Simplified Computation of Confidence Intervals for Relative Potencies Using Fieller's Theorem

By C. PHILIP COX and DONNA J. RUHL

Confidence intervals for relative potencies in bioassays are usually calculated by using Fieller's theorem, but the procedures presented in standard texts are computationally cumbersome. It is shown that Fieller's formula can be expressed in an alternative form which takes advantage of calculated quantities from the analysis of variance (ANOV) and thus simplifies computations. Slope ratio assays and parallel line assays are discussed, and 2 examples illustrate the use of the proposed alternatives.

CONFIDENCE intervals for relative potencies in bioassays based on normally distributed responses are calculated from the formula derived by Fieller (1) which, for present purposes, is restated as follows. Suppose that the ratio estimate of $\rho = \mu/\gamma$ is

$$R = u/v \qquad \text{(Eq. 1)}$$

where u, the unbiased estimate of μ, and v, the unbiased estimate of γ, are linear combinations of variates which are normally distributed with variance σ^2. Suppose also that the variance and covariance estimates are

$$V(u) = a_u s^2, \quad V(v) = a_v s^2, \quad CV(u, v) = a_{uv} s^2 \qquad \text{(Eq. 2)}$$

where s^2, with f degrees of freedom, is the unbiased estimate of σ^2, and a_u, a_v, and a_{uv} are known constants depending on the construction of u and v. The usual derivation of Fieller's theorem leads to R_L and R_U, the lower and upper 100 $(1 - \alpha)\%$ confidence limits on ρ, as

$$R_L, R_U = \frac{Rv^2 - s^2F_c a_{uv}}{v^2 - s^2F_c a_v} \mp \frac{\sqrt{s^2F_c\{a_u v^2 - 2a_{uv}uv + a_v u^2 - s^2F_c(a_u a_v - a_{uv}^2)\}}}{v^2 - s^2F_c a_v} \qquad \text{(Eq. 3)}$$

where F_c, the $100(1 - \alpha)\%$ tabulated critical value from the F-distribution, with 1 and f degrees of freedom, has replaced t^2 in the usual formulation.

Users (2) know that, as usually presented, the formula is computationally cumbersome, and it will be shown that the formula can be thrown into a simpler alternative form. The beneficial results for slope ratio and, particularly, parallel line assays are exemplified.

SLOPE RATIO ASSAYS WITH ONE TEST PREPARATION

For slope ratio assays with responses at the zero-dose level and at doses x_{Si} and x_{Tj}, $i = 1, 2, \ldots, k_1$ and $j = 1, 2, \ldots, k_2$, for the standard and test preparations, respectively, the relative potency estimate, R, is obtained as

$$R = b_T/b_S \qquad \text{(Eq. 4)}$$

where b_S and b_T are the estimated slopes of the (x, y) dose-response lines for the standard and test preparations, respectively. The 2 slopes are given by

$$b_S = \frac{1}{\Delta}\{(\Sigma' x_T^2)(\Sigma' x_S y) - (\Sigma' x_S x_T)(\Sigma' x_T y)\}$$

$$b_T = \frac{1}{\Delta}\{-(\Sigma' x_S x_T)(\Sigma' x_S y) + (\Sigma' x_S^2)(\Sigma' x_T y)\} \qquad \text{(Eq. 5)}$$

where, if Σ denotes summation over all the observations for each preparation, Σ' denotes "corrected" summation so that the quantities in Eq. 5 are obtained as follows:

$$\Sigma' x_S^2 = \Sigma x_{Si}^2 - \frac{(\Sigma x_{Si})^2}{N},$$

$$\Sigma' x_T^2 = \Sigma x_{Tj}^2 - \frac{(\Sigma x_{Tj})^2}{N},$$

$$\Sigma' x_S x_T = \frac{-(\Sigma x_{Si})(\Sigma x_{Tj})}{N} \qquad \text{(Eq. 6)}$$

$$\Sigma' x_S y = \Sigma x_{Si} y_{Si} - \frac{G(\Sigma x_{Si})}{N},$$

$$\Sigma' x_T y = \Sigma x_{Tj} y_{Tj} - \frac{G}{N}(\Sigma x_{Tj}) \qquad \text{(Eq. 7)}$$

in which N is the total number of observations, G is the grand total of all the responses, and

$$\Delta = (\Sigma' x_S^2)(\Sigma' x_T^2) - (\Sigma' x_S x_T)^2 \qquad \text{(Eq. 8)}$$

Hence, by comparison with Eqs. 1 and 2

$$u = b_T, \quad v = b_S \qquad \text{(Eq. 9)}$$

and Finney (3) shows that

$$a_u = \Sigma' x_S^2/\Delta, \quad a_v = \Sigma' x_T^2/\Delta, \quad a_{uv} = -\Sigma' x_S x_T/\Delta \qquad \text{(Eq. 10)}$$

If now quantities F_r and F_S are defined as

$$2F_r = (\text{regressions sum of squares})/s^2 \qquad \text{(Eq. 11)}$$

$$F_S = b_S^2/a_v s^2 \qquad \text{(Eq. 12)}$$

then it is shown in the *Appendix* that the confidence interval on the ratio, ρ, can be expressed as

$$R_L, R_U = \frac{RF_S - F_c(a_{uv}/a_v) \mp \sqrt{F_c(2F_r - F_c)/\Delta a_v^2}}{(F_S - F_c)} \qquad \text{(Eq. 13)}$$

Using Eq. 10, Eq. 13 can be put into the alternative form

$$R_L, R_U = \frac{R(\Delta b_S^2/s^2) + F_c(\Sigma' x_S x_T) \mp \sqrt{F_c(2F_r - F_c)\Delta}}{(\Delta b_S^2/s^2) - F_c(\Sigma' x_T^2)} \qquad \text{(Eq. 14)}$$

With Δ from Eq. 8, the alternatives given in Eqs. 13 and 14 are already more convenient than the usual form in the general case described. Further advantages occur in applications to the common symmetrical assays for which explicit values of a_u, a_v, and a_{uv} are available.

Thus, for the symmetrical 5-point assay with a zero dose and coded doses of 0.5 and 1 for each of the standard and test preparations,

$$\Sigma' x_S^2 = \Sigma' x_T^2 = \frac{16N}{100} \text{ and } \Sigma' x_S x_T = \frac{-9N}{100} \qquad \text{(Eq. 15)}$$

so that, from Eqs. 8 and 10,

$$\Delta = 175N^2/10^4, \; a_u = a_v = 64/7N, \; a_{uv} = 36/7N \qquad \text{(Eq. 16)}$$

Substitution in Eq. 13 leads to the very simple expression of the confidence limits as

$$R_L, R_U = \frac{16F_S R - 9F_c \mp \sqrt{175F_c(2F_r - F_c)}}{16(F_S - F_c)} \qquad \text{(Eq. 17)}$$

where, from Eq. 12,

$$F_S = 7Nb_S^2/64s^2 \qquad \text{(Eq. 18)}$$

Taking $175/256 \doteq 0.6836$, Eq. 17 becomes

$$R_L, R_U = \frac{F_S R - (0.5625)F_c \mp \sqrt{(0.6836)F_c(2F_r - F_c)}}{(F_S - F_c)} \qquad \text{(Eq. 19)}$$

In microbiological assays the quantity F_c/F_S, which is g as used by Finney (3), is often small enough to be neglected. In this case Eqs. 17 and 19 reduce to the very convenient approximate form

$$R_L, R_U = R \mp \frac{20}{Nb_S^2}\sqrt{F_c(\text{regressions sum of squares})s^2/7} \qquad \text{(Eq. 20)}$$

Numerical Example.—Values from the assay by Wood (4), analyzed in Finney (3), will be used to illustrate the computational procedures. The numerical quantities required are

$$N = 20, \quad b_S = 118.629, \quad R = 0.6847, \quad s^2 = 14.43 \text{ (15 d.f.)}$$

From the ANOV, the regressions sum of squares is 31456.9, while, for 95% confidence limits, $F_c = F_{1,15}(0.05) = 4.54$ from standard tables. Since F_S from Eq. 18 will plainly be large relative to F_c, the approximate formula can safely be used in this case. Hence, from Eq. 20

$$R_L, R_U = 0.6847 \mp \frac{1}{(118.629)^2}\sqrt{(4.54)(31456.9)(2.06)} = 0.6462, 0.7232$$

which compare well with the accurate results that are obtained below and given in Finney (3). To obtain the accurate values, $2F_r$ and F_S are first computed as

$$2F_r = 31456.9/14.43 = 2179.9653$$

and, from Eq. 18,

$$F_S = (7)(20)(118.629)^2/(64)(14.43) = 2133.3566$$

so that, from Eq. 19,

$$R_L, R_U = \frac{1}{2128.8166}[(2133.3566)(0.6847) - (0.5625)(4.54) \mp \sqrt{(0.6836)(4.54)(2175.4253)}] = 0.6464, 0.7236$$

PARALLEL LINE ASSAYS

The logarithm of the relative potency estimate in parallel line assays is obtained by Finney (3) as M where

$$M = \bar{x}_S - \bar{x}_T - \frac{(\bar{y}_S - \bar{y}_T)}{b} \qquad \text{(Eq. 21)}$$

in which $\bar{x}_S$ and $\bar{x}_T$ are the mean log-doses, $\bar{y}_S$ and $\bar{y}_T$ are the mean responses for the standard and test preparations, respectively, and b is the estimated common slope of the log-dose, response lines. Since $\bar{x}_S$ and $\bar{x}_T$ are taken as fixed, the confidence interval is therefore obtained for the ratio quantity

$$M - \bar{x}_S + \bar{x}_T = -(\bar{y}_S - \bar{y}_T)/b \qquad \text{(Eq. 22)}$$

Here the numerator and denominator on the right hand side are statistically independent so that, from Eq. 2, $a_{uv} = 0$. It is shown in the *Appendix* that the confidence limits can be represented as

$$R_L, R_U = \frac{1}{(F_r - F_c)}\left\{RF_r \mp \sqrt{\frac{a_p}{a_r}F_c(F_p + F_r - F_c)}\right\} \qquad \text{(Eq. 23)}$$

where

$$a_p = \left(\frac{1}{n_S} + \frac{1}{n_T}\right), \; a_r = \left\{\sum_s (x - \bar{x})^2 + \sum_T (x - \bar{x})^2\right\}^{-1} \qquad \text{(Eq. 24)}$$

and

$$\left.\begin{aligned} F_p &= \text{the F-ratio for preparations in the ANOV} \\ F_r &= \text{the F-ratio for regression in the ANOV} \end{aligned}\right\} \qquad \text{(Eq. 25)}$$

and n_S and n_T are the total number of responses to the standard and test preparations, respectively.

Some simplification occurs if F_c/F_r is small enough to be neglected but, in practice, the gain is so slight that the use of Eq. 23 may be generally recommended. Simplified forms can, however, be presented for the common, balanced 4- and 6-point parallel assays using explicit values for a_p and a_r as follows.

Four-Point Parallel Line Assay.—If S_1, S_2, are the total responses to the lower and upper doses of the standard preparation, respectively, and T_1 and T_2 are the corresponding response totals for the test preparation, and linear contrasts L_p and L_r are defined as

$$\begin{aligned} L_p &= -(S_1 + S_2) + (T_1 + T_2) \\ L_r &= -(S_1 + T_1) + (S_2 + T_2) \end{aligned} \quad \text{(Eq. 26)}$$

the logarithm of the relative potency is calculated from the ratio of $R = dL_p/L_r$, where d, as used by Finney (3), is the logarithm of the ratio between successive doses, this ratio being the same for both preparations. Since $V(L_p) = V(L_r)$ from Eq. 26, the confidence limits for dL_p/L_r are found by using Eq. 23 with $a_p = a_r$.

$$\left(\frac{dL_p}{L_r}\right)_L, \left(\frac{dL_p}{L_r}\right)_U = \frac{d}{(F_r - F_c)}\left\{\frac{L_p}{L_r} F_r \mp \sqrt{F_c(F_p + F_r - F_c)}\right\} \quad \text{(Eq. 27)}$$

where, as before, F_c is the $100(1 - \alpha)\%$ tabulated F-value with 1 and f degrees of freedom, f being the number of degrees of freedom for s^2 in the ANOV, F_p and F_r are as defined in Eq. 25.

If g is computed as

$$g = F_c s^2/(\text{regression mean square}) \quad \text{(Eq. 28)}$$

an alternative computational form of Eq. 27 is then

$$\left(\frac{dL_p}{L_r}\right)_L, \left(\frac{dL_p}{L_r}\right)_U = \frac{d}{(1 - g)} \times \left\{\frac{L_p}{L_r} \mp \sqrt{g\left(1 - g + \frac{\text{preparations mean square}}{\text{regression mean square}}\right)}\right\} \quad \text{(Eq. 29)}$$

which is perhaps the most expedient formulation.

Six-Point Parallel Line Assay.—If L_p and L_r are the usual contrasts for the 6-point assay, corresponding to those in Eq. 26, the confidence limits for $\bar{y}_T - \bar{y}_S/b = 4dL_p/3L_r$ are obtained from Eq. 23 as

$$\left(\frac{4dL_p}{3L_r}\right)_L, \left(\frac{4dL_p}{3L_r}\right)_U = \frac{4d}{3(F_r - F_c)} \times \left\{\frac{L_p}{L_r} F_r \mp \sqrt{\frac{3}{2} F_c(F_p + F_r - F_c)}\right\} \quad \text{(Eq. 30)}$$

$$= \frac{4d}{3(1 - g)} \times \left\{\frac{L_p}{L_r} \mp \sqrt{\frac{3g}{2}\left(1 - g + \frac{\text{preparations mean square}}{\text{regression mean square}}\right)}\right\} \quad \text{(Eq. 31)}$$

with all quantities as previously defined.

Numerical Example.—To illustrate the identification of the required quantities the 4-point assay of oestrin by Bülbring and Burn (5) as used by Finney (3) is taken. In that example $L_p = -42$, $L_r = 448$ and the ANOV was essentially

	d.f.	m.s.
Preparations	1	63
Regression	1	7168
Divergence	1	240
Residual error	13	551.15

where the term "divergence" is introduced in preference to "parallelism" or, uglier, "antiparallelism." Hence, for 95% limits,

$$F_c = F_{1,13}(0.05) = 4.67$$

and

$$g = (4.67)(551.15)/7168 = 0.3591$$

The ratio of upper to lower doses was 2 so that, with $d = \log 2$, from Eq. 29,

$$\left(\frac{dL_p}{L_r}\right)_L, \left(\frac{dL_p}{L_r}\right)_U = \frac{0.30103}{0.6409} \times \left\{-\frac{42}{448} \mp \sqrt{\left(0.3591(0.6409 + \frac{63}{7168}\right)}\right\} = -0.2709, 0.1828$$

The basic doses were 0.2 mcg. and 0.0075 ml., for the standard and test preparations, respectively, so that the limits for the actual relative potency estimate $\hat{\rho}_p$ are,

$$(\hat{\rho}_p)_L, (\hat{\rho}_p)_U = \frac{0.2}{0.0075} \text{ antilog } (\bar{1}.7291, 0.1828) = 14.29, 40.60 \text{ mcg./ml.}$$

PRECISION

The formulas derived above are useful in discussions of the precision of bioassays. For example, from Eqs. 29 and 30 the squared length of the confidence interval for 4- and 6-point parallel line assays is seen to depend on the quantity,

$$\frac{1}{(1 - g)^2}\left\{g\left(1 - g + \frac{\text{preparations mean square}}{\text{regression mean square}}\right)\right\} = \frac{g}{1 - g} + \frac{g}{(1 - g)^2}\left\{\frac{\text{preparations mean square}}{\text{regression mean square}}\right\} \quad \text{(Eq. 32)}$$

From the definition of g in Eq. 28, it therefore simply follows that the basic requirements are small values for F_c, s^2, and the mean square for preparations, and a large value for the regression mean square.

CONCLUSION

Detailed presentations of the above formulas have been made because of the assurance [Schultz (6)] that they give considerable computational advantage. In particular, the gain arises because values in the necessarily computed ANOV do double duty. The exact rather than the approximate formulas may be recommended, for parallel line assays at least, because once F_c/F_r has been calculated for arbitration, its retention involves little extra labor.

APPENDIX

Slope Ratio Assay.—Using the values for a_u, a_v, and a_{uv} for a slope ratio assay as given in Eq. 10, the expression $a_u v^2 - 2a_{uv}uv + a_v u^2$ under the radical of Eq. 3 can be written as

$$a_u v^2 - 2a_{uv}uv + a_v u^2 = v(a_u v - a_{uv}u) + u(a_v u - a_{uv}v)$$
$$= \frac{1}{\Delta}\{b_S(b_S\Sigma' x_S^2 + b_T\Sigma' x_S x_T) + b_T(b_T\Sigma' x_T^2 + b_S\Sigma' x_S x_T)\}$$
$$= \frac{1}{\Delta}\{b_S\Sigma' x_S y + b_T\Sigma' x_T y\} \quad \text{(Eq. 33)}$$

This follows from the normal equations of which Eq. 5 is the solution. Further, the numerator on the right of Eq. 33 is the sum of squares for regression in the ANOV. Also,

$$a_u a_v - a_{uv}^2 = \frac{1}{\Delta^2}\{(\Sigma' x_S^2)(\Sigma' x_T^2) - (\Sigma' x_S x_T)^2\} = \frac{1}{\Delta} \quad \text{(Eq. 34)}$$

Substituting from Eqs. 33 and 34 into Eq. 3, the confidence limits can therefore be written as

$$R_L, R_U = \frac{1}{b_S^2 - s^2 F_c a_v}[Rb_S^2 - s^2 F_c a_{uv} \mp \sqrt{s^2 F_c(\text{regressions sum of squares} - s^2 F_c)/\Delta}] \quad \text{(Eq. 35)}$$

Hence, with F_r and F_S defined as in Eqs. 11 and 12, the confidence limits can be expressed as

$$R_L, R_U = \frac{RF_S - F_c(a_{uv}/a_v) \mp \sqrt{F_c(2F_r - F_c)/\Delta a_v^2}}{F_S - F_c} \quad \text{(Eq. 36)}$$

as given in Eq. 13.

Parallel Line Assay.—For a parallel line assay, Eq. 3 with $a_{uv} = 0$ reduces to

$$R_L, R_U = \frac{Rv^2 \mp \sqrt{s^2 F_c(a_u v^2 + a_v u^2 - s^2 F_c a_u a_v)}}{v^2 - s^2 F_c a_v}$$
$$= \frac{1}{\left(\frac{v^2}{a_v s^2} - F_c\right)} \times \left\{\frac{Rv^2}{a_v s^2} \mp \sqrt{\frac{a_u}{a_v} F_c\left(\frac{u^2}{a_u s^2} + \frac{v^2}{a_v s^2} - F_c\right)}\right\}$$
$$= \frac{1}{(F_v - F_c)} \times \left\{RF_v \mp \sqrt{\frac{a_u}{a_v} F_c(F_u + F_v - F_c)}\right\} \quad \text{(Eq. 37)}$$

where F_u and F_v are defined as

$$F_u = u^2/a_u s^2 \text{ and } F_v = v^2/a_v s^2 \quad \text{(Eq. 38)}$$

For the general parallel line assay, comparison of Eqs. 1 and 22 shows that the above result can be applied to obtain the confidence interval for $M - \bar{x}_S + \bar{x}_T$ if

$$u = (\bar{y}_S - \bar{y}_T) \text{ and } v = b \quad \text{(Eq. 39)}$$

If n_S and n_T are the total number of responses to the standard and test preparations, respectively, the variance of $(\bar{y}_S - \bar{y}_T)$ is estimated as

$$V(u) = V(\bar{y}_S - \bar{y}_T) = \left(\frac{1}{n_S} + \frac{1}{n_T}\right)s^2 = a_u s^2 \quad \text{(Eq. 40)}$$

so that, from Eq. 38,

$$F_u = \frac{(\bar{y}_S - \bar{y}_T)^2}{\left(\frac{1}{n_S} + \frac{1}{n_T}\right)s^2} \quad \text{(Eq. 41)}$$

which itself is the F-ratio for preparations in the ANOV. Similarly

$$F_v = \frac{b^2}{s^2}\left\{\sum_S (x - \bar{x})^2 + \sum_T (x - \bar{x})^2\right\} \quad \text{(Eq. 42)}$$

which is the F-ratio for regression in the ANOV. If then F_p and F_r are defined as in Eq. 25, the confidence interval from Eq. 37 is

$$R_L, R_U = \frac{1}{(F_r - F_c)}\left\{RF_r \mp \sqrt{\frac{a_p}{a_r} F_c(F_p + F_r - F_c)}\right\} \quad \text{(Eq. 43)}$$

which establishes the result given in Eq. 23.

Identification and Differentiation of Organic Medicinal Agents III

Amine-Containing Antiparkinson Agents and Newer Muscle Relaxants

By LESLIE G. CHATTEN and LYNN A. DOAN*

A series of specific physical criteria, by which four amine-containing antiparkinson agents and a newer amine-containing skeletal muscle relaxant, currently in popular clinical application, can be identified and differentiated, is presented. Twenty-three derivatives of these compounds were prepared using a variety of characterizing agents which included picric acid, ammonium reineckate, sodium tetraphenylborate, chloroplatinic acid, and methyl iodide. By the use of microcrystal tests, and formation of derivatives, it is possible to differentiate biperiden, cycrimine, procyclidine, trihexyphenidyl, and phenyramidol. Photomicrographs are presented as a supplemental and additional parameter for characterization purposes.

VARIOUS techniques for the identification of trihexyphenidyl, cycrimine, and procyclidine hydrochloride salts have appeared in the literature. These include microcrystal tests and color spot tests (1), chromatographic studies (2–4), published infrared spectra (5), and derivatization (6–9).

A few isolated derivatives have been reported for phenyramidol hydrochloride (10–12) and those can be used as an aid to identification. No method for the qualitative estimation of biperiden hydrochloride could be found in the literature.

All of these preparations are potent systemic drugs and are intended for oral or parenteral administration; hence reliable criteria for their identification and differentiation are of great importance to the forensic chemist and toxicologist. It is the purpose of this investigation to develop a comprehensive series of several physical reference criteria which can be utilized to positively identify these compounds in the least amount of time.

EXPERIMENTAL

Apparatus.—Fisher-Johns melting point apparatus; Beckman IR-5A infrared spectrophotometer; Bausch & Lomb biological microscope; Metrohm potentiograph model E336.

Compounds Investigated.—Phenyramidol HCl or 2-β-hydroxyphenethylamino-pyridine HCl; biperiden HCl or [α-bicyclo (2.2.1)-hept-5-en-2-yl-α-phenyl-1-piperidino-propanol HCl]; cycrimine HCl or 1-cyclopentyl-1-phenyl-3-piperidino-1-propanol HCl; procyclidine HCl or 1-cyclohexyl-1-phenyl-3-pyrrolidino-1-propanol HCl; trihexiphenidyl HCl or 1-cyclohexyl-1-phenyl-3-piperidino-1-propanol HCl.

Reagents and Solutions.—All reagents used were A.C.S. grade or the highest grade commercially available. Aqueous and ethanolic (95%) solution of: trihexyphenidyl HCl, 0.25, 0.5, 1%; cycrimine HCl, 0.25, 0.5, 1%; procyclidine HCl, 0.25, 0.5, 1%; phenyramidol HCl, 0.25, 0.5, 1%; biperiden HCl, 0.05, 0.1%; aqueous Reinecke salt solutions, 0.1, 0.25, 0.5, 1.0%; aqueous and ethanolic (95%) picric acid solutions, 0.25, 0.5, 1.0%, and in acetone, 0.5, 1%; aqueous and ethanolic (95%) styphnic acid solutions, 0.16, 0.32, 0.64, and 0.25, 0.5, 1.0%, respectively; aqueous chloroplatinic acid solutions, 0.25, 0.5, 1.0%; ethanolic (95%) solutions of picrolonic acid, 0.25, 0.5, and 1.0%. These solutions were stored in 15-ml. amber dropper bottles.

Formation of Derivatives

All purified derivatives were dried in a vacuum desiccator over phosphorus pentoxide at room temperature for 24 hr. before the final melting point was taken on a Fisher-Johns melting point apparatus. Melting points were corrected by a calibration graph prepared from U.S.P. melting point reference standards.

Picrates.—The general procedure for preparation of picrates was that employed by Shriner *et al.* (13). The crude material was recrystallized from 95% ethanol and the equivalent weights determined by the titration technique of Clark and Wang (14). The data obtained, together with the elemental analyses (C, H, and N) verified the purity and identity of the derivatives.

Reineckates.—The procedure of Chatten and Levi (15) was used. The resulting derivatives were recrystallized by adding approximately 5–10 ml. of methanol and sufficient acetone dropwise to solubilize the derivative if it had not already dissolved. Water was then added dropwise with agitation until

a turbidity was seen to persist. All recrystallizations were performed without the aid of heat.

Purity and identity of the reineckates was established by elemental analyses (C, H, N, and Cr).

Tetraphenylborates.—The general technique of Koehler and Feldmann (16) was used. Products were recrystallized from methanol or methanol/acetone by adding water dropwise with agitation until a turbidity persisted and then cooled.

Equivalent weights of the tetraphenylborates were determined by the nonaqueous titration procedure of Chatten *et al.* (17). These data, together with the elemental analyses (C, H, N), confirmed the identity and purity of these derivatives.

Methiodides.—The procedure by Cheronis and Entrikin (18) for the preparation of methiodide derivatives was used. Products were recrystallized from isopropanol or acetone–ether.

Purity and identity was confirmed by elemental analyses (C, H, N).

Chloroplatinates.—The method outlined by Wild (19) for the preparation of chloroplatinic acid derivatives was modified and adapted for these amine hydrochloride salts.

Biperiden hydrochloride, being almost insoluble in water, was dissolved in a minimal amount of methanol to which a slight excess of aqueous chloroplatinic acid was added with stirring. The mixtures were allowed to stand for 20 min. in an ice bath and then filtered. The resulting products were purified by washing well with cold water.

Elemental analyses (C, H, N) confirmed the purity and identity of the derivatives.

Infrared Spectra

Infrared spectra of the parent compounds and derivatives were measured by the potassium bromide pellet technique.

Preparation of Photomicrographs

One drop of an aqueous or alcoholic solution of the amine muscle relaxant salt was placed on a microscope slide and 1 drop of a reagent solution was added. These were mixed well and covered with a cover glass. For the potassium iodide test, 1 drop of an aqueous solution of the parent compound was placed on a microscope slide, and a few particles of finely ground potassium iodide were sprinkled over the surface of the drop.

In all instances, the time of crystal formation was noted and the photomicrographs were taken before the slide became dry.

RESULTS AND DISCUSSION

Formation of Derivatives

The melting ranges of the derivatives prepared from the compounds under investigation, together with previously reported literature values, are presented in Table I.

Picrates.—A review of the literature has revealed that relatively few picrates have been reported for the basic amino muscle relaxants. Delaby *et al.* (11) have reported the preparation of the picrate of phenyramidol with a melting point of 151.0–152.0°.

Trihexyphenidyl and biperiden picrate were not obtained in a crystalline state. These products initially formed an oily mass, and repeated crystallization attempts from various solvents (ethanol, methanol, acetone) proved unsuccessful.

The other picrate derivatives were obtained in good yield, were easily purified, and had sharp, well distributed, characteristic melting points.

Reineckates.—In every instance, the amine muscle relaxants studied formed the anhydrous reineckate. This was verified by elemental analyses (carbon, hydrogen, nitrogen) and the gravimetric determination of chromium calculated as Cr_2O_3.

All reineckates prepared in this program were observed to have a reasonably sharp decomposition range. However, some overlap in the melting ranges of the derivatives was evident, thus necessitating the preparation of other derivatives for conclusive identification.

Tetraphenylborates.—It has been stated that washing TPB salts free of excess reagent, and drying under vacuum yields compounds which are sufficiently pure for characterization purposes (20, 21). In this investigation, the TPB derivatives were recrystallized to obtain well-defined crystalline products for infrared spectra. Crane (21) has shown several TPB salts to be heat labile, and for this reason the derivatives were prepared and recrystallized at room temperature.

Since good yields of easily purifiable product were obtained and well distributed melting points were noted, the tetraphenylborate salts proved to be highly desirable derivatives for qualitative identification. When titrated in nonaqueous media, excellent quantitative recoveries were obtained for all derivatives.

Methiodides.—The observed melting point of cycrimine methiodide is radically different from that reported in the literature. No apparent reason for this anomaly could be found other than the failure

TABLE I.—MELTING POINTS OF DERIVATIVES OF THE AMINE COMPOUNDS, °C.

Drug	Picrate	Reineckate	Tetraphenylborate	Methiodide	Chloroplatinate
Biperiden		160.0–164.0(dec.)	208.0–209.5	207.0–208.0	142.0–147.0(dec.)
Cycrimine	145.0–146.5	154.0–158.0(dec.)	157.5–159.0	145.0–146.0 235.0–237.0(9)	179.0–182.0(dec.)
Procyclidine	63.5–65.0	149.0–154.0(dec.)	148.0–150.0	204.0–205.0(dec.) 204.0–205.0(6)	199.0–203.0(dec.)
Trihexyphenidyl		159.0–162.0(dec.)	157.0–159.0	208.0–208.5 203.0–204.0(6,8)	132.0–137.0(dec.)
Phenyramidol	153.5–154.5 151.0–152.0(11)	156.0–158.0(dec.)	124.0–126.0	165.5–166.5 164.0–166.0(10)	156–160.0(dec.)

of the workers (9) to confirm identity of the derivative by elemental analysis.

The methiodides were readily prepared and easily purified derivatives with sharp melting points. Their only apparent disadvantage is the overlap in the melting ranges which precludes their use for qualitative identification without the preparation of additional derivatives.

Chloroplatinates.—All of the amino muscle relaxants studied in this investigation were monobasic and formed the 2:1 derivative with the divalent platinic anion.

The literature reveals no record that chloroplatinic acid has been used previously to characterize any of the amino muscle relaxants investigated in this program. All chloroplatinate derivatives decomposed on heating but the decomposition ranges were reproducible and characteristic. Recrystallization was a factor encountered during the preparation of these derivatives. Generally the chloroplatinates were only sparingly soluble in ethanol (95%) or methanol, and any amount of heating resulted in a partial or complete decomposition of the product. In order to avoid this the chloroplatinates were purified by washing well with cold distilled water prior to submission for elemental analyses. Excellent results were obtained and decomposition ranges were characteristic in each instance with no overlap.

Infrared Spectroscopy

Examination of the spectra of the parent compounds provided an additional parameter for differentiation, although the same functional groups (tertiary amino and alcoholic) are present in all of the drugs.

Medium to weak adsorption in the 3500 cm.$^{-1}$ region (OH stretching vibration) and medium absorption throughout the 3050–2850 cm.$^{-1}$ aromatic and aliphatic CH stretching region is common to the picrates in this investigation. Multiple or broad bands in the 2700–2250 cm.$^{-1}$ region due to NH^+ stretching vibrations, overtones, and combinations are also present. Intense bands at 1560 and 1360 cm.$^{-1}$ represent the nitro asymmetrical and symmetrical stretching vibrations, respectively. In the "fingerprint" region two sharp characteristic bands, common to the three spectra, appear at 785 and 740 cm.$^{-1}$.

Spectral interpretations appearing in a previous paper of this series (22) are applicable to the reineckates and tetraphenylborates, respectively. However, the methiodide spectra are sufficiently different to merit special mention. These latter spectra exhibit numerous common bands, in keeping with their structural similarity. Strong absorption bands at 3300 cm.$^{-1}$ due to OH stretching vibrations and medium to strong aromatic and aliphatic CH stretching throughout the 3050–2900 cm.$^{-1}$ regions are obvious for all methiodides except that of phenyramidol. In addition, the 8–16 μ region, with its very characteristic CH out-of-plane bending bands in the lower frequencies and especially the 9–14 μ region, is most useful for differentiation of these compounds.

The chloroplatinate spectra were poorly resolved, perhaps due to the damping effect of the anion, and hence were of no value for differentiation of the compounds.

Photomicrography

A large number of reagents were employed in an attempt to obtain complete and comparative sets of photomicrographs. However, success was limited to a few of these. All photomicrographs were taken at 50× magnification, and only those depicting distinctive crystal formations are reproduced in Figs. 1–5. It must be understood that the crystalline habits of these compounds are not to be used as the sole criterion for identification, but rather as an adjunct to the other physico-chemical methods previously discussed.

Phenyramidol hydrochloride was the only compound to yield well-defined microcrystals with either picric or styphnic acid and these are presented in Fig. 1. Combinations of these reagents with the other parent compounds yielded oils or oily films which would not crystallize.

lonate of phenyramidol could not be obtained in crystalline form under any of the varied conditions employed. The material invariably separated as a golden yellow oil. Clarke (1) has described the morphology of procyclidine picrolonate, and favorable agreement was noted with this investigation.

The method of Hucknell and Turfitt (23) was used for the preparation of the hydroiodides. As illustrated in Fig. 5, satisfactory photomicrographs were obtained for four of the five compounds studied. Phenyramidol yielded a fine amorphous precipitate, but the other compounds gave easily and rapidly prepared microcrystals.

The conditions under which the characteristic microcrystals were formed are summarized in Table II. All solutions are aqueous unless otherwise indicated.

SUMMARY

1. A series of specific physical criteria, by which four amine-containing antiparkinson agents and one amine-containing skeletal muscle relaxant can be positively identified and differentiated, has been presented.

2. Twenty-three derivatives of these drugs have been prepared in a systematic manner, of which 18 have not been reported to date in the literature.

3. The infrared spectra of these derivatives and their parent compounds have been obtained as a further parameter for their qualitative differentiation.

4. A series of photomicrographs have been included in Figs. 1–5, together with a summary of the conditions under which they were formed (Table II).

TABLE II.—AMINE MUSCLE RELAXANTS CHARACTERIZED BY MICROCRYSTALLOGRAPHY[a]

Parent Compd.	Picric Acid	Styphnic Acid	Chloroplatinic Acid	Ammonium Reineckate	Picrolonic Acid	Potassium Iodide
Biperiden HCl	...	...	...	0.1–0.1 (5)	0.1–0.25[b]	0.1 (15)
Cycrimine HCl	...	...	1.0–1.0 (15)	0.5–0.5 (5)	0.5–1.0[b]	0.5 (1)

Trihexyphenidyl HCl	...	...	...	0.5–0.5 (10)	0.5–1.0[b] (5)	1.0 (5)

[a] Muscle relaxant concentration (%), reagent concentration (%); numbers in parentheses denote time in minutes when crystals formed. [b] Ethanolic (95%) solution.

Chloroplatinic acid did not prove to be a satisfactory reagent for the identification of all the amine muscle relaxants in this study. Figure 2 shows distinctive, well-defined crystals for only cycrimine and procyclidine. The other compounds formed light amorphous precipitates which were not characteristic. Clarke (1) prepared the chloroplatinate of cycrimine and his description complimented our findings.

Ammonium reineckate proved to be an excellent reagent since characteristic and distinctive crystals were obtained for all five of the amine muscle relaxants. The results are depicted in Fig. 3.

Figure 4 shows that picrolonic acid proved to be a highly satisfactory reagent for characterization of four of the five compounds studied. The picro-

Some Wax Formulations of Sulfaethylthiadiazole Produced by Aqueous Dispersion for Prolonged-Release Medication

By EVELYN B. DRAPER* and CHARLES H. BECKER

Drug–wax particles were prepared by pouring heated aqueous solutions of surfactants into melted wax which contained dispersed sulfaethylthiadiazole (SETD). The systems then were slowly cooled to room temperature with stirring. The SETD–wax particles were recovered, washed, dried, and sieved into predetermined mesh size ranges. There appeared to be a direct relationship between drug release rate and average theoretical surface area of the SETD–Glycowax S-932 particles *in vitro*. This relationship was not seen in the SETD–beeswax particles. The dissolution rates of all the mesh ranges of particles studied seemed to be pseudo first order after the first 15 min. of testing. SETD–Glycowax S-932, 50- to 60-mesh particles, showed reasonably good prolonged-release properties in an *in vivo* urinary excretion study.

A NUMBER of methods and techniques have been used in the manufacture of oral dosage forms intended to impart prolonged, sustained, or long-acting therapeutic effect. The production of prolonged release of a drug in a wax matrix by means of aqueous dispersion or an emulsification process is mentioned in the literature, but detailed information is not given. Spray-congealing and spray-drying methods using wax with drugs have received quite a bit of attention.

Yamamoto and Baba (1) describe in their patent an aqueous dispersion method for producing wax pearls containing drug for prolonged-release medication. As an example, a melted wax containing dispersed drug is poured into a 2% polyvinyl alcohol aqueous solution, previously heated to 80°, and stirred until cool. The wax pearls that form are strained, washed with water, and dried. In this patent, several suitable dispersing agents are recommended and a number of wax or wax-like dissolution retardants are illustrated.

Kowarski *et al.* (2) describe a similar process in the preparation of prolonged-release sulfamethazine in small size batches. In this method, 2 parts of Japanese synthetic wax was melted with 1 part of sulfamethazine and poured into a running Waring blender containing cold water. After a few minutes of blending, the resulting suspension was filtered and dried. The particles were then washed with hydrochloric acid to remove sulfamethazine embedded on the outside of the granules, which was determined to be about 58% of the total drug in and on the granule.

The purpose of this investigation was to study some wax formulations of sulfaethylthiadiazole (SETD) produced by an aqueous-dispersion method for prolonged action. Bleached beeswax and Glycowax S-932 were used as the dissolution retarding materials. Beeswax was selected because it is a natural product and has plastic properties, whereas Glycowax S-932, a synthetic wax-like product is brittle. Both materials are edible, and the melting points of both are about the same, approximately 63°.

It was hoped that this study might reveal some

Some Wax Formulations of Sulfaethylthiadiazole Produced by Aqueous Dispersion for Prolonged-Release Medication

By EVELYN B. DRAPER* and CHARLES H. BECKER

Drug–wax particles were prepared by pouring heated aqueous solutions of surfactants into melted wax which contained dispersed sulfaethylthiadiazole (SETD). The systems then were slowly cooled to room temperature with stirring. The SETD–wax particles were recovered, washed, dried, and sieved into predetermined mesh size ranges. There appeared to be a direct relationship between drug release rate and average theoretical surface area of the SETD–Glycowax S-932 particles *in vitro*. This relationship was not seen in the SETD–beeswax particles. The dissolution rates of all the mesh ranges of particles studied seemed to be pseudo first order after the first 15 min. of testing. SETD–Glycowax S-932, 50- to 60-mesh particles, showed reasonably good prolonged-release properties in an *in vivo* urinary excretion study.

A NUMBER of methods and techniques have been used in the manufacture of oral dosage forms intended to impart prolonged, sustained, or long-acting therapeutic effect. The production of prolonged release of a drug in a wax matrix by means of aqueous dispersion or an emulsification process is mentioned in the literature, but detailed information is not given. Spray-congealing and spray-drying methods using wax with drugs have received quite a bit of attention.

Yamamoto and Baba (1) describe in their patent an aqueous dispersion method for producing wax pearls containing drug for prolonged-release medication. As an example, a melted wax containing dispersed drug is poured into a 2% polyvinyl alcohol aqueous solution, previously heated to 80°, and stirred until cool. The wax pearls that form are strained, washed with water, and dried. In this patent, several suitable dispersing agents are recommended and a number of wax or wax-like dissolution retardants are illustrated.

Kowarski *et al.* (2) describe a similar process in the preparation of prolonged-release sulfamethazine in small size batches. In this method, 2 parts of Japanese synthetic wax was melted with 1 part of sulfamethazine and poured into a running Waring blender containing cold water. After a few minutes of blending, the resulting suspension was filtered and dried. The particles were then washed with hydrochloric acid to remove sulfamethazine embedded on the outside of the granules, which was determined to be about 58% of the total drug in and on the granule.

The purpose of this investigation was to study some wax formulations of sulfaethylthiadiazole (SETD) produced by an aqueous-dispersion method for prolonged action. Bleached beeswax and Glycowax S-932 were used as the dissolution retarding materials. Beeswax was selected because it is a natural product and has plastic properties, whereas Glycowax S-932, a synthetic wax-like product is brittle. Both materials are edible, and the melting points of both are about the same, approximately 63°.

It was hoped that this study might reveal some

generalizations pertaining to the preparation of prolonged-release drug–wax particles produced by the aqueous-dispersion method, such as effect of temperature, emulsifier and rate of mixing, as well as to the release pattern of the drug from several specific mesh sizes of drug–wax particles.

The present study involves 3 parts: first, the preparation of the drug–wax particles; second, the study of their *in vitro* release patterns; and third, the *in vivo* evaluation using a urinary excretion study of 1 drug–wax product that proved satisfactory by the *in vitro* screening test.

EXPERIMENTAL

Throughout this investigation official or drug grade materials were employed wherever feasible, except for some chemicals used for test or assay purposes which were usually reagent grade. Sulfaethylthiadiazole (SETD) was obtained from American Cyanamid Co. Wherever the term SETD–beeswax or SETD–Glycowax is employed, this means an approximate ratio of 1 part of SETD to 3 parts of Glycowax S-932 or beeswax. Drug–wax particles designated 16 to 20, 30 to 40, and 50 to 60 mesh mean that the particles passed through the lower-numbered sieve but were retained or did not pass through the higher-numbered sieve.

Preparation of Various Mesh Sizes of SETD–Beeswax and SETD–Glycowax Particles.—Preliminary work showed that many factors had an influence on the production of various mesh sizes of SETD–wax particles as well as the release rate of the SETD from the wax matrix. A combination of sorbitan monooleate[1] and polysorbate 80[2] was found to be a suitable dispersant. To minimize variables as much as possible the following SETD–beeswax formula was used: bleached beeswax, 24.0 Gm.; SETD, 8.0 Gm.; sorbitan monooleate, 1.0 ml.; polysorbate 80, 1.15 ml.; and distilled water, 400.0 ml. The SETD–Glycowax formula employed was: Glycowax S-932, 24.0 Gm.; SETD, 8.0 Gm.; sorbitan monooleate, 1.0 ml.; polysorbate 80, 0.25 ml.; and distilled water, 400.0 ml.

The bleached beeswax or Glycowax S-932 and SETD were placed in a 1000-ml. beaker, heated on a water bath to 75°, and well dispersed. The sorbitan monooleate, polysorbate 80, and distilled water were combined in another beaker and heated to 80°. The aqueous phase was added slowly to the SETD–wax phase while hot with continuous stirring at a predetermined speed, using a Lightnin laboratory type, model F mixer, until the resulting dispersion reached a temperature of about 45°. Cooling the product to this temperature took about 25 min. When the combined hot SETD–wax and aqueous phase was stirred at about 150 r.p.m., the majority of the resulting SETD–wax particles produced were in the range of 12 to 30 mesh. When the mixture was stirred at about 300 to 400 r.p.m., most of the SETD–wax particles were in the range of 30 to 100 mesh.

The SETD–wax particles were separated from the aqueous phase by means of filtration through filter paper and washed with distilled water to remove any free SETD. The SETD–wax particles were then dried.

The air-dried SETD–beeswax and SETD–Glycowax particles were classified into 3 mesh sizes, namely, 16 to 20, 30 to 40, and 50 to 60, using U.S.P. sieves and the U.S.P. XVII method (3) for determining uniformity of fineness.

Assay of SETD Content in Wax Particles.—The SETD–beeswax particles were assayed for SETD by placing exactly 0.5000 Gm. of the air-dried sample in a 25-ml. portion of warm benzene and extracting the SETD with several portions of warm 3.5% HCl using a separator. The SETD–Glycowax particles were similarly treated, except the organic solvent employed was chloroform. In each case, the acid extract was made up to 100 ml. with distilled water in a volumetric flask. An aliquot portion was assayed for SETD content by the Bratton-Marshall colorimetric method (4). A Klett-Summerson colorimeter with a No. 54 filter was employed to determine the color intensity, which was compared to that of standard solutions.

In Vitro Dissolution Studies.—The *in vitro* evaluation of the various mesh sizes of SETD–beeswax and SETD–Glycowax particles for prolonged release was essentially the same as that described by Robinson and Swintosky (5). Using simulated gastric fluid (0.1 *N* HCl, pH 1.1), exactly 0.5000 Gm. of the air-dried SETD–wax samples was employed, 2 for each time interval. Likewise, an equivalent amount of the wax formation particles without SETD was treated similarly to serve as a blank. Three bottles (1 for the blank and 2 for the product) were withdrawn for analysis after intervals of 0.25, 0.5, 1, and 2 hr. and at appropriate times to determine when equilibrium of release was reached. For evaluation of dissolution in simulated intestinal fluid (alkaline pancreatin solution, pH 8.3), exactly 2.000 Gm. of the air-dried SETD–wax samples was used, 2 for each time interval. Similarly, a blank was employed, and test bottles were withdrawn for analysis after intervals of 0.25, 0.5, 1, 3, and 6 hr. and at appropriate times to determine when equilibrium of release of SETD was reached. With all samples, the content of each bottle was filtered and 1 ml. of the filtrate was diluted to an appropriate volume with distilled water in a volumetric flask. Then 1 ml. of the dilution was assayed for SETD content by the Bratton-Marshall colorimetric method (4) as described above. The rotating bottle dissolution apparatus employed was the same as that described by Souder and Ellenbogen (6). The temperature of the water bath was 30 ± 0.5°.

In Vivo Evaluation.—The method used in this study was basically the same as that described by Nicholson *et al.* (7) for the clinical evaluation of sustained-release tablets of SETD using urinary excretion studies. Four healthy adult males were utilized in the clinical evaluation of a 50- to 60-mesh formulation of SETD–Glycowax consisting of approximately 1 part of SETD and 3 parts of Glycowax S-932, which gave a satisfactory *in vitro* release pattern. As a control, 3.9 Gm. of plain SETD was administered in a suspension form in a sweetened, flavored, methylcellulose solution using the following 2-part formula: (*a*) methylcellulose,[3]

[1] Marketed as Span 80 by the Atlas Powder Co., Inc., Wilmington, Del.

[2] Marketed as Tween 80 by the Atlas Powder Co., Inc., Wilmington, Del.

[3] Marketed as Methocel.

400 cps., 3.0 Gm.; methyl salicylate, 0.2 ml.; distilled water, to 200.0 ml.; and (*b*) SETD, 3.9 Gm.; and sucrose, 20.0 Gm. Each subject was told to add the solid ingredients of part (*b*) to solution (*a*), mix well for several minutes, and drink. It was instructed that the bottle be rinsed well with about 2 fluid ounces of water to assure ingestion of all the SETD. Two weeks after the control was run, each subject received the same amount of SETD in a SETD–Glycowax combination, 50 to 60 mesh, in a suspension prepared from the 2-part formula described above.

Concentrations of the free and of the total (free plus conjugated) SETD in urine were determined colorimetrically as described by Bratton and Marshall (4).

Mathematical Calculation of Rates of Dissolution and Excretion.—The rates of dissolution and excretion were determined by use of the Noyes-Whitney equation: $dc/dt = k(C_e - C)$, where C is the concentration at time t, C_e is equilibrium solubility at the experimental temperature, and k is the rate constant.

C_e was determined in the *in vitro* tests to be the concentration at which there was no change with time. C_e in the *in vivo* tests was the cumulative amount excreted at the end of 72 hr.

From plots of log $(C_e - C)$ *versus* time,

$$k = -2.303 \frac{[\log(C_e - C)_2 - \log(C_e - C)_1]}{(t_2 - t_1)}$$

$$k = 2.303 \frac{[\log(C_e - C)_1 - \log(C_e - C)_2]}{(t_2 - t_1)}$$

RESULTS AND DISCUSSION

Preparation of Drug–Wax Particles.—In preliminary work, various nonionic emulsifiers and dispersants were tried. Yamamoto and Baba (1) recommended polyvinyl alcohol (PVA) in a similar process. The partially hydrolyzed PVA,[4] 50–42 grade, was evaluated in this study in varying concentrations, from 0.25 to 4.0%. Regardless of amount used, however, over 50% of the particles produced were of size 40 to 80 mesh. Not enough of the 20- to 40-mesh size could be produced. This investigation required a greater range and a more uniform distribution of particle size than was obtained with PVA.

The effect of the HLB of some surfactants upon particle size was studied. The required HLB values of beeswax (8) are 5 for a w/o emulsion and 10 to 16 for an o/w emulsion. Various proportions of sorbitan monooleate and polysorbate 80 were used with beeswax; and the combination which produced bead-like particles of satisfactory texture and the most desirable range and distribution of particle size had a HLB of 10 and was 1 part of sorbitan monooleate to 1.15 parts of polysorbate 80. The required HLB values of Glycowax S-932 were not available. However, the most satisfactory combination was 1 part of polysorbate 80 to 4 parts of sorbitan monooleate, having an HLB value of 6.44. The proportion of emulsifier to the total volume of dispersion made was less than 1% for both waxes because too much emulsifier would have had a pronounced effect on dissolution of SETD from the wax matrix.

[4] Marketed as Elvanol.

The temperature of the drug–wax phase and of the dispersion solution, the rate of cooling and the speed of mixing of the combined phase during the cooling period, and the ratio of dispersion medium to dispersed phase were all important factors in influencing the size of particles produced. The higher the temperature, the smaller the particles. Slower rates of cooling, increased amounts of dispersion medium in relation to dispersed phase, and higher speeds of mixing yielded smaller particles. Optimum conditions were determined and were kept constant thereafter.

In Vitro Dissolution Studies.—One of the objectives of this investigation was to study the effect of particle size upon rate of release of SETD from the wax matrix. For this reason the drug–wax particles were classified into size ranges of 16 to 20, 30 to 40, and 50 to 60 mesh. The average diameter of these would be 1050, 505, and 230 μ, respectively, assuming spherical shape, which is a ratio of approximately 4, 2, 1. Since specific surface area is inversely proportional to diameter of the particles, S_w = surface of particles/weight of particles = $\pi\Sigma nd^2/(\pi/6)_p\Sigma nd^3 = 6/pd$ (9), the ratio of specific surface area for the samples in all 3 groups is 1, 2, and 4.

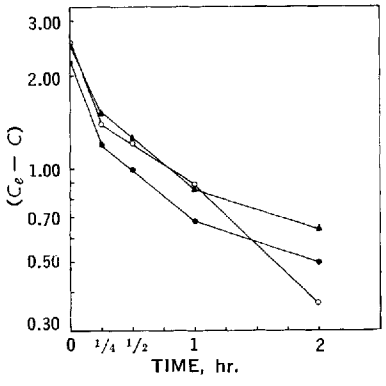

Fig. 1.—*In vitro* dissolution rates of SETD from various mesh sizes of SETD–beeswax particles in 0.1 *N* HCl. Key: ●, 16 to 20 mesh; ▲, 30 to 40 mesh; ○, 50 to 60 mesh.

It was theorized that the rate of dissolution of drug from the particles during the first 15-min. period in the test solutions would be in direct relation to specific surface area, since the particles were assumed to have a uniform distribution of drug on the surface. This theory proved to be correct for just the SETD–Glycowax product (Figs. 3 and 4). The SETD–beeswax particles showed a slower rate of release of SETD for the medium size range than for the smaller or larger (Figs. 1 and 2). The fact that this was slower than the smaller size range follows the theory. The fact that it was slower than the larger sized particles seemed very likely to be due to the aggregation of smaller particles to form some larger ones. Microscopic examination revealed that most of the larger particles were aggregates of smaller ones.

After the first 15-min. period, the rate of dissolution of SETD from the wax matrix varied in all cases (Figs. 1–4). The rate was constant from the end of the first hour to the termination of the test period, and was pseudo first order. The rate of dissolution should change as surface area changes. Some of the groups of particles showed dissolution rates of different ratio to apparent particle size during the last period of dissolution than during the first period. This could be due to the fact that some of the particles were more porous than others, the porosity being due to the speed of stirring causing some air to be trapped in the particles during preparation.

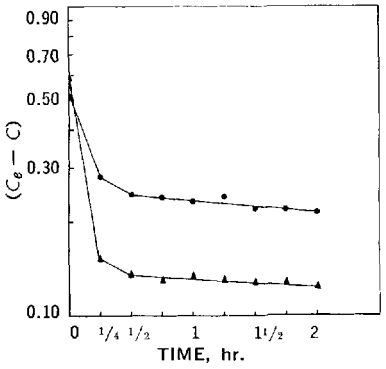

Fig. 3.—*In vitro* dissolution rates of SETD from various mesh sizes of SETD–Glycowax particles in 0.1 *N* HCl. Key: ●, 16 to 20 mesh; ▲, 30 to 40 mesh; ○, 50 to 60 mesh, $(C_e - C) = 0$.

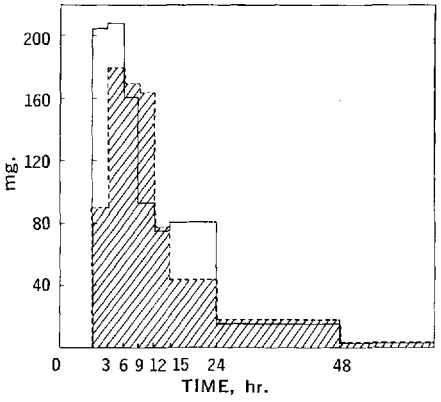

Fig. 6.—Average urinary excretion pattern of free SETD/hr. for 4 humans receiving a 3.9-Gm. oral dose of SETD in (*a*) plain form and (*b*) SETD–Glycowax combination. Key: □, plain SETD; ▨, SETD–Glycowax combination.

The per cent of SETD released in 0.1 *N* HCl (Figs. 1 and 3) was less than that in alkaline pancreatin solution (Figs. 2 and 4) for the same type sample and for the same time period. The rate of release was greater in the 0.1 *N* HCl, however. In alkaline pancreatin solution the peripheral portion of drug was apparently released at about the same rate as in the 0.1 *N* HCl. The increase in amount of release of SETD in the alkaline pancreatin solution could most likely be due to the fact that the wax matrix is partially solubilized, emulsified, and disintegrated by the surfactants and alkalinity of this solution.

