. 107–110°, which was recrystallized from methanol to give 602 mg. (43%), m.p. 109–110° [lit. m.p. 109.5–110° (12)], specific activity 106.9 μc./mmole. TLC showed one spot which corresponded to the only radioactive area on scanning (R_f 0.72). $\nu_{max.}$ 3050, 3020 (Ar—H); 2970, 2910 (C—H); 1580, 1490, sh. 1475 (C=C); 1087, 1040, 1010, 803 (1,4-disubstituted Ar—H); 763 (CCl_2); 532; and 499 cm.$^{-1}$ $\lambda_{max.}$ sh. at 211.5 (ε 17,060), 217.5 (ε 15,910), 231 (ε 19,710), and 268 mμ (ε 713). The NMR spectrum showed doublets at 4.58 δ (benzylic proton) and 6.33 δ (—$CHCl_2$) with J = 8.0 c.p.s., and a single aromatic peak at 7.33 δ.

DISCUSSION

The syntheses of these three DDD isomers have been reported previously. After initial isolation of *o,p'*- (III*a*) and *p,p'*-DDD (III*c*) from technical "DDT,"[5] Haller *et al.* (12) synthesized them in 39 and 63% yields, respectively, by the Friedel-Crafts alkylation of chlorobenzene with the appropriate carbinol (II) in the presence of 100% sulfuric acid. They obtained the *ortho* carbinol (II*a*) in only 6% yield by the addition of dichloroacetaldehyde to the Grignard reagent prepared from *o*-bromochlorobenzene (I*a*). The *para* carbinol (II*c*) was prepared in good yields by this method [67% (12)] or by reduction of 2,2,4'-trichloroacetophenone [96% (15)]. (See Scheme I.)

In an approach to the synthesis of the more biologically interesting *o,p'*-DDD, Inoi, Gericke, and Horton (13) obtained the *ortho* carbinol (II*a*) by reduction of the more readily available 2,2,2-trichloro-1-(*o*-chlorophenyl)ethanol (IV*a*) with aluminum amalgam in 90% ethanol. They synthesized several diphenyldichloroethanes by this method, including *o,p'*-, *m,p'*-, and *p,p'*-DDD (III*a*, *b*, and *c*), all in good yield. They also improved on the condensation of carbinol (II*a*) with chlorobenzene by using boron trifluoride-saturated sulfuric acid (47% yield).

Although the biological properties of *m,p'*-DDD (III*b*) have been mentioned several times in the literature, reports of the synthesis and physical properties have been limited. It was prepared by the reduction outlined above, being reported as an oil, b.p. 178–180°/0.5 mm. (13). Synthesis of the *meta* carbinol (II*b*) by the Grignard procedure was reported in 32% yield and *m,p'*-DDD (III*b*), using sulfuric acid in the Friedel-Crafts reaction and a laborious work-up, in 19% yield (14).

With the specific intention of preparing the ^{14}C labeled compounds, interest centered on the Friedel-Crafts route since this enabled incorporation of the labeled precursor at the last step. In preliminary investigations on the synthesis of the carbinol intermediates, the authors were unable to repeat the aluminum amalgam reduction of the trichloroethanol (IV*a*) [prepared according to Haller *et al.* (12) and Bergmann *et al.* (16)]. Attention turned to the Grignard synthesis. It was anticipated that slow addition of the Grignard reagent prepared from the bromobenzenes (I) to a cold ethereal solution of the unstable dichloroacetaldehyde would give an improvement in the yields. In this manner, yields of 35, 53, and 63% were obtained for the *o*-, *m*-, and *p*-carbinols (II), respectively.

The condensation reaction was studied extensively in an effort to maximize the radioactive yield. It is usual in Friedel-Crafts alkylations of benzene and its readily available derivatives to have them in excess relative to the alkylating agent, and to serve as solvent. As the chlorobenzene to be used was the labeled precursor and it seemed likely that the carbinols (II) would exhibit some instability with possible decomposition, trial reactions were run with varying proportions of chlorobenzene and carbinols and a twofold excess of the latter was found to give maximum yields. These varied from 56 to 75%, depending somewhat on the isolation procedure used. It was found most convenient to chromato-

[4] Purchased from Tracer Lab, Waltham, Mass.

[5] DDT, of various grades, is the product obtained from the condensation of chloral with chlorobenzene in the presence of sulfuric acid, and usually contains about 70% 1,1,1-trichloro-2,2,-bis-(*p*-chlorophenyl)ethane.

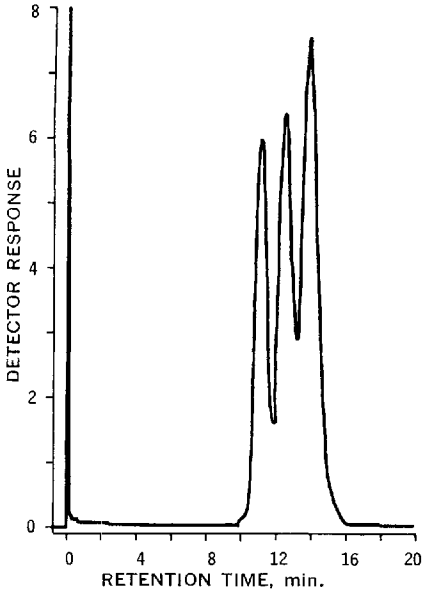

Fig. 1.—GLC tracing of 2.5 ng. each of *o,p'*-, *m,p'*-, and *p,p'*-DDD-^{14}C, injected in 6 μl. of benzene.

graph the crude product on activated silicic acid with benzene–hexane (1:4). In all three cases, an aromatic by-product was eluted before the DDD isomers. Since heterogeneous reactions tend to give variable results, tetrachloroethane and cyclohexane were tried as solvents. Yields were lower with the former and unaffected by the latter, although it did facilitate stirring. The labeled compounds were obtained in about 40% yields following recrystallization.

It has been pointed out frequently (17) that special purity analyses are required for radiochemicals intended for biological distribution studies. In this investigation the labeled isomers were checked for purity by thin-layer (TLC) and gas-liquid chromatography (GLC). With TLC, chemical purity was established by spot detection with ultraviolet light and iodine vapor, and radioactive purity by means of a radiochromatogram scanner. GLC was found to be the most effective analytical tool for assessment of purity. The type of column and conditions employed have been used extensively for detection of pesticide residues (18) and gave satisfactory separation of the three isomers (Fig. 1). The electron-capture detector used was capable of detecting trace impurities. This made it possible to show that each was isomerically pure. This was necessary as the condensation of *o*-, *m*-, and *p*-carbinols (II) with chlorobenzene can occur at both the *ortho* and *para* positions. Of most concern was the complete elimination of *o,p'*-DDD from *p,p'*-DDD, as the former is known to localize to a much greater extent in various tissues. This was readily seen as the gas chromatogram of *p,p'*-DDD-^{14}C showed a single peak even when 25 ng. (10 times that used in obtaining Fig. 1) was injected. It is curious to note that their order of retention does not correspond to their melting points, the lower melting *m,p'*-DDD following the sterically hindered *o,p'*-DDD. Additional isomers are being prepared to study this and other properties.

We examined the I.R., U.V., and NMR spectra of the three DDD isomers for possible use in assessing purity. Reports on spectral data for these compounds have been limited. McDonald and Watson (19) employed I.R. spectroscopy for differential analysis of *o,p'*-, and *p,p'*-DDD and used the distinguishing bands at 685 and 765 cm.$^{-1}$, respectively. In addition, *o,p'*-DDD has been observed to exhibit a strong characteristic band at 608 cm.$^{-1}$.

Inoi *et al.* (13) reported on the U.V. spectra of *o,p'*-DDD and some related compounds but made no comparisons. In the studies reported here, comparison of the *o,p'*-, *m,p'*-, and *p,p'*-isomers showed them to have similar but distinguishable U.V. absorption spectra.

The NMR spectra showed the greatest distinctions. In contrast with *m,p'*- and *p,p'*-DDD, the benzylic proton of *o,p'*-DDD showed a shift to lower field of 38 c.p.s. due to the deshielding effect of the *o*-chloro substituent. A similar downfield shift has been reported for the benzylic proton of benzhydryl derivatives possessing *o*-methyl groups (20). In addition, whereas the *o,p'*- and *p,p'*-isomers showed a single strong peak at approximately 7.34 δ for the aromatic protons, the *m,p'*-isomer displayed two major peaks at 7.26 and 7.29 δ.

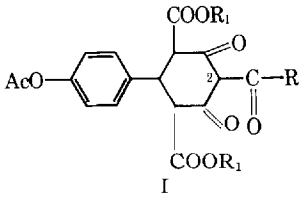
Potential Anticancer Compounds

Synthesis of 2-Carbamoyl and 2-Phenyl Carbamoyl Derivatives of 1,3-Cyclohexanedione-Type Compounds

By PHILIPPOS E. PAPADAKIS and GUY HAVEN

2-Carbamoyl and 2-phenylcarbamoyl derivatives of 1,3-cyclic diketones (I–VI) were synthesized as potential antibacterial and anticancer reagents.

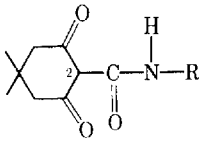
IN PREVIOUS publications (1, 2) the synthesis of 2-acyl and 2-aroyl derivatives of 1,3-cyclohexanedione-type compounds were reported. Compound I is an example where R = alkyl or aroyl and R_1 = ethyl.



I

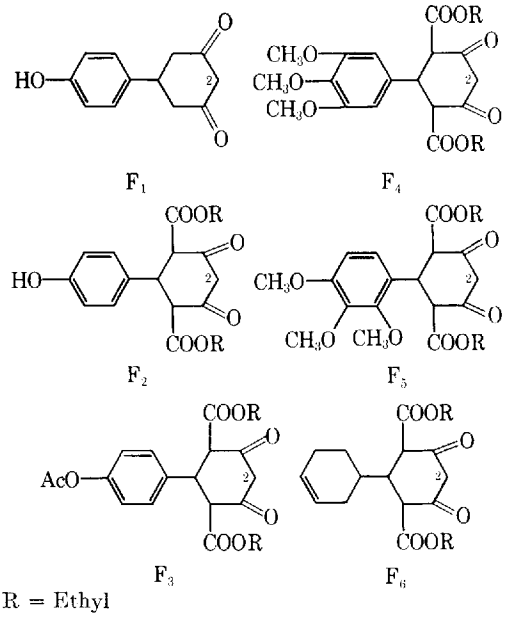
Carbon 2 in formula I has a tricarbonyl methane structure.

A Japanese team of scientists (3) found that the acylated or aroylated derivatives, at position 2 of the cyclic diketones they used, inhibited the multiplication of the Gram-positive bacteria while the carbamoyl and phenyl carbamoylated derivatives showed potency against both Gram-positive and Gram-negative bacteria, as well as a wide spectrum of antitumor activity. An example of such derivatives of the 5,5-dimethyl-1,3-cyclohexanedione (dimedone) is given by the formula (II) where R = H or C_6H_5.



II

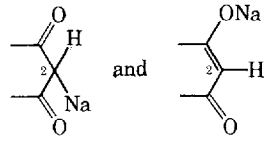
Papadakis *et al.* have synthesized derivatives of 1,3-cyclohexanedione (4–6) which have been used as intermediates for the preparation of physiologically important compounds (2, 7–10). Following are the formulas of such intermediates which have structural relationship to dimedone.



F_1 F_4 F_2 F_5 F_3 F_6

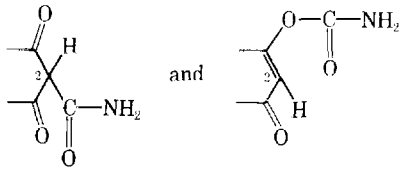
R = Ethyl

In view of the findings of Ukita *et al.* (3), it was thought advisable to prepare derivatives of each of the compounds I–VI having the —$CONH_2$ or —$CONHC_6H_5$ attached to 2-C of the cyclohexanedione ring. There are several methods by which such derivatives may be obtained but each has its own difficulties and side reactions. The phosgene (ClCOCl) reaction with the sodio derivative of each of the compounds I–VI would seem to afford a direct method for the preparation of the products desired. The method has the disadvantage that when each of the compounds F_1–F_6 is treated with NaOR, two structures result.



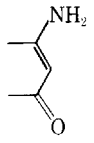
When the sodio derivatives are treated with phosgene and subsequently with ammonia, the following products may be obtained:

Received May 9, 1966, from the Special Laboratory of Nuclear Medicine and Biology, Veterans Administration Hospital, Omaha, Nebr. 68105.
Accepted for publication June 29, 1966.

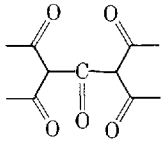


III IV

Product IV predominates. Ammonolysis of IV may render as by-products urea and

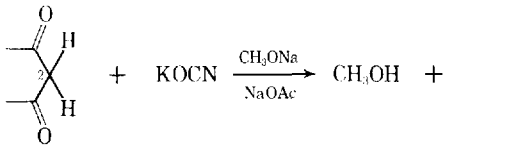


Another possibility is the formation of bis derivatives type V. When the cyclic diketone,



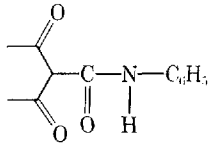
V

F_1, reacts with phosgene in the molar proportions of 2:3 and the product is treated with ammonia or aniline, compound VI is formed.



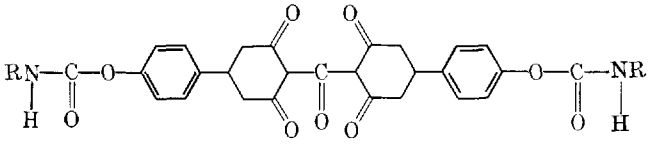
Scheme I

The 2-phenyl carbamoyl derivatives



of any of the formulas F_1–F_6 can be prepared by one of the reactions shown in Scheme II.

Similar side reactions can occur here as in the case of the preparation of the —$CONH_2$ derivative. In reaction *B* where aniline was used, there



VI

R = H or C_6H_5, respectively.

Such carbamoate or phenylcarbamoate derivatives have been isolated and analyzed (11).

There is also the possibility of polymerization between the sodioderivatives of F_1 and phosgene.

In another method each of the structures (F_1–F_6) was treated with phosgene in the presence of pyridine. Here also there is the possibility of formation of bis compounds. When any of the compounds (structures F_1–F_6) suspended in dioxane is mixed with the pyridine and the mixture, from a dropping funnel, is allowed to fall dropwise into the reaction mixture flask containing excess of a solution of 12% phosgene in benzene, the formation of the bis compound decreases.

Another method involves the reaction of any of the compounds (F_1–F_6) with potassium cyanate in the presence of $NaOCH_3$ and sodium acetate using dioxane and refluxing temperature. (Scheme I.)

is the possibility of carbanilide formation, C_6H_5-$NHCONHC_6H_5$. The method of mixing the reagents as indicated previously can adjust the relative concentrations, thereby decreasing the amount of the carbanilide formation.

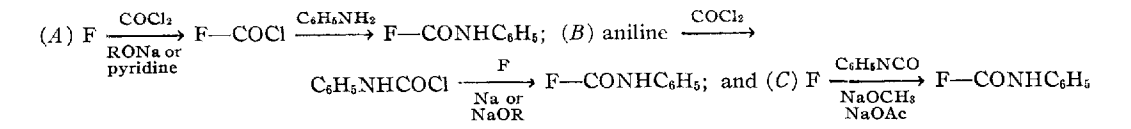
EXPERIMENTAL

In experiments *1*, *9*, and *12*, the phosgene method was used. The apparatus set up, safety precautions, and the general procedure are described in experiment *1*.

Instead of writing the long names of the compounds F_1, F_2, F_3 . . . etc., the respective letters will be used to represent the compounds. The names of the products will be given in the beginning of each experiment.

In experiments *10*, *11*, and *13*, the procedure was similar to that of experiment *1*, except that aniline was used instead of ammonia, followed by refluxing, concentrating, and processing.

Experiments *3*, *6*, *7*, and *14* were done using the phenyl isocyanate method as described.



Scheme II

1.—5 - (p - Hydroxyphenyl) - 2 - carbamoyl - 1,3-cyclohexanedione.—A mixture of 10.5 Gm. of F_1 (0.0515 mole), dioxane (30 ml.), and pyridine (8 ml.) was added slowly through a dropping funnel into a three-neck flask which contained 130 ml. of a solution of 12% phosgene in benzene. The reaction mixture flask was equipped with a dropping funnel, a condenser, and a magnetic stirrer. The top of the reflux condenser was connected with a flask containing NaOH to trap any $COCl_2$ vapor. All the apparatus was set up under the hood.

The phosgene–benzene solution was kept cold during the addition of the diketone–pyridine–dioxane mixture. The reaction mixture was allowed to stand at room temperature under the hood for 2 days, then it was refluxed for 2 hr. The flask containing the NaOH was connected to the water aspirator and controlled reduced pressure was applied to remove any unreacted phosgene. Arrangements were made for distillation. The heating was continued till the temperature reached 98°. After cooling, 30 ml. of dioxane was added to the mixture, and ammonia gas was bubbled through it for 2 hr. The mixture was allowed to stand overnight. The precipitate formed was filtered. The filtrate was concentrated to a red-orange syrup which was stirred with ether 3 successive times. The ether was decanted each time. The light tan residue was dried on porous tile. The combined solids (9 Gm.) were boiled with a limited amount of absolute alcohol and filtered hot. On cooling, the filtrate rendered crystals which were washed with distilled water and dried on porous tile, m.p. 167°–176°.

Anal.—Calcd. for $C_{13}H_{13}NO_4 \cdot H_2O$: C, 58.87; H, 5.64; N, 5.28. Found: C, 59.21; H, 5.30; N, 5.40.

The material above was dried at 100° and 1.5 mm., m.p. 183°.

Anal.—Calcd. for $C_{13}H_{13}NO_4$: C, 63.15; H, 5.26; N, 5.66. Found: C, 63.27; H, 5.65; N, 5.25.

The material which was not readily soluble in the hot alcohol, m.p. 185°, corresponds to the formula $C_{14}H_{14}N_2O_5$.

2.—5-(p-O-Carbamoate phenyl)-2-carbamoyl-1,3-cyclohexanedione.—*Anal.*—Calcd. for $C_{14}H_{14}N_2O_5$: C, 57.93; H, 4.82. Found: C, 58.02; H, 4.70.

3.—2 - Phenylcarbamoyl - 5 - (p - O - phenylcarbamoate phenyl) - 1,3 - cyclohexanedione.—F_1, 7.28 Gm. (0.035 mole), 0.805 Gm. of sodium dissolved in methanol, and 30 ml. of dioxane were mixed in a three-neck flask equipped with a reflux condenser and magnetic stirrer. After refluxing for 20 min., the apparatus was arranged for distillation of the methanol. The distillation was continued until the temperature reached 90°. Twenty milliliters of dioxane was added and 4.2 ml. of phenyl isocyanate. After 5 hr. of refluxing, the dioxane was distilled off under reduced pressure using a water bath. The residue was cooled and then washed with ether. The ether was decanted and the residue was stirred with water. The solution was acidified and the precipitate which formed was filtered and recrystallized from ethanol. It sinters at 193°. It turns to syrupy droplets at 198° and to a red-black melt at 223°–229°. Recrystallized from acetone, m.p. 209°–213°.

Anal.—Calcd. for $C_{26}H_{22}N_2O_5$: C, 70.57; H, 4.97; N, 6.33. Found: C, 70.16, 70.31, 70.53; H, 4.73, 5.22, 5.10; N, 6.32.

4.—5 - (p - Hydroxyphenyl) - 2 - carbamoyl - 4,6-dicarbobutoxy - 1,3 - cyclohexanedione.—F_2 (10.4 Gm.), sodium (0.92 Gm.) dissolved in butanol, urea (3.6 Gm.), and butanol (50 ml.) were refluxed 4 hr. Some urea sublimed and was deposited in the inner wall of the reflux condenser. Some ammonia was also forming, as shown when a piece of litmus paper held on the top of the condenser turned blue. Some methyl alcohol was added to lower the boiling temperature to 95° and prevent the subliming of urea. The materials dissolved in the beginning. Later a fine precipitate formed which changed from a greenish to a brown color.

After 4 hr. of refluxing, most of the butanol was distilled under reduced pressure. Water was added, and the mixture was acidified. The precipitate was stirred with cold alcohol and filtered. From the filtrate, after evaporation of the alcohol, the material obtained melted at 80°–85°, then resolidified, and remelted at 175°.

Anal.—Calcd. for $C_{13}H_{29}O_8N \cdot {}^1/_2H_2O$: C, 60.52; H, 6.57. Found: C, 60.08; H, 6.57.

5.—5 - (p - Hydroxyphenyl) - 1 - amino - 2-carbamoyl - 4,6 - dicarbethoxy - 1 - cyclohexenone-3.—F_2, 10.4 Gm. (0.03 mole), urea, 3.6 Gm. (0.06 mole), and dimethylformamide were refluxed 8 hr. After the refluxing, most of the solvent was evaporated under reduced pressure. Water was added. The mixture was stirred and filtered. The residue had a melting point of 187°–190°. The product shows blue fluorescence under ultraviolet light.

Anal.—Calcd. for $2(C_{19}H_{22}O_7) \cdot H_2O$: C, 59.84; H, 5.51; N, 7.34. Found: C, 59.39; H, 5.33; N, 7.40.

6.—2 - Phenylcarbamoyl - 5 - (p - hydroxyphenyl) - 4,6 - dicarbethoxy - 1,3 - cyclohexanedione.—F_2, 10.4 Gm. (0.03 mole), NaOAc, 2.46 Gm., C_6H_5NCO, 7.14 Gm. (0.06 mole), and $NaOCH_3$, 3.18 Gm. (0.03 mole) were refluxed in dioxane medium for 8 hr. After that, the mixture was acidified and the precipitate was filtered off, washed with distilled water and with alcohol, m.p. 226°. The filtrate was concentrated by evaporation under reduced pressure and the residue recrystallized from ethanol, m.p. 195°.

Anal.—Calcd. for $C_{25}H_{25}NO_8 \cdot H_2O$: C, 61.84; H, 5.60. Found: C, 61.54; H, 5.75.

7.—5 - (p - Acetoxyphenyl) - 2 - phenyl carbamoyl-4,6 - dicarbethoxy - 1,3 - cyclohexanedione.—F_3, 3.9 Gm. (0.01 mole), C_6H_5NCO (1.2 Gm.), NaOAc anhydrous (1 Gm.), and 30 ml. of dioxane were mixed. After 4 hr. of refluxing, most of the dioxane

was distilled under reduced pressure. The residue was stirred in water 3 hr. and then filtered. The crystals were dried and then washed with ether three times, 223° dec. Product was almost white (little pale yellow).

Anal.—Calcd. for $C_{27}H_{27}O_9 \cdot H_2O$: C, 61.48; H, 5.54. Found: C, 61.91; H, 5.05.

Anal.—Calcd. for $C_{25}H_{21}O_8 \cdot H_2O$: C, 62.37; H, 5.00. Found: C, 61.91; H, 5.05.

8.—5 - (p - Acetoxyphenyl) - 2 - carbamoyl - 4,6-dicarbethoxy - 1,3 - cyclohexanedione.—A mixture of F_3 (11.7 Gm.), KOCN (2.43 Gm.), $NaOCH_3$ (1.62 Gm.), NaOAc (2.46 Gm.), and 50 ml. of *N*-dimethylformamide was refluxed for 5 hr. The solution became greenish, then red-orange, and orange-brown. Chromatographic paper is stained orange. Under the influence of U.V. it shows strong greenish cream fluorescence. The calculated amount of hydrochloric acid was added to react with the KOCN, sodium methoxide, and sodium acetate. The solution was evaporated under reduced pressure and the residue stirred with ice water. The insoluble part was washed with ether and recrystallized from methanol, m.p. 193°.

Anal.—Calcd. for $C_{24}H_{28}N_2O_2$: C, 56.91; H, 5.57. Found: C, 56.50; H, 5.57.

The analytical results suggest that the amide of the carbamoyl of the title compound may have reacted with the dimethylformamide as follows:

$$F\text{—}CONH_2 + O{=}C(H)\text{—}N(CH_3)_2 \rightarrow RCON{=}CH\text{—}N(CH_3)_2$$

9.—5 - (p - Acetoxyphenyl) - 2 - carbamoyl - 1,4-carbolactone - 6 - carbethoxy - 1 - cyclohexenone-3.—An attempt was made to make the compound (experiment *8*) by the phosgene method used in experiment *1*, using as starting material F_3 instead of F_1. The product begins to gum at 210° and tars at 280°. It is insoluble in ether, dioxane, cold alcohol, and water.

Anal.—Calcd. for $[C_{21}H_{23}NO_9 \cdot H_2O] \cdot C_2H_5OH$: C, 56.29; H, 4.72. Found: C, 56.50; H, 5.11.

10.—5 - (3′,4′,5′ - Trimethoxyphenyl) - 2 - phenyl carbamoyl - 4,6 - dicarbethoxy - 1,3 - cyclohexanedione.—F_5, 4.22 Gm. (0.01 mole) (6), dioxane (30 ml.), and pyridine (1 ml.) were added slowly through a dropping funnel into a three-neck flask containing 15 ml. of a 12% solution of $COCl_2$ in benzene. The apparatus and procedure were similar to experiment *1* with the exception that 1 ml. of aniline instead of ammonia was used. After refluxing for several hours, the dioxane was evaporated under reduced pressure. The residue was stirred with distilled water and acidified, filtered, and dried, and then it was washed with ether, m.p. 193°–195°, as aniline hydrochloride melts at 198°, mixed melting points were taken, 150°–155°.

Anal.—Calcd. for $C_{28}H_{31}NO_{10}$: C, 62.10; H, 5.73. Found: C, 62.58; H, 5.48.

11.—5 - (3′,4′,5′ - Trimethoxyphenyl) - 1 - iminophenyl - 2 - phenylcarbamoyl - 4,6 - dicarbethoxy-1,3-cyclohexanedione.—Experiment *10* was repeated with the difference that excess aniline was used. A material was obtained which decomposed at 122°.

Anal.—Calcd. for $C_{34}H_{36}N_2O_9$: C, 66.88; H, 6.23. Found: C, 67.11; H, 5.82.

The analytical data correspond to the title compound.

12.—5 - (4′ - Cyclohexene) - 1 - amino - 2 - carbamoyl - 4,6 - dicarbethoxy - 1 - cyclohexenone - 3.—A mixture of F_6, 11.2 Gm. (0.033 mole), dioxane (50 ml.), and pyridine (3 ml.) was added slowly through a dropping funnel into a three-neck flask which contained 70 ml. of a solution of 12% phosgene in benzene. The apparatus set up, safety precautions, and the procedure were described in experiment *1*. After the ammonia treatment, the mixture was allowed to stand overnight at room temperature. The precipitate formed was filtered and then heated with alcohol. The part that did not dissolve was washed with ether and dried on porous tile. The material had a light tan color, m.p. 150°, clear at 152°.

Anal.—Calcd. for $C_{19}H_{26}N_2O_6 \cdot {}^1/_2\ H_2O$: C, 58.91; H, 6.99. Found: C, 58.70, 58.90; H, 7.29, 7.25.

13.—5 - (4′ - Cyclohexene) - 2 - phenylcarbamoyl-4, 1 - carbolactone - 6 - carbethoxy - 1 - cyclohexenone-3.—F_6, 3.35 Gm. (0.01 mole) in dioxane, was mixed with 1 ml. of pyridine. The mixture was added dropwise through a dropping funnel into a three-neck flask containing 15 ml. of a 12% solution of phosgene in benzene. The apparatus set-up, safety precautions, and procedure were similar to experiment *1*, except that after the distillation of any unreacted phosgene, aniline instead of ammonia was used. To the reaction mixture 1 ml. of aniline in 24 ml. of dioxane was added dropwise with stirring.

The mixture was refluxed for 1 hr., then concentrated. The precipitate formed was filtered then stirred with water to get rid of the pyridinium chloride. The residue was dried, washed with ether, and recrystallized from acetone, m.p. 230°.

14.—In another experiment equimolar quantities of F_6 and CH_3ONa in dioxane medium were refluxed for 0.5 hr. The apparatus was arranged for distillation. Part of the solvent was allowed to distil until the temperature reached 100°. To the remaining mixture, equimolar quantities of phenyl isocyanate and anhydrous sodium acetate were added, and the mixture was refluxed for 2 hr. The precipitate formed was washed with water, filtered, dried, and then washed with ether. The ether was decanted and the residue recrystallized from acetone, m.p. 228°–229°; m.p. with carbanilide 208°.

Anal.—Calcd. for $C_{23}H_{24}NO_6 \cdot 2H_2O$: C, 61.88; H, 6.27; N, 3.13. Found: C, 62.04; H, 5.86; N, 2.90.

The material dried at 100° and 1.5 mm. gave the following analysis.

Anal.—Calcd. for $C_{23}H_{24}NO_6$: C, 68.03; H, 6.57. Found: C, 68.25; H, 6.56.

15.—Diethyl - (3 - cyclohexenal) - malonate.—3-Cyclohexene-1-carboxaldehyde, 218 Gm. (2 moles), 320 Gm. of diethylmalonate (2 moles), and 15 ml. of piperidine were mixed and refluxed 24 hr. at 105°. The mixture became orange in color. Fractional distillation was applied under reduced pressure. The fraction boiling at 132°–138° and 0.7 mm. was taken as representing the title compound and was used for the next step.

16.—5 - (4′ - Cyclohexene) - 4,6 - dicarbethoxy 1,3 - cyclohexanedione.—Sodium (7.8 Gm.) dissolved in absolute ethanol was added with stirring to 50 ml. of ethyl acetoacetate. After 15 min. of refluxing it was poured into a 1000-ml. flask contain-

ing 100 Gm. of diethyl-(3-cyclohexenal)-malonate. The mixture was refluxed for 6 hr. The color of the solution turned red. Distillation of the solvents under reduced pressure followed using a flash evaporator. The residue was dissolved in cold distilled water. The solution was extracted twice with ether. The aqueous layer was adjusted to pH 7 and then it was extracted with ether once more. The water layer was acidified with 3 *N* hydrochloric acid. White crystals resulted which were filtered, washed with distilled water, filtered, and then washed with a 50:50 mixture of ether–petroleum ether, m.p. 111°–113°. Recrystallized 4 times from absolute alcohol, m.p. 133°–137°.

Anal.—Calcd. for $C_{18}H_{24}O_6$: C, 64.26; H, 7.19. Found: C, 64.45; H, 7.32; C, 64.45; H, 7.19.

Comparative Study of the Alternating and Direct Current Polarography of Several Δ^4-3-Ketosteroids

By JAMES L. SPAHR and ADELBERT M. KNEVEL

A study was undertaken to compare alternating current polarography with direct current polarography as a method of analysis of testosterone, methyltestosterone, and progesterone. A solution consisting of 50 per cent ethanol, buffer (pH 1.3), and tetrabutylammonium iodide was used as the sample medium. Results showed that the lowest practical concentrations of detection for both a.c. and d.c. polarography was $3.3 \times 10^{-5}M$. However, a.c. polarography gave greater precision than did the d.c. method.

A STUDY OF the analysis of Δ^4-3-ketosteroids by direct current (d.c.) polarography has been reported by several groups of workers (1–3). In the study conducted by Kabasakalian and McGlotten (3), it was reported that the diffusion current of testosterone and other related Δ^4-3-ketosteroids was directly proportional to the concentration in the range of 2×10^{-4} to $1 \times 10^{-2}M$. At low concentrations, however, deviations from linearity were observed in some cases. These workers pointed out that the deviations may have been due to the method of measuring the diffusion current rather than a change in diffusion properties, because the diffusion current plateau at low concentration was too steep. This explanation seems reasonable since ill-defined polarographic waves are not uncommon with ketones. One factor contributing to this poor definition may be that ketone half-wave potentials occur very close to the discharge potentials of the buffer components. This effect often makes it difficult to separate ketone diffusion current from buffer discharge current. Alternating current (a.c.) polarography offers the advantage of producing polarograms in which the reduction waves of the ketone and buffer components are often sufficiently separated so that diffusion currents can be measured more accurately. Furthermore, this technique is often more sensitive to organic compounds than is d.c. polarography. The objective of this study was to compare a.c. polarography with d.c. polarography as a method of analysis for several different Δ^4-3-ketosteroids.

EXPERIMENTAL

Apparatus.—The dropping mercury electrode capillary used in this study had a length of 9.3 cm. Under a pressure of 26.5 cm. of mercury and with an open circuit, the drop time was 4.86 sec. and *m* was 1.13 mg. $sec.^{-1}$. These characteristics were determined at 25° with the mercury dropping into 50% ethanol which was 0.1 *M* in tetrabutylammonium iodide.

The electrolysis cell was a tube 7 cm. in length with an inside diameter of 2.1 cm. The saturated calomel reference used throughout this work was contained in a Hildebrand half-cell. Junction be-

ing 100 Gm. of diethyl-(3-cyclohexenal)-malonate. The mixture was refluxed for 6 hr. The color of the solution turned red. Distillation of the solvents under reduced pressure followed using a flash evaporator. The residue was dissolved in cold distilled water. The solution was extracted twice with ether. The aqueous layer was adjusted to pH 7 and then it was extracted with ether once more. The water layer was acidified with 3 *N* hydrochloric acid. White crystals resulted which were filtered, washed with distilled water, filtered, and then washed with a 50:50 mixture of ether–petroleum ether, m.p. 111°–113°. Recrystallized 4 times from absolute alcohol, m.p. 133°–137°.

Anal.—Calcd. for $C_{18}H_{24}O_6$: C, 64.26; H, 7.19. Found: C, 64.45; H, 7.32; C, 64.45; H, 7.19.

Comparative Study of the Alternating and Direct Current Polarography of Several Δ^4-3-Ketosteroids

By JAMES L. SPAHR and ADELBERT M. KNEVEL

A study was undertaken to compare alternating current polarography with direct current polarography as a method of analysis of testosterone, methyltestosterone, and progesterone. A solution consisting of 50 per cent ethanol, buffer (pH 1.3), and tetrabutylammonium iodide was used as the sample medium. Results showed that the lowest practical concentrations of detection for both a.c. and d.c. polarography was $3.3 \times 10^{-5}M$. However, a.c. polarography gave greater precision than did the d.c. method.

A STUDY OF the analysis of Δ^4-3-ketosteroids by direct current (d.c.) polarography has been reported by several groups of workers (1–3). In the study conducted by Kabasakalian and McGlotten (3), it was reported that the diffusion current of testosterone and other related Δ^4-3-ketosteroids was directly proportional to the concentration in the range of 2×10^{-4} to $1 \times 10^{-2}M$. At low concentrations, however, deviations from linearity were observed in some cases. These workers pointed out that the deviations may have been due to the method of measuring the diffusion current rather than a change in diffusion properties, because the diffusion current plateau at low concentration was too steep. This explanation seems reasonable since ill-defined polarographic waves are not uncommon with ketones. One factor contributing to this poor definition may be that ketone half-wave potentials occur very close to the discharge potentials of the buffer components. This effect often makes it difficult to separate ketone diffusion current from buffer discharge current. Alternating current (a.c.) polarography offers the advantage of producing polarograms in which the reduction waves of the ketone and buffer components are often sufficiently separated so that diffusion currents can be measured more accurately. Furthermore, this technique is often more sensitive to organic compounds than is d.c. polarography. The objective of this study was to compare a.c. polarography with d.c. polarography as a method of analysis for several different Δ^4-3-ketosteroids.

EXPERIMENTAL

Apparatus.—The dropping mercury electrode capillary used in this study had a length of 9.3 cm. Under a pressure of 26.5 cm. of mercury and with an open circuit, the drop time was 4.86 sec. and *m* was 1.13 mg. $sec.^{-1}$. These characteristics were determined at 25° with the mercury dropping into 50% ethanol which was 0.1 *M* in tetrabutylammonium iodide.

The electrolysis cell was a tube 7 cm. in length with an inside diameter of 2.1 cm. The saturated calomel reference used throughout this work was contained in a Hildebrand half-cell. Junction be-

tween the sample solution and the reference was made with a bridge of 4% agar in saturated KCl.