It was theorized that the first part of dissolution of SETD from the drug–wax particle in both test solutions involved the simultaneous dissolution of drug by 2 first-order rates, $c = a_1e^{-k_1t} + a_2e^{-k_2t}$ (10). Dissolution data for 30- to 40-mesh SETD–beeswax particles were used in an attempt to test

this theory. From the semilog plot of $(C_e - C)$ *versus* time, the difference in $(C_e - C)$ values as obtained by the data during the first 0.75 hr. in the solution and that which would be obtained if the rate of dissolution was the same as that for the last period of the test was plotted semilogarithmically *versus* time. Since this gave a straight line, one rate appears to be that of the dissolution of the drug on the surface of the particle and the other that of the drug within the particle. Of course, the

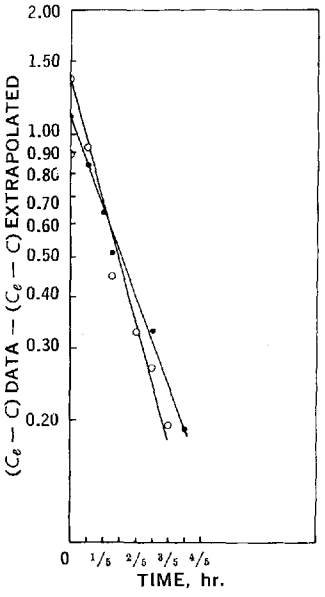

Fig. 7.—$(C_e - C)_{data}$ minus $(C_e - C)_{extrapolated}$ *vs.* time in hr. for 30- to 40-mesh SETD–beeswax particles in 0.1 *N* HCl and in alkaline pancreatin solution. Key: ○, in 0.1 *N* HCl; ●, in alkaline pancreatin solution.

rate during the last period of the test is also that of the drug within the particle. The rate calculated in Fig. 7 and theorized to be that of the surface SETD was 3.44 in 0.1 *N* HCl and 2.51 in alkaline pancreatin solution. It appears logical that this difference in rate may be due to the decrease in rate of diffusion in alkaline pancreatin solution caused by a partially emulsified layer, and possibly a concentration of colloidal particles around the SETD–wax beads.

In Vivo Study.—The SETD–Glycowax product of 50- to 60-mesh size was chosen because the *in vitro* results were most similar to the *in vitro* data of a well-known commercial prolonged-release preparation of SETD (11). Although *in vivo* release does not follow that of *in vitro*, it can be predicted from it by various patterns which can be correlated by experienced diagnosis.

From Figs. 5 and 6, it can be seen that the SETD–Glycowax particles as compared with plain SETD did show a decrease in the rate of release of SETD by about 50% during the first 3 hr. The rates were about the same for the second 3-hr. period. After this time, the rate increased for the SETD–Glycowax particles so that at the end of 24 hr. 71% of the total SETD had been excreted from the SETD–Glycowax particles as compared to 85% from plain SETD. The total free plus conjugated SETD excreted within 72 hr. after ingestion of SETD–Glycowax was 85%, whereas that released *in vitro* at equilibrium was 81%, a fairly close relationship. Since the ideal prolonged-release preparation maintains a proper therapeutic blood level for a 12- or 24-hr. period, the 50- to 60-mesh SETD–Glycowax product evaluated in this study appears to be a reasonably good prolonged-release preparation. Previous work (7) using SETD in urinary excretion studies showed the biological half-life to be about 6 hr. The present work showed a similar half-life period for SETD.

Pharmacological Studies of Norphenyl Hemicholinium 3

By S. N. THAMPI, FLOYD R. DOMER, VERNON B. HAARSTAD, and F. W. SCHUELER†

Norphenyl HC-3 (NP-HC-3), an analog of HC-3 in which the biphenyl nucleus is replaced by a monophenyl moiety, has been synthesized. NP-HC-3 has been shown to resemble the parent compound in most of its pharmacological properties. Its LD_{50} in mice was found to range from 45–680 mcg./Kg. NP-HC-3 in low doses induced a slowly progressive respiratory paralysis. In higher doses the neuromuscular blocking action was antagonized by choline. Neostigmine reversed only the effects observed with low doses of NP-HC-3. NP-HC-3 did not have adrenergic, antihistaminic, analgesic, or local anesthetic activity.

STRUCTURE-ACTIVITY relation studies concerning analogs of hemicholinium number 3 (HC-3) have been carried out by many investigators (1–4). The structure-activity relationships and actions on the peripheral nervous system of some of these analogs have been reviewed by Long (5). The hemicholiniums are characterized by a high toxicity which is slow in onset at minimal lethal doses. They interfere with cholinergic transmission at such sites as nerve-skeletal muscle junctions, autonomic ganglia, and postganglionic parasympathetic endings (6). To date HC-3 remains the most active of the analogs studied for the over-all hemicholinium-like action. The earlier modifications of the HC-3 molecule involved alterations in the cationic moiety and/or the biphenyl nucleus. Schueler (1) found that the phenacyl analog (*i.e.*, half of the parent compound) was inactive. The purpose of this paper is to discuss the synthesis and pharmacology of an analog of HC-3 in which the biphenyl nucleus has been replaced by a monophenyl moiety. This compound hereafter will be referred to as norphenyl-HC-3 (NP-HC-3).

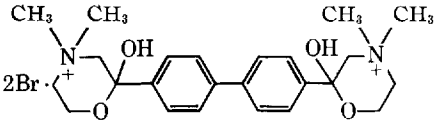
METHODS

Chemical Procedure

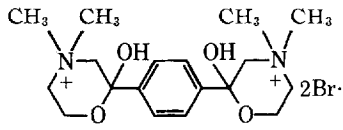
p-Bis(bromoacetyl)benzene was prepared according to the method described by Krohnke and Vogt (7) from 1,4-diacetylbenzene. The product was recrystallized from tetrahydrofuran in the form of stout hexagonal prisms, m.p. 178° (lit. value m.p. 177–178°).

1,4-Bis(1,1-dimethyl-3-hydroxy-3-morpholinyl) Benzene, Dibromide (NP-HC-3).—*p*-Bis-(bromoacetyl) benzene, 10 Gm. (0.031 mole), was dissolved in 200 ml. of boiling tetrahydrofuran. The resulting solution was treated with activated carbon[1] and filtered hot under suction, through diatomaceous earth supported on a sintered-glass funnel. β-Dimethylaminoethanol, 57 ml. (0.05 mole), was added to the hot filtrate, and the mixture was allowed to cool to room temperature. The resulting white precipitate was collected on a filter, washed well with tetrahydrofuran, and recrystallized from a mixture of absolute ethanol and methanol (3:2). The product, collected on a filter, washed well with diethyl ether, and dried over phosphorus pentoxide in a vacuum desiccator, afforded 10.50 Gm. (67.2%) of white crystals, m. p. 228° dec.

Anal.—Calcd. for $C_{18}H_{30}Br_2N_2O_4$: C, 43.39; H, 6.06; N, 5.62. $C_{18}H_{30}Br_2N_2O_4 \cdot H_2O$: C, 42.17; H, 6.37; N, 5.47.[2] Found: C, 42.52; H, 6.34; N, 5.54.[3]



HC-3



NP-HC-3

Pharmacological Procedures

Toxicity Studies in Mice.—Two strains of albino mice (Swiss Webster and $1CR^{CD-1}$) of both sexes, each weighing 20 ± 2 Gm. in groups of 20 were used for each dose of NP-HC-3. The drug was administered intraperitoneally in a volume of 0.01 ml./Gm. body weight in normal saline. In one experiment two LD_{50} determinations were made on the same day, one in the morning and the other in the late afternoon. The LD_{50} was computed by

† Deceased.

[1] Marketed as Norit by American Norit Co., Inc., Jacksonville, Fla.

[2] VBH and FWS (unpublished data) HC-3 has been found to crystallize in variable hydration states. NP-HC-3, as well as HC-3, is very hygroscopic before recrystallization. The water of crystallization is very difficult to remove from HC-3. Thus, it is felt that the NP-HC-3 could have picked up water before and retained it during the recrystallization.

[3] The chemical analysis was performed by Alfred Bernhardt Microanalytical Laboratories, Mulheim, Germany.

means of the probit-log dose method (8). The animals were observed for signs which differed from those of control animals, and the viscera were examined post-mortem in a few cases.

Antagonism Studies in Mice.—Swiss Webster albino mice of both sexes (20 ± 2 Gm. each) were used. All drugs were injected intraperitoneally in a volume of 0.01 ml./Gm. body weight in normal saline. Three groups of 10 mice received 1 mg./Kg. of NP-HC-3 followed 1 min. later by a second injection of saline, 10 or 20 mg./Kg. of choline. Three groups of 5 mice were given 1–3 mg./Kg. NP-HC-3 followed 1 min. later by saline, 150 or 300 mcg./Kg. of neostigmine.

Blood Pressure-Neuromuscular Preparation.—In this series of experiments, 5 mongrel dogs (9–15 Kg.), 5 albino rabbits (2–3 Kg.), and 2 chickens (2–3 Kg.) of either sex were used. All the animals were anesthetized with sodium pentobarbital (35 mg./Kg., i.v.). The blood pressure was recorded from cannulated arteries connected *via* a Statham pressure transducer to a Grass model 5-DWC polygraph. Heparinized saline (50 u./ml.) was used as an anticoagulant in this system. The Achilles tendon was isolated and tied with a thin copper wire, about an inch above the joint, sectioned distally, and attached to a force-transducer (model FT-03). The muscular contractions were recorded on the polygraph. The ipsilateral sciatic nerve was isolated, sectioned proximally, and the peripheral stump stimulated with a bipolar, shielded, platinum electrode, using a Grass stimulator (model S4G) so as to obtain maximal muscular contractions. The leg was immobilized with an iron pin which passed through the knee joint while the foot was clamped to a rigid frame. The trachea was exposed, cannulated, and artificial respiration was used whenever necessary. The femoral vein of the dog, the jugular vein of the chicken, and the ear vein of the rabbit were cannulated to permit drug administration. In the dog and the rabbit, blood pressure recordings were obtained from the right carotid artery, whereas in the chicken the femoral artery was used for this purpose. In both the dog and the rabbit the left vagus was isolated, ligatured, sectioned centrally, and the distal portion stimulated with a Mallory model 12 Rs6D inductorium.

Two chickens (2.5 Kg. male) were prepared as described above. In addition, the branch of the femoral artery feeding the gastrocnemius muscle was isolated, and a loose loop of thread was placed around it. A side branch was cannulated in the direction of blood flow to permit the injection of acetylcholine.

TABLE I.—BLOOD PRESSURE–NEUROMUSCULAR PREPARATION

No.	Wt., Kg.	Frequency of Stimulation/sec.	Dose, mg./Kg.	Onset of Actions, min.	% Neuromuscular Blockade	Duration of Blockade, min.	Remarks
				Dogs			
1	14.1	2	0.1		0	...	
			1.0	15	100	34	Died of respiratory failure at this time

			0.6	...	0	0	
			1.2	2	65	60	
2	2.6	0.9	1.0	15	100	30	Died during total blockade

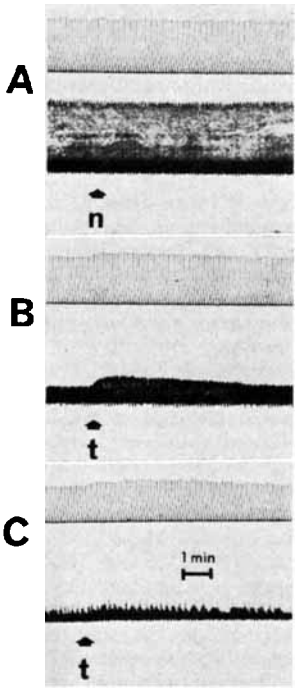

Fig. 1.—Bilateral contractions of the gastrocnemius muscles of the chicken. In the upper tracing the rate of supramaximal electrical stimulation of the ipsilateral sciatic nerve was 0.2/sec. The rate of stimulation in the lower tracing was 0.8/sec. In A, NP-HC-3 (1 mg./Kg.) was given intravenously (n). In B, the first injection of TEA (3 mg./Kg. i.v.) was given. In C, the fourth dose of TEA (3 mg./Kg., i.v.) was given.

Bilateral sciatic-gastrocnemius preparations were done with 3 rabbits and 2 chickens. The arrangement of the apparatus was the same as previously described except that the contractions of both the gastrocnemius muscles of each animal were recorded. One of the muscles was stimulated at a low frequency (0.2–0.4/sec.), and the other was stimulated at varying, higher frequencies. The blood pressure of the chickens was not recorded.

RESULTS

Toxicity Studies in Mice.—About 5 min. after the administration of a 700 mcg./Kg. dose of NP-HC-3 the animals exhibited dyspnea, exophthalmos, and ataxia. Some of the animals exhibited a Straub tail reaction. Then clonic convulsions developed and they stood on their hind limbs. Nearly half of them fell on their sides and died within 15–20 min. Survivors were apparently normal after 2 hr.

Irrespective of the increment of the doses above the lethal levels, a minimum of about 5 min. elapsed before the observable onset of action. At autopsy the heart was still beating, and the intestinal motility appeared to be stimulated slightly more than in control animals.

The LD_{50} (i.p.) in two different batches of ICR-CD-1 albino mice was 680 mcg./Kg. and 320 mcg./Kg. The LD_{50} (i.p.) of NP-HC-3 in a strain of Swiss Webster albino mice was 45.5 mcg./Kg. in the morning and 46.3 mcg./Kg. in the late evening of the same day. This is in contrast to the large variation which previously has been found with HC-3.

Antagonism Studies.—All mice receiving 1 mg./Kg. of NP-HC-3 died within 30–35 min. Three of ten given 10 mg./Kg. of choline died at 10–15 min. Only one of ten treated with 20 mg./Kg. of choline died in 15 min.

A dose of 150 mcg./Kg. of neostigmine protected all mice treated with 1 mg./Kg. of NP-HC-3. All mice died which were given 2 or 3 mg./Kg. of NP-HC-3. In these animals neostigmine produced no marked parasympathomimetic activity. Mice given 300 mcg./Kg. of neostigmine died within 3 min., and exhibited excessive salivation, lacrimation, urination, and defecation (SLUD syndrome). Animals which received this dose of neostigmine 1 min. after a 1 mg./Kg. of NP-HC-3 were slightly ataxic after 20 min. and did not exhibit the SLUD syndrome.

Blood Pressure-Neuromuscular Preparation.—Doses of NP-HC-3 from 0.1–1.5 mg./Kg. did not have any effect on the blood pressure of the dog, rabbit, or chicken. Also, it did not modify the control responses produced by vagal stimulation and double carotid occlusion of injections of acetylcholine, epinephrine, or histamine.

The results found with the neuromuscular preparations may be seen in Table I. Doses of 1 mg./Kg. or less exerted varying degrees of blockade. Increasing the rate of stimulation increased the amount of blockade as well as its duration, *e.g.*, dog 3. Choline (5–20 mg./Kg. i.v.) reversed the neuromuscular blockade either partially or completely. Four 3 mg./Kg. (i.v.) doses of tetraethylammonium bromide given at 3-min. intervals to a rabbit during partial neuromuscular blockade with NP-HC-3 caused a partial reversal of the blockade with the initial dose. The amount of reversal

TABLE II.—EFFECTS OF INTRAVENOUS NP-HC-3 (1 mg./Kg.) ON BILATERAL SCIATIC NERVE-GASTROCNEMIUS PREPARATIONS IN RABBITS AND CHICKENS

Animal	Wt., Kg.	Side	Frequency of Stimulation/sec.	Onset of Action, min.	% Neuromuscular Blockade	Duration of Blockade, min.	Choline, 10 mg./Kg.	Neostigmine, 1–3 mg./Kg.
Rabbit 1	2.6	Left	0.8	15	100	30	Completely reversed	No change
		Right	0.4	25	10	...	No change	Potentiation
Rabbit 2	4.0	Left	3.0	30	50	48	Partially reversed	No change
		Right	0.4	40	10	20	No change	Potentiation
Rabbit 3	3.4	Left	0.4	9	70	70	Partially reversed	...
		Right	0.8	4	90	85	Partially reversed	...
Chicken 1	3.4	Left	3.0	7	90	30	Partially reversed	...
		Right	0.4	20	50	25	No change	...
Chicken 2	3.0	Left	0.2	40	50	60	Partially reversed	...
		Right	0.8	25	95	120	Partially reversed	...

decreased with successive doses until no effect was observed (Fig. 1).

The effect of frequency of stimulation on the intensity and duration of neuromuscular blockade and the action of choline and neostigmine are listed in Table II. Here again, increasing the frequency of stimulation increased the rate of onset of neuromuscular blockade as well as the strength and duration of the blocking action. In rabbits, neostigmine (0.1 mg./Kg.) potentiated the strength of contraction on a side being stimulated at 0.4/sec. and had almost no effect on the side being stimulated at 3/sec. (Fig. 2, B). The same effect was seen with edrophonium (Fig. 2, C), in which case the potentiated height of contraction was more than twice that of the control. Following these 2 drugs, choline administration reversed completely the neuromuscular blockade in the leg being stimulated more rapidly and had no effect on the other side (Fig. 2, D). The contraction produced by a close-arterial injection of 6 mcg. of acetylcholine on the unstimulated muscle of a chicken was completely abolished 30 min. after the i.v. administration of 1 mg./Kg. of NP-HC-3 (Fig. 3 A–C). This was at the onset of the neuromuscular blockade. When the electrical stimulation was resumed following the administration of acetylcholine, there was an initial increase in the strength of the muscular contraction (Fig. 3, D). Ten micrograms of acetylcholine caused a slight depolarization which lasted about 0.5 min. During complete neuromuscular blockade either 6 or 10 mcg. of acetylcholine administered close-arterially during the electrical stimulation resulted in a burst of weak contractions. A dose of 10 mg./Kg. of choline administered i.v. resulted in a series of contractions which were 14% of control and which lasted for a period of 6 min. (Fig. 3, F).

Miscellaneous Studies.—NP-HC-3 did not have any effect on the rat or guinea pig ilia or on responses produced by test doses of acetylcholine, epinephrine, and histamine. It did not exhibit any non-narcotic analgesic activity in mice studied according to the method of Koster *et al.* (9) or any narcotic analgesic activity in mice tested according to the method described by D'Amour and Smith (10). There was also no topical or infiltrative local anesthetic activity found using the rabbit.

DISCUSSION

NP-HC-3 was synthesized in an attempt to investigate the minimum requirements for the hemicholinium-type of activity and also to gain more insight into the mechanism of action of the hemicholiniums. NP-HC-3 ranks next to HC-3 itself in potency among the compounds previously studied for the hemicholinium-type of activity. The primary toxic manifestations of NP-HC-3 are a slowly progressive respiratory depression and muscular weakness. As in the case of HC-3 the LD_{50} in mice varied widely with different batches of mice used, and the observed effects occurred after a latent period which was independent of the dose. On a molar basis the LD_{50} of NP-HC-3 was about 3 times that of the parent compound, HC-3.

The toxicity of both NP-HC-3 and HC-3 is antagonized by choline and neostigmine. As with HC-3 (11) there was a rough correlation among the lethal dose with NP-HC-3, the size of the animal, and the time required for the onset of action.

The neuromuscular blockade produced in the sciatic nerve-gastrocnemius muscle of the rabbit, chicken, and dog was slow in onset and could be augmented by increasing the rate of stimulation. The duration of the blockade was from 30 min. to 2 hr. With successive doses, the time of onset decreased, and the duration of the neuromuscular blockade increased. Similar effects were observed with curarization in humans by Bush and Baraka (12). The apparent potentiation of a second dose of tubocurarine had been discussed by Levy (13). He established a quantitative relationship between the duration of action and the concentration of the drug in successive doses. The observations made with NP-HC-3 are compatible with Levy's hypoth-

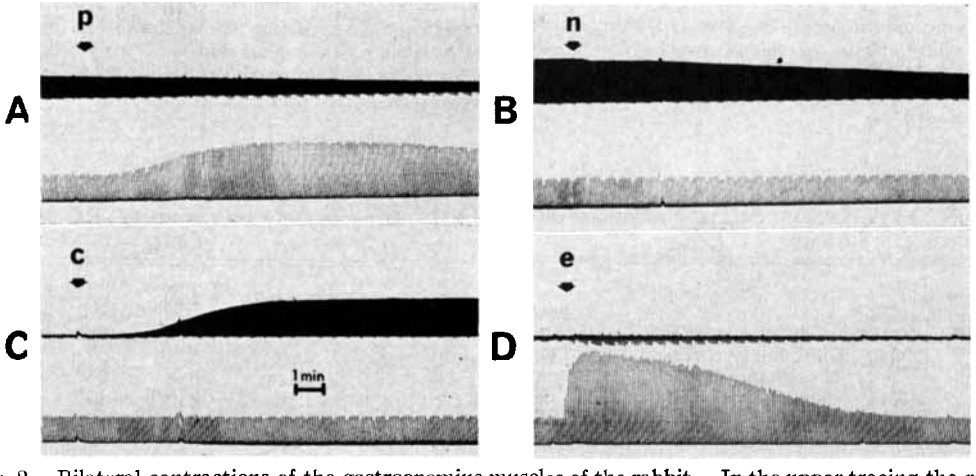

Fig. 2.—Bilateral contractions of the gastrocnemius muscles of the rabbit. In the upper tracing the rate of supramaximal electrical stimulation of the ipsilateral sciatic nerve was 3/sec. The rate of stimulation in the lower tracing was 0.4/sec. In A, NP-HC-3 (n) 1 mg./Kg., i.v. was given. In B, neostigmine (p), 0.05 mg./Kg., i.v. was given. In C, edrophonium (e), 0.2 mg./Kg., i.v. was given. In D, choline (c), 10 mg./Kg., i.v. was given.

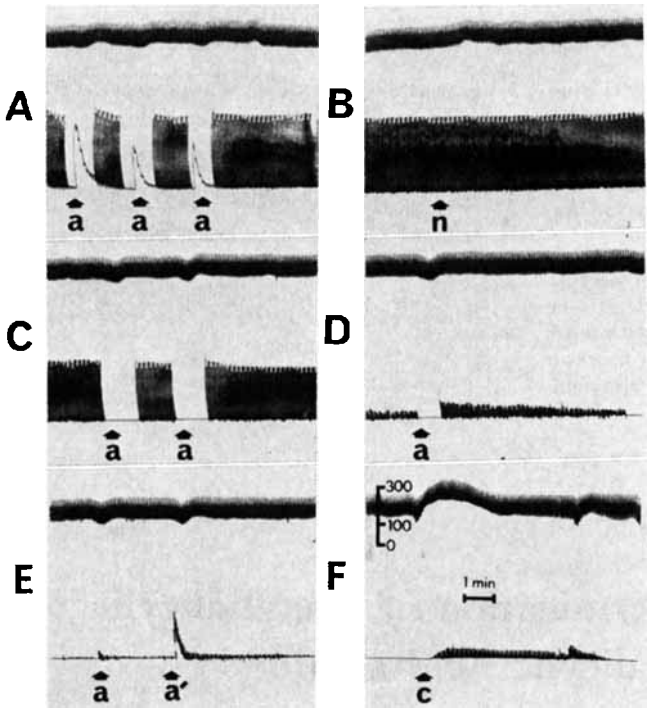

Fig. 3.—Femoral arterial blood pressure and gastrocnemius muscular contractions of the chicken. In A, three close-arterial injections of acetylcholine (a) 0.006 mg./Kg., i.v. In B, NP-HC-3 (n), 1 mg./Kg., i.v. was given. In C, D, and E acetylcholine was given in doses of 0.006 mg./Kg. (a) and 0.01 mg./Kg. (a^1) i.v. In F, choline (c), 10 mg./Kg., i.v. was given.

esis. The neuromuscular blockade produced by high frequency stimulation could be reversed partially, and often completely, with choline and not with neostigmine. However, with muscles being stimulated at a lower frequency, there was no antagonism with choline, whereas neostigmine caused a considerable augmentation in the height of contraction. This may be explained by assuming that during the total blockade seen during high frequency stimulation, all of the acetylcholine stores had been depleted. Thus, even relatively high concentrations of the indirect-acting neostigmine were ineffective in increasing the acetylcholine concentration to an effective level. On the other hand, choline, being the precursor of acetylcholine, replenished the reserves. During low frequency stimulation the acetylcholine stores were only partially depleted.

The temporary reversal observed with initial doses of tetraethylammonium (TEA) during total neuromuscular blockade with high frequency stimulation, and the ineffectiveness of subsequent doses of TEA, has been observed previously by Volle (14) with HC-3. TEA has been shown to be a releaser of acetylcholine from presynaptic nerve endings (15). This is suggestive of a situation in which NP-HC-3 or HC-3 inhibit the synthesis of acetylcholine in presynaptic nerves, and the effect observed with the initial doses of TEA was a facilitated release of the residual acetylcholine. The effect of TEA on the neuromuscular blockade produced by NP-HC-3 and HC-3 should also be reconsidered in the light of recent findings by Bhatnager *et al.* (16). They found that TEA and a variety of other quaternary ammonium compounds acted as inhibitors of acetylcholine synthesis in nervous tissue. The apparent paradox posed by the observations of Volle, Bhatnager, and ourselves may be resolved by pointing out that quaternary ammonium compounds such as HC-3, NP-HC-3, and TEA, may act in at least two ways: (*a*) they may either increase the fragility of the synaptic vesicles, or (*b*) they may inhibit formation of acetylcholine.

It is possible that these quaternary ammonium compounds act like detergents and cause an emulsification of the vesicular membranes. Under such conditions the acetylcholine formed would be exposed to immediate hydrolysis by acetylcholinesterase. In addition, the rate of transport of these quaternary ammonium compounds to the site of acetylcholine synthesis may be altered during varying levels of nervous activity, *e.g.*, resting *versus* high frequency stimulation. Perhaps this may be the reason why the increase in frequency of stimulation lowered the effective neuromuscular blocking doses and accelerated the onset and increased the duration of action.

The lack of response to the close-arterial injections of acetylcholine in the unstimulated gastrocnemius muscle of the chicken during the course of complete neuromuscular blockade indicates a curare-like effect of NP-HC-3. However, the temporary reversal of the neuromuscular blockade seen when acetylcholine was administered close-arterially during or immediately prior to electrical stimulation suggests an additional mechanism of action, *i.e.*, the injected acetylcholine is taken up by the nerve and is then available for release in response to stimulation. The release of the newly acquired acetylcholine from the nerve ending may require extraneous stimulation such as electrical impulses or TEA. The lack of effect of neostigmine during total neuromuscular blockade in preparations

stimulated at high frequencies could reflect either a deficiency of acetylcholine release or that the end plate receptors are already occupied. Observation that the blockade is reversed by acetylcholine injected close-arterially during stimulation indicates that the latter situation does not obtain. Therefore, since the receptors can still respond to administered acetylcholine, the evidence is in favor of a presynaptic, rather than a postsynaptic, mechanism of action.

NP-HC-3 may be assumed to act, at least in part, by decreasing the presynaptic supply of acetylcholine. The exact mechanism by which this is caused has not been elucidated. Replacement of the biphenyl by the monophenyl nucleus has not altered the hemicholinium-like activity, although there is a decrease in the toxicity.

Fluorometric Determination of Acetylsalicylic Acid and Salicylic Acid in Blood

By WINTHROP E. LANGE and SAUL A. BELL*

A useful micro-method has been developed for the paper chromatographic separation of acetylsalicylic acid and salicylic acid with subsequent determination of each compound by fluorometry from a 0.1-ml. sample of capillary blood. This method permits frequent determinations of both acetylsalicylic acid and salicylate blood levels on the same subject. The accuracy and precision of the micro-method has been studied. *In vivo* studies utilizing the method emphasized the validity of results obtained by a rapid micro-method of analysis.

MANY METHODS for the determination of salicylates in blood and in plasma have been described in the literature. The generally accepted methods of Brodie (1) and Routh (2) involve the extraction of the salicylate from the blood sample and the determination of the concentration colorimetrically by measuring the absorbance of an iron complex. However, Saltzman (3) and Chirigos (4) have described the determination of salicylate in biological tissues by measurement of the characteristic fluorescence of the salicylate ion on exposure to ultraviolet light.

The quantity of acetylsalicylic acid in the biological tissues was estimated from the difference between "free" salicylate and "total" salicylate, and conjugated salicylate being considered to be acetylsalicylic acid (5). Mandel (6) has reported a paper chromatographic procedure for the separation of acetylsalicylic acid from salicylic acid in a plasma sample, and their separate determination fluorometrically. Recently, Nikelly (7) described the gas chromatographic determination of acetylsalicylic acid in the presence of salicylic acid.

Although the information obtained from any of the above methods is valuable, there does not seem to be general agreement among investigators about the levels of acetylsalicylic acid in the blood after taking aspirin. Since the time span of the analgesic effect of aspirin (2–4 hr.) appears to be more closely related to the time that the acetylsalicylic acid persists in the blood, the blood level of acetylsalicylic acid would seem to be a critical measure of the potential analgesic effectiveness of an aspirin formulation. Thus, for the *in vivo* study of acetylsalicylic acid blood levels it is desirable to have a micro-method requiring small volumes of blood for the repeated sampling required to observe simultaneously sustained blood levels of acetylsalicylic acid and salicylic acid. The method should also be fast, practical, and accurate.

Fluorometric Determination of Acetylsalicylic Acid and Salicylic Acid in Blood

By WINTHROP E. LANGE and SAUL A. BELL*

A useful micro-method has been developed for the paper chromatographic separation of acetylsalicylic acid and salicylic acid with subsequent determination of each compound by fluorometry from a 0.1-ml. sample of capillary blood. This method permits frequent determinations of both acetylsalicylic acid and salicylate blood levels on the same subject. The accuracy and precision of the micro-method has been studied. *In vivo* studies utilizing the method emphasized the validity of results obtained by a rapid micro-method of analysis.

MANY METHODS for the determination of salicylates in blood and in plasma have been described in the literature. The generally accepted methods of Brodie (1) and Routh (2) involve the extraction of the salicylate from the blood sample and the determination of the concentration colorimetrically by measuring the absorbance of an iron complex. However, Saltzman (3) and Chirigos (4) have described the determination of salicylate in biological tissues by measurement of the characteristic fluorescence of the salicylate ion on exposure to ultraviolet light.

The quantity of acetylsalicylic acid in the biological tissues was estimated from the difference between "free" salicylate and "total" salicylate, and conjugated salicylate being considered to be acetylsalicylic acid (5). Mandel (6) has reported a paper chromatographic procedure for the separation of acetylsalicylic acid from salicylic acid in a plasma sample, and their separate determination fluorometrically. Recently, Nikelly (7) described the gas chromatographic determination of acetylsalicylic acid in the presence of salicylic acid.

Although the information obtained from any of the above methods is valuable, there does not seem to be general agreement among investigators about the levels of acetylsalicylic acid in the blood after taking aspirin. Since the time span of the analgesic effect of aspirin (2–4 hr.) appears to be more closely related to the time that the acetylsalicylic acid persists in the blood, the blood level of acetylsalicylic acid would seem to be a critical measure of the potential analgesic effectiveness of an aspirin formulation. Thus, for the *in vivo* study of acetylsalicylic acid blood levels it is desirable to have a micro-method requiring small volumes of blood for the repeated sampling required to observe simultaneously sustained blood levels of acetylsalicylic acid and salicylic acid. The method should also be fast, practical, and accurate.

Received July 28, 1965, from the Department of Pharmacy, Massachusetts College of Pharmacy, Boston, and the *Research Laboratories, Chesebrough Pond's, Clinton, Conn. Accepted for publication December 30, 1965.
The authors acknowledge the assistance of Mr. S. Z. Hicks, Jr., for performing the fluorometric assays and Mrs. Judith Nelson and Mr. Joseph Rowland for technical assistance.

METHODS AND PROCEDURES

The fluorometric assay described below is based on the characteristic chromatographic separation of acetylsalicylic acid and salicylic acid and the ultraviolet emission of alkaline salicylate ion at 415 mμ when activated at 325 mμ.

Blood Sampling.—To 100 μl. of blood in a 3-ml. centrifuge tube was added 250 μl. of ethylene dichloride (redistilled). The sample was stirred vigorously with a glass rod for 10 sec., 50 μl. of 6 *N* hydrochloric acid was added, and the mixture thoroughly mixed for 1 min. The sample was then centrifuged at 6000 r.p.m. for 15 sec., thoroughly mixed for 1 min., and centrifuged again for 1 min. It was found that for reproducible results the finger before puncture had to be pretreated with isopropyl alcohol and the blood sample representative of the capillary circulation.

Paper Chromatography.—The ethylene dichloride layer in the centrifuge tubes was withdrawn by means of a 250-μl. transfer pipet. The contents of the pipet were carefully streaked in a narrow band across a $1^1/_2 \times 15^5/_8$ in. strip of S & S 589 White Ribbon chromatography paper. The strips were dried and developed by ascending technique in chromatographic tanks containing a 0.75% nitric acid developing solution. The strips were developed at 25° until the solvent front reached 21 cm. (about 1 hr.), and then were removed from the tanks and air dried. Two 4-cm. wide rectangular pieces were cut from the strips at R_f 0.6 and 0.8 corresponding to the salicylic acid and acetylsalicylic acid, respectively. The pieces from the chromatographic strip were placed in 50-ml. conical flasks and exactly 5.0 ml. of 5 *N* sodium hydroxide was added. The alkali was allowed to remain for exactly 8 min. in contact with the papers. The flasks were gently swirled during the hydrolysis and extraction period.

Fluorescent Measurements.—The alkaline solutions were poured into 12 × 75 mm. cells and read in a fluorometer (Turner model 110) containing a "sandwich" excitation filter consisting of two 7-54 filters and a Wratten No. 34A filter; for the emission filter a half-thickness Corning No. 5-58 filter was used. A 4-cm. rectangle cut from the lower portion of a developed chromatograph strip was treated with exactly 5 ml. of 5 *N* sodium hydroxide to give an instrument blank.

Preparation of Standard Curves.—Known amounts of acetylsalicylic acid in the range of 0–1.0 mcg./100 μl. and 0–100 mcg./10.0 μl. of salicylic acid were added to whole citrated blood. These samples were carried through the complete chromatographic separation and fluorometric assay. The meter readings from the fluorometer were plotted against concentration to give standard curves for the salicylic acid and acetylsalicylic acid. To provide assurance of the continuing validity of the standard curves, standard samples were carried through the complete procedure periodically. So long as precautions were taken to control the temperature and drafts of the chromatographic room, the standard deviation reported in the discussion was not exceeded.

The drug concentration in plasma can be estimated from the whole blood concentration either by assuming a 50% hematocrit and using a factor of 2, or by using the equation 1/1 − (hematocrit × 0.01) if the subject's hematocrit has been determined. A comparison of results as calculated by the 2 methods is shown in Table I. The failure to consider the actual hematocrit or binding of the drug by plasma proteins has no effect on the validity of results comparing different dosages or different dosage forms in the same group of individuals.

TABLE I.—COMPARISON OF SALICYLIC ACID BLOOD LEVELS BY THE MICRO-METHOD AND THE BRODIE PROCEDURE

Sampling	Salicylic Acid, mg. %: Micro-Method, Subj. A[a]	Micro-Method, Subj. B[b]	Brodie, Subj. A	Brodie, Subj. B
Whole blood (venipuncture)	1.8	6.7	2.0	8.5
Whole blood (fingertip)	1.8	6.6	...	...
Plasma	3.3	12.5	4.2	15.8
Plasma (from whole blood)[c]	3.5	12.7	...	...
Plasma (from whole blood)[d]	3.6	13.2	...	...

[a] Dosage was 10-gr. aspirin; blood samples taken 2 hr. after dosage; hematocrit, 49%. [b] Dosage was 10 gr. aspirin every 4 hr. for a total of 70 gr.; blood samples taken 2 hr. after last dose; hematocrit, 48%. [c] Calculated from whole blood by applying a correction for hematocrit as follows: mg. % plasma = mg. % whole blood × 1/1 − (hematocrit × 0.01). [d] Calculated from whole blood by applying a correction factor of 2.

Comments on Analytical Procedures.—All of the procedures in the assay were studied to eliminate unnecessary steps and variables and to reduce background fluorescence to a minimum. All glassware was scrupulously clean, cells were selected to have low fluorescence readings, and only reagents with low native fluorescence were used. Special care was taken to prevent contamination by dust that might produce fluorescence. Variability of subjects was reduced by requiring the dose of medication to be taken in a fasting condition with a fixed quantity of water. When repeated dosage studies were conducted the subsequent doses were taken at fixed times in relation to meals. Subjects were cautioned regarding the use of topical preparations because of the possibility of their containing salicylates or ultraviolet absorbers.

The time required for acidification and extraction of the blood samples was found to be critical as is well known in order that hydrolysis of the acetylsalicylic acid might be minimized and that the extraction could be as complete as possible. The method of application of the sample to the chromatographic paper by streaking was critical because of the large volume to be spotted and the need for well-separated sharply defined developed zones of acetylsalicylic acid and salicylic acid. The spotting of the large volume of sample was facilitated by passing a current of cool air over the paper during the operation to speed the volatilization of the ethylene dichloride. The selection of the chromatographic paper was dependent on its purity and separation characteristics. Whatman No. 1 paper gave the same separation of acetylsalicylic acid and salicylic acid as the paper used, but had to be pretreated with dilute nitric acid solution due to a high and variable background fluorescence. With the

S & S paper the R_f for the salicylic acid was approximately 0.6 while the acetylsalicylic acid R_f was 0.8 at room temperature which agreed with the values reported by Mandel (6). The R_f values were established by visual examination of a paper strip containing a reasonable concentration of salicylic acid and acetylsalicylic acid under ultraviolet light. The salicylic acid appears as a blue fluorescent spot while the acetylsalicylic does not fluoresce. However, its R_f was determined by its hydrolysis to salicylic acid on the paper strip in the presence of ammonia vapors. Hydrolysis of the acetylsalicylic acid on the paper strips with alkali or ammonia vapors was found to be unnecessary. Kinetic studies showed complete conversion of the acetylsalicylic acid to salicylic acid and complete elution from the paper in from 5–8 min. in the 5 *N* sodium hydroxide solution.

The fluorescence of salicylic acid and acetylsalicylic acid was somewhat greater in solutions of higher sodium hydroxide concentration, but solutions stronger than 5 *N* disintegrated the paper substrate too rapidly and gave solutions difficult to handle due to their high viscosity. The filter combination used produced excitation at 318–327 mμ and emission fluorescence in the range of 350–480 mμ (maximum at 410 mμ). Other filter combinations were investigated but in most cases these combinations (*i.e.*, primary, Corning No. 7-54 and Wratten No. 34A; secondary, Corning No. 7-54) permitted some overlap of transmitted wavelengths. Fluorescence was found to be linearly proportional to the concentration of acetylsalicylic acid and salicylic acid up to 12 mg. % in 5 *N* sodium hydroxide and reproducible for a period of at least 1 hr.

In the preparation of standard curves for the salicylic acid and acetylsalicylic acid it was found that the recovery of either drug was higher from an aqueous solution than from whole blood. Thus, if aqueous solutions were used to prepare the standard curves one would obtain low concentration values during actual *in vivo* blood level studies. In a check of the accuracy and precision of the method it was found that 90 to 110% of acetylsalicylic acid and salicylic acid was recovered from whole citrated blood to which known amounts of the drugs had been added in the following ranges: acetylsalicylic acid—0.20, 0.50, and 1.20 mg. %; salicylic acid—2.00, 5.00, and 12.00 mg. %. In these same ranges, pairs of duplicate determinations made by the same analyst showed standard deviations of the pairs to be 0.015 to 0.021 mg. % for acetylsalicylic acid, and 0.07 to 0.14 mg. % for salicylic acid.

The micro-method was also studied in a comparison with the procedure of Brodie (1). Two subjects were given aspirin in different doses, and blood samples were assayed for salicylic acid by the 2 methods. Because the Brodie procedure is proposed for plasma separated from a sample of venous blood while the micro-method uses a sample of whole blood, subjects were sampled for both and each method was employed to estimate salicylic acid in both whole blood and in the separated plasma. The results are summarized in Table I. The data for the micro-method show good agreement between the venous whole blood and the capillary whole blood in both subjects. Also by applying a correction value for the hematocrit in each case the plasma salicylate values when calculated from whole blood agree well with that actually recovered from plasma by the micro-method. The higher results obtained by the Brodie method, which determines only salicylate, are possibly due to acetylsalicylic acid which hydrolyzed during the assay to salicylic acid.

APPLICATION OF THE PROCEDURE

This technique is not suitable for routine clinical use because of the critical time factor between collection of the blood sample and extraction of the acetylsalicylic acid. No more than 4 min. should elapse before completion of the extraction procedure, and no more than 6 min. should elapse before the extracted sample is ready for chromatography.

Past methods of analysis have, in general, depended on making the assumption that the difference between "total" and "free" salicylates in the plasma constituted the acetylsalicylic acid. Because of failure by some investigators to take into account the very rapid hydrolysis of acetylsalicylic acid by the serum esterase, investigators rarely agreed about the plasma levels. As a consequence, they were misled in drawing conclusions about the mechanism of absorption.

The authors have observed that absorption of acetylsalicylic acid is very rapid from the stomach, and therefore it can survive long enough to be absorbed into the blood stream. The authors have observed that absorption of acetylsalicylic acid from the intestines is much slower, and that, therefore, the rate of entry into the blood is too slow to permit an appreciable level to be built up. These observations are consistent with the conclusions of Schanker (8) and Smith (9). They both have shown that an increase in pH reduces the rate of absorption of acetylsalicylic acid and salicylic acid to a lesser extent.

TABLE II.—PLASMA SALICYLATE LEVELS[a]

Subj.	Drug Detd.	Dose Given	0.5	1	2	4	4.5	5	6	8
Av. (15 males)	ASA[b]	20r[c]	1.27	0.69	0.17	0.13	1.10	0.79	0.08	0.02
Av. (20 females)	ASA	20r[c]	1.20	0.76	0.28	0.17	1.61	0.89	0.14	0.03
Av. (15 males)	TS[d]	20r[c]	3.8	4.7	4.8	3.4	6.1	7.5	7.3	5.8
Av. (20 females)	TS	20r[c]	3.9	5.3	6.3	5.0	9.2	10.4	10.3	7.9
Av. (11 males)	ASA	20[e]	2.17	1.30	0.29	0.07	...	...	0.04	0.01
Av. (13 females)	ASA	20[e]	2.30	1.42	0.55	0.14	...	...	0.09	0.01
Av. (11 males)	TS	20[e]	6.4	8.6	9.5	8.4	...	...	6.8	6.4
Av. (13 females)	TS	20[e]	6.6	8.5	11.7	10.1	...	...	8.0	6.9

[a] mg. % in plasma was calculated from whole blood with assumed hematocrit of 50% in all cases. [b] ASA = acetylsalicylic acid. [c] 20r = two 5-gr. aspirin tablets at time zero and two 5-gr. tablets again at 4 hr. [d] TS = total salicylate. [e] 20 = four 5-gr. aspirin tablets taken at time zero.

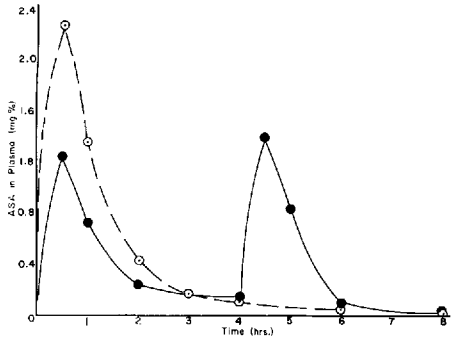

Fig. 1.—Comparison of average plasma levels of acetylsalicylic acid (ASA) after taking single and divided doses of aspirin at equal total dose of 20 gr. Key: ⊙, aspirin, single dose (4 × 5 gr.) 20-gr. dose at time 0; ●, aspirin, divided dose (2 × 5 gr.) 10 gr. at time zero and (2 × 5 gr.) 10 gr. after 4 hr. for a total 20-gr. dose.

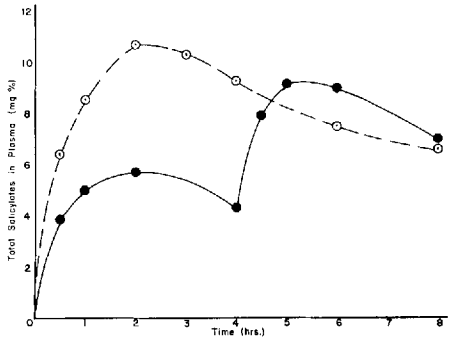

Fig. 2.—Comparison of average plasma levels of salicylates after taking single and divided doses of aspirin at equal total dose of 20 gr. Key: ⊙, aspirin, single dose (4 × 5 gr.) 20-gr. dose at time zero; ●, aspirin, divided dose (2 × 5 gr.) 10 gr. at time zero and (2 × 5 gr.) 10 gr. after 4 hr. for a total 20-gr. dose.

To provide a picture of the levels of acetylsalicylic acid and total salicylate in the blood after normal doses of aspirin, 35 subjects took 10 gr. of aspirin at time zero (8:00 a.m.) and a second 10 gr. exactly 4 hr. later. Blood samples were taken at various time intervals and assayed for acetylsalicylic acid and salicylic acid. Twenty-four of the above panel, at a later date, also took single 20-gr. doses of aspirin. The results of the 2 studies are summarized in Table II. Figure 1 is a graphic comparison of average plasma levels of acetylsalicylic acid after taking 10 gr. of aspirin repeated after 4 hr. for a total of 20 gr., and after taking 20 gr. of aspirin in a single dose. Figure 2 compares average total salicylate plasma levels after the same 2 dosage regimens.

The levels of acetylsalicylic acid and of the total salicylates in the plasma resulting from typical dosage regimens for aspirin provide a framework of reference for this new method of analysis of the content of drug and its principal degradation product in the blood. The peak values provide guidance in product formulation with respect to what levels in the plasma may be considered safe for a new aspirin dosage form. They also provide information which may be considered related to effectiveness. For instance it can be seen that a 20-gr. dose of aspirin, compared with a 10-gr. dose, gives a peak plasma level of acetylsalicylic acid almost twice as great (2.24 *versus* 1.25 mg. %). However, doubling the dose only slightly prolongs the plasma level of acetylsalicylic acid.

It will also be noted from Table II that differences are apparent in the average plasma levels for males and females. These are especially prominent in the total salicylate levels. A portion of this difference can be accounted for by the assumption made in calculating plasma levels that the hematocrits were all 50%. In the case of the females this would generally lead to a 9% high result. Also no consideration was given to differences in blood volumes of the individual subjects. This also on the average would show female plasma levels to be about 11% high.

A more detailed discussion of the clinical aspects of the micro-method and its implications in regard to the pharmacology of aspirin will be published at a later date.

Thyroxin–Triiodothyronine Concentrations in Thyroid Powders

By W. F. DEVLIN and H. WATANABE

Eleven thyroid powders were assayed for their respective goiter prevention activities in thiouracil treated rats. These activities were compared with the corresponding triiodothyronine and thyroxin levels of the powders as determined by a chemical method. A comparison between pronase, enzyme P, and an erepsin–trypsin mixture was made with respect to their effectiveness in releasing thyroxin and triiodothyronine from commercial thyroid. Pronase was demonstrated to be preferable. There was a consistent relationship between the triiodothyronine levels of the powders and the goiter prevention activities. This relationship was independent of the thyroxin level. Bioassay of diets containing measured amounts of thyroxin and triiodothyronine confirmed the validity of the chemical analyses and the preponderant contribution of the triiodothyronine component to goiter prevention by this assay.

OF ALL the iodine-containing substances in thyroid powders, it is believed that triiodothyronine (T_3) and thyroxin (T_4) account for the total biological activity (1). Reported discrepancies in activity between thyroid preparations (2, 3) might therefore be attributed to varying amounts of T_3 and T_4 even though the total iodine remains constant. Correlation between the iodothyronine content and biological activity has been hampered mainly by difficulties in chemical procedures which must take into account such factors as (*a*) iodothyronine instability in solution (4–6), and (*b*) the slowness of iodothyronine release from thyroid protein by most proteolytic agents (7, 8). In this report, the hydrolytic actions of pronase, enzyme P, and an erepsin–trypsin mixture have been compared with respect to their effectiveness in releasing T_4 and T_3 from thyroid powders. The T_4 and T_3 concentrations of thyroid powders were compared with their corresponding goiter prevention activities. The activities of diets containing measured amounts of T_4 and T_3 were employed to confirm the analyses.

METHODS

Iodoamino Acid Determination.—A quantity of the thyroid powder, containing 50–200 mcg. of iodine, was placed in 2 ml. of 0.05 *M* Tris buffer at pH 8.5. One milligram of pronase[1] or enzyme P[2] was added, and the mixture was incubated at 39° for periods of time ranging from 6–96 hr. For the erepsin–trypsin[3,4] digests, 10 mg. of each enzyme was added at the beginning of the digestion time and 5 mg. of erepsin was added daily thereafter. Occasional gentle shaking during the first hour of incubation was helpful in dispersing the powder. Butanol extraction, paper chromatography, and measurement of the thyronines were performed as previously described (7). U.S.P. reference standard triiodothyronine (liothyronine) and thyroxin (B grade, Calbiochem, Los Angeles, Calif.) were employed throughout as thyronine standards. The iodothyronine values reported were the average of 4 separate determinations.

Goiter Prevention Assay.—The biological activities of the thyroid samples were determined by the goiter prevention assay employing thiouracil-treated adult female rats as the test animals (9). For the preparation of diets containing T_3 and T_4, solutions of each thyronine were made up in acid ethanol (90 ml. of ethanol plus 10 ml. of 2 *N* H_2SO_4) at a concentration of 100 mcg./ml. The required volumes of the thyronine solutions were mixed in a mortar with 2-Gm. amounts of casein, then dried in a stream of nitrogen and dispersed in ground Fox Cubes.[5]

RESULTS AND DISCUSSION

Rate of Release of the Iodothyronines, T_3 and T_4, During Proteolysis in Tris Buffer.—In Fig. 1 the effectiveness of pronase and enzyme P in releasing iodothyronines from commercial thyroglobulin (sample 6, Table 1) is compared with that of erepsin and trypsin in combination. Similar peaks of recovery of T_3 and T_4 were obtained in both enzyme P and pronase digests. The largest amount of T_3 was recovered following 6 hr. digestion, and the amount of T_4 recovered reached a near maximum level at 24 hr. Pronase was considered to be superior because a greater quantity of the iodothyronines was recovered. The reduced recoveries of the T_3 and T_4 with longer digestion periods in enzyme P and pronase digests were apparently due to iodothyronine instability in this buffer medium. A similar decline in recoverable T_3 and T_4 from enzymatic hydrolysates as the period of digestion was lengthened, has been reported by others (10, 11). Since the stability of T_3 relative to T_4 in this medium is not known with precision, it is not possible to say that pronase favors the release of T_3 over

T_4 in the early stages of hydrolysis as might be deduced from Fig. 1. There was a steady increase in iodothyronine recoveries up to 96 hr. in the erepsin–trypsin digests which indicated that the rate of their release from the thyroid protein under these conditions exceeded the rate of degradation. The greater bulk constituted by the erepsin–trypsin mixture in the hydrolysate medium may have conferred a measure of stability to the free iodothyronines in solution. In this connection, Rosenberg has observed that the rate of disappearance of T_4 is less in Viokase thyroid hydrolysates when compared with pronase hydrolysates (11). Although the recoveries of T_3 and T_4 continued to increase during the digestion period with the erepsin–trypsin mixture in Tris buffer, the final amounts of T_3 and T_4 actually obtained were less than the peak levels found with the other enzymes.

In a previously reported investigation (7) comparable peak recoveries of T_3 and T_4 were achieved in 96-hr. erepsin–trypsin digests when performed in borate buffer. However, the short digest periods required by pronase action reduced risk of losses by degradation or microbiological contamination. Also Tris buffer provided a better buffering capacity than the borate medium. Therefore, optimum conditions for the proteolytic removal of T_3 and T_4 from commercial thyroid powders has been defined as overnight digestion (15–18 hr.) in the presence of 1 mg. of pronase per 2 ml. of Tris buffer.

Iodothyronines in Commercial Thyroid Powders.—Table I summarizes the results of analyses of the T_3 and T_4 content in 11 thyroid powders obtained from 4 different laboratories. Sample *9* was diluted with filler of unspecified composition to meet the requirements of the "United States Pharmacopeia" (12). Sample *1* possessed an exceptionally low iodothyronine level which was reflected in bioassay experiments here and elsewhere. Samples comparable in quality and activity to sample *1* have been judged "clinically defective" in human therapy trials.[6] In general, the beef thyroid powders had a lower per cent of total iodine than the hog powders.

Excluding the defective sample, the per cent of the total iodine accounted for by the T_3 component ranged from 2.9–5.9. The per cent of the total iodine accounted for by the T_4 component ranged from 13.7–22.7. The molar ratios ranged from 3.4–4.9 in the beef powders and from 2.0–3.1 in the hog powders. This species difference in $T_4:T_3$ *M* ratios seems to be a characteristic which results from simultaneous elevated T_4 levels and reduced T_3 levels in the beef thyroids when compared with those originating from the hog. Pileggi *et al.* (13) have reported essentially the same range of T_3 concentrations as listed in Table I but slightly lower T_4 levels in a number of commercial thyroid powders of unspecified species origin. The single sheep sample

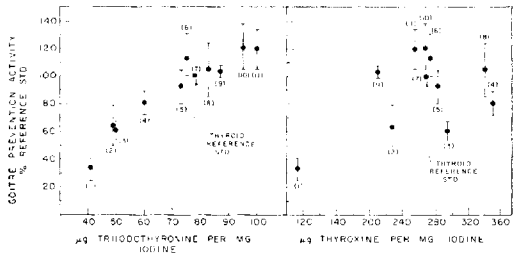

Fig. 2.—The relation between triiodothyronine and thyroxin concentrations in thyroid powders and goiter prevention activity in thiouracil-treated rats. The numbers in parentheses correspond with thyroid sample numbers listed in Table I. Vertical bars represent the 95% confidence limits for each estimate of potency.

reported in Table I had a molar ratio of 3.2; 22.6% of the total iodine was accounted for by the T_3 and T_4 components. In these respects, it was therefore intermediate between the hog and beef thyroid powders.

Goiter Prevention Versus T_3 Content in Orally Administered Thyroid.—In the goiter prevention assay the dose of desiccated thyroid was adjusted according to the total iodine content. Experiments employing this bioassay suggested that the T_3 component probably accounted for most of the response (14). To test this hypothesis, the individual T_3 and T_4 concentrations expressed as mcg./mg. total iodine in the thyroid powders were plotted against the respective goiter prevention activities (Fig. 2). All activities were expressed as a percentage of that possessed by the reference standard (sample 7, Table I). It was noted that, with the exception of sample 8, all thyroids possessing activity of more than 100 by this system of comparison originated from the hog. The T_4 levels within this group varied from 210–340 mcg./mg. iodine, and did not correlate well with the observed activities. However, in spite of the fluctuating T_4 levels, there remained a consistent relationship between the T_3 concentrations and the respective goiter prevention activities.

It was desirable also to compare the level of goiter prevention activity of thyroid powder with that of a synthetic mixture containing similar amounts of T_3 and T_4. If the same level of activity could be demonstrated in this manner, it would, in addition to lending support to the validity of the chemical analysis, show that neither the union of the hormones with thyroid protein at the time of administration nor the presence of other components normally present in thyroid powders contribute to the response. Consequently, the 3 diets listed in Table II were prepared. Diet *A* contained the reference thyroid powder while diet *B* contained a mixture of T_4 and T_3 in the same proportions as diet *A*. Diet *C* had the same content of T_3 as diets *A* and *B* but had no T_4. Diet *D* had T_4 only in a concentration which would reduce the gland weight in the assay to a suitable level for comparison with the other diets. For purposes of calculating the relative potency it was supposed that the added thyronines provided the same fraction of the total iodine content as the reference powder. The activities of the the powder and the corresponding thyronine mixture were approximately the same. The artificial mixture of T_4 and T_3 in diet *B* possessed only slightly higher activity than that of the reference powder. If the accuracy of the chemical analysis is accepted, this small discrepancy may be due to incomplete intestinal hydrolysis of the orally ingested powder and consequent reduced absorption of T_4 and T_3. This possibility has been raised by Levy and Knox (15) who observed a discrepancy of similar magnitude between the activities of a thyroid powder and its hydrolysate. Diet *C* which contained the same amount of T_3 as in the reference thyroid produced essentially the same activity as that of the powder itself. Diet *D*, with more than 5 times the thyroxin present in the reference powder diet mix, was only about one-seventh as active. The minor contribution of T_4 relative to T_3 under these conditions of assay is therefore confirmed. These findings are consistent with the relationships illustrated in Fig. 2.

It is acknowledged that the metabolic effectiveness of T_4 may be impaired in thiouracil-treated animals (16), and therefore in this assay the contribution of T_3 relative to T_4 will be somewhat exaggerated. However, the essential agreement between the activity of the powder and its corresponding T_3–T_4 mix suggests at least the validity of the T_3 measurement. It has now been deduced that the T_3 component of many thyroid tablets when administered orally during clinical therapy probably accounts for the greater part of the response (25).

The widely varying levels of T_4 and T_3 which have been reported for thyroid (17, 18) have often been attributed to the physiological state of the

[a] Sample numbers correspond to those appearing in Table I.

animals from which the glands were taken (19). Thyroid powders prepared on the North American continent for pharmaceutical use usually originate from gland pools representing large numbers of healthy animals. In those instances where the thyroid preparation had obviously low clinical activity (20), the possibility of losses or degradative changes during processing must be considered as a cause. Fresh thyroid tissue is known to possess autolytic activity (21) which could bring about selective losses of iodine-containing constituents, if, for example, the tissue were not processed or frozen immediately following collection. Also the unusual prospect of a thyroid powder acquiring a gain in activity during processing operations has been raised by Braverman and Ingbar (22). They have treated patients with commercial thyroid powder standardized to U.S.P. specifications which gave P.B.I. levels and other clinical responses indicative of markedly increased amounts of T_3 or some other equally potent thyroactive substance. Alternatively, this phenomenon might also be caused by a selective loss of T_4 during processing operations.

U.S.P. thyroid is required to contain 0.2 ± 0.03% iodine in thyroid combination (12). In Table III the levels of T_3 and T_4 have been calculated for U.S.P. thyroid as they would exist when prepared by dilution of the powders listed in Table I. From the average values, 1 gr. of a composite sample of the 4 beef thyroid samples would contain 39 mcg. of T_4 and 7.9 mcg. of T_3. Similarly, 1 gr. of U.S.P. thyroid prepared from the hog powders would have 33 mcg. of T_4 and 11.3 mcg of T_3. There is significantly less T_3 in the beef thyroid and this would account for previously reported lower levels of activity in beef thyroid when assayed by this method (14).

The present study suggested that the oral administration of desiccated thyroid reduced thiouracil-induced goiter in rats to an extent which was comparable to that brought about by an equivalent mixture of T_3 and T_4. In view of such factors as diet and species which are known to affect the availability of orally ingested T_4 (23, 24) the fraction of activity contributed by the T_4 component in a T_4–T_3 mixture may be influenced by the conditions of the experiment. Lavietes and Epstein (25) have demonstrated the difficulties in following the course of thyroid therapy from observation of serum P.B.I. levels when the T_4:T_3 ratio of the administered U.S.P thyroid is abnormally low. Clinicians have noted also some qualitative differences between the responses of T_3 and T_4 when administered separately (26, 27). In any event, an expression of potency for a thyroid powder will depend not only on its T_3 and T_4 content but also on the physiological effect selected as the response metameter.

Effect of Complex Formation on Drug Absorption III

Concentration- and Drug-Dependent Effect of a Nonionic Surfactant

By GERHARD LEVY, KAREN E. MILLER, and RICHARD H. REUNING*

The effect of various concentrations of the nonionic surfactant polysorbate 80 on the absorption of a number of alcohols and barbiturates by goldfish has been studied. The absorption rate of the barbiturates was increased significantly in the presence of low concentrations of polysorbate 80, and decreased by higher concentrations of the surfactant. The absorption rate of the alcohols studied was not affected significantly by the surfactant. The retardation of barbiturate absorption at higher polysorbate 80 concentrations, which occurred also during mechanical agitation of the solution (when diffusion of drug to the absorbing membranes is definitely not absorption rate limiting), is interpreted as being indicative of the absence of a dissociating effect of the biologic membranes on the drug–micelle complex. The drug–micelle complexes differ in this respect from the nonmicellar dye complexes studied previously, apparently due to the greater exposure of substances in simple 1:1 complexes. Equilibrium dialysis and surface tension determinations have been carried out in an attempt to elucidate the mechanisms of the effects of polysorbate 80 on drug absorption. It is shown by kinetic analysis that the modification of barbiturate absorption by polysorbate 80 represents the net effect of enhanced absorption and decreased thermodynamic activity of the drug due to micellar complexation.

NUMEROUS studies of the effect of surfactants on drug absorption have shown that these agents can either increase, decrease, or exert no apparent effect on the transfer of drugs across biologic membranes (1). Some of the complexities and biopharmaceutical aspects of this problem have been reviewed recently (2). It is now appreciated that the type and magnitude of effect can be a function of the concentration (3) and chemical nature of the surfactant and that a given surfactant also may have certain specific pharmacologic properties of its own (2). It has been suggested by one of the authors that the observed effect of a surfactant on absorption may represent, in a certain concentration range, the net result of both enhancement and retardation of absorption (2).

Most of the studies of surfactant effects on drug absorption have been carried out on microbial systems. The results thus obtained may have limited applicability to multicellular organisms, since the latter are able to maintain homeostasis much more effectively. Moreover, the presence of enzymes and other vital cell constituents in the cell membrane makes unicellular organisms particularly sensitive to direct effects of surfactants. Absorption studies using small animals, isolated intestines, or man present other difficulties—dilution effects and interaction with mucus and/or other components of intestinal fluids and tissues make it practically impossible to maintain a constant known concentration of surfactant and drug. The results of such experiments, therefore, can be interpreted only qualitatively or, at best, semiquantitatively. These difficulties are not encountered when using fish for absorption studies (4–6). The major advantage of the fish system is due to the large volume of drug solution which may be used; this permits the maintenance of an essentially constant concentration gradient of drug and surfactant across the biologic membrane, despite continuous absorption of the drug and possible binding of some of the surfactant to mucus and/or membrane constitutents. Previous studies have shown that the drug absorption characteristics of fish membranes are similar to those of rats (5), while the latter yield results similar to those obtained in man (7).[1]

The investigation described here is part of a continuing study of the effect of complex formation of drug absorption (8, 9). The purpose of the presently described investigation was to determine the effect of various concentrations of a representative nonionic surfactant, polysorbate 80, on the absorption of certain noninteracting and interacting drugs by goldfish. It was desired also to elucidate the mechanism of the observed effects, and to examine their relationship to certain physico-chemical characteristics of the drug–surfactant system.

[1] This statement refers to absorption by passive diffusion; there are appreciable differences between species in active transport characteristics.

EXPERIMENTAL

Goldfish, *Carassius auratus*, common variety, weighing from 15 to 25 Gm., were used. All fish utilized in a given set of experiments were from the same lot.

Drug Solutions.—All solutions were prepared in bulk on the day of the experiment from reagent, U.S.P., or N.F. grade chemicals. The drugs were dissolved in 0.05 *M* tris(hydroxymethyl)aminomethane (Tham) buffer, adjusted to pH 5.9 at 20° with hydrochloric acid.

Determination of Absorption Rate.—Single goldfish were placed in 250-ml. capacity beakers containing 175 ml. of drug solution at 20 ± 1°. The time of death, evidenced by cessation of gill and mouth movements, was noted. Absorption rate constants were calculated as previously described (5).

All determinations of time of death were carried out by the same individual. Prior to the experiment, all beakers containing the various drug solutions were labelled with code numbers by an individual not otherwise associated with the study. The codes were broken only after completion of the experiment.

Effect of Stirring on Time of Death.—Single goldfish were placed in 250-ml. capacity beakers containing 100 ml. drug solution at 28 ± 1°. Half of the solutions were stirred with a magnetic stirrer at about 500 r.p.m. The dimensions of the stirring bar were: diameter 0.25 cm., length 1.7 cm. The solutions could not be coded in this experiment since foaming on stirring made the surfactant-containing solutions readily recognizable.

Determination of Micellar Complexation.—The possible binding of ethanol by polysorbate 80 was investigated by equilibrium dialysis, using a method similar to that described previously (8). Ten milliliters of 2% w/v polysorbate 80 in 0.05 *M* Tham, pH 5.9, was placed in nylon dialysis bags.[2] Each bag was suspended in a 125-ml. conical flask containing 110 ml. of 2% v/v ethanol in 0.05 *M* Tham, pH 5.9. The solutions were equilibrated for 14 to 20 days at room temperature. The concentration of ethanol inside and outside the dialysis bag was then determined by the method of Hoult and Pawan (10).

The binding of secobarbital by polysorbate 80 was determined also by equilibrium dialysis. A number of different drug and surfactant concentrations were employed. The solvent system was 0.05 *M* Tham at pH 5.9. Due to the very poor permeability of the nylon membrane to secobarbital, cellulose dialyzer tubing[3] was used. In agreement with observations by others (11), this material was found to be impermeable to polysorbate 80. Equal concentrations of secobarbital were placed initially inside and outside the dialysis bag, and the solutions were equilibrated for 2 to 4 days at 20 ± 1°. The concentration of secobarbital on each side of the dialysis bag then was determined spectrophotometrically at 255 mμ, using 0.5 *M* sodium hydroxide solution as the diluent and blank. Polysorbate 80 interference in the secobarbital assay was additive; analytical results from polysorbate 80-containing solutions were corrected appropriately. The binding data yielded Freundlich-type isotherms (8) which permitted determination of the degree of binding at various total secobarbital concentrations.

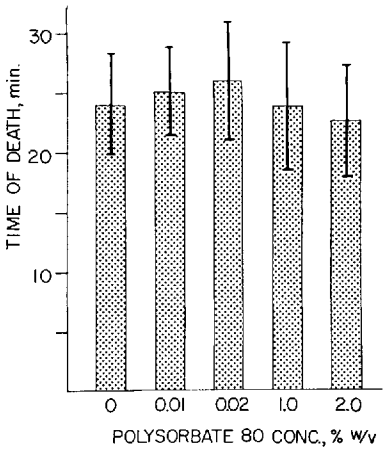

Fig. 1.—Effect of polysorbate 80 on the time of death of goldfish immersed in 5% ethanol solution (pH 5.9, 20°). Mean of 10 fish each. Vertical bars indicate ±1 standard deviation.

Surface Tension Determinations.—Surface tensions were determined with a Du Nouy tensiometer[4] at 20 ± 1°, using standard procedures for cleaning of the ring and for correction of the instrumental readings (12). To reduce surface aging effects, the solutions were swirled and agitated moderately immediately before each reading. The reported values are therefore dynamic rather than equilibrium values.

RESULTS AND DISCUSSION

It was found in preliminary experiments that immersion of goldfish in 0.01 to 2.0% polysorbate 80 solutions for 24 hr. had no apparent deleterious effect on the fish. This is consistent with the very low acute systemic toxicity of polysorbate 80 in other animals; for example, Nissim (13) reported that subcutaneous injection of up to 8 Gm. of polysorbate 80 per Kg. body weight did not produce any untoward effects in mice.

Polysorbate 80 had no significant effect on the rate of absorption of ethanol by goldfish, as judged by the time of death of the fish after immersion in 5% ethanol solution containing up to 2.0% of the surfactant (Fig. 1). Equilibrium dialysis showed that there was no binding of ethanol by polysorbate 80.

The surfactant had a pronounced, concentration-dependent effect on the absorption rate of secobarbital (Fig. 2). The barbiturate was absorbed more rapidly in the presence of low concentrations of polysorbate 80; higher concentrations of the surfactant decreased the rate of absorption significantly. Equilibrium dialysis indicated that there was considerable binding of secobarbital by polysorbate 80 when the concentration of the surfactant was in the range which caused retardation of secobarbital absorption. Since a previous study

(9) has shown that biologic membranes can have a dissociating effect on certain types of complexes, an experiment was designed to determine if the absorption-retarding effect of polysorbate 80 was due to the decreased thermodynamic activity of secobarbital as a consequence of its partial micellar complexation, or if the effect is due to a decreased rate of diffusion of the drug in micelles to the biologic membranes. For this purpose, the effect of polysorbate 80 on secobarbital absorption from intensively stirred solutions was compared to the effect obtained in unstirred solutions. There was no difference in the respective ratios of the times of death in solutions with polysorbate 80 to those without polysorbate 80 (Table I). Since the absorption-retarding effect of the surfactant was present also during rapid stirring, where diffusion of drug molecules and molecular aggregates is definitely not absorption rate limiting,[5] it may be concluded that fish membranes do not have a dissociating effect on secobarbital–polysorbate 80 micellar complexes. The difference in the effect of biologic membranes on micellar complexes and certain simple 1:1 complexes (9) is due probably to the greater exposure of drugs in the latter. This permits better contact and facilitates the interaction between the drug and the biologic membrane.

Differences in the times of death listed in Table I and those shown in Fig. 1 reflect the effect of temperature on the absorption rate and the lethal dose of secobarbital, and on the binding of the drug by polysorbate 80. Technical difficulties made it impossible to carry out the stirring experiments at 20°. Stirring itself apparently enhanced drug absorption; this was due probably to the more rapid flow of drug solution through the mouth and thereby across the gills. The gills are responsible for about 50% of the total drug absorption (6).

In view of the apparent lack of dissociating effect of the biologic membranes on the micellar complex

[5] It is believed that this is true even in unstirred solutions, due to the constant movement of the fish. The described experiment was carried out to establish this fact under more rigorous conditions.

of secobarbital and polysorbate 80, and the absorption enhancing effect of polysorbate 80 itself, the model shown in Scheme I is believed to represent the over-all effect of the surfactant.

The possibility that the more rapid absorption of secobarbital in the presence of low concentrations of polysorbate 80 is mediated by a nonmicellar secobarbital–polysorbate 80 complex will be considered in a subsequent paragraph. Disregarding this possibility, a kinetic model based on an equation derived previously (4, 5) would consist of the following relationships.

No polysorbate present: $k = L/(CT_L)$,
Polysorbate concentrations below CMC: $k' = L/(CT_L)$
Polysorbate concentrations above CMC: $k' = L/(C_f T_L)$

where k and k' represent the "normal" and the "enhanced" absorption rate constant, respectively; L is the lethal dose of the drug; C and C_f are the concentrations of total and free drug, respectively; T_L is the time of death, and CMC is the critical micelle concentration. This model may be verified by showing that the value of k' remains constant over a wide concentration range of polysorbate 80.

The apparent and corrected constants for secobarbital absorption in the presence of various concentrations of polysorbate 80 are listed in Table II. The corrected constants are based on the concentration of free secobarbital as determined by equilibrium dialysis. The low concentration of polysorbate (0.01%) is approximately the critical micelle concentration (14). Binding of secobarbital at this concentration was either absent or very slight (<5%). The values of k' were reasonably constant at 0.01, 1.0, and 2.0% polysorbate 80 concentrations and were appreciably greater than k. These results verify, within the limits of experimental accuracy, the kinetic model presented in the preceding paragraph. The data show also that the effect of the surfactant above the CMC represents the net result of absorption-enhancing and retarding effects, as has been suggested previously by one of the authors (2).

The question arises why polysorbate 80 enhances the absorption of secobarbital but has no such effect on the absorption of ethanol. It was thought possible that ethanol itself decreases the surface tension of the solution so much that addition of polysorbate 80 would have no appreciable additional effect. This possibility was ruled out experimentally (Table III). Moreover, it was found that

the surface tensions of secobarbital–polysorbate 80 and ethanol–polysorbate 80 solutions were quite similar at any given surfactant concentration. Alexander and Trim (3) have suggested that the enhanced absorption of a drug in the presence of surfactant concentrations below the CMC may be due to formation of a nonmicellar complex of increased interfacial activity which augments the amount of drug on the surface of the biologic membranes. No evidence for an association of secobarbital and polysorbate 80 at concentrations of 0.005 and 0.01% of the latter was obtained from solubility, equilibrium dialysis, and ultraviolet absorption data. However, it is possible that such interactions may yet be found by other, more sensitive methods.

Another possible reason for the difference in the effect of polysorbate 80 on the absorption of ethanol and secobarbital, respectively, can be related to the different routes of absorption of these 2 drugs. Ethanol can diffuse across membranes through pores, while secobarbital diffuses through the lipoid barrier (4). Polysorbate 80 in 0.01% concentration had no significant effect on the absorption of other low molecular weight alcohols but increased significantly the absorption of another barbiturate (Fig. 3). This lends support to the theory that polysorbate 80 could have a specific effect on the permeability of the lipoid barrier portion of the biological membrane. There is some direct and biochemical evidence which suggests such an effect (15).

[a] Dissolved in 0.05 M Tham, adjusted with HCl to pH 5.9 at 20°. [b] Mean of 4 determinations, obtained at 20 ± 1°.

Figure 3 shows also the results of another experiment with ethanol on a larger number of fish. The purpose of this experiment was to establish definitely that 0.01% polysorbate 80 had no effect on ethanol absorption. The results obtained with *n*-octanol, also depicted in Fig. 3, cannot be interpreted readily because the data were quite variable and since there was some evidence of formation of mixed micelles.

In summary, it appears that the absorption-enhancing effect of polysorbate 80 may be due to the formation of a nonmicellar drug–surfactant complex, or that it may represent a direct action of the surfactant on the lipoid barrier portion of the biologic membrane. The present data do not permit distinction between these possibilities. It is reasonable to assume that an effect of the surfactant on biologic membranes should be time-dependent, yet the kinetic analysis (which assumes a time-independent effect) gives no such indication. However, the time course of the permeability-

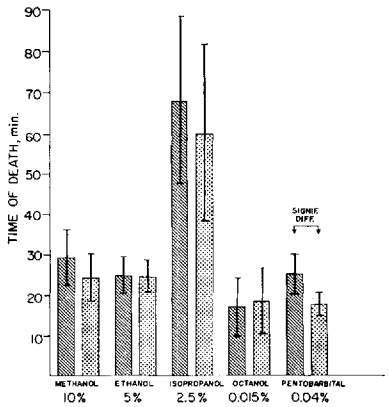

Fig. 3.—Effect of 0.010% polysorbate 80 on the time of death of goldfish immersed in solutions of various drugs in 0.05 M Tham (pH 5.9, 20°). Ethanol data are mean of 26 fish each, all others are the mean of 10 fish each. Vertical bars indicate ±1 standard deviation. Key: ▨, without polysorbate; ▩, with polysorbate 80, 0.01%.

enhancing effect could be such that most of the effect is elicited within a few minutes. Alternatively, the surfactant may promote better interfacial contact and thus increase the effective surface area of the membrane. Studies are now being initiated to determine if immersion of the fish in surfactant solutions for various periods of time will affect the rate of absorption of secobarbital upon subsequent immersion of the fish in secobarbital solutions without surfactant. This should establish whether or not the surfactant promotes drug absorption by modifying the barrier properties of the biologic membranes. However, the present investigation has shown already that the effect of polysorbate 80 on drug absorption is a function of the drug and of surfactant concentrations, and that an effect of polysorbate 80 concentrations above the CMC can represent the net result of absorption enhancement and retardation.

Comparative Absorption of Micronized and Nonmicronized Medroxyprogesterone Acetate in Man

By DAVID L. SMITH, ALBERT L. PULLIAM, and ARLINGTON A. FORIST

A specific, sensitive method has been developed for the analysis in urine of microgram quantities of the principal urinary metabolite of medroxyprogesterone acetate. The method consists essentially of the following steps: hydrolysis with β-glucuronidase, extraction with chloroform, Florisil column chromatography, thin-layer silica gel chromatography, and measurement of either ultraviolet absorption or fluorescence resulting from sulfuric acid treatment. The method has been used to compare the gastrointestinal absorption of medroxyprogesterone acetate from tablets containing either 10 mg. of micronized or nonmicronized medroxyprogesterone acetate. The 8-hr. excretion of metabolite following oral ingestion of the tablets by normal adult humans was employed as the measure of absorption. The increased metabolite output, resulting from the tablet prepared from micronized medroxyprogesterone acetate, was very highly significant ($p < 0.001$). Ten subjects in a crossover study excreted an average of 2.23 ± 0.19 (S.E.M.) times as much metabolite in 8 hr. after ingesting the micronized formulation as they did after ingesting the nonmicronized one.

THIS STUDY was undertaken to develop an analytical method for the purpose of determining whether a tablet prepared from 10 mg. of micronized medroxyprogesterone acetate[1] (I) would afford a significant increase in absorption compared to a tablet prepared from nonmicronized material. Since medroxyprogesterone acetate has very low solubility in water (~0.3 mg./100 ml. at 37°), its gastrointestinal absorption may be limited by its gastrointestinal dissolution rate; reducing its particle size, therefore, might be expected to increase its physiologic availability (1–4). Helmreich and Huseby (5), who employed doses of 50–200 mg. of medroxyprogesterone acetate, have already noted that particle size reduction might influence its absorption efficiency.

Helmreich and Huseby (6) identified the principal urinary metabolite of medroxyprogesterone acetate as 6β,17α,21-trihydroxy-6-methyl-pregn-4-ene-3,20-dione,17-acetate (II). Others (7) have reported it to be the 21-acetate (III). This metabolite, which is excreted in the human as a glucuronide, accounts for approximately one-half of the total drug-related material excreted in the urine (5). The 24-hr. urinary output in the human was found to range from about 4–8% of a 200-mg.

enhancing effect could be such that most of the effect is elicited within a few minutes. Alternatively, the surfactant may promote better interfacial contact and thus increase the effective surface area of the membrane. Studies are now being initiated to determine if immersion of the fish in surfactant solutions for various periods of time will affect the rate of absorption of secobarbital upon subsequent immersion of the fish in secobarbital solutions without surfactant. This should establish whether or not the surfactant promotes drug absorption by modifying the barrier properties of the biologic membranes. However, the present investigation has shown already that the effect of polysorbate 80 on drug absorption is a function of the drug and of surfactant concentrations, and that an effect of polysorbate 80 concentrations above the CMC can represent the net result of absorption enhancement and retardation.

Comparative Absorption of Micronized and Nonmicronized Medroxyprogesterone Acetate in Man

By DAVID L. SMITH, ALBERT L. PULLIAM, and ARLINGTON A. FORIST

A specific, sensitive method has been developed for the analysis in urine of microgram quantities of the principal urinary metabolite of medroxyprogesterone acetate. The method consists essentially of the following steps: hydrolysis with β-glucuronidase, extraction with chloroform, Florisil column chromatography, thin-layer silica gel chromatography, and measurement of either ultraviolet absorption or fluorescence resulting from sulfuric acid treatment. The method has been used to compare the gastrointestinal absorption of medroxyprogesterone acetate from tablets containing either 10 mg. of micronized or nonmicronized medroxyprogesterone acetate. The 8-hr. excretion of metabolite following oral ingestion of the tablets by normal adult humans was employed as the measure of absorption. The increased metabolite output, resulting from the tablet prepared from micronized medroxyprogesterone acetate, was very highly significant ($p < 0.001$). Ten subjects in a crossover study excreted an average of 2.23 ± 0.19 (S.E.M.) times as much metabolite in 8 hr. after ingesting the micronized formulation as they did after ingesting the nonmicronized one.

THIS STUDY was undertaken to develop an analytical method for the purpose of determining whether a tablet prepared from 10 mg. of micronized medroxyprogesterone acetate[1] (I) would afford a significant increase in absorption compared to a tablet prepared from nonmicronized material. Since medroxyprogesterone acetate has very low solubility in water (~0.3 mg./100 ml. at 37°), its gastrointestinal absorption may be limited by its gastrointestinal dissolution rate; reducing its particle size, therefore, might be expected to increase its physiologic availability (1–4). Helmreich and Huseby (5), who employed doses of 50–200 mg. of medroxyprogesterone acetate, have already noted that particle size reduction might influence its absorption efficiency.

Helmreich and Huseby (6) identified the principal urinary metabolite of medroxyprogesterone acetate as 6β,17α,21-trihydroxy-6-methyl-pregn-4-ene-3,20-dione,17-acetate (II). Others (7) have reported it to be the 21-acetate (III). This metabolite, which is excreted in the human as a glucuronide, accounts for approximately one-half of the total drug-related material excreted in the urine (5). The 24-hr. urinary output in the human was found to range from about 4–8% of a 200-mg.

Received December 9, 1965, from The Upjohn Co., Kalamazoo, Mich.
Accepted for publication January 28, 1966.
The authors express their appreciation to Dr. R. A. Huseby for making his manuscript available prior to publication, to Dr. J. C. Babcock for advice and criticism, to Drs. J. W. Hendrix and J. G. Wagner for design and execution of the clinical phase of the study, to Dr. L. C. Schroeter for particle size and surface area measurements, and to Dr. D. Ayer and Mr. J. A. Campbell for the synthesis of compounds II and III, respectively.

dose with more than 80% of medroxyprogesterone acetate-related material excreted in the feces (5). These data alone do not indicate poor absorption, however, since biliary excretion of medroxyprogesterone acetate and/or its metabolites is extensive even after intravenous administration of medroxyprogesterone acetate (8).

The approach of Helmreich and Huseby (5), who measured the amount of the major urinary metabolite excreted in the urine, seemed to be the most practical measure of absorption. A comparison of the absorption of medroxyprogesterone acetate at the 10-mg. dose level by measurement of the metabolite excreted in the urine required a very sensitive analytical method. The method developed is an extension of previously described procedures (5, 9, 10) and consists essentially of the following steps: (*a*) hydrolysis with β-glucuronidase, (*b*) extraction with chloroform, (*c*) Florisil[2] column chromatography, (*d*) thin-layer silica gel chromatography, and (*e*) measurement of either the specific ultraviolet absorption or fluorescence resulting from sulfuric acid treatment.

EXPERIMENTAL

Test Tablets.—Both tablets contained 10 mg. of medroxyprogesterone acetate and 0.05 mg. of ethinyl estradiol,[3] except that in one of them the medroxyprogesterone acetate was micronized. The micronized medroxyprogesterone acetate, which was used in the preparation of the compressed tablet, had a size distribution so that 99.9% of the particles were smaller than 10 μ diameter. Micronized and nonmicronized medroxyprogesterone acetate possessed specific surface areas, prior to preparation of the tablets, of approximately 7.4 $M.^2$/Gm. and 1.2 $M.^2$/Gm., respectively. Both of the formulations contained the other excipients of the commercial tablet.

Subjects and Conduct of Absorption Tests.—The tablets were ingested orally by normal female (postmenopausal) volunteers after an overnight fast; no food was taken until 2 hr. after administration of the tablet, and fluid intake was controlled. The ages and weights of the subjects are given in Tables II and III. Two tests were conducted: 1 tablet nonmicronized *versus* 1/2 tablet nonmicronized and, several months later, 1 tablet micronized *versus* 1 tablet nonmicronized. Both tests were of the crossover type, and required 2 weeks each. On day 1 of each week, control urine (8 a.m. to 4 p.m.) was collected and on day 2 one of the test tablets was ingested at 8 a.m. and urine collected from 8 a.m. to 4 p.m. The urine samples from each subject were randomly coded, but were assayed in parallel to avoid complicating the results with possible day-to-day assay variations.

Analytical Procedure.—The procedure used for the determination of the 6,21-dihydroxy metabolite of medroxyprogesterone acetate differs from the Helmreich and Huseby procedure (5) primarily in that it employs thin-layer chromatography.

Six milliliters of 0.5 *M* pH 4.7 acetate buffer was added to 60 ml. of the urine to be examined in a 100-ml. volumetric flask, and 15 ml. of 5000 units β-glucuronidase/ml.[4] added. The flask was placed in a constant-temperature bath at 47° for 18 hr. The hydrolyzed urine was transferred to a 250-ml. separator and extracted twice with 100 ml. of $CHCl_3$ as follows. The funnel was shaken vigorously for 1 min. and then allowed to stand for 1 hr.; the remaining emulsion was broken by gently swirling the separator. The $CHCl_3$ extracts were drained into a second 250-ml. separator, and the combined extracts washed with 20 ml. of 0.1 *N* NaOH and 20 ml. of 0.1 *N* HCl. Five minutes were allowed for each wash. The washed extract was drained into a 250-ml. beaker and evaporated to dryness under nitrogen at temperatures below 45°. The residue was dissolved in 5 ml. of $CHCl_3$ and transferred quantitatively to a previously prepared Florisil column (see below). The column was eluted with 25 ml. of $CHCl_3$, 25 ml. of 2% CH_3OH in $CHCl_3$, and 50 ml. of 25% CH_3OH in $CHCl_3$. The 25% CH_3OH–$CHCl_3$ fraction was collected in a 50-ml. wide-mouth centrifuge tube and evaporated to dryness under nitrogen at temperatures below 45°. The centrifuge tube was washed down with 5 ml. $CHCl_3$, 3 ml. $CHCl_3$, and 1 ml. $CHCl_3$, evaporating to dryness after each wash. The residue was dissolved in a small volume of $CHCl_3$ and quantitatively transferred to a fluorescent, 20 × 20 cm. Silica Gel G thin-layer plate of 250 μ thickness. The plate was developed to its full length with $CHCl_3$–C_2H_5OH (17:3), and the metabolite zone located by fluorescence quenching. The silica gel corresponding to the location of the metabolite was removed from the plate and transferred to a 35-ml. centrifuge tube. The metabolite was eluted from the silica gel by shaking with two 10-ml. portions of absolute methanol; after centrifuging, each eluate was decanted into a 50-ml. beaker. The combined eluates were evaporated to dryness under nitrogen at temperatures below 45°. Exactly 0.5 ml. of absolute methanol was added to the residue followed by exactly 4.5 ml. of 70% H_2SO_4. After the solution had stood for 30 min., the ultraviolet spectrum was recorded from 340–380 mμ with a Cary spectrophotometer.

If the fluorescence end point was to be used, the sulfuric acid solution was allowed to stand for 3 hr., and then with a precalibrated spectrophotofluorometer the fluorescence intensity at 535 mμ[5] resulting from activation at 465 mμ[5] was recorded using an Aminco-Bowman spectrophotofluorometer. The metabolite concentration in the urine and the total output were calculated from the appropriate standard curve, taking into consideration the total urine volume and dilution and yield factors. In the present study, an assay yield of 65.7 ± 2.2% was obtained. Correction for the "blank" was

made by subtracting the result obtained with a pretreatment urine sample.

Preparation of the Florisil Column.—The Florisil was washed and activated as follows: 1 Kg. of Florisil (60–100 mesh) was washed by shaking sequentially with 2 L. of 95% ethanol for 1–2 hr., 2 L. of 25% CH_3OH—$CHCl_3$ for 2 hr., and 2 L. of fresh 25% CH_3OH–$CHCl_3$ overnight. The Florisil was then filtered and washed twice with 1-L. portions of absolute ethanol, dried, and then activated at 600° for 4 hr. The Florisil columns were prepared by packing 25-ml. burets (11 mm. diameter), plugged with glass wool, to a height of 7 cm. with gentle tapping. The columns were eluted with 50 ml. of $CHCl_3$ before adding the samples.

RESULTS

Analytical End Points for the 6,21-Dihydroxy Metabolite.—Since the 17-acetate (II) was not available for calibration at the outset of this study, the 21-acetate (III) was used. When II was synthesized, it was shown to have a response equivalent to III and IV in the end points used. This is in agreement with the results of Zaffaroni (11), who found that free steroids and their acetates gave identical sulfuric acid-induced absorption spectra.

Sulfuric Acid-Induced Ultraviolet Absorption.—Like many steroids (12), II, III, and their hydrolysis product (IV) exhibit an induced ultraviolet absorption upon treatment with concentrated sulfuric acid. Sulfuric acid-induced absorption has comparable sensitivity to the method of Porter and Silber (13), and is more specific for II and III. The 63% sulfuric acid-induced ultraviolet absorption of III at 360 mμ reaches a maximum value within 30 min. and is stable for at least 2 hr. When corrected for background by the Allen method (14), the ultraviolet absorption is linear from 1–10 mcg./ml. with a relative standard deviation of 1.6% (Table I). The Allen absorbance is defined by the equation:

$$A_{Allen} = A_{360m\mu} - {}^1/_2 (A_{380m\mu} + A_{340m\mu}) \quad \text{(Eq. 1)}$$

This correction, which is designed to eliminate the effects of linear background absorption due to impurities, yields a blank which is essentially independent of the urine volume and increases the selectivity of the end point. The induction of ultraviolet absorption by concentrated sulfuric acid in a solution of the metabolite, which was isolated from urine of the medroxyprogesterone acetate-treated subject (*vide infra*), was found to have a relative standard deviation of 1.7% at the 3 mcg./ml. level.

Sulfuric Acid-Induced Fluorescence.—Concentrated sulfuric acid also induces in compounds II, III, and IV an intense fluorescence maximum at 535 mμ when activated at 465 mμ. In this respect, they are similar to corticosterone (15). The 63% sulfuric acid-induced fluorescence response of III is linear from 0.005–10.7 mcg./ml. with a relative standard deviation of 5.7% (Table I). Replicate determinations of the production of fluorescence by the metabolite, which was isolated from the urine of a medroxyprogesterone acetate-treated subject, showed a relative standard deviation of 4.9% at the 3 mcg./ml. level. The fluorescence reaches a maximum in about 2 hr. and is stable for at least an additional 2 hr. The Allen correction could not be employed using the fluorescence end point because the impurities showed a nonlinear wavelength response.

Isolation of the Metabolite from Urine.—Various amounts of III were added to the urine of a normal, nontreated, female subject and carried through the procedure of Helmreich and Huseby (5). III could not be detected in the 25% CH_3OH–$CHCl_3$ fraction from the Florisil column; instead, all of it appeared in the 2% CH_3OH–$CHCl_3$ fraction in which the fluorescence response was directly proportional to the amount of III added to the urine. This result indicated that the metabolite was not III, as reported by Castegnaro and Sala (7), since the 25%

CH_3OH–$CHCl_3$ fraction contains by far the major portion of urinary metabolite.

Since III did not behave like the metabolite in the Helmreich and Huseby isolation procedure, it obviously could not be used to test or modify this procedure. Consequently, a 24-hr. urine collection from a female patient, who had been receiving 200 mg. of medroxyprogesterone acetate daily for 1 week, was obtained as a source of the metabolite.[6] This urine will be referred to as the "medroxyprogesterone acetate urine." Aliquots (0, 1, 2, 4, 6, and 10 ml.) of this urine were added to aliquots of a urine sample from a normal, nontreated female to give a total volume of 30 ml. Using the Helmreich and Huseby procedure, both fractions from the Florisil column were examined for the metabolite. By both the fluorescence and ultraviolet end points, the response of both the 2 and 25% CH_3OH–$CHCl_3$ fractions were proportional to the volume of medroxyprogesterone acetate urine added. The major portion of the responding material (90% by ultraviolet; 80% by fluorescence) was found in the 25% CH_3OH–$CHCl_3$ fraction. The results of these preliminary experiments with the Helmreich and Huseby procedure were so encouraging it was decided to test the procedure by assaying the 8-hr. urine samples from 5 subjects who had received either 1 or one-half tablet of the nonmicronized formulation. Employing duplicate assays, the increased urinary output of the metabolite resulting from 1 tablet over and above that from one-half tablet was just significant at the 95% confidence level. Although these results were encouraging, the Allen absorbance averaged only 0.022 at the 10-mg. medroxyprogesterone acetate dose level. These results indicated that although the Helmreich and Huseby procedure was applicable to the determination of the 6,21-dihydroxy metabolite at the low levels resulting from 10 mg. of medroxyprogesterone acetate, its sensitivity would have to be increased in order to statistically demonstrate small absorption differences.

Addition of Thin-Layer Chromatography (TLC) to the Helmreich and Huseby Procedure.—In an attempt to reduce the response of the blank, TLC was added to the procedure following the Florisil chromatography. After the 25% CH_3OH–$CHCl_3$ eluate was evaporated to dryness, the residue was dissolved in a small volume of $CHCl_3$, quantitatively transferred to a thin-layer plate, and developed with $CHCl_3$–C_2H_5OH (17:3). With this developing system the metabolite has an R_f of about 0.7 and moves ahead of most of the urinary components in the extract. In order to locate the position of the metabolite on the TLC plate and to study the effect of TLC on the procedure, aliquots of the medroxyprogesterone acetate urine were added to aliquots of a urine sample from a normal, nontreated female to give a total volume of 30 ml. These spiked samples were assayed essentially as before but with the addition of TLC to the procedure. Although at least ten TLC zones were observed in the 25% CH_3OH–$CHCl_3$ fraction, the density of one zone clearly increased with the volume of the medroxyprogesterone acetate urine added. Sections of the TLC plate were eluted with methanol, and assayed by measuring the ultraviolet absorption at 360 mμ following addition of 63% sulfuric acid. The metabolite zone produced 94% of the total absorption at 360 mμ. Another zone, whose R_f corresponded to the alcohol (IV), accounted for the remaining 6%. The addition of TLC to the procedure increased its specificity and lowered the background considerably, but decreased the over-all yield by about 20%.

Further Efforts to Increase Sensitivity and Assay Yield.—Further experiments were carried out with the medroxyprogesterone acetate urine in an attempt to improve the sensitivity of the procedure, *e.g.*, the extracting solvent, its volume, extraction time, number of extractions, and agitation method were varied in an attempt to increase yield and precision. It was found, for example, that an extraction method employing vigorous shaking by hand followed by allowing the emulsion to stand for 1 hr. gave higher yields and better precision than the use of an automatic wrist-action shaker.

Florisil chromatography decreases considerably the blank contribution from nonspecific background material (determined by the fluorescence end point or total ultraviolet absorption at 360 mμ) but does not remove any of the fluorescence-quenching TLC zones, *i.e.*, the chloroform extract and the 25% CH_3OH–$CHCl_3$ fraction show the same TLC pattern.

The yield of metabolite was increased by decreasing the contact time between the extracting solvent and the NaOH and HCl wash solutions. In the final procedure, the contact time of these wash steps was strictly controlled and minimized.

A relatively high concentration of β-glucuronidase was used in the present studies to insure complete hydrolysis. The 18-hr. incubation with β-glucuronidase at 47° was sufficient for complete hydrolysis, *e.g.*, 18 and 42 hr. incubation gave the same end point response.

The use of the total ultraviolet absorption at 360 mμ was investigated in an attempt to increase sensitivity. As shown by the data of Table I, the use of the Allen correction decreases the sensitivity by one-half. Because of variation in the absolute ultraviolet absorbance of the blanks at 360 mμ, however, the ultraviolet results were poor when the Allen correction was not used.

Washing and activating the Florisil decreased the total ultraviolet absorption of the blank considerably, but did not affect the assay yield.

The addition of TLC to the procedure and the optimization of other variables resulted in a three to fourfold increase in the sensitivity of the procedure. The assay yield was determined by adding the metabolite to water and performing the entire procedure. The yield determined in this manner was 65.7 ± 2.2%. Considering the complexity of the procedure, the yield and precision were considered quite satisfactory.

Stability of the Metabolite.—Originally, it had been intended to determine the yield every day that a set of assays were run by the use of a parallel yield determination, *i.e.*, by adding aliquots of a "standard solution" of the metabolite in methanol to control urine. In fact, this procedure was followed for some time until it was discovered that the yield was actually decreasing with time. TLC of the methanol solution of metabolite, which had been standing for some time, showed three zones,

[a] Age and weight (Kg.), respectively.

whereas the fresh solution had shown only one. In four TLC systems the decomposition products of the metabolite possessed R_f values identical to III and IV. The sum of the absorbances of the three zones, as determined by sulfuric acid-induced ultraviolet absorbance at 360 mμ, remained constant, *i.e.*, the appearance of the zones corresponding to III and IV was accompanied by a corresponding decrease in II. The half-life of disappearance of the metabolite in methanol at room temperature is estimated to be about 3 days. No significant decomposition of II takes place during the analytical procedure used in the present study.

Evaluation of Metabolite Excretion as a Measure of Absorption (One Tablet versus One-Half Tablet).—To test the modified analytical procedure and the hypothesis that the amount of metabolite excreted in the urine is directly related to the amount of medroxyprogesterone acetate absorbed, urine samples were assayed from 5 subjects who had received 1 tablet and one-half tablet of the nonmicronized formulation in a crossover design (Table II). The assay easily distinguished between no drug, one-half tablet and one tablet. Both fluorescence and ultraviolet absorption were employed as the end points. With the modified procedure and using only single determinations, both the ultraviolet and fluorescence end points gave an 8-hr. output of metabolite for every subject in the order: $0 < 0.5 < 1$ tablet. The increased urinary output of the 6,21-dihydroxy metabolite resulting from 1 tablet over and above that from one-half tablet was statistically significant at the 99% confidence level by both end points, when calculated by averaging the ratios obtained for each subject. The average amount of metabolite excreted in the urine in 8 hr. following one-half tablet of the nonmicronized formulation was 121 ± 20 mcg. and 134 ± 64 mcg. (±S.E.M.) by the ultraviolet and fluorescence end point, respectively. The average amount of metabolite excreted in the urine in 8 hr. following 1 tablet of the nonmicronized formulation was 285 ± 13 and 337 ± 21 mcg. (±S.E.M.) by the ultraviolet and fluorescence end points, respectively.

Comparison of Excretion of Metabolite after Ingesting the Micronized and Nonmicronized Formulations.—Each of the 10 subjects excreted a larger amount of metabolite after ingestion of the micronized tablet (Table III). Only the ultraviolet end point was employed, since the sensitivity of the fluorescence end point was not required. There was a very highly significant difference ($p < 0.001$) between the nonmicronized and micronized formulations. The average micronized/nonmicronized ratio ±95% confidence limits of metabolite excreted was 2.23 ± 0.43, when calculated by averaging the individual ratios. The micronized/nonmicronized ratio ±95% confidence limits, calculated from the average amount of metabolite excreted in 8 hr., was 2.12 ± 0.57. The average amount of metabo-

lite excreted by the 10 subjects in 8 hr. was 312 ± 30 mcg. (S.E.M.) and 660 ± 47 mcg. following the nonmicronized and micronized formulations, respectively (3.1 and 6.6% of the dose, respectively).

DISCUSSION

Ten subjects were employed in a crossover design in order to minimize the effect of possible week-to-week variables, *e.g.*, a change in the percentage of drug which is converted to the measured metabolite or a change in the percentage of drug absorbed independent of formulation differences. The increase, therefore, in the quantity of metabolite excreted in the urine in 8 hr. after ingesting the micronized formulation undoubtedly results from increased absorption. The applicability of the procedure used was demonstrated by showing that an average of about twice as much metabolite was excreted in 8 hr. after ingesting 1 tablet as after one-half tablet.

The greater urinary excretion of the metabolite during the first 8 hr. following ingestion of micronized medroxyprogesterone acetate must result from the increased rate of absorption of medroxyprogesterone acetate from this formulation. Because of the finite transit time of drug through the gastrointestinal tract, this increased 8-hr. excretion of metabolite very likely reflects an increase in the eventual total amount absorbed. The latter interpretation is based on the data of Helmreich and Huseby, who found that even at doses 20 times greater than used in the present study, an average of about 70% of the 24-hr. excretion of metabolite occurred during the first 8 hr.

The metabolite is not the 21-acetate (III), as reported by Castegnaro and Sala (7), since the latter possesses different TLC R_f values from the metabolite in four systems and, unlike the metabolite, is eluted from the Florisil column in the 2% CH_3OH–$CHCl_3$ fraction. When the 17-acetate (II) was subsequently synthesized by an unambiguous method (16), it was shown to undergo the 17- to 21-acetate migration in methanol and to have the same R_f values as the metabolite in several systems, thus substantiating the 17-acetate assignment of Helmreich and Huseby (6). The observed conversion of II to III probably explains why Castegnaro and Sala identified the metabolite as the 21-acetate. Since the latter workers also found the metabolite in the 25% CH_3OH–$CHCl_3$ fraction of the Florisil column, the acetate group migration must have occurred after Florisil chromatography. This acetate group migration is not unique with the metabolite. Similar behavior has been noted by Gardi *et al.* (17), who observed that corticosteroid 17-monoesters could be rearranged quantitatively to the corresponding 21-monoesters.

Direct Spectrophotometric Determination of Salicylic Acid, Acetylsalicylic Acid, Salicylamide, Caffeine, and Phenacetin in Tablets or Powders

By A. W. CLAYTON and R. E. THIERS*

A simple ultraviolet spectrophotometric method has been developed for the simultaneous determination of up to 5 different common analgesic compounds. The technique can be applied to mixtures of the compounds or to tablets or powders containing common excipients. A water–isopropanol mixture capable of dissolving chloroform is used as spectrophotometric solvent at 3 different wavelengths and under 3 different conditions of acid or base content. One absorbance measurement per constituent is required.

STANDARD analytical methods for the determination of commonly used analgesic and antipyretic compounds in tablets or powders generally involve multiple steps, and often include special separation methods. Thus in the method of the Association of Official Agricultural Chemists (1) for analysis of mixtures containing phenacetin, caffeine, and acetylsalicylic acid the compounds are separated by column chromatography prior to measurement. Other techniques of separation have been used, such as solvent extraction (2, 8), and many methods of measurement have been proposed, including infrared spectrophotometry (3), ultraviolet spectrophotometry (4, 5), titration (2), phosphorimetry (6), and nuclear resonance spectroscopy (7).

Of these approaches ultraviolet spectrophotometry seems to offer the greatest promise of accuracy combined with simplicity and the ability to measure a number of constituents. Mixtures of compounds have been analyzed in this fashion by several workers, in some cases after preliminary separation from each other (4, 5, 8–11). However, common excipients employed in the formulation of actual analgesic powders or tablets also possess ultraviolet absorption and can interfere.

A simple method has been developed which can simultaneously determine up to 5 common analgesic compounds together, in simple mixtures or in tablets and powders containing the common excipients used in manufacture. Separation of the 5 compounds is unnecessary. A mixture of isopropanol and water is used as solvent for spectrophotometry under 3 different conditions of acid or base content. Five absorbance measurements are made, and from the 5 values obtained the amounts of acetylsalicylic acid (ASA), salicylamide (SAL), salicylic acid (SAA), caffeine (CAF), and phenacetin (PHE) in the original sample can be calculated easily and accurately.

Received December 23, 1965, from the Control Laboratory, B. C. Remedy Co., Durham, N. C.

EXPERIMENTAL

Apparatus and Reagents.—*Spectrophotometer.*—A Beckman DU 2 spectrophotometer was used, except for the acquisition of the spectra shown in Fig. 1, which were obtained on a Bausch & Lomb model 505 spectronic spectrophotometer. In all cases standard 1 cm. square fused silica cells were employed.

Solvents.—Spectral grade, analytical reagent chloroform and isopropanol (Mallinckrodt Chemical Co.) were used.

Mixed Solvent.—An acid solution of isopropanol and water was made by placing 400 ml. of isopropanol in a volumetric flask, adding about 500 ml. of water, adding 0.5 ml. concentrated hydrochloric acid, mixing, then diluting to volume with water.

Hydrochloric Acid.—Mallinckrodt, analytical reagent grade.

Sodium Hydroxide.—Harleco APHA, ammonia free, 50% solution (Hartman-Leddon Co., Philadelphia, Pa.).

Acetylsalicylic Acid.—Monsanto, U.S.P. grade.

Salicylamide.—S. B. Penick Co., N.F. grade.

Salicylic Acid.—Merck, reagent grade.

Phenacetin.—Monsanto, U.S.P. grade.

Caffeine.—Monsanto, U.S.P. grade.

All 5 analgesic compounds were checked by infrared spectrophotometry.

Spectrophotometric Reference Solution.—A reference or "blank" solution for spectrophotometry was made by pipeting 1.00 ml. of chloroform into a 200-ml. volumetric flask, adding about 80 ml. of mixed solvent, mixing carefully, then diluting to the mark with mixed solvent and remixing.

Procedure.—Weigh accurately about 1 Gm. of the dry powder or tablet to be tested. Place this sample into a 100-ml. volumetric flask. Add chloroform to volume and mix to dissolve all soluble matter. Set aside for 15 min., or until the undissolved material has settled, leaving a clear supernatant fluid.

Pipet 1.000 ml. of this supernatant fluid into each

of three 200-ml. volumetric flasks labeled A (for acidic), B (for basic), and H (for hydrolyzed). Add about 100 ml. of mixed solvent to each and mix. Add 1.0 ml. of 50% NaOH to each of flasks B and H and mix. Wait 15 min. to ensure complete hydrolysis of ASA, then add to flask H 3.0 ml. of 12 *N* HCl to render the solution acid again, and mix. Dilute all 3 to the mark with mixed solvent.

If all 5 components are to be determined, read the absorbance against the reference solution, of solution A at 250, 273, and 301 mμ, of solution B at 333 mμ, and of solution H at 301 mμ. If fewer components are to be measured, appropriate omissions and short cuts may be introduced by inspection of the equations below in the light of the specific problem.

Calculations.—If the absorptivity, *a*, of phenacetin, for example, at 333 mμ is designated a_{333}^{PHE},

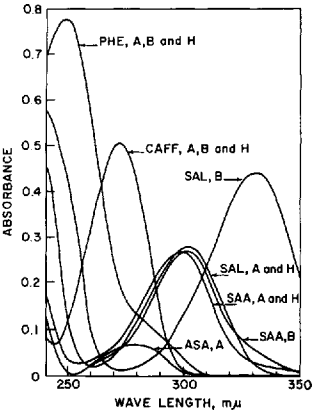

Fig. 1.—Spectra of 0.1 mg./L. solutions of the 5 compounds in mixed solvent.

$$A_{333}^{total} = a_{333}^{ASA}(ASA) + a_{333}^{SAL}(SAL) + a_{333}^{SAA}(SAA) + a_{333}^{CAF}(CAF) + a_{333}^{PHE}(PHE) \quad \text{(Eq. 3)}$$

Each of the 5 measurements made in the procedure provides an A^{total} for one particular set of conditions of wavelength and acid–base treatment. For each set of conditions a unique set of values of the various absorptivities exists. Five simultaneous equations may therefore be set up from which the 5 desired concentrations may be calculated. Other components of the original sample which are insoluble in chloroform do not interfere in the measurement. The chloroform itself is wholly soluble in the mixed solvent and its absorbance at the lower wavelengths is exactly cancelled by the reference solution.

Table I gives the value of *a*, the absorptivity, for each component under each condition and wavelength involved in the calculation. Figure 1 shows the spectra of 0.1 mg./L. solutions of the 5 compounds under the conditions shown.