The instrument used in this study was a Sargent polarograph model XXI (E. H. Sargent & Co., Chicago, Ill.) modified according to Miller (4) for a.c. polarography. During the course of this study it was found necessary to modify the Miller circuit by adding a downscale compensator. The reason for the modification was that the base current of a.c. polarography was somewhat larger than the corresponding residual current of d.c. polarography. Many times at high sensitivity settings the supporting electrolyte alone caused a pen deflection so large that the a.c. peak went off scale. The downscale compensator on the model XXI polarograph could not be used to bring the peak on scale, because it is inoperative during a.c. operation using the Miller modification. In this study it was found necessary to introduce a downscale compensator in the a.c. circuit since low concentrations of steroid required high sensitivity values. Although this accessory was introduced into the circuit specifically for this study, it should increase the value of the a.c. modification of the model XXI in cases where high sensitivity is required. The details of this circuit have been reported elsewhere (5).

Reagents.—The buffers used were those reported by Kabasakalian and McGlotten (3). The components were observed to be polarographically inert in the voltage range employed. The need for a medium of 50% ethanol was dictated by the limited solubility of the steroids. The ethanol was distilled from commercial absolute ethanol in the presence of sodium ethoxide and diethyl phthalate (6). This preparation was necessary because the commercial material contained some reducible impurities. Alkyl phenoxy polyethoxy ethanol[1] was used as the maximum suppressor. A polarographic grade of tetrabutylammonium iodide was used as the supporting electrolyte. All other reagents were of A.R. grade. The steroids studied were testosterone,[2] methyltestosterone,[3] and progesterone.[4]

Sample Preparation and Handling.—In most of this work 50% ethanol containing the buffer and supporting electrolyte was used as the sample medium. Although potassium chloride is the most commonly used supporting electrolyte in d.c. polarography, it was not satisfactory for this study. Preliminary a.c. polarograms using methyltestosterone in 50% ethanol with 0.5 *M* KCl revealed that ethanol produced a tensametric peak. This phenomenon has been described by Breyer and Hacobian (7). The peak appeared at a potential very close to the reduction potential of the steroid and completely obscured the steroid wave. Other common inorganic supporting electrolytes such as KNO_3 gave the same results. Organic quaternary ammonium compounds were then tested and found to eliminate the ethanol tensametric peak in the potential region of interest. The supporting electrolyte finally chosen for this study was tetrabutylammonium iodide.

Electrolysis solutions were prepared by pipeting the appropriate aliquot of a standard ethanolic steroid solution into a 10-ml. volumetric flask, adding 0.1 ml. of 0.2% alkyl phenoxy polyethoxy ethanol, sufficient ethanol to measure exactly 5 ml., a calculated amount of supporting electrolyte, and finally diluting to the mark with aqueous buffer. Since the volume of the aliquot varied with the final concentration of the steroid desired, it was necessary to add enough ethanol to measure exactly 5 ml. before diluting with buffer. Tetrabutylammonium iodide was added to the flask before diluting with the aqueous buffer because it is only slightly soluble in water. The concentrations of the aqueous buffers were twice the values desired so that after dilution by the ethanol the final buffer concentrations were those listed in Table I. Sample solutions were transferred to the electrolysis cell and deaerated with nitrogen for 15 min. During the deaeration period and during the polarographic run the sample container was partially immersed in a water bath held at 25° ± 0.1°. The d.c. run was made immediately after deaeration. The instrument was then switched to a.c. operation and the a.c. run was made. pH determinations of each solution were made after electrolysis. The pH of individual samples varied slightly (0.1–0.2 units) from the values listed in Table I.

10.3	0.100 *M* triethylamine	0.025 *M* HCl

pH Effect on Wave Form.—The object of this portion of the research was to determine the pH at which the polarographic wave had the form best suited for quantitative analysis. The judgment was made on the basis of peak height and form.

Alternating current and d.c. polarograms were recorded for all three steroids at all pH values. In order to assure that observed effects were due to pH it was necessary to keep the ionic strength constant. The amount of tetrabutylammonium iodide required to bring the ionic strength to 0.2 was calculated and added to the sample at the time of preparation.

The solutions for the pH study were prepared by pipeting 5 ml. of an alcoholic steroid solution containing 1 mg./ml. of steroid into a 10-ml. volumetric flask, adding maximum suppressor and supporting electrolyte, and diluting to the mark with the appropriate aqueous buffer.

The a.c. calibration point was determined as follows: using a 2800 ohm resistance[5] substituted for the cell; a sensitivity setting of 0.300; and an applied a.c. voltage of 70 mv., the slidewire calibration potentiometer was adjusted until the re-

corder read 250 mm. The samples were then run at a sensitivity setting of 0.600.

Quantitative Studies.—All the quantitative work was carried out at pH 1.3 using methyltestosterone. For the steroid concentration range from $3.3 \times 10^{-4}M$ (100 mcg./ml.) to $6.6 \times 10^{-3}M$ (2 mg./ml.) a 50% ethanol solution was used. For the lower concentration range, from $3.3 \times 10^{-5}M$ (10 mcg./ml.) to $3.3 \times 10^{-4}M$, 25% ethanol was used. It was observed that the a.c. peaks were slightly higher in the lesser alcohol concentration. This was to be expected due to the series resistance effect.

For all the d.c. studies a direct potential scanning rate of 2.34 mv./sec. was used. For the a.c. studies a scanning rate of 2.34 mv./sec. was used in the high concentration range and 1.85 mv./sec. in the low concentration range.

The following a.c. calibration point was used for the high concentration range. The resistance substituted for the cell was 2800 ohms, the sensitivity setting was 0.300, the applied alternating potential was 70 mv., and the slidewire calibration potentiometer was adjusted until the recorder pen read 250 mm. The sensitivity was adjusted to the setting which produced a peak height of 50–125 mm.

For the low concentration range the instrument was standardized as follows. The resistance substituted for the cell was 2800 ohms, the sensitivity setting was 0.300, the applied alternating potential was 70 mv., the slidewire calibration potentiometer was adjusted until the pen read 250 mm., the downscale compensator was adjusted until the pen read 100 mm., and the slidewire potentiometer was readjusted until the pen again read 250 mm. The sensitivity was then set to 0.020 when the samples were polarographed.

In this low concentration range the downscale compensator was of the most value because it permitted the use of high sensitivity settings not possible without it. It enabled zero to be shifted downscale and thus the a.c. curve could be positioned on the chart paper. In other words, at high sensitivity settings the a.c. curve appeared high on the electrical scale due to high base current, and the downscale compensator enabled the electrical scale to be shifted with respect to the chart paper.

RESULTS

Results of the pH Study.—The current values of the d.c. polarographic waves which are shown are the average of the oscillations due to the dropping mercury. All the polarograms were recorded with the damping switch off. The amount of oscillation which resulted is shown by a typical polarogram of methyltestosterone in 50% ethanol at pH 1.3 in Fig. 1.

The current values of the a.c. curves are the values at the maximum age of the mercury drop, *i.e.*, the highest point in the recorder pen oscillation. All alternating current scales are arbitrary since the recorder scale was not calibrated in absolute alternating current. The values on this scale were obtained by multiplying the peak height in mm. by the polarograph sensitivity setting. Figure 2 is an a.c. polarogram of methyltestosterone which shows: (*a*) the oscillations due to the dropping mercury, (*b*) how the a.c. peak height was measured.

Figure 3 shows the d.c. waves for testosterone at

pH values 1.3 to 6.1. Figure 4 shows the corresponding a.c. waves. Methyltestosterone and progesterone gave essentially the same a.c. and d.c. results as those obtained for testosterone. Above the pH range shown, the waves were very similar to that obtained at pH 6.1.

In general, the polarographic waves of ketones are not ideal. They occur at very negative potentials and the diffusion current plateau and residual current have distinctly different slopes. In order to obtain reliable analytical results with the d.c. procedure, the method of evaluating the wave must be rigidly standardized. The a.c. wave tends to facilitate quantitative interpretation. The reduction of the steroid and buffer discharge are separated and the chances for error are lessened.

From Fig. 4 it was decided that pH 1.3 was optimum for quantitative work.

Results of Quantitative Studies.—The method used for determining the diffusion current from recorded d.c. polarographic waves was that described by Willard, Merritt, and Dean (8). Figure 2 illustrates how the a.c. waves were evaluated.

The d.c. results of the high concentration range are shown in Fig. 5 and the a.c. results are shown in Fig. 6. The relationship between a.c. current and concentration is not linear at high concentration and, therefore, is not as analytically useful as the d.c. curve.

The d.c. results of the low concentration range are shown in Fig. 7 and the a.c. results are shown in Fig. 8. Each concentration shown in Figs. 7 and 8 was run in triplicate. Where only two points appear, it was found that two results were identical. The concentration-current curves are calculated regression lines and the experimental points are plotted. R for the d.c. relationship is 0.994 and for the a.c. it is 0.997.

The value of the downscale compensator is illustrated by comparing Fig. 8 and Fig. 9. These are plotted on the same scale. The slope for the line in Fig. 8 is 0.034 and the slope in Fig. 9 is 0.019. Using the downscale compensator, the peak was about twice as high as without it.

DISCUSSION

While d.c. diffusion current depends on concentration gradients near the electrode surface, the a.c. current depends on the concentration of electroactive species on the drop surface. When adsorption of either the oxidized or reduced form occurs on the mercury drop, as is usually the case with organic compounds, the concentration-peak current curve is nonlinear. According to the Langmuir adsorption theory, molecules will be adsorbed on a surface until the surface is covered with a monolayer of adsorbed molecules (9). This means that no matter what the bulk concentration of a solution of electroactive species, the a.c. current reaches a limiting value when the surface of the mercury drop becomes saturated. The a.c. current is, therefore, not a linear function of bulk concentration, but approximates an adsorption isotherm. However, at low bulk concentration, when the mercury drop surface is nearly bare, the peak current-concentration relationship is essentially linear, and can be used for quantitative analysis.

In the quantitative study of methyltestosterone,

it was determined that the lowest practical limit of detection for both the a.c. and the d.c. methods was 3.3 × 10^{-5}*M*. Below this concentration the instrument did not give a reliable response with either method.

Although the lower limits of detection are essentially the same for a.c. and d.c., the a.c. procedure was found to be more precise. The presence of trace amounts of oxygen at low concentrations

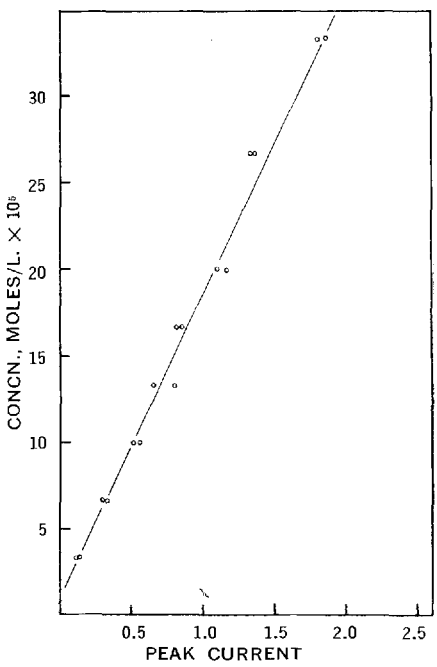

Fig. 9.—Peak current-concentration curve for methyltestosterone without using the downscale compensator: concentration range, 3.3 × 10^{-4} *M* to 3.3 × 10^{-5} *M*; medium, 25% ethanol and tetrabutylammonium iodide at pH 1.3.

of steroid can result in large errors in d.c. polarography, whereas the presence of oxygen does not affect a.c. results. It was observed during this study that occasionally 20 min. of deaeration did not completely remove all of the oxygen present. It was further observed that adequate grounding of the chassis of the a.c. accessory was absolutely essential. Without grounding a stable reference point could not be maintained. Stray a.c. voltages from the line cause undesirable electrical noise which can be minimized by shielding leads to the polarograph.

SUMMARY

An a.c. polarographic method has been developed for the analysis of several Δ^4-3-ketosteroids and compared to the d.c. method. The results show that lower limits of detection for both methods were essentially the same. However, the a.c. procedure was found to be more precise.

Antagonism of Free Fatty Acid Release from Rat Epididymal Fat Tissue by Desmethylimipramine

By K. F. FINGER and J. G. PAGE

Desmethylimipramine (DMI) has been shown to be an antagonist of free fatty acid (FFA) mobilization from rat adipose tissue by both *in vivo* and *in vitro* techniques. Utilizing *in vitro* adipose tissue slices, homogenates, and cell-free preparations, it has been established that (*a*) the *in vitro* antagonism of FFA mobilization occurred whether the mobilization was induced by catecholamines or by other means and (*b*) the addition of DMI to an already activated lipase preparation caused a prompt cessation of lipolytic activity. These results indicate that DMI directly antagonized lipolytic enzymes and that effects on the adrenergic receptor are secondary to the primary inhibition phase. Desmethylimipramine antagonism of catecholamine-induced free fatty acid (FFA) mobilization was also observed to occur *in vivo*.

DURING THE past decade, considerable research effort has been placed on the investigation and development of antagonists of the catecholamine-induced mobilization of free fatty acids (FFA). In addition to providing agents of potential therapeutic usefulness, this type of research can and has served the purpose of elucidating the role of fat mobilization in certain disease states. Among the agents found to antagonize catecholamine-induced mobilization of FFA have been nicotinic acid (1), nethalide (2), the classical α and β adrenergic blocking agents (3), prostaglandins (4), and most recently, analogs of methoxamine (5, 6). The therapeutic value of antagonists of FFA mobilization, however, remains to be proved.

During the course of the authors' studies pertaining to the interaction of catecholamines and certain other phenethylamines with the adipose tissue adrenergic receptor system, desmethylimipramine (DMI) was investigated for its possible effects in modifying the action of catecholamines in this system. Previous work had shown that DMI was capable of enhancing adrenergic effects on certain receptor systems (7, 8), and it was with this in mind that DMI was investigated. Results indicated that DMI was an antagonist of catecholamine-induced mobilization of FFA, *in vitro* (9). This report is concerned with further investigations of the action of DMI on adipose tissue, and, in particular, its locus of action.

EXPERIMENTAL

Materials.—The chemicals used in this study and their sources are as follows: *l*-epinephrine bitartrate (Winthrop Laboratories); *l*-norepinephrine bitartrate (Nutritional Biochemical Corp.); and desmethylimipramine[1].

Methods.—The *in vitro* experiments described in this report utilized nonfasted male, white, Holtzman rats weighing between 200 and 250 Gm. All animals were maintained in their animal quarters at least 1 week prior to their use. The method of sacrifice, preparation, and handling of the epididymal fat tissue and the assay procedures employed have been described previously (9).

In those experiments employing homogenates of adipose tissue, the homogenates were prepared by adding a known weight of epididymal fat tissue to a volume of 0.25 *M* sucrose to make a 1:3 final homogenate, homogenization being accomplished by a motor driven, chilled Tenbroeck glass homogenizer.

Cell-free preparations of lipase were prepared by centrifuging the above-described homogenate at 12,000 × g for 10 min. at 4°, discarding the accumulated fat cake and aspirating off the supernatant phase. It was found that the supernatant phase contained the active lipase with little or no lipolytic activity being associated with either the fat cake or the 12,000 × g sediment in this system.

One milliliter of supernatant was then added to a media containing 2.5 ml. of 20% of 0.06 *M* phosphate buffer, pH 6.8, and 5.0 ml. of distilled water. At zero time, 0.5 ml. of substrate (12.5% emulsion of peanut oil prepared with acacia as the emulsifier) was added, and samples were taken at 0, 20, 40, and 60 min. for assay of FFA by the procedures previously described (9). Assays of the homogenate system were conducted in an identical manner except no exogenous substrate was employed, the endogenous triglycerides of the adipose tissue serving as the substrate in these experiments. It should be pointed out that acacia was found to be the emulsifier of choice primarily because other emulsifiers tried, such as the polysorbates, interacted with the DMI to an extent sufficient to prevent DMI from exerting any effect on the system.

For the *in vivo* experiments described herein, male Holtzman rats weighing between 400 and 600 Gm. were anesthetized with sodium pentobarbital, 35 mg./Kg., i.p., their femoral and carotid arteries cannulated to provide for i.v. administration of drug and the taking of blood samples for FFA analysis,

respectively. The DMI was administered *via* the femoral vein over a 3-min. period, while norepinephrine (20 mcg./Kg.) was administered rapidly *via* the femoral vein. Blood samples were collected in heparinized tubes and stored over ice until centrifuged to obtain plasma samples. The FFA assays were conducted on 0.5 ml. of plasma obtained in this manner by the modified method of Dole (10, 11).

RESULTS AND DISCUSSION

Effect of DMI on Catecholamine-Induced FFA Release from Adipose Tissue Slices.—In an earlier study, it was reported that DMI antagonized catecholamine-induced release of FFA from rat epididymal fat tissue (9). Those studies were conducted utilizing a preincubation period in which the DMI was allowed to interact with the tissue for approximately 15 min. prior to the addition of the catecholamine. In the present experiment, it was decided to first allow the catecholamine (epinephrine) to maximally stimulate lipolytic activity in the adipose tissue slices and to add the DMI at a time when FFA release was occurring at a maximal rate. The results of this study are shown in Fig. 1. In these experiments, the adipose tissue slice preparation was divided into two portions. Epinephrine (final concentration 6.5×10^{-6} *M*) was added at zero time to each vessel and samples taken at 15 and 30 min. Immediately after the 30-min. sample, DMI (final concentration 1×10^{-3} *M*) was added to one incubation vessel and distilled water added to the other. Samples were then taken at 45 and 60 min. from both vessels. FFA analyses indicated that DMI caused the rapid cessation of FFA release as is indicated in Fig. 1. The control preparation continued releasing FFA at a constant rate. These results indicated that DMI was capable of antagonizing an already activated lipolytic system suggesting that the site of inhibition may be beyond the activation step, although this does not rule out the possibility that the inhibition is at the site of activation. Recent studies (12, 13) have indicated that the activation of lipolytic activity by the catecholamines involves the catecholamine stimulated conversion of ATP to 3′,5′-cyclic AMP which, in turn, activates the lipolytic enzymes. Thus, in such a sequence of events, several possible sites of inhibition are possible. Attempts were made to stimulate FFA release by the addition of 3′,5′-cyclic AMP to the adipose tissue slices. However, these efforts failed presumably because the cyclic AMP did not enter the adipose tissue slices or, as has been suggested (12), the 3′,5′-cyclic AMP is not sufficiently stable in this system to stimulate effectively lipolytic activity. Further attempts will be made, in this regard, utilizing more stable and lipid soluble analogs of cyclic AMP.

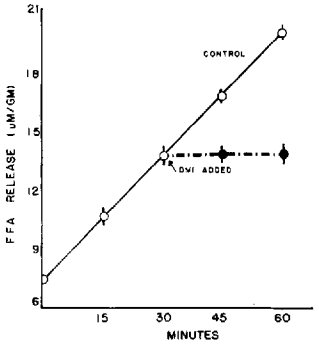

Fig. 1.—Effect of DMI on catecholamine-induced FFA release from adipose tissue slices. Vertical lines indicate standard error of the mean. Each point represents the mean of six determinations.

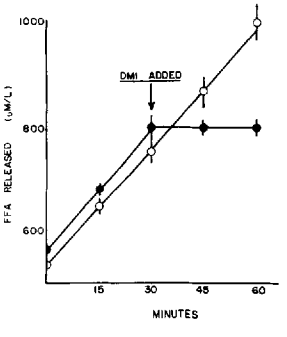

Fig. 2.—Effect of DMI on lipolytic activity of adipose tissue homogenates. Key: ○, control; ●, system to which DMI was added at 30 min. Vertical lines indicate standard error of the mean. Each point represents the mean of six determinations.

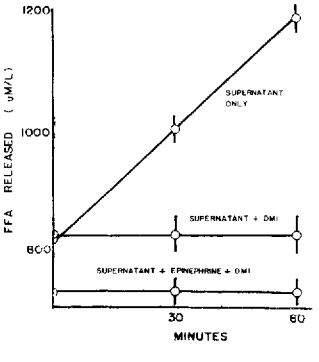

Fig. 3.—Effect of DMI on cell-free lipolytic activity. Vertical lines indicate standard error of the mean. Each point represents the mean of six determinations.

Effect of DMI on Lipolytic Activity of Adipose Tissue Homogenates.—It is characteristic of this type of preparation that the process of homogenization causes the maximal activation of lipolytic activity in the absence of any added catecholamine or other stimulant. Indeed, the addition of epinephrine to this system caused no further release of FFA above that observed in the absence of added catecholamine. Thus, the use of this system allowed the authors to investigate the effects of DMI on lipolytic activity in the absence of any added catecholamine.

In these experiments, a homogenate of adipose tissue was divided into two identical portions. Each incubation mixture was assayed for FFA at 0, 15, and 30 min. After the 30-min. sample was taken, DMI (final concentration 1×10^{-3} *M*) was added to one mixture and distilled water was added to the other. Samples were then taken at 45 and 60 min. from each preparation. The results of these experiments are shown in Fig. 2. It is again apparent that the addition of DMI caused the rapid cessation of FFA release while there was no diminution in the control FFA release. Although inhibition of the activation step is not entirely disproved, these results again suggest that the antagonism of FFA release exhibited by DMI occurred at a site remote from the activation step.

Effect of DMI on Cell-Free Lipolytic Activity.—Figure 3 illustrates the results obtained in studies conducted with the cell-free preparations. In

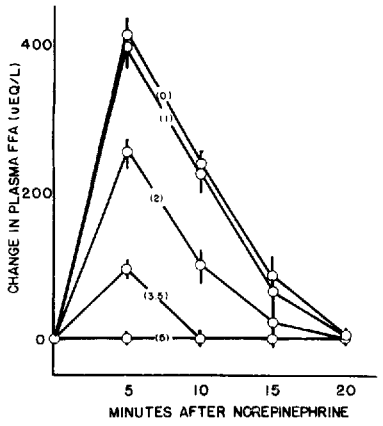

Fig. 4.—Inhibition of catecholamine-induced FFA mobilization, *in vivo*. Figures in parentheses indicate i.v. dose of DMI. Vertical lines indicate standard error of the mean. Each point represents the mean of six determinations.

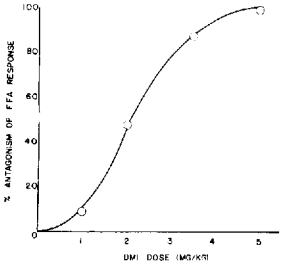

Fig. 5.—Dose-response relationship for inhibition of catecholamine - induced FFA mobilization, *in vivo*, by DMI. Each point represents the mean of six determinations.

these studies, employing a peanut oil emulsion as the substrate, maximal FFA release occurred without the addition of exogenous stimulants. The addition of DMI to yield a final concentration of 1×10^{-3} *M* completely abolished the FFA releasing activity of the preparations. The addition of epinephrine (1×10^{-6} *M*) did not reverse the antagonism as can be seen by the zero slope shown in Fig. 3. These results show that DMI is capable of antagonizing lipolytic activity with or without the addition of catecholamine.

In preliminary experiments, not reported here, the inhibition exhibited by DMI was overcome by the addition of additional enzyme (replacing the water in the media with an equal volume of supernatant enzyme preparation) but not with the addition of large quantities of catecholamine. It would thus appear that the DMI inhibition of lipolytic activity is dependent upon its interaction with enzymic material rather than at an adrenergic receptor site.

In Vivo Effects of DMI.—To ascertain whether DMI possessed the ability to inhibit FFA release *in vivo*, the drug was administered to animals, intravenously, at doses of 1.0, 2.0, 3.5, and 5.0 mg./Kg. Thirty minutes later, following the removal of a control blood sample, norepinephrine (20 mcg./Kg.) was administered *via* rapid i.v. injection. Norepinephrine was chosen for these experiments to minimize any variations in FFA mobilization due to the hyperglycemic responses so characteristic of other catecholamines. Blood samples were then taken at 5-min. intervals for a 20-min. period. The results of these experiments are shown in Fig. 4.

It can be seen in this graph that DMI possessed appreciable *in vivo* activity in antagonizing the norepinephrine-induced release of FFA, significant reductions in FFA mobilization being apparent at DMI doses of 2.0, 3.5, and 5.0 mg./Kg. The dose-response relationship for this inhibition is shown in Fig. 5.

It has been reported by Santi and Fassina (14) that the administration of DMI caused an elevation of plasma FFA, the maximal elevation being observed 150 min. after the administration of 25 mg./Kg. of DMI. These findings were confirmed in this laboratory. The apparent discrepancy in regard to the effects of DMI on plasma FFA can be explained in terms of the doses employed in the two studies and in the time course of events. Utilizing the interperitoneal route of administration, significant elevations of plasma FFA were obtained 150 min. after drug administration at a DMI dose of 25 mg./Kg., but not at a dose of 10 mg./Kg. or lower. Intravenous administration of DMI at doses up to 5.0 mg./Kg. caused no elevation of FFA. Furthermore, the elevations of FFA observed at the higher dose of DMI were rather slow in onset, becoming apparent only after approximately 100 min. following drug administration. DMI failed to elevate FFA, even at 25 mg./Kg., in the reserpinized rat. These results indicated that DMI may mobilize FFA through its central stimulatory activity (adrenergic mechanisms) and these effects may have a different time course than the DMI inhibitory effects on FFA release. These parameters are currently being investigated and will be reported in detail at a later date.

CONCLUSION

The data obtained in this study show that DMI is capable of inhibiting lipolytic activity in adipose tissue slices, homogenates, and cell-free preparations and also exhibits this property *in vivo*. The results suggest that DMI exerts its primary inhibitory effects at a site beyond the adrenergic receptor, probably at the enzymic site although conclusive proof of this postulate is lacking at this time.

Metabolic Study of 2-(Acetyl-imino)-3-[2-hydroxy-2-(2-thienyl)-ethyl]-thiazoline in Chickens

Detection of an Active Metabolite, 5,6-Dihydro-6-(2-thienyl)-imidazo[2,1-*b*]thiazole

By FERNAND T. N. ALLEWIJN and PAUL J. A. DEMOEN

After oral treatment of chickens with antazonite (R 6438), six basic products have been found by thin-layer chromatography in extracts of feces, one of them being the parent compound. The most important metabolite (metabolite No. 3) was isolated by column chromatography, and its structure was elucidated by physicochemical methods and confirmed by synthesis and analysis. The new product, 5,6-dihydro-6-(2-thienyl)-imidazo[2,1-*b*]thiazole (antienite, R 8141) was about 4 times as active as the original compound. There is some evidence suggesting that the anthelmintic activity of R 6438 is due to this metabolite. Two other metabolites were identified by comparison with existing substances on thin-layer chromatoplates. Further synthetic and parasitological work has shown that chemical modification of R 8141 may result in still more active substances. The most interesting analog, 2,3,5,6-tetrahydro-6-phenyl-imidazo[2,1-*b*]thiazole (tetramisole, R 8299) has been chosen for further detailed parasitological and pharmacological investigation.

THIENPONT and co-workers (1, 2) assigned good anthelmintic activity to 2-(acetyl-imino)-3-[2-hydroxy-2-(2-thienyl)-ethyl]-thiazoline (R 6438, antazonite). When given orally to chickens in a dose of 160 mg./Kg. body weight, all *Ascaridia* sp., all *Heterakis* sp., and about 30% *Capillaria* sp. are expelled within 48 hr.

In order to gather information about the metabolism of R 6438, serum, different organs, eggs, and the feces of hens treated with the product were analyzed. The samples were homogenized, extracted by conventional techniques, and the extracts were analyzed by thin-layer chromatography (TLC) on Silica Gel G. A modified Liebermann-Burchard reagent was used as a spray to reveal the spots.

In the feces of chickens, at least five metabolites of antazonite occurred, together with the parent compound. Metabolite No. 3 was found in the greatest concentration, accounting for about 20% of the administered dose. The sum of the other metabolites was less than 5% of the dose of R 6438 given.

To elucidate the structure of the different metabolites, a total amount of 6 Gm. of R 6438 was given to 8 chickens, each animal receiving 750 mg., divided in three oral portions of 250 mg. The doses were administered at intervals of 32 and 38 hr. The feces (2.5 Kg.), collected over a period of 4.5 days after the first treatment, were dried, homogenized, and suspended in dilute acid. The basic compounds were extracted and purified by liquid–liquid extraction, and the final solution was concentrated to a small volume. This concentrate was used for thin-layer and for column chromatography on silica gel.

The fractions of eluate containing the major metabolite were combined and concentrated. Small samples of it were used for measurement of ultraviolet and infrared spectra. Both absorption patterns suggested a structure containing a 2-substituted, nonconjugated thienyl ring, and a C=N double bond in a five-membered ring. It was presumed at that moment that the product could be 5,6-dihydro-6-(2-thienyl)-imidazo[2,1-*b*]thiazole. The remainder of the concentrate was treated with oxalic acid yielding an oxalate salt, which, after recrystallization, gave 190 mg. of a crystalline product. This salt was analyzed (basic equivalent, C, H, N, and S determination, U. V. and I. R. spectra, TLC) and shown to be $C_9H_8N_2S_2.C_2H_2O_4$. TLC showed that it was a pure product, whereas both spectra and analyses were in agreement with the proposed formula. Treatment of one hen with 100 mg. of the material (corresponding to 70 mg. of the base) showed that the metabolite possessed enhanced anthelmintic properties (1).

Received May 6, 1966, from the Analytical Department, Research Laboratories, Janssen Pharmaceutica, Beerse, Belgium.

Accepted for publication July 12, 1966.

This study was supported by grants from the Instituut tot Aanmoediging van het Wetenschappelijk Onderzoek in Nijverheid en Landbouw.

The authors thank Mr. J. L. M. Loomans and Mr. W. A. Seth Paul for spectral measurements and interpretations, Mr. A. A. F. Sels and Mr. W. C. A. Verkest for elemental analyses, and Mrs. I. Dergent and the other members of the analytical department.

5,6 - Dihydro - 6 - (2 - thienyl) - imidazo[2,1 - *b*]-thiazole was prepared synthetically (3); the melting point of its oxalate salt and mixed melting point with the oxalate of the metabolite isolated from the feces proved the identity of the structures. TLC patterns, ultraviolet, and infrared spectra of both oxalates were also identical.

Two other metabolites were identified by comparison of their TLC patterns with those of known products related to R 6438. One of them, designated as metabolite No. 1, is an unsaturated analog of metabolite No. 3 and is 6-(2-thienyl)-imidazo[2,1-*b*]thiazole (R 5987) (3). The other identified product, designated as metabolite No. 5, is the deacetylated derivative of R 6438 and is 2-amino-3[-2-hydroxy-2-(2-thienyl)-ethyl]-thiazoline (R 6299) (3). Both metabolites are practically devoid of anthelmintic properties (1). The remaining two metabolites (No. 2 and 4) could not be identified with certainty. However, it is supposed that both metabolites are degradation products of metabolite No. 3. This is supported by the fact that an analogous breakdown has been observed during metabolic studies on 5,6-dihydro-6-phenyl-imidazo[2,1-*b*]thiazole (R 8193), which is strongly related to R 8141. The structure of the metabolite No. 2 would then be 2-thio-5-(2-thienyl)-imidazolidine, whereas No. 4 would correspond to 2-oxo-5-(2-thienyl)-imidazolidine.

It is supposed that the anthelmintic activity of R 6438 is due to its major metabolite, R 8141. This is supported by the following facts.

(*a*) R 6438 is active as an anthelmintic in poultry, but not in rats (1). Its metabolite, R 8141, is active in both species. This metabolite occurs in feces of chickens and pigeons, but not in feces of rats. (*b*) About one-fifth of the R 6438 administered orally to chickens is found as R 8141 in feces. This metabolite is about 4 times as active as R 6438.

The metabolic degradation of R 6438 is represented in Scheme I.

EXPERIMENTAL, RESULTS, AND DISCUSSION

Physicochemical Properties of Antazonite.—Antazonite, 2-(acetyl-imino)-3-[2-hydroxy-2-(2-thienyl)-ethyl]-thiazoline, has the structure as shown in Scheme I. It was synthetized by Raeymaekers (3). It occurs as a yellowish to brown-white, fine powder without odor or taste, with a melting point between 131 and 134°. The solubility of antazonite in water increases with decreasing pH (Table I). It is soluble in chloroform, methyl alcohol, ethyl alcohol, and acetone, sparingly soluble in isopropyl alcohol and methyl isobutyl ketone, and slightly soluble in diethyl ether.

The change in U.V. absorption upon variation in pH of the solutions indicates that antazonite has a pK value of about 3.6.

Principles of Extraction of R 6438.—The extraction of R 6438 is based on the fact that the compound forms a water-soluble salt, the solubility of which increases with decreasing pH. When the aqueous solution is made alkaline, antazonite precipitates, so the free base can be transferred into a water-immiscible organic solvent, such as ether, chloroform, or benzene.

Based on these principles, the first experiments were carried out on eggs of chickens, which were treated orally with one dose of 160 mg. R 6438/Kg. body weight. After extraction of these eggs and TLC of the extracts, four spots were found. The total amount of these different compounds was about 90–260 mcg./egg, within 48 hr. In order to elucidate the structure of these unknown products, further work was done on the feces of chickens.

Treatment of the Hens and Collection of Feces.—Eight white leghorn chickens, maintained each in a cage were given antazonite in No. 00 gelatin capsules, with invervals of 32 and 38 hr. Each bird was given 750 mg. of R 6438 and 600 mg. of sodium bicarbonate. They were given water and food *ad libitum*.

Fecal collections were made 32, 60, 84, and 108 hr. after the first treatment. (The results of each collection are given in Table II.)

Extraction of the Feces.—The feces of each collection were dried *in vacuo* at a temperature of 50°, whereafter the dried fecal output was homogenized in a Glencreston ball mill. (Afterward the drying process seemed to be unnecessary.) The homogeneous powder is suspended in 3 L. of 1 *N* hydrochloric acid and shaken for 1 hr. The suspension is filtered on a Büchner funnel, and the residue is treated again with 2 L. of distilled water. The filtrate, which is clear and deep-brown in color, is alkalized with 10 *N* sodium hydroxide (pH 10) and extracted with 4 + 3 + 3 L. of diethyl ether.

After concentration to about 1 L., the ether extract was extracted with 200 + 100 + 50 ml. of 0.1 *N* hydrochloric acid. The water layer was alkalized with 5 ml. of 10 *N* sodium hydroxide and extracted 3 times with 50 ml. of chloroform. The extract was concentrated by evaporation *in vacuo* to a volume of 20 ml., leaving a clear dark brown solution.

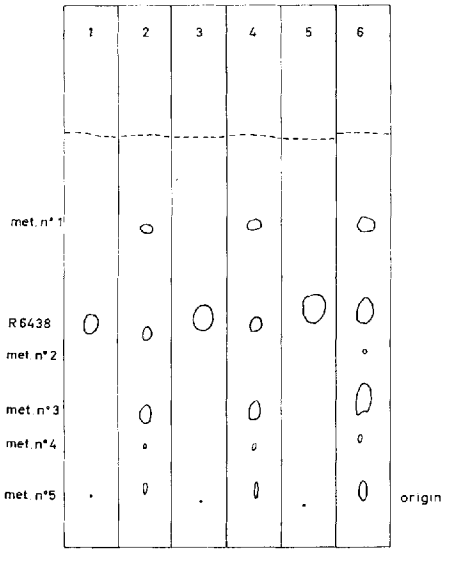

Fig. 1.—Thin-layer chromatogram of the concentrated fecal extract on Silica Gel G, 250 μ. Key: strips 1, 3, and 5: 1, 2, and 5 mcg. of R 6438; strips 2, 4, and 6: 1, 2, and 5 μl. of concentrated fecal extract.

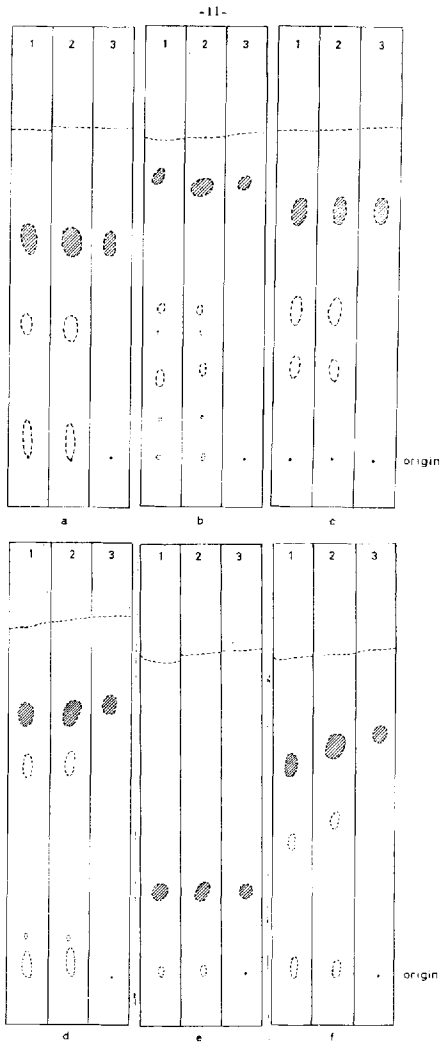

Fig. 2.—Identification of metabolite No. 1. Thin-layer chromatography of the concentrated extract on silica gel, 250 μ. Key: strip 1, 1 μl. of the concentrated extract; strip 2, a mixture of 1 and 3; strip 3, 1 mcg. of R 5987. Solvent systems are: a, methyl alcohol; b, chloroform–methyl alcohol (95:5 v/v); c, methyl alcohol–acetate buffer pH 4.7 (90:10 v/v); d, ethyl acetate; e, methylene chloride; f, methyl isobutyl ketone.