As can be seen from both the figure and table, (*a*) the difference between the absorbance of solutions H and A at 301 mμ is wholly due to hydrolysis of acetylsalicylic acid to salicylic acid, (*b*) the absorbance of solution B at 333 mμ is predominantly due to salicylamide, (*c*) the absorbance of solution A at 301 is largely due to salicylic acid and the above two, (*d*) and finally, in solution A caffeine is the compound with by far the highest absorptivity at 273 mμ, while at 250 mμ phenacetin has this distinction. These facts permit a simpler but equally accurate approach to the calculations than the conventional solution of 5 simultaneous equations. In this approach a preliminary approximate calculation is made by equating to zero certain small absorptivities. This gives the following equations:

$$A_{301}^{H} - A_{301}^{A} = 2.10\,(ASA) \quad \text{(Eq. 4)}$$

which provides a value for (ASA)

TABLE I.—ABSORPTIVITIES[a]

Compd.	Condition: 333 mμ Flask B	301 mμ Flask A	301 mμ Flask H	273 mμ Flask A	290 mμ Flask A
ASA	0.11	0.05	2.15	0.63	0.52
SAL	4.40	2.81	2.81	0.57	1.73
SAA	0.17	2.75	2.75	0.48	0.96
CAF	0.02	0.05	0.05	4.92	1.57
PHE	0.03	0.28	0.28	1.81	8.02

[a] The absorbance values listed are those observed when 1.000 Gm. of each pure component is treated by the procedure described. Their units are therefore "absorbance units per Gm. in the original weighed sample." The values given are averages of triplicate measurements on each of triplicate weighed dry samples of the pure components repeated 4 separate times over a number of weeks.

and the concentration of phenacetin as (PHE), then the absorbance due to phenacetin at 333 mμ, A_{333}^{PHE}, will be given by:

$$A_{333}^{PHE} = a_{333}^{PHE}(PH) \quad \text{(Eq. 1)}$$

At any given wavelength, *e.g.*, 333 mμ the measured absorbance, A_{333}^{total}, is the sum of the absorbances of the various components.

$$A_{333}^{total} = A_{333}^{ASA} + A_{333}^{SAL} + A_{333}^{SAA} + A_{333}^{CAF} + A_{333}^{PHE} \quad \text{(Eq. 2)}$$

and therefore

$$A_{333}^{B} = 0.11\,(ASA) + 4.40\,(SAL) \quad \text{(Eq. 5)}$$

which provides a value for (SAL)

$$A_{301}^{A} = 0.05\,(ASA) + 2.81\,(SAL) + 2.75\,(SAA) \quad \text{(Eq. 6)}$$

which provides a value for (SAA)

$$A_{273}^{A} = 0.63\,(ASA) + 0.57\,(SAL) + 0.48\,(SAA) + 4.92\,(CAF) + 1.81\,(PHE) \quad \text{(Eq. 7)}$$

$$A_{250}^{A} = 0.52\,(ASA) + 1.73\,(SAL) + 0.96\,(SAA) + 1.57\,(CAF) + 8.02\,(PHE) \quad \text{(Eq. 8)}$$

TABLE II.—MIXTURE NUMBER[a]

Compd.	1 Taken	1 Found	2 Taken	2 Found	3 Taken	3 Found	4 Taken	4 Found	5 Taken	5 Found
ASA	0.200	0.194	0.350	0.353	0.300	0.294	0.250	0.247	0.300	0.301
SAL	0.300	0.297	0.000	0.000	0.300	0.302	0.150	0.149	0.100	0.097
SAA	0.000	0.000	0.000	−0.002	0.000	0.000	0.100	0.096	0.150	0.148
CAF	0.000	0.000	0.050	0.050	0.040	0.042	0.200	0.209	0.050	0.048
PHE	0.250	0.254	0.250	0.253	0.000	−0.001	0.050	0.052	0.100	0.103
Total	0.750	0.745	0.650	0.654	0.640	0.637	0.750	0.753	0.700	0.697

[a] Results are in Gm.

Equations 7 and 8 can easily be solved for (CAF) and (PHE).

The final calculation is made by rewriting Eqs. 5 and 6 to include all terms, as follows, then recalculating in the same manner as above but including the preliminary values for the terms missing in the first approximation.

$$A^{A}_{333} = 0.11\,(ASA) + 4.40\,(SAL) + 0.17\,(SAA) + 0.02\,(CAF) + 0.03\,(PHE) \quad (Eq.\ 5a)$$

$$A^{A}_{301} = 0.05\,(ASA) + 2.81\,(SAL) + 2.75\,(SAA) + 0.05\,(CAF) + 0.28\,(PHE) \quad (Eq.\ 6a)$$

For concentrations usually encountered in practice a third approximation is seldom necessary; and if any prior knowledge of approximate composition exists, it can usually be employed to make the first calculation the only one required.

If fewer than 5 constituents are known to be present, fewer readings and equations are obviously sufficient. The known absence of salicylamide makes the B flask and 333 mμ reading unnecessary, and of acetylsalicylic acid, the H flask and its reading. If salicylic acid is known to be absent it is possible to omit one step, but the omission is not recommended, since this step provides a measure of any hydrolysis of acetylsalicylic acid which might have occurred during storage or manufacture of the product analyzed.

The value $A^{H}_{301} - A^{A}_{301}$ can, of course, be obtained directly by making solution A the reference or "blank" sample at 301 mμ for solution H.

Discussion.—Three features of the method described combine with the known advantages of ultraviolet spectrophotometry to provide a simple and accurate procedure. First, the utilization of isopropanol–water as a solvent (as distinct from chloroform, etc.) permits spectra to be measured under either acidic or alkaline conditions, and permits the utilization of the solitary 333 mμ absorbance of basic salicylamide. This mixed solvent also dissolves sufficient chloroform to enable one to dilute a chloroform solution with an aqueous solution and still have a one-phase system. The lower limit of the concentration of isopropanol in the mixed solvent is in fact set by the amount of chloroform which must be dissolved. An important practicality—the mixed solvent handles like water and is more convenient than organic solvents. Second, the technique of rapid hydrolysis of acetylsalicylic acid to salicylic acid in basic solution followed by a return to acid conditions (solution H) provides a direct assay for the former compound in the presence of any other material unaffected by the treatment. Experiments were performed to determine the optimal concentration of base and time of hydrolysis. The values chosen provide complete hydrolysis in a conveniently short time interval without causing decomposition. Third, it is a fortunate fact that the excipients generally used in the manufacture of tablets and powders are not only insoluble in chloroform but settle out of suspension very rapidly when shaken with chloroform. Centrifugation, originally designed as part of the procedure, proved unnecessary. A variety of excipients were treated by the procedure described and in no case was any absorbance observed in the mixed solvent. These include talc, cornstarch, lactose, sucrose, microcrystalline cellulose,[1] dextrin, gelatin, acacia, tragacanth, fumaric acid, sodium chloride, and potassium chloride.

Ordinarily the spectrophotometric measurement of so many components and the setting up of so many simultaneous equations is neither convenient nor accurate. In this case, however, it has been possible to choose conditions where certain of the absorptivities approach zero, while others are maximal. In addition one set of the chosen conditions has, by hydrolysis, reduced the number of components present. The calculations are thus greatly simplified.

The procedure is inherently simple and accurate. As a test of these factors, 5 different known mixtures were prepared and presented to a technician who, although experienced in spectrophotometry, had never analyzed mixtures by this procedure. The results obtained on the one sample which was analyzed from each mixture are given in Table II. Duplicate absorbance readings were made on each cell of sample, but no replication of samples was permitted. Results were calculated (from the averages of the absorbance readings) exactly as described above with no prior knowledge of sample composition assumed. The total error in 25 determinations was −0.004 Gm.; the average deviation was ±0.002 Gm.

This procedure has been in use for 6 months in routine analysis and quality control of products containing some but not all of the 5 compounds, as well as numerous excipients. It is rapid, complete analysis of one sample requiring about 10 min. of the operator's time when multiple samples are being run, with another 10 min. required for calculation. Its precision, based on repeated analysis of standards during this time, can be expressed as a coefficient of variation of 0.5%. When necessary, this value could easily be decreased further by employment of techniques of ultra high precision spectrophotometry (12).

Effects of Ionizing Radiation on Two Gelatin Fractions III

Carbonyl Group Analyses and Electron Spin Resonance Studies

By LEONARD P. PRUSAK* and BARTLEY J. SCIARRONE

Two fractions, F-I and F-II, obtained by alcohol fractionation of commercial pigskin gelatin, and having molecular weight values of 173,000 and 86,000, respectively, showed the following relationship with respect to additional carbonyl group content resulting from low-level irradiation under a 3 Mev. Van de Graaff: 1 per cent solution > 5 per cent solution (gel) > film. Irradiated films (F-I and F-II) showed doublets with 25 gauss line separation in electron spin resonance studies. These, together with previously published data, indicate that the gelatin fractions undergo molecular weight changes through free radical mechanisms involving scission, crosslinking, and weak bond formation.

In previous papers (1, 2) the authors showed the isolation of 2 fractions, F-I and F-II, from commercial pigskin gelatin; the irradiation technique used with a 3 Mev. Van de Graaff accelerator; acid-base titration behavior; sedimentation velocity and intrinsic viscosity studies; and molecular weight determinations.

We now give further experimental data which indicate that irradiation of these gelatin fractions produces changes in structure through free radical mechanisms.

The currently accepted concept regarding radiation effects on organic materials is that chain scission is synonymous with molecular weight decrease, and crosslinking is a sign of molecular weight increase. Intermediate variations are explained on grounds that both scission and crosslinking occur. This thinking may be extended to the irradiation of complex polymers, assuming that conditions are employed which lead to these ultimate effects. It is doubtful, on the basis of experimental data available today, that gelatin is susceptible to predictable irradiation behavior.

Some factors which must be considered before rupture or linkage are proposed as explanations for shifts in molecular weight of irradiated gelatin include solvent–solute interaction, absorbed irradiation dose, presence or absence of oxygen, solute concentration, nature of solvent, thermal history, aging, irradiation temperature, etc.

Since the formation of free radicals in solids and liquids exposed to irradiation has been established, explanations of molecular weight shifts in irradiated gelatin require consideration of free radical formation. This, in turn, poses the question as to indirect effects of the solvent if irradiation is carried out on a fluid system. Experimental evidence indicates that irradiation of oxygenated protein solutions, such as gelatin, results in the formation of carbonyl functions (3, 4) and that these are traceable to intermediate free radicals. Radiolytic cleavage of the peptide chain yields an amide and an additional carbonyl group:

Effects of Ionizing Radiation on Two Gelatin Fractions III

Carbonyl Group Analyses and Electron Spin Resonance Studies

By LEONARD P. PRUSAK* and BARTLEY J. SCIARRONE

Two fractions, F-I and F-II, obtained by alcohol fractionation of commercial pigskin gelatin, and having molecular weight values of 173,000 and 86,000, respectively, showed the following relationship with respect to additional carbonyl group content resulting from low-level irradiation under a 3 Mev. Van de Graaff: 1 per cent solution > 5 per cent solution (gel) > film. Irradiated films (F-I and F-II) showed doublets with 25 gauss line separation in electron spin resonance studies. These, together with previously published data, indicate that the gelatin fractions undergo molecular weight changes through free radical mechanisms involving scission, crosslinking, and weak bond formation.

In previous papers (1, 2) the authors showed the isolation of 2 fractions, F-I and F-II, from commercial pigskin gelatin; the irradiation technique used with a 3 Mev. Van de Graaff accelerator; acid-base titration behavior; sedimentation velocity and intrinsic viscosity studies; and molecular weight determinations.

We now give further experimental data which indicate that irradiation of these gelatin fractions produces changes in structure through free radical mechanisms.

The currently accepted concept regarding radiation effects on organic materials is that chain scission is synonymous with molecular weight decrease, and crosslinking is a sign of molecular weight increase. Intermediate variations are explained on grounds that both scission and crosslinking occur. This thinking may be extended to the irradiation of complex polymers, assuming that conditions are employed which lead to these ultimate effects. It is doubtful, on the basis of experimental data available today, that gelatin is susceptible to predictable irradiation behavior.

Some factors which must be considered before rupture or linkage are proposed as explanations for shifts in molecular weight of irradiated gelatin include solvent–solute interaction, absorbed irradiation dose, presence or absence of oxygen, solute concentration, nature of solvent, thermal history, aging, irradiation temperature, etc.

Since the formation of free radicals in solids and liquids exposed to irradiation has been established, explanations of molecular weight shifts in irradiated gelatin require consideration of free radical formation. This, in turn, poses the question as to indirect effects of the solvent if irradiation is carried out on a fluid system. Experimental evidence indicates that irradiation of oxygenated protein solutions, such as gelatin, results in the formation of carbonyl functions (3, 4) and that these are traceable to intermediate free radicals. Radiolytic cleavage of the peptide chain yields an amide and an additional carbonyl group:

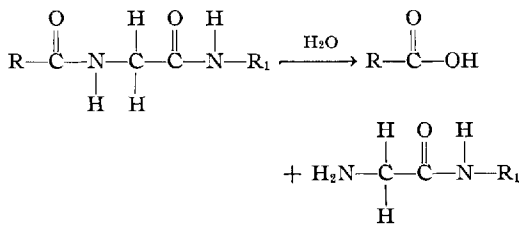
as opposed to hydrolytic fracture, which yields an acid and free amino group:



Proof of additional carbonyl group formation has been obtained (3) by isolation of a number of α-keto acids from irradiated gelatin—namely, oxalacetic, α-ketoglutaric, glyoxalic, pyruvic, and phenylpyruvic. Formation of these is believed to occur through an imino intermediate which yields the acid on hydrolysis.

Numerous details regarding the precise mechanistic sequences and interrelationships of free radical formation, chain scission, and crosslinking are yet to be resolved, but it can be said with reasonable certainty that these events do occur in irradiated gelatin. Data are presented here to show that additional carbonyl group formation affords an excellent means for correlating the degree of scission and/or crosslinking in the gelatin fractions as functions of irradiation dose and physical state (film or aqueous solution).

Since the formation of stable free radicals containing unpaired electrons in irradiated organic solids has been established, the application of electron spin resonance to the determination of the free radical quanta has assumed considerable importance. Because others (5, 6) have shown that the application of this method to proteins gives meaningful results, spin resonance measurements on irradiated gelatin films were included in the present work.

EXPERIMENTAL

Carbonyl Analysis.—Determination of carbonyl group formation was made according to the procedure of Lappin and Clark (7) using the 2,4-dinitrophenylhydrazone derivative of acetaldehyde as a reference standard. Hydrazone content was determined in terms of μm. carbonyl/Gm. of gelatin at 440 mμ with a Beckman DU spectrophotometer. Additional carbonyl group formation was obtained by difference between controls and irradiated samples. The data are given in Table I.

Electron Spin Resonance Studies.—Film strips of F-I and F-II were submitted to the scanned beam of the 3 Mev. Van de Graaff accelerator as previously described (1), and the resulting average absorbed doses were calculated immediately following irradiation. They were: 0.46, 0.67, 1.71, and 3.12 Mrads, respectively. The films were exposed to these doses at room temperature (24°C.), inserted in heat-sealed aluminum foil packages, and immediately immersed in liquid nitrogen (77°K.). Controls were included to the point of irradiation.

Spin resonance measurements, conducted on all samples on the day of irradiation, were made using a Varian 100 kc. field modulation EPR spectrometer at a microwave frequency of 9000 Mc./sec. Various degrees of attenuation of resonance intensity were used to obtain readable signals. Therefore, in order to have comparable measures of free radical population all resonance intensities, measured on an arbitrary scale, were normalized to the instrument parameters sweep 50 and gain 50. (See Table II.) A log-log plot of normalized resonance signal intensity *versus* dose is shown in Fig. 1.

RESULTS

Carbonyl Analysis.—In the case of 1 and 5% solutions of both fractions, straight line relationships were obtained from plots of dose (Mrad.) *versus*

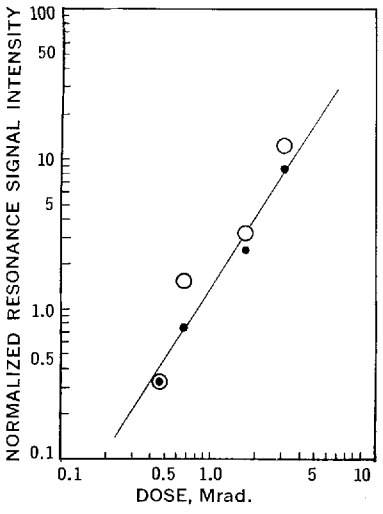

Fig. 1.—Plot of the linear relationship between EPR signal intensity, normalized to the instrument parameters sweep 50 and gain 50, and the dose impinging upon films of F-I (●) and F-II (○).

μm. carbonyl formed per Gm. of protein. Furthermore, some correlation was evident between the same concentration levels of the separate fractions. Figure 2 shows a plot of dose *versus* μm. carbonyl/Gm. of gelatin in 5% solution of both fractions. Data for obtaining the best possible straight line were computed by regression analysis. Slope values for 1% solutions of F-I (4.2×10^{-2}) and F-II (6.2×10^{-2}) were remarkably close, but the values for 5% solutions differed by a factor of 10 (*cf.* Fig. 2). Nonetheless, it can be stated that in irradiated solutions the number of carbonyl groups formed per Gm. of protein is directly proportional to the dose imparted and is concentration dependent.

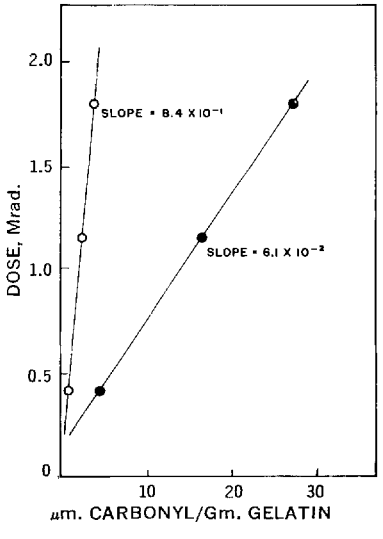

Fig. 2.—Arithmetic relationship between the dose, impinging upon a 5% solution of F-I (●) and F-II (○), and the resulting extra μm. of carbonyl groups produced/Gm. of the gelatin fraction.

Figure 3 shows a semilog plot of dose *versus* μm. carbonyl/Gm. of gelatin in irradiated films of F-I and F-II. In contrast to 1 and 5% solutions, the films showed less carbonyl formation, and proportional relationship to the logarithm of the dose. It would appear that carbonyl groups were formed at the same rate in the 2 gelatin fractions despite widely different average molecular weights.

G values, or the number of events (carbonyl groups formed) per 100 ev. (electron volts) absorbed energy, were derived from the formula:

$$G = \frac{\text{No. of changed molecules} \times 100}{E\ (\text{ev.})}$$

$$= \frac{(\mu\text{m./Gm.})\ (6.06 \times 10^{17})\ (100)}{(\text{Mrad.})\ (\text{ev./Gm./Mrad.})}$$

The expression above applies to materials irradiated in the dry state, *i.e.*, films, since the second term

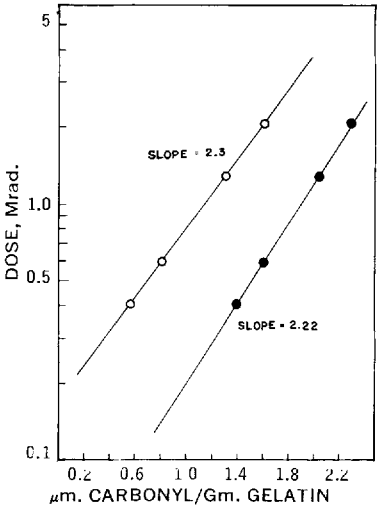

Fig. 3.—Semilog relationship between the dose, impinging upon films of F-I (●) and F-II (○), and the resulting extra μm. of carbonyl groups produced/Gm. of the gelatin fraction.

in the denominator refers to grams. In the case of 1% solutions, the second term was appropriately adjusted to enable calculation of energy absorption (*E*) on the basis of 100 ml. (1 Gm. of protein in 100-ml. vol.). Similarly, with the 5% solutions, another adjustment was made in the second term to permit calculation of energy absorption of a 20-ml. vol. Thus, the second expression in the denominator is, respectively, for

film: 6.37×10^{19} ev./Gm./Mrad.
1% solution: 6.37×10^{21} ev./100 ml./Mrad.
5% solution: $6.37 \times 10^{20} \times 2$ ev./20 ml./Mrad.

The *G* (carbonyl) values for both fractions are given in Table III.

Results for all samples were somewhat lower than the $G = 1.2$ reported by Garrison (3) for gelatin solutions (5 mg./ml.) irradiated with ^{60}Co γ-rays at a dose rate of about 2×10^{17} ev./ml./min. This difference in values can be accounted for by observing that Garrison's rate is equivalent to about 0.2

TABLE III.—EXPERIMENTALLY DETERMINED CARBONYL FORMATION *G* VALUES

0.41	0.46	0.14
0.60	0.63	0.24
1.15	0.66	0.54
2.10	0.50	0.43

Mrad./hr. (2×10^{17} ev./ml./min. = 1.2×10^{22} ev./L./hr. Since 1 Mrad./hr. = 6.37×10^{22} ev./L./hr., 1.2/6.37 = 0.188, or 0.2 Mrad./hr.). In the 3 Mev. Van de Graaff, on the other hand, all dose rates were imparted on a "per second" basis. Thus, in the range of doses used in the present experiments (0.4–2.0 Mrad.), the dose rates differed by factors ranging from 7,200 to 36,000 (greater). Since the efficiency of free radical formation is reduced at higher dose rates through recombinations caused by high local concentration, the higher dose rate is responsible for the lower *G* (carbonyl) values.

Of collateral interest in connection with the *G* (carbonyl) value calculations, are the previously referred to Wiederhorn experiments (2), which showed that in parent gelatin (from which F-I and F-II were fractionated) the molecular weight between crosslinks increased as the irradiation dose increased. This implies the formation of thermostable covalent bonds, a requirement for copolymerization. F-I and F-II, on the other hand, did not respond to the crosslinking test at any irradiation level (at least through the crosslinking mechanism), hence failed to polymerize despite carbonyl formation. This, in turn, would suggest that either the number of carbonyl groups formed was inadequate (Table III), or that a crosslinking factor present in the parent source was lacking in the purified fractions, or both.

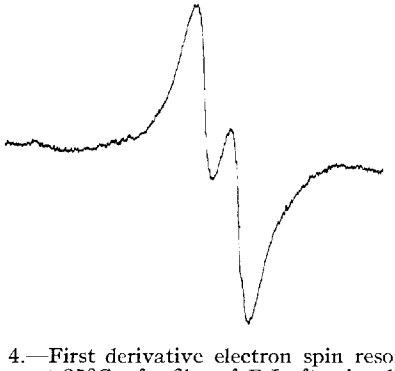

Fig. 4.—First derivative electron spin resonance spectrum at 25°C. of a film of F-I after irradiation with accelerated electrons giving a total dose of 3.12 Mrad. Instrument parameters used were sweep = 50, gain = 50.

Electron Spin Resonance Studies.—Figures 4 and 5 are first derivative resonance curves of F-I and F-II irradiated at 3.12 Mrad., and Figs. 6 and 7 show resonance curves on controls, all observed at room temperature. Figures 4 and 5 also illustrate the typical doublet of 25 gauss line separation obtained for all irradiated samples.

One of the samples, F-I, irradiated at 3.12 Mrad. at 25°C. was observed at 77°K. Total erasure of the doublet occurred when the gain was reduced to 125 and the sweep held at 50. By increasing the gain to 160 and reducing the power by 15 decibels, the same sample (at 77°K.) gave a doublet of 25 gauss line separation, indicating that at low temperature the signal was readily saturated. Shouldering beyond the points of inflection was evident, indicating possible dipolar broadening.

Shifting the sweep and gain to 32 and 200, respectively, retaining the sample at 77°K., and reducing the power by 20 decibels gave a doublet of 20 gauss line separation and retained evidence of shouldering. The sample was then removed from the nitrogen atmosphere and raised to room temperature (25°C.). At sweep 32, gain 500, −15 decibels, the pattern approached that originally obtained at room temperature with a doublet of 25 gauss. Retention of the doublets despite shifts in resonance temperature conditions (following irradiation at room tempera-

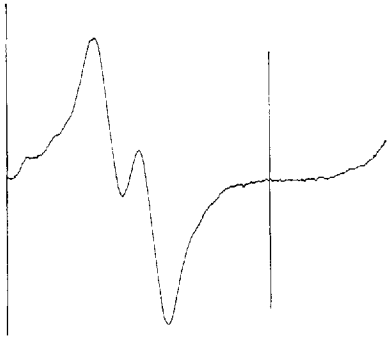

Fig. 5.—First derivative electron spin resonance spectrum at 25°C. of a film of F-II after irradiation with accelerated electrons giving a total dose of 3.12 Mrad. Instrument parameters used were sweep = 50, gain = 32.

ture) from 25°C. to 77°K. to 25°C. shows (5) that free radicals produced at room temperature remain in the same chemical form upon cooling and subsequent warming, and that changes in room temperature patterns following lowering of the temperature to 77°K. are reversible. The increase in signal strength at low temperature is primarily due to $1/T$ dependence of the magnetic susceptibility.

By normalizing the resonance curves to sweep 50 and gain 50 constant values (Table II), and plotting the resulting data as a function of dose (Mrad.) on a log-log scale, linear trends were obtained (Fig. 1) for F-I and F-II. Deviations from the straight line plot can be attributed to variations in sample weight and positions of the films in the cavity.

From Table III one can readily determine the relative increases in free radical formation for F-I and F-II when subjected to identical increases in irradiation dose, keeping the initial free radical and

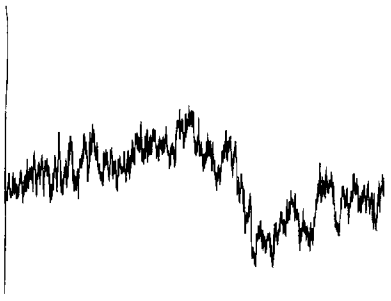

Fig. 6.—First derivative electron spin resonance spectrum at 25°C. of a control (unirradiated) film of F-I. Instrument parameters used were sweep = 500, gain = 800.

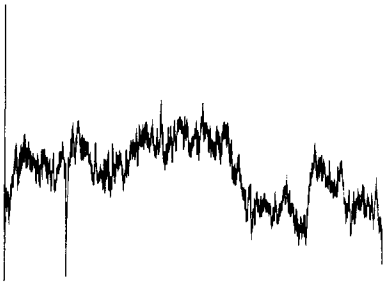

Fig. 7.—First derivative electron spin resonance spectrum at 25°C. of a control (unirradiated) film of F-II. Instrument parameters used were sweep = 500, gain = 800.

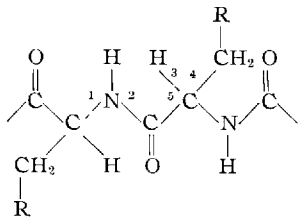
dosage norms as bases for comparison. A 32% increase in radiation from 0.461 to 0.679 Mrad. elicited a 56% increase in free radicals in F-I and a 78% increase in F-II. A further increase of 60% in radiation produced 69% more free radicals in F-I, but only a 50% increase in F-II, the latter indicating a downward trend in free radical formation despite a 2.5-fold increase in energy over the previous run. Finally, a further 45% increase in irradiation produced 71% more free radicals in F-I and a 75% increase in F-II. In both films, therefore, the higher the dose absorbed, the greater the excess of unpaired electrons. Contrary to the expectation that radical concentration, in terms of gain strength, should be directly proportional to the absorbed radiation, the data show that radical concentration is proportional to the three-halves power of the radiation dose.

DISCUSSION

Assuming that the predominating amino acid components in gelatin are alanine, glycine, proline, and hydroxyproline with no representation of —S—S— linkages in the absence of cystine (8), the most probable site of radiation damage would appear to be the α-carbon in the polypeptide back bone.

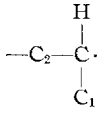
Viewing the protein configuration as:



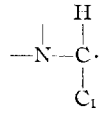
fracture of the C—N bond at 1 would require 25 gauss for the proton, with a possible structure for —CH_2, and a 10 gauss triplet at the nitrogen. Fracture at 2 would require a 25 gauss proton, a 10 gauss triplet at the nitrogen, and a single line for the carbon with a double bonded oxygen. Should fracture occur at 3, the proton would split off, with possible evidence of a 5 gauss triplet at the nitrogen and a —CH_2 triplet. Fracture at 4 would require a 25 gauss triplet to account for the —CH_2—R group, as well as a 25 gauss doublet (carbon) and a 5 gauss triplet (nitrogen). This could occur, for example, in the event of recombination of ·CH_2—R. Finally, fracture at 5 would give a singlet, a 25 gauss doublet, a 5 gauss triplet, and possibly evidence for CH_2.

It would appear that the observed spectra are characteristic of the

free radical. Formation of

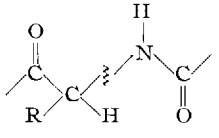


would give a doublet of 25 gauss, but protons on C_1 and C_2 might lead to additional structure, if they were noncoplanar with the carbons. Formation of



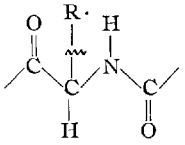
also would give a 25 gauss doublet, and a possible triplet, with 5 gauss separation due to the nitrogen. The latter splitting could be broadened by nitrogen quadrupolar interactions. If

formation occurred, a 25 gauss doublet (H) and a 10 gauss triplet (N) splitting would be evident if quadrupolar broadening did not occur. Of the 2 remaining possibilities



appears to be the less likely since it would involve twice the nitrogen splitting. It seems reasonable to

conclude that formation of the following free radical structure:



is feasible since the data are indicative of spin being on an atom which is bonded to only one hydrogen.

Proof is not available here for postulating with absolute certainty at which of these positions free radical formation occurs. However, it is interesting to note Gordy's (6) conclusions, based on more extensive experimental data, that the peptide free radical resulting from radiation damage to proteins forms at a glycine residue.

It should be observed that the spin-proton interactions did not elicit any qualitative differences in resonance between the 2 protein fractions studied, despite a 2:1 ratio in molecular weight values. Doublets were conspicuously persistent at all irradiation levels, although one fraction showed a successively lesser tendency to increase in molecular weight as the dose was increased, and the other increased in molecular weight as higher doses were applied.

CONCLUSIONS

Low temperature alcohol fractionation of acid-treated pigskin gelatin yielded 2 distinct fractions having different average molecular weights and characteristic acid/base binding properties (1). Dilute solution intrinsic viscosity studies on these fractions (2) showed higher values for the higher molecular weight (173,000) fraction, F-I, than the lower (86,000) fraction, F-II, as expected. The similarity in acid/base binding capacity in the 2 fractions may be best explained on the ground that F-II was constituted of shorter fragments of chains similar to those prevailing in the larger fragments. The virtually superimposable acid-base titration curves over the entire titration range support the proposition that the same N-terminal and C-terminal groups existed in the high molecular weight, F-I, and low molecular weight, F-II, controls.

Of additional importance, particularly with respect to films, is the total absence of water, hence the lack of OH· and H· radicals, to cause alterations in protein structure through secondary effects. Further evidence that more concentrated gelatin is less susceptible to radiation damage is provided in Table I, which shows lower values for carbonyl production in 5% solutions and films of F-I and F-II, than corresponding 1% solutions.

It is *not unreasonable* to suggest that fracture of electrovalent bonds in the gelatin structure occurs on irradiation and that these breaks are responsible for molecular weight reduction. Indeed, evidence that free radicals were formed in films of F-I and F-II contributes to the validity of this proposal, especially when considered in the light of Fig. 3. These data indicate that as the radiation dose is increased, the rate of free radical formation rises. More importantly, at least when considered as a film, the damaged gelatin appears to retain the unpaired electron structure. Thus, retention of high numbers of free radicals reflects minimal recombination, hence absence of crosslinking.

Since the intrinsic viscosity studies and the molecular weights calculated from these data were based on experiments with 1% solutions (2), evidence of disproportionate retention of stable free radicals in films cannot be extrapolated to interpretation of changes in molecular weights predicated on solution experiments. Nonetheless, it seems permissible to reason that free radicals are formed in solutions (as they are in films), but the differences in radiation environment lead to dissimilar results. Irradiated films tend to retain free radicals because the compactness of the molecule locks the radicals into their created positions. Ultimately, after absorption of moisture, the molecular structure becomes loosened, and the radicals are able to shift. Irradiated solutions, on the other hand, do not retain free radicals in abundance because the concurrent high energy impact on solute and solvent creates, in addition to solute free radicals, unpaired electrons in the solvent structure. These are, in the case of water, OH· and H·. The formation of stable free radicals and a structurally less compact solute configuration facilitates (*a*) inactivation by abstraction of hydrogen from another molecule and (*b*) recombination and coupling. Assuming that each of these reactions occurs to a variable degree in irradiated gelatin solutions, it could be suggested for F-I that (*b*) predominates at low radiation levels, causing an increase in molecular weight. As the irradiation levels become greater in intensity, the ability of the free radicals to recombine and couple is progressively decreased and (*a*) controls.

Gelatin in solution answers the description of a polyelectrolyte (9), its isoelectric behavior being dependent upon which groups, the carboxyl or the amine, predominate in the gross structure. Its principal amino acid components are glycine, proline, and hydroxyproline, with lesser amounts of lysine, hydroxylysine, histidine, and arginine. Cystine and tryptophan are lacking.

The acid-base titration curves previously reported (1) tend to confirm the differences in behavior between the high and the low molecular weight fractions. At 1% concentration, irradiation did not appear to affect either the acid or the base functions of either fraction until the dosage was increased to the 2 and 3 Mrad. levels. At that point the basic groups were reduced in number, with a slight increase in bound carboxyls. The midportions of the 1% curves were unaffected in F-II, but F-I showed a decrease in bound imidazole groups at the low radiation level, with a gradual approach to the control value as the energy was increased.

In 5% concentrations, neither F-I nor F-II imidazole groups were affected. However, both fractions suffered carboxyl and amino depletion with the greatest damage imparted to the higher molecular weight protein. Apparently as the concentration of the protein is increased, radiation effects become more pronounced and tend to disrupt drastically the charge organization without affecting the isoelectric point. Irradiation of F-I and F-II in the solid state, on the other hand, caused little deviation in charge.

Carbonyl analyses in terms of μm./Gm. follow an arithmetic progression in approximate proportion to

the absorbed dose (Table I). Conversion of these data to G (carbonyl) values shows somewhat more carbonyl groups in F-I than in F-II per 100 ev. absorbed dose. By taking averages of the G values and drawing comparisons between F-I and F-II within the respective physical states irradiated, it will be seen that in the 1% solutions the averaged G values differed by a factor of 2; in 5% solution the difference increased to a factor of 6; but in films the difference factor fell to about 1.5. Within each group, on the other hand, there appeared to be reasonable consistency in G values and a noticeable lack of deviation, irrespective of variation in water content.

The anomalies may be due, at least in part, to the fact that irradiation was conducted in the absence of low temperature controls. Thus, at room temperature some free radicals tend to recombine to form carbonyl groups. Others enter into crosslinking reactions. The rates of recombination will vary depending on solute concentration, temperature variations, dose imparted, and other factors. In films, the conditions are such that the free radicals are not only deprived of free movement due to the relatively fixed configuration of the molecule, but also of participation in secondary reactions with solvent free radicals.

Notwithstanding this shortcoming, the relative pattern of carbonyl production on a weight basis assigns the lowest quantity to films and the highest to 1% solutions, the 5% solutions being intermediate. The relationship offers at least a partial basis for concluding that a greater number of free radicals are formed in irradiated dilute solutions of proteins than in those more concentrated because of solute–solvent interaction during the ionization event. Although G values in all cases remained below unity, there is no reason to minimize the conclusion that these data are in substantial agreement with Garrison's $G = 1.2$ (3) for carbonyl production in gelatin solutions influenced by ^{60}Co γ-rays. As explained in detail earlier, the lower values obtained in our experiments are attributable to the higher dose rate imparted, which functionally reflects the efficiency of free radical production.

Decarboxylation and deamination occurred in irradiated gelatin solutions in proportion to absorbed dose. Dilute solutions of the low molecular weight fraction were not severely damaged by low energy radiation, but the higher molecular weight fraction appeared to be injured at the imidazole portion. Neither the high nor the low molecular weight fraction was altered in charge groups when irradiated in the dry state, but free radicals were formed in both when irradiation was imparted at room temperature. No alteration in free radical structure occurred when irradiated gelatin films were brought to 77°K. nor when they were subsequently returned to room temperature.

Variations in solvent–solute ratios of gelatin solutions reflected differences in the number of new carbonyl groups formed on a weight basis. Higher carbonyl values per unit weight of protein were obtained in dilute than in concentrated solutions, confirming the secondary effects of water in altering the solute structure on irradiation. Relatively lower G (carbonyl) values were obtained in F-II than in F-I.

It seems permissible to conclude that the end effects of low level irradiation emanating from an electron beam upon fractions of gelatin obtained from the same source are predictable only to the extent that free radical and carbonyl group formation occur. The degree of radiation damage is proportional to the absorbed dose. The presence or absence of water in the system being irradiated also determines the extent of denaturation as reflected in carbonyl group formation. No direct evidence is available that aggregation plays the dominating role in molecular weight increase as a result of irradiation. In view of the extensive free radical formation and the strong indications of solvent–solute interaction during the irradiation event, it is a fair inference that increases in molecular weight in irradiated dilute gelatin solutions can be attributed to crosslinking through covalent and weak hydrogen bonds.

Cholinergic Anionic Receptors III

Steric Requirements for Quaternary Ammonium Inhibitors of Acetylcholinesterase II

By J. C. KELLETT, JR.*, and W. CLARK DOGGETT†

The inhibitory activity of 36 structurally related quaternary ammonium compounds was undertaken as a logical extension of our earlier report studying the discrete nature of the anionic receptor of a typical cholinergic receptor, acetylcholinesterase. The results permit some sophistication in the discussion of the several mechanisms apparently operative in this system.

IN AN earlier report (1) the authors postulated that the inhibition of acetylcholinesterase (AChE) by simple quaternary ammonium compounds could be ascertained as a function of affinity for the enzyme and that certain relationships existed between the ionic volume of the inhibitory ion and its affinity for the enzyme. Our results prompted a logical extension of the compounds under evaluation in order to clarify the role of ion volume in affinity for a cholinergic receptor.

To meet this end 36 quaternary ammonium compounds were prepared and examined enzymologically. The compounds were: *N*-alkyltrimethylammoniums, *N*-alkyltriethylammoniums, and *N*-alkylquinuclidiniums, where the alkyl group was varied from methyl through decyl plus isopropyl; tetrapropylammonium; tetrabutylammonium; and tetrapentylammonium. These compounds include 3 homologous series, many of which have been examined in other cholinergic systems. Several interesting related compounds are included such as the isopropyl derivatives and the tetraalkyl derivatives. The conformational uniqueness of the quinuclidinium compounds was discussed in an earlier paper (1).

The fundamental rationale for studying competitive inhibition of AChE in a study of the receptor site was similarly established in the first report.

EXPERIMENTAL

Chemistry

Properties and recrystallization solvents for all salts are given in Table I.

Received December 1, 1965, from the School of Pharmacy, University of North Carolina, Chapel Hill.

Accepted for publication January 11, 1966.

This investigation was supported by grant NB 05420 from the National Institute for Neurological Diseases and Blindness, National Institutes of Health, U. S. Public Health Service, Bethesda, Md.

The authors express their appreciation to Miss N. E. Paterson for the preparation of some of the previously known compounds in this paper and to Dr. G. H. Cocolas for his frequent consultation.

† National Science Foundation Undergraduate Research Participant, supported by grant GE-1929.

Quinuclidine.—The method of Leonard and Elkin (2) as modified in an earlier paper (1) was used. A significant improvement over earlier reports involves an increase in the rate of flow of the vapors of the 4-(2-hydroxyethyl) piperidine by raising the pot temperature to about 200° with the elimination of the air bleed. This reduced the amount of polymer formed in the catalyst bed and the volatile impurities previously obtained in the product. Larger batches could be run before the receiving apparatus became clogged.

N-Alkylquinuclidinium Salts.—One-tenth mole each of the appropriate alkyl halide and quinuclidine were sealed with 100 ml. of absolute ethanol in a citrate bottle for 18 hr. with intermittent shaking. The solvent was then removed by vacuum evaporation, and the salt recrystallized.

N-Alkyltrimethylammonium Salts.—The reaction described for *N*-alkylquinuclidinium salts was used for the preparation of *N*-alkyltrimethylammonium compounds by utilizing water as the solvent and lengthening the reaction time to 1 week.

N-Alkyltriethylammonium Salts.—All *N*-alkyltriethylammonium compounds except *N*-isopropyl[1] were prepared by refluxing 0.1 mole of the appropriate alkyl halide with 0.1 mole of triethylamine in 100 ml. absolute ethanol for 18 hr. The solvent was removed and the solid purified as previously described.

N-Isopropyltriethylammonium Bromide.—Diethylisopropylamine was synthesized according to the procedure of Caspe (3). This compound was subsequently reacted with ethyl bromide according to Robinson (4).

Tetrapentylammonium Bromide.—Tripentylamine, 0.1 mole, and 1-pentyl bromide, 0.1 mole, were reacted together as described for the synthesis of 1-alkylquinuclidinium salts.

Enzymology

pH-stat titrimetric determinations were made of AChE activity using an apparatus and a procedure described previously (1). The conditions used in these experiments (different from those reported earlier) were: enzyme[2] concentration, 0.01 mg./ml.; NaCl concentration, 0.15 *M;* $MgCl_2$ concentration, 0.05 *M*, and acetylcholine (ACh) concentration, variable. ACh perchlorate was used.

The velocity of the hydrolysis reaction determined over a period of 5 min. (after an initial 2

[1] Only triethylammonium bromide could be isolated from attempts to react triethylamine with isopropyl bromide.

min. of reaction) was determined in the presence of varying concentrations of inhibitor and substrate. The K_m (the Michaelis constant) for this system, determined graphically from Lineweaver-Burk plots, was 1.82×10^{-4}.

All values for K_i were determined graphically from Lineweaver-Burk plots utilizing at least a fourfold range in [S].[3] Each velocity determination was made at least twice, and a minimum of 4 points were plotted for each K_i determination. It was observed that several of the compounds tested displayed noncompetitive kinetics when employed in concentrations at or above I_{50}. For uniformity, therefore, the [I] values used fall be-

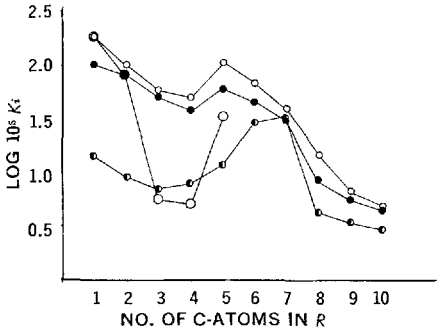

Fig. 1.—The relationship between K_i and length of alkyl chain of ammonium compounds. Key: large circle, R_4N^+; small circle, $(CH_3)_3N^+$—R; ●, $(C_2H_5)_3N^+$—R; ◐, $C_7H_{13}N^+$—R.

tween I_{20} and I_{30}. Under these conditions, all compounds tested display competitive kinetics in this system. The expression used to determine K_i on the $-1/(S)$ intercept was

$$K_i = \frac{K_p}{K_m[I] - \frac{1}{[I]}}$$

where $-1/K_p$ is the value of $1/[S]$ at the intercept. All data are summarized in Table I.

RESULTS AND DISCUSSION

Figure 1 displays a comparison between K_i and the chain length in the 3 homologous series and the R groups of the tetraalkylammonium compounds. A significant difference between the data presented here and the first paper merit comment. This difference relates to the minimum in the line for tetraalkylammonium. Earlier it was found to be at tetrapropylammonium; in this work it is at tetrabutylammonium. The authors have established that this difference (as well as some other quantitative differences) arises from the changed conditions of assay. The present procedure is used more commonly. The point remains that correlation of structure to activity in ACh–AChE systems is quite sensitive to the conditions of assay and should be compared accordingly.

Figure 1 reveals an interesting group of parallels. Note particularly the parallelism shown by the methyl, ethyl, and propyl homologs in the trimethylammonium and triethylammonium series; even more striking is the relationship among the octyl, nonyl, and decyl homologs in the trimethylammonium, triethylammonium, and quinuclidinium series. It is obvious that a parallelism exists between the entire series of triethylammonium and trimethylammonium compounds. These parallels are strongly suggestive of mechanistic parallelism.

The bioisosteric quinuclidinium series fails to display such complete similarity to the other 2 homologous series. The first 3 members and the last 3 members are near parallel, but 2 distinct differences are obvious. First, there is a dramatic quantitative difference in affinity between the first 3 quinuclidinium compounds and their trimethylammonium or triethylammonium bioisosteres. Second, the group butyl, pentyl, hexyl, and heptylquinuclidinium actually form a group of reversed slope from the trimethylammonium or triethylammonium series.

Apparently there is a lack of correlation between the tetraalkylammonium series and any of the N-alkyltrialkylammonium series, in terms of the function alkyl group length.

Figure 2 illustrates the relationship between K_i and the volume of the inhibitory ion. From this figure it is apparent that ion volume data do not offer a general explanation for an inhibitory ion's affinity for the enzyme. However, there is a crude generalization evident from the tendency for all of the compounds tested (*except* the lower members of

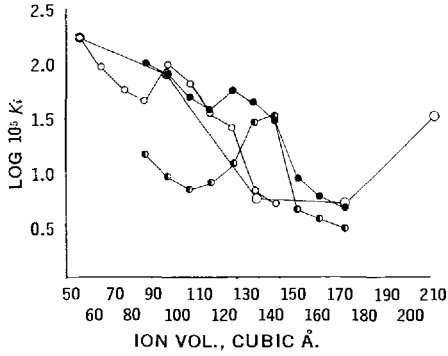

Fig. 2.—The relationship between K_i and ion volume of inhibitory cation. Key: large circle, R_4N^+; small circle, $(CH_3)_3N^+$—R; ●, $(C_2H_5)_3N^+$—R; ◐, $C_7H_{13}N^+$ – R.

the quinuclidinium series) to scatter around a line terminating in a minimum value for K_i at 170 Å.[3] Suggestions on a mechanism parallel between compounds is not evident from this figure. Indeed, much variation in affinity is obvious within a given volume increment which must be due to structural differences among equivolume ions. There are no minima of K_i as a function of volume common to 2 or more homologous series.

Not illustrated in the figures are the data from the isopropyl compounds. Table I reveals that the isopropyl compounds have in every case lower values of K_i than their n-propyl analogs. Simi-

[3] These data are consistent with values obtained from v/v_i *versus* [I] plots.

larly, these compounds represent further equivolume ions with an affinity for AChE which is uniformly enhanced by changing an *n*-propyl group for an isopropyl group. The implications of this observation are several in number, but no conclusion is evident. The fact that adding an alpha-carbon to an ethyl-substituted ammonium ion produces a better inhibitor than adding a terminal methyl group implies that the receptor surface does not contain a simple channel at all but is irregular in nature near the anionic center. The production of a different conformational perturbation by the isopropyl compounds is not deducible from these results, but must be considered. Obviously, the effect of α branching on one or more of these homologous series would constitute an interesting experiment.

According to Belleau (5) the compounds in the *N*-alkyltrimethylammonium series act in inducing 2 different conformational perturbations (with a transitory phase in between) dependent upon the length of the alkyl substituent. The parallelism between the *N*-alkyltrimethylammonium and *N*-alkyltriethylammonium series in this work strongly suggests that the same mechanism is operative for either series. The qualitative similarity between the 3 lowest and 3 highest members of all 3 of the homologous series (as well as the quantitative similarity between the 3 highest members) suggests that a similar mechanism is being invoked in each case. This similarity is independent of ion volume, as adequately demonstrated by Fig. 2.

These suggestions are modified by the lack of parallelism between the "middle region" of the *N*-alkylquinuclidinium series and the other 2 series. This feature, together with the quantitative dissimilarity displayed by the lower members, suggests that an entirely different mechanism is being demonstrated by the quinuclidinium derivatives up to C-7.

It is apparent that several forces are active in determining affinity for AChE. Very closely interdependent are: (*a*) ion volume, (*b*) chain length of longest alkyl chain, (*c*) the conformational possibilities of the ion, and (*d*) the exact mechanism whereby the ion acts (*i.e.*, type of conformational perturbation induced in the receptor).

Specifically excluded are arguments based on relative electron deficiency of the ion. It appears that this area is best thought of in terms of the conformational possibilities of the ion, rather than to attempt to quantify charge. All the compounds are easily dissociated at the concentrations employed. Therefore, the only electrostatic variables anticipated are those arising from the relative availability of the charge center(s). It appears from this approach to the problem that a very significant function of affinity is the shielding of the quaternary nitrogen atom, or the availability of the α-carbon atoms to a plane surface. Some discussion of α plane availability as related to cholinergic activity has been given by Thomas (6, 7).

CONCLUSIONS

No single simple molecular function serves to predict affinity of simple quaternary ammonium ions for the anionic site of AChE. The several features, related above, that obviously affect affinity are interdependent to a high degree. For example, it appears that for optimum affinity, some gross criteria of ion volume must be met; however, if the ion has other unique features enhancing affinity (such as the compact quinuclidinium "head"), the disadvantage conferred by the "wrong" size may be offset. In addition, it is likely that changing one molecular feature changes the mechanism whereby the ion acts. Therefore, the optimum molecular requirements must be stated in terms of a single mechanism to have meaning. The present state of these experiments does not permit this fine a conclusion.

Therefore, it is apparently correct to say that, among simple quaternary ammonium ions (*a*) the affinity of members in a homologous series tends to increase (with significant variations at intermediate positions) to a maximum in the region of 170 Å.^{3} volume of the ion; (*b*) butyl groups (rarely propyl) represent a maximum of affinity (however less than octyl, nonyl, or decyl) within a homologous series; (*c*) restricting the conformational variability of the cationic "head" generally enhances affinity; and (*d*) it is suggested that at least 4 discrete "mechanisms" of action are demonstrated by the compounds in this report. Changes of mechanism refer, in this context, to changes in the conformational perturbation type effected in the protein.

Effect of Glidants in Tableting

By LARRY L. AUGSBURGER and RALPH F. SHANGRAW

A method of measuring the fluidity of semifluid powders is described and used to investigate the role of various silica-type glidants in the direct compression of microcrystalline cellulose and a spray-dried lactose/microcrystalline cellulose blend on 2 different tablet presses. All silica-type glidants were found to improve the flow properties of microcrystalline cellulose as reflected in increased tablet weights and decreased weight variations, whereas a reversal of these effects was noted when the filler was the spray-dried lactose blend. While flow enhancement was attributed to a coating of the filler particles by the glidant, the reverse effect noted in the latter case was attributed in large measure to an increase in the bulk volume of the blend. No difference between the 2 tablet presses was found when the coefficients of variation were tested statistically. A pyrogenic silica and a silico-aluminate were found to be the most effective glidants in terms of over-all performance. These glidants were found effective in concentrations as low as 0.1 per cent by weight when added to microcrystalline cellulose and showed an optimum glidant activity at a concentration of about 0.5 per cent by weight.

THE FLOW of particulate solids is involved in many pharmaceutical operations such as tableting, encapsulation, solid-solid blending, tumbling, or fluidized bed drying. However, in none of these operations is flow any more critical, both in terms of product quality and production economics, than in the transport of solids from the hopper of tablet machines to and into the die cavities of a tablet press.

The limiting factor in the tableting of powders is often the flow properties of the material to be tableted. Uniform tablet weights and uniform doses of active ingredients, as well as production rate, are dependent on the ability of particulate matter to feed into the dies in a reproducible manner. In the past, poor flow properties have been overcome by granulating the powder or blend to be compressed. Unfortunately, granulation involves a series of steps which consumes a great deal of time and utilizes additional men, materials, and equipment. Recent advances in pharmaceutical technology and engineering have eliminated the need for granulation in many cases by making direct compression possible. Direct compression has been made commercially feasible with the advent of induced die feeding units which force-feed the die cavities, and the production of more fluid fillers by means of such engineering processes as spray-drying, instantizing, and controlled crystallization. The use of glidants has also been advocated for improving the flow properties of divided solids (1).

Glidants are defined as substances which improve granulation flow in the hopper or into the die cavity. The study of the usefulness of adjuvants in improving the flow properties of materials to be tableted has been largely confined to substances more properly defined as "lubricants" (2–4). The only "glidant" studies that have been reported in the pharmaceutical literature have been concerned with talc. Interest has developed recently, however, in the use of certain synthetic colloidal silicas to improve the fluidity of particulate solids. For example, a pyrogenic silica and a silico-aluminate were examined for their ability to improve the flow properties of spray-dried egg yolk (5). In general, the colloidal silicas consist principally of silicon dioxide and are characterized by low bulk density and very fine particle size.

Although glidants are apparently used in pharmaceutical operations, a survey of the literature has revealed the lack of any definitive study demonstrating the usefulness of glidants in tableting. Furthermore, there are no reports of a critical evaluation of the newer, silica-type flow conditioners. Consequently, a study of glidants in tableting, with particular emphasis on these silica-type flow conditioners appeared to be justified. Since tablet production of the future may well depend to a large extent upon direct compression, this study was designed, in

Abstracted from a thesis submitted by Larry L. Augsburger to the Graduate School, University of Maryland, Baltimore, in partial fulfillment of Master of Science degree requirements.

particular, to establish the usefulness of glidants in direct compression.

EXPERIMENTAL

Before an investigation of glidants could commence, it was necessary to establish an experimental procedure which would truly measure increases in fluidity and, preferably, have practical industrial significance. Although angle of repose measurements and flow rate through orifices give results relatable to fluidity, reproducibility is relatively poor. It was felt that the simple measurement of tablet weight, which is a reflection of the ability of a powder or granulation to flow into a die cavity, would not only give comparable fluidity values, but would also have practical importance from a production standpoint.

Intuitively, it may be predicted that the addition of a glidant will, by enhancing fluidity, result in the more efficient filling of a die cavity. This more efficient die fill should then be reflected in increased tablet weights and decreased weight variation for the same size die and fill volume. Preliminary experimentation proved this premise to be true and glidants were evaluated using tablet weight as the measured parameter.

Materials.—Relatively free-flowing powders, microcrystalline cellulose[1] and spray-dried lactose,[2] were used as fillers, thereby eliminating the need for granulation. Microcrystalline cellulose possesses many unique advantages which make it an ideal filler to be used for such a study (6). In the first place, microcrystalline cellulose is fluid enough so that it will flow sufficiently well by itself to allow for production of uniform tablets at relatively high tablet machine speeds. At the same time, measurable effects can still be attained when glidants are added. Furthermore, because it is an "anti-adherent," it can be directly compressed without the need for a lubricant to aid ejection of the tablets from the die. As will be seen later, this is an extremely important quality, as it eliminates the need for lubricants which will cloud the action of glidants, making it impossible to separate individual effects. Microcrystalline cellulose also gives a very hard tablet at low pressures, minimizing tablet press vibration and decreasing the chances of erosion or chipping of tablets causing weight variation not attributable to die fill.

The glidants studied and their suppliers appear in Table I.

Preparation of Powders.—Uniform treatment of the powders to be evaluated was extremely important since reproducibility and meaningful results can only be obtained from this type of experiment if the history of each batch is carefully duplicated.

All powders were weighed and placed in a Patterson Kelly V-mixer model LB331 with no agitation bar. Mixing time was carefully controlled at 15 min. In order to promote good blending and uniform dispersion, all glidants or lubricants (which were needed with high concentrations of spray-dried lactose) were passed through a 100-mesh screen before blending with fillers. The importance of screening such additives, particularly when experimental batches are small, was stressed by Marlowe (7). The powders were removed from the blender and compressed immediately whenever possible to eliminate possible aggregation effects, which may result on standing. All blending and compression, except for the runs on the Stokes machine, were carried out in semi air-conditioned laboratories where relative humidity remains constant.