Thin-Layer Chromatography.—Small aliquots (1–5 μl.) of the concentrated extract were spotted on Silica Gel G chromatoplates (250 μ) and developed with a solvent system consisting of chloroform–methyl alcohol (95:5, v/v) (Fig. 1).

The air-dried chromatograms were sprayed with a modified Liebermann-Burchard reagent. This consists of ethyl alcohol–sulfuric acid, d. 1.84–acetic anhydride (80:10:10, v/v). Antazonite and its metabolites containing the thiophene ring system produce a blue color with this reagent after about 20 min. at a temperature of 110°.

At least six Liebermann-Burchard-active spots are found; two are very faint (metabolites No. 2 and 4).

Identification of Metabolites No. 1 and 5.—Metabolite No. 1 corresponds to 6-(2-thienyl)-imidazo[2,1-*b*]thiazole (R 5987) (Scheme I). This has been concluded after TLC on Silica Gel G with different moving liquids (Fig. 2): methyl alcohol, chloroform–methyl alcohol (95:5, v/v), methyl alcohol–acetate buffer pH 4.7 (90:10, v/v), ethyl acetate, methylene chloride, and methyl isobutyl ketone.

The R_f values of metabolite No. 1 correspond to those of the synthetically made R 5987.

Metabolite No. 5 was identified as deacetylated antazonite, 3-[2-hydroxy-2-(2-thienyl)-ethyl]-2-imino-thiazoline (R 6299). (See Scheme I.) The reference compound was chromatographed alone and co-chromatographed with the fecal extract. Three different moving liquids prove the structure of metabolite No. 5 (Fig. 3): methyl alcohol, ethyl acetate, and methyl alcohol–acetate buffer pH 4.7 (90:10, v/v).

Identification of Metabolite No. 3.—*Isolation Technique.*—This main metabolite was isolated by column chromatography on silica gel 0.05–0.20 mm. (E. Merck A. G., Darmstadt, 7734). An amount of 120 Gm. of the silica gel was suspended in methyl alcohol and poured in sections into a glass tube with an internal diameter of 3.0 cm. The column (35 cm. in length) was equilibrated at room temperature with about 200 ml. of methyl alcohol. The extract (about 15 ml.) was then placed on the column.

The chromatogram was first developed with methyl alcohol at a flow rate of 5 ml./hr., 10-ml. fractions being collected. After 1000 ml. of effluent, the developing solution was replaced by methyl alcohol containing 1% ammonia, of which 500 ml. was used.

Results of the Column Chromatography.—Each fraction of effluent was examined by thin-layer chromatography using 10-μl. quantities. The following separation was obtained: fractions 16 to 24, R 5987 and antazonite; fractions 23 to 64, the unknown metabolite (No. 3); fractions 106 to 124, deacetylated antazonite (R 6299).

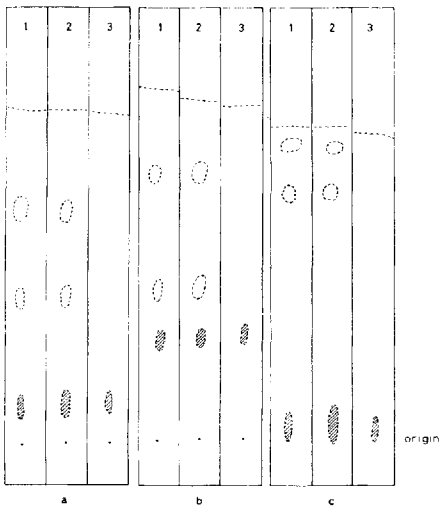

Fig. 3.—Identification of metabolite No. 5. Thin-layer chromatography of the concentrated extract on Silica Gel G, 250 μ. Key: strip 1, 1 μl. of the concentrated extract; strip 2, a mixture of 1 and 3; strip 3, 1 mcg. of R 6299. Solvent systems are: a, methyl alcohol; b, methyl alcohol–acetate buffer pH 4.7 (90:10 v/v); c, ethyl acetate.

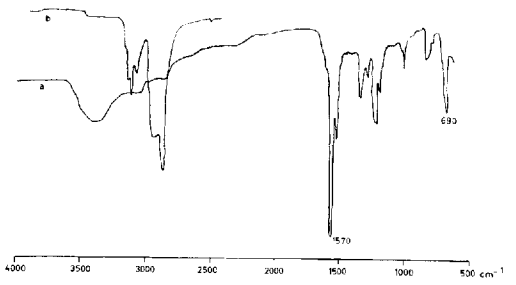

Fig. 4.—Infrared scan of one of the fractions 26–64 after evaporation. Key: a, KBr-disk; b, solution in carbon tetrachloride.

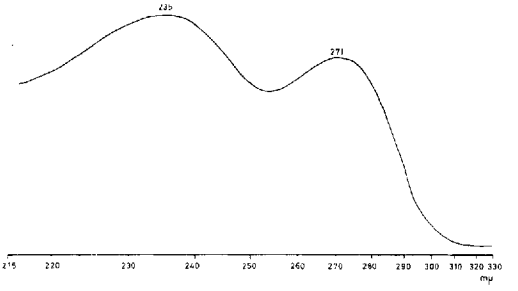

Fig. 5.—Ultraviolet scan of the same fraction (Fig. 4) in isopropyl alcohol.

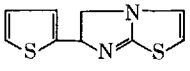
Spectrophotometric Measurements.—U.V. and I.R. spectra of one of the fractions 26–64 were run. From the I.R. spectrum (Fig. 4) the following assignments could be made. The presence of —OH, =NH, and C=O is excluded. The 690 cm.$^{-1}$ band can be assigned to the γCH of the thiophene ring while the 1570 cm.$^{-1}$ band probably originates from a C=N group situated in a five-membered ring.

Examination of the U.V. spectrum (Fig. 5) revealed the presence of a nonconjugated thiophene ring (235 mμ). In this manner structure I



I

could be deduced (5,6-dihydro-6-(2-thienyl)-imidazo[2,1-*b*]thiazole).

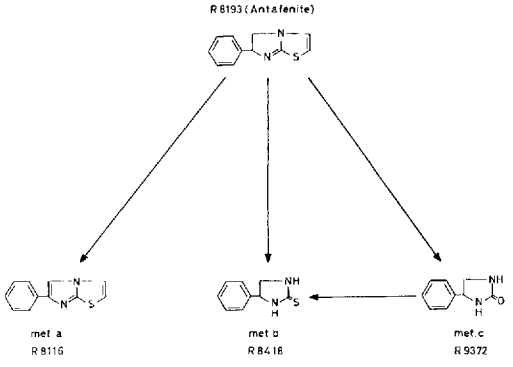
Crystallization and Analytical Results.—The fractions 26 to 60 were concentrated by evaporation *in vacuo*, and the remaining oily substance was crystallized as the oxalate salt from isopropyl alcohol.

The melting point after drying at 70° for 2 hr. was 191–192°.

Anal.—Calcd. for $C_9H_8N_2S_2.(COOH)_2$: C, 44.28; H, 3.38; N, 9.39; S, 21.50. Found: C, 44.05; H, 3.36; N, 9.55; S, 21.51.

The mixed melting point with the synthetically made oxalate (R 8025) was not depressed (192–193°). The ultraviolet spectrum (isopropyl alcohol) showed absorption bands at 237 mμ (ε 10,200) and 266 mμ (ε 9,320).

Possible Structure of Metabolites No. 2 and 4.—These two metabolites were not identified with certainty. Both metabolites could be degradation products of the major metabolite. This suggestion is supported by metabolic studies on 5,6-dihydro-6-phenyl-imidazo[2,1-*b*]thiazole (R 8193). The metabolic fate of R 8193 (antafenite) is represented in Scheme II.



Scheme II

Metabolites a and b were identified by thin-layer chromatography on Silica Gel G with several moving liquids. The spots were revealed with Dragendorff's reagent modified by Thies and Reuther (4).

Metabolite c was isolated by column chromatography on silica gel 0.05–0.20 mm. in the same manner as described above. The structure was elucidated by infrared spectrophotometry, and, after synthesis of the product, by thin-layer chromatography.

Comparison between the metabolic patterns of R 6438 (R 8141) and R 8193 suggests that analogous breakdown takes place, with the formation of analogous metabolites. The similarity between the R_f values of both groups of metabolites also confirms this suggestion (Fig. 6). It is concluded, therefore, that metabolite No. 2 could be 2-thio-5-(2-thienyl)-imidazolidine. Accordingly, metabolite No. 4 could be 2-oxo-5-(2-thienyl)-imidazolidine.

Anthelmintic Activity of R 8141 and R 6438.—One hen was treated with 100 mg. of the oxalate salt of metabolite No. 3 (R 8025). This corresponds to 70 mg. of the base. Examination of the feces showed the anthelmintic activity of the metabolite. In further parasitological studies the oxalate salt (R 8025) was replaced by the hydrochloride salt (R 8141).

The anthelmintic properties of the different substances in chickens can be summarized as follows.

(*a*) R 6438, 2-(acetyl-imino-3-[2-hydroxy-(2-thienyl)-ethyl]-thiazoline (antazonite). An oral dose of 160 mg./Kg. body weight has 100% effectiveness against *Heterakis* sp. and *Ascaridia* sp. Only 30% of *Capillaria* sp. are expelled.

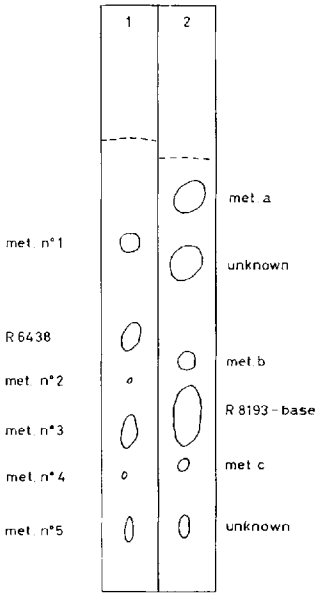


Fig. 6.—Comparative thin-layer chromatography of fecal extracts of chickens after oral treatment with R 6438, resp. R 8193. Key: strip 1, moving liquid–chloroform–methyl alcohol (95:5 v/v), spray reagent, Liebermann–Burchard; strip 2, moving liquid, chloroform–methyl alcohol (90:10 v/v); spray reagent, Dragendorff's reagent.

(*b*) R 8141, 5,6-dihydro-6-(2-thienyl)-imidazo-[2,1-*b*]thiazole (antienite). One oral dose of 40 mg./Kg. expels all *Heterakis* sp., *Ascaridia* sp., and *Capillaria* sp. from the chickens.

(*c*) R 8193, 5,6-dihydro-6-(2-phenyl)-imidazo-[2,1-*b*]thiazole (antafenite) has the same anthelmintic activity as R 8141, but the product is not so well tolerated.

(*d*) R 8299, 2,3,5,6-tetrahydro-6-phenyl-imidazo-[2,1-*b*]thiazole (tetramisole)[1] has been chosen for further parasitological and pharmacological work for several reasons. The dose required is less than 20 mg./Kg. body weight; the aqueous solution is sufficiently stable at room temperature; the product can be administered in several ways (orally, subcutaneously, or intramuscularly); and no side effects were observed (1).

Diffuse Reflectance Studies of Solid–Solid Interactions II

Interaction of Metallic and Nonmetallic Adjuvants with Anthracene, Prednisone, and Hydrochlorothiazide

By MICHAEL BORNSTEIN* and JOHN L. LACH

Spectral information is presented on chemisorption-diffuse reflectance studies of metallic and nonmetallic adjuvant interaction with anthracene, prednisone, and hydrochlorothiazide. The systems investigated indicate that the primary mechanism responsible for the bathochromic, hyperchromic, and visual color changes is that of charge transfer chelation.

THIS COMMUNICATION is the second in a series in which diffuse reflectance spectra (DRS) of chemisorbed systems of pharmaceutical importance are examined. In the first report (1), the complexing properties of oxytetracycline, phenothiazine, anthracene, and salicylic acid have been investigated in order to verify the existence of such solid–solid interactions in pharmaceutical systems. Based on these data and theoretical considerations, it was felt that these interactions probably exist in other drug–adjuvant systems.

The purpose of this study was to continue this investigation in order that additional information be obtained concerning the nature of these interactions. Complexing data for anthracene, prednisone, and hydrochlorothiazide, with a number of metallic and nonmetallic adjuvants, is presented along with a discussion of probable mechanisms involved.

EXPERIMENTAL

Reagents.—Alcohol recrystallized anthracene, m.p. 218° (Eastman Organic Chemicals); prednisone U.S.P., m.p. 233–235° dec. (American Roland); hydrochlorothiazide, m.p. 273–275° (Merck, Sharp and Dohme); acid (anionotropic) alumina (Woelm); basic (cationotropic) alumina (Woelm); aluminum hydroxide, magnesium borate (K & K Laboratories); talc, attapulgite (colloidal) (Minerals and Chemicals Phillip); kaolin (colloidal), calcium carbonate, dibasic calcium phosphate, zinc stearate, stearic acid; anhydrous methyl alcohol.

Procedure.—The routine experimental procedure for preparing the complexes and method of analysis have been described in a previous report (1). All samples were prepared by aqueous equilibration in 25 ml. of distilled water for a period of 24 hr.

Received April 25, 1966, from the College of Pharmacy, University of Iowa, Iowa City.

Accepted for publication July 15, 1966.

Presented to the Basic Pharmaceutics Section, A. PH. A. Academy of Pharmaceutical Sciences, Dallas meeting, April 1966.

RESULTS AND DISCUSSION

It has been shown in our previous publication (1) that large spectral shifts involved in the 400 mμ region, along with significant color changes observed, indicate that these interactions are of the donor–acceptor or charge transfer type. Spectral data dealing with anthracene, prednisone, and hydrochlorothiazide further indicate that these interactions are of a charge transfer variety.

ANTHRACENE–ADJUVANT SYSTEMS

The first group of systems to be discussed is the anthracene–adjuvant interactions. Anthracene was selected in that our preliminary studies, together with various literature reports, suggest that it undergoes various donor–acceptor interactions. For example, Aalbersberg *et al.* (2), in discussing complexes of aromatic hydrocarbons with strong Lewis acids, show electronic absorbance spectra from solution between basic anthracene (M) and such Lewis acids (A) as BF_3, PF_5, $SbCl_5$, and SO_3 and imply that these complexes may be covalent, MA, or contain M^+ ions. Solution MA spectra resemble those of MH^+, suggesting addition of A and H^+ at the same C atom in the —CH_2 bridges. Leonhardt and Weller (3), in studying proton–donor effects of hydrated cations with aromatic hydrocarbons, found that the order of proton donor capacity of metallic ions was as follows.

$Mg^{2+} > Ca^{2+} > Ba^2 > Li^+ > Na^+$. Perkampus and Kranz (4) studied anthracene complexes of Al_2O_3 with the aid of U.V. spectroscopy and found that the complexes do not fulfill the laws of normal electron donor–acceptor complexes and concluded that these were not charge transfer complexes. Rooney and Pink (5), in the EPR study of anthracene adsorption of a silica–alumina catalyst, compared the color of his complexes with spectra of anthracene dissolved in 98% H_2SO_4 and found that the color of the adsorbed species was identical to the corresponding H_2SO_4 solution, indicating that the adsorbed species is a radical resulting from the transfer of a single electron from the aromatic molecule to a hole in the surface, probably located at a Lewis acid site. Bhaltacharya (6) measured charge transfer interaction energies of I complexes with anthracene and other hydrocarbons in CCl_4 and found that the charge transfer energy was not

appreciably affected by the change in the dielectric constant of the medium, and, therefore, postulated that charge transfer must take place between the molecule, held together by forces other than electrostatic.

The adjuvants chosen for this study were selected on the basis of the metal fraction they contain or because of their usage in pharmaceutical formulation. Several of the adjuvants included in this study have also been investigated with respect to their effects on the absorption of various phenothiazine derivatives (7, 8).

This type of drug–adjuvant interaction, presented in Fig. 1, deals with the complex formation between anthracene and acid (anionotropic) alumina. It becomes apparent in examining this figure that Fig. 1,B, representing an equilibrated anthracene–alumina system, is significantly different from that of the physical mixture (1,A) and from the spectra of the individual components (1,C and 1,D). Upon interaction, a visual color change was evident; the physical mixture was white in color while the interacted sample acquired a reddish-tan hue. Along with the color change, a huge bathochromic shift is observed in the 400 mμ region along with a new shoulder formation and decrease in reflectance. It might also be pointed out that, in this system, the spectrum of the control is somewhat similar to that of pure anthracene, but the interacted sample loses some spectral fine structure in the region of 350–400 mμ. Furthermore, not only are significant spectral changes observed in the visible region, but a large change also occurs in the U.V. region of the spectrum. The absorbance peak observed at 290 mμ in the control is almost absent in the equilibrated sample, suggesting the complexity of this chemisorption phenomenon and the probable existence of a number of mechanisms. The individual spectrum of pure anthracene and pure alumina, in the region of 425–900 mμ, show no absorption while the interacted sample strongly absorbs in the visible region. The large bathochromic shift observed in the equilibrated sample occurs at a higher wavelength than that which would be produced by

a summation of the individual spectra of anthracene and alumina. Such a bathochromic shift along with the inability to elute the interacted anthracene sample with a large volume of water (1) further indicates the chemical nature of this strong interaction.

Although the spectra of an anthracene-basic alumina system are not shown due to space consideration, this system does exhibit similar spectral changes after equilibration, but to a lesser extent. Although a bathochromic shift and decreased reflectance were apparent, they were not as pronounced as the anthracene–acidic alumina system shown in Fig. 1. Since the shifts occur with both protophilic and protogenic excipients, it is suggested that anthracene may function either as an electron donor or acceptor, depending on the adjuvant available for interaction. Since greater shifts were observed in the acid alumina system, under the same experimental conditions, it may be reasoned that either less energy is required for the activation of the anthracene–acid alumina system or that fewer Lewis base sites were available for chemisorption with the anthracene. Similar changes were also observed when equilibrating anthracene with aluminum hydroxide. In this system, however, a white to orange visual color change was observed along with a slightly smaller shift in the visible region, but greater intensity increase in the area of 270–340 mμ.

In addition to the aluminum-containing systems mentioned above, a group of magnesium-containing adjuvants were also investigated. Results of magnesium trisilicate and magnesium hydroxide interactions have been previously reported (1). Figure 2 represents an anthracene–magnesium borate system. Here again, the usual bathochromic shift, loss of fine structure, and decreased reflectance associated with such an interaction, are found in the interacted sample. An anthracene–talc system may be found in Fig. 3. Talc, defined as native hydrous magnesium silicate, with a small portion of aluminum silicate, shows relatively little interaction affinity for anthracene, as seen in the small

spectral changes, both in the 220–300 mμ as well as in the 425–900 mμ regions. A larger change does occur, however, between 310–400 mμ. This change probably indicates some interaction of the metallic ion with the adsorbate since analogous changes were observed with attapulgite, which is hydrous magnesium aluminum silicate, and with kaolin which is hydrous aluminum silicate. The magnitude of anthracene–adjuvant change was found to be of the following order: kaolin > attapulgite > talc.

The difference in spectral changes of metal-containing anthracene–adjuvant systems may reside in the fact that although the magnesium or other ions may be present in talc and other metal-containing systems, they may be held tightly by the anionic fraction of the adjuvant and are, therefore, unavailable for interaction. This metal "attraction" difference exists between adjuvants since many surfaces are more saturated than others and the valency requirements of their surface atoms may be thought to be more fully satisfied by bonding with nearby atoms, therefore facilitating less chemisorption. Another cause for differences in saturation between metallic adjuvants may be the result of different amounts of hydration in adjuvant systems. For example, talc (primarily native hydrous magnesium silicate) may have a large portion of its active sites unavailable for charge transfer interaction since these sites are occupied by water molecules, resulting in the weaker electrostatic forces which may include hydrogen bonding.

An additional magnesium-containing system, found in Fig. 4, represents an anthracene–magnesium carbonate interaction. On equilibration, one again sees the usual bathochromic shift, along with decreased reflectance.

In addition to the aluminum and magnesium-containing adjuvants, anthracene interactions were also studied with calcium carbonate and dibasic calcium phosphate. The spectra of the anthracene–calcium carbonate system, shown in Fig. 5, indicate that the degree of interaction was minor, since the spectra of the equilibrated and nonequilibrated mixtures are comparable. The slight increased reflectance observed in curve 5,B (bottom) is attributed to the loss of small amounts of anthracene in the equilibrating procedure. The lack of any significant interaction with this calcium-containing adjuvant, as compared to the large changes observed in the magnesium and aluminum-containing systems,

suggests that the mechanism of paramount importance in this chemisorption process is one of chelation. This lack of calcium adjuvant–anthracene interaction is further illustrated in Fig. 5 (top), which again shows minor changes in the anthracene–$CaHPO_4$ system. However, since $CaHPO_4$ does show some decreased reflectance as compared to the $CaCO_3$ system, one may attribute this difference to proton site interactions, resulting from hydrogen-bond interaction rather than chelation. The lack of a color change in the calcium-containing adjuvant systems is in good agreement with the spectral data. As with the calcium-containing adjuvants, zinc stearate showed very little interaction tendency with anthracene, as illustrated in Fig. 6. Although other zinc-containing adjuvants were not studied, it is felt that the zinc ion would show low interaction tendencies with this anthracene system. It is further interesting to note that stearic acid itself shows no important interaction affinity for anthracene and the minor changes observed in the spectrum, Fig. 6, may be due to van der Waal or hydrogen-bond type of interactions.

With respect to the general mechanism of chemisorption, there is no specific agreement by what mechanism(s) this phenomenon proceeds. Weiss (9) suggested that all molecular complexes essentially have an ionic structure, B^+A^-. He points out that a low ionization potential for the base, B, and a high electron affinity for the Lewis acid, A, should give a stable complex. Here the color of molecular complexes, as in quinones or nitro compounds with unsaturated hydrocarbons, is described as being essentially of ionic character formed from the two components by an electron transfer from unsaturated hydrocarbon or its derivative (A), to the quinone or polynitro compound (B). Matsen and associates (10), in discussing charge transfer adsorption on metals, describe the metals as Lewis acids. In a similar manner, one might expect the unsaturated anthracene, due to its "basic" character, to transfer electrons to Al^{3+} or Mg^{2+} due to their acidic sites.

Mulliken (11) suggests that molecular complexes are a union of a Lewis acid (electron acceptor) and a Lewis base (electron donor) resulting in the formation of charge transfer complexes. Here, the electron of the adsorbate absorbs a quantum of radiation and is excited, not to a higher energy level of this molecule, but rather to one of the vacant high energy levels of the adsorbent. Therefore, in addition to absorption in the ground state (N), the molecule may combine to an excited state (E), resulting in an intense absorption band $\lambda N \rightarrow \lambda E$. This probability often accounts for the color changes observed when molecular complexes are formed. Similarly, in the anthracene–adjuvant systems presented in this communication, the large increase in intensity observed in the U.V. region (290 mμ), Fig. 1, may be attributed to a charge transfer complex between the Lewis base, anthracene, and the Lewis acid, Al^{3+}. Akamatu (12) has suggested, however, that in some anthracene chemisorption complexes, the metallic components transfer electrons to hydrocarbons, which in this case serve as acceptors rather than donors. This is probably the case when using the basic (cationotropic) alumina adsorbent discussed above.

It is interesting to compare Figs. 3, 4, and 6, containing anthracene equilibrated with magnesium carbonate, talc, and stearic acid, respectively; here bathochromic shifts and intensity differences also decrease respectively as one compares the three systems. These differences could be explained by

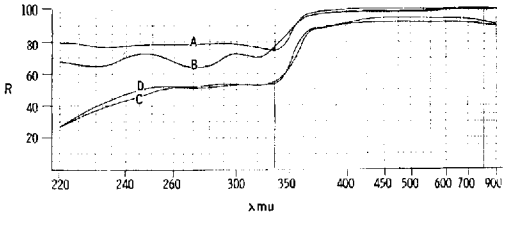

Fig. 22.—DRS of hydrochlorothiazide with zinc stearate or stearic acid. Key: A, hydrochlorothiazide (200 mg.) zinc stearate (0.750 Gm.) control; B, sample; C, hydrochlorothiazide (100 mg.)—stearic acid (2.00 Gm.) control; D, sample.

stating that the larger shifts are related to donor–acceptor forces which represent a charge transfer interaction along with the weaker hydrogen bonding, while in the talc and stearic acid, the weaker electrostatic forces predominate. It is also probable that some small spectral differences do result from regular reflection (1) and particle-size variations.

On further examination of the anthracene system, it is observed that aqueous equilibration of the anthracene–adjuvant mixture (Fig. 1,B) results in the disappearance of the band maxima at 290 mμ along with a loss of fine vibrational structure in the 350–400 mμ region. This band and fine structure also exist in anthracene solution spectra as seen in Fig. 7, as well as in the anthracene–adjuvant unequilibrated physical mixture (Fig. 1,A). In contrast to such a change, the equilibrated oxytetracycline–adjuvant system previously reported (1), show the formation of a new reflectance band at 320 mμ. It is further interesting to note that the maximum absorbance band is also present in transmittance spectra of oxytetracycline solutions but absent in the unequilibrated oxytetracycline–adjuvant mixture. Although no explanation is offered at this time, it nevertheless does illustrate the complexity of these interactions and the probability of a change of mechanism involved.

Based on the spectral data and visual color changes presented and already discussed, it is highly likely that the major mechanism involved in this anthracene chemisorption interaction, with various type adjuvants, is one of chelation since the metallic ions do show a specificity with respect to the degree of interaction. For example, aluminum and magnesium interactions were significantly larger than those observed with calcium and zinc-containing adjuvants. It is, therefore, difficult to make generalizations regarding such interactions in that the nature and the degree of interaction will vary with the type of drug and adjuvant employed.

PREDNISONE–ADJUVANT SYSTEMS

Since a number of reports have appeared in the literature dealing with the possible inactivation of prednisone by excipient-type materials used in solid dosage forms (13, 14) and since prednisone represents a polyfunctional steroidal molecule used in milligram quantities in therapeutics, an investigation of this drug with various adjuvants was undertaken. Although no color change was observed on equilibration of prednisone with acidic alumina, Fig. 8, an examination of the spectral data does indicate that prednisone undergoes a significant interaction. In addition to the usual bathochromic shifts observed, the presence of the equilibrated prednisone–adjuvant spectrum at a higher wavelength than that of the physical mixture or the pure prednisone, further supports this high degree of reactivity. Equilibration of prednisone with basic alumina results in similar spectral changes, but to a lesser extent.

A comparison of prednisone–aluminum hydroxide interaction, Fig. 9, with the above alumina system clearly illustrates the spectral changes possible with the use of different adjuvants. In an aluminum hydroxide system, no significant bathochromic shifts are observed, but a large hyperchromic change occurs in the U.V. region, suggesting the variety of mechanisms possible in such interactions.

This is further observed in magnesium-containing adjuvants, as illustrated in Fig. 10. In this prednisone–magnesium borate system, equilibration facilitates small intensity changes in the U.V. region, along with a new band formation between 350–400 mμ and a smaller bathochromic shift. The use of magnesium trisilicate as the adjuvant results in comparable spectral changes, accompanied by a larger intensity increase in the U.V. region.

Furthermore, even though ions may be present in such adsorbents as talc, attapulgite, and kaolin, their interaction tendencies with prednisone are minor, as illustrated in Fig. 11. As was previously pointed out in the anthracene–adjuvant systems, the degree of saturation of individual adjuvants varies, resulting in different reaction potentials. This difference in availability or reaction potential of these ions is shown in the prednisone–magnesium carbonate interaction, illustrated in Fig. 12. Here again, large intensity and bathochromic changes in the U.V. and near the U.V. region are observed.

A comparison of prednisone–calcium carbonate equilibration, Fig. 13, indicates a lack of interaction of this drug with calcium, as seen from the minor intensity changes in the U.V. region. Equilibration of prednisone with $CaHPO_4$ produced spectral changes of similar nature to the calcium carbonate system, except for a slightly greater hyperchromic effect. This change in reactivity between $CaHPO_4$ and $CaCO_3$ may again be attributed to proton site interactions possible in the $CaHPO_4$ system.

In addition to aluminum, magnesium, and calcium-containing adjuvants, prednisone was also equilibrated with zinc stearate. Spectral data presented in Fig. 14 indicate a strong reactivity of prednisone for this adjuvant. In the previously discussed anthracene system, however, the same adjuvant showed very little interaction tendency. This difference in reactivity of prednisone and anthracene for the zinc stearate adjuvant, along with the lack of any interaction of prednisone with stearic acid, shown in Fig. 15, illustrates the chemical specificity of these charge transfer reactions.

The above information presented on these prednisone–adjuvant systems again indicates that although no visible color differences are observed on equilibration, large spectral changes do suggest strong interactions with various characteristics, depending on the adjuvant studied. Although the control and equilibrated sample's reflectance spectra somewhat resemble the prednisone transmittance spectrum in solution (Fig. 16,A) solid–solid interaction often facilitates the elucidation of new vibrational structure in the near U.V. region, not present in the prednisone solution spectra. Furthermore, the spectral changes of prednisone complexes differ from anthracene systems since aluminum-containing adjuvants appear to facilitate a greater degree of interaction with anthracene, while zinc ions play an important role in prednisone–adjuvant chemisorption.

HYDROCHLOROTHIAZIDE–ADJUVANT SYSTEMS

This medicinal agent has been selected for the study of these drug–adjuvant interactions due to its unique polyfunctional chemical nature and because of its widespread use as a therapeutic agent.

As in the prednisone–adjuvant interactions, although no color change was observed on equilibration of hydrochlorothiazide with basic alumina, an examination of Fig. 17 indicates that this system does undergo important interaction.

A somewhat different spectral graph was obtained on equilibrating hydrochlorothiazide with acidic alumina, Fig. 18, as compared to that of the basic alumina, since the usual bathochromic shift was absent and an intensity change of only 5% was observed. A possible explanation for this lack of reactivity in the hydrochlorothiazide–acid alumina system may be due to the presence of stronger electron-donating sites in hydrochlorothiazide, represented by the dioxide or sulfamoyl groups. Since hydrochlorothiazide and acidic alumina both function as Lewis bases, their lack of significant interaction, Fig. 18, is reasonable. However, hydrochlorothiazide does react strongly with basic alumina (cationotropic) or aluminum hydroxide, Fig. 19, which function as Lewis acids.

In addition to the aluminum-containing adjuvants, hydrochlorothiazide was also equilibrated with a group of magnesium-containing excipients. Figure 20, B, dealing with a hydrochlorothiazide–magnesium carbonate interaction, indicates that although no visible color change was observed in this, or any other hydrochlorothiazide system investigated, large intensity changes are seen in the U.V. region; these hyperchromic changes are also accompanied by important shoulder formation, not found in the pure hydrochlorothiazide reflectance spectrum (Fig. 20,D), in the physical drug–adjuvant control (Fig. 20,A), in the pure adjuvant's spectrum (Fig. 20,C), but present in the solution transmittance spectrum (Fig. 16,B). Similar spectral changes were also seen on equilibrating hydrochlorothiazide with magnesium borate or magnesium trisilicate adjuvants.

In contrast to these adjuvants, talc, attapulgite, or kaolin produced only minor intensity changes on equilibration with hydrochlorothiazide, again indicating minor interaction tendency for this drug. Hydrochlorothiazide shows different spectral changes with calcium adjuvant equilibration, as seen in Fig. 21. An examination of this figure indicates that equilibration of hydrochlorothiazide with $CaCO_3$ facilitates the formation of new bands, although the usual bathochromic shift seen with aluminum and magnesium systems was absent. This drug was also equilibrated with dibasic calcium phosphate. In the anthracene and prednisone systems, $CaHPO_4$, functioning as the adjuvant, showed somewhat greater interaction tendencies than observed with calcium carbonate. However, the interaction of $CaCO_3$ in the hydrochlorothiazide system was found to be in reverse, Fig. 21, indicating the $CaCO_3$ functions as a stronger Lewis acid (electron acceptor) in this system.

The interaction data presented and discussed indicate that a donor–acceptor chelation mechanism is operative in these systems and is further supported in the zinc stearate, stearic acid interaction differences with hydrochlorothiazide, as shown in Fig. 22, again pointed out the greater interaction tendency of the metal-containing adjuvants.

CONCLUSION

Chemisorption interaction data have been presented for anthracene, prednisone, and hydrochlorothiazide with a number of metallic and nonmetallic adjuvant systems. Although minor spectral contributions may be attributed to van der Waal and hydrogen bond-type interactions, particularly in nonmetallic adjuvants studied, the large bathochromic and hyperchromic spectral changes observed on equilibration are primarily the result of strong charge transfer chelation interactions.

Results indicate that anthracene and prednisone function mainly as Lewis acids in alumina systems, while hydrochlorothiazide primarily exhibits Lewis base properties. The interactions observed are, therefore, highly dependent on the chemical properties of the adsorbate and the adsorbent.

Although these surface chemisorption phenomena exist as a unimolecular film and may be of no great consequence when physically adsorbed multilayers of the drug exist, particularly when the ratio of the therapeutic agent to adjuvant is high, they do become significant when the drug–adjuvant ratio is low. In such systems, where the medicinal agent is primarily chemisorbed as a unimolecular layer, one would expect to find large deviation in dissolution rates and blood levels in biological systems. It is of significant interest to point out here that one cannot overlook the distinct possibility of the excipient itself existing as a chemisorbed layer covering the surface of the drug resulting in similar alterations of the physical or biochemical behavior of the medicament in dosage forms where the drug–adjuvant ratios are high. Diffuse reflectance spectroscopy therefore provides a simple means of studying the possible existence of such interactions in solid dosage forms.

Diffuse Reflectance Studies of Solid–Solid Interactions III

Interaction Studies of Oxytetracycline with Metallic and Nonmetallic Adjuvants

By JOHN L. LACH and MICHAEL BORNSTEIN*

Spectral data are presented for chemisorption studies of oxytetracycline and oxytetracycline HCl with a number of metallic adjuvants containing aluminum, calcium, magnesium, zinc, and sodium ions as well as for some nonmetallic adjuvants including stearyl alcohol, cetyl alcohol, stearic acid, silica gel, starch, tannic acid, tragacanth, and polyethylene glycol 6000. The interactions, studied with equilibration, compression, and moisture techniques, indicate that a metal ion or polyfunctional adsorbent molecule is necessary for these charge transfer interactions.

In previous reports (1, 2), Lach and Bornstein have demonstrated that several drugs undergo chemisorption with a number of pharmaceutical adjuvants. Using diffuse reflectance spectroscopy (DRS), it was shown that salicylic acid, phenothiazine, anthracene, prednisone, and hydrochlorothiazide form complexes with a number of adsorbents commonly used in pharmaceutical dosage forms. Furthermore, it was pointed out that these reactions may occur either by compression techniques or equilibration of the components of the complex in aqueous or nonaqueous media. Interaction properties of oxytetracycline with magnesium trisilicate and activated alumina were also investigated, and results indicate that DRS of equilibrated or compressed samples produce large bathochromic shifts and intensity changes accompanied by significant visual color variation, indicative of charge transfer interactions.

The purpose of this investigation is to further study this oxytetracycline interaction with various metallic and nonmetallic adjuvants. Information from this investigation would give additional information as to the possible nature of the mechanism or mechanisms involved in this interaction.

EXPERIMENTAL

Reagents.—Recrystallized oxytetracycline, m.p. 182° dec. (Pfizer & Co.), oxytetracycline HCl (Pfizer & Co.), calcium phosphate (dibasic), calcium phosphate (tribasic), calcium hydroxide, calcium carbonate, calcium stearate, cetyl alcohol, stearyl alcohol, stearic acid, magnesium stearate, magnesium oxide, magnesium hydroxide, magnesium trisilicate, magnesium chloride, magnesium silicate,[1] magnesium carbonate, magnesium sulfate, talc, zinc stearate, aluminum hydroxide, silica gel, polyethylene glycol 6000,[2] starch, tannic acid, acacia, tragacanth, and dehydrated ethanol.

Procedure.—The routine experimental procedure for preparing the complexes and method of analysis have been described in a previous communication (1). All samples have been prepared by equilibration in 25 ml. of distilled water for 24 hr., except when otherwise indicated (2). The following is a special technique adopted for this study.

Moisture Effects.—This study involves the exposure of dried, physically mixed drug–adjuvant components to humidity conditions. The control is prepared by triturating a mixture of drug and adjuvant which were first individually vacuum dried for 0.5 hr. at 115°; the DRS of this physical mixture is then measured.

The moist sample is prepared by transferring a portion of this physical mixture onto an evaporating dish and placing it in a wax sealed desiccator in which water is substituted for the desiccant; the material is then allowed to stand in this humidity chamber for a designated period, after which time the moist sample is removed and its DRS is measured.

The above moist sample may also be vacuum dried for 0.5 hr. at 115° prior to DRS reading, in order to eliminate spectral moisture effects.

Past Work.—The complexes of interest in these studies vary in degree between the weaker van der Waal variety discussed by Higuchi and Lach (3), whose energy of reaction is derived mainly from dipole–dipole interactions, to the stronger intermolecular electron exchange mechanism described by McGlynn (4). These stronger charge transfer transitions of donor–acceptor complexes are often found as absorbancee bands in the near U.V. or visible region of the electromagnetic spectrum. According to Andrews and Keefer (5), this is often the case when acceptors are π acids.

Other pertinent reports in this area include com-

plex formation studies between adjuvants (6, 7) and various medicinal agents. Several examples may also be cited which deal with the complex formation of multivalent metallic cations, including Mg^{2+} and Ca^{2+}, with tetracyclines (8, 9). Other studies deal with the ability of magnesium, calcium, and aluminum (10–12) to alter the antibacterial action of various tetracyclines. In view of these developments, it is not surprising to find literature reports indicating significant gastrointestinal absorption differences between complexed and uncomplexed forms of tetracyclines (13, 14).

RESULTS AND DISCUSSION

Survey of Adjuvants with Oxytetracycline.—As has been pointed out, this investigation was undertaken to further study a number of oxytetracycline–adjuvant systems with respect to this interaction and the possible mechanism(s) involved. A number of representative spectral systems are presented and discussed. Other spectral data obtained in this study are not included in this report due to space consideration; however, they are included in the discussion.

Spectral data presented in Fig. 1 illustrate the interaction between oxytetracycline and aluminum sulfate. Here curve B represents an oxytetracycline–aluminum sulfate system, equilibrated in dehydrated ethanol, while the physical dry mixture (control) is represented by curve A. Spectra C and D (Fig. 1) represent curves of the individual aluminum sulfate and oxytetracycline components, respectively. An examination of these spectra reveals that the alcohol-equilibrated sample is significantly different from the physically mixed control and also from the spectra of the individual components. These differences include a large bathochromic shift of approximately 200 mμ in the visible region, accompanied by an intensity change in the U.V. region. Visual evidence of this interaction was also noted by a color change between the control and sample, where the physical mixture had a faint yellow color while the alcohol-equilibrated sample acquired an orange hue. These large spectral and physical differences are indicative of a strong charge transfer interaction (1, 2, 15). Similar spectral changes were also observed when equilibrating oxytetracycline with anionotropic and cationotropic alumina (1) in aqueous media. The nature of the solvent (aqueous or nonaqueous) apparently does not interfere significantly with this interaction, as has been previously pointed out (1), thus indicating a high degree of chemisorption. The presence of this strong interaction is further illustrated by the fact that the alcohol equilibrated oxytetracycline–aluminum sulfate sample (Fig. 1, B) produces a 200 mμ bathochromic shift, occurring at a higher wavelength than that for the reflectance spectrum of pure oxytetracycline (Fig. 1, D). This spectral observation further substantiates this strong interaction in that a summation of the drug-adjuvant spectrum would not result in this degree of change. It is of further interest to point out here that the addition of water to a mixture of oxytetracycline and alumina results in the release of a noticeable amount of heat along with the formation of bubbles, again indicating a large degree of interaction for this exothermic system.

Another aluminum-containing system, Fig. 2, represents spectra of aqueous equilibration of a dry physical mixture of oxytetracycline with aluminum hydroxide. Although the bathochromic shift is somewhat different from that of the aluminum sulfate interaction, the change in intensity is greater. This hyperchromic change in intensity is accompanied by a new band formation at 310 mμ. Possible reasons for this band formation have been previously discussed (1, 2).

In addition to the aluminum-containing adjuvants mentioned above, several calcium-containing systems were also investigated. These adjuvants also react with oxytetracycline producing the usual bathochromic shifts accompanied by significant hyperchromic changes, new band formation, as well as additional shoulder formation in the visible region. It should also be pointed out that visual color changes in calcium-containing systems were smaller than those described in the aluminum-containing adjuvants; here a color change from light yellow to a deeper more intense yellow was often noticed. Spectral data of oxytetracycline–calcium hydroxide equilibration, found in Fig. 3, point out some of these changes between the physically mixed control (A) and the equilibrated sample (B). An examination of this figure illustrates the fact that the bathochromic shift in this calcium hydroxide system is similar in magnitude to the aluminum hydroxide system found in Fig. 2. A difference between these two figures is evident, however, since the calcium-containing system has a smaller intensity change, especially in the region of 310–330 mμ where oxytetracycline–aluminum hydroxide band formation is more intense than that observed with the corresponding calcium hydroxide system. Nevertheless, calcium hydroxide does appear to react with oxytetracycline, as seen from various spectral changes in Fig. 3.

Other oxytetracycline systems producing similar spectral changes with aqueous equilibration to those described above include systems containing oxytetracycline with calcium carbonate, or calcium stearate, not shown in this communication due to space consideration.

Spectral data of aqueous equilibration of dibasic calcium phosphate or tribasic calcium phosphate with oxytetracycline are somewhat similar to that of calcium hydroxide with a bathochromic shift of 80 mμ and small band formation for oxytetracycline–$CaHPO_4$ while the oxytetracycline–$Ca_3(PO_4)_2$ system shows a 30 mμ bathochromic shift accompanied by intensity changes similar to those seen with the dibasic salt. Color changes from faint yellow to a deeper yellow were also observed in these calcium-containing systems. This interaction difference between $CaHPO_4$ and $Ca_3(PO_4)_2$ with oxytetracyline may be attributed to the fact that the former salt has a proton which could more easily provide an active site for interaction, because of its greater tendency to accept electrons from the adsorbate. It is also possible that a greater degree of hydrogen bonding is facilitated with $CaHPO_4$ systems as discussed in a previous report (2).

Another group of metal adjuvants investigated were those containing magnesium ions. Figure 4 represents spectra of an equilibrated and nonequilibrated oxytetracycline–magnesium hydroxide system. The changes observed after equilibration

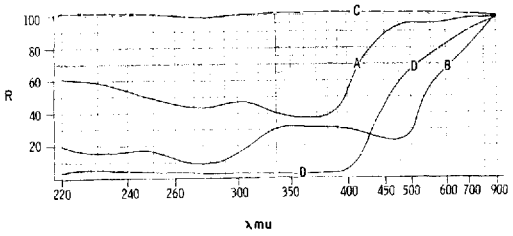

Fig. 1.—DRS of oxytetracycline (50 mg.) and aluminum sulfate (2.00 Gm.), equilibrated in dehydrated ethyl alcohol. Key: A, control (physical mixture); B, equilibrated sample; C, aluminum sulfate, 100%; D, oxytetracycline, 100%.

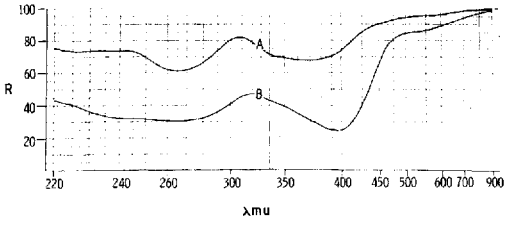

Fig. 3.—DRS of oxytetracycline (50 mg.) and calcium hydroxide (2.00 Gm.). Key: A, control; B, sample.

again include a bathochromic shift of about 50 mμ, a hyperchromic change, new band formation as well as a shoulder formation at 500 mμ. Similar spectral changes were observed with other oxytetracycline–magnesium-containing systems investigated. Included in this group are talc (native hydrated magnesium silicate), magnesium oxide, magnesium stearate, and synthetic magnesium silicate.[1] The interaction of oxytetracycline with synthetic magnesium silicate produces a bathochromic shift, intensity change, band formation, and shoulder formation to a greater degree than talc due to this material's high surface area, high porous structure, large internal surface, and high adsorption capacity. Similar changes were also observed on equilibrating oxytetracycline with zinc stearate, although the visual color change was not as pronounced.

Since data indicate that these interactions may be due primarily to the metallic ion in these systems, a study of nonmetallic adjuvants with respect to these interactions was undertaken. The interaction of oxytetracycline with stearyl alcohol or cetyl alcohol, shown in Fig. 5, illustrates this lack of interaction involved. An examination of this figure indicates that neither the stearyl alcohol, nor cetyl alcohol–oxytetracycline spectrum shifted to any appreciable degree after equilibration, as was expected. There is neither evidence of significant intensity variation, new band formation, shoulder formation, nor visual color change. The small variation in reflectance observed may be due to particle size difference, light scattering, or weak electrostatic attractions (2). Similar spectral results were also obtained on equilibrating oxytetracycline with stearic acid.

Since calcium stearate, magnesium stearate, zinc stearate, and other metal-containing adjuvants react strongly with oxytetracycline, as evidenced by large spectral changes, while stearyl alcohol, cetyl alcohol, and stearic acid do not, the interactions observed are primarily due to the metallic ion portion of the adjuvant. The other spectral and visible color observations previously indicated (1, 2) further suggest that this is a charge transfer chelation interaction.

It should be pointed out, however, that other nonmetallic adjuvants, containing polyfunctional groups, show spectral changes on equilibration with oxytetracycline, although these systems have inherently different spectral characteristics. An example of this type of change may be found in

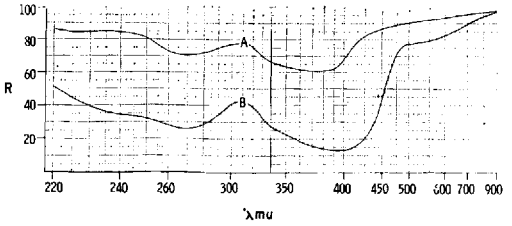

Fig. 4.—DRS of oxytetracycline (50 mg.) and magnesium hydroxide (2.00 Gm.). Key: A, control; B, sample.

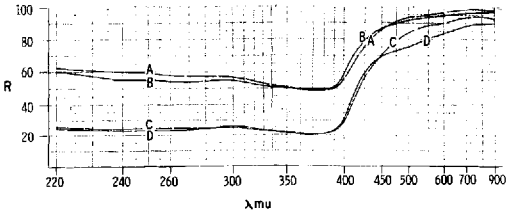

Fig. 5.—DRS of oxytetracycline (50 mg.) with stearic acid (2.00 Gm.) or with cetyl alcohol (2.00 Gm.). Key: A, oxytetracycline–stearic acid control; B, oxytetracycline–stearic acid sample; C, oxytetracycline–cetyl alcohol control; D, oxytetracycline–cetyl alcohol sample.

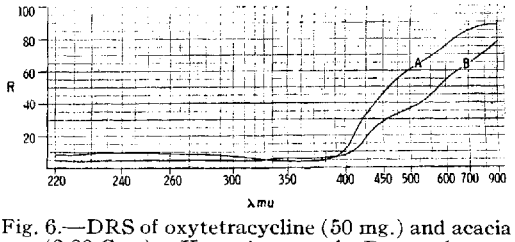

Fig. 6.—DRS of oxytetracycline (50 mg.) and acacia (2.00 Gm.). Key: A, control; B, sample.

Fig. 6, showing spectra of an equilibrated and non-equilibrated oxytetracycline–acacia system. Since acacia is a polyfunctional material, it is reasonable to assume that one or more of the functional groups may react with oxytetracycline by a donor–acceptor mechanism (16), producing the observed spectral change in the visible region. It should also be pointed out that other adjuvants, including tannic acid and starch, react with oxytetracycline to give similar changes; spectra of these systems are not presented due to space considerations. Figure 7 represents the spectra of an equilibrated and non-equilibrated oxytetracycline–polyethylene glycol 6000 system. The large bathochromic shift, hyperchromic effect, and visual color changes observed in equilibrating this system may again be attributed to an interaction between oxytetracycline and the ether linkage of the ethylene oxide units of the polyethylene glycol polymer. This observation is in agreement with published reports dealing with polyethylene glycol interactions in aqueous solution (3, 17). A bathochromic shift of similar magnitude, along with a visual color change from light yellow to a deep red-brown, was also observed on equilibrating oxytetracycline with silica gel.

Key: A, control (physical mixture); B, physical mixture left in moisture chamber for 30 hr. and measured as a moist sample; C, compression of the moist sample (B) at 30,000 p.s.i. for 5 min.

Particle-Size Variation.—Since particle size may produce variation in the reflectance spectrum (18), the authors' preliminary study dealing with this aspect indicates that some variation was obtained, although the changes are of a minor nature. For example, the spectrum of an equilibrated oxytetracycline–magnesium trisilicate complex was not altered to any significant degree when this equilibrated sample was subjected to reduction in particle size by homogenizing the powder for 0.5 hr. with the use of a Virtis blender. An examination of the filtered, vacuum dried sample's spectrum was comparable to that of the equilibrated control.

Although variation in particle size does have some effect on the regular reflection (1), the general characteristics of the control and homogenized sample spectra were essentially similar except for minor variations in the order of ±2%.

Moisture Effects.—Since solid pharmaceutical dosage forms involve the use of excipient materials such as fillers, binders, disintegrators, and lubricating agents, and since a certain percentage of moisture is necessary for the preparation of such dosage forms, as in the case of tablets, a preliminary investigation dealing with the effects of moisture was undertaken. Results presented thus far, dealing with drug–adjuvant interactions, were facilitated by compression or by equilibration techniques, either in aqueous or nonaqueous media. The present study involves the exposure of the dried, physically mixed drug–adjuvant components to humidity conditions for various time intervals.

Figure 8 illustrates this moisture effect with respect to spectral changes. Here curve A is the

diffuse reflectance spectrum of a dry physical mixture of oxytetracycline HCl and magnesium trisilicate and serves as the control. A portion of this dry physical mixture was then transferred onto an evaporating dish and placed in a wax-sealed desiccator in which water was substituted for the desiccant and allowed to stand for a period of 24 hr. This moist sample was then dried to eliminate moisture effects, and the DRS, represented by Fig. 8, curve B, was taken. Figure 8, C, represents the spectrum of physical mixture which has been equilibrated in water, filtered, and dried. An examination of curve B indicates that interaction does take place under moist conditions since this curve is comparable to the spectrum of the equilibrated sample (Fig. 8, C), except for an intensity change and the shoulder formation at 475 mμ. This greater intensity change, observed in the equilibrated sample, is probably due to a greater degree of interaction, since more surface area is exposed in equilibrating techniques. These spectral changes were accompanied by the usual color change from light yellow to a deep yellow color. It is of interest to note that the spectra of pure dry and moist oxytetracycline HCl or magnesium trisilicate, exposed to the same moist conditions, were similar in nature and did not vary by more than ±2%.

A similar effect is shown in Fig. 9, representing the interaction of oxytetracycline with sodium chloride. Spectrum A represents a physical mixture (control) of vacuum dried oxytetracycline and NaCl. A portion of this dried mixture was subjected to the moist humidity chamber previously described, and allowed to remain in this atmosphere for 3 hr. The DRS of this moist sample was then obtained and is represented by curve B. Figure 9, C, represents the spectrum of this moist sample which was vacuum dried. It is interesting to note that an interaction was observed with NaCl (Fig. 9, B), which cannot be totally attributed to a moisture effect, since drying of this moist sample does not cause a reversal in the spectrum back to the control, but instead, a higher degree of interaction results (Fig. 9, C). This may be explained on the basis that drying removes some of the surface water molecules from the adsorbent, producing additional reactive sites which facilitate the increased chemisorption or interaction.

Other adjuvant systems, investigated for oxytetracycline moisture effects, include anhydrous magnesium sulfate, magnesium chloride, and stearic acid. An examination of Fig. 10 again points out large spectral changes induced when a physical mixture of oxytetracycline and anhydrous magnesium sulfate is allowed to sit in a moisture chamber for 12 hr. Here curve A represents a physical mixture of individually dried oxytetracycline and magnesium sulfate, while curve B is the spectrum of a moist sample. These spectral changes along with an important color change from a whitish yellow to a deep yellow intensity are again indicative of a strong interaction. Similar spectral changes are also observed when subjecting an oxytetracycline–magnesium chloride mixture to a moist atmosphere. A difference between the sodium chloride and magnesium chloride reaction with oxytetracycline does exist, however, since the moisture exposed oxytetracycline–NaCl sample shifts, seen in Fig. 9, are of a magnitude of about 75 mμ while a bathochromic shift of about 150 mμ is observed with a corresponding oxytetracycline–magnesium chloride system. The greater spectral shift observed with the magnesium chloride system would be expected since magnesium chelates of oxytetracycline are known, and the interaction would be of a stronger variety than that produced by the sodium salt. It is interesting to point out again, however, that these changes are not observed between a physical mixture and moist sample of oxytetracycline and stearic acid. Spectral curves of the latter two systems have not been presented due to space considerations and chelation explanations for these differences have been discussed in previous sections.

Curves C and D (Fig. 10) represent spectra of dry and moist oxytetracycline, respectively. It is evident from these curves, and other adjuvant spectral data, that moisture effects of the individual components of these complexes are minor compared to the huge spectral differences when a physical drug–adjuvant mixture is allowed to remain in a moist environment.

The significance of such interactions can be easily applied to the area of tableting. The preparation of tablets usually requires that some moisture be present in the process of granulation, prior to tablet compression. Although such interactions, if they do occur, are already present in these granules, the effect of compression further accentuates this interaction. This effect is illustrated in Fig. 11, which represents the dry physically mixed control (curve A), the moist sample (curve B), and the compressed moist sample (curve C). An examination of the curves in this figure indicates that a greater degree of interaction may be obtained under compression pressures, as represented by the increased intensity and bathochromic change, even though the sample has already interacted due to moisture chamber equilibration. Furthermore, vacuum drying of these moisture equilibrated samples and subsequent compression does not destroy this interaction.

CONCLUSION

An examination of the large number of adjuvants which may react with oxytetracycline, together with the large spectral changes of specific systems, suggests the desirability of preliminary screening for the possible existence of such drug–adjuvant interactions in the formulation of dosage forms. Although no experimental data are available concerning the effect of these surface interactions with respect to dissolution and adsorption rates, it is felt that the possible existence of such interactions should be recognized. The literature does, however, contain information which strongly suggests that such interactions are responsible for the variation in blood level drug concentrations.

Since chemisorption primarily involves the surface area of the adjuvant, this type of interaction may not be of great therapeutic value when the drug to excipient ratio is sufficiently large, in that the chemisorbed unimolecular layer covering the surface of the adjuvant does not manifest itself until all the other physically adsorbed layers of the drug are removed. However, such drug–adjuvant interactions are extremely important when the ratio of the therapeutic drug to the amount of adjuvant or excipient is extremely low. In such ratios, the therapeutic agent primarily exists as the interacted

unimolecular layer and would be expected to significantly alter the dose response obtained. It is well to point out here that such interactions would not only manifest themselves in solid dosage forms, as in the case of tablets and capsules, but could also occur in suspensions and ointments, where drug–adjuvant ratios are usually low. It is of significant interest to point out here that one cannot overlook the distinct possibility of the excipient itself existing as a chemisorbed layer covering the surface of the drug resulting in similar alterations of the physical or biochemical behavior of the medicament in dosage forms where the drug–adjuvant ratios are high.

Data presented in this study further illustrate the possibility that donor–acceptor interaction of many varieties play an important role in these drug–adjuvant interactions. This has been illustrated by different magnitudes of spectral shifts observed among aluminum, calcium, magnesium, zinc, and sodium-containing adjuvants as well as nonmetal-containing excipients represented by stearyl alcohol, stearic acid, cetyl alcohol, acacia, tragacanth, tannic acid, and polyethylene glycol. The degree of interaction observed further depends on the nature of the drug and the type of adjuvant used. For example, calcium-containing adjuvants interact strongly with oxytetracycline but show very little interaction tendency for anthracene.

Studies are currently in progress in these laboratories dealing with the effects of such interactions on various aspects of drug dosage formulation and absorption.

LSD Analogs

N-Methyl-*N*-*p*-(and *m*-)methoxyphenyl-β-alanine Derivatives

By KENNETH J. LISKA, JAMES L. JOHNSON, JAMES P. MASTRIAN, and MARIE L. STEENBERG

Patterned after a fragment of the LSD molecule, the ethyl esters, simple amides, and *N*,*N*-diethylamides of *N*-methyl-*N*-*p*-(and *m*-)methoxyphenyl-β-alanine were prepared for evaluation as psychotomimetics. Of five compounds tested, three exhibited some degree of antiserotonin activity in the isolated rat fundus preparation. One of these three appeared also to be anticholinergic.

ATTEMPTS HAVE been made to elucidate an active psychotomimetic moiety in the lysergic acid diethylamide (LSD) molecule (1, 2). In the present work, the *N*-methyl-*N*-phenyl-β-alanine fragment of LSD was selected for study; an electron-rich methoxy group *para* or *meta* on the ring was intended to approximate the contribution made by the pyrrole nitrogen.

structure), produced by addition of *N*-methyl-*p*-anisidine or *N*-methyl-*m*-anisidine to ethyl acrylate, were converted into the simple amides (R = NH_2) employing ammonia water at refrigerator temperatures. When the corresponding aminolysis employing the ethyl ester of *N*-methyl-*N*-*p*-methoxyphenyl-β-alanine and diethylamine was attempted at room temperature, at 75° for 72 hr., or at 160° for 22 hr., no amide formation could be detected by infrared spectral examination of the crude reaction products. Only unchanged ester appeared to be recovered. This diethylamine aminolysis was also attempted using catalytic amounts of water (at 110° for 64 hr.), sodium ethoxide (room temperature for 65 hr.), and calcium chloride (112° for 15 hr.). Again, only unchanged ester could be detected by infrared examination of the crude reaction products. Since the *N*,*N*-diethylamide in the *para* series could not be obtained by aminolysis, it and the *N*,*N*-diethylamide in the *meta* series were prepared by treating *N*,*N*-diethyl-3-bromopropionamide with either *N*-methyl-*p*-anisidine or *N*-methyl-*m*-anisidine. As a further proof of structure, the ethyl ester in the *para* series was hydrolyzed to the free acid, which was isolated as the amino acid hydrochloride salt.

Pharmacological testing for serotonin inhibitory activity was performed utilizing the isolated rat fundus. Five compounds were tested: the ethyl esters in both series, the simple amide in the *para* series, and the *N*,*N*-diethylamides in both series (compounds I, II, III, V, and VI. See under *Experimental*). Compounds I, II, and VI antagonized the action of serotonin on the isolated rat fundus. Compound VI appeared to be the most potent antagonist tested, showing inhibition at concentrations as low as 1.4 mcg./ml. and an ED_{50} of 2.2 mcg./ml. Compounds II and I were effective antagonists of serotonin, exhibiting approximately 50% inhibition at concentrations of 7.4 and 28.2 mcg./ml., respectively. Compound II also antagonized acetylcholine-induced contractions; 0.14 mg./ml. produced a 50% inhibition. Compounds I, II, and VI appear as relatively weak serotonin antagonists when their activities are compared to the activity of LSD on the mouse uterus (3). The most active compound (VI) appears to have a dual mechanism, antiserotonin and anticholinergic. These results are summarized in Table I. Compounds III and V were inactive.

EXPERIMENTAL[1]

N-Methyl-p-anisidine.—This was prepared from commercial *p*-anisidine according to the method of King and Tonkin (4), b.p. 139–141° (27 mm.). HCl salt, m.p. 121–123°. Major I.R. spectral peaks in $cm.^{-1}$: 3405 (m), 1506 (s), 1230 (s), 1030 (s), 815 (s).

N-Methyl-m-anisidine.—This was prepared from commercial *m*-anisidine following the directions of King and Tonkin (4) for the *para* compound, b.p. 119–120° (11 mm.), n_D^{24} 1.5670; picrate from alcohol, m.p. 147.5–149.5°. Major I.R. spectral peaks in $cm.^{-1}$: 3405 (m), 1600 (s), 1490 (s), 1204 (s), 1155 (s), 820 (m), 750 (m), and 680 (m).

N,N-Diethyl-3-bromopropionamide.—This was prepared according to the method of Gearien and Liska (5), b.p. 82–100° (0.5 to 1.0 mm.).

Ethyl 3-(N-Methyl-N-p-methoxyphenylamino)-propionate (I).—To a mixture of 52.0 Gm. (0.38 mole) of *N*-methyl-*p*-anisidine and 57.0 Gm. (0.57 mole) of ethyl acrylate was added 2 ml. of glacial acetic acid, and the mixture refluxed for 7 hr., then allowed to stand overnight. The product was taken up in ether, washed once with saturated sodium bicarbonate solution, once with water, dried over anhydrous sodium carbonate, the ether evaporated, and distilled. Discarding a forerun, the authors collected the fraction, b.p. 144–148° (0.1 mm.). The yield was 60.4 Gm. (67%) of pale yellow oil. Ester CO (str) 1720 $cm.^{-1}$.

Anal.—Calcd. for $C_{13}H_{19}NO_3$: C, 65.82; H, 8.02; N, 5.90. Found: C, 66.01; H, 8.10; N, 6.00.

The HCl salt could not be obtained in a solid form. Picrate, from alcohol, m.p. 126–129°.

Ethyl 3-(N-Methyl-N-m-methoxyphenylamino)-propionate (II).—A mixture of 12.2 Gm. (0.089 mole) of *N*-methyl-*m*-anisidine, 9.0 Gm. (0.089 mole) of ethyl acrylate, and 1 ml. of glacial acetic acid was heated under reflux for 5 hr. and then allowed to stand overnight. The workup was the same as for the *para* compound. Obtained was 12.0 Gm. (57%) of a pale yellow oil, b.p. 145–150° (0.1 mm.). Ester CO (str) 1720 $cm.^{-1}$.

Anal.—Calcd. for $C_{13}H_{19}NO_3$: C, 65.82; H, 8.02; N, 5.90. Found: C, 66.05; H, 8.16; N, 6.10.

The HCl salt could not be obtained in a solid form. Picrate, from alcohol, m.p. 104–106°.

3-(N-Methyl-N-p-methoxyphenylamino)-propionamide (III).—Ammonia water (25 ml. of 29% ammonia) was enclosed with 8.8 Gm. (0.037

[1] Melting points and boiling points are uncorrected. Infrared data from a Beckman IR-8. Analyses by Galbraith Laboratories and Weiler & Strauss.

mole) of ethyl 3-(*N*-methyl-*N*-*p*-methoxyphenylamino)propionate and stored with occasional shaking in a refrigerator for 10 days. The supernatant liquid was then decanted from the semisolid mass, a fresh 25-ml. portion of ammonia added, and the mixture allowed to stand an additional 3 days. The supernatants upon chilling to 0° yielded crude amide which was combined with additional amide obtained by cold ether extraction of the semisolid mass. Recrystallization from ligroin yielded fluffy white needles, m.p. 110–112°. Obtained 1.0 Gm. (13%). Amide CO (str) 1670 cm.$^{-1}$.

Anal.—Calcd. for $C_{11}H_{16}N_2O_2$: C, 63.46; H, 7.69; N, 13.46. Found: C, 63.24; H, 7.76; N, 13.23.

3 - (N - Methyl - N - m - methoxyphenylamino)-propionamide (IV).—This simple amide was prepared in 14% yield following approximately the same procedure used for the *para* isomer. Recrystallized from water, m.p. 94.5–96°. Amide CO (str) 1670 cm.$^{-1}$.

Anal.—Calcd. for $C_{11}H_{16}N_2O_2$: C, 63.46; H, 7.69; N, 13.46. Found: C, 63.66; H, 7.80; N, 13.27.

3 - (N - Methyl - N - p - methoxyphenylamino)-propionic Acid Hydrochloride.—The hydrolysis of ethyl 3-(*N*-methyl-*N*-*p*-methoxyphenylamino)propionate (10.0 Gm., 0.042 mole) was accomplished by refluxing with 50 ml. of 10% HCl for 4 hr. The volume of water was reduced to about one-fifth. The solution was allowed to stand overnight, whereupon 3.2 Gm. of pure, highly crystalline amino acid hydrochloride, m.p. 159–160°, was obtained. Evaporation of the remainder of the water and trituration of the solids with anhydrous ether yielded an additional 2.7 Gm. of pure product for a total yield of 57%. The salt recrystallizes well from absolute alcohol.

Anal.—Calcd. for $C_{11}H_{16}ClNO_3$: Cl, 14.43. Found: Cl, 14.19.

3 - (N - Methyl - N - p - methoxyphenylamino)-N′,N′-diethylpropionamide (V).—A solution of 10.2 Gm. (0.049 mole) of *N*,*N*-diethyl-3-bromopropionamide, 6.9 Gm. (0.049 mole) of *N*-methyl-*p*-anisidine, 5.3 Gm. (0.05 mole) of anhydrous sodium carbonate, and 15 ml. of benzene was heated at gentle reflux for 7.5 hr., and then allowed to stand overnight. The mixture was filtered, the solids washed with ether, the combined filtrates freed of solvents, and distilled. After a large forerun, the fraction, b.p. 183–186° (0.09 mm.), was collected as a yellow oil, amounting to 3.9 Gm. (30%). Tertiary amide CO (str) 1625 cm.$^{-1}$. n_D^{23} 1.5396.

Anal.—Calcd. for $C_{15}H_{24}N_2O_2$: C, 68.18; H, 9.09; N, 10.61. Found: C, 68.35; H, 9.20; N, 10.80.

The HCl salt was prepared crystalline but was very hygroscopic. The picrate could not be obobtained in a solid form. Methiodide, recrystallized from absolute ethanol, m.p. 121–124°, slightly hygroscopic.

3 - (N - Methyl - N - m - methoxyphenylamino)-N′,N′-diethylpropionamide (VI).—A mixture of 6.0 Gm. (0.044 mole) of *N*-methyl-*m*-anisidine, 9.1 Gm. (0.044 mole) of *N*,*N*-diethyl-3-bromopropionamide, 4.6 Gm. (0.044 mole) of anhydrous sodium carbonate, and 15 ml. of benzene was heated at gentle reflux for 5 hr. The mixture was cooled, filtered, the freed solids washed with benzene, and the combined benzene filtrates dried over sodium sulfate. After removal of the solvent, the residue was distilled and the fraction collected, b.p. 173–181° (0.09 mm.). Obtained 4.3 Gm. (37%) of a yellow oil, n_D^{23} 1.5448. Tertiary amide CO (str) 1629 cm.$^{-1}$.

Anal.—Calcd. for $C_{15}H_{24}N_2O_2$: C, 68.18; H, 9.09; N, 10.61. Found: C, 68.03; H, 8.98; N, 10.71.

The HCl salt could not be prepared in a solid state. The picrate was crystallized, after 5 days standing, from ethanol, m.p. 125–127°. Methiodide from absolute ethanol, m.p. 108–111°, hygroscopic.

PHARMACOLOGY

Wistar rats of both sexes (100–150 Gm.) were fasted for 24 hr., killed by a blow on the head, and the stomach removed. The fundus was removed and cut into a strip by opening the tissue along the lesser curvature and cutting to preserve the longitudinal muscle as described by Vane (6). The fundus strip was suspended in a 10-ml. muscle bath containing modified Ringer solution (7) (Gm./L.: NaCl, 9.0; KCl, 0.42; $CaCl_2 \cdot 2H_2O$, 0.06; $NaHCO_3$, 0.5; and glucose, 0.5) maintained at 37° and oxygenated with pure oxygen.

The strip was permitted to stretch in the organ bath for 1 hr., after which the minimum amount of serotonin required to give a response of 4–5 cm. was determined. This varied from 0.1–1.0 ng./ml. of bathing solution. This amount of serotonin was added to the bath at 6-min. intervals and the tissue washed twice between doses. Three equivalent responses to serotonin were followed by the addition of a known quantity of the drug, diluted in normal saline, 1 min. before the next addition of serotonin. If inhibition occurred, the tissue was washed until recovery was noted, and two equivalent responses to serotonin were recorded before the tissue was used for another test. Four different doses of each drug were selected so that the highest dose gave a complete blockade of serotonin and the lowest a 5–10% blockade. The volume of each dose was less than 0.4 ml.

Effect of Ultrasound on Particle Size of Suspensions of Polyethylene Spheres

By M. A. SHEIKH, J. C. PRICE, and R. J. GERRAUGHTY

The effect of ultrasound energy on the particle size of polyethylene spheres in aqueous suspension, with and without additives such as surfactants and deflocculating agents, and using variable times of exposure to ultrasound, were studied. Particle size was determined microscopically and expressed as the mean diameter of the particles. It was found that ultrasonic waves, at a frequency of 100 kc., caused a significant reduction in particle size only if surfactants were present. It was also observed that surfactants having high HLB values were the most efficient of all additives. Increasing time of exposure to the ultrasound waves brought about a continued reduction of particle diameter up to 2 hr., but that after this time the particle size stabilized, and further exposure produced no significant decrease in the mean diameter of the polyethylene spheres.

IN RECENT YEARS, ultrasonic energy has been shown to cause particle size reduction in emulsions (1–4) and suspensions (5–9).

There are conflicting reports on the influence of the total time of exposure to the ultrasonic waves, however. Some authors stated that an optimum period was needed and that continued exposure could even cause an increase in particle size in emulsions (2, 3). Others found that after an optimum exposure time there is little or no change in particle size of emulsions (4). A similar observation has been made with suspensions (6). Another paper reports that the particle size reduction continued as the time of exposure was lengthened (8). It is very possible that the conflicting results of these studies might have been due to differences in the intensity and frequency of ultrasound that was used or to variance in the crystalline structure of the compounds used in the suspensions.

It was the aim of this investigation to correlate, if possible, the time of exposure to ultrasound to the degree of size reduction of suspension particles in a highly reproducible suspension under closely controlled experimental conditions; a second objective was to evaluate the effect of various concentrations of surfactants and deflocculants on the exposed suspensions. The third objective was to determine if the concentration of suspension particles is important.

A generator producing sound waves at a frequency of 100 kc. was selected. It was felt that higher frequencies could cause some side reactions to occur which might introduce other variables, and very high plate power is required to produce cavitation at higher frequencies.

Received April 26, 1966, from the College of Pharmacy, University of Rhode Island, Kingston.

Accepted for publication June 28, 1966.

Based on a thesis submitted by M. A. Sheikh to the Graduate School, University of Rhode Island, in partial fulfillment of Master of Science Degree requirements.

Presented to the Pharmaceutical Technology Section, A.PH.A. Academy of Pharmaceutical Sciences, Dallas meeting, April 1966.

EXPERIMENTAL

Equipment and Materials.—The apparatus used to supply ultrasonic power for all experiments consisted of a 100-kc. generator,[1] and a bath equipped with a barium titanate transducer. A round copper coil, attached to a circulating constant-temperature bath, was inserted in the transducer bath in order to keep the temperature constant at 25 ± 1° during the investigation.

The instrument selected for the determination of the particle size of the suspensions was a Spencer microscope with an AO Spencer micrometer.[2]

A microfine polyethylene resin,[3] was selected to prepare the experimental suspensions. This substance offers several characteristics to commend it for this use: (*a*) the polyethylene is hydrophobic and cavitation occurs more easily at hydrophobic surfaces; (*b*) the particles are spherical and, therefore, easy to count; (*c*) there are two size ranges available, 3–20 μ diameter (Microthene 500) and 8–30 μ (Microthene 510); and (*d*) the material is inexpensive.

Procedure.—An 0.5% suspension of Microthene 500 or 510 was used as the basic suspension. Additives were used in varying concentrations at different times to study their effect. These included the surfactants polysorbate 20[4] and sodium lauryl sulfate, and the deflocculating agents Darvan,[5] Daxad,[5] and Marasperse.[6] The suspension to be exposed was placed in a 125-ml. flask, and this was immersed in the transducer bath so that the level of the suspension was always below the level of water in the transducer bath. Temperature was kept constant at 25°, and the generator plate voltage was kept at 1000 v. After varying intervals of time, representative samples of the suspension were withdrawn from the flask, particle sizes were determined microscopically by measuring the diameters of 200 particles for each sample, and the mean diameter was calculated for each sample. Later the concentration of Microthene 500 and Microthene 510 was varied from 0.5 to 4%. Poly-

sorbate 20 was added to all of these suspensions in a concentration of 0.1%.