Compression.—Tablets were compressed on either a Stokes model B-2 or a Colton model 216 rotary tablet machine. Once the experiment commenced, the die fill adjustment was locked so that it remained constant throughout the course of the investigation. Occasionally, it was necessary to adjust compression pressure as glidants and fillers were changed in order to allow for production of tablets which were hard enough to withstand handling. Feed frames were adjusted close to the die table during direct compression to minimize leakage of powders. The same $^{7}/_{16}$ in. concave punches and dies were used in all experiments. Hopper filling was accomplished by placing a polyethylene bag full of the powder or granulation into the hopper and gently pulling the bag out from around the particulate mass.

Sampling.—The tablet press was allowed to run for approximately 1 min. before collecting tablets. One hundred tablet samples were drawn from the collected tablets by a "grab sample" method without replacement. Each tablet in the sample was weighed on a Mettler balance accurate to 0.1 mg. The weight of each tablet was recorded to the nearest milligram. The statistics determined were mean tablet weight, standard deviation, and coefficient of variation. The percentage change in mean tablet weight between the test tablets and control tablets was also calculated.

Experiment 1.—This experiment was carried out using microcrystalline cellulose and a blend consisting of 70 parts spray-dried lactose and 30 parts microcrystalline cellulose on a weight to weight basis.

The object of the experiment was twofold: (*a*) to compare the relative efficiency of various selected glidants when added to the 2 different tablet fillers;

(*b*) to compare these effects on 2 different rotary tablet machines to determine whether there was any significant between-machine effects. The same tooling was used on both machines. For the purposes of comparison, an attempt was made to adjust the initial fill on both machines so that identical average weights of the control batches (plain filler) were obtained.

The glidants were tested at a concentration of 1% by weight. In addition, magnesium stearate, at a concentration of 0.5% by weight, was added as a lubricant to the filler containing spray-dried lactose. Initially, the additives were preblended with about one-third, by volume, of the respective fillers. After about 30 sec. of shaking in a polyethylene bag, the preblend was added to the remaining two-thirds of the batch in the V-blender. Each batch of 1500 Gm. was then divided into 2 series, one of which was run on the Colton press and the other on the Stokes press at an average speed of 800 tablets/min. (Tables II–V.)

Experiment 2.—In view of the suggestion in the literature that fines (8) or talc (9) concentration is critical for effective fluidity, this experiment was undertaken to determine the role that glidant concentration plays in over-all powder flow. Glidants *A* and *B* were studied since they represent glidant types. Batches of 500 Gm. each, containing 0.1, 0.25, 0.5, 0.75, 1.0, and 2.0% by weight of glidant were prepared by simple blending according to the previously described procedures. Tablets were compressed on the Colton press at its maximum output of 1200 tablets/min. (Table VI).

Experiment 3.—The object of this experiment was to investigate the effect of press speed upon glidant efficiency. It was hoped that this experiment would affirm the present method of evaluation as a measure of powder fluidity. Glidants *A* and *B* in concentrations of 0.5% by weight were used as the previous experiment had shown that 0.5% was an optimum glidant concentration. The tablets were prepared on the Colton press at outputs of 480, 800, and 1200 tablets/min. (Table VII.)

RESULTS

As anticipated, experiment *1* showed a general increase in tablet weight and decrease in coefficients of variation for tablets compressed from microcrystalline cellulose when glidants are added. Surprisingly enough, the microcrystalline cellulose/spray-dried lactose blend showed results apparently reverse from those obtained with the plain microcrystalline cellulose. While it would appear that the standard deviations of the Stokes series were less than that obtained from tablets prepared on the Colton press, statistical analysis showed that there was no significant difference between the 2 series at the 95% confidence level. Similarly, statistical

testing of the difference in variation between the spray-dried lactose blend tablets produced on the 2 machines revealed no significant differences at the 95% confidence level.

Experiment 2 showed that tablet weights increased, with little or no improvement in weight variation, up to a concentration of about 0.5%. As glidant concentration was increased beyond this point, tablet weights decreased, showing, for the most part, little or no change in weight variation.

Although the glidants were quite effective at each production rate in experiment *3*, it was apparent that as press speed increased, powder fluidity became more critical, as evidenced by decreased mean tablet weights and a tendency toward an increase in coefficient of variation.

DISCUSSION

The physical and chemical properties of the silica-type glidants used in these experiments are listed in Table I. Glidant *B* is unique in that it is a silicoaluminate while the other glidants are colloidal silicas consisting primarily of silicon dioxide. Although glidant *B* has an ultimate particle size on the same order of magnitude as glidants *A* and *D* (10–20 mμ), it exhibits a mean effective particle size of 0.5–1 μ as a result of the manufacturer's "densification treatment" for increasing the bulk density (5). Glidant *C* has also been "densified" and exhibits a larger mean agglomerate size than does glidant *D*.

Glidants *A* and *B* appeared to be the most effective of the glidants in terms of over-all performance. In general, the glidants with the smaller particle sizes tended to be the most effective ones, although glidant *B*, with its larger effective particle size, proved surprisingly effective.

The weight increases observed in these experiments cannot be explained by the filling of void spaces with glidant alone (10). The true density of microcrystalline cellulose is about 1.54 Gm./cm.^{3}, and its bulk density is about 0.29 Gm./cm.^{3}. From these data it can be shown that about 81% of the total volume occupied by the powder is void space. On the other hand, the true density and bulk density of glidant *A* is 2.2 Gm./cm.^{3} and 0.039 Gm./cm.^{3}, respectively (11). In a similar manner, it can be shown that about 98% of the volume occupied by this glidant is void space. Thus, if the void space of microcrystalline cellulose was filled by glidant *A*, there would be an increase in weight of only 11%. Since glidant *A* in concentration of 1% (by weight) was able to increase tablet weights by as much as 24%, it is quite obvious that some function other than the filling of void spaces must be involved. Presumably, this function is the coating of particles (5, 10), resulting in an increased fluidity which manifests itself by allowing the particles to fill the die cavity in a more efficient manner. Furthermore, this process of coating the microcrystalline cellulose particles, instead of merely filling in the voids, would actually increase the bulk volume of the powder blend, thereby making any increase in weight of the final tablet even more significant than was demonstrated, since any weight increase must in part be negated by an increase in bulk volume.

The results with the spray-dried lactose/microcrystalline cellulose blend were not anticipated. In this series, the glidants which were the most effective in causing weight increases with microcrystalline cellulose were the most effective in causing weight decreases in this test, but not necessarily in the same order. Rather, there was a general agreement with bulk density in that the glidants exhibiting the lowest bulk density, disregarding particle size, elicited the greatest loss in mean weight. This pattern suggests that the decrease in tablet weights is a result of an increase in the bulk volume of the total blend, due to the addition of the extremely high bulk volume silicas. This suggestion follows since the bulk of the spray-dried lactose blend, being of considerably larger particle size than the microcrystalline cellulose, presents a smaller total surface area to which the glidant particles can become attached. In addition, the spray-dried lactose blend offers a smaller void space and less chance for the glidant to simply fill in between the particles. It is also quite possible that this blend may already have possessed maximum fluidity, owing to the free flowing properties of spray-dried lactose itself, and the addition of glidant actually hindered flow by acting as excess fines. No doubt, some clouding of glidant activity could have also resulted from the inclusion of magnesium stearate, which was necessary to allow for tablet ejection from the dies.

Because of these many factors, it was impossible to determine whether any useful purpose had been accomplished by adding glidants to the spray-dried lactose blend. However, the fact that coefficients of variation tended to increase and not decrease would seem to indicate that the glidants actually hindered fluidity in this case.

The effects of glidant concentration of microcrystalline cellulose tablets proved quite interesting. Effectiveness was demonstrated with a concentration of only 0.1% by weight. The additions of glidant beyond the 0.5% level caused no further increases in tablet weight but rather resulted in a decrease. Coefficients of variation showed uniform improvement over the control at all concentrations of glidant *A* but tended to be higher than the control for batches containing glidant *B*. This difference between glidants as reflected in coefficients of variation can be accounted for on the basis of the smaller effective particle size of glidant *A*. The fact that, beyond a concentration of 0.5%, tablet weights decreased, may be due to an increase in bulk volume of the mixture. If the glidant does adhere to particle surfaces rather than fill in void spaces, as indicated, then the effect would be to increase the particle diameter and hence, to increase the bulk volume.

The effect of machine speed points out the critical nature of powder or granule fluidity in tableting. As press speed increases, dwell time decreases, and the need for fluidity becomes more apparent. This effect was reflected in a decrease in tablet weight for the same die-fill as machine speed increased. Along with this effect was a tendency toward higher coefficients of variation at higher press speeds. Although they were affected by speed, both glidant blends, *A* and *B*, showed significant glidant effects at each speed run.

The use of calcium acetate in experiment *1* was analogous to the use of acetic acid or a soluble acetate in the cement industry. According to the

theory, fine particles of calcium acetate form on the surface of cement particles, rendering the cement free-flowing (12). These studies show that calcium acetate does not affect flow properties in the same way as the silicas. Indeed, in no case was a significant increase in mean tablet weight elicited. However, in most cases, there was a marked decrease in coefficient of variation, indicating that calcium acetate exerted some influence on flow properties. No explanation is presently obvious and more work is necessary before any conclusions can be drawn.

On the basis of the experimental results there is little question that glidants can play an important role in tablet compression, particularly in the direct compression of semifluid, nongranulated powders. The results obtained in these experiments are not only of theoretical importance, but are also of particular practical importance to tableting due to the method of evaluation employed. The experimental method employed proved to yield measures of particulate fluidity which may be more meaningful to the tableting industry than such methods as angle of repose and orifice flow since the measured parameter was actual tablet weights. However, since tablet sizes (or die-fill volume) only represent small parcels of the particulate mass, a large number of tablet weights were required in order to obtain a truly representative parameter. This aspect tended to make the method a tedious one.

On rare occasions unexplainable extreme weight variations were found, using this method of evaluation. This phenomenon occurred only twice in more than 60 runs and, in one case, involved a preliminary study. In the other cases which occurred during a regular run, the sample was repeated in replicate, and the average of the replicate was reported. This fact is noted in Table VII.

One of the problems associated with the use of glidants arises out of their very fine particle size and low bulk density. These qualitites make them very "dusty," thereby creating a problem in convenience of handling as well as posing an inhalation hazard. A second problem of more concern to industry arises out of the abrasiveness of silicas. This abrasiveness may result in wear of tooling in long-term use, necessitating replacement, and increasing production costs.

While glidants may play an important role in tableting, it may very well be that a quantitative evaluation of them will have even more significance in other pharmaceutical operations such as capsule filling or solid-solid blending.

SUMMARY AND CONCLUSIONS

1. A procedure is described, based on tablet weight and weight variation, which may be used effectively to measure the fluidity of semifluid powders and which gives results directly relatable to the tableting of such powders.

2. The technique is used to investigate the role of various silica-type glidants in direct compression on 2 different tableting machines using microcrystalline cellulose and a spray-dried lactose/microcrystalline cellulose blend as fillers.

3. All silica-type glidants were found to improve the flow properties of microcrystalline cellulose as reflected in increased tablet weights and decreased weight variations. The weight increases observed are attributed to the coating of filler particles with glidant, thereby allowing them to flow more readily and uniformly into the die cavities.

4. On the whole, glidants *A* and *B* were the most effective of the silica-type glidants when tested with microcrystalline cellulose as a filler. Glidant *E* was the least effective glidant. Glidant efficiency could generally be correlated with particle size, the smaller glidant particles effecting greater increases in tablet weight and decreases in weight variation.

TABLE VII.—THE EFFECT OF MACHINE SPEED AND GLIDANTS ON WEIGHT AND WEIGHT VARIATION OF MICROCRYSTALLINE CELLULOSE TABLETS

Glidant 0.5% Concn.	30 r.p.m. (480 Tablets/min.)			50 r.p.m. (800 Tablets/min.)			75 r.p.m. (1200 Tablets/min.)		
	Av. Wt., mg.	S.D., mg.	Coefficient of Variation, %	Av. Wt., mg.	S.D., mg.	Coefficient of Variation, %	Av. Wt., mg.	S.D., mg.	Coefficient of Variation, %
Control	262.1	2.80	1.07	259.2	3.32	1.28	253.5	3.30	1.30
A	311.1	1.55	0.50	305.7	3.19	1.04	304.5	3.43	1.13
B	306.3	2.77	0.90	302.2	3.10	1.03	291.6	7.28	2.50

5. All silica-type glidants were found to produce a decrease in mean tablet weight along with a tendency toward an increase in coefficient of variation for the same size die fill when used with the spray-dried lactose/microcrystalline cellulose blend. This phenomenon was attributed in large measure to the extremely high bulk volumes of the silica-type additives which have the effect of increasing the bulk volume of the entire powder blend, thereby decreasing effective tablet weights.

6. The statistical testing of coefficients of variation revealed no difference between the Stokes model B-2 tablet machine and the Colton model 216 tablet machine at the 95% confidence level.

7. Glidants *A* and *B* proved effective in concentrations as low as 0.1% by weight when added to plain microcrystalline cellulose. No increase in glidant activity was observed with concentrations beyond 0.5% by weight.

8. For the same die fill, tablet weights decreased and coefficients of variation tended to increase as tablet machine speeds increased when glidants *A* or *B* were added to microcrystalline cellulose. As would be expected, a powder fluidity becomes more critical when press speed is increased.

9. Although calcium acetate has proved to be an effective glidant in the cement industry, it did not increase tablet weights when added to microcrystalline cellulose or the spray-dried lactose/microcrystalline cellulose blend. It did appear to decrease coefficients of variation, but no explanation is offered.

Automated Assay for the Antibiotic Lincomycin

By GEORGE C. PRESCOTT

A chemical assay for the antibiotic lincomycin has been developed which is based on the colorimetric determination of methanethiol generated from the acid hydrolysis of the methylthioglycosido group of the antibiotic. Fermentation beers and production samples as well as purified materials can be assayed by this procedure. Automation of this method increased the number of (completed) assays per man day from about 30 to about 150. Application of the assay to a series of standard solutions has given a mean recovery of 101 per cent and a standard deviation of 5.1 per cent. Analysis of a centrifuged beer containing added increments of lincomycin has given a mean recovery of 95.5 per cent and a standard deviation of 6 per cent.

LINCOMYCIN[1] is a medium spectrum antibiotic having the structure shown in I (1).

In 1962 the author developed an assay method which was based on the colorimetric determination of methanethiol generated from the acid hydrolysis of the methylthioglycosido group of the antibiotic (2). A particular advantage of this assay was that the thiol was separated from the interfering background material by distillation before it was reacted with the color reagent. Fermentation beers and production samples as well as purified products were assayed by this procedure. Early attempts to automate this assay with an automatic analyzer[2] were un-

Automated Assay for the Antibiotic Lincomycin

By GEORGE C. PRESCOTT

A chemical assay for the antibiotic lincomycin has been developed which is based on the colorimetric determination of methanethiol generated from the acid hydrolysis of the methylthioglycosido group of the antibiotic. Fermentation beers and production samples as well as purified materials can be assayed by this procedure. Automation of this method increased the number of (completed) assays per man day from about 30 to about 150. Application of the assay to a series of standard solutions has given a mean recovery of 101 per cent and a standard deviation of 5.1 per cent. Analysis of a centrifuged beer containing added increments of lincomycin has given a mean recovery of 95.5 per cent and a standard deviation of 6 per cent.

LINCOMYCIN[1] is a medium spectrum antibiotic having the structure shown in I (1).

In 1962 the author developed an assay method which was based on the colorimetric determination of methanethiol generated from the acid hydrolysis of the methylthioglycosido group of the antibiotic (2). A particular advantage of this assay was that the thiol was separated from the interfering background material by distillation before it was reacted with the color reagent. Fermentation beers and production samples as well as purified products were assayed by this procedure. Early attempts to automate this assay with an automatic analyzer[2] were un-

The author acknowledges the help and suggestions of Mr. Andres Ferrari of the Technicon Corp., Chauncey, N. Y., particularly in using polyethylene and glass tubing for methanethiol gas and for the gas separator hook-up; the technical assistance of C. J. Kleinhuizen, Jr., and his positioning of the mixing coils and fittings and the use of positive air pressure; and is indebted to J. R. Marsh for the drawing of the automatic analyzer flow diagram.

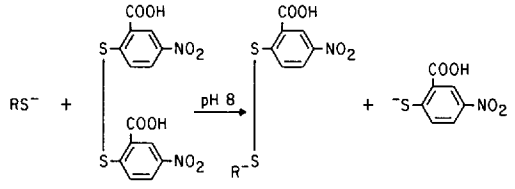
[1] Marketed as Lincocin by The Upjohn Co., Kalamazoo, Mich.

[2] AutoAnalyzer, Technicon Controls, Inc., Chauncey, N. Y.

successful due to absorption of methanethiol gas by the Tygon tubing. This difficulty was eliminated by allowing the gas to contact only glass or polyethylene tubing. Other important improvements included the use of a water-soluble color reagent, better positioning of the mixing coils and gas separator, and the use of positive pressure on the system. Automation increased the number of (completed) assays per man day from about 30 to about 150.

The reactions involved in the assay are: acid cleavage of lincomycin to yield methanethiol, separation of the thiol, and reaction with a disulfide color reagent at pH 8.0 to release the highly colored anion. Full color development is almost instantaneous at room temperature.

The reaction of thiols with 5,5′-dithiobis(2-nitrobenzoic acid) (DTNB) is shown in Scheme I.



Scheme I

EXPERIMENTAL

Instrumentation.—Technicon sampler No. 2, proportioning pump, colorimeter, and recorder.

Reagents.—*A.*—Sulfuric acid, approximately 12 *N*.

B.—Color reagent, 0.01% 5,5′-dithiobis(2-nitrobenzoic acid) (DTNB). Dissolve 100 mg. of the reagent in 5 ml. of ethanol and dilute to 1 L. with water. The reagent appears to be stable for at least 1 month. In fact it is desirable to allow the reagent to stand for 24 hr. or longer as the slight haze which develops when the water is added disappears during this time.

C.—Tris buffer 0.1 *M*, pH 8.0. Dissolve 12.12 Gm. of 2-amino-2-hydroxymethyl-1,3-propanediol in 54.5 ml. of 1.0 *N* hydrochloric acid and dilute to 1 L. with water.

D.—Polysorbate 20.[3]

Procedure.—Set up the equipment as shown in the flow diagram (Fig. 1). Use a timing cam with the sampler 2 which allows 30 sec. for the sample and 90 sec. for wash or a rate of 30 samples/hr. Standardize the automatic analyzer as shown in the test manual.

The following points in technique have been found to be essential for a satisfactory assay.

(*a*) Tygon tubing is unsatisfactory for handling methanethiol gas. Glass and polyethylene tubing have been found to be satisfactory and *must* be used where indicated in the diagram.

(*b*) The gas separator must be connected in the manner indicated in the diagram which allows the aliquot for analysis to flow by gravity. The normal procedure of pumping this aliquot is unsatisfactory due to the Tygon manifold tubing.

(*c*) The mixing coils must be placed in a vertical position rather than in the usual horizontal position. The fittings must also be positioned in the approximate angle indicated.

(*d*) A positive air pressure of 3 lb./sq. in. greatly improves the bubble pattern and eliminates any back pressure in the system.

(*e*) As with most assays with this automatic analyzer the bubble pattern is greatly improved by using a small amount of surface-active agent in the reagents. The following amounts of polysorbate 20 seem to be about optimum under present conditions: 0.05 ml./L. in the acid, 0.1 ml./L. in the buffer, and 0.05 ml./L. in the water wash. The polysorbate 20 should be added to the acid and buffer on the same day that they are used.

Sample Preparation.—Prepare samples to contain from 25–150 mcg./ml. of lincomycin base per ml. of water. The pH of the solution is not critical since the sample will be hydrolyzed with strong acid. Highly colored samples cause no difficulty since the methanethiol gas is separated from the liquid before the colorimetry. However, solutions containing large amounts of carbonates or other materials which evolve gas on acidification must be degassed by acidifying at room temperature (lincomycin is not hydrolyzed at room temperature). Samples containing more than traces of volatile solvents should be evaporated and redissolved in water. Since the sample pick-up tubing is only 0.034 in. i.d., it is obvious that samples containing suspended solids must be clarified.

Standard Curves.—*Standard Curve for Purified Samples.*—Prepare standards to cover the assay range using lincomycin hydrochloride monohydrate primary standard. It has been found convenient to prepare standards containing 30, 60, 90, 120, and 150 mcg./ml. of lincomycin base equivalent in water. The concentration of lincomycin in each standard solution is calculated as lincomycin base, using a conversion factor based on the lincomycin base equivalent contained in the lincomycin hydrochloride monohydrate reference standard. These standards appear to be stable for several weeks at room temperature.

Standard Curve for Fermentation Beer Samples.—Prepare standards to cover the assay range in the same manner as described above, except use spent beer for the diluent in place of water. This spent beer must show no activity by either bioassay or chemical assay. It should be diluted with water to about the same dilution as the unknown samples.

Calculations.—Plot a transmission curve from the recorded peak averages of standards (Fig. 2). Draw a line connecting the transmission peaks of the standards and determine the concentration of each unknown from this curve. In most cases the curve is linear over the assay range, and it is equally satisfactory to determine the slope of the standard curve and calculate the concentration of the unknowns using this value. However, when the standard curve is not linear or does not pass through the origin the unknowns must be read directly from the curve. During the course of a long run it is necessary to correct for instrumental drift. This is the chief reason for running a standard for every 3

[3] Marketed as Tween 20 by the Atlas Powder Co., Wilmington, Del.

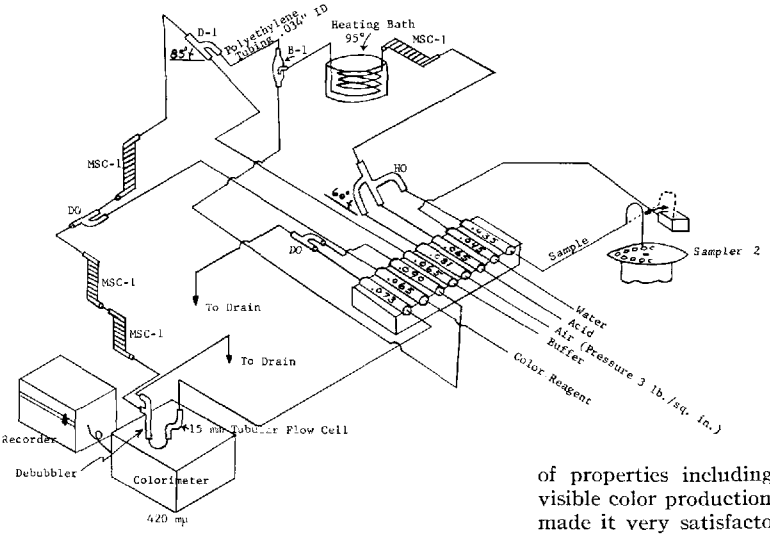


Fig. 1.—Automatic analyzer flow diagram for lincomycin using sampler 2. All glass fittings are designated by the Technicon AutoAnalyzer code.

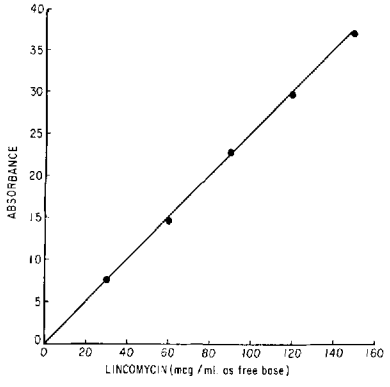

Fig. 2.—Standard curve for lincomycin assay.

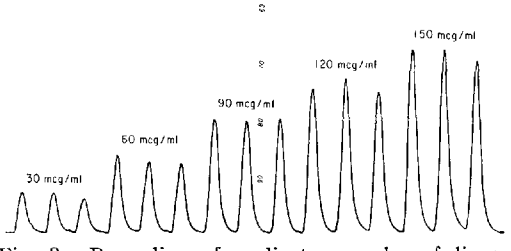

Fig. 3.—Recording of replicate samples of lincomycin standards.

samples throughout the entire run. This instrumental drift is inherent to the automatic analyzer and has been discussed by Thiers and Ogelsby (7).

RESULTS AND DISCUSSION

Choice of Reagent.—Several colorimetric reagents for thiol groups were investigated before the present reagent, 5,5′-dithiobis(2-nitrobenzoic acid) (3), was chosen. This reagent possessed a combination of properties including high sensitivity, stability, visible color production, and water solubility which made it very satisfactory for this assay. Some of the reagents investigated and rejected are: *N*-ethylmaleimide (4), bis(*p*-nitrophenyl)disulfide (5), 2,2-diphenyl-1-picrylhydrazyl (6), and sodium nitroprusside.

Specificity.—As would be expected, lincomycin analogs and metabolic products having a hydrolyzable thiol group give full molecular response in the assay. This applies to methylthiolincosaminide (1) as well as other lincomycin-related antibiotics (8). Most of the ingredients of the fermentation media do not show any response. These include methionine, ethionine, corn steep liquor, and Wilson's peptone No. 159. Blackstrap molasses, however, exerts a slight positive bias when it is added to standard samples. This may be the reason for the positive bias of fermentation samples when they are calculated from standards prepared in water. This bias is small and somewhat variable, averaging around 5%. Better agreement between the 2 assays is obtained by calculating the beer samples from a standard curve in which the crystalline standard is diluted with spent beer as described under *Standard Curves*.

Precision.—The plot of concentration *versus* absorbance is virtually linear at least over the concentration range of 25–150 mcg./ml. of lincomycin. At the described rate of assay there is no sample interaction as shown in the recording of replicate samples (Fig. 3). Application of the method to a series of standard solutions has given a mean recovery of 101% and a coefficient of variation of 5.1%. Analyses of a centrifuged beer containing added increments of lincomycin have given a mean recovery of 95.9% and a coefficient of variation of 6.0%.

Enumeration of Primary Tissue Cells by an Electronic Device

By WILLIAM F. DALY, LEON P. PIASCIK, JR., and JAMES L. BITTLE

Cell yields from primary tissue suspensions of chicken embryos, rhesus, and cercopithecus monkey kidneys, were compared using the hemocytometer and Coulter counter, to determine the suitability of the electronic device for routine tissue culture practices. Plating efficiencies indicated that the Coulter counter is equal to or better than the hemocytometer for enumeration purposes. Results with the counter were more consistent and were reproducible, and there was a twofold saving in time, as well as elimination of the necessity of visual counts. The electronic counter has been used routinely in the laboratory for the past year, and in all instances, suitable monolayers for tissue culture production have been obtained.

A SIMPLE, quick, and reproducible method for determining cell yield from primary tissue has become a necessity for large scale tissue culture production. Many methods of estimating mammalian cell populations have been reported (1, 2) but the hemocytometer and the index-of-viability dyes, *e.g.*, trypan blue (3, 4) and eosin (5, 6), have been the most widely used means of determining viable cell concentrations. However, hemocytometer counts have proved time consuming and subject to serious error (7, 8), and the dye-exclusion tests are not always reliable indicators of cell cultivability (9).

This laboratory utilizes an electronic counter[1] which enumerates individual cells by a form of electronic "gating," for establishing cell inoculum. The instrument has been evaluated for blood cell counting (10, 11), and its application in growth studies has been demonstrated (12). The purpose of this paper is to compare the data obtained with both the hemocytometer and the electronic counter, and to determine the suitability of the instrument for routine tissue culture practices. The evaluation scheme closely paralleled that described by Brecher *et al.* (10).

EXPERIMENTAL

Culture Methods.—Primary cell suspensions were prepared from freshly harvested chicken embryos, rhesus, and cercopithecus monkey kidneys. Following trypsinization (1, 13, 14) the cells were resuspended in appropriate growth media, thoroughly mixed, and samples were removed for enumeration. The remaining cell suspension was diluted, inoculated into culture bottles, and incubated at 36°. Confluence monolayers developed in 16–18 hr. for chicken embryo cultures and 7 days for monkey kidney cultures.

Enumeration.—Enumeration with the electronic counter is accomplished by a form of electronic "gating." As a particle is drawn through a small aperture (100 μ), an equal amount of electrolyte is displaced causing a voltage drop due to an increase in aperture impedance. The resultant pulses are amplified, recorded by a decade counter, and visualized on an oscilloscope (10–12). For the authors' use, the instrument was calibrated with ragweed pollen according to the method described by Coulter Electronics.[2]

For monkey kidney cells the optimum threshold setting on model A was found to be 20 with aperture current setting of 3 and a gain of 2, whereas for chicken embryo cells settings were 5, 2, and 5, respectively. Cells were suspended in phosphate-buffered saline (15) and 4 successive counts were taken on each sample, representing 4 aliquots of the same cell population, or a total of 2 ml.

Hemocytometer.—Hemocytometer counts were made on samples composed of equal parts of cell suspension and 0.5% trypan blue. The viable cells in 2 squares (2 sq. mm.) were counted and multiplied by a dilution factor of 10,000 to obtain total cells per milliliter. This, therefore, represents a sampling of $^1/_{10,000}$ of 1 ml. Dead cells were also enumerated and a percentage of the total determined on each count.

Reproducibility Techniques.—Both systems were further evaluated by comparing multiple counts on the same primary cell suspension. Five different suspensions of rhesus monkey cells were enumerated with at least 20 counts obtained on each suspension with each method. In all instances, the cell suspensions were slowly mixed on a magnetic stirrer, and samples were removed and enumerated by both methods within a 2-hr. period (10). The mean cell counts obtained from the 5 monkey suspensions were compared, and the standard deviations and standard errors were determined.

Routinely, over a 6-month period, 3 types of primary cell suspensions—chicken embryo, rhesus, and cercopithecus monkey kidneys—were subjected to comparison counts with the hemocytometer and the electronic counter. Representative samples were taken of each suspension and single counts were obtained. The data for each tissue (Fig. 1) were plotted and fitted to a regression line (16) to determine the association existing between both procedures in evaluating a primary cell system.

A modified plating-efficiency technique was applied to both enumerating systems. A primary

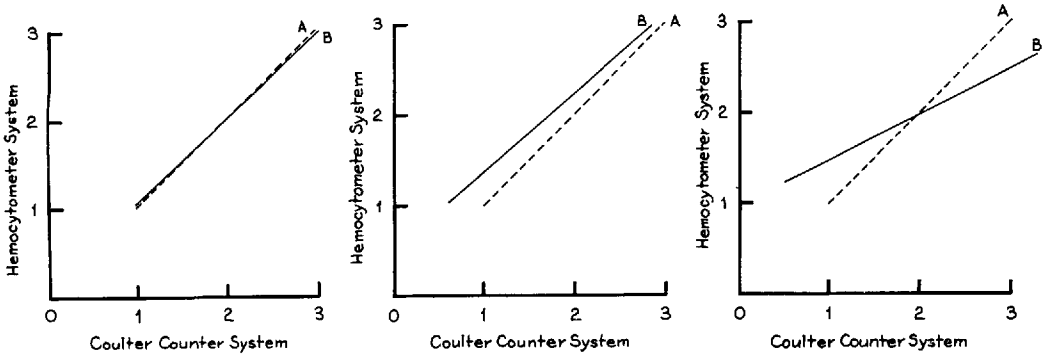

Fig. 1.—Relationship between hemocytometer and Coulter systems in evaluating primary tissue suspensions. Key: A, theoretical; B, Coulter counts plotted against hemocytometer counts. Counts are expressed in millions of cells per milliliter of suspension. Left: chicken embryo; middle: rhesus monkey kidney; right: cercopithecus monkey kidney.

suspension of rhesus monkey kidney cells was enumerated and, from this, two series of cultures were planted as determined from the counts of both systems. Each series consisted of two 2-oz. bottles at concentrations of 6,000, 12,000, 25,000, 50,000, 100,000, 200,000, and 300,000 cells/ml. Cell monolayer development was observed daily for 10 days.

RESULTS

The pooled standard deviation for the electronic method was 8.42×10^4 cells/ml. as compared with a standard deviation of 18.31×10^4 cells/ml. for the hemocytometer (Table I). The variability of each enumerating system on 5 separate monkey kidney suspensions is illustrated in Fig. 2 which represents that portion (95%) of the counted cells which lie in the interval of + or − 2 standard deviations. The standard errors for the electronic counter were all less than 2.4 while hemocytometer standard errors all exceeded 3.3 (Table I).

The data obtained from the routine comparison of primary cell suspensions provided correlation coefficients of 0.82 (chicken embryo), 0.76 (rhesus monkey kidney), and 0.70 (cercopithecus monkey kidney) which demonstrates the favorable relationship existing between both enumerating systems. The regression lines (Fig. 1) indicate the probability of a linear relationship.

Differentiation between counting systems was observed at a planting rate of 2.5×10^4 cells/ml. The cell cultures prepared from cells enumerated by the Coulter method had moderate growth in 10 days (40% confluency) as compared with 10–15% confluency in hemocytometer-enumerated cell cultures. No significant growth was noted at cell concentrations of 6000 and 12,000 cells/ml., whereas confluent monolayers were observed in 6 days at a concentration of 50,000 cells/ml. and in 4 days at concentrations of 100,000, 200,000, and 300,000 cells/ml.

DISCUSSION

The high degree of variation existing between mean hemocytometer and electronic counts has been demonstrated (Table I). It was shown from the 5 separate monkey kidney suspensions that the standard deviation for the electronic counter varied between 6.35–10.58 $\times 10^4$ cells/ml., whereas the standard deviation for the hemocytometer counts varied between 14.72 and 21.77 $\times 10^4$ cells/ml. The pooled standard deviation for the hemocytometer was more than twice that of the electronic counter. The standard errors agree well with those reported by Brecher (10), with the electronic counter errors all less than 2.4, while those of the hemocytometer all exceed 3.3.

The routine analysis of comparison counts provided correlation coefficients which demonstrate that both systems are fairly comparable. The coefficients are lower than those reported by Harris (12), probably because primary suspensions contain numerous cell types, blood, and debris. Correlation of hemocytometer and electronic counts was very good for chicken embryo tissue (Fig. 1, left), but to a lesser degree for simian tissue (Fig. 1, middle and right). In this study the cause of discrepancy was not determined, but the postulation of Mattern

[a] Coulter counter.

et al. (11), that errors in hemocytometry must be involved, is accepted.

The plating efficiencies indicate that the electronic counter is equal to or better than the hemocytometer for determining cell inoculum. At a planting concentration of 2.5×10^4 cells/ml. a slightly higher per cent confluency was noted in the Coulter cultures.

From the data collected, it was noted that the number of nonviable cells from any one of the 3 cell suspensions never exceeded 10% of the total. Therefore, it must be assumed that the problem of variation in cell viability was overcome by the use of a standardized system of tissue culture preparation that consistently yielded a uniform population of viable cells.

This study indicates that the electronic counter is suitable for routine tissue culture practices, since it is more consistent than the hemocytometer and possesses excellent reproducibility. It is evident that the degree of variation existing in hemocytometry could eventually be responsible for the establishment of erroneous planting rates causing either a decrease or increase in the number of total cells available, which would directly affect the number of cultures obtained from a primary suspension. The utility of the electronic counter for routine operation is further supported by a twofold saving in time and the elimination of many stress factors that may contribute to erroneous visual counts. The electronic counter has been in operation in this laboratory for the past year as the standard enumerating method. During this period, 400 cercopithecus monkey kidneys, 220 rhesus monkey kidneys, and 61 lots of chicken embryo (approximately 206 embryos/lot) were trypsinized, planted, and in all instances gave rise to suitable monolayers for tissue culture production.

Detection of *In Situ* Compound Instability by Two-Dimensional Thin-Layer Chromatography

By MELVIN H. PENNER, JOSEPH M. TALMAGE, and MILTON GELLER

Two-dimensional TLC, widely used for the resolution of chemically related compounds which cannot be resolved effectively by development in one solvent, has been employed for the detection of side reactions of the compound with the adsorbent or decomposition due to instability in the solvent system. The method involves the use of the same solvent system in both directions of development. Alteration of the compound is manifested by the appearance of secondary spots located off the theoretical diagonal line. Quingestrone and quingestanol acetate, both of which are steroidal 3-cyclopentyl enol ethers and show such instability, are presented as examples.

TWO-DIMENSIONAL chromatography using a different solvent for each development has shown particular value in the resolution of chemically related compounds which cannot be resolved effectively by development in one solvent. This technique has been used successfully by Brenner and Niederwieser (1, 2) for the resolution of 22 of the more common amino acids on Silica Gel G. Similar two-dimensional systems have been used for the resolution of 15 plasticizers (3), for 14 physiologically active indole derivatives (4), and for 9 tryptophane metabolites (5).

A substance is considered homogeneous in a chromatographic sense when the resulting chromatogram yields only 1 spot. In an extremely large number of cases, such homogeneity indicates genuine chemical purity. However, the appearance of multiple spots on a chromatoplate and the conclusion that the original substance is impure may be an erroneous one. In order to determine whether a compound undergoes a reaction with the adsorbent and/or decomposes during chromatography due to instability in the solvent system, the authors have employed two-dimensional thin-layer chromatography in which the same solvent is used in both directions. It is now recognized that a single pure substance may lead to the formation of more than 1 spot (6). Keller and Giddings (7) have reviewed in detail the problem of multiple spots in chromatography. Steroid 16β-esters have been shown to undergo reactions on alumina layers (8), and ethylene ketals have been hydrolyzed on silica gel plates (9). Alumina in columns has been reported by Mangold (10) to catalyze ester hydrolysis, isomerization of double bonds, and other reactions. Sterols are chemically altered when chromatographed on columns of dry silicic acid, and Linford (11) recommended that these compounds be separated by partition chromatography on silicic acid containing 35–40% water. Other citations of side reactions with the adsorbent have been reported by Stavely (12), Sarett (13), and Mattox and Mason (14). A comprehensive discussion of this problem has been presented by Neher (15). These alterations are by no means restricted to steroids and have been reported for sugars (16) and vitamins (17, 18).

Stahl (19) reported the use of a separation-reaction-separation (SRS) technique to study the inactivation of pyrethrines. This simple technique allowed the recognition of changes in the individual components of the mixture intentionally caused by irradiation of the chromatoplate with U.V. or sunlight following separation in the first direction. These alterations were quite evident after subsequent chromatographic development with the same solvent in the second dimension.

Two examples of steroidal 3-cyclopentyl enol ethers which show chromatographic instability are presented. It is now standard practice in this laboratory to chromatograph all substances by this technique which exhibit multiple spots by one-dimensional TLC.

EXPERIMENTAL

Procedure.—Commercially prepared standard silica gel plates, 20 × 20 cm., purchased from Analtech, Inc., were used in this study. These plates were activated for 30 min. at 105° just prior to use. Samples were applied as 0.2% solutions in hexane and approximately 10 mcg. of steroid spotted to 3 adjacent corners on the plate approximately 2.5 cm. from each edge. In this manner, the behavior of the compounds in each direction was apparent in the completed chromatogram.

Development.—The following solvent systems were used: (*a*) heptane–acetone, 2:1; (*b*) cyclohexane–ethyl acetate, 7:3; (*c*) cyclohexane–ether, 6:4; (*d*) heptane–propanol, 4:1; (*e*) toluene–methanol, 19:1.

The 3 points of application were marked and a finish line, 10 cm. from the starting points, was drawn in the layer with a needle. When the solvent front reached this line, the plate was removed from the development chamber, air dried, rotated 90°, and developed once more in the same solvent. Upon completion of this double development, the plates were air dried.

Detection.—For the detection, 50% methanolic sulfuric acid was found to be the most useful reagent. The entire surface of the plate was sprayed with the reagent and then heated in an oven at 105° for

Accepted for publication December 28, 1965.

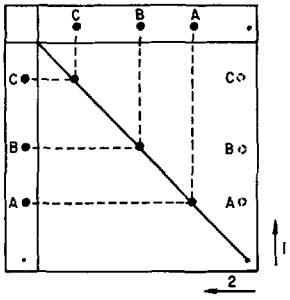

Fig. 1.—Theoretical distribution of a stable mixture in a two-dimensional chromatogram using the same solvent system in both directions.

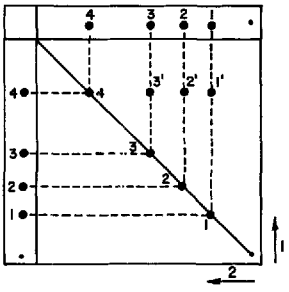

Fig. 2.—Two-dimensional chromatography of quingestanol acetate (17α-ethinyl, 19-nortestosterone acetate-3-cyclopentyl enol ether). Solvent system: heptane – acetone (2:1).

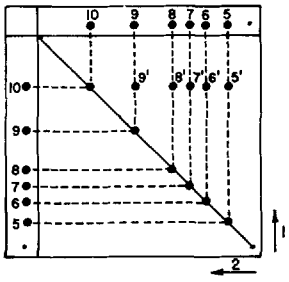

Fig. 3.—Two-dimensional chromatography of quingestrone (progesterone 3-cyclopentyl enol ether). Solvent system: toluene – methanol (19:1).

10–15 min. In addition to observing the colors formed upon heating, the plate was viewed under long wavelength U.V. light (360 mμ) to detect those spots which did not produce colored areas.

RESULTS AND DISCUSSION

In theory, if no alteration of the compound were to take place during the two-dimensional chromatography of a mixture using the same solvent system in both directions, all substances would be arranged in a diagonal line (Fig. 1). After the first development, the 3 substances comprising the mixture applied at the origin distribute themselves according to their R_f values as is indicated in Fig. 1 by the interrupted circles. After the second development with the same solvent system, all spots appearing above or below this diagonal correspond to substances which have been produced between the first and second chromatography (secondary spots). Both steroids when chromatographed by paper chromatography in heptane/methyl cellosolve (20) (capable of separating the decomposition products from the parent compound) represented 1 spot material.

Figure 2 represents the chromatographic pattern obtained for quingestanol acetate when heptane/acetone (2:1) was used as the solvent system in both directions. The following spots have been identified: (*1*) 6β-hydroxy-17α-ethinyl-19-nortestosterone acetate, (*2*) 6α-hydroxy-17α-ethinyl-19-nortestosterone acetate, (*3*) 17α-ethinyl-19-nortestosterone acetate, (*4*) 17α-ethinyl-19-nortestosterone acetate-3-cyclopentyl enol ether. Zones 1′, 2′, 3′ are indicative of decomposition of quingestanol acetate (4) during chromatography in the second dimension. Solvent systems B, C, and D gave evidence of similar decomposition patterns.

Figure 3 represents another example of the use of the two-dimensional technique for the detection of instability during TLC. Chromatographically pure quingestrone was chromatographed in both dimensions using toluene–methanol (19:1). Again from the completed chromatogram, it is evident that this steroid has undergone decomposition during the development as is evident from spots 5′–9′. Spots 5, 6, 9, and 10 have been identified as 6β-hydroxyprogesterone, 6α-hydroxyprogesterone, progesterone, and quingestrone, respectively. Spots 7 and 8 are minor and have not been identified. It has been postulated that quingestrone is unstable on silica gel due to an ether interchange reaction with the hydroxyl groups of silica gel. When comparatively large quantities of material are spotted, trails appear which furnish evidence of the decomposition pathway.

SUMMARY

Two-dimensional thin-layer chromatography using the same solvent system for development in both directions has been applied for determining compound instability during chromatography. Two examples of steroidal 3-cyclopentyl enol ethers which show such instability are presented. This technique has many advantages over elution and rechromatography of the parent compound, namely: (*a*) speed, (*b*) provides evidence of decomposition pathways, (*c*) for sensitive compounds, elution and concentration of the eluate may cause further alteration of the compound, (*d*) strongly adsorbed compounds may not be eluted in sufficient quantities, and (*e*) destructive spray reagents may be the only method of detection possible. The use of this method allows for the unequivocal determination of whether the cause of multiple spots by conventional TLC is indeed due to the presence of a mixture or an unstable compound.

Some Observations on Nonlogarithmic Titration Curves for the Determination of Dissociation Constants and Purity

By LEWIS J. LEESON and MICHAEL BROWN

The method of Benet and Goyan for the determination of purity and ionization constant of a weak acid or base was investigated and found to work well. The general equation was modified in order to extend its applicability to titrations involving a volume change. The question of the correct type of activity coefficient to be used for calculating the data was considered, and some experimental evidence presented to indicate that the results are not markedly influenced by the one employed.

In recent publications (1, 2) Benet and Goyan have presented a technique for determining both the purity and the dissociation constant of a weak acid or base. This procedure is based on a nonlogarithmic linear plot of titration data. In these laboratories the authors use their method routinely, and have found it to be an excellent one. It is felt, however, that two points in the method warrant further discussion. The first is that the equation presented by Benet and Goyan assumes no volume change occurring during the titration. The second point is concerned with the correct activity coefficient to be used in the computations. Therefore, the basic equation has been rederived to make it generally applicable to all titrations, whether or not a volume change occurs. In addition, studies have been performed in an attempt to decide upon the correct type of activity coefficient to be used in the calculations.

EXPERIMENTAL

All pH measurements were made on the expanded scale of a Radiometer model 25 SE meter equipped with an A. H. Thomas 4855-B 10 glass electrode and a Corning fiber-type calomel electrode. Samples were prepared by adding to the titration vessel 100 ml. of nitrogen-sparged, triple distilled, pyrogen-free water; 2 ml. of 0.0953 *N* HCl solution (where necessary); sufficient 2 *M* KCl solution to obtain the desired ionic strength; and the sample to be titrated. Blank solutions were prepared identically. Titrations were performed under nitrogen in a water-jacketed vessel, the temperature of which was 25 ± 0.1°. A 5-ml. semimicro buret was employed; the titrant was 0.1008 *N* KOH solution standardized by titration with potassium acid phthalate, and the 1 *N* acetic acid was Fisher certified reagent. All linear relationships were calculated by the method of least squares.

DISCUSSION

Modification of the Equation.—The following equation was developed by Benet and Goyan (2) for the titration of an acid HA with a strong base MOH:

$$Z = A^0 - \frac{1}{K^c} Z\,[H^+] \qquad \text{(Eq. 1)}$$

where

Z = concentration of conjugate base formed during titration = $[H^+] + [M^+] - [OH^-]$,
$[M^+]$ = concentration of M^+ ion in solution from addition of MOH,
A^0 = concentration of all acid species in solution = $[HA] + [A^-]$, and
K^c = apparent ionization constant of acid HA.

Upon first examination, Eq. 1 appears to be a linear function. Therefore a plot of Z *versus* $Z[H^+]$ should be a straight line with a slope of $-1/K^c$, and an intercept of A^0, from which value the purity may be determined. On further consideration, however, it is apparent that this is true only when the total volume change, which occurs during a titration, is considered negligible. Since A^0 represents the sum of all forms of HA present in solution at any time, a volume increase, which results by addition of titrant, will cause A^0 to vary from the beginning to the end of the titration. Therefore in cases where the titration volume cannot be considered constant, Eq. 1 does not represent a linear function. Although it is recognized that Benet and Goyan were able to consider their volume changes negligible, in this work a volume increase of 2–5% is not uncommon. Therefore, the authors felt it desirable to alter Eq. 1 so as to circumvent any error that may be introduced by a volume change.

If one were to consider the system in terms of absolute amount of material (number of moles) in the titration vessel rather than concentration (moles/liter), the equation can be rederived to make it independent of volume change. For the titration of an acid HA with a strong base MOH, the equation of electroneutrality may be written in terms of absolute molar quantities rather than concentration units.

$$H^+ + M^+ = A^- + OH^- \qquad \text{(Eq. 2)}$$

where

H^+ = absolute numbers of moles of hydrogen ion present in solution,
M^+ = absolute number of moles of base added to the solution,
A^- = absolute number of moles of conjugate base present in solution, and
OH^- = absolute number of moles of hydroxyl ion present in solution.

Therefore

$$Z' = A^- = H^+ + M^+ - OH^- \qquad \text{(Eq. 3)}$$

The apparent ionization constant for HA may be written:

$$K^c = \frac{[A^-]\,[H^+]}{[HA]} = \frac{A^-\left(\frac{10^3}{V}\right)[H^+]}{HA\left(\frac{10^3}{V}\right)} = \frac{A^-\,[H^+]}{HA} = \frac{A^-\,[H^+]}{(A^0 - A^-)} \qquad \text{(Eq. 4)}$$

V = volume of solution in milliliters,
$[HA]$ = concentration of acid = $HA\ (10^3/V)$,
HA = absolute number of moles of acid,
$[H^+]$ = concentration of hydrogen ion,
A^0 = absolute number of moles of acid added initially = $HA + A^-$.

Substituting from Eq. 3 into Eq. 4 and rearranging,

$$Z' = A^0 - \frac{1}{K^c} Z'[H^+] \qquad \text{(Eq. 5)}^1$$

Although Eq. 5 is identical in appearance to Eq. 1, there are important differences which make it an exact linear function. The A^0 term in Eq. 5 represents *absolute* number of moles of acid added to the solution. All the terms used to calculate Z' (including H^+) are also *absolute* quantities. The $[H^+]$ in Eq. 5, however, is a *concentration* term.

The modified equation of Benet and Goyan permits the use of their method without any assumptions as to volume increase during titration. In addition, it also decreases the amount of calculations required, since the only adjustment necessary for volume change is made with the hydrogen ion. In practice, HCl is often added to the solution being titrated,[2] so that calculations in terms of concentration units would require an adjustment for both Cl^- and M^+ ions at each point in the titration. However, if calculations are made with absolute quantities, the amount of Cl^- is a constant and is equal to the absolute amount of HCl added, whereas M^+ is merely the volume of MOH added multiplied by its normality.

The authors have found that working in terms of absolute amounts of materials is a good general method for decreasing the computations required in titrimetric techniques. Its use in chelation studies, where numerous species are present (chelating metal, M^+, Cl^-, etc.), has again been found to simplify calculations because only one volume adjustment is necessary in most cases.

TABLE II.—COMPARISON OF RESULTS WITH ACETIC ACID USING BOTH TYPES OF ACTIVITY COEFFICIENTS

	Results		
	$\gamma\pm$	Kielland	Theory
% Purity	99.96	100.1	100.0
Thermodynamic pKa	4.76	4.74	4.75[a] 4.76[b,c]

[a] Determined from conductance measurements (5). [b] Data reported at an ionic strength of 0.0004 M (6). [c] Data reported at infinite dilution (7).

Activity Coefficient.—For evaluating Z', it is necessary to convert the hydrogen ion activity, obtained from the pH value, to a concentration term by use of an activity coefficient. In their work, Benet and Goyan used the single ion activity coefficients determined from theoretical considerations by Kielland (3). For the authors' calculations, the more familiar, experimentally obtained, $\gamma\pm$ values as listed in Lewis and Randall (4) were employed. These two types of activity coefficients differ somewhat.

In an attempt to determine which activity coefficient value is the better for use in these studies, blank solutions were prepared containing all constituents except the material being titrated. Therefore, since the ionic strength and amount of HCl present were known, the apparent activity coefficient could be evaluated by converting the pH of a solution to hydrogen ion activity, and dividing this by the known hydrogen ion concentration. The results of this study (Table I) indicate that the values obtained more closely approximate the $\gamma\pm$ values than they do the theoretically determined ones.

In addition, the purity and ionization constant of acetic acid were calculated using both the Kielland and $\gamma\pm$ values (Fig. 1). When $\gamma\pm$ is employed, the relationship is linear over the entire range studied, whereas with data at higher ionic strengths (0.09 and 0.05) the Kielland single ion coefficient

[1] For the titration of a base to which a fixed amount of HCl (W) has been added, $Z' = A^0 - K^c \frac{Z'}{[H^+]}$ where $Z' = W + OH^- - H^+ - M^+$.

[2] When an amount of HCl (W) is added to the solution, $Z' = H^+ + M^+ - W - OH^-$. These studies are often performed in a pH range where the hydroxyl ion is considered negligible, and $Z' = H^+ + M^+ - W$.

produces a curved segment at lower pH values.[3] In calculating the purity and ionization constant, only the linear portion of each plot was used. Nevertheless, it may be seen (Table II) that the intercept obtained (and therefore the purity evaluated) is not markedly influenced by the choice of activity coefficient. It is rather the ionization constant that reflects the difference, as may be seen by the two slopes in Fig. 1. A plot of pKa′ *versus* $\sqrt{\mu}$ demonstrated an essentially linear relationship for both sets of data. These were extrapolated to infinite dilution to evaluate a thermodynamic ionization constant. The results (Table II) indicate that the pKa obtained with both values are consistent with the literature (5–7). Therefore, since the two sets of data are the same, the type of activity coefficient employed for calculations appears to be a matter of personal choice.

[3] In this area of the titration, hydrogen ion makes its greatest contribution to Z' values, so that an error in the activity coefficient would be most evident at these higher acidities. This is comparable to Benet and Goyan's type A curve in Fig. 1 (2) for the case where high erroneous pH values are substituted. In all cases the Kielland values are higher than the $\gamma\pm$, and would result in a lower hydrogen ion concentration.

Identification of Some Barbiturates by Paper and Thin-Layer Chromatography

By Z. F. AHMED, Z. I. EL-DARAWY, M. N. ABOUL-ENEIN, M. A. ABU EL-NAGA, and S. A. EL-LEITHY

Paper and thin-layer chromatographic procedures are described which can serve to separate a multiple mixture of 12 different barbiturates of toxicological interest.

THE APPLICATION of paper and thin-layer chromatography seems, so far, to be the most promising approach in the identification of barbiturates (1–9). The different procedures adopted leave much to be desired and a simple method for the separation and identification of a multiple mixture of barbiturates is of great value in medico-legal analysis.

A simple, rapid method of separation and identification of 12 barbiturates encountered either alone or in a mixture during the toxicological studies in the National Centre of Criminological Research is reported in this paper. The procedures adopted are based on the application of both paper and thin-layer chromatographic techniques to the following barbiturates: phenobarbital U.S.P., cyclobarbital,[1] barbital U.S.P., diallylbarbituric acid N.F., allylisopropylbarbituric acid,[2] butobarbital,[3] amobarbital U.S.P., secobarbital U.S.P., methylphenobarbital,[4] ethyl-*n*-hexylbarbituric acid,[5] pentobarbital U.S.P., and hexobarbital.[6]

EXPERIMENTAL

Paper Chromatography

The earlier attempt of Kybing (3) and Ledvina (4) for the chromatographic separation of barbiturates on formamide paper gave promising results. It was, therefore, decided to find out the most appropriate system of formamide and the developing solvent which fulfills speedy and efficient separation.