RESULTS

The mean particle sizes of Microthene 500 and 510 suspensions containing varying concentrations of polysorbate 20 and sodium lauryl sulfate are shown in Tables I–IV. It is apparent that the addition of these agents facilitated a substantial reduction in particle size after 2 hr. exposure time, but that, usually, a plateau was reached at that time, and longer exposure caused little or no further reduction in the mean particle diameter.

It is also apparent that a 0.05 to 0.1% concentration of surfactant is satisfactory, and that higher concentrations do not increase the effectiveness of the ultrasound.

A study of the effect of the HLB (10) of surfactants was made by using mixtures of sorbitans[7] and polysorbates. The results are shown in Table V. It appears that there is little difference in effect on particle size reduction if the HLB of the surfactant mixture is greater than 10, but that as the HLB is reduced below that point, the effect of ultrasound is reduced.

There is no significant difference in the magnitude of the decrease between Microthene 500 and Microthene 510 if the decrease in particle size is computed on the basis of percentage of change of mean particle diameter.

Particle size reduction of Microthene suspensions in the presence of deflocculants such as Marasperse, Darvan, and Daxad was negligible, and practically the same as when no additive at all was used. These agents are charged particles which are adsorbed on the surface of the suspended particles preventing flocculation by electrical repulsion without appreciably affecting surface tension. Table VI, which shows the effect of ultrasound in a Microthene suspension in the presence of Darvan, is typical.

The effect of increasing the concentration of the suspended phase is shown in Tables VII and VIII. It is apparent that the effect of ultrasound in reducing particle size becomes less marked as the concentration of the suspended phase increases.

DISCUSSION

In all of the experiments in which there was a substantial reduction in particle size of the suspended material, a plateau was noticed after an exposure time of about 2 to 2.5 hr., after which time no further significant reduction in size occurred. These results parallel the results reported by Singiser and Beal (4) for a liquid–liquid system although this study is concerned with a solid–liquid system. No reasonable explanation for this effect can be obtained from the data available, but it was seen consistently.

Substantial reduction in mean particle diameter occurred only in the presence of surfactants. This result can be explained partially from the character of the suspensions obtained. When surfactants having high HLB values were present, the particles were readily dispersed, and, therefore, the individual particles were completely surrounded by liquid; in the absence of surfactants the particles tended to remain clumped together and, therefore, not surrounded by liquid. Since the ultrasound waves and cavitation shock waves are transmitted to the particles through the liquid medium, a much reduced effect would be expected in the poorer suspensions.

It was observed that the deflocculating agents used did not lessen flocculation of the Microthene particles to a significant degree. The very small

[a] All suspensions contained 0.1% polysorbate 20.

size reduction in these suspensions could be explained on the same basis as above, *i.e.*, the ultrasound waves and cavitation shock was not transmitted to the individual particles.

The effect of increasing the concentration of the suspended phase was quite predictable. In addition to the possibility of a greater degree of flocculation as more particles were present, it was noted that higher concentrations appeared to have a damping effect on cavitation by the ultrasound waves as evidenced by decreased agitation in the flask.

SUMMARY AND CONCLUSIONS

1. The purpose of this investigation was to study the effect of ultrasonic energy on the particle size of certain highly reproducible suspensions. It was observed that ultrasound waves had some reducing effect in all cases.

2. The effect of the time of exposure to ultrasonic energy appeared to be that the size changed significantly up to a period of 2 hr. and that after that a plateau was reached.

3. The use of deflocculating agents did not cause any significant change in the reduction of the particle size.

4. It was also noted, from this study, that a minimum concentration of a surfactant was necessary to obtain maximum effect on particle size reduction but that addition of surfactant above this concentration produced no noticeable change.

5. The HLB of the surfactant also has an effect on the reduction in the particle size. Surfactants with high HLB were found to be most effective, and if the HLB was less than 10, practically no effect was observed.

6. As the concentration of the suspended phase was increased, the change in particle size of suspension became less marked.

7. In view of the results of this study, it can be concluded that ultrasonic energy might be a useful tool for the reduction of particle size of certain pharmaceutical suspensions to make them more stable.

Interaction of Various Phenethylamines with the Adrenergic-Adipose Tissue Receptor System, *In Vitro*

By K. F. FINGER and D. R. FELLER

The interaction of several phenethylamines with the rat adipose tissue adrenergic receptor system has been studied utilizing the release of free fatty acids as an index of the interaction. It has been established that structural modifications of the basic phenethylamine molecule produced marked changes in the affinity of the agonists for this system and, to a lesser degree, in the intrinsic activity constants. *N*-Substitution of large alkyl functions increased affinity most markedly. Hydroxylation of the β carbon of the ethylamino side chain also enhanced affinity, while changes in the ring substitution produced changes varying from complete loss of all activity to alterations in the affinity constants. Phenethylamine, tyramine, ephedrine, amphetamine, and metanephrine were found to be inactive in this system. The catechol nucleus appears to confer optimal activity upon the agonist molecule, but structural modifications, particularly upon the side chain nitrogen, markedly affect the ability of the molecule to release free fatty acids from adipose tissue, *in vitro*.

RECENT STUDIES have indicated the increasing importance of the mobilization of free fatty acids (FFA) in (*a*) normal body metabolism as a primary energy source (1, 2) and (*b*) as a factor or contributing factor in certain disease states (3). For these reasons, considerable research emphasis has most recently been placed on studies designed to elucidate the controlling mechanisms involved in the mobilization of FFA from triglycerides in adipose tissue.

The fact that the sympathetic nervous system and in particular the catecholamines play an important role in the mobilization of FFA has been recognized for a number of years (4, 5). Recent work has shown that the catecholamine-induced mobilization of FFA occurs along pathways similar to those elucidated by Sutherland and Rall (6) for the catecholamine-induced glycogenolytic processes of liver, *i.e.*, it appears that the catecholamines stimulate the conversion of ATP to 3′,5′-cyclic AMP, which, in turn, catalyzes the conversion of an inactive lipase to an active lipase (7, 8). The lipolytic enzymes thus activated catalyze the stepwise hydrolysis of triglycerides to yield free fatty acids.

Many studies have been reported concerning the effects of catecholamines on the release of free fatty acids both *in vivo* and *in vitro*. However, few, if any, have defined the structure-activity relationships involved in the interaction of catecholamines with the adipose tissue-adrenergic receptor or have provided a sufficient degree of quantitation to allow such relationships to be made. It is the purpose of this report to present findings with respect to the structure-activity relationships involved in the interaction of substituted phenethylamines with the rat epididymal fat tissue, *in vitro*. This knowledge is deemed important for an understanding of the nature of drug–receptor interaction in this tissue and for the development of highly selective agonists and antagonists of FFA release in the future.

Received April 25, 1966, from the School of Pharmacy, University of Wisconsin, Madison.

Accepted for publication July 7, 1966.

Presented to the Pharmacology and Biochemistry Section, A.PH.A. Academy of Pharmaceutical Sciences, Dallas meeting, April 1966.

This work was supported in part by grant AM 08082 from the National Institute of Arthritis and Metabolic Diseases, National Institutes of Health, and a general research support grant from the U. S. Public Health Service, Bethesda, Md.

EXPERIMENTAL

Materials.—The chemicals[1] employed in this study and their source of supply are as follows: tyramine HCl, *d,l*-metanephrine HCl, dopamine HCl, *l*-phenylephrine HCl, *l*-isopropyl arterenol HCl, phenylpropanolamine HCl, and β-phenethylamine (Mann Research Laboratories); metaraminol bitartrate and ephedrine sulfate (Merck, Sharp & Dohme Laboratories); isoxuprine HCl (Mead Johnson Laboratories); nylidrin HCl (U. S. Vitamin Corp.); *l*-epinephrine bitartrate (Winthrop Laboratories); protochylol (Lakeside Laboratories); dextroamphetamine sulfate (K & K Laboratories); *l*-norepinephrine bitartrate and bovine albumin, fraction V (Nutritional Biochemicals Corp.). All concentrations expressed in this paper refer to the free base.

Methods.—Nonfasted, male Sprague–Dawley rats, weighing between 200 and 250 Gm., were maintained in their animal quarters at least 1 week prior to being employed in an experiment. The animals were sacrificed by stunning and decapitation. The anterior one-third of the epididymal fat pads were rapidly removed, placed in freshly prepared Krebs-Ringer bicarbonate buffer (pH 7.4), and minced with a small scissors to yield pieces weighing 5–10 mg. Tissue slices from six rats were pooled for each experiment.

Incubations of fat pads and the determination of the rate of FFA release as function of agonist concentration were conducted by procedures previously described (9).

[1] The authors thank their colleagues in the pharmaceutical industry for generously supplying many of the chemicals used in this study.

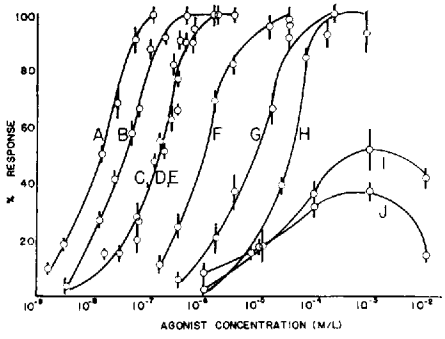

Fig. 1.—Dose-response curves for various phenethylamine agonists on mobilization of FFA from rat epididymal fat tissue, *in vitro*. Key: A, protochylol; B, isopropyl arterenol; C, epinephrine; D, norepinephrine; E, nylidrin; F, isoxuprine; G, metaraminol; H, dopamine; I, phenylephrine; J, phenylpropanolamine. From four to six determinations were made at each agonist concentration for all compounds presented in this paper. The values plotted represent the mean ± the standard error as indicated by the vertical lines.

The rates of FFA release, expressed in terms of μmoles of FFA released/Gm. of adipose tissue/hr., were calculated from the data obtained by serially sampling the incubation vessel at 0, 20, 40, and 60 min. after addition of the agonist to the media. In these studies, a maximal rate of FFA release of 18 μmoles/Gm./hr. was obtained and was found to be independent of the agonist employed. This maximal figure was employed to calculate the per cent response of the system in all studies described in this report.

RESULTS AND DISCUSSION

Dose - Response Relationships.—The dose-response relationships obtained for the active compounds employed in this study are presented in Fig. 1. It is apparent from these data, that with the exception of phenylephrine and phenylpropanolamine, all compounds were capable of producing a maximal release of FFA from adipose tissue slices, *in vitro*. The compounds varied, however, in their relative ability to mobilize FFA. Thus, in considering compounds A through H shown in Fig. 1, the rank order of compounds listed in order of decreasing potency is protochylol > isopropyl arterenol > epinephrine = norepinephrine = nylidrin > isoxuprine > metaraminol > dopamine. Phenylpropanolamine (compound J) and phenylephrine (compound I) possess properties which sharply differentiate them from the others. Thus, these latter two molecules show the property of auto-inhibition which manifests itself in a decrease in FFA release as the concentration of agonist is increased beyond a certain value.

Analysis of these data suggest that the catechol nucleus conveys optimal activity upon the molecule in agreement with the postulates of Belleau (10) regarding the interaction of catecholamines and ATP at the adrenergic receptor. Structural modifications of the catecholamine structure, however, produced pronounced alterations in the relative ability of these moieties to mobilize FFA from the adipose tissue slices. Norepinephrine and dopamine differ only in the presence or absence of the hydroxyl function on the β carbon of the side chain, yet these two compounds differ by a factor of about 160 in their activity in mobilizing FFA. Thus, side chain hydroxylation appears to increase FFA mobilizing activity.

Similarly, *N*-substitution of large alkyl functions enhanced activity as can be seen by comparing the dose-response curves for protochylol and isopropyl arterenol with those of epinephrine and norepinephrine. Indeed, the larger *N*-substitution found in protochylol enhanced its potency to a value approximately twice that of isopropyl arterenol, the compound previously found to be the most potent mobilizer of FFA in this system (9). Methylation

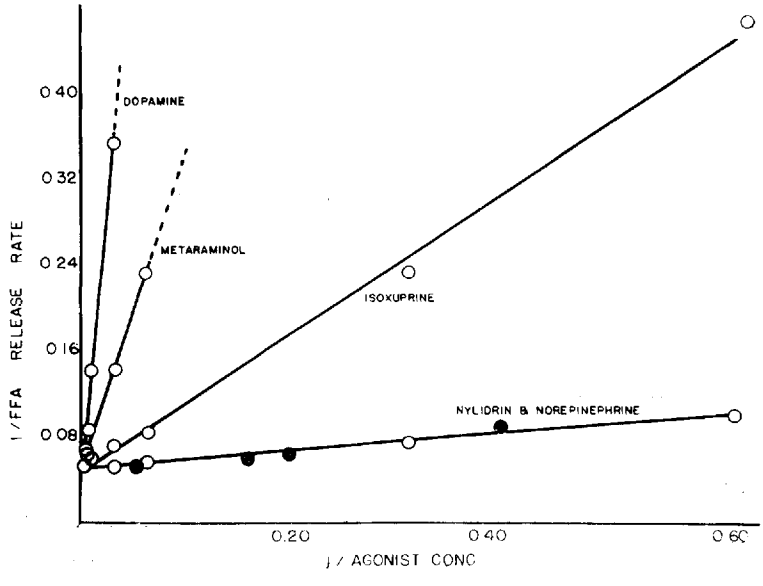

Fig. 2.—Double reciprocal plot illustrating effects of agonists on the rate of FFA release, *in vitro*. Concentrations of agonists were in terms of moles/L. × 10^{-7}.

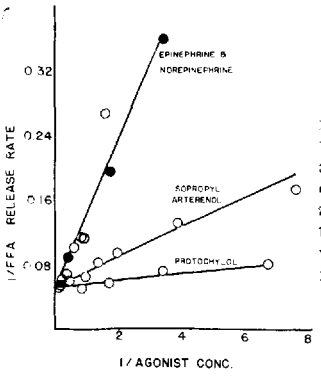

Fig. 3.—Double reciprocal plot illustrating effects of agonists on the rate of FFA release, *in vitro*. Concentrations of agonists were in terms of moles/L. $\times 10^{-7}$.

of the amino nitrogen did not, however, produce a statistically significant alteration in the dose-response relationship (compare epinephrine with norepinephrine).

The influence of *N*-substitution is also evident when one compares the dose-response relationships found for the noncatecholamines tested. Nylidrin, a compound lacking a catechol nucleus but possessing a rather large substituent on the side chain nitrogen, was found to be equipotent with epinephrine and norepinephrine while isoxuprine was found to be approximately one-fifth as potent as epinephrine or norepinephrine. The effect of this type of molecular alteration is also evident when comparing the dose-response relationships of nylidrin and isoxuprine with the other noncatecholamines shown in Fig. 1, namely metaraminol, phenylpropanolamine, and phenylephrine.

In contrast to the above-mentioned alterations in dose-response curves obtained by varying chemical structure, substitution on the α carbon of the side chain did not appear to alter biological activity in any significant manner.

Double Reciprocal Relationships.—The equation described by Ariens (11) relating the relative response of a tissue to an agonist and the concentration of agonist employed has been modified slightly to yield

$$R = \frac{(I)(A)}{Ka + A}$$

where R is the response of the tissue measured as the rate of FFA release/Gm. of tissue/hr., I is the intrinsic activity constant or maximal response obtainable at an infinity concentration of the agonist, A is the concentration of agonist employed, and Ka is the apparent dissociation constant of the agonist–receptor tissue complex. Placing the above expression in the double reciprocal form yields

$$1/R = (Ka/I)(1/A) + 1/I$$

[a] Intrinsic activity constant. [b] Compound shows properties of a dualist or partial agonist.

Plotting the data as $1/R$ *versus* $1/A$ yields a straight line with a slope numerically equal to Ka/I and an intercept of $1/I$. Analysis of the data in this manner provides an efficient means of calculating the intrinsic activity constant (I) and the affinity constant (the reciprocal of the apparent dissociation constant for the drug–receptor tissue complex, Ka) from the intercept and the slope of the line, respectively. The data obtained in this study and plotted in this manner are shown in Figs. 2 and 3. The data for norepinephrine have been included in both graphs for comparative purposes.

In Fig. 2, it is apparent from the steep slopes of the dopamine and metaraminol lines that these compounds are relatively weak agonists in this system as compared to isoxuprine, nylidrin, and norepinephrine. It is also apparent that all curves intercept the y-axis at a common point, indicating equal intrinsic activities.

In Fig. 3, a different scale for the x-axis was employed to permit the plotting of the data for the more active agonists in the double reciprocal manner. It is apparent in this graph that (*a*) the lines extrapolate to an intercept identical with that obtained in Fig. 2 indicating the same intrinsic activities for all compounds, and (*b*) in this system, the highest affinities were shown by protochylol and isopropyl arterenol, both compounds being clearly more potent than epinephrine and norepinephrine.

Structure–Activity Relationships.—The structure-activity relationships obtained in this study have been summarized in Table I. In this table, the intrinsic activity constants are expressed as ratios of the maximal response obtained with an agonist to the maximal response obtainable in the system (11), and the affinity constant is expressed as the pD_2 of Miller, Becker, and Tainter (12), defined as the negative logarithm of the agonist concentration required to produce a response equal to 50% of the maximal response obtainable in the system. These constants can be derived from either the dose-response relationships shown in Fig. 1 or from the intercept and slope value of the lines shown in Figs. 2 and 3. Inactive compounds have also been included in the table of data.

The data summarized in Table I indicate the effects structural modification of the basic phenethylamine structure had on the ability of the compounds to stimulate the mobilization of FFA from adipose tissue, *in vitro*. The parent compound, phenethylamine, was found to be completely inactive in this system, thus possessing zero intrinsic activity. Para-hydroxylation (tyramine), or α carbon methylation (amphetamine), did not increase activity to a measurable level, while β-carbon hydroxylation along with α-carbon methylation had variable results. (Compare the inactive ephedrine with the slightly active phenylpropanolamine.) Placing a hydroxyl function in the 3 position of the ring significantly increased FFA mobilizing activity (metaraminol). Ring hydroxylation in the *para* position coupled with N-substitution markedly enhanced FFA mobilizing activity (isoxuprine and nylidrin). The catechol nucleus appeared to confer optimal activity upon the molecule, however, as seen by the relatively high affinity constants possessed by these type compounds (epinephrine and norepinephrine). The affinity of the catecholamine can be enhanced, however, by N-substitution of large or bulky alkyl functions (isopropyl arterenol and protochylol) and diminished by removal of the β-hydroxyl group of the side chain (dopamine). Methylation of 3-OH group of epinephrine completely abolished FFA mobilizing activity (metanephrine).

CONCLUSION

It is concluded from these studies that (*a*) while the catechol nucleus appeared to confer optimal activity upon the agonist molecule, significant mobilization of FFA from rat epididymal fat tissue was achieved by monohydroxylated ring structures, (*b*) the hydroxyl function on the β carbon atom of the side chain played an important role in determining the affinity of the compound for the adipose tissue receptor system, (*c*) N-substitution of large alkyl functions greatly enhanced fat mobilizing activity, and (*d*) compounds whose action is mediated by release of endogenous catecholamines were not active in this system. Furthermore, from the information obtained in this study, it appears that both α- and β-type adrenergic stimulants are capable of stimulating the mobilization of FFA but that the β-type adrenergic stimulants are much more active in this regard than are the α stimulants.

Solubility Profiles for the Xanthines in Aqueous Alcoholic Mixtures I

Ethanol and Methanol

By A. N. PARUTA* and S. A. IRANI

The solubilities of caffeine, theophylline, and theobromine were determined in two binary mixtures as a function of the dielectric constant. The binary mixtures chosen were water and two *n*-alkyl alcohols, ethanol and methanol. The alcohol was chosen on the basis of the dielectric constant range produced so that various "cuts" along the solubility curve could be obtained. The dielectric requirements (DR's) found in these systems could then be matched with previous findings. The DR's found in this study correlate to a fair degree with past work; however, a consistent new peak at a dielectric constant of about 40 was also found. These systems were experimentally designed so that solubility could be expressed in various concentration notations as well as mole fraction.

THE SOLUBILITY profile for the xanthine drugs in dioxane–water mixtures in terms of dielectric requirements has been given previously (1). It also had been shown the dielectric requirements (DR's) for salicylic acid (2) were relatively constant for a diverse spectrum of binary mixtures and that the magnitude of solubility at a given DR varied widely.

In a continuing effort to investigate the relative constancy of DR's in various binary mixtures, the present study on the xanthines was undertaken. In this case, the solubilities of the xanthines were determined in mixtures of two semipolar, *n*-alkyl alcohols with water. The two alcohols, ethanol and methanol, were chosen on the basis of giving a desired dielectric constant range so that isolation and limitation of a given number of the total DR's found in dioxane–water could be accomplished. The main purpose of this work was to determine if the DR's found with alcohol–water mixtures were the same as the DR's found in dioxane–water mixtures.

It should be noted that caffeine contains one more methyl group than the other xanthines, theophylline and theobromine, which are positional isomers. In the dioxane–water system, it was found that the first three DR's for caffeine were about 3–4 dielectric constant units below the first three DR's for the other xanthines. Whether this difference is due to the chemical difference noted above or experimental variation is not really known. However, it has been assumed that the latter was true and the xanthines show approximately the same DR's in dioxane–water mixtures. Whereas previous data were presented only in a mg./ml. convention, the experimental system in this study was so designed through density measurements to allow for presentation of solubility in various concentration notations as well as mole fraction. It has been shown (3) that the DR's are concentration notation dependent and it was felt that these systems should be similarly treated.

EXPERIMENTAL

Solubility Determinations.—The protocol for solubility determinations has been described previously (4, 5). All runs were done at 25° and each of the three runs made were subjected to both spectrophotometric and gravimetric analysis. Internal averaging was performed and the results are reported for the three run average.

Materials.—Caffeine was obtained from Nepera Chemical Co., Inc., theophylline from Matheson, Coleman and Bell, 7094 TX450, and theobromine N.F. from Penick, lot NBT 4092. Ethanol was obtained from U. S. Industrial Chemical Corp., sealed absolute, methanol from Allied Chemical, reagent ACS code 1212. Distilled water was used throughout this study. All materials were used directly as supplied by the manufacturer.

Equipment.—A water bath and attendant controls were used as an equilibration environment at 25°. Twenty-four hours was the time allowed for equilibration. A Bausch & Lomb spectronic 505 was used for spectrophotometric analysis, and a vacuum desiccator was used to dry samples to constant weight.

RESULTS AND DISCUSSION

The solubility of caffeine at 25° in the various concentration notations given *versus* the dielectric constant of the binary mixtures studied is shown in Fig. 1.

In Figs. 2 and 3, the solubility of theophylline and theobromine at 25° in the mg./ml. of solution convention is illustrated as a function of the dielectric constant of the binary mixtures studied.

Since the solubility curves for theophylline and theobromine, in the mg./Gm. of solution and mole fraction conventions are analogous to those in Fig. 1 for caffeine they have been omitted from these figures. The variation of DR's with concentration notation has been summarized in Table II.

The DR's found for the xanthines in these alcohol–water mixtures have been summarized in Table I. The values of the DR's for the xanthines in dioxane–water mixtures are also shown in order to contrast the various binary mixtures used. For theobromine in the methanol–water system, a shoulder at a dielectric constant value of about 40 was not clear cut. Although slight shouldering can be seen at a dielectric constant value of about 38, the existence of this DR is questioned. There is some indication that shouldering occurs at a dielectric constant of about 42 on the mole fraction basis, but this also does not necessarily prove a DR existence with another concentration convention.

Although the DR's in these alcohol–water mixtures correlate well with the DR's previously found in dioxane–water mixtures (1), a new DR at a value of 42–44 was also found. No explanation for this new peak is given; however, were this peak to exist in dioxane–water mixtures, it would fall in the valley between the third and fourth DR's for these mixtures. It is possible that alcohol–water mixtures behave mechanistically different toward the xanthines, in so far as the extent of solvation and/or hydration is concerned relative to the cyclic ether, dioxane. This will be discussed in a latter portion of this communication.

These figures illustrate also a low degree of dielectric requirement sensitivity to concentration notation. A maximum change of about 2–5 dielectric constant units is found in going from the pharmaceutical convention to the mole fraction expression. The DR's found for the xanthines relative to concentration notation have been tabulated and summarized in Table II.

Since the solubility of the xanthines has been determined in several mixtures including dioxane–water mixtures (1), it was felt judicious to determine and compare the ratios of solubility of the xanthines to one another in each pure solvent and at the common dielectric requirements. It had been shown that the ratios of solubility for the xanthines (defining theobromine = 1) in dioxane–water mixtures at the DR's were closer to the ratios of solubility in water. This was felt to imply the importance of the aqueous hydration of the xanthines. The mag-

[a] See under *Results and Discussion.* This value of solubility was chosen at a dielectric constant of 40, although no shouldering was evidenced.

nitudes of solubility and solubility ratios have been summarized as shown in Table III.

These ratios have been plotted and are shown in Fig. 4. In the dioxane–water system, the ratios of solubility at the DR's found are seen to approximate the ratios in water. However, both the ethyl and methyl alcohol show different patterns. For theophylline, the ratios in going from pure water to pure ethanol or pure methanol increase linearly as the DR's decrease and approach the dielectric constant of the alcohol. For caffeine, the ratios in going from pure water to pure ethyl or methyl alcohol go through a maxima. Obviously, there is a potentiation effect for caffeine in the co-solvency of alcohol–water mixtures which does not occur with dioxane–water mixtures.

The linear increase for theophylline and the curve for caffeine may imply more effective and/or different hydration or solvation leading to the various hydrates or solvates having their own solubility characteristics. These effects may aid in explaining the multiplicity of peaks obtained in these co-

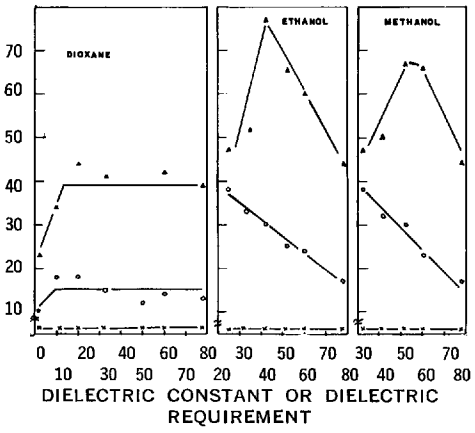

Fig. 4.—A plot of the solubility ratios (theobromine = 1) for the xanthines at the DR's found and in the pure solvents used. Key: ×, theobromine; O, theophylline; ▲, caffeine.

solvent mixtures and the newly observed peak at a dielectric constant value of about 40.

It was felt to be instructive to view these solubility curves from the point of view of co-solvency. Ideally, a co-solvent effect would deal with a solubility curve having only one maximum. In this case, co-solvency efficiency could be expressed as the ratio of the magnitude of solubility at the maximum to the magnitude of the solubility in either pure solvent.

Such, however, is not the case with the xanthines where a multiplicity of maxima occur. In order to determine the co-solvency efficiency of a given mixture, it would be necessary to determine the ratios of solubility at each dielectric requirement for a given xanthine relative to a pure solvent. Further, were one to compare the xanthines and solvent systems relative to one another, it would also be necessary to determine the co-solvency efficiency at each dielectric requirement relative to the pure solvent where the magnitude of solubility is the same, *i.e.*, water. In Table IV, the co-solvency efficiency for the xanthines in alcohol–water mixtures and dioxane–water mixtures is presented. The co-solvency efficiency has been defined as the solubility at a given dielectric requirement for each xanthine relative to the solubility in water for each xanthine. In other words, the co-solvency efficiency is the number of times the solubility of a given xanthine is increased over the solubility in pure water at a given dielectric requirement.

From inspection of Table IV, several approximate trends can be delineated. The efficiency of increasing solubility relative to water can be obtained for the solvent systems under consideration from Table IV. For a dielectric requirement of 30, common to dioxane–water and ethanol–water only, dioxane is seen to cause the greatest co-solvent effect. At a dielectric requirement of 40, common to ethanol–water and methanol–water mixtures, ethanol shows the largest co-solvent effect. At DR's of 50 and 60, common to all three solvent systems, ethanol has the highest efficiency at both values, whereas dioxane is better than methanol at DR 50 and slightly better than methanol at DR 60. Furthermore, at the common DR of 50 and 60, ethanol and methanol discriminate the xanthines to a larger extent. For example, at a DR of 50, the solubility ratios for the xanthines vary about 0.3 in dioxane–water mixtures, about 1.0 in ethanol–water mixtures, and 1.1 in methanol–water mixtures. This also indicates that dioxane increases the solubility of the xanthines to about the same extent at a given DR, whereas both ethanol and methanol increase the solubility to varying extents at a given DR.

As can be seen, as the dielectric constant of the second component (alcohol, dioxane) increases, the greatest co-solvency efficiency occurs at higher dielectric requirement values. In the dioxane–water system, the maximum co-solvency effect ($C.E._{max.}$) for the xanthines is seen to occur in the dielectric constant range of 20–30. By defining a term $DR_{max.}$, the dielectric constant of maximum co-solvency and taking the difference between this value and the dielectric constant of the second component, values of $DR_{max.} - \epsilon_2$ can be obtained. These values are simply the number of dielectric constant units above the dielectric constant of the second component where co-solvency efficiency is maximized. By taking the average $C.E._{max.}$ for the three xanthines in a given solvent system, values for $DR_{max.} - \epsilon_2$ are determined as shown in Table V.

It is obvious that for each of these systems, the average co-solvency efficiency is maximized at a dielectric constant value of 21–23 units greater than the dielectric constant of the pure second component. Furthermore, as the $DR_{max.}$ increases in value with an increase in the dielectric constant of the second component, the $DR_{max.}$ value gets closer and closer to the dielectric constant of the common component of these solvent systems, *i.e.*,

TABLE IV.—SUMMARY OF THE CO-SOLVENT EFFICIENCY [SOLUBILITY (DR, mg./ml.)/(WATER mg./ml.)] FOR THE XANTHINES IN VARIOUS BINARY MIXTURES

System	DR 11–14	DR 20–22	DR 30–34	DR 41–43	DR 50–55	DR 58–61	Substance

water. Of course, these values should have different magnitudes, shown in column four, but they are proportionately related to the dielectric constant of the second component. Interesting enough, the average $DR_{max.}$ in methanol–water mixtures is equidistant between the dielectric constants of the pure components. It would be of more interest to view the xanthines in a comparative sense since in the xanthine drugs there exists a chemical difference (for caffeine) and theophylline and theobromine are positional isomers. Each xanthine in the three solvent systems under consideration can be handled separately relative to the dielectric constant of maximum co-solvency. In this case, the exact value of the DR (Table I) at maximum co-solvency has been used or when the co-solvency efficiency was equal at 2 DR's, an average value of the exact DR was used. Thus, the $DR_{max.} - \epsilon_2$ for each xanthine in the solvent systems used have been summarized in Table VI.

In order to illustrate the variation of $DR_{max.} - \epsilon_2$ found for the xanthines, a composite figure is given (Fig. 5) of the solubility of each xanthine in mg./ml. for ethanol–water mixtures.

Although caffeine on an individual basis is the same as the average value, *i.e.*, 21–23, theophylline falls below the average range, while theobromine falls above the average range. Furthermore, the variation of theophylline and theobromine from the average value is about the same, theophylline being 3–4 units below the average, whereas theobromine is 3–4 units above the average. The order of the xanthines with respect to the increasing magnitude of $DR_{max.} - \epsilon_2$ is theophylline, 18 < caffeine, 22 < theobromine, 25. As has been noted previously, the magnitude of the co-solvency efficiency (Table IV) for theophylline was equal to or greater than that of either caffeine or theobromine in the solvent systems studied.

The DR's obtained in this study for the xanthines in alcohol–water mixtures showed good correlation with the DR's obtained previously with dioxane–water mixtures. A consistent new peak at a dielectric constant of about 40 was also found for these alcohol–water mixtures. In this regard, the solubilities of the xanthines are being determined in a glycol ether (ethylcellosolve)–water mixtures to see if the DR of 40 is unique to the alcohols.

The xanthines show a low degree of DR sensitivity to concentration notation for the alcohol–water mixtures.

The solubility ratios, defining theobromine as unity, in the pure solvents and at the dielectric requirements found showed a linear trend for theophylline and a curve having a maxima for caffeine.

The co-solvency efficiency, defined as the ratio of the magnitude of solubility at a given DR to the magnitude of solubility in water, showed maximum efficiency on the average at about 20 dielectric constant units above the dielectric constant of the pure second component. For the individual xanthines, the $DR_{max.} - \epsilon_2$ was seen to be in the order, theophylline < caffeine < theobromine; however, the co-solvent efficiency for theophylline was equal to or greater than either caffeine or theobromine in all the solvent systems studied. This would imply that the solubility of theophylline is affected to a greater degree in contrast to caffeine or theobromine and the dielectric constant of maximum co-solvency may lie closer to the dielectric constant of the pure second component.

The solubilities of the xanthines are being studied in ethylcellosolve–water mixtures relative to the above points and the authors' results will be the subject of future communications.

Solubility Profiles for the Xanthines in Aqueous Solutions of a Glycol Ether II

Ethyl Cellosolve

By ANTHONY N. PARUTA* and SHAPUR A. IRANI

The solubilities of the xanthines were determined in ethyl cellosolve–water mixtures as a function of the dielectric constant of these solvent mixtures. This mixture of a glycol ether with water was chosen in order to contrast the dielectric requirements found with those observed in alcohol–water and dioxane–water mixtures. The dielectric requirements found for the ethyl cellosolve–water system correlate to a good degree with previous findings. A dielectric requirement of 40 was also found which was not found in dioxane–water mixtures but was present in the alcohol–water mixtures. These systems were experimentally designed so that solubility curves could be expressed in various concentration notations as well as mole fraction.

IN A CONTINUING effort of investigating the relative consistency of dielectric requirements (DR's) for a given solute(s) in various binary mixtures (1–3), the present study was undertaken. The dielectric requirement is defined as the dielectric constant of maximum solubility in a given solvent mixture.

It had been found (2, 3) that the DR's for the xanthines in aqueous mixtures of a cyclic ether, dioxane, and normal alkyl alcohols, ethanol and methanol, were fairly consistent; however, in the aqueous alcoholic systems a new peak at a DR of about 40 was also found. It was felt important to see if this new peak at a value of 40 could be found in another aqueous mixture with a semipolar solvent. In this case, a glycol ether was chosen considering this to be sufficiently different in nature from a cyclic ether and a normal alcohol. The solvent chosen was ethyl cellosolve since it had a dielectric constant intermediate between dioxane and the alcohols and also had the property of being infinitely soluble in water. The dielectric constant range produced by these mixtures would be about 15–78, and it was expected that this range should accommodate 4 of the 5 DR's found in dioxane–water mixtures having values of about 20, 30, 50, and 60.

These systems were experimentally designed through density measurements so that solubility could be expressed in various concentration notations as well as mole fraction. It had been shown that the observed DR's are concentration notation dependent (3) and it was felt that these systems should be similarly treated.

EXPERIMENTAL

Solubility Determination.—The protocol for solubility determinations has been described previously (1–3). All runs were done at 25°, and each of the three runs performed was subjected to both spectrophotometric and gravimetric analysis. Internal averaging was done for each run, and the results reported are for the three-run average.

Materials.—Caffeine was obtained from Nepera Chemical Co., theophylline from Matheson, Coleman and Bell, 7094Tx450, and theobromine N.F. from Penick, lot NBT 4092. Ethyl cellosolve was obtained from Union Carbide, 5753753. Distilled water was used throughout this study. All materials were used directly as supplied by the manufacturer.

Equipment.—A water bath with attendant controls was used as an equilibration environment at 25°. Twenty-four hours was the time allowed and found sufficient for equilibration. A Bausch & Lomb Spectronic 505 was used for spectrophotometric analysis and a vacuum desiccator was used to dry samples to constant weight.

RESULTS AND DISCUSSION

The solubility of caffeine in the various concentration conventions noted *versus* the dielectric constant of ethyl cellosolve–water mixtures is shown in Fig. 1. The concentration notation of mg./Gm. of solvent has been omitted from this figure and subsequent figures since the solubility curve coincides very closely to the mg./Gm. of solution solubility curve. In Figs. 2 and 3, the solubility of theophylline and theobromine plotted in the usual fashion are shown.