The following systems were investigated: (*A*) paper impregnated with formamide, (*B*) solvent containing formamide, and (*C*) formamide included in both the paper and the solvent.

Paper.—Sheets of Whatman No. 1 filter paper were impregnated with 20–30% formamide in acetone for about 10–15 min. The air-dried sheets were kept in a dark place away from dust. It is recommended that the paper be freshly impregnated.

Solvents.—Chloroform–benzene–ammonium hydroxide, concentration 13:3:6, was employed for system *A* (paper impregnated with formamide). Chloroform–*n*-butanol–formamide–5 *N* ammonium hydroxide, concentration 5:3:1:3, was employed for system *B* (solvent containing formamide). Chloroform–benzene–formamide–5 *N* ammonium hydroxide, concentration 12:2:1:5, was employed for system *C* (formamide included in both the paper and the solvent).

Reagent.—Silver reagent: (*a*) Silver nitrate, A. R., 0.5% methanolic solution. (*b*) Methanol–ammonium hydroxide, concentration 9:1. (*c*) Sodium hydroxide, A. R., 5% methanolic solution. The reagent is prepared by mixing solutions (*a*), (*b*), and (*c*) in the ratio 5:1:2. The reagent has to be freshly prepared.

Standard Solution of Barbiturates.—The above-mentioned barbiturates were used in a chloroform solution of a concentration of 1.5 mcg./μl.

Procedure.—The sheets were spotted in duplicate with 3–4 μl. of the chloroformic solution of the barbiturates and placed into a chamber previously saturated with the stationary phase. The solvent front de-

TABLE I.—R_f VALUES OBTAINED USING STANDARD SOLUTIONS OF BARBITURATES[a]

Barbiturate Used	Solvents A	B	C
Barbital	0.06	0.65	0.09
Phenobarbital	0.07	0.58	0.06
Secobarbital	0.13	0.80	0.56
Diallylbarbituric acid	0.15	0.68	0.12
Cyclobarbital	0.18	0.70	0.23
Allylisopropylbarbituric acid	0.19	0.69	0.29
Butobarbital	0.24	0.73	0.35
Amobarbital	0.31	0.72	0.46
Pentobarbital	0.41	0.83	0.64
Ethyl-*n*-hexylbarbituric acid	0.58	0.79	0.78
Methylphenobarbital	0.63	0.71	0.90
Hexobarbital	0.77	0.76	0.85

[a] R_f values given here represent the average of 6 determinations.

TABLE II.—R_f VALUES OF BARBITURATES OBTAINED BY USING SILICA GEL G AND KIESELGUHR[a]

Barbiturate Used	Mobile Phase[b] (a)	(b)	(c)
Phenobarbital	0.20	—	—
Cyclobarbital	0.30	0.46	...
Barbital	0.31	0.13	...
Diallylbarbituric acid	0.34	0.24	...
Allylisopropylbarbituric acid	0.50		...
Butobarbital	0.53	...	...
Amobarbital	0.58	...	...
Secobarbital	0.63	...	0.43
Methylphenobarbital	0.64	...	0.90
Ethyl-*n*-hexylbarbituric acid	0.64	...	0.67
Pentobarbital	0.66	...	0.50
Hexobarbital	0.77	—	—

[a] R_f values given here represent the average of 6 determinations. [b] (*a*) for Silica Gel G; (*b*) and (*c*) for kieselguhr.

scended to the proper height (30 cm.) within 2–2.5 hr. After drying at room temperature in a stream of air for 10–15 min., the barbiturates were developed as white spots using the standard method of spraying with silver reagent (10). Table I shows the typical results obtained using the standard solution of barbiturates.

Thin-Layer Chromatography

Apparatus.—The apparatus used was essentially the one designed by Stahl (11) using 20 × 20 cm. glass plates.

Adsorbent.—Silica Gel G (Merck); kieselguhr (Merck) impregnated with formamide.

Mobile Phase.—(*a*) Ethyl acetate *n*-hexane–ammonium hydroxide, concentration 20:9:10, was employed for the Silica Gel G. (*b*) Carbon tetrachloride–chloroform, concentration 1:2, was employed for kieselguhr. (*c*) Carbon tetrachloride–chloroform, concentration 1:1, was employed for kieselguhr.

Reagent.—Silver reagent (10).

Standard Solution of Barbiturates.—The above-mentioned barbiturates were used in a chloroformic solution of a concentration of 1.5 mcg./μl.

Procedure.—Each plate was covered to a thickness of about 250 μ with a paste consisting of 4 Gm. of silica gel in 12 ml. of distilled water (or 4 Gm. kieselguhr in 16 ml. of 20% formamide in acetone). Precautions were taken to prevent air bubbles. The chromatoplates were dried in air for 15 min. at 105° (for silica gel) and 1 hr. at 60° (for kieselguhr).

The plates while still hot were spotted in duplicate with 3–4 μl. of the chloroformic solution of the barbiturates, and placed into a chamber containing the mobile phase. The solvent front ascended to the proper height (15 cm.) within 45 min. (in case of silica gel) and 20 min. (in case of kieselguhr). After drying at room temperature in a stream of air for 15 min., the barbiturates were developed as white spots against a grayish brown background using the standard method of spraying with silver reagent (10).

DISCUSSION

The 2 systems, *viz.*, paper impregnated with formamide and formamide included in both the paper and the solvent afforded satisfactory means of separation of the multiple mixture of barbiturates. The only 2 instances in which the separation failed when applying these 2 systems were phenobarbital–barbital and cyclobarbital–allylisopropyl barbituric acid mixtures as shown in Table I.

Regarding the thin-layer chromatography, silica gel gave 5 distinct ranges of R_f values, *viz.*, phenobarbital (R_f 0.2), cyclobarbital–barbital–diallylbarbituric acid (R_f 0.32), allylisopropylbarbituric acid–butobarbital–amobarbital (R_f 0.54), secobarbital – methylphenobarbital – ethyl - *n* - hexylbarbituric acid–pentobarbital (R_f 0.64), and hexobarbital (R_f 0.77). When applying kieselguhr as adsorbent, the cyclobarbital–barbital–diallylbarbituric acid mixture as well as secobarbital–methylphenobarbital–ethyl-*n*-hexylbarbituric acid–pentobarbital mixture could be effectively separated as shown in Table II.

Physicochemical and Physiologic Factors Affecting the Absorption of Warfarin in Man

By ROBERT A. O'REILLY*, EINO NELSON†, and GERHARD LEVY‡

The relationship between the *in vitro* dissolution kinetics and the *in vivo* intestinal absorption characteristics of tablet preparations of the coumarin anticoagulant warfarin has been studied. The composition of the dissolution medium had a significant quantitative and qualitative effect on dissolution kinetics. Warfarin absorption in man varied with respect to lag time, absorption rate constants, and the type of kinetics observed. These variations may result from variable gastric emptying times and from differences in the pH of gastric fluids.

THE IMPORTANCE of pharmaceutical formulation in modifying the gastrointestinal absorption of drugs from tablets has been documented extensively (*References 1–3* and references cited therein.) To predict the *in vivo* absorption characteristics of various preparations, reliable *in vitro* testing procedures must be available. Recent studies (4, 5) have suggested that the development of such testing procedures may be feasible. Consistent absorption rate and complete physiologic availability are desired characteristics for all drugs, but these properties are particularly necessary for the coumarin anticoagulants. These agents have important therapeutic indications, *e.g.*, coronary heart disease, pulmonary embolism, and prevention of clotting after insertion of artificial heart valves. The magnitude and duration of pharmacologic activity of this class of drugs is a function of drug level in the body (6); excessively high coumarin levels can lead to hemorrhage with potentially disastrous consequences. The incidence of bleeding during anticoagulant therapy is related directly to excessive reduction of prothrombin activity (7).

The dosage form characteristics of coumarin anticoagulants can have a pronounced effect on their absorption. Lozinski (8) reported that a change in formulation of bishydroxycoumarin tablets caused such an augmentation of the therapeutic response that hemorrhage ensued in some instances. O'Reilly *et al.* (9) administered bishydroxycoumarin as tablets, powder, and solution and found appreciable differences in and correlations between the time of maximum blood levels and the onset of action. The drug was rapidly absorbed as a solution and slowly absorbed as tablets. From 10 to 30% of the dose was recovered in the feces after administration of tablets; no unchanged drug was found in the feces after intravenous administration. Warfarin is more readily and completely absorbed than bishydroxycoumarin (9). A comparison of warfarin blood levels after oral administration of 100 mg. in solution, in tablets containing the drug as the free acid, and in tablets containing sodium warfarin, showed that the most rapid absorption occurred from solution (9). Surprisingly, the free acid in tablets was as readily absorbed as the sodium salt in tablets (9).

The purpose of the present study was to compare the *in vitro* dissolution and *in vivo* absorption characteristics of different tablet preparations of warfarin and to examine the relationship between these two properties.

† Deceased.

EXPERIMENTAL

Absorption Study.—Normal adult volunteers received 100 mg. of warfarin (as 25-mg. tablets) orally in the morning on an empty stomach. The tablets were swallowed whole together with 250 ml. of water. Food was withheld for at least 2 hr. after drug administration. Blood specimens were obtained at frequent intervals (3 to 7 samples) during the first 6 hr., and then at 12, 24, 48, and 72 hr. after drug administration. Warfarin concentrations in plasma were determined by the method of O'Reilly *et al.* (10). The amount absorbed as a function of time was calculated by the method of Wagner and Nelson (11).

Determination of Dissolution Rate.—*In vitro* dissolution tests were carried out by the beaker method of Levy and Hayes (12). For the initial screening tests 350 ml. water was used as the dissolution medium and a stirring rate of 60 r.p.m. was employed. In subsequent tests, the dissolution medium consisted of 300 ml. of 0.01 to 0.1 *N* hydrochloric acid for the first 30 min. Fifty milliliters of tris(hydroxymethyl)aminomethane solution of sufficient concentration to yield a final pH of 7.4 was then added. A stirring rate of 50 r.p.m. was employed in these experiments. From 3 to 5 tablets were used for each test. Warfarin was determined spectrophotometrically at 270 and 306 mμ in the organic phase obtained after chloroform (5 ml.) extraction of a 3-ml. aqueous sample acidified by addition of 1 ml. of concentrated HCl.

Tablet Preparations.—The several tablet preparations tested consisted of commercially available as well as experimental formulations obtained from a pharmaceutical manufacturer. Each of the tablets contained 25 mg. of warfarin as the free acid or the sodium salt.

RESULTS AND DISCUSSION

The *in vitro* dissolution rate in water of 7 different tablet preparations was evaluated. Markedly different rates were observed; dissolution half-lives ranged from 4 to about 1400 min. Data for 4 of the preparations are shown in Fig. 1. A and C are commercial products containing sodium warfarin, B is an experimental formulation containing sodium warfarin, and D is an experimental formulation containing warfarin as the acid. Preparations A and B dissolved rapidly, C dissolved slowly, and D very slowly. Accordingly, forms A, C, and D were chosen for clinical study.

The times for 50% *in vivo* absorption (including absorption lag time) of the 3 preparations in a total of 10 tests are listed in Table I. There were marked

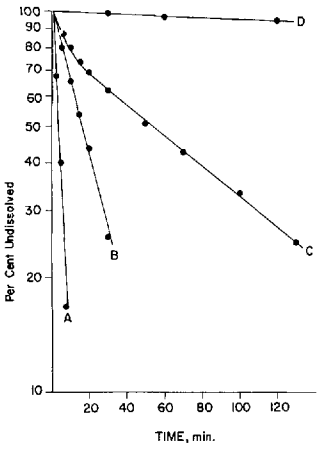

Fig. 1.—Semilogarithmic plot of per cent warfarin undissolved from several tablet formulations *vs.* time. The medium used was distilled water.

TABLE I.—TIME FOR 50% ABSORPTION[a] OF WARFARIN FROM DIFFERENT TABLET PREPARATIONS

Subject	Sex	Age	Prep. A	Prep. C	Prep. D
1	M	32	20	135	57
2[b]	F	36			48
3	M	24	21		
			84	230	
4	M	25	78	230	114

[a] In minutes. [b] This subject received 75 mg.; all others received 100-mg. doses.

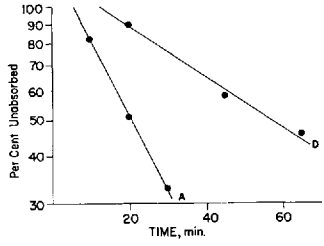

Fig. 2.—Apparent first-order absorption of warfarin from preparations A (subject *3*) and D (subject *1*).

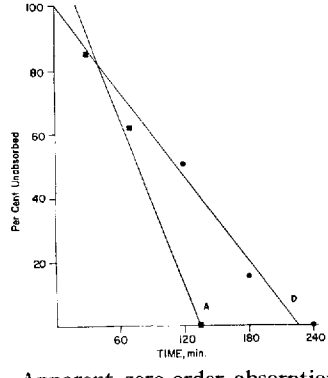

Fig. 3.—Apparent zero-order absorption of warfarin from preparations A (subject *3*) and D (subject *4*).

intra-product differences which overshadowed any product-to-product differences. Based on the dissolution rate experiments, product D was expected to be very slowly and incompletely absorbed. Actually, absorption was quite rapid and complete in each case, as determined from the area under the blood level *versus* time curves and the prothrombin times. The variability of absorption was apparently not due to individual differences between test subjects; subject *3* showed a fourfold variation in absorption half-time on repeated experiments.

Although the variability of absorption made it difficult to obtain blood samples at optimum intervals, the kinetics could be determined in most of the experiments. Preparations A and D, which differed so markedly in the *in vitro* dissolution test, were of particular interest. They were absorbed by both apparent first and zero-order kinetics. Data indicative of apparent first-order absorption are shown in Fig. 2, and examples of apparent zero-order absorption kinetics are depicted in Fig. 3.

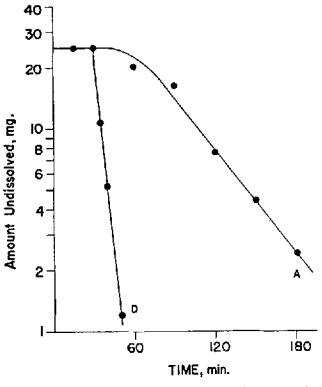

Fig. 4.—Apparent first-order dissolution of warfarin preparations A and D. Conditions: 30 min. dissolution in 0.1 *N* HCl, then dissolution in the medium brought to pH 7.4 by adding tris(hydroxymethyl)aminomethane.

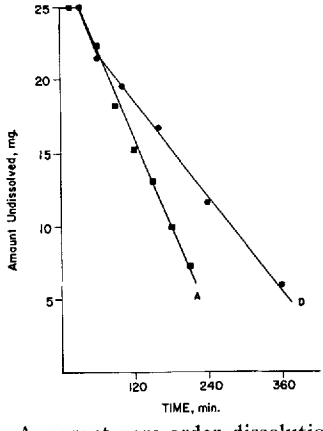

Fig. 5.—Apparent zero-order dissolution of warfarin preparations A and D. Conditions: 30 min. dissolution in 0.01 *N* HCl, then dissolution in the medium brought to pH 7.4 by adding tris(hydroxymethyl)aminomethane.

The marked contrast between the results of the clinical study and those of the dissolution experiments prompted an examination of the conditions of the dissolution procedure and their effect on the dissolution kinetics of warfarin in different tablet preparations. Small changes in stirring rate did not affect significantly the relative dissolution rates of the different preparations. The use of a buffer solution at pH 7.4 instead of water did not result in significant changes. Essentially no dissolution occurred in 0.01 to 0.1 *N* hydrochloric acid solutions because of the extremely low aqueous solubility of warfarin acid. However, tablets A and D disintegrated readily in 0.1 *N* hydrochloric acid but not in water or in 0.01 and 0.05 *N* hydrochloric acid. Based on this observation and the analogy to the passage of drug from the acidic environment of the stomach to the more neutral intestinal fluids, dissolution rates were determined under the following conditions. The tablets were placed in 0.01, 0.05, or 0.1 *N* hydrochloric acid for 30 min., and tris-(hydroxymethyl)aminomethane was then added to increase the pH of the medium to 7.4.

Under these conditions tablets A and D dissolved by apparent first-order kinetics after exposure to 0.1 *N* hydrochloric acid (Fig. 4), and by apparent zero-order kinetics after exposure to 0.05 or 0.01 *N* hydrochloric acid (Fig. 5). While tablets A dissolved about 350 times more rapidly than tablets D in water (Fig. 1), tablets D dissolved about 14 times faster than tablets A in pH 7.4 buffer after exposure to 0.1 *N* hydrochloric acid (Fig. 4).

The results of the dissolution experiments with hydrochloric acid solutions as the initial medium correlate with the clinical studies, and serve to explain the surprisingly rapid absorption of the warfarin acid tablets. The dissolution data, together with physiologic considerations, may also explain the qualitative and quantitative variability observed in the absorption study. Warfarin is almost insoluble in acidic gastric fluids and is therefore apparently not absorbed from the stomach. This has been demonstrated already in previously reported experiments (9) and may account for the lag times for absorption. For example, the longer time required by subject *1* to absorb warfarin from solution than from tablets A probably resulted from fortuitously rapid gastric emptying of the tablets in the latter instance. The variation in the type of absorption kinetics observed (*i.e.*, zero-order or first-order) can result from variations in the pH of gastric fluids within the physiologic range (13). Thus, absorption of warfarin from tablets A and D is determined in part by gastric emptying rate and gastric pH. Absorption from tablets C is probably influenced mainly by gastric emptying, since dissolution was not affected markedly by variations in the concentration of hydrochloric acid in the *in vitro* experiments.

The results of this study show the pronounced effect of solvent composition on dissolution kinetics of drugs in certain tablet formulations. The study illustrates also the difficulty of obtaining correlations with *in vitro* dissolution rates when absorption is influenced markedly by gastric emptying rate. Similar results were obtained recently with enteric-coated tablets (14). Because of the long half-life of warfarin (10), the blood levels of this drug are relatively insensitive to variations in absorption rate, unless absorption is so slow that the drug is absorbed incompletely. With more rapidly eliminated drugs, wide variations in absorption rates could limit seriously their usefulness for oral administration, even if complete absorption occurs in each case. The need for pretreatment with acid in order to obtain rapid dissolution, observed with tablets A and D, suggests that these tablets have a matrix which dissolves or disintegrates readily only in acid. It would be desirable that, in most instances, conventional compressed tablets be so formulated that release of the active ingredient is not a sensitive function of pH in the physiologic range.

Analgesic and Local Anesthetic Activity of Dimethyl Sulfoxide

By RALPH W. MORRIS

To provide data with which to settle some of the current controversy over the clinical claims for dimethyl sulfoxide (DMSO) specific pharmacologic tests were performed. DMSO is "relatively nontoxic" to rodents but appears to be more toxic as the phylogenetic order is ascended. Considerable irritation results from the introduction of DMSO into the conjunctival sac of the rabbit. No topical or nerve block anesthetic activity was demonstrated. Infiltration anesthetic potency of DMSO was so low as to be of no therapeutic importance. No analgesia, free of sedation, was found. Topical application of trypan blue with DMSO produced considerable dermal staining but no distribution of the dye as contrasted with the rapid systemic absorption and distribution of the dye when given subcutaneously with DMSO. No evidence was obtained in these experiments which could support clinical claims made to date.

CONSIDERABLE controversy has been aroused by recent claims of striking clinical activity by dimethyl sulfoxide (DMSO) in certain musculoskeletal injuries and inflammations, including acute and chronic subacromial bursitis, acute musculoskeletal trauma, osteoarthritis, rheumatoid arthritis, gouty arthritis, scleroderma, and Dupuytren's contracture (1, 2). In an attempt to resolve some of the controversy specific pharmacologic tests were selected to determine whether the reported activity in man could be demonstrated in laboratory animals. Special consideration was given to testing for DMSO activities most nearly associated with the therapeutic claims of "local analgesia," "penetrant carrier," and "relatively nontoxic" (1).

EXPERIMENTAL

DMSO, certified reagent grade, Fisher Scientific Co., was kept in tightly sealed bottles since DMSO is very hygroscopic, rapidly picking up 70% of its own weight in water while evolving as its heat of solution 60 cal./Gm. at 20° (3). Analgesic activity was made relative to several standard analgesics (*i.e.*, morphine sulfate, meperidine hydrochloride, and codeine phosphate). Analgesic activity was determined in Carworth Farms (CF-1) mature female albino mice by the classical hot plate method, essentially that of Ohlsson (4), and by the Bianchi and Franceschini (5) modification of the Haffner tail clamp method (6). The DMSO was administered intraperitoneally, 0.01 ml./Gm. of mouse body weight, in at least 4 doses between 5.5 and 11.0 Gm./Kg., diluting with 0.9% saline whenever necessary. Design was such that the sample size was at least 10 and usually 20 mice per test dose of each drug. Three types of local anesthetic activity were investigated: topical anesthesia by the classical corneal response in rabbits, infiltration anesthesia by the guinea pig intracutaneous wheal technique of Bulbring and Wajda (7), and nerve block anesthesia by a modification of the frog sciatic nerve-gastrocnemius muscle preparation of Sinha (8). Three to 6 guinea pigs with 6 response sites per guinea pig were used for each dose of drug in the intracutaneous wheal test. Procaine and lidocaine hydrochlorides served as standards.

The effects of DMSO on membrane permeability were determined by noting the latent periods required for the adsorption, distribution, and subsequent discoloration of connective tissues from topically and subcutaneously administered trypan blue in mice. All median response doses (*i.e.*, ED_{50} and LD_{50}) and their 95% confidence limits were determined by the method of Litchfield and Wilcoxon (9), whereas all other statistical analyses were performed by the methods of Snedecor (10).

Received September 9, 1965, from the Department of Pharmacognosy and Pharmacology, College of Pharmacy, University of Illinois at the Medical Center, Chicago.

Accepted for publication January 12, 1966.

The author expresses his appreciation for the technical assistance of Oliver Mitchell and Hiroshi Nakano.

RESULTS AND DISCUSSION

Toxicity.—A primary concern with the introduction of any new substance into human pharmacology is the precision with which projections of acute human toxicity can be made from tests on laboratory animals. Table I summarizes the available data on the acute lethality of DMSO as obtained from the literature (11, 12) and experiments recently completed in this investigator's laboratory. From Table I it would appear that a variably increasing lethality to DMSO occurs as the phylogenetic order is ascended.

Ventricular fibrillation and death occurred within 3 min. after the administration of 1.65 Gm./Kg. of 100% DMSO into the marginal ear vein of the rabbit. The LD_{50} for intravenous DMSO in female albino rabbit was 1.34 Gm./Kg. based on 3 doses between 1.10 and 1.65 Gm./Kg. given to a total of 28 rabbits. Female rabbits appear to be more sensitive to DMSO than are rodents, but are about equally sensitive as male dogs (Table I). DMSO

TABLE I.—ACUTE LETHALITY OF DIMETHYL SULFOXIDE

Animal	Rt. of Administration[a]	LD_{50} in Gm./Kg. (95% Confidence Limits)
Chicken	Oral	13.74[b]
Mouse		
	i.v.	5.75[c]
	i.p. (male)	10.10 (9.22–11.06)
	i.p. (female)	9.95 (9.35–10–59)
	Oral	21.40[c]
	Oral	21.98[b]
Rat		
	i.v.	5.36[c]
	Oral	28.30[c]
Rabbit	i.v. (female)	1.34 (0.96–1.88)
Dog		
	i.v. (male)	2.40[c]
	i.v. (male)	1.50[d]

[a] Routes of administration: i.v., intravenous; i.p., intraperitoneal. [b] From Brown *et al.* (11). [c] From Wilson *et al.* (12). [d] Preliminary value based on intravenous titration in 4 dogs.

might therefore be said to be "relatively nontoxic" (1) when relating chickens or rodents to rabbits and dogs. To date human toxicity following topical application consists of warmth, erythema, itching, local urticaria, increased skin pigmentation, dermatitis, fatigue, and lethargy (2). This observed topical toxicity plus the relative ease with which DMSO is said to be absorbed through the epidermis (1) should arouse considerable concern over the potential systemic toxicity of DMSO in man if it were applied *via* a route of administration (*e.g.*, parenteral) or to hyperpermeable tissue (*e.g.*, inflamed or open wounds) thereby facilitating an even more rapid and extensive absorption and distribution than by the topical route. There has been a recent report of a death possibly related to an acute allergic reaction to DMSO (13). Such reports must be thoroughly investigated, however.

Analgesia.—The unusual term "local analgesia" as used by Rosenbaum *et al.* (1) does not give recognition to the striking pharmacologic difference between analgesics and local anesthetics. Therefore, specific tests were made to determine if DMSO was a local anesthetic, an analgesic, or both. (Table II.) The analgesic ED_{50} for DMSO and morphine sulfate in mice are 6700 and 15 mg./Kg., respectively, using the Haffner tail clamp method 20 min. after the intraperitoneal administration of the test solutions. The other analgesics tested are all less potent than morphine which is in keeping with their known clinical potency. Attempts to determine DMSO analgesic activity in mice by the classical hot plate method were unsuccessful because DMSO produced extensive sedation thereby making the mouse incapable of performing the test response (*i.e.*, jumping to the lip of a 10-in. high glass cylinder sitting on a thermostatically controlled hot plate maintained at 60 ± 0.5°). On the basis of this observation a sedative rather than analgesic ED_{50} for subcutaneously administered DMSO was determined as being 6.92 Gm./Kg. Criteria for the sedative end point was the presence of a thoroughly depressed, immobile, but not ataxic mouse which was still capable of righting itself from the dorsal to the ventral positions within a 30 sec. test period (*i.e.*, neither asleep nor anesthetized). Such similarity in the DMSO sedative and analgesia ED_{50} values seriously question whether the failure of the mice to respond to the Haffner tail clamp stimulus might not be equally as well explained on the basis of sedation as analgesia. This possibility is presently being explored.

TABLE II.—CENTRAL NERVOUS SYSTEM ACTIVITY OF DIMETHYL SULFOXIDE IN THE MATURE FEMALE ALBINO MOUSE

Pharmacologic Activity	ED_{50}, mg./Kg. (95% Confidence Limits)	No. Doses	Total Sample Size
Sedation, s.c.			
DMSO	6920 (3980–12040)	2	20
Analgesia, i.p. Haffner tail clamp			
DMSO	6700 (6200–7240)	5	110
Morphine sulfate	11.6 (9.47–14.21)	5	110
Meperidine HCl	38.3 (31.39–46.73)	3	90
Codeine phosphate	34.5 (28.51–41.75)	4	100
Dextropropoxyphene HCl	36.7 (31.75–42.43)	3	60

	ED_{50} in % Soln. (95% Confidence Limits)
Topical	
Rabbit (female):	
DMSO	Inactive[a]
Infiltration	
Guinea pig (female):	
DMSO	51.0 (38.5–67.6)
Lidocaine HCl	1.17 (0.90–1.52)
Procaine HCl	0.84 (0.62–1.13)
Sciatic nerve block	
frog: DMSO	Inactive[a]

[a] No anesthesia produced by maximum dosage used, a 100% solution.

Local Anesthesia.—No alterations in the pupillary response to penlight illumination or to touch with a glass probe were noted during 2 hr. test periods following the instillation into the conjunctival sac of the rabbit of 0.25 ml. of DMSO solutions, varying from 30 to 100%. In contrast to the nonirritant report of Brown (11) all 24 female albino rabbits that received DMSO, irrespective of the per cent concentration, experienced considerable conjunctival inflammation and limbic corneal vasodilatation. The irritation and vasodilatation cannot be solely the consequence of the heat of solution (*i.e.*, counter-irritant activity) since even 30% solutions (well below the 62% equillibrium point of DMSO–water mixture) produced irritation and vasodilatation. The duration of the severe irritation (30.8 ± 20.7 min.) does not appear to be dose dependent; however, the experiments were not designed to provide statistical evaluation of such a regression function. A positive corneal reflex to touch with a glass probe (*i.e.*, an eyelid movement) was present before and throughout the 90 min. period following the introduction of all per cent solutions of DMSO into the conjunctival sac. In all 24 rabbits tested with DMSO, blockade of the corneal reflex was produced after 90 min., the blockade persisting for the remainder of the test period (*i.e.*, 120 min. in 19 rabbits and 165 min. in 5 rabbits). No explanation of this delayed blockade of the corneal reflex is possible, since the experiments were not designed with this question in mind.

The ED_{50} of DMSO as an infiltration anesthetic was 51.0% solution compared to the ED_{50} of 1.17 and 0.84% solutions for lidocaine and procaine hydrochlorides, respectively. (Table III.) No evidence of nerve block anesthesia was obtained when 100% DMSO was tested on each of four sciatic nerve-gastrocnemius muscle preparations; therefore, further nerve block testing was discontinued.

Membrane Permeability.—Topical application of 1% solutions of trypan blue in either distilled water or DMSO solutions varying from 50–100% to the shaved scapular area of the mouse failed to induce systemic absorption and distribution of trypan blue, although extensive staining at the site of application occurred with the solutions containing

DMSO. However, the administration of 1% trypan blue in solution with 50–100% DMSO facilitated the speed with which subcutaneous injections of 1% trypan blue were absorbed and distributed to the connective tissues in the ears, tail, and paws of mice. Trypan blue in DMSO solutions were significantly more rapidly distributed than 1% trypan blue in distilled water (*i.e.*, 6.9% more rapidly in 50% DMSO and 3.9% faster in 100% DMSO: each with $p < 0.001$). After 24 hr. all mice that had received topical administration of 1% trypan blue, with or without DMSO, showed no signs of the typical bluish discoloration of connective tissues. On the other hand, the previously noted statistically significant effect of subcutaneously administered DMSO on the absorption and distribution of trypan blue solutions were even more evident after 24 hr., *i.e.*, all visible connective tissues were dark blue after trypan blue in 100% DMSO, moderately blue in 50% DMSO, and pale blue when in distilled water.

All animals receiving DMSO, regardless of dosage, very rapidly (*i.e.*, usually within 2 or 3 min.) gave strong evidence in their expired air of extremely rapid DMSO metabolism, *i.e.*, to dimethyl sulfone in mice, guinea pigs, rabbits, and dogs (11, 14); to dimethyl sulfide in cats (15); and to unspecified metabolites in man (1, 2, 14). Shortly thereafter similar evidence could also be found in the urine, feces, and saliva.

The rapidity with which DMSO is metabolized jeopardizes precise determinations of chronic toxicities and confounds acute toxicities, especially when the DMSO is administered by any route other than the intravenous. Even DMSO data by the intravenous route of administration would have to be considered misleading if one accepts the literature reports that DMSO induces perivascular inflammation (12) and extensive protein denaturation as evidenced by the rapid development of hemolytic anemia (12, 15). No evidence of perivascular inflammation was seen in any of the 13 rabbits that survived the 1.10 Gm./Kg. dose of DMSO during the acute toxicity tests or during the 6 hr. of intravenous administration of DMSO in each of 4 dog carotid artery blood pressure preparations (16).

Unequivocal evaluation of the toxicologic and pharmacologic data for DMSO is therefore rather difficult. First, the physical properties, especially the heat of solution (3, 11), confounds attempts to attach chemical and/or biological mechanisms to observed pharmacologic responses. Second, the biochemical instability of DMSO in the systemic circulation is so great that an uncertain number of potentially and variably toxic metabolities are very rapidly produced. Third, determining precise values for such an impotent agent as DMSO makes for rather inaccurate estimates of its very subtle activities. Fourth, the public and scientific controversy attendant to the plethora of DMSO lay articles published to date[1] creates an atmosphere in which strictly objective evaluations by all parties is difficult. Recent statements by the Food and Drug Administration, U. S. Department of Health, Education, and Welfare (17–19), and in *Medical Letter* (2, 13) have introduced some stability into the very controversial therapeutic merits of DMSO.

On the basis of the experiments reported here, no evidence was obtained in support of the therapeutic claims of "local analgesia," "penetrant carrier," or "relatively nontoxic" in humans (1).

dl-2,6-Diamino-4-hexynoic Acid, a Growth Inhibitor

By JOHN L. NEUMEYER and WILLIAM FIRSHEIN*

***dl*-2,6-Diamino-4-hexynoic acid, a lysine analog, was synthesized by the interaction of *N*-(4-chloro-2-butynyl)phthalimide and the sodium salt of ethyl acetamidomalonate. A two-step hydrolysis yielded the desired acetylenic diamino acid. *dl*-Lysine, identical with the known amino acid, was obtained by the reduction of the triple bond in I. This acetylenic analog of lysine inhibited the growth of DNA, RNA, and protein synthesis in resting cell suspensions of pneumococci at a concentration of 100 mcg./ml.**

THE UNSATURATED amino acids, methallylglycine and crotylglycine, were first prepared by Albertson and co-workers, (1) and were found to be potent inhibitors of microorganisms. On the basis that olefinic unsaturation produces powerful inhibition of microorganisms, Gershon and co-workers (2) prepared two amino acids containing the acetylenic linkage, propargylglycine and 2-amino-3-methyl-4-pentynoic acid, and found that these acetylenic analogs were more potent growth inhibitors than their ethylenic analogs.

Similarly, several cyclopentenyl, cyclopentyl, and cyclohexenyl amino acids have been demonstrated (3, 4) to be competitive inhibitors of certain naturally occurring amino acids in various microorganisms. Unsaturation within the cycloalkyl moiety in all cases resulted in compounds acting as amino acid antagonists. The importance of steric requirements was further exemplified by Shive and co-workers (4) who synthesized *cis* and *trans* dehydrolysine and found the *trans* compounds to be the only isomer active as a competitive lysine antagonist.

Davis *et al.* (5) have recently reported that the introduction of a carbon-carbon triple bond into the carbon chain of lysine (I) forces the lysine into a fixed conformation and yields a competitive growth inhibitor of *Leuconostoc dextranicum* 8086. The authors were thus prompted to report their findings on the synthesis and biological properties of *dl*-2,6-diamino-4-hexynoic acid (I), their investigations having been carried out independently.

$$NH_2CH_2C{\equiv}C{-}CH_2CHNH_2COOH$$

"Acetylenic" Lysine

I

The authors' biological results (Table I) show that at a concentration of 100 mcg./ml., "acetylenic" lysine (I) is an effective inhibitor of DNA, RNA, and protein synthesis. Higher concentrations than 100 mcg./ml. do not increase the inhibition, while lower concentrations than 100 mcg./ml. are less effective. The control levels are depressed equally for all three components (about 80% inhibition). Since these results are obtained with "resting" cells (with respect to multiplication), it cannot be stated definitely that similar results would be obtained in growing (multiplying) cultures. However, since the synthesis of three essential components (DNA, RNA, and protein) required for *any* multiplication are inhibited by the modified lysine, it is likely that multiplication in growing cultures would also be inhibited. As for the mechanism of action of "acetylenic" lysine, at least two possibilities exist. One is that modified lysine may be a general growth inhibitor rather than a specific antagonist of DNA, RNA, and protein synthesis, since it is unlikely that the drug would affect reactions involved in the synthesis of all three components. Rather, it is possible that "acetylenic" lysine acts on some basic cell process that indirectly affects DNA, RNA, and protein synthesis, such as respiration. Two is that since the modified lysine was reported (5) to be a competitive antagonist of lysine, it is possible that the drug inhibits protein synthesis specifically, which then results in an inhibition of DNA and RNA synthesis.

EXPERIMENTAL[1]

N-(4-Chloro-2-butynyl)phthalimide.—To a solution of 74 Gm. (0.6 mole) of 1,4-dichloro-2-butyne (General Aniline and Film Corp.) in 1000 ml. of dimethylformamide at 90° in a 2-L. 3-necked flask equipped with a stirrer, thermometer, and a funnel was slowly added with constant stirring 55 Gm. (0.3 mole) of potassium phthalimide. Stirring with heating (90°) was continued for 4 hr. after which the solution was poured into an ice-water mixture.

The precipitate which formed was filtered (suction) and washed with 200 ml. of 5% sodium hydroxide followed by two washings with 200 ml. of water. The white crystals were dried (vacuum) and recrystallized from ethanol to yield 28 Gm. (40%), m.p. 121–122°. [Lit. (5) m.p. 120–121°.]

Anal.—Calcd. for $C_{12}H_8ClNO_2$: C, 61.75; H, 3.41; Cl, 15.21. Found: C, 61.69; H, 3.61; Cl, 15.15.

Ethyl 2-Acetamido-2-carbethoxy-6-phthalimido-4-hexynoate.—To a 500-ml. 3-necked flask fitted with a condenser and mechanical stirrer was added a solution of 21.8 Gm. (0.1 mole) of ethyl acetamidomalonate (Winthrop Laboratories) in 200 ml. of absolute ethanol. After the malonate had completely dissolved in the ethanol, 2.3 Gm. of sodium was added and the mixture was rapidly taken up to reflux temperature. At this point 30.4 Gm. of

Received December 8, 1965, from Arthur D. Little, Inc., Cambridge, Mass.
Accepted for publication February 11, 1966.
*Department of Biology, Wesleyan University, Middletown, Conn.

[1] All melting points are uncorrected and were obtained in a Thomas-Hoover silicone-filled capillary melting point apparatus.

N-(4-chloro-2-butynyl)phthalimide was added in 1 part. The reaction mixture was then heated at reflux for 8 hr., allowed to cool, and the solid precipitate was filtered off. The precipitate was then extracted with hot absolute ethanol and the extract was allowed to cool. White crystals of the hexynoate separated. These crystals were again recrystallized from absolute ethanol to yield 37% of product, m.p. 149–150°. [Lit. (5) m.p. 139–142°.]

Anal.—Calcd. for $C_{21}H_{22}N_2O_7$: C, 60.86; H, 5.35; N, 6.76. Found: C, 61.24; H, 5.62; N, 7.08.

Ethyl 2-Acetamido-6-phthalimido-4-hexynoate.—A small amount could be isolated from the above reaction by evaporation of the filtrate from the reaction mixture. The resulting red residue was triturated with water, the water decanted off, and the remaining solid recrystallized from absolute ethanol, m.p. 224–226°.

Anal.—Calcd. for $C_{18}H_{18}N_2O_5$: C, 63.15; H, 5.30. Found: C, 63.09; H, 5.55.

dl-2,6-Diamino-4-hexynoic Acid Hydrochloride.—Ethyl 2-acetamido-2-carbethoxy-6-phthalimido-4-hexynoate (41.5 Gm., 0.1 mole) was hydrolyzed with 5.5 Gm. of 85% aqueous hydrazine in 200 ml. of ethanol by the method of Sheehan (6). As the solution was taken up to reflux temperature, the hexynoate slowly went into solution and the reaction became clear, but shortly thereafter, phthalhydrazide began to precipitate as a white solid. After 1 hr. of stirring at reflux, the reaction mixture was cooled to room temperature, and the phthalhydrazide was filtered off. The reaction liquor was then reduced under vacuum to yield a viscous semi-clear yellow residue. Without further isolation the crude hydrazine hydrolysate was dissolved in a small amount of water and then was added to an excess of concentrated hydrochloric acid. This mixture was then stirred at reflux for 1.5 hr. The reaction mixture was cooled to room temperature and the solvents partially removed under vacuum, cooled in an ice bath, and filtered. This filtration was carried out in order to remove any residual phthalhydrazide.

The filtrate, containing the product, was then completely evaporated under vacuum, the residue triturated with acetone to yield a crystalline product. The product thus formed consisted of a mixture of the monohydrochloride and the dihydrochloride of "acetylenic" lysine (I). Pure monohydrochloride (11.1 Gm., 62% yield) was obtained by recrystallization of the mixture of the mono- and dihydrochlorides from an ethanol–water–pyridine solution. This compound melted at 236° when a sample was placed in the oil bath at 220° and heated at approximately 2°/min.[2]

Anal.—Calcd. for $C_6H_{10}N_2O_2 \cdot HCl$: C, 40.35; H, 6.16; Cl, 19.85; N, 15.69. Found: C, 40.56; H, 6.21; Cl, 19.3; N, 15.71.

Catalytic Hydrogenation of 2,6-Diamino-4-hexynoic Acid Monohydrochloride.—A solution of the monohydrochloride (0.1816 Gm.) of the acetylenic amino-acid (I) in water (10 ml.) was catalytically hydrogenated over platinum oxide (0.053 Gm.) at room temperature and atmospheric pressure. When 2 *M* equivalents of hydrogen had been absorbed, the catalyst was removed, the filtrate was reduced to dryness under reduced pressure, and the residue was crystallized from 5 ml. of 95% ethanol containing 2 drops of pyridine. The crystals which formed were filtered off and dried, m.p. 260–262°. [Lit. (7) m.p. 262–264°.] The melting point of a mixture of an authentic sample of *dl*-lysine monohydrochloride with a sample of the product isolated above was not depressed (m.p. 261–262°). The infrared spectra of this product was identical with that of an authentic sample of *dl*-lysine monohydrochloride.

Biological Test Methods.—Virulent pneumococci derived from type III (strain A66) were grown in 3 L. of a casitone, tryptone (both Difco), albumin (fraction V from bovine serum albumin, Armour) medium supplemented with glucose and K_2HPO_4 (8) for 24 hr. at 37°. After this time, additional glucose and phosphate were added and the cells were incubated for 3 hr. The viable cell count after this 3-hr. period was approximately $4–6 \times 10^9$ cells/ml. The culture was centrifuged in a refrigerated centrifuge (International) at 30,000 × g for 20 min., washed 3 times with cold Na-K-phosphate buffer (0.02 *M*, pH 7.5), and inoculated into 3 ml. of a suspending medium consisting of this same buffer, glucose, casitone (both 1.0%), and catalase (0.005%, Nutritional Biochemicals). The suspending medium was prepared double strength so that additions could be made without affecting the over-all concentration of the basic constituents. *dl*-2,6-Diamino-4-hexynoic acid hydrochloride was added in 4 concentrations: 25, 50, 100, and 200 mcg./ml. (in the suspending medium). All samples were prepared in duplicate and the inoculated suspensions contained $1–2 \times 10^9$ viable cells/ml. The suspensions were incubated at 37° for 70 min. in a gyrotory water bath shaker (New Brunswick Scientific) at 200 r.p.m. DNA, RNA, and protein were then extracted as described previously (9) and measured by the procedures of Brody (10), Drury (11), and Lowry *et al.* (12), respectively.

[2] Davis *et al.* (5) reported their 2,6-diamino-4-hexynoic acid dihydrochloride as having a m.p. 178–183° dec.

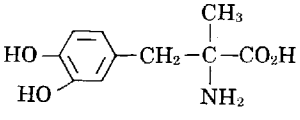
Cyclic Methyldopa Analogs as Potential Antihypertensive and Antineoplastic Agents

By J. H. BURCKHALTER and GÜNTER SCHMIED*

Three cyclic methyldopa analogs (III*a*, *b*, and *c*) were synthesized by hydrolysis of the appropriate spirohydantoins (V), which were obtained through the Bucherer synthesis. Amino acids (III*a* and *b*) and hydantoins (V*a* and *c*) were inactive against experimental tumors. The 5 hydantoins tested were devoid of anticonvulsant effect.

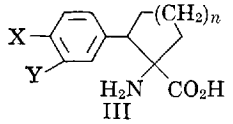
THE AMINO acid, methyldopa (I), is a recognized drug for hypertension (1), while another amino acid, 1-aminocyclopentane-1-carboxylic acid (NSC-1026, II), possesses inhibitory activity against



I

II

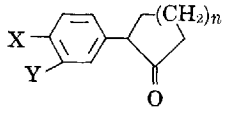
tumors (2). The structures of these substances, which are aliphatic α-amino acids fully substituted at the α position, suggested the synthesis of hybrids of I and II which are represented by structure III.



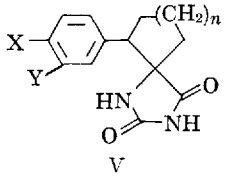
III

a, ($n = 1$, X = Y = H)
b, ($n = 2$, X = Y = H)
c, ($n = 2$, X = Y = OH)

The approach to compounds of type III was through appropriate ketones IV which were converted by



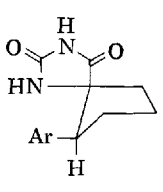
IV



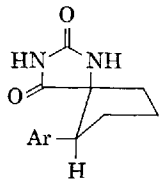
V

means of potassium cyanide and ammonium carbonate in a Bucherer-Bergs synthesis (3) to the spirohydantoins (V*a–e*) of Table I. Demethylation of hydantoins V*b*, *d*, and *e* to phenolic spirohydantoins (V*f*, *g*, and *h*) of Table I was effected by means of refluxing overnight with 47% hydriodic acid and glacial acetic acid. All the hydantoins of Table I exhibited characteristic infrared absorption at 3.1 μ and a doublet in the carbonyl region between 5.6 and 5.9 μ.

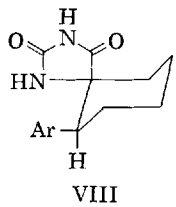
Hydantoins of structure V are representable by the following structures as *cis-trans* pairs (VI and VII; VIII and IX). However, separation of any



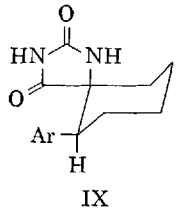
VI



VII



VIII



IX

isomers was not possible by means of thin-layer chromatography. In each case only a single spot was observable. This observation agrees with the recent conclusion (4) that the Bucherer-Bergs synthesis is stereoselective and only a small percentage yield of a second isomer is sometimes isolable.

Methods employing barium hydroxide or hydrogen chloride in glacial acetic acid failed to hydrolyze the spirohydantoins (V). Despite poor solubility, hydantoins (V*a* and V*c*) were hydrolyzed by heating at 140–150° with 60% sulfuric acid (5). After neutralization of the mixture with barium carbonate and desalting by ion-exchange resin, the yield of amino acid was 33% of III*a* and 51% of III*b*. The *N*-(2,4-dinitrophenyl) derivative of each amino acid was prepared. Amino acid (III*c*) was obtained by hydrolysis of hydantoin (V*e*) and demethylation of the unisolated intermediate by means of hydriodic acid. The crude hydriodide was converted to the hydrochloride of III*c* by ion exchange. Over-all yield from the hydantoin was 12%.

PHARMACOLOGICAL RESULTS

The following summary of results available to date was prepared from reports submitted by Dr. Joseph Leiter, Cancer Chemotherapy National Service Center, Bethesda, Md. Detailed information concerning test procedures may be found in publications from that office (6).

Amino acids (III*a* and *b*) and spirohydantoins V*a* and *c* were screened by the Southern Research Institute, Birmingham, Ala., and were all found to be nontoxic and inactive against sarcoma 180, solid Friend virus leukemia, and lymphoid leukemia L-1210 in mice and also inactive in cell culture.

Professor Ewart Swinyard, College of Pharmacy, University of Utah, found that spirohydantoins V*a*, *c*, *f*, *g*, and *h* were devoid of appreciable anti-

[a] Product analyzed correctly for monohydrate until dried at 150° (0.3 mm.). Previously reported by Tiffeneau, M., Tchoubar, B., Saiaslambert, M., and LeTellier-Dupré, M., *Bull. Soc. Chim. France*, **1957**, 445; m.p. 255°, yield 25%.

convulsant activity in mice as measured by maximal electroshock seizure test.

Owing to the difficulty of obtaining screening of compounds obtained under a grant from the National Institutes of Health, no data are available pertaining to possible antihypertensive activity of the amino acid (III).

EXPERIMENTAL

2 - Arylcycloalkanones.—2 - Phenylcyclopentanone (7), 2-phenylcyclohexanone (8), and 2-(4-methoxyphenyl)-cyclohexanone (9) were obtained as described in the literature. 2-(4-Methoxyphenyl)-cyclopentanone had not been prepared before. The method described in *Reference 9* was used, but difficulty was encountered in its isolation. Its identity was established by formation of the hydantoin (V*b*). 2-(3,4-Dimethoxyphenyl)-cyclohexanone, a new compound, was obtained from 3,4-dimethoxybenzaldehyde by a general method (10), but similarly the hydantoin (V*e*) was made from the crude ketone.

Spirohydantoins (Table I).—The general procedure of preparation was based upon that of Henze and Speer (11). The appropriate ketone was mixed with 2 equivalents of potassium cyanide and 4 equivalents of ammonium carbonate in about 300 ml. of 50% alcohol per 0.1 mole of ketone. In the case of V*c*, the starting ketone was first dissolved in 50 ml. of alcohol. The mixture was stirred for about 4 to 5 hr. at 58–60°. Cooling the mixture to room temperature yields a pure first crop. Furthermore, less pure product was obtained by evaporation of the filtrate to about two-thirds of its *volume and* then acidifying. (Hood!) The hydantoins were recrystallized from 50% alcohol.

Thin-layer chromatography of hydantions, using silica gel as adsorbent and with a developing time of 50 min., gave the following R_f values of approximately the same magnitude, for solvent system chloroform/acetone (1:1) and chloroform/acetone (2:1), respectively: V*a*, 0.83 and 0.59; V*c*, 0.79 and 0.54; and V*e*, 0.77 and 0.49. Sulfuric acid spray and heat were used for development of spots.

Demethylation of Hydantoins Vb, d, and e.—A mixture of 0.01 mole of the methoxyphenylspirohydantoin, 20 ml. of 47% hydriodic acid, and 20 ml. of glacial acetic acid was heated at reflux overnight. After the mixture was cooled and diluted with water, crystallization was induced. Evaporation of the mother liquors gave less pure product.

1 - Amino - 2 - phenylcyclopentane - 1 - carboxylic Acid (IIIa).—A mixture of 23 Gm. (0.1 mole) of crude hydantoin (V*a*) and 400 ml. of 60% sulfuric acid was heated with stirring for 6 hr. at 140–150°. The cooled solution was neutralized with barium carbonate, the precipitated barium sulfate was removed by filtration and washed several times with hot water. From the hot water 2.3 Gm. of unchanged V*a* separated. The solution was concentrated and desalted by absorption of the amino acid in a strongly acidic ion-exchange resin (Dowex 50), washing out the anions and replacing the amino acid with 2 *N* ammonia. When, upon concentrating, the amino acid began to crystallize, an equal volume of hot alcohol was added. Cooling gave 6.9 Gm. (34% yield) of III*a*, m.p. 290° dec. With paper chromatography, only 1 spot was obtained. Whatman's No. 1 paper was employed in ascending flow of solvent at room temperature for the following R_f values: 0.86 (120 butanol/30 glacial acetic acid/50 water); 0.89 (160 phenol/40 water); 0.83 (150 phenol/40 ethanol/10 water); 0.70 (60 butanol/60 pyridine/60 water). Ninhydrin spray was used for development.

Anal.—Calcd. for $C_{12}H_{15}NO_2$: C, 70.22; H, 7.37; N, 6.82. Found: C, 70.18; H, 7.41; N, 6.85.

N - (2,4 - Dinitrophenyl) - 1 - amino - 2 - phenylcyclopentane - 1 - carboxylic Acid.—This was made from III*a* and 2,4-dinitrophenyl-1-fluorobenzene (12). Two recrystallizations from dilute alcohol gave a product, m.p. 220–230° dec. Paper chromatography produced tailing. Thin-layer chromatography using Silica Gel G as adsorbent and solvent system 95 chloroform/5 methanol/1 glacial acetic acid gave after 50 min. R_f value 0.70 (single spot).

Anal.—Calcd. for $C_{18}H_{17}N_3O_6$: C, 58.45; H, 4.09; N, 11.38. Found: C, 58.68; H, 4.39; N, 11.20.

1 - Amino - 2 - phenylcyclohexane - 1 - carboxylic Acid (IIIb).—As in the preparation of III*a*, 26.2 Gm. (0.1 mole) of crude hydantoin V*c* was hydrolyzed. After 6 hr., 38% of V*c* was recovered, 28% after 24 hr., and none remained after 2 days of heating but carbonization resulted. In the last case, the yield of III*b* was 51%, m.p. 286–290° dec. Paper chromatography gave only 1 spot, and R_f values for the same solvent system used for III*a* were, respectively, 0.87, 0.85, 0.82, and 0.73.

Anal.—Calcd. for $C_{13}H_{17}NO_2$: C, 71.20; H, 7.82; N, 6.39. Found: C, 71.02; H, 8.02; N, 6.36.

N - (2,4 - Dinitrophenyl) - 1 - amino - 2 - phenylcyclohexane-1-carboxylic Acid.—This was made (12) as a derivative of III*b*, m.p. 204–206° dec., after 2 crystallizations from 50% alcohol. R_f 0.68 (thin-layer, adsorbent Silica Gel G, 95 chloroform/5 methanol/1 glacial acetic acid).

Anal.—Calcd. for $C_{19}H_{19}N_3O_6$: C, 59.22; H, 4.97; N, 11.16. Found: C, 59.34; H, 5.05; N, 11.10.

1 - Amino - 2 - (3,4 - dihydroxyphenyl) - cyclohexane-1-carboxylic Acid (IIIc) Hydrochloride.—A mixture of 20 Gm. (0.062 mole) of crude hydantoin (V*e*) and 400 ml. of 60% sulfuric acid was stirred and heated at 135–140° for 2 days. The dark solution was neutralized with barium carbonate. The precipitated barium sulfate was removed by filtration, washed with hot water, and the combined solutions evaporated to dryness to give 10 Gm. of dark brown material. It was dissolved in 100 ml. of 47% HI and heated at reflux for 24 hr. Diluted with water and filtered, the brown solution was extracted with ether. The aqueous layer was evaporated to dryness. The product was dried under reduced pressure to remove excess hydrogen iodide, after which it was dissolved in water and adsorbed on an ion-exchange column (Dowex 50). The iodide ions were removed with water and the amino acid eluted with 4 *N* hydrochloric acid. The solution was evaporated to dryness to give 3 Gm. of a slightly gray solid. It was purified by several reprecipitations from glacial acetic acid by ether. A yield of 1.8 Gm. (10% from V*e*) of slightly tan solid III*c* hydrochloride was obtained, m.p. > 300°.

The product is acidic and gives a dark green color with ferric chloride. I.R. spectrum shows a broad band at 2.8 to 4.55 μ, suggesting phenolic and carboxylic hydroxyls, C—H and RNH_3^+ absorption. A carbonyl peak appears at 5.8 μ.

Anal.—Calcd. for $C_{13}H_{18}ClNO_4$: C, 54.20; H, 6.31; N, 4.87. Found: C, 54.34; H, 7.00; N, 4.65.

Diisopropylammonium Dichloroacetate I. Assay, Distribution Coefficient, and Solubility Studies

By GEORGE E. CREVAR and ROBERT W. GOETTSCH*

Solubility and distribution coefficient values were determined for the drug, diisopropylammonium dichloroacetate, using a nonaqueous titration method. A second assay procedure is presented for the drug utilizing the modified Fujiwara colorimetric method.

IN RECENT YEARS, several papers have described the pharmacological properties of diisopropylammonium dichloroacetate.[1] The hypotensive properties of the drug have been reported (1–3). The antitoxic action of diisopropylammonium dichloroacetate has been demonstrated against potassium cyanide and quinine hydrochloride (4). Biological studies with diisopropylammonium dichloroacetate have indicated its effect on the blood levels of galactose, glycine, and cholesterol (5), on the utilization of amino acids by the liver and other tissues (6), and on the interference with oxidation-reduction processes (7). Villari, Mazzacca, and Coraggio (8) observed the activation effect of diisopropylammonium dichloroacetate on mice infected with MHV-3 (mouse hepatitis virus).

During preliminary biopharmaceutical investigations of diisopropylammonium dichloroacetate, it was necessary to find suitable assay procedures for solubility and distribution coefficient studies. A colorimetric assay for diisopropylammonium dichloroacetate has been reported by Maruyama and Hasegawa (9). Their procedure is based on the color reaction involving naphthorescorcinal and glyoxalic acid, an alkaline degradation product of diisopropylammonium dichloroacetate. More recently, a colorimetric method for the determination of polyhalogenated organic compounds was reported by Leibman and Hindman (10). The method used by these authors is a modification of the Fujiwara alkaline pyridine reaction (11).

The purpose of this paper is to report on the application of two analytical procedures for the assay of diisopropylammonium dichloroacetate: a colorimetric method based on the modified Fujiwara technique (10) and a nonaqueous titration procedure (12). These assays have proven applicable for the determination of the solubility and the distribution coefficient of this agent.

EXPERIMENTAL

Nonaqueous Titrimetry

Analysis of Diisopropylammonium Dichloroacetate.—The nonaqueous titration procedure described by Fritz (12) was utilized for the analysis of diisopropylammonium dichloroacetate. Each milliliter of 0.1 *N* potassium methoxide solution is equivalent to 23.014 mg. of the drug.

Analysis of Solutions of Diisopropylammonium Dichloroacetate.—Aliquots of diisopropylammonium dichloroacetate solutions (aqueous and nonaqueous) were pipeted into 100-ml. beakers and the solution allowed to evaporate to dryness. The residue was dissolved in 20 ml. of neutralized DMF and the solution titrated with potassium methoxide solution as previously described.

Solubility Studies.—An amount of diisopropylammonium dichloroacetate known to be in excess of that required for a saturated solution was weighed accurately and placed in a glass-stoppered bottle containing the solvent. The bottle was placed in a rotating constant-temperature bath and equilibrated for 2 hr. at 26 ± 0.1°. After equilibration, aliquot samples of the supernatant liquid were removed and assayed for the drug by nonaqueous titration.

Distribution Coefficient Studies.—The distribution coefficients of diisopropylammonium dichloroacetate between benzene–water and chloroform–water systems were determined by nonaqueous procedures. Accurately weighed samples of the compounds were added to glass-stoppered bottles containing 5 ml. of distilled water and 5 ml. of the organic solvent. The bottles were placed on a rotating constant-temperature bath and equilibrated for 2 hr. at 26 ± 0.1°. After equilibration, the 2 layers were separated and analyzed for diisopropylammonium dichloroacetate by nonaqueous titration.

Colorimetric Procedure.—Aqueous solutions of diisopropylammonium dichloroacetate were analyzed colorimetrically by the modified Fujiwara reaction (10). The proposed procedure differs from that reported by Leibman and Hindman (10) in that it is recommended that suitable standard solutions of this drug be run simultaneously. This general procedure was extended to the determination of the solubility of diisopropylammonium dichloroacetate in several solvents.

RESULTS

Table I shows the results obtained from the analysis of diisopropylammonium dichloroacetate by a nonaqueous titration procedure. The method proved to be suitable for the crystalline salt as well as for aqueous and nonaqueous solutions of the drug. The nonaqueous procedure is accurate, rapid, and has many potential applications.

TABLE I.—ANALYTICAL DATA FROM NONAQUEOUS TITRATION STUDIES

Diisopropylammonium Dichloroacetate	mg. Taken	mg. Found	% Recovery[a]

[a] All data represent studies conducted at 26 ± 0.1°. Leaders indicate data were not determined. [b] Concentration of the drug partitioned between 5 ml. of organic phase and 5 ml. of aqueous phase. [c] The value of n was found to be 2.3.

TABLE IV.—COMPARATIVE SOLUBILITY STUDIES BY NONAQUEOUS AND COLORIMETRIC PROCEDURES

Solvent	Solubility in Gm./100 ml. Soln. Nonaqueous	Solubility in Gm./100 ml. Soln. Colorimetric[a]
Distilled water	58.0 ± 0.33	60
Ethanol, 95%	46.3 ± 0.31	48.5
Chloroform	50.6 ± 0.21	[b]
Benzene	15.6 ± 0.22	15

[a] Standard deviations were not determined for the colorimetric assay. [b] The colorimetric procedure is not applicable with chloroform as the solvent (10).

Tables II and III, respectively, include data demonstrating the use of this method for the determination of solubilities and distribution coefficients.

In the solubility studies, solvents were selected to cover a broad range of dielectric constants (2.28–80). It was observed that, with the exception of chloroform, the solubility of diisopropylammonium dichloroacetate increased as the polarity of the solvent increased. The solubility in chloroform was much greater than anticipated from the polarity of the solvent (Table II). It is proposed that the increased solubility of this drug in chloroform may be attributed to an association between solute and solvent molecules.

An examination of the distribution studies of diisopropylammonium dichloroacetate (Table III) reveals that in the partitioning between benzene and water, the expression of $K = C_{org.}/C_{H_2O}$ is a constant value. This type of expression was not adequate for calculating the distribution coefficient between chloroform and water. However, a constant value was obtained from the use of the following expression: $K = C_{org.}/(C_{H_2O})^n$ where the value of n is obtained from the slope of the line by plotting log $C_{org.}$ against log C_{H_2O}. The data obtained suggest an association of the drug molecule in the organic phase.

The modified Fujiwara colorimetric procedure proved to be suitable as an assay method for this drug. However, reproducible results were obtained only if appropriate standards were run simultaneously with the test solutions. In analyzing 4 samples of the same concentration (0.4 mg./ml.) in 2 successive runs, the average deviations of the absorbance measurements were found to be ±0.003 and ±0.004. The utilization of a standard curve gave variable results. It was also found necessary to use a freshly prepared benzidine–formic acid reagent. Additional studies on the solubility of diisopropylammonium dichloroacetate in several solvents were conducted utilizing the modified Fujiwara colorimetric procedure. The data obtained from these studies are in agreement with those obtained in the nonaqueous titration experiments (Table IV).

This colorimetric procedure may prove valuable in studying the degradation of this drug and related molecules possessing the dichloroacetic acid moiety.

Estimation of Thiamine by Inverse Isotope Dilution II

By WAYNE G. HARRIS*, WAYNE V. KESSLER, JOHN E. CHRISTIAN, and ADELBERT M. KNEVEL

In a continuation of a previous study, the cleavage of thiamine hydrochloride by sodium sulfite was proved to be a quantitative reaction. An inverse isotope dilution procedure based on this cleavage was shown to be both accurate and precise in the analysis of pure thiamine hydrochloride in quantities of 10, 50, and 100 mg. It was also used in the analysis of thiamine hydrochloride in 4 pharmaceutical products.

A previous paper (1) reported a preliminary study of a thiamine assay by inverse isotope dilution. Thiamine hydrochloride was cleaved with sodium sulfite-^{35}S to form ^{35}S labeled 4-amino-2-methylpyrimidyl-5-methanesulfonic acid as the derivative. Quantitative assays of thiamine in the presence of other vitamins were performed.

This assay procedure was studied further. The cleavage reaction was proved to be quantitative by direct isotope dilution. Samples containing 10, 50, and 100 mg. of thiamine hydrochloride and 4 commercial products were assayed. The results are reported in this paper.

EXPERIMENTAL

Preparation of Carrier.—The carrier was prepared in the manner reported previously. Purity was proved by paper chromatography with 2 solvent systems, propanol–ammonia (2:1) and butanol–acetic acid–water (4:2:1), and by potentiometric titration. The latter method gave an average purity of 100.3% for 3 determinations.

Measurement of Radioactivity.—The radioactivity of all samples was measured in the manner previously reported. Samples were counted for a period of time sufficient to maintain a counting error of 1.0% or less.

Proof That Cleavage Reaction Is Quantitative.—Williams *et al.* (2) reported that the cleavage reaction is quantitative. This report was based on the weight of product recovered in a cleavage reaction. The recovery was less than 100%.

In order to prove that the reaction is quantitative, direct isotope dilution was used. Labeled derivative was prepared by cleaving 5 Gm. of thiamine hydrochloride with sodium sulfite-^{35}S in the manner used for the preparation of the carrier. The purity of the product was confirmed by paper chromatography with the 2 solvent systems used for the carrier.

The direct isotope dilution procedure was performed in duplicate. Approximately 400 mg. of thiamine hydrochloride (U.S.P. reference standard), previously dried to constant weight over phosphorus pentoxide, was weighed accurately into a weighing bottle. The thiamine was dissolved in 3 ml. of water, 3.00 ml. of a 1 *M* sodium sulfite solution was added, the pH was adjusted to 4.9–5.0 with 2.6 *N* hydrochloric acid, and the reaction mixture was set aside for 12 hr.

A solution of the labeled derivative was prepared by dissolving 100.5 mg. in sufficient ammonia T.S. to make 25.00 ml. To the reaction mixture was added 5.00 ml. of this solution, the pH was again adjusted to 4.9–5.0, and the mixture was set aside for 12 hr. The crystals were collected with suction, washed with about 25 ml. of ice cold water, transferred to a 50-ml. beaker, and dissolved in the least amount of ammonia T.S. The pH was adjusted to 4.9–5.0 with glacial acetic acid, and the mixture was allowed to stand at room temperature for 12 hr. The crystals were collected, washed, and dissolved in about 5 ml. of water by boiling. The mixture was set aside at room temperature for 12 hr. The crystals were then collected, washed, and dried in an oven at 105° for 2 hr.

Approximately 50 mg. of the product was accurately weighed and dissolved in sufficient ammonia T.S. to make 50.00 ml. A sample was prepared for counting by adding 1.00 ml. of this solution to 15 ml. of scintillator. In a similar manner, a sample of the labeled derivative was prepared for counting in order to determine its initial specific activity.

The results are shown in Table I.

Table I.—Yield of Cleavage Reaction

Thiamine HCl Cleaved, mg.	Labeled Derivative Added, mg.[a]	Final Specific Activity, c.p.m./mg.	Thiamine HCl Recovered, mg.	Recovery, %
501.4	20.1	4378	499.7	99.7
342.2	20.1	6207	342.6	100.1

[a] Initial specific activity was 69,982 c.p.m./mg.

D[a]	100	105.8 ± 0.20	102	100.1

[a] Tablet. [b] Vitamin B complex capsule. [c] Average of 3 replicates.

Analyses of Thiamine Hydrochloride at 10, 50, and 100-mg. Levels.—These analyses were performed in the manner presented in the previous paper with the following exceptions. The thiamine hydrochloride was a manufacturing grade (Roche). The quantity and specific activity of the labeled sodium sulfite were adjusted to the amount of thiamine hydrochloride cleaved. For the 50 and 100-mg. levels, 6 mg. of carrier was used for each milligram of thiamine hydrochloride cleaved; for the 10-mg. level, the ratio was 30 to 1. In addition to recrystallization with glacial acetic acid, the carrier diluted derivative was recrystallized from water. The initial specific activity of the labeled derivative at each level was determined by performing the cleavage reaction on U.S.P. thiamine hydrochloride reference standard. The results are shown in Table II.

Analyses of Thiamine Hydrochloride in Pharmaceutical Products.—Four pharmaceutical products (Table III) with thiamine hydrochloride contents ranging from 5 to 100 mg. were selected for analysis. These analyses were performed in the manner used for pure thiamine hydrochloride with the following exceptions. For product *A*, the ratio of carrier added to thiamine hydrochloride cleaved was 60 to 1. The binders, diluents, and other insoluble materials present in the products were removed after the carrier was added by filtration with a Büchner funnel and a double thickness of Whatman No. 1 filter paper. Due to the large amounts of insoluble materials present, it was thought that constant stirring of the reaction mixture would be necessary for quantitative cleavage. It was shown that this was not necessary. For each product, 6 samples were cleaved. To 3 of these samples was added thiamine hydrochloride (Roche, for ampul use) as an internal standard in an amount equal to the labeled thiamine hydrochloride content of the product.

The average tablet weight and the average net capsule weight were determined for each product. For products *C* and *D*, 12 tablets were powdered in a mortar and an amount of the powder equivalent to 10 tablets was dissolved in water in a volumetric flask. An aliquot of this solution was used in the analysis. For product *A*, single tablets were used directly in the analysis. For product *B*, capsule fill equivalent to the average was used.

Products *B* and *D* were assayed by the thiochrome method by the supplier.

The results are shown in Table III.

DISCUSSION

The direct isotope dilution analysis proved that the cleavage reaction is quantitative. Thiamine hydrochloride, U.S.P. reference standard, was used to assure high purity.

The accuracy and precision of the inverse isotope dilution analysis were good for both pure thiamine hydrochloride and pharmaceutical products. For the pure thiamine hydrochloride the accuracy and precision were within 1 and 2.2%, respectively, for all 3 levels. For the pharmaceutical products, the precision and accuracy indicated by recovery of internal standard were comparable.

The reason for the poor agreement between the 2 methods of analysis for product *B* is not apparent. The recovery of internal standard was complete, and the analysis was run twice with consistent results.

SUMMARY

The inverse isotope dilution method was shown to be applicable for the analysis of pure thiamine hydrochloride in quantities of 10 mg. or greater. It was used for the analysis of thiamine hydrochloride in pharmaceutical products and was successful in three out of four.

Modified Computer Programs for Determining Eutectic Temperatures

Sir:

In a recent publication (1), the errors associated with both an expression for calculating eutectic temperatures and the computer program for solving this expression were elucidated. The general form of the equation which was derived from freezing point depression and solubility curves (2) was as follows:

$$\log\left(\frac{1}{T_e} - \frac{1}{T_0}\right) = -\frac{Lf'}{2.303R}\left(\frac{1}{T_e} - \frac{1}{T_0'}\right) - \log\frac{Lf}{R} \quad \text{(Eq. 1)}$$

where Lf and Lf' = the heat of fusion of the solvent and differential heat of solution, respectively; T_0 and T_0' = melting point of the solvent and of the solid, respectively; and T_e = the eutectic temperature.

Because of an approximation introduced in the freezing point equation during the derivation of the eutectic expression in which $-x$ was substituted for ln $(1 - x)$, deviation occurs for highly soluble salts where the mole fraction, x, exceeds a value of 0.1. However, a new program has been written in which the approximation has been eliminated in accordance with the following expression:

$$1 = \exp\left[-\frac{Lf'}{R}\left(\frac{1}{T_e} - \frac{1}{T_0'}\right)\right] + \exp\left[-\frac{Lf}{R}\left(\frac{1}{T_e} - \frac{1}{T_0}\right)\right] \quad \text{(Eq. 2)}$$

To simplify the expression, the following definitions are introduced:

$$A = Lf/R \qquad A' = Lf'/R$$
$$B = Lf/RT_0 = A/T_0 \qquad B' = Lf'/RT_0' = A'/T_0'$$

Then

$$1 = \exp\left[-A'/T_e + B'\right] + \exp\left[-A/T_e + B\right] \quad \text{(Eq. 3)}$$

Cesium chloride	−24.1	−27.89	−24.98	...

An initial trial value of T_e equal to 273.1°K. is taken resulting in a value, Y, for the right hand side of Eq. 3, and Y' is calculated from $T_e' = T_e + \Delta T$, where $\Delta T = 0.01\ T_e$.

Then

$$\frac{\Delta Y}{\Delta T} = \frac{Y' - Y}{T_e' - T_e} \qquad \text{(Eq. 4)}$$

The error in Y is $1 - Y$, which can be corrected by incrementing T_e by an amount ϕ, where

$$\frac{\Delta Y}{\Delta T} = \frac{1 - Y}{\phi} \quad \text{or} \quad \phi = (1 - Y)\frac{\Delta T}{\Delta Y} \qquad \text{(Eq. 5)}$$

The next trial value will be $T_e + \phi$ and this procedure is repeated until the error in Y is arbitrarily small. In this procedure, the correction ϕ to be applied to the trial value of the eutectic can be calculated immediately, not requiring two previous iterations as in the former program. The procedure converges rapidly, usually after three iterations. Furthermore, since the correction does not depend on division by previous improvements, no difficulty is encountered when these values approach zero, as occurred, for example, in the former program for large values of Lf' and T_0'.

A program was written in Fortran II, and an IBM 1401 (8K) computer was used to print a revised table of eutectic temperatures in a condensed form to include values of Lf' from 100–5900 cal. in increments of 200 cal., and melting points T_0' from 20–60° in increments of 20° and from 60–300° in increments of 40° (Table I). The maximum error involved in interpolating values from the condensed table is 0.5°.

Independently, a somewhat different program for solving Eq. 2 was written in Manchester Autocode, and an ICT 1301 computer was used to obtain a similar table of eutectic temperatures as a function of Lf' and T_0'. The results of the two methods agree within 0.01°.

Since most pharmaceuticals do not exceed a 0.1 mole fraction concentration in water, the difference in the values obtained using Eq. 2 as compared to those using the approximation given by Eq. 1 is not of practical significance as shown in Table II. The major discrepancies as would be expected occur for highly soluble salts above 0.1 mole fraction in water.

Some previously published values (2, 3) have been recalculated with the new programs and they are listed in Table II.

The deviation which occurs in calculated and experimental values was discussed in the previous papers and is presently undergoing investigation.

Identity of Viminalol Acetate

Sir:

In their work on substances occurring in *Sarcostemma viminale*, Torrance and Marais (1) showed that this plant contained, in addition to β-amyrin and friedelin, a compound which they called viminalol acetate, and which they stated appeared to belong to the lupeol series. In the present investigation it is shown unequivocally that the compounds described by Torrance and Marais (1) as viminalol and viminalol acetate were in all respects identical with α-amyrin and α-amyrin acetate.

In the previous communication (1) the best melting point reported after chromatography on alumina for viminalol acetate, referred to as *B*, was 160–162°. Thin-layer chromatography, however, showed that this material was not pure. After repeated chromatography of this substance on aluminum oxide using benzene as solvent, a product was finally obtained with a melting point of 200–215°, which gave a single spot on thin-layer chromatography. A pure sample of *B* was eventually obtained by hydrolysis of *B*, in ethanolic potassium hydroxide, to the alcohol. The alcohol was crystallized from 95% ethanol until a constant melting point of 180–182° was obtained. Thin-layer chromatography of this alcohol gave a single spot. This pure alcohol was then acetylated, using pyridine and acetic anhydride in the cold, to give a product which, after crystallization from alcohol, gave a chromatographically pure substance of melting point 216–219°. This melting point remained constant after recrystallization.

A comparison of these melting points with that of α-amyrin 186° (2, 3) and of α-amyrin acetate 226° (2, 3) suggested the possibility of viminalol acetate being identical with α-amyrin acetate.

A number of derivatives of viminalol acetate were prepared and their melting points compared with the corresponding derivatives of α-amyrin and α-amyrin acetate described in the literature. From the physical constants given in Table I for viminalol acetate, α-amyrin acetate, and their derivatives it can be seen that viminalol acetate was in fact α-amyrin acetate.

TABLE I.—SUBSTANCES AND MELTING POINTS

Substance	M.p., °C.
α-Amyrin acetate	216–219°; lit., 226° (2, 3)
Viminalol acetate	216–219°
α-Amyrin	182°; lit., 186° (2, 3)
Alkaline hydrolysis product of viminalol acetate	180–182°
α-Amyrone	126° (2, 3)
Chromic acid oxidation of hydrolysis product of viminalol acetate	124–127°
α-Amyrenonal acetate	278° (2, 3)
Chromic acid oxidation product of viminalol acetate	278–280°
α-Amyrene	115° (2, 3)
Clemmensen reduction product of viminalol	108–111°

Furthermore, no depression in the melting points of α-amyrin and α-amyrin acetate were obtained on admixture with viminalol and viminalol acetate, respectively. (Table I.)

Thin-layer chromatography at room temperature (22°) using silica gel (G nach Stahl) and a solvent system of ethyl acetate–cyclohexane (2:8) on α-amyrin, viminalol, α-amyrin acetate, and viminalol acetate gave R_f values of 0.53 for α-amyrin and viminalol and 0.94 for α-amyrin acetate and viminalol acetate.

Finally, comparison of the infrared spectra of viminalol and viminalol acetate with authentic samples of α-amyrin and α-amyrin acetate showed that the substance previously described (1) as an unknown triterpene acetate, *viz.*, viminalol acetate is identical with α-amyrin acetate.

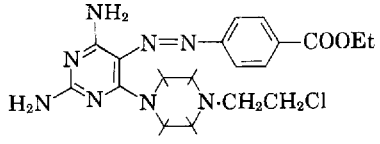
2,4-Diamino-6-substituted-5-(4-carbethoxyphenylazo)pyrimidines as Irreversible Inhibitors of Folic Acid Reductase

Sir:

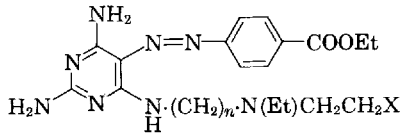
The theory of competitive, or active-site-directed, irreversible inhibition of enzymes has been discussed by Baker (1) and others (2–5). To achieve this type of inhibition, the inhibitor must form an initially reversible enzyme–inhibitor complex and, while in this form, be able to form a covalent bond between reactive groups located on the enzyme and on the inhibitor to yield a covalently bound enzyme–inhibitor complex.

Previous studies (6–9) have shown that 5-arylazopyrimidines possess antifolic properties. Evidence has been presented which suggests that a series of 2,4-diamino-6-substituted-5-arylazopyrimidines are competitive antagonists of rat liver folic acid reductase (10). Thus, it seemed possible that irreversible antagonists might be designed by the incorporation of appropriately located alkylating groups into the 5-arylazopyrimidine molecule.

Some irreversible inhibition was noted (10) with *N*-2-chloroethyl-*N'*-[2,4-diamino-5(4-carbethoxyphenylazo)-6-pyrimidyl]piperazine (I), but this was not particularly marked since lengthy preincubation (8 hr.) of the inhibitor and enzyme was necessary to produce a significant level of irreversible inhibition (10). It seemed probable that the ineffectiveness of I was due to the conformational rigidity of the alkylating side chain which would preclude, save in the most favorable circumstances, effective interaction between the alkylating group and a corresponding nucleophilic site on the enzyme. Accordingly, we have prepared (Table I) a series of 2,4-diamino-5-(4-carbethoxyphenylazo)pyrimidines (II) bearing alkylating 6-substituents of varying chain length and with increased flexibility relative to I. (The synthesis of these compounds and a more detailed analysis of their behavior will be published together in a later paper.)



I



II

The alkylating inhibitors (VIII–XII, Table I) produced irreversible inactivation at rates which were dependent on the length of the 6-alkyl chain despite the similar chemical reactivities of the alkylating groups (11). In order to exclude the possibility that these compounds inactivate folic reductase by random alkylation processes, we have studied the activity of *N*-(2-chloroethyl)-*N*-ethyl-*n*-butylamine (XIII), a compound that represents the alkylating moiety of X. When incubated with folic reductase at the same concentration as X, XIII required 90 min. to produce 50% inactivation and is clearly much less efficient than X which required only 6 min. to produce the same degree of inactivation. Furthermore, incubation of the enzyme with XIII and 2,4,6-triamino-5-phenylazopyrimidine [a competitive reversible antagonist, $K_I = 1.4 \times 10^{-8} M$, (10)] did not alter the time for 50% inactivation, suggesting (*a*) that any conformational change induced by the enzyme–inhibitor interaction does not expose a nucleophilic group that can be alkylated by XIII and (*b*) that XIII produces enzyme inactivation by a nonspecific process.

The data in Table I show that the alkylating

TABLE I.—INHIBITION OF FOLIC ACID REDUCTASE[a] BY 2,4-DIAMINO-6-SUBSTITUTED-5-(4-CARBETHOXYPHENYLAZO)PYRIMIDINES (II)

Compd.	*n*	X	$[I/S]_{50}$[b]	Time for 50% Inactivation, min.[c]
III	2	OH	2.9	>200

XII	6	Cl	1.9	10
XIII	$CH_3(CH_2)_3N(Et)CH_2CH_2Cl$			90

[a] Folic acid reductase activity was determined at 37° in the presence of 20 μM NADPH, 10 μM sodium citrate, 10 μM $MgCl_2$, 100 μM dimethyl glutarate buffer (pH 6.1), 80 μM folic acid, rat liver homogenate supernatant and inhibitor in water to a final volume of 0.5 ml. (12). [b] $[I/S]_{50}$ is the ratio of the concentrations of inhibitor and substrate required to produce 50% inhibition of enzyme activity. Since $K_I/K_M \approx [I/S]_{50}$ these figures provide an approximate guide to the relative affinities of substrate and inhibitor. Because of the possibility of irreversible inactivation by VIII–XII during the determination of enzyme activity, the $[I/S]_{50}$ values for these compounds are only approximate. [c] Time for 50% inactivation of the enzyme in the absence of inhibitor was 240 min. Inactivation studies were done with an inhibitor concentration of $2 \times 10^{-4} M$.

and nonalkylating inhibitors bind less efficiently to the enzyme than folic acid ($K_M = 6.2 \times 10^{-6}$ M). Variation of the chain length of the 6-substituent has a relatively small effect on the $[I/S]_{50}$ ratios for both the alcohols (III–VII, $[I/S]_{50}$ range, 2.9–5.6) and the chloro compounds (VIII–XII, $[I/S]_{50}$ range, 1.9–3.0). However, incubation of the enzyme with the inhibitor before addition of the substrate resulted in varying degrees of irreversible inactivation of the enzyme. Enzyme inactivation in the presence of the reversible inhibitors (III–VII) was identical to that occurring in the absence of these inhibitors.

The data presented in this communication seem to establish the existence of a nucleophilic site on the enzyme folic acid reductase that can be specifically alkylated by appropriately designed antagonists. Further work is in progress, using analogs of these antagonists, that may further establish the position of this nucleophilic site relative to other binding sites of folic acid reductase.

REVIEWS

Accepted Dental Remedies 1966. Council on Dental Therapeutics. American Dental Association, 222 E. Superior St., Chicago, Ill. 60611, 1965. xvi + 275 pp. 15 × 22.5 cm. Price $3.00. Paperbound.

The 1966 edition is the thirty-first edition of this well-known handbook of dental therapeutics. Revision once again has resulted in changes in the organization of the material and division into five sections; the previous edition had three. Of the five sections, one represents new material—Therapeutic Guides. The indexes have been incorporated into the fifth section, and the first three—General Principles of Medication, Therapeutic Agents, and Therapeutic Aids—remain the same.

Therapeutic Guides includes a chapter in which conditions such as bleeding, hairy tongue, moniliasis, leukoplakia, etc., are discussed and suggestions for treatment given. Another new chapter is Current Therapeutic Trends in which brief monographs on recently marketed drugs are presented. These drugs are widely advertised, and although some may eventually be accepted by the Council, others are included especially to emphasize the hazards associated with their use.

The discussion on reporting drug reactions has been expanded. The Council on Therapeutics is now cooperating with the FDA in its program on adverse reactions and to further aid the practitioner, brief adverse reaction report forms have been included inside the back cover of the book.

Basic Biochemistry. By M. E. Rafelson, Jr., and S. B. Binkley. The Macmillan Co., 60 Fifth Ave., New York 11, N. Y., 1965. xi + 350 pp. 15.5 × 24 cm. Price $8.50 hardbound; $6.50 paperbound.

This brief textbook provides a basic outline of the principles of biochemistry. The material is presented in a clear and readable style. Discussion is limited but this fact is acknowledged by the authors who suggest more complete reference texts which can be consulted for supplementation of this material. The first few chapters are devoted to descriptive chemistry of acids, bases, and buffers; carbohydrates; lipids; proteins; nucleic acid and nucleoproteins; enzymes; and high energy compounds and oxidative phosphorylation. The remaining chapters are devoted to the metabolic pathways which utilize these compounds. The text

throughout is illustrated with many structural formulas, some of which are often not presented in more advanced texts since it is assumed that they are known.

New Drugs: 1965 Edition. Evaluated by A.M.A. Council on Drugs. American Medical Association, 535 N. Dearborn St., Chicago, Ill. 60610, 1965. xii + 510 pp. 16 × 24 cm. Price $5.00

New Drugs 1965 is a new publication of the American Medical Association's Council on Drugs. The Council has discontinued its previous publication, *New and Nonofficial Drugs*. The hope is that *New Drugs* will provide the practicing physician with a more usable reference. The scope, organization, and format are entirely different from earlier publications.

The approach to the discussion of drugs is therapeutic and drugs are grouped into chapters according to use. Previous publications categorized drugs according to pharmacologic action. For instance, in *NND*, antidepressants, and analeptics were both included in the chapter covering central stimulants. In *New Drugs* there is a separate chapter discussing each category.

The general discussion which begins each chapter covers many of the drugs available for that particular therapeutic use regardless of whether a monograph is included in the chapter. Monographs appear only for those drugs which have been introduced within the past 10 years.

The monographs provide unbiased information on the drugs and the Council emphasizes that these are not approved drugs; in some cases unfavorable evaluations are given. It is pointed out also in certain instances that a drug may be used for a particular condition, but further evaluation is necessary to substantiate its value. A total of 271 single entity drugs are covered in this edition. The information included in the monograph includes generic and chemical name, actions and uses, adverse reactions and contraindications, pharmacology, dosage, preparations available, trade name(s), and manufacturer(s).

New Drugs will be revised and published annually. Monographs for drugs over ten years old will be dropped and newer agents will be added, and as more information is gained about drugs still included, these monographs will be revised to incorporate this information.

Hawk's Physiological Chemistry. 14th Ed. Edited by BERNARD L. OSER. McGraw-Hill Book Co., 330 West 42nd Street, New York, N. Y., 1965. xv + 1472 pp. 16.5 × 23.5 cm. Price $19.50.

The title of the book has been changed with this 14th edition from its original title *Practical Physiological Chemistry* to *Hawk's Physiological Chemistry*. This timely volume is the result of the collaborative efforts of scientists and researchers outstanding in the many aspects of the biochemical field. *Hawk's Physiological Chemistry* is a comprehensive text which includes modern theory and practice without losing sight of the fundamental concepts and methodology which have historically constituted the structure of the science of biochemistry.

This 14th edition contains several innovations in nomenclature and abbreviations. Some of the older terminology has been modified to conform with recommendations of the International Union of Biochemistry. For example, readers will notice that NAD or nicotinamide adenine dinucleotide is used in place of DPN, Coenzyme I, or diphosphopyridine nucleotide and that its reduced form is abbreviated $NADH_2$. In keeping with this, NADP or nicotinamide adenine dinucleotide phosphate replaces TPN, Coenzyme II, or triphosphopyridine nucleotide; its reduced form is $NADPH_2$.

Some of the subjects receiving special emphasis in this new edition are the composition, configuration, and role of the nucleic acids and related compounds; the enzymes and cofactors involved in metabolic pathways; the biotransformations of nutrients and their metabolites and their estimation in blood and tissues; the use of radioisotopes for the study of metabolic processes; current concepts of the biochemistry of muscular contraction, blood coagulation, respiratory metabolism, detoxification, and so forth. The initial chapters of this book deal with basic physiochemical principles and with the chemistry of the major components of physiological tissues. This sophisticated discussion of the chemical principles important to biochemistry is clearly expressed in surprising detail. The information in all chapters is well documented for further study. Each chapter or section contains analytical procedures and instrumental techniques which may be used as laboratory experiments or aids to the researcher. Some of these procedures and techniques are new, replacing those no longer in wide use. However, many examples of the older, perhaps less precise, procedures have been retained because of their continued usage or historical importance. The reader will find numerous diagrams, illustrations, and tables throughout the text. Particularly noteworthy is the color print of a model of the molecular structure of deoxyribose nucleic acid in the frontispiece which is symbolic of the recent epoch-making developments in the elucidation of the structural configuration and biochemical and genetic significance of the ribonucleotides. This comprehensive textbook in physiological chemistry should prove indispensable to those in the medical and allied professions.

The reader will find numerous diagrams, illustrations, and tables throughout the text. Particularly noteworthy is the color print of a model of the molecular structure of deoxyribose nucleic acid in the frontispiece which is symbolic of the recent epoch-making developments in the elucidation of the structural configuration and biochemical and genetic significance of the ribonucleotides. This comprehensive textbook in physiological chemistry should prove indispensable to those in the medical and allied professions.

Official Methods of Analysis of the Association of Official Agricultural Chemists. Edited by WILLIAM HORWITZ. Association of Official Agricultural Chemists, P.O. Box 540, Benjamin Franklin Station, Washington, D. C. 20044, 1965. xx + 957 pp. 18 × 26.5 cm. Price $22.50.

The changes and advances in analytical techniques are revealed in this 10th edition of *AOAC Official Methods of Analysis*. The major portion of new methods adopted within the last five years utilize spectrophotometry and/or chromatography. The methods presented in this book are required by regulatory and research workers in the various areas of agriculture and public health. They are used by the FDA, Department of Agriculture, Internal Rev-

throughout is illustrated with many structural formulas, some of which are often not presented in more advanced texts since it is assumed that they are known.

New Drugs: 1965 Edition. Evaluated by A.M.A. Council on Drugs. American Medical Association, 535 N. Dearborn St., Chicago, Ill. 60610, 1965. xii + 510 pp. 16 × 24 cm. Price $5.00

New Drugs 1965 is a new publication of the American Medical Association's Council on Drugs. The Council has discontinued its previous publication, *New and Nonofficial Drugs*. The hope is that *New Drugs* will provide the practicing physician with a more usable reference. The scope, organization, and format are entirely different from earlier publications.

The approach to the discussion of drugs is therapeutic and drugs are grouped into chapters according to use. Previous publications categorized drugs according to pharmacologic action. For instance, in *NND*, antidepressants, and analeptics were both included in the chapter covering central stimulants. In *New Drugs* there is a separate chapter discussing each category.

The general discussion which begins each chapter covers many of the drugs available for that particular therapeutic use regardless of whether a monograph is included in the chapter. Monographs appear only for those drugs which have been introduced within the past 10 years.

The monographs provide unbiased information on the drugs and the Council emphasizes that these are not approved drugs; in some cases unfavorable evaluations are given. It is pointed out also in certain instances that a drug may be used for a particular condition, but further evaluation is necessary to substantiate its value. A total of 271 single entity drugs are covered in this edition. The information included in the monograph includes generic and chemical name, actions and uses, adverse reactions and contraindications, pharmacology, dosage, preparations available, trade name(s), and manufacturer(s).

New Drugs will be revised and published annually. Monographs for drugs over ten years old will be dropped and newer agents will be added, and as more information is gained about drugs still included, these monographs will be revised to incorporate this information.

Hawk's Physiological Chemistry. 14th Ed. Edited by BERNARD L. OSER. McGraw-Hill Book Co., 330 West 42nd Street, New York, N. Y., 1965. xv + 1472 pp. 16.5 × 23.5 cm. Price $19.50.

The title of the book has been changed with this 14th edition from its original title *Practical Physiological Chemistry* to *Hawk's Physiological Chemistry*. This timely volume is the result of the collaborative efforts of scientists and researchers outstanding in the many aspects of the biochemical field. *Hawk's Physiological Chemistry* is a comprehensive text which includes modern theory and practice without losing sight of the fundamental concepts and methodology which have historically constituted the structure of the science of biochemistry.

This 14th edition contains several innovations in nomenclature and abbreviations. Some of the older terminology has been modified to conform with recommendations of the International Union of Biochemistry. For example, readers will notice that NAD or nicotinamide adenine dinucleotide is used in place of DPN, Coenzyme I, or diphosphopyridine nucleotide and that its reduced form is abbreviated $NADH_2$. In keeping with this, NADP or nicotinamide adenine dinucleotide phosphate replaces TPN, Coenzyme II, or triphosphopyridine nucleotide; its reduced form is $NADPH_2$.

Some of the subjects receiving special emphasis in this new edition are the composition, configuration, and role of the nucleic acids and related compounds; the enzymes and cofactors involved in metabolic pathways; the biotransformations of nutrients and their metabolites and their estimation in blood and tissues; the use of radioisotopes for the study of metabolic processes; current concepts of the biochemistry of muscular contraction, blood coagulation, respiratory metabolism, detoxification, and so forth. The initial chapters of this book deal with basic physiochemical principles and with the chemistry of the major components of physiological tissues. This sophisticated discussion of the chemical principles important to biochemistry is clearly expressed in surprising detail. The information in all chapters is well documented for further study. Each chapter or section contains analytical procedures and instrumental techniques which may be used as laboratory experiments or aids to the researcher. Some of these procedures and techniques are new, replacing those no longer in wide use. However, many examples of the older, perhaps less precise, procedures have been retained because of their continued usage or historical importance. The reader will find numerous diagrams, illustrations, and tables throughout the text. Particularly noteworthy is the color print of a model of the molecular structure of deoxyribose nucleic acid in the frontispiece which is symbolic of the recent epoch-making developments in the elucidation of the structural configuration and biochemical and genetic significance of the ribonucleotides. This comprehensive textbook in physiological chemistry should prove indispensable to those in the medical and allied professions.

Official Methods of Analysis of the Association of Official Agricultural Chemists. Edited by WILLIAM HORWITZ. Association of Official Agricultural Chemists, P.O. Box 540, Benjamin Franklin Station, Washington, D. C. 20044, 1965. xx + 957 pp. 18 × 26.5 cm. Price $22.50.

The changes and advances in analytical techniques are revealed in this 10th edition of *AOAC Official Methods of Analysis*. The major portion of new methods adopted within the last five years utilize spectrophotometry and/or chromatography. The methods presented in this book are required by regulatory and research workers in the various areas of agriculture and public health. They are used by the FDA, Department of Agriculture, Internal Rev-

enue Service, and corresponding state agencies, and industry.

The areas covered by the book are agricultural materials which include fertilizers and pesticide formulations; foods; drugs, cosmetics, and colors; extraneous materials, microbiological methods, vitamins, and standards; and the reference tables and index.

In the area of basic pesticides in formulations, 14 new methods have been adopted; for pesticide residues, 12 new methods have been adopted. Food additives as such have been included for the first time. Three methods have been adopted for extractives from packaging materials. Eight new methods were adopted for oils and fats, and 15 new methods for drugs in feeds.

This edition is 125 pages larger than the previous one. In an attempt to contain all methods in a single volume in the next edition, the AOAC has designated certain methods as surplus. These are methods approved but believed to be no longer in use. In future editions these methods will be listed only with reference to the 10th edition unless sufficient proof is given to the AOAC that these methods are still being used.

As a further reflection of the expanded coverage of the work of the AOAC, they have changed their name to the Association of Official Analytical Chemists. However, this change occurred after type for this 10th edition was set.

Foundations of Anesthesiology. By ALBERT FAULCONER, JR., and THOMAS E. KEYS. Charles C Thomas, 301-327 East Lawrence Ave., Springfield, Ill., 1965. Two volumes: I, 1–715 + 50 pp.; II, 719–1337 + 50 pp. 17.5 × 24.5 cm. Price $38.50.

This unusually interesting and informative compilation represents a comprehensive review of the literature on anesthesiology, with particularly thorough emphasis on works of historical and classical interest. Dr. Faulconer, Head of the Mayo Clinic Section of Anesthesiology, and the Mayo Clinic librarian, Mr. Keys, have arranged the text in eight sections, titled: Respiratory Physiology, Inhalation Anesthesia, Rectal Anesthesia, Regional Anesthesia, Intravenous Anesthesia, Accessory Agencies and Technics, Depth of Anesthesia, and Theories of Narcosis.

The papers in each section are arranged in chronological sequence, thus, Section 1 starts with the report in 1543 by Andreas Vesalius on "Artificial Respiration on a Sow," and ends with a report in 1930 by Heymans and Bouckaert titled "Sinus Caroticus and Respiratory Reflexes I. Cerebral Blood Flow and Respiration. Adrenaline Apnoea." Theories of narcosis range from the paper by Marie-Jean-Pierre Flourens in 1847 on the "Action of Ether on the Nervous Centers" to Linus Carl Pauling's "A Molecular Theory of General Anesthesia" published in 1961. Each section starts with an introductory discussion. For easy reference, the composite Table of Contents, Index of Personal Names, and Index of Subjects are repeated in each of the two volumes.

Microsomal Dealkylation of Drugs

Substrate Specificity and Mechanism

By ROBERT E. MCMAHON

ABOUT TWENTY-FIVE years ago Butler and Bush (1) reported the *in vivo* demethylation of dimethylbarbital in the dog. This observation represented the first example of the *N*-demethylation of a synthetic drug. In the intervening years the dealkylation reaction has become recognized as a major pathway of drug metabolism. However, studies at the *in vitro* level have been undertaken only in recent years. The first such study was that of Mueller and Miller at Wisconsin. They found (2) that the demethylation of the carcinogenic dye, *p*-dimethylaminoazobenzene could be effected by an *in vitro* system composed of the liver microsomal fraction, an enzyme in the soluble fraction together with oxygen, NADP, NAD, and hexose phosphate. In the 2 years that followed this discovery, the field developed rapidly and the general characteristics of the reaction became well established.

Among the early studies were those of LaDu *et al.* (3) and of Axelrod (4, 5). These workers demonstrated that the oxidative *N*-dealkylation of amines is catalyzed by the microsomal fraction (derived from the endoplasmic reticulum) from mammalian liver and requires molecular oxygen and NADPH. The requirement for a soluble enzyme, NADP, and hexose phosphate experienced by the earlier workers proved to be a requirement for a NADPH generating system. It was also demonstrated that alkyl groups other than methyl were oxidatively removed by the *N*-dealkylase system.

The over-all oxidative *N*-dealkylation reaction has the following stoichiometry:

$$R_2NCH_2R \xrightarrow{[O]} R_2NH + RCHO$$

A key discovery of the Brodie (6) group was that the *N*-demethylase activity was a member of a family of oxidative enzymes involved in the metabolism of drugs. All of these enzymes are located in the microsomal fraction of mammalian liver and require NADPH and molecular oxygen. In addition to dealkylation these enzymes catalyze aromatic hydroxylation, side chain oxidation, *S*-oxidation of thioethers, *N*-oxidation of tertiary amines, and the oxidation of phosphorothionates. A key property of these enzymes is their remarkable nonspecificity.

A number of excellent reviews of the general field of microsomal enzyme systems are available. Among these, the recent reviews by Gillette (7), Siekevitz (8), and Shuster (9) are particularly informative. In this review we plan to consider recent developments in the field of microsomal dealkylation from the viewpoint of the medicinal chemist interested in structure–activity studies and in the mechanism of the reaction. The review has been divided into three sections:

Received from the Lilly Research Laboratories, Eli Lilly and Co., Indianapolis, Ind.

TABLE I.—*In Vitro* DEMETHYLATION RATES

VI	35	1.75	2.89	3.60

structure–activity studies, the mechanism of the reaction, and a tabulation of important pharmacological agents which undergo *in vivo* dealkylation.

STRUCTURE ACTIVITY CONSIDERATIONS

Known substrates of the microsomal dealkylase system include tertiary amines, secondary amines, *N*-alkyl amides, *N*-alkyl carbamates, *N*-methyl barbituric acids, *N*-methyl sulfonamides, *N*-methyl pyrophosphoramides, *N*-methyl imides, *N*-methyl purine bases, arylalkyl ethers, and aryl methyl thioethers. The characteristics of the dealkylation of each of these classes of compounds are summarized below. A discussion of the chemical nature of reaction intermediates and of the possible mechanism of the reaction is presented in the concluding paragraphs.

Tertiary Amines.—The number of tertiary amines which are known to be dealkylated by the microsomal system is very large. Substrates of such widely varying structures have been found to be active that it is difficult to imagine any single chemical or physical property which could be used to correlate the experimental observations. However, Gaudette and Brodie (10) presented experimental evidence that an important requirement for the substrate is that it be lipid soluble. This proposal was particularly attractive since the endoplasmic reticulum is the principal lipid-bearing structure of the cell. Further, it provided an explanation of why foreign amines were readily acted upon by this system while naturally occurring polar amines, such as methylated amino acids, were not dealkylated.

The question of lipid solubility has been explored in detail by McMahon (11) who studied the relationship between lipid solubility (as measured by distribution between *n*-heptane and pH 7.4 buffer) and the rate of demethylation in both an *in vitro* system and in the intact animal. The compounds investigated were I, *dl*-propoxyphene; II, *dl*-propoxyphene carbinol; III, *p*-chlorophenylpropyldimethylamine; IV, phenylpropyldimethylamine; V, phenylethyldimethylamine; and VI, benzyldimethylamine.

The relative rates of demethylation of these six substrates by microsomes from three species are summarized in Table I. H/W represents the ratio of the equilibrium concentration in heptane to that in pH 7.4 buffer. It is clear from these data that there is a direct correlation of increasing rate with increasing lipid solubility. The two most lipid soluble amines, I and II, however, present an exception. In this case the esterification of the hydroxyl group of II results in a small increase in lipid solubility as expected, but it also results in a somewhat lowered demethylation rate. The introduction of the polar and reactive hydroxyl group produced an effect which overrides simple lipid solubility considerations. Apparently it is important in studies of this sort to select series of compounds which differ from each other by the presence or absence of such relatively inert groups as methylene, phenyl, halogen, etc. The results do suggest that a study of structure–activity relationships in a series of compounds in which the lipid solubility is high and not limiting might be rewarding.

In order for the *in vitro* work described above to be valuable to the medicinal chemist, it was important to correlate it with *in vivo* data in the same species. Radiocarbon labeling served for these studies. The results presented in Table II show an excellent correlation with the *in vitro* results.

With one minor exception the *in vivo* results correlate directly with *in vitro* rates. These studies then demonstrated a relationship between lipid solubility and both *in vitro* and *in vivo* demethylation rates. Also, although the *in vivo* rates of demethylation varied from species to species, the relative order of substrate activity was approximately the same in each species. It is likely that systematic studies of species variation will only be successful when a narrowly defined series of compounds such as these are used.

The structure–activity studies on the effect of lipid solubility were next extended to series of substrates which were totally aliphatic in nature (12). From this study, which will not be reviewed in detail here, it was abundantly clear

TABLE II.—*In Vivo* DEMETHYLATION RATES

Compd.	% Demethylation in 200 min. in— Guinea Pig	Rat	Mouse
I	61	50	47
II	84	55	83
III	58	21	20
IV	55	11	12
V	46	12	11
VI	18	16	9

that there is a direct correlation between lipid solubility and substrate activity. Recently Hansch, Steward, and Iwasa (13) have described an interesting mathematical treatment of the results of the demethylation studies cited above (11, 12) and have concluded that in these series the rate of demethylation could be correlated with lipid solubility and with the pKa of the amine.

There seems little doubt that lipid solubility is an important factor (perhaps the major factor) in controlling the rate of demethylation of tertiary amines. Other factors, probably chemical in nature, are also most certainly involved. To study these factors, however, will require careful and rigorous structure–activity studies. Thus, in a group of randomly selected compounds which are not chemically related, the effect of any single parameter will be obscured [*cf.* Mazel and Henderson (14)].

Secondary Amines.—Although secondary amines were among the earliest substrates to be studied (3, 4, 15), no systematic structure–activity studies have been reported. For example, lipid solubility is undoubtedly an important factor influencing the rate of demethylation of secondary amines, but no data are available at present which bear on this question. However, there are data available which allow comparisons of tertiary and secondary amines as substrates.

For example, a comparison (16) has been made of the kinetics of the demethylation of certain tertiary dimethylamines as compared to the corresponding secondary methylamine. In general it was found that the maximum rate (V_m) of demethylation is greater for tertiary amines. It is believed that the kinetic factor arising from the fact that the tertiary amine has two methyl groups while the secondary amine has but one is at least partly responsible for this observation. Secondary methylamines appear from k_m data to have a greater affinity for enzyme than does the corresponding tertiary dimethylamine. In the secondary amine there is less steric hindrance about the nitrogen which may facilitate binding. In addition, in each of the pairs of amines studied, the electron pair on nitrogen was more readily available for binding (*i.e.*, the secondary amine is the stronger base). Secondary amines are also considerably less responsive to the action of the potent demethylation inhibitor DPEA (17, 18) than are tertiary amines.

The difference in rate of demethylation of tertiary and secondary amines can have interesting pharmacological consequences. For example, McMahon *et al.* (19) found that in both the *in vitro* and *in vivo* systems acetylmethadol was demethylated at a rate considerably greater than was noracetylmethadol, the secondary amine analog. The result of this rate differential was that administration of acetylmethadol led to the accumulation of noracetylmethadol in tissues. Since noracetylmethadol itself is an active analgesic, these data serve to explain the clinical observation that the administration of acetylmethadol to patients leads to accumulated drug effects (20). Another example is that of the antidepressant imipramine. Gillette *et al.* (21) have presented experimental evidence that the delayed onset of action and the antidepressant properties are due to the *in vivo* formation of des-*N*-methyl imipramine.

One important systematic structure–activity study involving the dealkylation of both secondary and tertiary amines has yet to be carried out, *i.e.*, the *N*-dealkylation of amines in which the alkyl group removed is larger than methyl and ethyl. A few examples are known, however. LaDu *et al.* (3) have demonstrated the removal of the *N*-butyl group while Axelrod and Cochin (22) and Leadbeater and Davies (23) have studied the deallylation of nalorphine. The *in vivo* opening of the pyrrolidine ring of nicotine (24, 25), the debutylation of ethoxybutamoxane (26) and chlorethoxybutamoxane (27), and the *N*-deallylation of levallorphan (28) are further examples. The *in vitro* dealkylation of *N*-cyclopropyl-4-phenyl-4-carbethoxypiperidine has also been observed (McMahon, unpublished data).

O-Dealkylation.—In 1948 Huggens, Jensen, and Cleveland (29) reported the *O*-dealkylation of *p*-nitroanisole and *p*-nitrophenetole in both the intact rat and in liver homogenates. In 1955 Axelrod (30) demonstrated that the *O*-demethylation of codeine was closely related to *N*-demethylation by showing the demethylation to be catalyzed by liver microsomes and to require NADPH and oxygen. The products were morphine and formaldehyde. A later study from the same laboratory (31) concerned the effect of ring substitution upon the rate of demethylation of anisole derivatives. It was found that the *p*-substituted analogs were more readily demethylated than the *o*- or *m*-derivatives. The decreasing order of the rate of metabolism for *p*-substituted anisoles was CN, CHO, $NHCOCH_3$, COOH, $CH_2—NH_2$, allyl, NH_2, H. It is difficult at present to correlate these data with the electronic effects produced by the substituents. It is probable that both k_m and $V_{max.}$ are affected by aromatic substitution so

that it would probably be necessary to do a complete kinetic study of a series of substrates.

McMahon *et al.* (32) have studied the rate of dealkylation of a series of *p*-nitrophenylalkoxyethers in order to determine the effect of changing alkyl groups. In general it was found that with increasing chain length of normal alkyl groups, the rate of dealkylation decreases. However, when electron donating groups were introduced adjacent to the methylene, increased rates were observed. For example, allyl, cyanomethyl, and benzyl were more active substrates than *n*-propyl or chloroethyl. The dialkylaminoethoxy grouping which occurs frequently in drugs does not undergo *O*-dealkylation. It is likely that in this case *N*-dealkylation occurs as an alternative pathway. In studying the effect of aromatic substitution on the rate of dealkylation of substituted *p*-nitrophenyl benzyl ethers, a very clear steric effect emerged when groups were placed *ortho* to the methylene group.

In experiments in intact animals, it was found that an excellent correlation exists between the *in vitro* rates and the *in vivo* rates (32).

It is likely that *O*-dealkylation may not be confined to phenolic ethers but that totally aliphatic ethers will be found to be cleaved. In this connection the recent report (33) of the cleavage of glycerol ethers of long chain fatty alcohols is of considerable interest. This reaction requires molecular oxygen and liver microsomes but showed a requirement for a tetrahydropteridine as a cofactor as well as the usual NADPH. These observations suggest a possible relationship between this activity and the phenylalanine hydroxylation which has been the subject of the elegant researches of Kaufman (34).

For information on detailed experimental conditions which govern microsomal *O*-demethylation, the report by Nilsson (35) on the demethylation of the estrogenic isoflavone, biochanin A, should be consulted.

N-Alkylamides and Related Compounds.—The extensive researches by Butler and his associates have shown many *N*-methyl barbiturates and related *N*-methyl heterocyclics to be demethylated in the intact animal. [See Fishman (36) for a review and bibliography of the Butler studies.] Other examples include the demethylation of the herbicide, diphenamid (37), the demethylation of *N*-methyl-α-phenyl-α-ethylglutarimide (38), and the demethylation of diazepam (39, 40) and of chlordiazepoxide (41).

An early report of the *in vitro* demethylation of an amide was that of Hodgson and Casida (42) who investigated the demethylation of *N*-methyl carbamates and demonstrated the reaction to be a typical microsomal oxidation requiring oxygen and NADPH. More recent *in vitro* work (43, 44) has shown the demethylation of *N*-methyl barbiturates, *N'*-methylsulfonylureas, and simple amides to be microsomal *N*-demethylations as well.