The DR's observed in the ethyl cellosolve–water system for the xanthines have average values of about 30, 40, 48, and 60. The DR's in ethyl cellosolve–water mixtures and dioxane–water mixtures (2) have been summarized in Table I. The DR of 40, which was observed in alcohol–water mixtures (3), was also found in ethyl cellosolve–water mixtures; however, this DR of 40 was not found in the dioxane–water system. Thus, this new DR is not unique to alcohol–water mixtures since it has also been found in ethyl cellosolve–water mixtures. To illustrate this point, a composite figure has been prepared showing the solubility

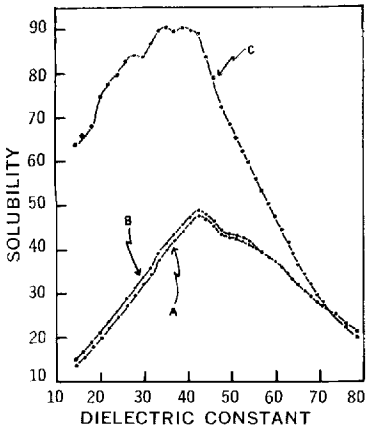

Fig. 1.—A plot of the solubility of caffeine at 25° *vs.* the dielectric constants of ethyl cellosolve–water mixtures. Key: A, solubility expressed as mg./ml.; B, solubility expressed as mg./Gm. of solution; solubility expressed as mole fraction (m.f. $\times 10^4$).

curves on a mg./ml. basis for caffeine in the four binary solvent systems studied. This is shown in Fig. 4. In the case of dioxane–water mixtures, a dielectric constant of 40 is seen to fall in a valley between the third and fourth DR's for this system. If a peak or shoulder does exist at about this value it would be, at best, difficult "to see" due to the nature of the curve and the inherent experimental variation involved. This figure also reveals another interesting point. At a dielectric requirement of 30, common to three binary mixtures, dioxane–water mixtures produce a strong peak, whereas both ethanol–water and cellosolve–water mixtures produce only a weak shouldering effect. At a dielectric constant of about 50, common to all four binary mixtures, aqueous dioxane and aqueous methanol produce definite peaks; whereas, aqueous cellosolve and aqueous ethanol again produce a shouldering effect.

There is a probablility that various hydrates/solvates (2), each with its own solubility characteristics, cause these complex individually overlapping solubility curves. It was thought that the production of a new peak (DR) in a given system would

TABLE II.—SUMMARY OF FIRST OR EXPECTED DR FOR XANTHINES IN BINARY MIXTURES STUDIED[a]

Systems	ϵ_2	DR	DR − ϵ_2	Peak or Shoulder Observed
Dioxane–water	2.2	13	10.8	Yes
Ethanol–water	24.3	34.5	10.2	Yes
Methanol–water	32.4	42.0	9.6	Yes
Ethyl cellosolve–water	14.5	20.7[b]	6.2	No

[a] Data from *References 2* and *3*. [b] Expected DR of about 20–22 found in dioxane–water mixtures.

be possible at the expense of DR's close to this new value. In other words, a given species could exist in two different solvent mixtures, depending on the composition of the mixtures and each component's contribution to the solvated state of that species. This does not seem to be the case in alcohol–water or cellosolve–water mixtures. Although a new DR of about 40 is found, the DR's of about 30 and 50 are also present which indicate that the DR of 40 is not a mixture of the two DR's surrounding it. However, it can also be seen that the strong peak at a DR of 30 in dioxane–water is reduced to a slight shouldering effect in aqueous ethanol and aqueous ethyl cellosolve. It would seem that this is partially due to the dielectric constant range of the solvent system chosen. The co-solvency efficiency has been discussed previously (3) and will be further elucidated in a latter portion of this communication.

Table I also shows that a DR of about 20 found in dioxane–water mixtures was not found in ethyl cellosolve–water mixtures. The dielectric constant range of aqueous cellosolve, *i.e.*, 14.5–78, certainly encompasses a dielectric constant of 20, but the solubility curves did not indicate any peaks or shoulders in this dielectric constant area. Upon re-examination of the data for the four binary mixtures studied, it was noted that the first DR observed starting from the second or semipolar component was a certain number of dielectric constant units above the value for the second component. Table II summarizes the first average DR found or expected and the difference between this value and the dielectric constant of the second component.

It is apparent that the first or expected DR resides at a definite value above the dielectric constant of the second component. The DR observed for the first three binary mixtures is seen to be about 10–11

Theobromine	1	1	1	1	1	1

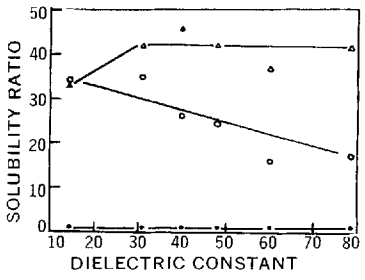

Fig. 5.—A plot of the solubility ratios for theophylline and caffeine relative to theobromine (unity) in each pure solvent and at the common dielectric requirements. Key: ●, theobromine; ○, theophylline; ▲, caffeine.

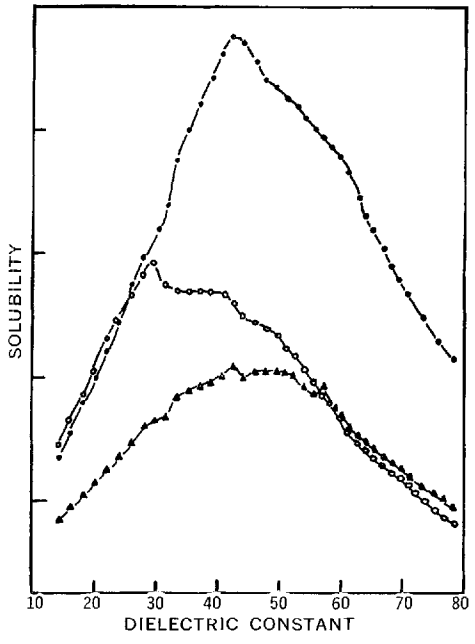

Fig. 6.—A plot of the solubility curves for caffeine (●), theophylline (○), and theobromine (▲) *vs.* the dielectric constants of ethyl cellosolve–water mixtures. The solubility scale does not describe magnitude since only the nature of the curves is being compared.

units above ϵ_2. Thus, a peak or shoulder may not be found unless the second component has a dielectric constant about 10–11 units below the expected DR. This approximate value of 10–11 units is, of course, only operative for the range and systems studied, and may only apply for the solutes under consideration.

It is interesting to note in this regard, that the suspected shouldering for theobromine at a dielectric constant of 38 in methanol–water mixtures (3) resides only 5.6 dielectric constant units above ϵ_2 and this probably indicates it cannot be seen.

Since there can be a variation of 3–4 dielectric constant units (2) in any given DR for these solutes, it is possible that theobromine falls below this approximate difference (DR $-$ ϵ_2) of 10–11 units. The very low solubility of theobromine also mitigates easily detecting shouldering in the solubility curve.

It has previously been shown (3) that the value of the DR was sensitive to concentration notation. In the case of succinic acid, there was greater DR sensitivity for dioxane (mol. wt. = 88) than for ethanol (mol. wt. = 46) in going from the pharmaceutical convention to mole fraction. For the xanthines (3), it was shown there was low DR sensitivity to methanol (mol. wt. = 32) and ethanol (mol. wt. = 46). In Figs. 1–3, it can be seen that there is high DR sensitivity for caffeine and theophylline, but low sensitivity for theobromine. It is felt that the very low solubility of theobromine and very small incremental changes of solubility with varying composition damps the possible shifting with a high molecular weight solvent such as cellosolve (mol. wt. = 90). This could also possibly account for the new DR at a value of 25, since a small deviation of a given value from a smooth curve could produce a shoulder or peak depending on the magnitude of the deviation. Assuming caffeine and theophylline to be typical, it would seem that DR sensitivity to various concentration notations depends upon the molecular weight of the second component. Since water is the other component common to all these binary mixtures, DR sensitivity to concentration notation would also depend upon the difference in molecular weight of the two components used.

The DR's found for the xanthines in ethyl cellosolve–water mixtures in the various concentration notations used are summarized in Table III.

Since the DR's found for the xanthines were relatively constant, it was felt that these solubility curves might be parallel to one another, indicating proportionality of the magnitude of solubility. Consequently, the ratios of the solubilities in each pure solvent and at the common DR's were taken defining the solubility of theobromine as unity. The solubility of the xanthines in mg./ml. for each pure solvent and at the common DR's and the solubility ratios have been summarized in Table IV. Previous results (2) indicated that the ratios in dioxane–water mixtures were closer to the solubility ratios in pure water, and this was felt to imply the importance of aqueous solvation. Other results (3) for the xanthines in aqueous methanol and aqueous ethanol showed a potentiated effect for caffeine and a linear rise for theophylline in going from the solubility ratios in pure water to pure ethanol and methanol. The solubility ratios in ethyl cellosolve–water mixtures have been calculated and are presented in Fig. 5. In this case, it can be seen that the solubility ratios for theophylline rise approximately linear going toward pure ethyl cellosolve and are similar to the results observed in alcohol–water mixtures. On the other hand, the solubility ratios for caffeine are close to the ratios in pure water, being similar to the results observed in dioxane–water mixtures. This would indicate that each of the xanthines interacts differently with the second component in terms of the nature of the hydrate/solvate formed.

In order to visualize the above, a composite figure has been prepared in which the solubility of the xanthines in mg./ml. has been plotted *versus* the dielectric constants of ethyl cellosolve–water mixtures (Fig. 6). Several things can be noted in this

TABLE V.—SUMMARY OF CO-SOLVENCY EFFICIENCY [SOLUBILITY, mg./ml., DR_x/SOLUBILITY, mg./ml., WATER] FOR XANTHINES IN ETHYL CELLOSOLVE–WATER MIXTURES AT COMMON DR'S FOUND

System	DR 30	DR 40	DR 50	DR 60	Substance
Ethyl cellosolve–	1.63	2.23	2.00	1.67	Caffeine
water	3.49	3.25	3.01	1.93	Theophylline
	1.68	2.08	2.04	1.92	Theobromine

TABLE VI.—SUMMARY OF DIFFERENCE OF MAXIMUM CO-SOLVENT EFFICIENCY ($DR_{max.}$) AND DIELECTRIC CONSTANT OF THE SECOND COMPONENT (ϵ_2) FOR INDIVIDUAL XANTHINES IN ETHYL CELLOSOLVE–WATER AND OTHER MIXTURES[a]

Substance	Ethyl Cellosolve $DR_{max.} - \epsilon_2$	$DR_{max.} - \epsilon_2$[a]
Caffeine	28	22–23
Theophylline	16	17–20
Theobromine	28	24–26

[a] Data from *Reference 3.*

figure. Theophylline shows a strong peak at a DR of 30, whereas both caffeine and theobromine indicate slight shouldering effects. Caffeine at a DR of 42 shows a peak and at a DR of 60 a shoulder in the solubility curve. However, theobromine shows weak peaks at both DR's of about 42 and 60. Variations of this type lead into a consideration of co-solvency efficiency. The co-solvency efficiency is defined as the solubility at a given dielectric requirement relative to the solubility in water for a given solute. In other words, the co-solvency efficiency is the number of times the solubility of a given solute is increased over the solubility in pure water at a given dielectric requirement. This term has been defined previously (3) and it was found that for previous systems studied the dielectric constant of average maximum co-solvency for the xanthines occurred at 21–23 units above the dielectric constant of the second component, ϵ_2. Furthermore, it was also found that on an individual basis for each xanthine, caffeine fell in the average of 21–23 units while theophylline fell below, *i.e.*, 17–20, and theobromine was above the average, *i.e.*, 24–26. The co-solvency efficiencies have been tabulated and are given in Table V. The values of $DR_{max.} - \epsilon_2$ on an individual basis for each xanthine in ethyl cellosolve–water mixtures have been summarized in Table VI. The values obtained for the previous binary mixtures studied (3) have been included to contrast the xanthines on an individual basis. It can be seen that both caffeine and theobromine deviate from the values found previously, but theophylline is about the same relative to $DR_{max.} - \epsilon_2$ in ethyl cellosolve–water mixtures.

Several things can be noted here; first, the magnitude of solubility of theophylline in pure ethyl cellosolve (Table IV) is higher than the solubility of caffeine. This is the first time that this reverse order has been found in the solvents studied. Normally, the order of solubility is caffeine > theophylline > theobromine. Second, the co-solvency efficiency of the present solvent system toward theophylline is greater than either caffeine or theobromine at the maximum, and this has been noted previously (2, 3) in dioxane–water and alcohol–water mixtures. The solubility ratios (Fig. 5) also indicated a mixed pattern for ethyl cellosolve–water mixtures relative to the patterns found in previous mixtures.

Although there seems to be a generally patternized response for the xanthines in diverse binary mixtures, more studies should be conducted to resolve many of the points brought out in these communications.

Some of the points intended for future study would include the possible dependency of DR's on the nature, type, and dielectric constant span produced by the second or semipolar component.

It may also be judicious to investigate the nature of the xanthine species involved when at common DR's a strong peak or weak shoulder is produced.

SUMMARY

The DR's obtained in this study for the xanthines in ethyl cellosolve–water mixtures showed good correlation with the DR's found in alcohol–water mixtures (3) and dioxane–water mixtures (2) except the former two systems showed a consistent new peak at a DR of about 40. The expected DR at a value of 20 was not found in ethyl cellosolve–water mixtures and this was felt to be due to the closeness of the expected DR to the ϵ_2 (Table II).

The xanthines, at least caffeine and theophylline, showed a high DR sensitivity to concentration notation and this is felt to be due to the high molecular weight of the second component.

The solubility ratios, defining theobromine as unity, showed a pattern for caffeine similar to that found with dioxane–water mixtures, whereas theophylline showed a pattern similar to that found with alcohol–water mixtures but dissimilar to that found in dioxane–water mixtures. The co-solvency efficiency and the $DR_{max.} - \epsilon_2$ showed relative consistency relative to order and magnitude.

In aqueous dioxane and aqueous alcohol (2, 3), the difference $DR_{max.} - \epsilon_2$ was 17–20 units for theophylline, whereas the difference in ethyl cellosolve–water mixtures was about 16 units.

For caffeine and theobromine (2, 3), the range of $DR_{max.} - \epsilon_2$ in the former mixtures was 22–23 and 24–26 units, respectively. In ethyl cellosolve–water mixtures $DR_{max.} - \epsilon_2$ for caffeine and theobromine were about 28 units. The order of $DR_{max.} - \epsilon_2$ in the solvent system studied were found to be theophylline < caffeine ≤ theobromine. The higher maximum co-solvency efficiency for theophylline in all these solvent systems (3) is relatively consistent, the order being theophylline > caffeine > theobromine except in ethanol where theophylline ≈ caffeine.

Mechanism of Action of Starch as a Disintegrating Agent in Aspirin Tablets

By NATUBHAI R. PATEL* and RAYMOND E. HOPPONEN†

A study was made of the mechanisms by which starch may cause disintegration of tablets. Dried cornstarch was found to increase in volume by 78 per cent when suspended in water. In aspirin tablets where contact of starch grains is continuous in the interparticle spaces, disintegration is rapid and effective even when void spaces are eliminated. Where contact is not continuous, disintegration is slowed and appears to depend on the degree of contact between starch grains and aspirin particles and on the size of interparticle spaces. The primary mechanism appears to be a swelling action. Capillarity *per se* does not appear to have a disintegrating effect.

STARCH IS widely used as a disintegrating agent in tablets. It has been generally accepted that it acts as a disintegrating agent through a swelling action when exposed to water (1). Crisafi and Becker (2) have demonstrated that starch will absorb about 20% of its weight of water in 24 hr. when exposed to an atmosphere of 95% relative humidity at 27°. They make no mention of any volume changes involved in the process. Kerr (3), in his book on starch, states that in the natural state starch is insoluble in cold water but appears to absorb 25 to 30% and does not swell appreciably. Curlin (4) has suggested that the disintegrating effect is due to capillary action rather than swelling. The objective of this study was to investigate the mechanism by which starch functions as a tablet disintegrating agent.

EXPERIMENTAL

Swelling of Starch in Water.—Cornstarch (Argo brand) dried for 2 hr. at 110° was measured microscopically using a calibrated eye piece. Measurements were made along the longest dimension of the grain using high power (10× eyepiece and 45× objective). Slight adjustments of focus were made to get the sharpest image. Two-hundred grains were measured for each sample. Slides made of dry starch without a suspending medium gave an arithmetic mean diameter of 9.0 μ and a mean volume diameter of 10.8 μ. A light liquid petrolatum suspension gave values of 9.1 and 10.5 μ, respectively. When suspended in water at room temperature (23°), the arithmetic mean diameter increased within a few seconds to 11.2 μ, the mean volume diameter to 13.1 μ. The differences are statistically significant at the $P = 0.01$ level using the t test. Using the mean volume diameter and assuming a spherical shape, the increase in volume was calculated to be 78% of the original.

Mode of Disintegration of Tablets Containing Starch.—To eliminate variables other than the disintegrating agent, aspirin was chosen as the material for tableting. It was desired to note the effect of different sized spacings between the tablet particles on the mode and rate of disintegration and to eliminate as much as possible other spaces within the tablet. To this end, aspirin powder (U.S.P. grade, Merck) was recrystallized from acetone. The crystals were dried at 90° and screened into several sizes using a Fisher Ro-Tap sifter and standard screens (Tyler series). The crystal sizes were designated as $^{14}/_{20}$ (all crystals passing a No. 14 screen but not a No. 20), $^{20}/_{40}$, $^{40}/_{60}$, $^{60}/_{100}$, and below 100 (all crystals passing a No. 100 screen. The starch was dried at 110° for 2 hr. and stored in a tightly closed container until used. Tablets were compressed on a Colton model 3E single punch tablet press using concave 8.8-mm. punches. The material for each tablet (0.5 Gm.) was weighed out, placed manually in the die, and the machine turned slowly by hand to produce as much uniformity as possible in the tablets. The finished tablets were individually weighed and the thickness measured with a vernier caliper to insure uniformity in dimensions. Disintegration times were determined in a U.S.P.-type apparatus at 20 c.p.m. using distilled water at 23° and a No. 10 mesh screen on the bottom of the basket. Table I reports the results on aspirin tablets containing 10% by weight of starch. The results represent the averages obtained on 7 tablets at each crystal size.

The manner of disintegration changed between the $^{40}/_{60}$ and the $^{60}/_{100}$ tablets. The $^{14}/_{20}$, $^{20}/_{40}$, and $^{40}/_{60}$ tablets fell apart rapidly into a mass of crystals. The $^{60}/_{100}$ and below 100 tablets showed a progressive disintegration from all sides and a steadily shrinking core.

Samples of the tablets were examined microscopically to note the manner of distribution of starch. Transverse sections were made and scraped smooth with a razor blade. The sections were stained with iodine solution and examined after drying. The $^{14}/_{20}$ tablets showed a heavy concentration of starch grains in all the channels between the aspirin crystals. The $^{20}/_{40}$ and $^{40}/_{60}$ tablets showed a similar pattern but with decreasing amounts of starch in the channels. The $^{60}/_{100}$

tablets displayed lines of starch granules around each crystal with many discontinuities where no starch was visible. In the below-100 tablets, starch grains were scattered in small groups among the aspirin crystals with few continuities in the channels.

Since the disintegration times of the tablets containing 10% starch were so short, a series was prepared with only 5% starch. Two additional crystal size designations were made, $^{100}/_{250}$ and below 250. The tablets were prepared in the same manner as previously. The screen on the disintegrating apparatus was replaced with a No. 6 screen to facilitate passage of the larger size crystals. The results, reported in Table II, represent the average disintegration times for five tablets.

The $^{14}/_{20}$ and $^{20}/_{40}$ tablets separated rapidly into large particles. The $^{40}/_{60}$ and $^{60}/_{100}$ tablets slowly broke up into large fragments which then disintegrated into crystals. The $^{100}/_{250}$ tablets separated in slices from the faces to the center, the slices then separating into granules. The below-250 tablets were not affected for some time, then separated into slices from the faces toward the center. The slices slowly separated into granules. Microscopic examination of the tablets revealed that the starch channels were continuous only in the $^{14}/_{20}$ and $^{20}/_{40}$ tablets.

TABLE I.—DISINTEGRATION TIMES OF ASPIRIN TABLETS CONTAINING 10% STARCH

Crystal Size	Time, sec.
$^{14}/_{20}$	60[a]
$^{20}/_{40}$	24[a]
$^{40}/_{60}$	12
$^{60}/_{100}$	18[b]
Below 100	35[b]

[a] The tablets fell into large particles in less than 10 sec. However, the particles passed the screen very slowly; thus, the recorded times are not a true measure of the time for the tablet to lose its shape and identity. [b] The tablets disintegrated toward the center from all sides retaining their shape during disintegration. The time indicated essentially marks the time of disintegration of the last of the tablet core.

TABLE II.—DISINTEGRATION TIMES FOR ASPIRIN TABLETS CONTAINING 5% STARCH

Crystal Size	Time, sec.
$^{14}/_{20}$	17
$^{20}/_{40}$	17
$^{40}/_{60}$	55
$^{60}/_{100}$	50
$^{100}/_{250}$	120
Below 250	>900

Penetration of Water into Tablets.—The change of the mode of disintegration of tablets containing 10% starch from the $^{40}/_{60}$ to the $^{60}/_{100}$ tablets and the appearance of discontinuities in the pattern of starch distribution in the $^{60}/_{100}$ tablets suggests a relationship between the two. Conceivably, the change in disintegration could be due to a change in the facility or the degree of penetration of water into the tablet. Samples of each crystal size group of the tablets were tested to determine to what extent water would penetrate into the tablet in a given time period. A series of flat-faced tablets with 10% starch were prepared for this purpose. The thickness of each tablet was measured with a vernier caliper. A 0.05-ml. drop of iodine solution, containing 50% alcohol to retard swelling of the starch, was placed in the center of a small watch glass coated with liquid paraffin to prevent spreading of the drop. The tablet was placed in contact with the drop and penetration allowed to proceed for 10 sec. The tablet was removed, blotted dry, and allowed to dry at room temperature. It was then carefully shaved with a razor blade to remove the colored portion, and the thickness of the remainder measured. The tablets showed the following per cent of penetration: $^{14}/_{20}$, 49%; $^{20}/_{40}$, 38%; $^{40}/_{60}$, 38%; $^{60}/_{100}$, 22%; and below 100, 9%.

Effect of Capillarity Alone.—To determine the effect of capillarity without expansion as a disintegrating effect, tablets of aspirin and dextrose were prepared and tested for disintegration time. Dextrose was chosen because it is a highly water-soluble material with a strong attraction for water. It has a chemical structure closely related to that of starch. It should be able to draw water into the spaces between the hydrophilic aspirin crystals without any concomitant swelling. Powdered dextrose (U.S.P. anhydrous, Mallinckrodt) was passed through a No. 80 screen and added in 10% concentration to $^{40}/_{60}$ aspirin crystals. Compression into 0.5-Gm. tablets was done with 8.8-mm. flat-faced punches. The material for each tablet was individually weighed and 5 series of tablets of increasing hardness were prepared by lowering the position of the upper punch for each succeeding series. When subjected to a disintegration test they showed the following disintegration times (average of four tablets): 140, 130, 191, 210, and 253 sec. The mode of disintegration in this case appeared to be a loss of cohesiveness of the tablet as the dextrose dissolved. The tablets gradually eroded away as fragments separated from the outer sides. The fragments for the most part were of the size of the aspirin crystals used. It appeared that the crystals simply fell away as the dextrose layer dissolved. There were no indications that disintegrating forces were acting in the interior of the tablet. A drop of

TABLE III.—VOID SPACES IN FLAT-FACED TABLETS OF ASPIRIN CONTAINING 5% STARCH

dilute aqueous gentian violet solution placed on the surface of these tablets penetrated approximately 50% of all tablets in 4 min., except the softest in the series which was completely penetrated in less than 2 min.

The effect of capillarity was further checked by the use of aluminum hydroxide tablets. Aluminum hydroxide powder (dried gel, Reheis) was made into granules by slugging. Preparation of slugs in the usual manner was not possible because jamming of the machine occurred. Individual slugs were prepared by manually placing the aluminum hydroxide in the die and turning the machine by hand. Before preparing each slug, the punches and the die were lightly lubricated with magnesium stearate applied with a camel hair brush. The slugs were crushed and screened into granules of three sizes, $^{14}/_{20}$, $^{20}/_{60}$, and below 60. When compressed into tablets with 10% starch and tested, they disintegrated in times of 8, 18, and 20 sec., respectively. Microscopic examination of the tablets stained with iodine solution showed the distribution of starch to be continuous around the aluminum hydroxide particles. When placed in 95% ethanol, where penetration of solvent can still occur but no swelling of starch results, the tablets did not disintegrate. The penetration of the tablets by ethanol was checked by the same procedure as used to determine the penetration of aspirin tablets by an iodine solution. A measured drop of an ethanolic solution of iodine was used. In 10 sec. it penetrated the tablets to an average depth of 50% of the total thickness. This would seem to indicate that swelling is a necessary condition for disintegration but does not entirely eliminate the possibility of capillarity as a disintegrating force. The surface tension of ethanol is only about one-third that of water. In its simplest terms, the pressure produced by capillarity can be equated to $2\ \gamma/r$, where γ is the surface tension of the liquid, and r is the radius of the capillary. The difference in surface tensions of ethanol and water could very well be sufficient to prevent any capillary effect from being noted. The search for a liquid with a surface tension near that of water, capable of wetting starch, and not able to dissolve aspirin too readily nor too rapidly, suggested glycerin. It has a surface tension of 63 dynes/cm. compared to a value of 73 for water (5). It did not cause disintegration of $^{20}/_{40}$-aspirin tablets containing 10% starch even after 12 hr. of contact. The penetration of glycerin into the interior of the tablets was checked to insure that it did occur. A drop of glycerin (the volume was not measured because the viscosity makes such measurement almost meaningless) containing 0.6% iodine was placed on the surface of flat-faced $^{20}/_{40}$ tablets. It penetrated to an average depth of 30% in 2 min. These results again suggest that capillarity does not constitute a disintegrating force in this situation.

Relation of Void Space to Disintegration Time.—Since the volume of starch increased in water, the authors felt it would be of interest to investigate the relationship of the volume increase and the void-space volume of the tablets. In order to measure the volume, 8.8-mm. flat-faced punches were used to prepare the tablets. The dimensions of the tablets were measured with a vernier caliper. The densities of the aspirin crystals and of the starch were determined by the pycnometer method (6) using petroleum ether as the liquid. At 20° the density of aspirin was found to be 1.396 Gm./ml., that of starch 1.513 Gm./ml. Void spaces were determined as the difference between the volume calculated from the dimensions of the tablet and the volume of the tablet solids calculated from their densities.[1]

Table IV.—Influence of Compression Force on Void Space and Disintegration Time of Aspirin Tablets Containing 10% Starch

Pressure, lb./sq. in.	Void Space, %	Time, sec.

15000	0.46	10	60

Tablets prepared from equal weights of different sizes of crystals and compressed to an equal volume should exhibit the same amount of void space, although the size of individual pores may differ substantially. A good uniformity of void volume was found in such a series prepared with 5% starch. The results are reported in Table III representing the averages of four tablets in each group.

Since the void volumes are substantially the same, the size of the openings between particles must get smaller as the crystal sizes get smaller and the number of crystals per tablet increases. This would lead either to the presence of interparticle spaces too small to permit ready entry of water or to discontinuities between starch grains in the spaces. Either circumstance would explain the longer disintegration time and the change in mode of disintegration for tablets of small crystal size.

The average volume of starch in the tablets was 0.00984 ml. which on swelling by the 78% indicated in water suspension would increase by 0.00768 ml. The increase is less than the void volume but, since disintegration requires only that the aspirin

[1] The void space calculated in this manner may not accurately represent the spaces between crystals since crushing of crystals during compression may lead to formation of new spaces in which no starch will be found. However, it will represent a good first approximation of the space into which water can penetrate.

particles be forced apart from each other, the effect could be exerted by starch grains properly located between aspirin particles even though empty spaces remained in the tablet structure. This suggests that an optimum ratio of starch volume to void space may exist at which disintegration would be most effective. In an attempt to find such a ratio, a series of tablets was prepared using 10% starch and $^{40}/_{60}$ aspirin crystals. Flat-faced tablets were prepared using a Carver hydraulic laboratory press to supply the compression force. The material for each tablet was individually weighed, placed in the die, and compressed. The pressures recorded were the dial readings of the press. The tablets were weighed and measured to determine void spaces and their disintegration times then determined. The averages obtained on six tablets at each pressure are reported in Table IV.

The disintegration times were too close together to detect any real minimum due to starch–void ratios. It was surprising to find that even at the highest pressures used, when void spaces were substantially eliminated, a rapid disintegration was still effected. This would indicate that as long as the starch grains were in continuous contact with each other their affinity for water would draw it into the tablet without regard to pore size. The three hardest tablets in the series (those with times of 10 sec.) showed a change in the mode of disintegration. They disintegrated from the outer sides toward the center.

If an optimum ratio of starch volume to void space did exist, it should be most readily detected when the channels were not completely filled with starch grains. To check this point, a series of flat-faced tablets was prepared from $^{40}/_{60}$-aspirin crystals with 5% starch. The results on six tablets at each pressure are recorded in Table V.

The decrease in disintegration time at 5000 lb. of pressure would seem to indicate the most favorable combination of conditions for this particular series. In each case the calculated increase in starch volume is larger than the total void space.

DISCUSSION

The increase in volume of starch in water strongly suggests that this is the principal mechanism for its action as a disintegrating agent. The disintegration of starch-containing tablets of aluminum hydroxide in water but not in ethanol and of aspirin tablets in water but not in glycerin adds support to this view. Where contact of starch grains in the interparticle spaces is continuous, disintegration is most rapid and is only slightly affected by changes in the amount of interparticle void space. In this situation, even when void space is substantially eliminated, starch is capable of drawing water into the interior of the tablet and producing rapid disintegration. When contact of starch grains in the interparticle channels is not continuous, the situation changes. The time for disintegration increases and the mode of disintegration changes. The appearance of a minimum disintegration time produced in aspirin tablets containing 5% starch in discontinuous contact might be attributed to two factors under the experimental conditions used. Berry and Ridout (7) have suggested that decreases in disintegration time would be produced by increasing contact between tablet particles and starch grains. This appears to be the case until a minimum time is reached. At this point, the second factor, a limit to the pore size which will allow entry of water into the tablet, begins to operate. A smaller pore size which could be occluded by air would hinder entry of water as was demonstrated by Wurster and Seitz (8). This would be particularly true in the case of a hydrophobic substance such as aspirin. In this situation, disintegration of the tablet would be slowed but could continue, either as the pores are enlarged by expanding starch grains near the surface of the tablet, or as diffusing water vapor progressively reaches and swells starch grains deeper in the interior of the tablet. Capillarity *per se* does not appear to have a disintegrating effect, although it may be a factor in aiding the entry of water into the tablet when the pore size is favorable.

Interaction of Nonionic Hydrophilic Polymers with Phenols I

Interaction of Phenol and Hydroxyphenols with Certain Macromolecules

By B. N. KABADI* and E. ROY HAMMARLUND

There have been numerous studies of the interactions of certain phenols with nonionic macromolecules—particularly those dealing with a loss of antimicrobial properties of the phenols when combined with nonionic polymers. Relatively little attention, however, has been given to the possible disruption of the solubilizing and stabilizing properties of the polymers themselves when in combination with certain phenols. Miscibility titration studies were made by interacting the following polymers: PEG, PPG, PVP, and methylcellulose with the following phenols: catechol, pyrogallol, resorcinol, hydroquinone, tannic acid, and phenol. Photometric turbidimetric titration studies of interacting polyoxyethylene ethers, polyoxyethylene monostearates, and polysorbates with tannic acid were also carried out. Dextrose altered the complexing tendency of tannic acid by decreasing the solubility of tannic acid in PEG 6000 and increasing its solubility in PVP. Since tannic acid was found to interact strongly with nonionic hydrophilic polymers, its possible influence upon the stability of various pharmaceutical formulations containing nonionic hydrophilic polymers should not be overlooked.

INVESTIGATION has indicated that phenolic materials interfere with various nonionic hydrophilic polymers which are employed frequently in pharmaceutical and cosmetic formulations as solubilizing, stabilizing, or emulsifying agents (1–6). The interactions of various nonionic hydrophilic polymers and phenols have been the concern of many further studies (7–14), usually undertaken to explore the mechanisms of the various interactions and thereby make possible the prediction of their probable occurrence. Most prior work has focused upon the interference of the complex with the antimicrobial properties of the phenol rather than upon its interference with the solubilizing and stabilizing properties of the polymer. The present inquiry investigated the nature of the inactivation of certain nonionic polymers by various widely occurring hydroxyphenols which may be found in many pharmaceutical formulations that contain plant products. Methods employed were visual turbidimetric titration and photometric turbidimetric titration. Results are presented in the form of phase diagrams.

EXPERIMENTAL

Materials.—The nonionic polymers used were: polyethylene glycol (PEG) 1500, 1540, 4000, 6000, and 20,000; polyvinylpyrrolidone (PVP); polypropylene glycol (PPG) 400 and 1200; polysorbate 20, 40, 60, and 80;[1] polyoxyethylene monostearate;[2] polyoxyethylene ethers;[3] alkyl phenoxy polyethoxy ethanol;[4] methylcellulose 15 cps. All polymers were commercial samples. The phenols employed were phenol, resorcinol, tannic acid, catechol, pyrogallol (all reagent grade), and hydroquinone (technical grade).

Visual Turbidimetric Titration Method.—The experimental technique was similar in principle to that used by Higuchi and co-workers (11, 12), Ahsan *et al.* (15), Marcus *et al.* (16), and Karabinos *et al.* (17) in their studies of the interaction of phenols with macromolecules. One to 10 ml. of the polymer solutions was added to a series of 50-ml. tubes and each volume was adjusted to 10 ml. with distilled water. The phenol solution was added dropwise to the continuously stirred polymer solution until a distinct turbidity marked the end point of the titration. The same operation was repeated on each tube containing various dilutions of the polymer solutions.

The phenol and hydroxyphenol solutions were 6% w/v and the tannic acid solution was 1% w/v, except for the methylcellulose titration in which 0.1% tannic acid was used. The concentrations of the polymer solutions were: polyethylene glycol[5] 1500, 1540, 4000, 6000, and 20,000, 20.0% w/v; polyvinylpyrrolidone,[6] 4.0% w/v; methylcellulose, 15 cps., 1.0% w/v; polypropylene glycol,[7] 1200, 0.2% w/v; and polypropylene glycol,[7] 400, 20.0% w/v.

From the concentration and volume of the poly-

mer solutions used the corresponding number of monomer-gram equivalents of polymer per liter was calculated (except for methylcellulose) and this value was plotted *versus* the final concentration of the phenolic solution in the mixture at the end point. The effect of dextrose on the interaction of PEG 6000 and PVP with tannic acid was likewise determined. The procedure used was the same as above except that the polymers were dissolved in 1 *M* aqueous dextrose solutions instead of in water. The data thus obtained from the titrations of the various polymers and phenols are plotted in the form of phase diagrams (Figs. 1–6).

Photometric Turbidimetric Titration Method.—The nonionic polymer solution was added slowly to a constantly stirred 10-ml. volume of 0.1% w/v tannic acid solution in a 50-ml. flask. At the first sign of turbidity an aliquot solution was removed, and its absorbance was measured at 625 mμ in a Bausch & Lomb Spectronic 20 colorimeter. The 0.1% tannic acid solution was used as the blank. Following this initial reading the aliquot was returned to the titration vessel, and more polymer solution was added to the mixture in 0.2-ml. increments. Absorbance readings were repeated until the solution in the titration flask became transparent (zero absorbance) which took about 0.5 hr. This titration procedure was carried out for each of the nonionic polymers tested. The solution absorbance was plotted *versus* the total volume of the polymer solution added. Figures 7–9 show the data thus plotted.

RESULTS AND DISCUSSION

Figures 1–6 show the phase diagrams of the complexation reactions between hydroxyphenols

and various hydrophilic polymers. In all these diagrams the points at low concentrations were less precise due to difficulty in discerning the end point. A heterogeneous system consisting of the white, oily complex dispersed throughout the aqueous phase existed at concentrations above any given curve. The mixtures were clear below each curve. The graphs in Figs. 1–5 have positive slopes which indicate that the insoluble complex was solubilized by an excess of uncomplexed polymer solution. In Fig. 6 the negative slope in the phase diagram of the methylcellulose was identical to that obtained from the interaction between phenol and PPG 1200 by Guttman and Higuchi (11). Likewise, the graph was similar to those which show interaction between phenol and certain surfactants below their critical micelle concentrations (CMC) (15, 16). For precipitation to occur, any decrease in the concentration of one reactant requires a corresponding increase in the concentration of the other. The negative slopes in this type of phase separation appear to be characteristic of polymers with negative temperature coefficients of solubility.

Since dextrose occurs as one of the products of tannic acid hydrolysis, its effect on the solubility of tannic acid in hydrophilic polymers was studied (Figs. 3 and 4). Dextrose was found to decrease the solubility of tannic acid in PEG 6000 and to increase the solubility of tannic acid in PVP.

The order of phenolic concentrations required for precipitation by PEG 20,000 (Fig. 5) was found to be phenol < resorcinol < hydroquinone < catechol < pyrogallol. Guttman and Higuchi (11) reported the sequence with PVP to be resorcinol < hydroquinone < phenol < catechol. No simple explanation appears to be evident for the discordant position of phenol in these two series.

In Figs. 7 and 8 there is a sharp increase in absorbance at a critical polymer concentration for all of the systems. This is due undoubtedly to a sudden increase in aggregation of the tannin–polysorbate complex above the CMC of the surfactant solutions. The absorbance reached a maximum and then began to decrease as the oily complex which formed became solubilized in the excess of polymer solution. A rapid decrease in the absorbance of the system resulted. Although the concentration of the surfactant at the point of the sudden increase in absorbance differs from its CMC values, the marked change in turbidity may be related to micelle formation in the complex system.

Figure 7 shows that each of the polysorbates produced a turbidity upon the addition of tannin. Figure 8 shows the absorbance breaks at different fixed concentrations of polysorbate 20 upon titration with tannic acid solution. Because of the marked differences between the graphs of the separate polysorbates, the photometric turbidimetric titration method employing tannic acid was found to be a useful method for distinguishing qualitatively between these surfactants. However, with a series of polyoxyethylene ethers having the same aliphatic chain length but with different size glycol chain lengths, there appeared to be no correlation between the concentration of the surfactants at their absorbance discontinuities and the monomer content of the surfactants.

The shapes of the titration curves of the polyoxyethylene ethers were nearly identical to those of the polysorbates which are shown in Figs. 7 and 8—although the sudden absorption increase at some critical point was not so sharp with the ethers as with the polysorbates. Moreover, aqueous solutions of polyoxyethylene ethers (No. 30, 42, 52, and 72) were too turbid initially to determine

any further change in their absorbance properties. The polyoxyethylene monostearates and alkyl phenoxy polyethoxy ethanol did not show any abrupt increase in absorbance at a critical point above their CMC because they produced uniformly turbid mixtures. This was due possibly to a lack of purity of the commercial products. Polyethylene glycol and PVP polymers, which do not exhibit a CMC, gave smooth curves as expected without any breaks. Their graphs are shown in Fig. 9.

Although the interaction or binding of tannin as such may not necessarily be detrimental to pharmaceutical products, the fact that tannin occurs in numerous pharmaceutical formulations of natural origin could cause frequent unexpected incompatibilities if surfactants were added or whenever these products were mixed with other preparations containing surfactants. The decrease in the concentration of the stabilizers or solubilizers through their binding with tannin will obviously decrease the effective concentration of the stabilizing agent which may lead to the ultimate breakdown of some liquid pharmaceutical products. Except by complete separation of the ingredients, the only way that this incompatability may be overcome is by the addition of excess dispersing agent (18). Allawala and Riegelman (19) have pointed out that for optimum conditions of preservative effectiveness, the ratio of phenol to surfactant should be at a minimum. Therefore, in preserved tannin-containing pharmaceuticals this incompatibility with surfactants should be considered.

Interaction of Nonionic Hydrophilic Polymers with Phenols II

Interaction of Phenol and Hydroxyphenols with Certain Polyethylene Glycols

By B. N. KABADI* and E. ROY HAMMARLUND

The general nature of the interaction between phenol and PEG was investigated utilizing equilibrium dialysis through a cellophane membrane and NMR analysis of the insoluble complexes. Equilibrium dialysis experiments indicated that there was no correlation between the binding of phenols and the increase in acidity associated with the addition of hydroxyl groups on the phenol nucleus. An increase in temperature was found to decrease the degree of binding of phenol with PEG. NMR data indicated that for high molecular weight PEG's complexed with phenol and *p*-chlorophenol, the insoluble, oily complexes contained two ETO base moles to each cosolute molecule.

ALTHOUGH THE interactions of nonionic polymers, e.g., polyvinyl pyrrolidone (PVP) and polysorbate 80, with various phenolic derivatives have been investigated rather extensively, the analogous reactions of polyethylene glycols (PEG) with phenols have received much less attention (1–4). Higuchi and co-workers (5, 6) have studied the interaction of PEG's and barbiturates and iodine in potassium iodide solution. They demonstrated that at a high cosolute concentration a complex formed which had a stoichiometric ratio of 2 base moles of ethylene oxide units (ETO) of the glycol to each cosolute molecule.

Various attempts to determine the mechanism of such interactions and the stoichiometric relationships of the complexes formed by interaction

of phenols and PEG derivatives have resulted in the appearance of contradictory statements in the literature (7–10). These are due largely to the many experimental difficulties encountered and the insufficiency of reproducible experimental evidence. Some of the difficulties which have prevented the determination of a definite stoichiometry of the formed complexes are: (*a*) the oily insoluble nature of the precipitate prevents the use of the conventional solubility titration method; (*b*) commercial nonionic surfactants are not pure products; (*c*) above their CMC's surfactants form micelles, and because of their solubilizing potential, these micelles would interfere with the isolation of a complex for study.

To avoid most of these difficulties this current study was limited to the PEG's because they are more homogeneous than the surfactants and they do not form micelles in water.

The object of this study was to investigate the general nature of the interaction between phenol and PEG and to attempt to determine the stoichiometry of the resulting complex by correlating equilibrium dialysis data of the reaction mixtures with NMR data obtained from the isolated oily complex. A literature search failed to reveal that NMR data had been employed previously in this type of an investigation on PEG–phenol complexes.

PEG 20,000 was chosen for this study for two reasons: (*a*) previous reports indicated that the low molecular weight PEG's did not form complexes, whereas the higher molecular weight PEG's did (5, 9, 11, 12); (*b*) PEG's with molecular weights of 6000 and less permeated cellulose dialyzing membranes, whereas PEG 20,000 did not, thus equilibrium dialysis could be used as an analytical tool (1).

EXPERIMENTAL METHODS AND RESULTS

Reagents

Phenol, *p*-chlorophenol, pyrogallol, phloroglucinol, and resorcinol (all reagent quality); PEG 300, 400, 1500, 6000, and 20,000 (commercial products).

Preparation of PEG 20,000 for Dialysis.—A 4.0% w/v commercial PEG 20,000 polymer solution was placed in Visking,[1] seamless, cellulose, dialyzing tubes which were then tied securely at both ends and dialyzed at room temperature against a large volume of distilled water. The dialysate was replaced with fresh distilled water at 4-hr. intervals, and the dialysis was continued until there was no frothing in the dialysate solution. This procedure usually took about 5 days. The dialyzed PEG 20,000 solution was dried under reduced pressure. The dried residue was powdered and this was employed in the equilibrium dialysis study. The yield was approximately 90%.

[1] Union Carbide Corp., Visking Division, Chicago, Ill.

Equilibrium Dialysis Method.—The equilibrium dialysis technique used in the present study was essentially the same as that used by Patel *et al.* and others (1, 3, 13). The phenols were estimated quantitatively by using a Beckman DU spectrophotometer. The wavelengths used for the various assays were: phenol, 270 mμ; resorcinol, 275 mμ; pyrogallol, 264 mμ; phloroglucinol, 267 mμ; and *p*-chlorophenol, 272 mμ.

Twenty milliliters of 0.5% w/v of the glycol polymer solution under study was placed in a series of cellophane bags. Each was then tightly tied and placed in a 125-ml. glass-stoppered flask containing 20 ml. of various concentrations of phenol solution ranging from quite dilute to saturated solutions. The control contained water in place of PEG solution. The flasks were agitated for 18 hr. at a constant temperature of 5°. Preliminary experiments had shown that equilibrium was reached under these conditions. The mixtures in the dialysis bags developed various degrees of cloudiness ranging from slightly turbid to extremely opaque, oily emulsions. The amount of phenol in the dialysate solutions was determined spectrophotometrically from its molar absorptivity, and the bound phenol

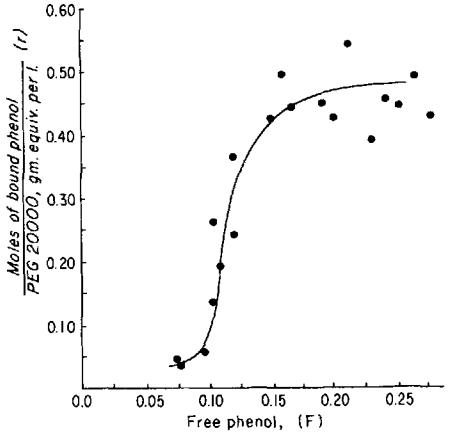

Fig. 1.—Interaction of phenol and PEG 20,000.

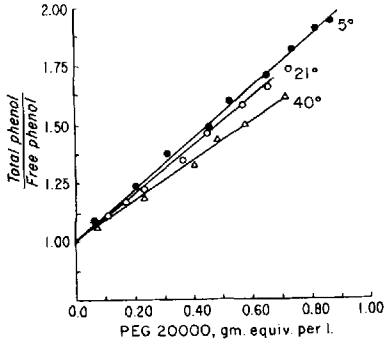

Fig. 2.—Effect of temperature on the binding of phenol and PEG 20,000.

concentration was calculated by difference from the control blank.

The data for the various concentrations of phenol bound to PEG 20,000 are plotted in the form of a Langmuir curve as shown in Fig. 1. At the lower concentrations the data were fairly reproducible; however, at the saturated concentration of phenol the points designating the amount of bound phenol were scattered. This same experiment was repeated using *p*-chlorophenol, and its Langmuir isotherm was found to be of the same shape as that of phenol in Fig. 1.

Effect of Temperature on Binding of Phenol by PEG.—The equilibrium dialysis experiment was carried out at different temperatures by keeping the phenol concentration constant and varying the concentration of the polymer. The results are plotted in Fig. 2 which shows that an increase in temperature decreased the degree of binding only slightly. This was due possibly to disruption of hydrogen bonding between the phenolic hydroxyl and the ether oxygen of the glycol.

Binding of PEG and Certain Hydroxyphenols.—The equilibrium dialysis method was used to study

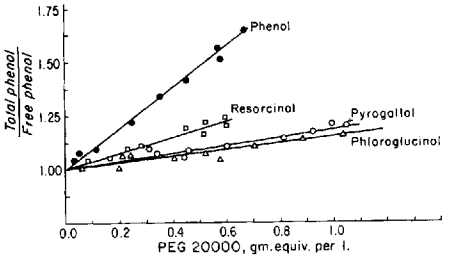

Fig. 3.—Binding of certain phenols with PEG 20,000.

the binding of certain hydroxy phenols with PEG. The data are plotted in Fig. 3. One might expect that as the number of the phenolic hydroxyl groups increased with a corresponding increase in the acidity, the phenols and PEG would interact more strongly. However, the amount of interaction in this case was found to be less, indicating that some others factors were involved. It appears likely that not all of the hydroxyl groups of the phenols are involved directly in complexation with polyglycols, and it is also possible that the degree of hydration of the various phenols may influence the complex formation. Furthermore, phloroglucinol, unlike the other phenols studied, did not precipitate PEG solution in any concentration indicating a lack of "squeezing out" action of the phloroglucinol–PEG complex from water.

Nuclear Magnetic Resonance Studies

The complexes of the various phenols and PEG 20,000 were difficult to work with because of their sticky nature and low solubility in water. The lack of light absorption of the PEG prevented the use of this analytical technique. Furthermore, the quantitative dialysis method could not be used to study the interaction of the low molecular weight

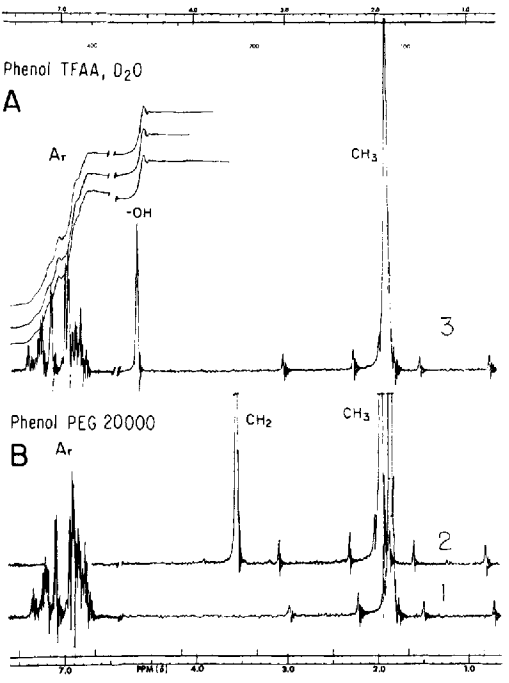

Fig. 4.—NMR spectra of phenol and PEG 20,000 in acetonitrile containing 1% TMS. Key: B1 and A3, phenol; B2, PEG 20,000.

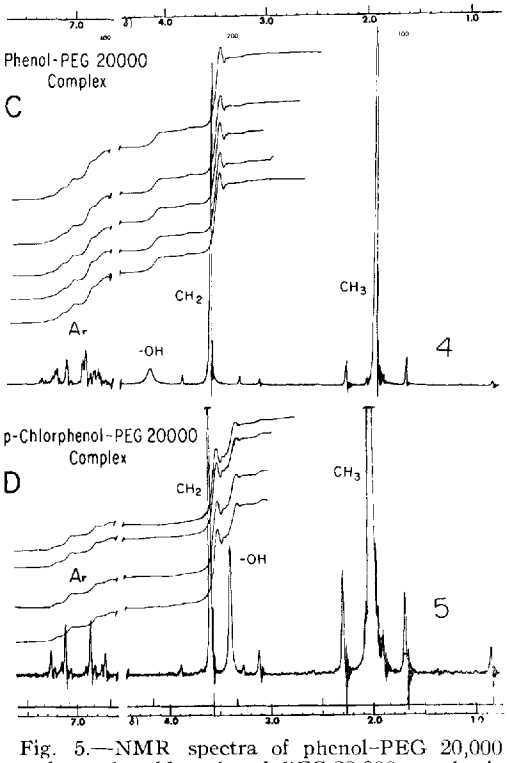

Fig. 5.—NMR spectra of phenol–PEG 20,000 complex and *p*-chlorophenol–PEG 20,000 complex in acetonitrile containing 1% TMS. Key: C4, phenol–PEG 20,000 complex; D5, *p*-chlorophenol–PEG 20,000 complex.

PEG's because they permeated the membranes. These difficulties were overcome by utilizing nuclear magnetic resonance (NMR) analyses to ascertain the ratio of PEG protons to phenol protons in the oily complex.

Preliminary Work on Pure Samples.—The NMR spectra were obtained using an analytical high resolution NMR spectrophotometer (Varian Associates A-60). Preliminary NMR spectra of pure phenol in acetonitrile containing 1% tetramethylsilane (TMS) did not indicate a hydroxyl proton, Fig. 4, B1. The addition of traces of D_2O and trifluoroacetic acid (TFAA) to the sample to catalyze the exchange of hydroxyl protons with D_2O produced the desired phenolic hydroxyl proton signal. The spectrum of this mixture is shown in Fig. 4,A. PEG 20,000 was added to this mixture and the NMR data were obtained. The signal from the phenol and PEG hydrogens did not overlap and could be integrated successfully as shown in Fig. 4,B. However, similar studies on phenol–PVP and the various phenol–polysorbate[2] mixtures did not produce conclusive results because of the complexity of their NMR spectra.

Examination of the spectra of several known ratios by weight of phenol and PEG upon integration disclosed that the ratios of the aromatic protons of phenol to the methylene protons of glycol were close to the calculated values within experimental limits. This spectrum is shown in Fig. 5,C. The lowest field signal which appeared as a multiplet centered at about $\Delta = 7$ and was due to the protons attached directly to the aromatic nucleus. The middle signal which appeared as a sharp singlet at $\Delta = 3.56$ was from the protons of the polyoxyethylene chain. The high field signal at $\Delta = 1.9$ was from the methyl protons of the solvent, acetonitrile. The position of the signal of the hydroxyl protons varied between 3 and 5 Δ values depending upon the water content of the sample.

Analyses of Oily Complexes of PEG and Phenol.—The oily complex mixtures formed by the interactions between a high concentration of phenol individually with PEG 6000 and PEG 20,000 each were collected from within the cellophane dialysis bags which had been agitated slowly for about 18 hr. at 5° in a shaker bath. The NMR spectrum of the oily portion was obtained in acetonitrile containing traces of TMS, D_2O, and TFAA, and was found to be identical in all respects to the spectrum shown in Fig. 5,C. Therefore, in this investigation the NMR spectrometry was found to be applicable as an analytical tool for determining the ratio of bound phenol to polymer. The actual structure of the phenol–polymer complex or any changes in its structure in the elected solvent, acetonitrile, have not been investigated. The integrated ratios of the aromatic protons of phenol to the methylene protons of PEG in the oily complex obtained from the different concentrations of phenol were not constant. However, following a thorough washing of the oily complex with distilled water, fairly reproducible ratios were obtained and are shown in Table I. The ratio of the methylene protons to the aromatic protons was found to be between 1.5 and 1.6.

[2] Marketed as Tweens by Atlas Chemical Industries, Inc., Wilmington, Del.

In a study of the low molecular weight PEG's, 1% w/v solutions of the PEG's were added to equal volumes of 7% phenol solutions and kept overnight in a separator. Oily complexes formed in the lower layer in each funnel and the NMR spectra of the complexes were obtained as previously described both before and after washing with water. It was found that the ratio for PEG 1500 before washing varied considerably from its predicted value (Table I). Likewise, the values for PEG 300 and 400 after washing were not as expected. The remaining ratios came out close to the predicted values. In a similar manner PEG 6000 and 20,000 were interacted with *p*-chlorophenol, and its oily complex was washed with water and gave proton ratios close to the predicted value as seen in Table I.

The water content of the insoluble material varied considerably from sample to sample. The integrated ratio of the water protons was always less than 3 moles considering the ratio of protons of 1 mole of phenol or 2 ETO units of glycol. However, the presence of any water associated with the insoluble complex was not investigated extensively.

TABLE I.—INTEGRATED RATIOS OF METHYLENE PROTON TO AROMATIC PROTON NMR PEAK AREAS FOR PHENOL– AND *p*-CHLOROPHENOL–PEG COMPLEXES

	Methylene Protons/Aromatic Protons (8/5)		
PEG Complexed with Phenol	Before Washing	After Washing	Predicted[a]
200,00	1.509	1.592	1.6
6000	1.470	1.524	1.6
1500	1.24	1.558	1.6
600	...	1.558	1.6
400	...	1.118	1.6
300	...	0.780	1.6
PEG Complexed with *p*-Chlorophenol			(8/4)
20,000	...	2.2	2.0
6000	...	1.7	2.0

[a] Assuming that there were 2 base mole units of ethylene glycol (8 protons) to 1 mole of phenol (5 protons) or *p*-chlorophenol (4 protons).

DISCUSSION

The Langmuir isotherm in Fig. 1 indicated that at low concentrations of free phenol the binding tendency for phenol is rather small. At somewhat higher concentrations of free phenol, the amount of binding depended upon the phenol concentration, and this portion of the curve shows a rapidly increasing slope. At still higher phenol concentrations, the results were not satisfactory because the points were highly scattered. The binding of phenol and PEG as shown by the dialysis data was similar to the binding of phenol by PVP (1) or cetylpyridinium chloride by methylcellulose and polysorbate 80 (14). Deluca and Kostenbauder (14) considered that isotherms such as these sometimes resulted when adsorption of a critical quantity of cosolute caused changes in the configuration of

the tightly coiled polymer molecules resulting in the availability of additional binding sites.

Although the stoichiometric relationship between the ETO of the PEG and phenol was not clearly defined in the dialysis experiments, the behavior of the polymers in the presence of increasing concentrations of phenol were meaningful. Since phenols have a greater tendency for hydrogen bonding than do water molecules (15), the addition of a small amount of phenol to the PEG would lead to the displacement of a few water molecules per polymer. At these low concentrations of phenol, the binding tendency of phenols seems to be comparatively small, and the complex remains in solution. As the ratio of phenol to glycol is increased, phenol would be expected to alter the orientation of the polyphenol complex, and some hydrogen bonded water molecules will be displaced. At the same time the water solubility of the phenol also is reduced by the interaction of the phenolic hydroxyl group with the ETO chains because the hydroxyl group is no longer available for hydrogen bonding with water molecules. This combination of the reduction in solubility of the phenol and the disorganization of the hydrated polymer could explain the precipitation of a hydrated phenol–polymer complex at a critical point. This was found to occur at a very low concentration of phenol.

At the point where the precipitation began to occur, the formation of this precipitate would change convoluted linear polymer chains into a more compressed configuration (16). This rearrangement apparently was initiated by the binding of relatively few phenol molecules which sterically made available many more binding sites for the attachment of additional phenol because this change in state was accompanied by a significant increase in phenol binding, *i.e.*, there was binding of phenol to PEG beyond the point of initial precipitation. Thus, the tendency for an individual phenol molecule to attach itself to a polyether molecule was relatively small, but when several phenol molecules combined with an ether chain, a favorable environment for additional binding was created. As a result more phenol molecules were bound and were held on the complex in the same fashion as with the nonionic surfactant micelles. This phenomenon was seen in the very high phenol region of the dialysis experiment. In this region the oily complex which separated out of the aqueous phase might possibly bind more and more phenol molecules, or the oily colloidal phase may act as a new separate phase which has a considerable attraction to the phenol molecules, and there will be partitioning of phenol between this complex and the aqueous phase. An alternative explanation would be that the oily complex possibly interfered in the equilibrium process of dialysis which caused the points on the graph in Fig. 1 to be scattered over a wider region (17).

Kato (18) has shown the presence of a "micelle-like" structure in simple aqueous solutions of a number of glycols. Thus, the attachment of the aromatic moiety to the water-soluble polyglycol molecules appears to have conferred hydrophobic characteristics to the association complex in proportion to the amount of phenol complexed (19). The solubility of the complex thus would be altered due to binding of phenol to a polymer and the insoluble complex would increase the turbidity which ultimately resulted in the separation of an oily phase when the phenol concentration was high.

Although the commonly used equilibrium dialysis method could not be applied effectively to determine the stoichiometric composition of the complex, a relatively new experimental procedure to this field—the NMR spectrometric method—has been utilized.

Thin-Layer Chromatography of the Selective Rat Toxicant, Norbormide

By CASIMIR A. JANICKI, RONALD J. BRENNER, and BARBARA E. SCHWARTZ

Norbormide has been reported to be a mixture of stereoisomers. A technique for the qualitative identification and quantitative determination of the major isomers of norbormide has been developed. Norbormide is separated into its isomers on thin-layer plates consisting of 99 per cent Silica Gel G and 1 per cent colloidal alumina, using a solvent mixture of ethyl acetate–chloroform (7:3). The isomers are extracted into 0.1 *M* hydrochloric acid–ethanol (7:1). The isomers are assayed by U. V. absorption or by the use of fluorescence. Some ultraviolet and fluorescence characteristics of the isomers are presented. Data are presented to show the accuracy and precision of the TLC–U.V. method.

NORBORMIDE,[1] 5-(α-hydroxy-α-2-pyridylbenzyl)-7-(α-2-pyridylbenzylidine)-5-norbornene-2,3-dicarboximide, has been found to be a selective rat toxicant (1, 2). As currently synthesized it consists of a mixture of stereoisomers which were separated by a variety of paper and thin-layer chromatography methods (3). These isomers were observed to vary greatly in their toxicity toward rats (4). The isomers have been classified as *cis* (S, T, W, Y) and *trans* (R, X, U, V) and further as endo (U, V, W, Y) and exo (R, S, T, X) (3). Because of this difference in biological activity, it was necessary to develop a method which would separate the isomers so that a quantitative assay of each could be carried out. Thin-layer chromatography was chosen because of the speed and sharpness of separations possible.

A thin-layer separation technique is described which separates norbormide into three isomers, designated as X, W, and Y, a mixture of two isomers Z, and a by-product in the synthesis, 7-(α-2-pyridylbenzylidine)-5-norbornene-2,3-dicarboximide (McN-1392). The mixture of the two isomers known as Z is separated further into its two isomers U and V by a second thin-layer chromatographic step. As much as 1 mg. of norbormide has been quantitatively separated into five of the eight possible racemates. Spectrophotometric and spectrofluorometric assays of the separated isomers are described.

EXPERIMENTAL

Apparatus.—The Desaga-Brinkmann complete basic equipment No. 600[2] for TLC was used for the preparation of plates. Glass plates were 2 × 8 in. A Beckman DK-2A was used for the ultraviolet absorption measurements and an Aminco-Bowman spectrophotofluorometer No. 4-8106 for fluorescence measurements.

Reagents.—Analytical reagent grade or equivalent grade reagents were used in the study. Silica Gel G was obtained from Brinkmann[2] and colloidal alumina,[3] technical grade, from E. I. Dupont de Nemours and Co., Inc.

Preparation of Plates.—A slurry of 4 Gm. of colloidal alumina and 100 ml. of water was prepared. The slurry was diluted 10 to 70 ml. with methanol. To the methanol slurry was added 40 Gm. of Silica Gel G, and the resulting slurry mixed to a uniform consistency. The glass plates were covered with a 250-μ layer of adsorbent using a fixed thickness spreader. The plates were air-dried for an hour and then at 70° for 30 min. The plates were stored in a storage rack at room temperature, 50% relative humidity, and used without any prior activation. The addition of the colloidal alumina in the silica gel provides an excellent binding with the glass surface. The use of colloidal alumina as a binder has recently been published (5).

Standard Solutions.—Solutions of the isomers of norbormide and McN-1392 were prepared by dissolving accurately weighed amounts in a 1:1 chloroform–methanol solution, and taking to a known volume. Standard solutions for the spectrophotometric analyses of the isomers were prepared by dissolving accurately weighed amounts in ethanol, and taking to volume with 0.1 *M* hydrochloric acid. The final solution was 7:1 of 0.1 *M* hydrochloric acid–ethanol.

Sample Solutions.—Samples of norbormide, norbormide isomers, and isomer mixture Z were dissolved in a 1:1 chloroform–methanol solution to obtain a concentration of 8 mg./ml. McN-1392 was dissolved to give a concentration of 2 mg./ml.

Thin-Layer Method.—Solutions of the isomers of norbormide, McN-1392, and samples of commercial norbormide were applied to the silica plate about 2 cm. from the starting edge using a Hamilton syringe pipet. For the qualitative studies from 20 to 100 mcg. of sample was applied to the plate, using a gentle stream of air to keep the spots less than 5 mm. in diameter. A maximum of 5 spots was applied across a single plate. In the quantitative studies from 800 to 1000 mcg. of norbormide was applied in a series of spots resulting in a band whose width did not exceed 5 mm.

Received May 16, 1966, from the Pharmacy Research Department, McNeil Laboratories, Fort Washington, Pa. 19034.

Accepted for publication July 18, 1966.

The authors thank Mrs. M. C. Christie for the preparation of the thin-layer plates, and the Chemistry Department for the pure samples of norbormide isomers.

[1] Norbormide has been designated the American Standards Association common name.

[2] Brinkmann Instruments, Inc., Westbury, N. Y.

[3] Trademarked as Baymal.

The silica plates were developed using the ascending technique in glass jars. No paper wicks were used in the jars. Development was allowed to continue until the solvent front reached within 1 in. of the top of the plate. The plates were removed, air-dried for 5 min., and placed back into the jars for another solvent pass with the same solvent. The solvent system for the initial separation of norbormide was chloroform–ethyl acetate (7:3). For the separation of the isomer mixture Z into isomers U and V, a solution of ethyl acetate–butyl ether–acetic acid (15:5:1) was used for a total of six solvent passes. *n*-Butyl acetate can be substituted for ethyl acetate with identical results.

The separation of isomer mixture Z into isomers U and V was checked by paper chromatography (3). The separated isomers were spotted on Whatman No. 1 paper which was then sprayed with the aqueous phase of the mixture *n*-butanol–*n*-butyl-acetate–hydrochloric acid–water (75:25:6:100). The chromatogram was placed into a tank, equilibrated with the aqueous phase, and developed for 40 hr. with the organic phase of the solvent mixture.

Detection of the Isomers.—Shortwave ultraviolet light was used to locate the position of the stereoisomers on paper or silica plates. Iodine vapor or Dragendorffs' reagent can be used to detect the isomers visually on the silica plates.

RESULTS

Qualitative Analyses of the Stereoisomers.—Using the solvent system given previously for the initial separation of norbormide, commercial samples of norbormide were found to separate into 5 spots. In the order of increasing distance from the origin they were: mixture Z, isomer Y, isomer W, McN-1392, and isomer X. Further development runs did not separate mixture Z into its components. When a solvent system of chloroform–ethyl acetate (7:3) was used and 6 to 8 solvent passes, Z did separate into the isomers U and V. As the concentration of Z increased from 50 to 300 mcg. the front running spot tailed into the back spot finally resulting in a single spot. The mixture Z was separated using the butyl ether, ethyl acetate, acetic acid solvent mixture described previously. The order of separation in increasing distance from the origin was U, V. Table I lists the average distances traveled from the origin by the isomers separated from norbormide. R_f values were not calculated because of the multiple solvent pass technique. The values of the distances traveled represent the average of 40 separations of various batches of norbormide. The values given for U and V are those obtained from the separation of isomer mixture Z. Isomers R, S, and T were not found in any significant amounts in norbormide. Isomers R, S, and T could not be separated from the other isomers by the given TLC method but were separated on cellulose plates prepared with microcrystalline cellulose superfine[4] using the organic phase of the mixture *n*-butyl alcohol–hydrochloric acid–water (100:6:100) as the solvent system (3). The order of separation in increasing distance from the origin was W, V, U, and Y, R, and S, T, X.

TABLE I.—RELATIVE DISTANCES FROM THE ORIGIN OF THE ISOMERS OF NORBORMIDE AND MCN-1392 IN mm.

Sample	Isomer	Relative Distance, mm.
Norbormide	X	91 ± 4
	McN-1392	85 ± 4
	W	80 ± 4
	Y	73 ± 3
	Z	62 ± 4
Isomer mixture Z	V	78
	U	53

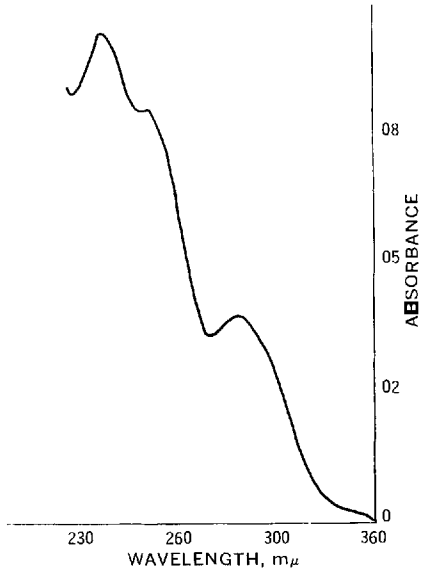

Fig. 1.—Ultraviolet absorption spectrum of norbormide in 0.1 *M* hydrochloric acid–ethanol (7:1).

Quantitative Analyses of Norbormide.—With successful resolution of norbormide into its isomers and McN-1392, the investigations were extended to studies of the resolution of mixtures for quantitative analyses. A solution containing known amounts of isomers was chromatographed, examined under ultraviolet light, and the bands outlined carefully with a sharp stylus. The adsorbent within the outlined area was scraped with a spatula onto glassine paper. The area was dry-washed with a small amount of silica gel, adding the wash to the sample. The adsorbent was transferred to a 1-oz. bottle fitted with a screw cap containing a plastic liner. An amount of 0.1 *M* hydrochloric acid–ethanol (7:1) solution was pipeted into the bottle, to obtain an approximate concentration of 0.02 mg./ml. The samples were shaken on a mechanical shaker for 1 hr., centrifuged, and the clear supernatant liquid transferred to a clean container.

Commercial precoated plates of Silica Gel G which did not contain the colloidal alumina were tried. The quantitative separations of both norbormide and norbormide isomer mixture Z were very unsatisfactory. No attempt was made to prepare TLC plates of Silica Gel G without the colloidal alumina.

Spectrophotometric Assay. The ultraviolet absorption spectrum of each sample was recorded from 360 to 230 mμ in 1-cm. cells using 0.1 *M* hydrochloric acid–ethanol (7:1) as the reference solution.

TABLE II.—SOME ULTRAVIOLET CHARACTERISTICS FOR THE NORBORMIDE ISOMERS AND McN-1392 IN 0.1 *M* HYDROCHLORIC ACID–ETHANOL (7:1)

Sample	Max., mμ	mcg./ml./ΔA	ε	Max., mμ	ε	Absorbance Characteristic Near 260 mμ
R	295		5600	236	15,800	A peak
S	291		5200	232	13,700	Plateau
U	303	78.622	6700	239	20,800	Break
V	302	69.268	7000	239	19,300	Peak
W	300	65.329	8500	238	19,100	Break
X	295	90.073	6000	238	19,500	Break
Y	300	86.595	6400	236	13,400	Peak
Z	302	76.284	6900	238	19,500	Plateau
McN-1392	302	46.394	7500	238	17,200	Continuous

For each isomer an ultraviolet absorption curve was recorded. Approximately the same amount of Silica Gel G as in the sample was added to a volume of standard isomer solution identical to the volume of the sample. For a 1-mg. sample of norbormide 8, 4, 10, 16, and 4 ml. of the solvent was used for isomers W, X, Y, mixture Z, and McN-1392, respectively. The silica was added to the standards to match the composition of the sample solutions as closely as possible. The concentration of the isomers and McN-1392 in per cent by weight was determined by the following equation:

$$\% \text{ isomer} = \frac{(\text{mcg./}\mu\text{l./}\Delta A)_{\text{std.}} \times \Delta A_{\text{sample}} \times \text{dilution factor} \times 100}{\text{sample wt., mcg.}}$$

where ΔA, the corrected absorbance, is the absorbance of the maximum near 300 mμ minus the absorbance at 350 mμ. The ultraviolet absorption spectrum of norbormide at a concentration of 0.025 mg./ml. (1-cm. cells) in 0.1 *M* hydrochloric acid–ethanol (7:1) is given in Fig. 1. Absorption maxima are located at 300 and 238 mμ. The spectra of the individual isomers of norbormide are of the same general nature as that shown in Fig. 1. The maximum near 300 mμ was chosen to measure the concentration of norbormide since it is least affected by impurities one may encounter in a silica plate. The ultraviolet background absorbance of silica in the hydrochloric acid–ethanol solvent is linear from 360 to about 280 mμ. Since the background may vary, the absorbance near 300 mμ may be corrected for the background by subtracting the absorbance at 350 mμ.

For the purposes of identity a summary of some of the major ultraviolet absorption characteristics in 0.1 *M* hydrochloric acid–ethanol (7:1) is presented in Table II. The exo isomers, R, X, and S, have lower ε values for the higher wavelength maxima which are near 295 mμ than the endo isomers, U, V, W, and Y, at their maxima near 300 mμ. The values obtained for the factor mcg./ml./ΔA for some of the isomers are also given in Table II. They were used in the actual calculations for determining the isomer percentages given in other tables.

To test the accuracy of the assay method, three samples containing weighed amounts of the isomers W, X, Y and isomer mixture Z were assayed. The results of the assays are presented in Table III. Mixture *3* was assayed 3 times. In each case the recovery of X from mixture *3* was high. In general the recoveries of the isomers are good. Standard deviations were calculated in the usual manner.

Two samples of different lots of norbormide were assayed 6 times to test the precision of the method. The data are presented in Table IV. The 95% confidence intervals, based on the Student *t* are given for each result.

Twenty-five lots of norbormide were assayed over extended periods of time by several investigators. The mean results and 95% confidence intervals were calculated and are as follows: isomer W, 18.3% ± 4.3%; isomer X, 10.1% ± 4.3%; isomer Y, 28.7% ± 5.1%, and isomer mixture Z, 38.9% ± 4.9%. The results do not indicate significant differences in the isomer content of the different lots of norbormide.

Separation of Isomer Mixture Z.—The mixture of isomers Z was assayed by the quantitative TLC procedure already described. The composition of Z, which had been isolated and recrystallized to a constant melting point material (3), is given in Table V. Mixture Z is approximately 60% isomer V. Samples of Z separated by TLC from the other isomers in a norbormide sample were also assayed and the data given in Table V. The TLC method of separating Z from the norbormide isomers W, X, and Y has been described. However, instead of adding

TABLE III.—RECOVERY OF THE ISOMERS OF NORBORMIDE FROM STANDARD MIXTURES

Recovered	103 ± 4	115 ± 3	274 ± 5	288 ± 16

TABLE IV.—THE COMPOSITION OF SOME NORBORMIDE SAMPLES WITH 95% CONFIDENCE INTERVAL

Sample	% W	% X	% Y	% Z
A	19.0 ± 2.8	10.1 ± 6.9	30.3 ± 2.5	34.2 ± 2.8
B	17.0 ± 4.9	12.7 ± 4.1	26.7 ± 4.4	37.3 ± 4.1

TABLE V.—COMPOSITION OF ISOMER MIXTURE Z

Sample	% U	% V
Mixture Z	36 ± 2	62 ± 3
Mixture Z[a]	37 ± 1	61 ± 2
Mixture Z[b]	40 ± 1	59 ± 1
Z[a]	14.0 ± 1.9	29.6 ± 2.4

[a] Separated by TLC from norbormide.

TABLE VI.—MOLAR FLUORESCENCE VALUES OF THE NORBORMIDE ISOMERS

Sample	Molar Fluorescence (Arbitrary Fluorescent Value Divided by the *M* Concn.)
Isomer R	3.33×10^9
Isomer S	2.49×10^9
Isomer U	5.85×10^9
Isomer V	6.51×10^9
Isomer W	2.40×10^9
Isomer X	3.47×10^9
Isomer Y	2.74×10^9
Isomer mixture Z	6.27×10^9
McN-1392	0.82×10^9

the 7:1 mixture of 0.1 *M* hydrochloric acid–ethanol, 25 ml. of methanol was added and the sample shaken for 1 hr. on a mechanical shaker. The sample was centrifuged and exactly 20 ml. of the clear solution was evaporated to dryness without the aid of heat. The residue was quantitatively taken up in methanol and streaked on the silica plates. The silica plate was developed as previously described.

Paper chromatography was used to determine the sharpness of separation of U and V. If the silica plates were not kept at 25° and 50% relative humidity there was from 5 to 10% tailing of the front running band V into the slower band U. The data given for Z separated from the other isomers by TLC represents separations from 5 different lots of norbormide. The standard deviations are also given in the table. Isomer mixture Z, obtained by recrystallization techniques, was found to contain U and V in the ratio of about 4:6 while, mixture Z separated from samples of norbormide by TLC contained them in the ratio of about 1:2.

Fluorescence Assay.—The norbormide isomers were also assayed by measurement of their fluorescence in acid. All the isomers have an activation maximum at 320 ± 5 mμ and a fluorescence maximum at 460 ±5 mμ in a 1:7 ethanol–0.1 *M* hydrochloric acid solvent. When arbitrary fluorescence units were plotted against concentration, a straight line relationship was found for each isomer in the concentration range of 1 to 10 mcg./ml. The method of assay is the same used for the spectrophotometric assay except that the sample dilution is increased. Standards containing approximately the same amount of silica as the samples are taken through the sample extraction procedure with 1:7 ethanol–0.1 *M* hydrochloric acid. Because of the care needed to avoid traces of impurities anywhere in the fluorometric assay, the spectrophotometric assay is preferred. Good agreement has been observed between the fluorescence and spectrophotometric assays for samples assayed by both methods. The molar fluoresence, arbitrary fluorescence units divided by the molar concentration, is given in Table VI for the major isomers of norbormide.

Ion-Pair Extraction of Pharmaceutical Amines II

Extraction Profile of Chlorpheniramine

By TAKERU HIGUCHI and K. KATO

The extractability of chlorpheniramine in its ion-pair form has been investigated under several conditions to determine the suitability of the process for separation and isolation of the drug in analytical samples. Chlorpheniramine, chosen as an example of a drug having two basic centers per molecule, exists in aqueous solution as a mixture of uncharged, singly charged, and doubly charged species. Data are presented to show that the drug can be extracted as the chloride, bromide, maleate, trichloroacetate, picrate, etc. The extraction-pH profiles of both the picrate and the bromide correspond closely with the theoretical relationship. As with the monoacidic amines, extraction into the organic phase requires the presence of proton donating species. Experimental data suggest, for example, that the extracted species is coordinated with 5 molecules of chloroform.

THE EFFECTS of various anions and the dependence on solvating agents present in the organic phase on the formation of ion pairs extractable into lipoidal solvents were previously presented (1), with dextromethorphan as an example of a monoprotic amine. The current work deals with the behavior of a diprotic organic base, chlorpheniramine.

It has been found that, in addition to showing a marked dependency on the masking or complex-

Ion-Pair Extraction of Pharmaceutical Amines II

Extraction Profile of Chlorpheniramine

By TAKERU HIGUCHI and K. KATO

The extractability of chlorpheniramine in its ion-pair form has been investigated under several conditions to determine the suitability of the process for separation and isolation of the drug in analytical samples. Chlorpheniramine, chosen as an example of a drug having two basic centers per molecule, exists in aqueous solution as a mixture of uncharged, singly charged, and doubly charged species. Data are presented to show that the drug can be extracted as the chloride, bromide, maleate, trichloroacetate, picrate, etc. The extraction-pH profiles of both the picrate and the bromide correspond closely with the theoretical relationship. As with the monoacidic amines, extraction into the organic phase requires the presence of proton donating species. Experimental data suggest, for example, that the extracted species is coordinated with 5 molecules of chloroform.

THE EFFECTS of various anions and the dependence on solvating agents present in the organic phase on the formation of ion pairs extractable into lipoidal solvents were previously presented (1), with dextromethorphan as an example of a monoprotic amine. The current work deals with the behavior of a diprotic organic base, chlorpheniramine.

It has been found that, in addition to showing a marked dependency on the masking or complex-

ing agent in the organic phase, the extent of ion-pair formation by the chlorpheniraminium cation is a function of the drug species in solution. The studies indicate that the singly protonated form of the drug can give rise to ion pairs, but none were detected with the doubly protonated form. This species specificity would allow separation of chlorpheniramine from monoacidic organic bases simply by ion-pair extraction at two appropriate pH values.

RESULTS AND DISCUSSION

Extraction as a Function of the Anion and Solvating Agent Concentrations. Studies of the partitioning behavior of ion pairs formed from the chlorpheniraminium cation with a number of inorganic and organic anions were carried out as reported previously on dextromethorphan (1). The nature of the partition data in this instance is evident in a typical set of data illustrated in Fig. 1. This particular plot shows the results obtained with varying concentrations of bromide ion in systems containing different concentrations of chloroform as the masking agent in cyclohexane. The pH of the aqueous layer was adjusted to pH 3.5 with citrate buffers. All data are corrected for the amount of the free base which could be extracted in the absence of ion-pair forming anions.

The system can be represented by the following relationship:

$$BH_{aq.}^{+} + X_{aq.}^{-} \overset{K_e}{\rightleftharpoons} [BH^{+}X^{-}]_{org.} + nM \overset{K_c}{\rightleftharpoons} [BH^{+}X^{-}\cdot M_n]_{org.} \quad \text{(Eq. 1)}$$

where $BH_{aq.}^{+}$ represents the monoprotonated chlorpheniraminium cation in the aqueous phase and $X_{aq.}^{-}$ the anion in the aqueous layer, in this case bromide; $[BH^{+}X^{-}]_{org.}$, the ion pair in the organic phase, and $[BH^{+}X^{-}\cdot M_n]_{org.}$, the solvated ion pair; K_e represents the classical extraction constant (2) and K_c, the stability constant for the complex formation.

Although from subsequent data it will be shown that BH^{++}, the doubly protonated chlorpheniraminium cation does not appear to be extractable in ion-pair form for the anionic species studied so far, the expression for the apparent partition coefficient must consider its presence in the aqueous phase, therefore:

$$PC_{app.} = \frac{[BH^{+}X^{-}]_{org.}}{[BH^{+}]_{aq.} + [BH^{++}]_{aq.}} \quad \text{(Eq. 2)}$$

It is readily apparent from Fig. 1 that $PC_{app.}$ is highly dependent on the concentration of chloroform. The data again suggest that the chloroform interacts with the ion pair in the organic layer and apparently renders it more compatible with the organic solvent by masking the anionic ion. As shown earlier at constant bromide ion concentration, $PC_{app.}$ is proportional to $(CHCl_3)^n$, where n is the number of molecules of chloroform reacting or associating with each ion pair, a plot of log $PC_{app.}$ *versus* log $[CHCl_3]$ yielding a straight line with a slope equal to n. Figure 2 shows such a plot for the chlorpheniramine–bromide system at constant bromide concentrations but varying chloroform concentrations. Evaluation of the slopes yields a coordination value of 5 for this system.

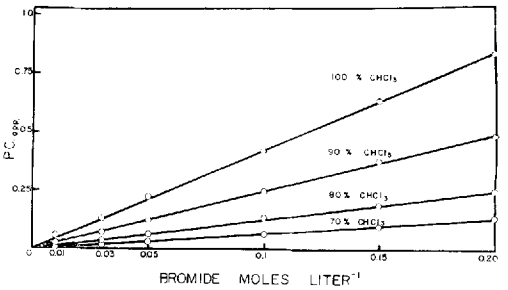

Fig. 1.—The effect of bromide ion on the partitioning of chlorpheniramine at pH 3.5 as a function of chloroform concentration in the organic phase.

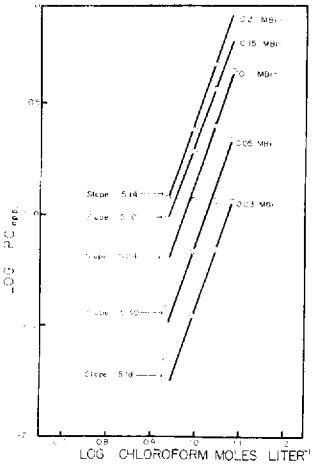

Fig. 2.—The dependency of apparent partition coefficient of chlorpheniramine on the concentration of $CHCl_3$ in the presence of Br at pH 3.5.

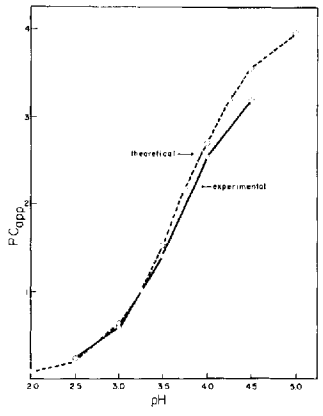

Fig. 8.—pH profile of apparent partition coefficient chlorpheniramine–bromide ion pair. Chlorpheniramine, 10^{-3} *M*; bromide, 0.5 *M*; organic phase, $CHCl_3$; 0.05 *M* citrate buffer.

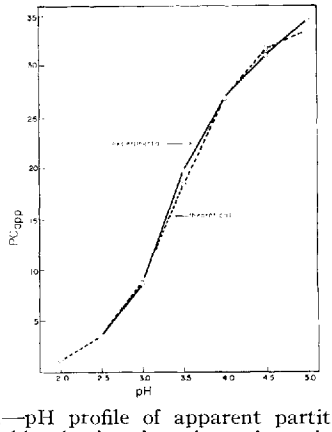

Fig. 9.—pH profile of apparent partition coefficient of chlorpheniramine–picrate ion pair. Chlorpheniramine, 10^{-4} *M*; picrate, 2×10^{-3} *M*; organic phase, 55% $CHCl_3$; in cyclohexane; 0.05 *M* citrate buffer.

other studies to be related to the bulk and hydrophobicity of the anion. In this case, as well as that of the bromide interaction, a plot of log $PC_{app.}$ *versus* $[CHCl_3]$ yielded straight lines as evidenced in Fig. 4 at varying concentrations of picrate anion. From the slopes of the lines it was determined that again 5 molecules of chloroform interacted with each picrate ion pair.

Investigations were also carried out with constant concentrations of chloride, maleate, and trichloroacetate anions under conditions of varying chloroform concentrations. Figure 5 again shows a linear relationship between log $PC_{app.}$ and log $[CHCl_3]$. Table I summarizes the apparent stoichiometry of the interactions of a number of chlorpheniramine–anion ion pairs with chloroform, as well as the extraction constants at 1 and 10 *M* chloroform concentration. Although an expression can be derived for the over-all equilibrium constant as follows:

$$K_e K_c = K_0 = \frac{PC_{app.}}{[X^-][M]^n}\left(1 + \frac{[H^+]}{K_a}\right) \quad \text{(Eq. 3)}$$

where K_0 is the over-all equilibrium constant; K_a is the dissociation constant for $BH^{++} \rightleftharpoons BH^+ + H^+$; in this case 1×10^{-4}, as determined spectrophotometrically.

It is more meaningful to compare the extraction constants at various concentrations of chloroform according to the following equation:

$$K_e = \frac{PC_{app.}}{[X^-]} \cdot \left(1 + \frac{[H^+]}{K_a}\right) \quad \text{(Eq. 4)}$$

Although at this time it is not possible to establish what factors influence the stoichiometry of the complex formed, from this and other work on dextromethorphan, it appears that changes in the anion alter the interaction.

Effect of Polyvalent Anions on the Apparent Partition Coefficient and the Importance of Chlorpheniramine Species in Solution.—As noted earlier, chlorpheniramine exists in aqueous phase in its singly protonated, doubly protonated, or its free base form, the relative concentrations depending on the pH of the system. It was of interest to determine if the sulfate and citrate anions would form ion pairs at different pH values. It was thought that since these anions could exist as doubly charged species they might interact with BH^{++} and form ion pairs.

Figure 6 shows that at a given pH and changing sulfate concentrations the $PC_{app.}$ is essentially independent of $[SO_4^{--}]$ concentration. Below pH 3.0, no chlorpheniramine could be detected in the organic layer. The slight increase in $PC_{app.}$ with pH appears to be extraction of the free base. The effect of citrate anions was determined at pH 3.5 increasing the total citrate concentration from 0.05 mole $L.^{-1}$ to 0.2 mole $L.^{-1}$. The results shown in Fig. 7 show that no ion-pair formation was detected. As sulfate anions show no tendency to form ion pairs, potassium sulfate was used to maintain a constant ionic strength in the studies dealing with bromide, picrate, chloride, maleate, and trichloroacetate anions.

To determine the ion-pair forming ability of the two protonated species of chlorpheniramine, a series of experiments were conducted at constant chlorpheniramine concentrations, constant ionic strength, and varying pH. In one series a constant bromide-ion concentration was maintained and in another a constant picrate. Figures 8 and 9 show similar profiles and would suggest that in both cases the BH^{++} did not form ion pairs, and only BH^+ interacted with the anion to form the extractable species. The theoretical curves in both figures were calculated on this assumption.

Equation 3 can be rearranged to the following form:

$$\frac{1}{PC_{app.}} = \frac{1}{K_0[X^-][M]^n} + \frac{[H^+]}{K_0 K_a [X^-][M]^n} \quad \text{(Eq. 5)}$$

Consequently, a plot of $1/PC_{app.}$ *versus* $[H^+]$ should yield a straight line with a slope of $1/K_0K_a[X^-][M]^n$ and an intercept of $1/K_0[X^-][M]^n$.

Figures 10 and 11 show that both the bromide and picrate data from Figs. 8 and 9 follow the dependency predicted from Eq. 5. The theoretical curve in Figs. 8 and 9 would be calculated from this equation when the appropriate values for n, K_a, and K_0 were utilized.

The K_a for the dissociation of the doubly protonated form was determined spectrophotometrically and found to be 1×10^{-4} at ionic strength of 0.55, but the values obtained from the intercepts and slopes of Figs. 8 and 9 deviated from this value. In the case of the bromide interaction, K_a was found to be 1.84×10^{-4}, and in the picrate system 3.64×10^{-4}.

These differences between the pKa values determined by spectrophotometric determinations and those calculated from Figs. 10 and 11 might possibly be due to interactions resulting in ion-pair formation in the aqueous layer which was not considered in Eq. 1.

From the foregoing and the previous work on dextromethorphan (1), it can be recognized that if chlorpheniramine and dextromethorphan were present in combination in the same system, they would be readily separated by selective ion-pair extraction. At pH 1 in the presence of bromide, dextromethorphan would form ion pairs and could be extracted by the organic phase. Chlorpheniramine being essentially completely in the doubly charged form would not form ion pairs. After separation of dextromethorphan, the pH could be increased to 3.5 and the antihistamine determined.

EXPERIMENTAL

Reagents.—Chlorpheniramine maleate U.S.P.[1] Based upon assay by the U.S.P. nonaqueous titration, it was found to be 99.65% $C_{20}H_{23}ClN_2O_4$.

Chloroform, analytical reagent, was shaken with phosphorus pentoxide and distilled to remove the ethanol. Two per cent (v/v) of *n*-amyl alcohol was added as stabilizer.

All water was glass distilled in the presence of potassium permanganate.

All other reagents were of analytical grade.

Chlorpheniramine Sulfate Stock Solution.—This solution was utilized in the tests determining the apparent partition coefficient in all cases except as described under the maleate system.

Preparation.—Dissolve 3.9 Gm. of chlorpheniramine maleate in 100 ml. of distilled water. Adjust to pH 8–9 and extract with three 50-ml. vol. of

[1] Supplied through the courtesy of the Schering Corp., Bloomfield, N. J.

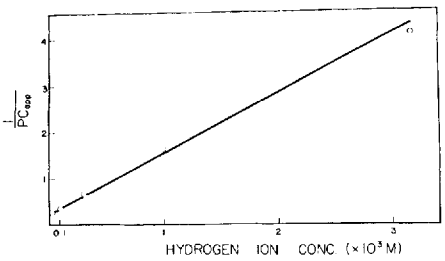

Fig. 10.—Reciprocal apparent partition coefficient of chlorpheniramine in the presence of 0.5 *M* bromide ion as a function of hydrogen-ion concentration.

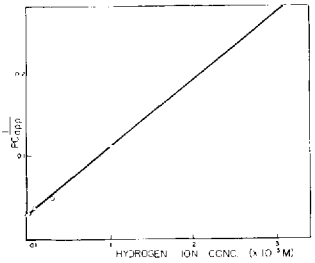

Fig. 11.—Reciprocal apparent partition coefficient of chlorpheniramine in the presence of 2×10^{-3} *M* picrate ion as a function of hydrogen-ion concentration.

cyclohexane. The combined extracts are washed with 50 ml. of distilled water. The cyclohexane is then extracted with three 50-ml. vols. of 0.05 *M* sulfuric acid. The solution is assayed spectrophotometrically and adjusted to a concentration of 5×10^{-2} mole/L. by the addition of distilled water.

Procedure of Partition.—*Procedure A.*—This procedure was employed for the partitioning of chlorpheniramine in the presence of bromide, chloride, maleate, and trichloroacetate anions. Solutions were prepared by dissolving acid or potassium salt of anion in the mixture of chlorpheniramine stock solution and citrate buffer (0.05 *M* citric acid, the pH adjusted by addition of 0.05 *M* potassium hydroxide solution). The concentration of chlorpheniramine in the solution was determined spectrophotometrically at the wavelength of absorption maximum using the calibration curve made from chlorpheniramine stock solution. The wavelengths of absorption maximum at each pH were as follows: pH 2.5, 265 mμ; pH 3.0, 264 mμ; pH 3.5, 263 mμ; pH 4.0, 262 mμ; pH 4.5–5.5, 261 mμ. Twenty milliliters of the aqueous solution was placed in a 60-ml. separator, and an equal volume of the organic phase was added. The mixture was allowed to stand for 1 hr. at 25° to allow the temperature to equilibrate. The sample was then shaken for 30 min. Both phases were separated, and the concentration of chlorpheniramine in the aqueous phase was determined. The concentration in the organic phase was calculated by subtracting the concentration in the aqueous phase from the initial concentration. In order to correct for the concentration of free base extracted into the organic phase, the same procedure was carried out for the blank solution which was prepared from chlorpheniramine, buffer, and containing potassium sulfate to adjust the ionic strength. The apparent partition coefficient was calculated from the following equation:

$$\text{apparent partition coefficient, } PC_{app.} = \frac{\text{total concn. in organic phase} - \text{concn. of free base in organic phase}}{\text{concn. in aqueous phase}}$$

The correction for free base concentration was not made for determining the apparent partition coefficient in the studies of the concentration dependency of sulfate and citrate because of the lack of suitable method. In the experiment with maleate ion, the determination of chlorpheniramine was made in the organic phase using the calibration curve made from chlorpheniramine maleate because the absorption of the anion interfered with the determination in the aqueous phase.

Procedure B.—This procedure was used for the partition of chlorpheniramine in the presence of picric acid. Solutions of chlorpheniramine and of picric acid were prepared, respectively, at the same pH using 0.05 *M* citrate buffer. In a 60-ml. separator 10 ml. of the chlorpheniramine solution and 10 ml. of the picric acid solution were placed, and 20 ml. of organic phase was added to this mixture. After both phases were brought to the temperature equilibrium at 25°, they were shaken for 30 min. Both phases were separated, and a 10-ml. aliquot of the organic phase was placed into a second 60-ml. separator, to which 5 ml. of the picric acid solution and 5 ml. of the buffer were added. The remaining organic phase of the first extraction served for determining the absorbance of the first extraction, A_1. The second separator was treated in the same manner as the first, and the organic phase separated was used for determining the absorbance due to the second extraction, A_2. The absorbance was determined at the wavelength of maximum absorption, 342 mμ, using the pure organic phase as the reference. A blank extraction, without chlorpheniramine, was carried out to correct for the free picric acid which was extracted along with the ion pair. A mixture of 10 ml. of the picric acid solution and 10 ml. of the buffer was shaken with 20 ml. of the organic phase in the same manner as cited above. Absorbances, A_1' and A_2', were determined for the blank extraction, and the apparent partition coefficient was calculated according to the following:

$$PC_{app.} = \frac{A_2 - A_2'}{(A_1 - A_1') - (A_2 - A_2')} u$$

where u is volume ratio of both phases, $V_{aq.}/V_{org.}$ The volume ratio, u, was changed according to the magnitude of the apparent partition coefficient. Chlorpheniramine free base shows no absorption in the wavelengths near 342 mμ.

pKa$_1$ of Chlorpheniramine.—Solutions were prepared from chlorpheniramine stock solution, potassium bromide, and 0.05 *M* citrate buffer at varied pH between 1.6 and 6.4. The concentration of chlorpheniramine was 2×10^{-4} *M* and of bromide was 0.5 *M*. The absorbances were determined at the wavelength of 261 mμ, and pKa was calculated according to the method of Flexner (3).

Antagonism of Convulsive and Lethal Effects Induced by Propoxyphene

By ROBERT E. FIUT, ALBERT L. PICCHIONI, and LINCOLN CHIN

A toxicological study was performed to demonstrate the effectiveness of several proposed antidotes against the convulsant and lethal effects of propoxyphene hydrochloride. Intravenous administration of levallorphan tartrate, nalorphine hydrochloride, or naloxone hydrochloride at a dose of 1 mg./Kg. significantly increased convulsion threshold and mortality threshold of mice and rats infused with propoxyphene hydrochloride. Treatment with levallorphan tartrate, 1 mg./Kg., plus sodium pentobarbital, 10 mg./Kg., or sodium pentobarbital alone, 10 mg./Kg., prevented propoxyphene-induced convulsions in a large percentage of mice and rats. The combination treatment was effective in elevating mortality threshold in both species, but was no more effective in this respect than a narcotic antagonist alone. Pentobarbital failed to modify mortality threshold. It is recommended that any one of the narcotic antagonists, without pentobarbital, be used to counteract the toxic symptoms of propoxyphene hydrochloride poisoning.

PROPOXYPHENE HYDROCHLORIDE is a widely used analgesic which has been involved in a number of accidental poisonings. The symptoms of massive overdose are referable to the central nervous system and have been reported to include severe depression, hyperactive reflexes, convulsions, respiratory depression, apnea, cyanosis, coma, and death (1–10).

Results of animal studies suggest that the narcotic antagonists are potentially useful for the treatment of propoxyphene toxicito (11–14). In recent years, narcotic antagonists have been used in the treatment of a number of clinical cases of propoxyphene intoxication and appear to be useful in antagonizing the respiratory depression caused by the analgesic (2, 6–8, 10). However, the value of narcotic antagonists against propoxyphene-induced convulsions has been inadequately documented and is controversial. For example, Parker believes that nalorphine may precipitate convulsions when it is used to counteract propoxyphene and cautions against its use as an antidote (5). McCarthy and Keenan (6) reported that nalorphine had no appreciable effect against convulsions in a lethal case of propoxyphene poisoning. On the other hand, in another fatal case, Frasier and coworkers (2) found that the antagonist *N*-allylmorphinan counteracted convulsions caused by the analgesic. Furthermore, a case report by Hara (3) suggests that nalorphine was of value in stopping convulsions displayed by another victim of propoxyphene overdose.

Since there is some uncertainty with respect to the use of narcotic antagonists in propoxyphene poisoning, further investigations to evaluate their effectiveness as specific antidotes are essential. Also, since some investigators have used (2, 8) or suggested the use (1) of central nervous system depressants, *e.g.*, barbiturates, to control convulsions produced by propoxyphene, studies are needed to determine the possible role of depressants in the treatment of poisoning by the analgesic.

The purpose of the present investigation is to determine the relative capacity of three chemically different narcotic antagonists, a barbiturate, and a barbiturate in combination with a narcotic antagonist to control the convulsive and lethal effects induced by propoxyphene in mice and rats. The results obtained constitute the basis of this report.

EXPERIMENTAL

Male CF No. 1 mice, weighing between 25 and 30 Gm., and male Sprague-Dawley rats weighing between 200 and 250 Gm., were randomized according to species into groups of 10. One group from each species was used to test each of the following intravenous treatments: nalorphine hydrochloride, levallorphan tartrate, or naloxone hydrochloride, 1 mg./Kg.; sodium pentobarbital, 10 mg./Kg.; a combination of levallorphan tartrate, 1 mg./Kg.; and sodium pentobarbital, 10 mg./Kg.; or normal saline, 2 ml./Kg. (control group). Three minutes later, propoxyphene hydrochloride, 1.0% for mice and 0.5% for rats, was infused into the animals according to the intravenous infusion technique described by McQuarrie and Fingl (15). The propoxyphene solutions were infused at the rate of 0.005 ml./sec. by means of a constant-infusion apparatus (16) until 2 end points were observed. The first

Received April 25, 1966, from the Division of Pharmacology and the Arizona Poisoning Control Information Center, College of Pharmacy, The University of Arizona, Tucson 85721.

Accepted for publication July 12, 1966.

Presented to the Pharmacology and Biochemistry Section, A.PH.A. Academy of Pharmaceutical Sciences, Dallas meeting, April 1966.

Grateful acknowledgment is made to Eli Lilly & Co. for the supply of propoxyphene hydrochloride, to Merck Sharp & Dohme for nalorphine hydrochloride, to Roche Laboratories for levallorphan tartrate, to Endo Laboratories for naloxone hydrochloride, and to Abbott Laboratories for sodium pentobarbital.

This investigation was supported by a grant from Eli Lilly & Co., Indianapolis, Ind.

end point consisted of 3 sec. of persistent clonus, and the second end point consisted of death. Relative effectiveness of the drug treatments was determined by comparing the time required for the onset of convulsions or death in the test group of animals with that of the control groups of animals. The data obtained were evaluated by analysis of covariance (17) and the results expressed as threshold ratios (*i.e.*, test value/control value).

RESULTS

Antagonism of Convulsions Caused by Propoxyphene.—The capacity of the three narcotic antagonists to elevate convulsion threshold in mice and rats is shown in Figs. 1 and 2, respectively. The mean infusion time of propoxyphene for clonus was 55 sec. in control mice and 181 sec. in control rats. The convulsion threshold in mice was increased 60, 41, and 23% ($p < 0.05$), and in rats it was increased 50, 57, and 60% ($p < 0.05$) by levallorphan, nalorphine, and naloxone, respectively. There was no significant difference among the three narcotic antagonists with regard to their relative capacity to elevate convulsion threshold in either mice or rats.

In the case of the pentobarbital-treated animals, 50% of the mice and 70% of the rats displayed no clonus even when propoxyphene was infused to the end point of death. Similarly, when the animals were pretreated with the drug combination levallorphan–pentobarbital, 50% of the mice and 60% of the rats displayed no convulsion.

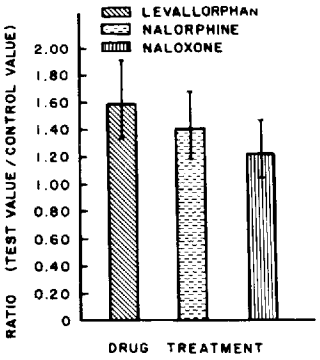

Fig. 1.—The effect of levallorphan tartrate, nalorphine hydrochloride, and naloxone hydrochloride on the convulsion threshold of propoxyphene in mice.

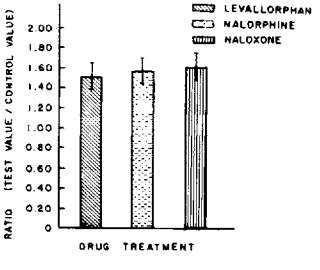

Fig. 2.—The effect of levallorphan tartrate, nalorphine hydrochloride, and naloxone hydrochloride on the convulsion threshold of propoxyphene in rats.

Antagonism of Lethal Effects of Propoxyphene.—The capacity of the various drug treatments to protect mice and rats from the lethal effects of propoxyphene is shown in Figs. 3 and 4, respectively. The mean infusion time for death following intravenous infusion of propoxyphene was 74 sec. in control mice and 372 sec. in control rats. The mortality threshold in mice was increased 60, 50, 59, and 34% ($p < 0.05$), and in rats it was increased 114, 127, 132, and 98% ($p < 0.05$) by levallorphan, nalorphine, naloxone, and the drug combination levallorphan–pentobarbital, respectively. There was no significant difference among these four drug treatments with regard to their relative capacity to elevate mortality threshold in either mice or rats. In contrast to the other drug treatments, pentobarbital, given alone, failed to produce a significant increase in mortality threshold in either animal species.

DISCUSSION

The results of this study show that pretreatment of mice and rats with the narcotic antagonists, nalorphine, levallorphan, or naloxone, markedly increases the amount of propoxyphene required to induce convulsions in these animals, as indicated by an increase in infusion time of the analgesic. Although the experimental design in this investigation required that the antagonists be administered prior to propoxyphene, previous studies in this laboratory have demonstrated that a narcotic antagonist, *e.g.*, nalorphine, arrests convulsions initiated by the analgesic in rats (13). That the narcotic antagonists can counteract established propoxyphene convulsions was also demonstrated by Chapman and Walaszek (12) who administered nalorphine subcutaneously to rats at the onset of the first convulsion and observed a reduction in the duration of convulsion. Even more dramatically, it can be demonstrated in rats that *intravenous* administration of nalorphine after onset of propoxyphene-induced convulsion prevents further episodes of seizure within 90 sec. following injection of the narcotic antagonist (13).

The results of the present study also show that pretreatment with any one of the narcotic antagonists tested markedly increases the amount of propoxyphene required to cause death in mice and rats. In this regard, Chapman and Walaszek (12) reported that pretreatment of rats with nalorphine increased the LD_{50} of the analgesic from 68 to 105 mg./Kg. In addition, these workers showed that the administration of nalorphine, after a toxic dose of propoxyphene which causes 50% mortality in rats, completely abolishes death. Harpel and Mann (14) also reported that nalorphine or levallorphan pretreatment increased the survival rate of mice injected with a lethal dose of propoxyphene.

It is of interest to note that despite the capacity of the drug combination, levallorphan–pentobarbital, to prevent convulsions caused by lethal doses of propoxyphene in a high percentage of mice and rats, the mortality thresholds of these animals were not significantly different from those of animals

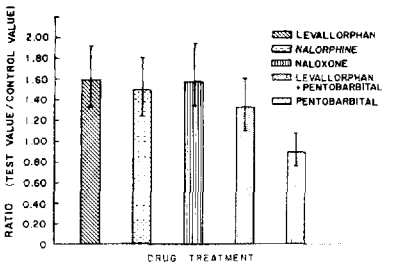

Fig. 3.—The effect of levallorphan tartrate, nalorphine hydrochloride, naloxone hydrochloride, levallorphan tartrate plus sodium pentobarbital, and sodium pentobarbital on mortality threshold of propoxyphene hydrochloride in mice.

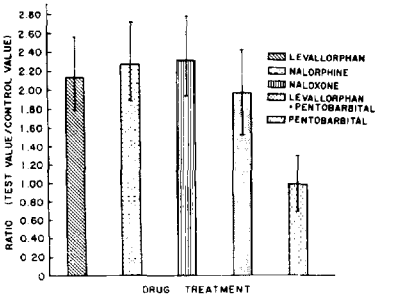

Fig. 4.—The effect of levallorphan tartrate, nalorphine hydrochloride, naloxone hydrochloride, levallorphan tartrate plus sodium pentobarbital, and sodium pentobarbital on mortality threshold of propoxyphene hydrochloride in rats.

pretreated with levallorphan, nalorphine, or naloxone. Indeed, *no* increase in mortality threshold occurred in mice and rats administered pentobarbital alone, a pretreatment procedure which prevented convulsions in a high percentage of the animals given lethal doses of propoxyphene. In view of these findings, it is tempting to speculate that convulsion *per se* may not contribute as much to the lethal effect of propoxyphene as do other factors, such as respiratory depression induced by this drug. If this be the case, then a barbiturate would not reduce mortality, because it does not antagonize the respiratory depression. On the other hand, the results of the present study do not rule out the possibility that convulsion *per se* may contribute to the lethal effect of propoxyphene; the dose of pentobarbital employed could have reduced the convulsive component of toxicity but simultaneously increased the respiratory component such that no significant alteration in propoxyphene-induced lethality was apparent. It is conceivable that there may be an optimal dose of barbiturate which produces an anticonvulsive effect against propoxyphene without causing respiratory depression. However, clinically speaking, it would be difficult as well as potentially hazardous to determine such an optimal dose because of differences in degree of toxicity displayed by victims of propoxyphene poisoning and because respiratory depression resulting from overtitration with a barbiturate would add to postconvulsive and propoxyphene-induced respiratory depression. When a barbiturate is used in conjunction with one of the narcotic antagonists, it is also possible that the respiratory depressant action of the barbiturate, which is not antagonized by these antidotes (18, 19), could reduce the salutary effect of a narcotic antagonist against the lethal action of propoxyphene. Hence, it would appear inadvisable to use a barbiturate alone or in combination with a narcotic antagonist, in the treatment of intoxication caused by propoxyphene. On the other hand, since the narcotic antagonists are known to antagonize the respiratory depressant action of propoxyphene (2, 6–8, 10), and since the present investigation confirms the effectiveness of these drugs in counteracting convulsions and in counteracting the lethal action caused by propoxyphene, it is recommended that one of the narcotic antagonists alone be employed in the treatment of propoxyphene poisoning.

Hydrolytic Behavior of Isoalloxazines Related to Riboflavin I

Identification of an Intermediate and Products in the Base-Catalyzed Degradation of 9-Methylisoalloxazine

By DEODATT A. WADKE and DAVID E. GUTTMAN

Hydrolytic breakdown of 9-methylisoalloxazine was investigated in pH 9.0 borate buffer and in 0.5 *N* sodium hydroxide. Spectral and thin-layer chromatographic analysis of the degraded solutions revealed that different products were formed depending on the reaction conditions. Thus, at high pH and in the presence of air, 1,2-dihydro-1-methyl-2-keto-3-quinoxaline carboxylic acid was predominantly formed, while at pH 9.0, 1,2,3,4-tetrahydro-1-methyl-2,3-dioxo-quinoxaline was the main product. At pH 9.0 under anaerobic conditions the predominant products were the keto acid and 1,2-dihydro-1-methyl-2-oxo-quinoxaline. Examination of the degrading solutions by thin-layer chromatography revealed the presence of an intermediate in the reaction pathways. This intermediate was successfully isolated and identified to be 5-(6-methylaminophenylimino) barbituric acid anil.