Miscellaneous Substrates.—The most interesting recent development has been the demonstration by Mazel and co-workers that the microsomal dealkylases will readily *S*-demethylate various *S*-methyl ethers (45). This discovery serves to emphasize again the remarkable nonspecificity of the microsomal oxygenase systems.

Another interesting report is that of Schreiber and co-workers (46) who found that *N*-methyl sulfonamides are demethylated by the microsomal system, thus confirming earlier (47) *in vivo* observations. Smith, Keasling, and Forist (48) have also described the dealkylation of *N*-alkyl sulfonamides. They observed the *in vivo* removal of methyl, ethyl, allyl, isopropyl, butyl, and pentyl groups from the corresponding *N*-alkyl-*p*-bromobenzenesulfonamide in mice. The dealkylation of sulfonamides is reminiscent of microsomal oxidation of the cholinesterase inhibitor, octamethyl pyrophosphoramide (49). In this case the reaction does not go to completion spontaneously since the intermediate *N*-hydroxymethyl intermediate is reasonably stable (see below).

The observations of Henderson and Mazel (50) on the demethylation of various methylated purine bases should also be mentioned. In view of the role of methylated purines as minor constituents of RNA and DNA, these observations may have special significance (51).

Other Enzymes Which Catalyze Oxidative Dealkylation.—In addition to the liver microsomal system, other enzyme systems occur in nature which can oxidize *N*-methyl groups. There are, for example, several instances in alkaloid biogenesis in plants in which the oxidation of an *N*-methyl group appears to occur. In the Tilden lecture (1963), Battersby (52) speculated that the berberine bridge carbon may have its origin in the *N*-methyl group of a suitably substituted 1-benzyl-*N*-methyl-isoquinoline. It was proposed that in this conversion the initial oxidative step might be *N*-oxidation as had been proposed earlier by Wenkert (53) in connection with other alkaloid biotransformations. Direct attack on the methyl group, either by a heterolytic or a free radical mechanism, was suggested as an alternative mechanism (52). Although it has now been

demonstrated by radiocarbon studies that the *N*-methyl group is indeed the source of the berberine bridge, the oxidation mechanisms involved remain obscure (54, 55).

The discovery of the alkaloid leurocristine (56) among the alkaloids of *Vinca rosea* is also of interest. This alkaloid is identical with vincaleucoblastine except that the *N*-methyl has been replaced by an N—CHO group. This conversion could well have taken place in a two-step process through a hydroxymethyl intermediate in exactly the same way that nicotine is converted to cotinine (25) or tremorine is converted to oxytremorine (57) in the liver. *O*-Demethylation also occurs in plants. The elegant research of Rapoport (58) on the biogenesis of morphine leaves no doubt that thebaine is a precursor of morphine which means that two successive *O*-demethylations must occur on the pathway to the latter alkaloid. The demethylation of nicotine to nornicotine in the intact *N. glutinosa* plant has recently been established by Alworth and Rapoport (59).

Another class of enzymes which catalyze oxidative *N*-dealkylation and for which *N*-oxide intermediates have been suggested are found in liver mitochondria. These enzymes are responsible for the *N*-demethylation of *N*-methyl amino acids, such as *N*,*N*-dimethylglycine, as well as the oxidation of certain polar amines, such as dimethyl tryptamine, and appear to be dehydrogenases which require NAD as cofactor.

Horning and co-workers (60) have suggested that the dealkylations catalyzed by these mitochondrial dehydrogenases proceed *via* *N*-oxide intermediates. This suggestion was based on the observation of these workers and of others that *N*-oxides of certain tertiary amines and of dimethylamino acids rearrange in the presence of iron complexes to form carbinol amines which in turn dissociate to aldehyde and dealkylated amine or amino acid (61–67). Although subsequent studies (68, 69) have shown that the oxidation of dimethyltryptamine does not proceed through an *N*-oxide intermediate, the question of whether *N*-oxides are involved in the demethylation of dimethylamino acids has not been resolved.

MECHANISM OF MICROSOMAL DEALKYLATION

In their early work on the *in vitro* demethylation of dimethylaminoazobenzene, Mueller and Miller (2) presented indirect evidence to support the view that the reaction proceeded through an *N*-hydroxymethyl intermediate:

$$R_2NCH_3 \rightarrow [R_2NCH_2OH] \rightarrow R_2NH + HCHO$$

It is now well established that such an intermediate is involved and in certain cases is stable enough to be detected. For example, the active intermediate formed by microsomal oxidation of octamethyl pyrophosphoramide was demonstrated to be *N*-hydroxymethylheptamethyl pyrophosphoramide (49, 70–72).

A particularly relevant observation was that of Keberle *et al.* (38) who found among the metabolites of *N* - methyl -α- phenyl -α- ethylglutarimide the glucuronide of the *N*-hydroxymethyl intermediate (I). Recently McMahon and Sullivan (37) have found an analogous metabolite of the herbicide diphenamid (II). In these cases the hydroxymethyl intermediate has been "trapped" by conversion to a stable derivative, the glucuronide.

The most direct evidence, however, comes from the work of Dorough and Casida (73) who found that the unconjugated *N*-hydroxymethyl derivatives were relatively stable metabolites of α-naphthyl *N*-methylcarbamate and *o*-isopropoxyphenyl *N*-methylcarbamate.

There seems to be little doubt then that the hydroxymethyl compound is indeed an intermediate of *N*-dealkylation. It also seems reasonable to assume that *O*- and *S*- dealkylations proceed through analogous intermediates. There remains, however, the question of how the hydroxymethyl intermediate is formed in the microsomal dealkylation reaction. As a consequence of the work on alkaloid biosynthesis and on the mitochondrial amino acid demethylases discussed, it has been proposed that the *N*-hydroxymethyl intermediate arises from the rearrangement of a tertiary amine *N*-oxide intermediate.

Cotinine	...	*N*-demethylation	Dog	(136)

Continued on next page.

Several facts support this point of view. For example, Hanaki and Ishidate (74, 75) have developed a chemical system consisting of ascorbic acid and chelated iron which will demethylate dimethylaminoazobenzene through an intermediate *N*-oxide. Furthermore, studies with the microsomal system have shown that it can indeed form *N*-oxides from certain tertiary amines (76–78). Finally, it has been reported (79) that dimethylaniline *N*-oxide is readily converted to methylaniline and formaldehyde in the presence of liver microsomes. [This report, however, conflicts with an earlier report of Gillette (80) who found dimethylaniline *N*-oxide to be a poor substrate for these systems.]

There are, however, a number of observations which cast doubt on the *N*-oxide mechanism. Although this mechanism would be satisfactory for the dealkylations of tertiary amines, other mechanisms must be evoked to explain the dealkylation of the many other types of compounds which are dealkylated by microsomes. Another difficulty arises from the extensive work of Kiese on the oxidation of aniline derivatives by liver microsomes. He has shown (81) that the k_m value for oxygen in the *N*-oxidation reaction is some 40 times greater than it is for the *N*-dealkylation reaction. This would seem to rule out *N*-oxidation as an intermediate step in *N*-dealkylation. Recently McMahon and Sullivan (82) found that the microsomal demethylation of radiocarbon labeled *l*-propoxyphene in the presence of a pool of cold *l*-propoxyphene *N*-oxide did not result in the incorporation of radioactivity into the oxide pool. This observation also argues against the involvement of an *N*-oxide intermediate in dealkylation. An analogous study with erythromycin and erythromycin-*N*-oxide led Mao and Tardrew (83) to the conclusion that the *N*-oxide was not a reaction intermediate.

Also if *N*-oxide formation occurred as the rate-determining step, an isotope effect such as that seen in the demethylation of trideuteriomorphine (84) would not be expected. In addition the observation (12, 13) that steric interference about the nitrogen atom does not affect the re-

[a] Although the metabolism of morphine has been studied very extensively, there is at present little evidence that *N*-demethylation is a significant pathway. For example, Rapoport (personal communication) has investigated the metabolism of radiomorphine in humans with some care and has found no normorphine among the metabolites. For a complete discussion of the metabolism of morphine and of other analgesics, see Way and Adler (160). [b] Pohland, Sullivan, and Lee, personal communication. [c] For complete bibliography see *Reference 160*. [d] For a discussion of the demethylation of substituted anisoles, see Williams (161). [e] These workers (32) have studied the *in vivo* cleavage of a wide variety of alkyl and arylalkyl-*p*-nitrophenyl ethers.

action rate argues against the *N*-oxide mechanism.

On the basis of data available at present it seems likely that *N*-oxidation and *N*-dealkylation represent alternative pathways for the metabolism of tertiary amines. In this connection the recent reports by Ziegler and co-workers (77, 78) are of interest. They have shown that cholate treatment of microsomes does not destroy the *N*-oxidizing capacity of the microsomes, although such a treatment frequently results in the loss of dealkylase and hydroxylase activity. Thus, the *N*-oxidizing capacity of microsomes may well be a separate system from that required for dealkylation.

Mention should be made of the suggestion of Oae (85, 86) that the demethylation of methionine might proceed through a sulfoxide intermediate (Pummerer reaction). Since methionine is metabolized by methyl transfer rather than methyl oxidation, such a mechanism would not be applicable for its demethylation, but the Oae work does nevertheless raise the question of possible involvement of sulfoxides in microsomal *S*-demethylation.

At the present time the microsomal dealkylation reaction is best understood as a hydroxylation reaction:

$$RXCH_2R' \xrightarrow[\text{oxygen''}]{\text{''Active}} RXCHOHR \rightarrow RXH + O{=}\overset{H}{C}{-}R'$$

X = *O*, *S*, or *N*.

This type of mechanism is attractive for several reasons. For example, it recognizes the close relationship between dealkylation and the microsomal hydroxylation reaction which it so closely resembles. It is also a general mechanism applicable regardless of the nature of X or R. In addition there exists ample analogy in both organic chemistry and biochemistry for the oxidative attack upon a saturated carbon atom.

Although considerable progress has been made in recent years in understanding the oxygen activating system of microsomes, the nature of

the "active oxygen" species that is formed is still obscure. Early investigators, including Udenfriend (87), Mason (88), Hayano (89), and Corey (90) discussed microsomal hydroxylation in terms of heterolytic mechanisms, but more recently free radical intermediates have received more attention. From results with nonenzymatic hydroxylation systems, Breslow and Lukens (91) have suggested hydroxyl radicals as the active hydroxylating species. On the basis of both enzymatic and nonenzymatic hydroxylation studies, Staudinger (92) has suggested the active intermediate to be either the OH or the OOH radical. Evidence for a free radical mechanism has also been presented by Nilsson, Orrenius, and Ernster (93). Finally Gillette (7) reviewed the literature on microsomal oxidation of drugs and found a free radical mechanism to be most consistent with the facts as they are now known.

The interaction of free radicals with *N*-methyl groups has ample analogy in chemical studies (94–96). In fact, Needles and Whitfield (96) have recently shown that dimethylamides are readily demethylated by a free radical mechanism in aqueous solution containing persulfate ion. Further work with systems of this sort would be of considerable value since they appear to be suitable models for the enzymic reaction.

The observation that *N*-dealkylation occurs even more rapidly than does *N*-demethylation (22, 23) is readily understandable in terms of a free radical mechanism, since the intermediate, resonance stabilized, allyl radical, $-\mathrm{N}(\dot{\mathrm{C}}\mathrm{H})-\mathrm{CH}=\mathrm{CH}_2$ would be expected to form readily. For the same reason the ready *O*-dealkylation of *O*-allyl, *O*-benzyl, and *O*-cyanomethyl aryl ethers (32) can be rationalized in terms of a free radical mechanism. It is interesting to note that the radical formed in *S*-demethylation would be substantially stabilized by electron-sharing resonance which is possible in the case of sulfur since it can expand its valence shell to nine electrons by utilizing a vacant 3d orbital (97).

Additional evidence for the free radical mechanism can be found in studies on side chain hydroxylation by microsomes. It is well known that (ω-1)-hydroxylation occurs to a much greater extent than does ω-hydroxylation. This may be due to the greater stability of the $-\dot{\mathrm{C}}\mathrm{H}\mathrm{CH}_3$ radical as compared to $-\mathrm{CH}_2\dot{\mathrm{C}}\mathrm{H}_2$. Also, there are many examples known in which hydroxylation occurs on a benzylic carbon instead of in the aromatic ring itself as might be expected (98–101). The known stability of benzyl radicals serves to explain these observations. In a number of studies of side chain hydroxylation in which a careful analysis of products has been made, it has been found that in addition to the major product smaller amounts of most other possible isomeric alcohols are also observed (102–104). Such nonspecificity is frequently observed in free radical reactions.

Additional support for a free radical mechanism has been recently presented by Hayaishi (105). He has proposed a generalized hypothesis for the action of oxygenases which involves a ternary complex of oxygen, ferrous iron, and substrate which reacts by a concerted one electron transfer to yield oxygenated substrate.

At present then it appears that microsomal dealkylation is best understood as a free radical hydroxylation reaction.

DEALKYLATION IN THE INTACT ANIMAL

In Table III is presented a listing of a variety of compounds that have been demonstrated to undergo dealkylation when administered to the intact animal. The listing is not comprehensive, but an effort has been made to include compounds of various chemical and physiological types.

Pharmacological Activity of Thalicarpine

By R. A. HAHN*, J. W. NELSON, A. TYE, and J. L. BEAL

The effect of the alkaloid thalicarpine on the cardiovascular system of the anesthetized dog and on several smooth muscle preparations has been studied. In the dog, 2 mg./Kg. produced moderate pressor activity of rather long duration which was sometimes accompanied by a mild tachycardia. This effect does not appear to involve a neural pathway but may be due to a direct action either on the heart or on vascular smooth muscle. Intense, long lasting, noncholinergic hypotension was observed with doses of 10 mg./Kg. Direct depressant effects were seen on several smooth muscle preparations as well as reduction of spasmogenic effects induced by various drugs.

KUPCHAN *et al.* were the first to isolate the alkaloid thalicarpine and to describe its effect on mean arterial blood pressure of the cat (1). They reported that doses up to 5 mg./Kg. caused a transient lowering of blood pressure, while a dose of 10 mg./Kg. caused death. The hypotensive activity, in their opinion, was due to bradycardia, respiratory depression, and a weak adrenergic blocking action.

As part of a continuing study of the genus *Thalictrum* we have observed moderate pressor activity after the administration of 2 mg./Kg. of thalicarpine in the anesthetized dog. The pressor activity was sometimes accompanied by a mild tachycardia. A dose of 10 mg./Kg. was observed to produce an intense depressor response and bradycardia, with some degree of hypotension being observed for 1–3 hr. During this time of prolonged hypotension, no evidence of toxic symptoms was observed. The administration of thalicarpine to the anesthetized cat always produced a transient depressor response.

Reported here are the results of a study of the action of thalicarpine on mean arterial blood pressure of the anesthetized dog and on several smooth muscle preparations.

EXPERIMENTAL

Adult mongrel dogs of either sex were anesthetized with sodium pentobarbital (35 mg./Kg., i.p.). After surgical anesthesia was achieved the trachea was cannulated and bilateral cervical vagotomy performed. The right carotid artery was cannulated and blood pressure recorded *via* a mercury manometer on a kymograph. The right femoral vein was then cannulated with a 3-in. length of polyethylene tubing for the injection of drug solutions. When infusions were administered the left femoral vein was cannulated and the infusion given by means of a Harvard infusion pump. Heart rate was recorded by means of a Sanborn Twin Viso-

Pharmacological Activity of Thalicarpine

By R. A. HAHN*, J. W. NELSON, A. TYE, and J. L. BEAL

The effect of the alkaloid thalicarpine on the cardiovascular system of the anesthetized dog and on several smooth muscle preparations has been studied. In the dog, 2 mg./Kg. produced moderate pressor activity of rather long duration which was sometimes accompanied by a mild tachycardia. This effect does not appear to involve a neural pathway but may be due to a direct action either on the heart or on vascular smooth muscle. Intense, long lasting, noncholinergic hypotension was observed with doses of 10 mg./Kg. Direct depressant effects were seen on several smooth muscle preparations as well as reduction of spasmogenic effects induced by various drugs.

KUPCHAN *et al.* were the first to isolate the alkaloid thalicarpine and to describe its effect on mean arterial blood pressure of the cat (1). They reported that doses up to 5 mg./Kg. caused a transient lowering of blood pressure, while a dose of 10 mg./Kg. caused death. The hypotensive activity, in their opinion, was due to bradycardia, respiratory depression, and a weak adrenergic blocking action.

As part of a continuing study of the genus *Thalictrum* we have observed moderate pressor activity after the administration of 2 mg./Kg. of thalicarpine in the anesthetized dog. The pressor activity was sometimes accompanied by a mild tachycardia. A dose of 10 mg./Kg. was observed to produce an intense depressor response and bradycardia, with some degree of hypotension being observed for 1–3 hr. During this time of prolonged hypotension, no evidence of toxic symptoms was observed. The administration of thalicarpine to the anesthetized cat always produced a transient depressor response.

Reported here are the results of a study of the action of thalicarpine on mean arterial blood pressure of the anesthetized dog and on several smooth muscle preparations.

EXPERIMENTAL

Adult mongrel dogs of either sex were anesthetized with sodium pentobarbital (35 mg./Kg., i.p.). After surgical anesthesia was achieved the trachea was cannulated and bilateral cervical vagotomy performed. The right carotid artery was cannulated and blood pressure recorded *via* a mercury manometer on a kymograph. The right femoral vein was then cannulated with a 3-in. length of polyethylene tubing for the injection of drug solutions. When infusions were administered the left femoral vein was cannulated and the infusion given by means of a Harvard infusion pump. Heart rate was recorded by means of a Sanborn Twin Viso-

recorder. In those dogs which were pretreated with reserpine (1 mg./Kg., i.p., 24 hr. prior to experimentation) the dose of sodium pentobarbital was reduced to 20 mg./Kg. (2).

Adult cats of either sex were anesthetized with sodium pentobarbital and prepared in a similar manner.

Helically cut 3-cm. strips of descending thoracic rabbit aorta were prepared according to the method of Furchgott (3). The tissue was bathed with Krebs bicarbonate solution and gassed with a mixture of 95% oxygen and 5% carbon dioxide in a 10-ml. tissue bath at a constant temperature of 37°. Movements were recorded isotonically on a slow moving kymograph by means of a frontal lever, with a magnification of 1:10 and a tension of 2 Gm. After mounting of the tissue, 1.5 hr. were allowed for equilibration before the addition of drugs. Two-centimeter lengths of adult rabbit ileum and uteri of adult rats were set up in a similar apparatus. These tissues were bathed with Tyrode's solution and 0.5 hr. was allowed for equilibration before the addition of drugs. A resting tension of 2 Gm. was used with the rat uterus, while light tension was used in the case of rabbit ileum.

Solutions of thalicarpine were prepared in physiological saline with the aid of dilute hydrochloric acid, those of dibenamine in polyethylene glycol, while all other drug solutions were prepared in physiological saline. Injection volumes administered to *in vivo* preparations never exceeded 1 ml. and were followed by a 1-ml. flush of saline, while drug solutions added to *in vitro* preparations never exceeded 0.2 ml. All drug solutions were prepared fresh on the day of the experiment. All doses refer to mg. or mcg. of the parent compound. Thalicarpine[1] was isolated and purified according to the method of Tomimatsu *et al.* (4).

Each observation represents a minimum of 3 experiments.

The following drugs were used: thalicarpine, dibenamine, reserpine phosphate, norepinephrine bitartrate, epinephrine bitartrate, dichloroisoproterenol hydrochloride, isoproterenol hydrochloride, dimethylphenylpiperazinium iodide, atropine sulfate, histamine phosphate, tripelennamine hydrochloride, methacholine chloride, and vasopressin.

RESULTS

Figure 1 shows the effect of administration of 2 mg./Kg. of thalicarpine to the anesthetized, vagotomized dog. A pressor response with gradual onset occurred with a peak mean value of +29.2 ± 2.0 mm. of Hg (mean ± standard error) with some degree of hypertension lasting for 10–35 min. Occasionally the pressor response was accompanied by a mild tachycardia. Some animals responded to this dose of thalicarpine in a biphasic manner; a slight, short-lived fall in blood pressure followed by the sustained pressor response. Further administration of this dose of thalicarpine was ineffective in producing a pressor response, and only transient depressor activity was seen. Doses of thalicarpine less than 2 mg./Kg. did not produce any demonstrable effect on arterial blood pressure.

[1] Its identity as thalicarpine was established by infrared comparison and mixed melting point determination with an authentic sample kindly supplied by Dr. S. M. Kupchan.

Upon the injection of 10 mg./Kg. of thalicarpine to the anesthetized vagotomized dog, a prompt intense depressor response occurred (Fig. 2). The maximal depressor response had a mean value of −112.5 ± 8.5 mm. of Hg and some degree of hypotension was observed for 1–3 hr. Bradycardia (30–40 beats/min.) accompanied this depressor activity. Despite this precipitous fall in blood pressure, no evidence of overt toxic effects was observed, the EKG and respiratory patterns being the same as observed before the injection. Doses of thalicarpine between 5 and 10 mg./Kg. produced increasing depressor activity.

Doses of thalicarpine up to 5 mg./Kg., when given to the anesthetized cat, produced only transient depressor activity. Pressor activity was never seen upon either the initial or subsequent injections.

In an attempt to determine the mechanism by which thalicarpine brought about the initial pressor response in the dog at the 2 mg./Kg. dose level, several experiments were conducted.

To determine if the release of endogenous catecholamines was necessary for the response, dogs were pretreated with reserpine (1 mg./Kg., i.p., 24 hr. prior to experimentation). A typical response of the reserpinized dog to 2 mg./Kg. of thalicarpine is shown in Fig. 3. Reserpine pretreatment did not prevent the initial pressor activity. Furthermore, when the initial pressor activity of thalicarpine had been demonstrated and further injections produced only a fall in blood pressure, the infusion of norepinephrine (1 mg. in 30 min.) did not return the ability of thalicarpine to increase arterial blood pressure. Dibenamine pretreatment (10 mg./Kg.), which abolished the pressor activity of injected epinephrine, had no effect on the pressor activity of thalicarpine.

To ascertain if augmentation of cardiac activity played a part in the pressor effect of thalicarpine, dogs were pretreated with dichloroisoproterenol (DCI). Although this pretreatment effectively abolished control responses to isoproterenol, thalicarpine still produced a pressor response (Fig. 4). DCI was also ineffective in preventing the depressor response to subsequent injections of thalicarpine.

A ganglionic stimulant action on the part of thalicarpine would not appear to account for the pressor action in view of the results obtained with dibenamine or with DCI. These drugs are known to be α- and β-adrenergic receptor blocking agents, respectively, and since neither agent blocked the response, a neural pathway does not seem to be

Fig. 1.—The response of the anesthetized, vagotomized dog to 2 mg./Kg. of thalicarpine. The initial injection produced a pressor response, while a subsequent injection caused only a fall in blood pressure. Key: blood pressure in mm. of Hg; heart rate indicated by numbers above blood pressure tracing (beats/min.); T, thalicarpine.

involved. In addition, no augmentation of dimethylphenylpiperazinium (DMPP)-induced pressor activity was observed when DMPP (25 mcg./Kg.) was injected during a typical pressor response to thalicarpine.

The depressor action of repeated injections of thalicarpine at the 2 mg./Kg. dose was not blocked by atropine pretreatment, although the depressor effect of injected acetylcholine was completely abolished (Fig. 4). Vagotomy also did not alter the response. The possibility of histamine release was ruled out when pretreatment with tripelennamine did not block the thalicarpine effect, although injected histamine was prevented from causing its usual depressor response in the dog (Fig. 3).

The precipitous and long lasting hypotensive response to 10 mg./Kg. of thalicarpine was not altered by cervical vagotomy or atropine pretreatment. DMPP-induced pressor responses, known to be mediated through ganglionic stimulation, were the same during the prolonged hypotension produced by thalicarpine as they were at preinjection times. Similarly injected epinephrine (2–4 mcg./Kg.) produced the same rise in blood pressure during the intense thalicarpine hypotension as it did during preinjection times.

When thalicarpine was added to a bath with isolated rabbit ileum a prompt relaxation occurred. Upon washing, this effect was abolished and normal activity resumed. When methacholine chloride was introduced the characteristic spasm was seen; however, pretreatment with thalicarpine greatly reduced the methacholine-induced spasm of the ileum. This effect became less with time (Fig. 5). Normal contractions of the rat uterus were inhibited both in frequency and amplitude upon the addition of thalicarpine into the bath. Vasopressin-induced spasms of the uterus were completely blocked after thalicarpine. With repeated washing of the tissue the vasopressin effect returned (Fig. 6). Similar results were obtained on epinephrine-induced contractions of the rabbit aortic strip. After pretreatment with thalicarpine, in concentrations having no effect of their own (10–40 mcg./ml.), contractions

due to epinephrine were greatly reduced, the effect being reversed with time and repeated washing of the tissue.

DISCUSSION

The administration of 2 mg./Kg. of thalicarpine to the anesthetized vagotomized dog produced a fairly long lasting pressor response with a gradual onset. If liberation of endogenous catecholamines was necessary for the response, then pretreatment with reserpine should block this action, since reserpine is known to deplete sympathetically innervated tissue of catecholamine stores and, thus, reduce the response of various organs to sympathetic nerve stimulation and to indirectly acting sympathomimetic amines (5–7). Thalicarpine-induced pressor activity was observed in the reserpinized dog, and thus, liberation of catecholamines does not appear necessary for the response. When the initial pressor activity to thalicarpine had been demonstrated and further administration of thalicarpine produced only depressor activity, norepinephrine infusion could not restore the pressor action. When the α-adrenergic receptor blocking agent, dibenamine, was given in a dose sufficient to block the pressor effect of injected epinephrine, the pressor activity of thalicarpine was not altered. Therefore, the increase in arterial blood pressure due to thalicarpine is not due to release of catecholamines or a direct α-receptor stimulant effect.

In dogs pretreated with DCI, thalicarpine pressor activity was observed, although positive chronotropic activity of control injections of isoproterenol was blocked (Fig. 4). DCI has been demonstrated to block the positive chronotropic and inotropic effects of adrenergic stimuli in dogs, while it is ineffective against similar responses produced by digoxin or theophylline (8).

Since the pressor activity of thalicarpine does not appear to be due to an epinephrine-like effect, the possibility exists that the effect may be similar to the cardiac action of digoxin which is not altered by DCI. Papaverine also has direct positive inotropic effects (9), and if one views the structure of thalicarpine as reported by Kupchan and Yokoyama (10), it is apparent that thalicarpine contains the basic moiety of papaverine. The possibility exists, therefore, that the pressor activity of thalicarpine may be due to a direct positive inotropic effect to increase cardiac output, especially since a positive chronotropic action was not always seen with thalicarpine.

Some transient direct stimulant effect on vascular smooth muscle might also be a possibility as the cause of the pressor action, although bath concentrations of thalicarpine up to 40 mcg./ml. produced no contraction of the isolated rabbit aortic strip. Vasopressin has been shown to be a potent vasoconstrictor in the intact animal but without effect on rabbit aortic strips (11); a similar situation may exist in the case of thalicarpine.

The rise in blood pressure produced by injections of DMPP during typical thalicarpine hypertension was of the same magnitude as that produced by control injections. DMPP has been shown to be a ganglionic stimulant (12), and if thalicarpine also possessed this activity, then an additive pressor action might be expected. Such was not the case and, therefore, ganglionic stimulation as a basis for the pressor effect of thalicarpine does not appear likely. Furthermore, if ganglionic stimulation is a factor a neural pathway would be involved and dibenamine, DCI, or reserpine pretreatment should have blocked the response.

The hypotension induced by repeated injections of 2 mg./Kg., or by a single injection of 10 mg./Kg. of thalicarpine, does not appear to be cholinergic in nature for atropine did not alter this effect, although it effectively blocked injected acetylcholine (Fig. 4). Cervical vagotomy also had no effect on this response to thalicarpine.

It has been reported that 10 mg./Kg. of thalicarpine caused death in the anesthetized cat (1). In our experiments the administration of this dose of thalicarpine to the dog, and doses of 5 mg./Kg. in the cat, never produced overt signs of toxicity, or death. Animals receiving this dose of thalicarpine appeared normal with respect to EKG and respiratory patterns, and in general appearance. Although the depressor response was intense and long lasting, the blood pressure did return to approximately preinjection levels (Fig. 2). We do not exclude the possibility, however, that this depressor effect may represent thalicarpine toxicity.

The observations that epinephrine and DMPP produced similar pressor effects during thalicarpine hypotension to those at preinjection times indicate that adrenergic blockade or ganglionic blockade are not prime causes of the potent hypotension.

Thalicarpine, in bath concentrations of 10–40 mcg./ml., produced a prompt relaxation of the isolated ileum and uterus. Spasms of the ileum produced by methacholine and those of the uterus produced by vasopressin, were greatly reduced by thalicarpine pretreatment (Figs. 5 and 6). Thalicarpine pretreatment of the isolated rabbit aortic strip also greatly inhibited epinephrine-induced contractions. This effect was reversed on all 3 preparations with time and repeated washings of the tissues. Thus our results indicate a nonspecific inhibition of smooth muscle activity and an ability to antagonize spasmogenic effects of drugs of diverse nature on various smooth muscle as an important pharmacological effect of thalicarpine. This peripheral inhibitory effect of smooth muscle plus bradycardia may well be the cause of the potent hypotension observed with higher doses of thalicarpine.

Analogs of Tetrahydrofolic Acid XXXV

Hydrophobic Bonding to Dihydrofolic Reductase VII. Species Differences with Substituted 4,6-Diamino-1,2-dihydro-*s*-triazines

By B. R. BAKER* and BENG-THONG HO

Twenty-four 4,6-diamino-1,2-dihydro-*s*-triazines with varying substituents on the 1- and 2-positions have been compared as inhibitors of the dihydrofolic reductase from pigeon liver and from *E. coli* B. Since the 4,6-diamino-1,2-dihydro-*s*-triazine most probably binds to the enzyme in the same area as the pteridine ring of the substrate, dihydrofolate, little difference was seen in complexing of the 1, 2, 2-trimethyl derivative (VI); this result was anticipated since the active site of an enzyme cannot be varied appreciably and still have a functioning enzyme. In contrast, hydrophobic bonding to the enzymes by alkyl or aryl groups on the 1- and 2-positions of the inhibitors could be anticipated to show differences in binding between the two species, since it should be possible for the relatively nonfunctional hydrophobic region on the enzyme to be quite variable from species to species and still allow the enzyme to function. The biggest differences between the two species were observed when substituents were attached to the 1-phenyl group of 4,6-diamino-1-phenyl-2,2-dimethyl-1,2-dihydro-*s*-triazine (I) or larger groups than methyl were introduced on the 2-position. Differences in conformational requirements for hydrophobic bonding to the two enzymes are presented.

THAT ALKYL or aryl groups attached to the 5-position of pyrimidines or the 1-position of 1,2-dihydro-*s*-triazines can give strong hydrophobic bonding to dihydrofolic reductase has recently been discovered (1); further studies (2) substantiated the proposal that the aryl groups were also bonded hydrophobically rather than by a charge transfer complex with the enzyme. Some of the conformational aspects of hydrophobic bonding to the dihydrofolic reductase from pigeon liver have also been investigated (3). The hydrophobic bonding region is most probably not in the area where dihydrofolate is complexed (4, 5); if it is adjacent to the 4-position or 8-position of dihydrofolate when the latter is complexed with dihydrofolic reductase (6), this hydrophobic region would therefore be in a nonfunctional part of the enzyme just adjacent to the active site. Furthermore, it might be expected that outside of the active site, one hydrophobic amino acid could be replaced by another hydrophobic amino acid without affecting the function of the active site, whereas amino acid replacement within the active site could be expected to be much more sensitive with respect to enzyme activity (7). *Ergo*, it can be anticipated that there should be species differences in the nonfunctional hydrophobic area presumed to be adjacent to the active site of dihydrofolic reductase. Some aspects of hydrophobic bonding to the dihydrofolic reductase from *E. coli* B and their relationship to the dihydrofolic reductase from pigeon liver is the subject of this paper. Furthermore, 2 previous studies—one from this laboratory (8) and one by Burchall and Hitchings (9, 10)—on the effect that substitution on the 5- and 6-positions of pyrimidines has on the comparative inhibition of dihydrofolic reductases from different sources can now be better envisioned when considered in the light of differences in hydrophobic bonding.

RESULTS AND DISCUSSION

Four discrete series of dihydro-*s*-triazines with variants at either the 1-position or 2-position were compared as inhibitors of the dihydrofolic reductase from pigeon liver and from *E. coli* B; the results are reported in Table I.

Series A.—*1-$C_6H_5(CH_2)_n$-Variants.*—The syntheses of the compounds in this series have been previously described (12). With both enzymes insertion of 1 methylene group (II) between the 1-aryl group and the *s*-triazine of I was detrimental to binding, being 10-fold with the *E. coli* B enzyme and thirtyfold with the pigeon liver enzyme; thus with both enzymes, when the aryl group is out of the plane of the triazine, a loss in binding occurs. By comparison of the 1-benzyl-*s*-triazine (II) with the 1-methyl-*s*-triazine (VI), it can be seen that the phenyl group of II gives little binding to the *E. coli* enzyme, but a 22-fold increment in binding to the pigeon liver enzyme, presumably due to the phenyl group, still remains. The next higher homolog, phenylethyl (III), can now have the phenyl ring nearly coplanar with the *s*-triazine ring; as a result, activity is better than benzyl (II) with both enzymes. On the *E. coli* B enzyme, the phenethyl (III) side-chain is just as effective as the phenyl side-chain (I); in contrast, phenethyl (III)

[a] The technical assistance of Maureen Baker and Karen Smith with these assays is acknowledged. [b] A 45–90% saturated ammonium sulfate fraction prepared from pigeon liver acetone powder and assayed with 6 μM dihydrofolate and 12 μM TPNH as previously described (11) at pH 7.4 in Tris buffer. [c] *E. coli* B cell walls were broken with a French pressure cell at 20,000 p.s.i. A 45–90% saturated ammonium sulfate fraction was prepared as previously described (11), then assayed with 6 μM dihydrofolate and 30 μM TPNH. [d] Data from *Reference 12*. [e] Data from *Reference 1*. [f] Data from *Reference 2*. [g] Data from *Reference 8*. [h] Picrate salt.

is 6.5-fold less effective than phenyl (I) with the pigeon liver enzyme.

Maximum effectiveness against both enzymes is shown with the phenylpropyl side-chain (IV), with phenylbutyl (V) being 1.5–3 times less effective. However, the increment between phenyl (I) and phenylpropyl (III) is much larger (48-fold) with the *E. coli* enzyme than with the pigeon liver enzyme (fourfold); most of this difference is due to the fact that the 1-phenyl (I) binds to the pigeon liver enzyme 27-fold better than the *E. coli* B enzyme, possible reasons for which are discussed later. Furthermore, the greatest specificity toward the pigeon liver enzyme (27-fold) is shown by the 1-phenyl side-chain (I), but none of the compounds in this series are more effective on the *E. coli* B enzyme than the pigeon liver enzyme.

Series B.—*1-Alkyl Variants.*—The synthesis of these compounds has been previously described (1). With straight-chain alkyl substituents maximum hydrophobic bonding with the pigeon liver enzyme occurred in *n*-butyl (IX) with *n*-hexyl (XI) being equal and *n*-octyl (XII) perhaps twofold better; in contrast, with the *E. coli* B enzyme, *n*-hexyl (XI) was 2.3-fold better than *n*-butyl (IX) and *n*-octyl (XII) was 3.4-fold better than *n*-hexyl (XI). Extension of the series would be required to reveal whether maximum straight-chain hydrophobic bonding to the *E. coli* B enzyme had occurred at *n*-octyl.

Branching of the *n*-butyl group (IX) to isoamyl (X) gave a sixfold increment in binding on the pigeon liver enzyme, and X was the most effective alkyl group found for the enzyme from this source (1, 3); the isoamyl group (X) gave a threefold increment in binding over the *n*-butyl group (IX) with the *E. coli* enzyme, but—in contrast to the pigeon liver enzyme—the isoamyl group (X) was still less effective than the *n*-octyl group (XII). Whether chain-branching farther out the chain than the C-3 branch of isoamyl (X) would give a still better inhibitor of the *E. coli* B enzyme is as yet unknown.

It was previously noted (1) that the increment in binding between methyl (VI) and *n*-butyl (IX) to the pigeon liver enzyme was 200-fold; this is well within the 1000-fold (10-fold per methylene) that is theoretically possible. However, it was pointed out that there was a twentyfold increment in binding in proceeding from ethyl (VI) to *n*-propyl (VIII) and a thirtyfold increment in *n*-propyl (VIII) to *n*-butyl (IX), both of which are above the 10-fold increments theoretically possible. The fact that methyl to butyl gave only a 200-fold increment—which is within the theoretical 1000-fold

increment in binding for 3 methylene groups—was rationalized by assuming a conformational change in the enzyme; if this conformational change in the enzyme required no more than 900 cal./mole, then this 900 cal./mole could be supplied by the five-fold difference between the 200-fold increment observed in proceeding from methyl to butyl and the 1000-fold increment theoretically possible. Thus, the greater than 10-fold increment in binding between *n*-propyl and ethyl or *n*-butyl and *n*-propyl is still energetically possible including the energy required for a conformational change in the pigeon liver enzyme. With the *E. coli* B enzyme only the change between ethyl and *n*-propyl gave greater than a 10-fold increment (13-fold) which indicates that little or no conformational change in this enzyme need take place for maximum hydrophobic binding; it should be further noted that the maximum increment in hydrophobic bonding by straight-chain alkyl groups with the *E. coli* enzyme is only 180-fold (between methyl and *n*-octyl) whereas the pigeon liver enzyme has a maximum increment of 530-fold between methyl and *n*-octyl groups.

In this series, the isoamyl-*s*-triazine (X) shows the most specificity toward the pigeon liver enzyme, being 12-fold more effective than on the *E. coli* B enzyme; the most specific compound toward the *E. coli* B enzyme is the ethyl-*s*-triazine (VII) which is 3.5-fold more effective than on the pigeon liver enzyme.

Series C.—*1-Phenyl with m- and p-Substituents.*—The synthesis of these compounds and their inhibition on pigeon liver dihydrofolic reductase have been previously described (2, 12). In this series is seen the largest spread in specificity between the two enzymes in both directions. The *E. coli* B enzyme is relatively insensitive to *m*- or *p*-substituents, the maximum variation being between 7.2 μM for the *p*-(*n*-butyl)-substituent (XV) to 0.6 μM for the *m*-benzoyl (XVII) and *m*-chloro (XVIII) substituents, a 12-fold spread; in contrast, the pigeon liver enzyme is extremely sensitive to substitution, varying from 0.0085 μM for the *m*-chlorophenyl group (XVIII) to 160 μM for the *p*-biphenyl group (XIII) at the 1-position of the *s*-triazine, a 19,000-fold spread. As a result the *p*-(*n*-butyl)-phenyl-*s*-triazine (XV) is 110-fold more effective on the pigeon liver enzyme than the *E. coli* B enzyme; similarly, the *m*-chlorophenyl-*s*-triazine (XVIII) and the *p*-(benzyl)phenyl-*s*-triazine (XIX) are 71 and 77-fold, respectively, more effective on the pigeon liver enzyme. In contrast, the *p*-biphenyl-*s*-triazine (XIII) and the 9-fluorenon-2-yl-*s*-triazine (XVI) are 28 and 57-fold more effective, respectively, on the *E. coli* B enzyme. Note that the benzoyl group of XVII causes a 10-fold loss in binding to the pigeon liver enzyme, but a fivefold gain in binding to the *E. coli* B enzyme. When the *m*-benzoylphenyl group of XVII is cyclized to the 9-fluorenon-2-yl group as in XVI, only a 2.5-fold loss in binding occurs in the *E. coli* B enzyme, but a further 77-fold loss in binding to the pigeon liver enzyme occurs; thus, the pigeon liver enzyme cannot tolerate a large flat substituent at the 1-position, but the *E. coli* B enzyme can. Reduction of the ketone of XVII to give the *m*-benzyl derivative (XX) causes little change with the *E. coli* B enzyme, but 46-fold better inhibition is seen with the pigeon liver enzyme.

The most active and one of the most specific compounds for the pigeon liver enzyme in this series is *m*-chlorophenyl-*s*-triazine (XVIII) at 0.0085 μM. The most active compound in this series for the *E. coli* B enzyme is the *m*-phenethylphenyl-*s*-triazine (XXI) at 0.092 μM, but this compound has no specificity toward the *E. coli* B enzyme since XXI is even more effective on the pigeon liver enzyme.

Series D.—*Variants at the 2-Position.*—The synthesis of these compounds and their evaluation on pigeon liver dihydrofolic reductase have been previously described (12). Structural change at the 2-position by introduction of larger groups has a much more detrimental effect on binding to the pigeon liver enzyme than the *E. coli* B enzyme. Note that replacement of the 2,2-dimethyl group of the 1-phenylbutyl-*s*-triazine (V) by 2-(*p*-acetamidophenyl) (XXII) reduces binding to the pigeon liver enzyme by a factor of 15-fold, but reduces binding to the *E. coli* enzyme by only a factor of twofold. Similarly, the same 2-substituent exchanged on the 1-(*m*-chlorophenyl)-*s*-triazine (XVIII) to give XXIII causes a 19,000-fold loss in binding to the pigeon liver enzyme, but only an 850-fold loss to the *E. coli* B enzyme; it should be noted that this structural change giving a 1,2-diaryl-*s*-triazine reduces coplanarity of at least one phenyl and possibly both phenyls with the *s*-triazine ring (13). When the 2, 2-dimethyl group of the 1-ethyl-*s*-triazine (VII) is replaced by phenyl to give XXIV, it results in only a fivefold reduction in binding to the *E. coli* B enzyme, but a 68-fold reduction in binding to the pigeon liver enzyme occurs. A study of other 2-substituents with IV and V could well lead to higher affinity to the *E. coli* B enzyme than the pigeon liver enzyme since the latter is more sensitive to structural change at this 2-position; note that XXIV, although it is a poor inhibitor, is fiftyfold more effective on the *E. coli* B enzyme than the pigeon liver enzyme and that no compound in this series shows the converse order of affinity.

Relative Topography of Hydrophobic Bonding to the Two Enzymes.—The difference in binding to the two enzymes can give considerable insight into the differences in topography of the hydrophobic regions of the two enzymes. It is well established that the phenyl group of I*a* must be nearly coplanar with the triazine ring for maximum binding (13) to the enzyme since introduction of an *o*-chloro group causes a great reduction in the affinity of the inhibitor to both enzymes due to the restricted rotation of the 1-phenyl-*s*-triazine system imposed by the *o*-chloro group (8, 12). Since there is strong experimental support for the 1-phenyl group being hydrophobically bonded to the enzyme (2), it is a reasonable assumption that the 1-phenyl group of I*a* and a 1-alkyl group of VIII*a* are bonded in the same

IXa, R = CH_3

XXIIa

region. The alkyl group can then be staggered in the plane of the triazine either away from the 2-position as in VIII*a* or toward the 2-position as in VIII*b*. Since XXII and XXIV can still bind reasonably well to both enzymes, a downward-stagger of the VIII*b* type is not possible due to the 2-phenyl group of XXII occupying the same space as the C_2-methylene group of the side chain. With the upward-staggered conformation, there is no steric interaction between the C_2-methylene group and the 2-phenyl, but there is now a possible steric interaction between the C_1-methylene group and the 2-phenyl group; this C_1-methylene steric interaction does not occur if the 2-phenyl group is in a plane perpendicular to the triazine, but is strong if the plane of the phenyl group is moved 90°. It follows that the *E. coli* B enzyme has more tolerance for the 2-phenyl group approaching a plane perpendicular to the triazine than the pigeon liver enzyme, since little activity is lost in the *E. coli* B enzyme when VII is converted to XXIV or V is converted to XXII; the large reduction in affinity to the pigeon liver enzyme indicates that this enzyme cannot tolerate the 2-phenyl group approaching a plane perpendicular to the *s*-triazine ring.

Note that the *n*-propyl-*s*-triazine (VIII) is nearly as effective as the 1-phenyl-*s*-triazine (I) on the *E. coli* B enzyme, but that I is 100-fold more effective than VIII on the pigeon liver enzyme. Models clearly indicate that C_1, C_2, and C_3 of the phenyl group exactly overlap the C_1, C_2, and C_3 groups of an alkyl side chain when they have conformations I*a* and VIII*a*, respectively. Since the 1-propyl-*s*-triazine (VIII*a*) binds almost as well as the 1-phenyl-*s*-triazine (I*a*) to the *E. coli* enzyme, it is reasonable to propose that most of the phenyl bonding of I*a* occurs through the C_1, C_2, and C_3 carbons; the remaining 1.6-fold difference between I*a* and VIII*a* might be due to slight additional bonding by the C_4 or C_6 carbons of the phenyl or the C_1, C_2, and C_3 carbons of the phenyl of I*a* may hydrophobically bond a little better than the corresponding carbons of VIII*a;* this 1.6-fold difference, however, is practically negligible.

The 100-fold better binding of the 1-phenyl of I*a* than the 1-propyl of VIII*a* to the pigeon liver enzyme suggests that at least 2 more carbons of the benzene ring—in addition to C_1, C_2, and C_3—are complexed hydrophobically to this enzyme; one of these carbons is most probably C_4 since the isoamyl group (X) with its skewed C_4 and C_4' carbons has been shown to have both of these carbons hydrophobically bonded (3).

Both the *n*-octyl (XII) and the phenylbutyl-*s*-triazine (IV*a*) are better—and about equally effective—inhibitors of the *E. coli* B enzyme than the 1-phenyl-*s*-triazine (I*a*) by a factor of 11-to 14-fold. Furthermore, XII and IV*a* are about 10-fold better inhibitors than the *n*-butyl-*s*-triazine (IX*a*); since the terminal four carbons of XII can only increase affinity to the enzyme by hydrophobic bonding of one or more of these terminal carbons, it follows that the phenyl group of IV*a* does likewise. In contrast, the pigeon liver enzyme has only a twofold greater affinity for the octyl group of XII than the butyl group of IX*a*, but the phenylbutyl group of IV*a* is complexed eightfold better than the butyl group of IX*a;* it follows that the additional hydrophobic bonding to the pigeon liver enzyme past the *n*-butyl group requires the relatively flat interaction that can occur with a benzene ring, but the *E. coli* B enzyme can bind either a flat or staggered group in this area. The greater tolerance to type of group attached to the 1-phenyl substituent by the *E. coli* B enzyme has also been pointed out under *Series C*.

Of further interest is that there is less than a twofold difference in binding to the two enzymes with the 1-methyl-*s*-triazine (VI), but there is a 12-fold difference with the *i*-amyl-*s*-triazine (X) and even larger differences in both directions with XV and XVI. (See *Series C*.) Since it is highly probable that the 4,6-diamino-*s*-triazine moiety binds within the normal complexing region for the pteridine ring of the substrate, dihydrofolate, and since the active site of an enzyme has a considerable limitation on structural change which will still allow the enzyme to be operable, little difference should be seen in binding of the 4,6-diamino-*s*-triazine moiety to the enzyme. In contrast, large differences in hydrophobic bonding were anticipated and found since this is a nonspecific part of the enzyme which could readily vary from species to species and still leave an operable enzyme.

Further examples of species differences in the ability of dihydrofolic reductase to bind 2,4-diamino-heterocycles that have varying hydrophobic groups have been collated by Burchall and Hitchings (9); their observations fit into the differences in hydrophobic bonding that are described here. They also noted that the biggest species differences existed when substituents on the 1-phenyl group or 2-position of the *s*-triazine were varied.

Although differences in hydrophobic bonding to the dihydrofolic reductase between invading organisms such as bacteria and protozoa on the one hand, and mammalian enzymes on the other hand, are sufficiently large to enjoy a chemotherapeutic advantage with reversible inhibitors *in vivo* (9), such differences between a cancer cell and the host are most probably too small to have any chemotherapeutic advantage with reversible inhibitors of the 2,4-diamino-heterocycle type. By utilizing both hydrophobic bonding to dihydrofolic reductase

and the bridge principle of specificity with active-site-directed irreversible inhibitors (14), it should be possible to magnify immensely any small difference between the hydrophobic areas of the tumor tissue and host dihydrofolic reductases; this small difference would be unusable or even undetectable with reversible inhibitors. Since active-site-directed irreversible inhibitors of the dihydrofolic reductase from pigeon liver have been found which utilize the hydrophobic bonding region (15, 16), only a small difference in the hydrophobic region of a tumor tissue dihydrofolic reductase would be sufficient for high specificity—such as a change of a valine for a leucine or a slightly different conformation in the hydrophobic region caused by a single amino acid exchange in another region. Such a small difference could be exploited by attaching a bridging moiety to the hydrophobic bonding moiety of an inhibitor so that the subsequent attack by the bridging group to form a covalent bond to a nucleophilic site on the enzyme is subject to proper juxtapositioning by the hydrophobic area on the enzyme. Such studies are currently being pursued.

Effect of Certain Drugs on Perfused Human Placenta VI

Serotonin Antagonists

By CHARLES O. WARD and RONALD F. GAUTIERI

The antiserotonin action of several compounds was investigated in the vasculature of the isolated perfused human placenta. Average onset, duration of action, and per cent decrease at maximal antagonism were used to discern the antiserotonin capability of the smallest effective dose of each compound necessary to antagonize the pressor action of serotonin. Their ability to antagonize the vasoconstrictor effect of serotonin, in decreasing order of effectiveness, was: cyproheptadine, LSD, diphenhydramine, chlorpromazine, promethazine, promazine, and dibenamine. Cyproheptadine, which had a relatively short duration of action, caused the greatest decrease to the pressor action of serotonin, while chlorpromazine and diphenhydramine exhibited the longest duration of action. The mechanisms by which these agents antagonized the vasopressor effect of serotonin are attributed to a blockade of α-adrenergic receptors, competition for specific receptor sites, and/or direct negative musculotropic action. It is suggested that the human placenta, rather than tissues of other species, may serve as the organ of choice to evaluate the potential effectiveness of serotonin antagonists useful in therapeutics.

ALTHOUGH the vasoconstrictor property of serotonin has been known since 1869 (1), the interplay between its physiologic and pathologic functions, as well as the elucidation of its pharmacologic mechanisms, awaited the development not only of reliable assays for its estimation in biologic tissues, but also techniques for determining the potency of agents specifically antagonistic to it.

Many compounds have been shown to antagonize the stimulant effect of serotonin on smooth muscle, and among the several organs used to demonstrate this phenomenon are the gastric fundus of the rat (2), estrogen-primed rat uterus (3), isolated rabbit ear (4), sheep artery rings (5), and the guinea pig ileum (6). The effect of serotonin on diuresis (7) and blood pressure (8) in the intact animal also has been used to show the antiserotonin effect of these agents. While these techniques are generally sensitive to minute doses of serotonin, and though the results are usually reproducible in the particular procedure

TABLE I.—COMPARISON OF SEROTONIN ANTAGONISM BY SEVERAL COMPOUNDS IN PERFUSED HUMAN PLACENTAL VESSELS

Drug	Dose	Expt., No.	Av. Max. Antagonism, min.	Range of Duration of Action, min.	Av. Decrease at Max. Antagonism, %
Chlorpromazine	0.5–1.0 mg.	3	20.0	21–79	67.8
Promazine	0.5–1.0 mg.	5	14.0	9–46	47.4
Promethazine	0.5–2.0 mg.	6	16.2	11–49	52.7
LSD	100.0–200.0 mcg.	6	10.8	11–30	75.6
Cyproheptadine	100.0 mcg.	3	11.0	17–28	86.2
Diphenhydramine	10.0 mg.	3	31.7	24–63	68.9
Dibenamine	2.0 mg.	4	26.3	17–52	46.4

employed, conflicting results occur often enough to make it difficult to predict the effect of these antagonists in humans.

Variation among the several species of animals used is considerable, both in response to serotonin and to its antagonists as well. For example, the intravenous injection of serotonin in dogs increases the heart rate and blood pressure, while the rabbit responds to similar doses with hypotension and bradycardia (8). The gramine derivatives, medmain and methylmedmain, are serotonin antagonists on the rat uterus but have no effect on antidiuresis (7). Morphine is ineffective as a serotonin antagonist on strips of the gastric fundus of the rat (2), the isolated rat uterus, and the isolated rabbit ear, but has potent antiserotonin actions on the guinea pig ileum (6). The ergot alkaloids, however, are poor serotonin antagonists on the guinea pig ileum (9), but give excellent results in other tissues, including sheep artery rings (5), the isolated rat uterus (3), and the blood vessels of the isolated human placenta (10). Hydralazine increases serotonin-induced contractions of the guinea pig gut, with only slight, if any, effect on the rat intestine (11). On the other hand, the vasoconstrictor action of serotonin on the blood vessels of the human placenta is occasionally antagonized by hydralazine (12). Another adrenergic blocking agent, dibenamine, has also been shown to exhibit serotonin-like and antiserotonin actions, in that it inhibits diuresis when given alone to the intact rat, then blocks the antidiuretic effect of subsequent doses of serotonin (13).

The obvious conclusion is that no one animal preparation can be used to assay for all serotonin antagonists, and even if one were available, this would not be an exact indication that the same effects would be noted when the drugs were given to man.

Serotonin has been implicated as a causative factor in the toxemias of pregnancy (14, 15), certain forms of mental disease (16), allergic disorders (17), and collagen diseases (18); in the toxemias of pregnancy the toxic effects of serotonin are thought to be the result of a constriction of the blood vessels of the placenta with resulting ischemia (15).

Thus, it is imperative that a method for evaluating the therapeutic effects of serotonin antagonists in man be available. Therefore, it was the purpose of this investigation to evaluate the antiserotonin activity of several known serotonin antagonists on the vasculature of the human placenta in order to predict more accurately the degree of antagonism of these agents in human tissue.

MATERIALS AND METHODS

Full-term human placentas, obtained from the hospital 15 to 20 min. after normal delivery, were used throughout this investigation. Each was transported to the laboratory in a glass container filled with approximately 1 L. of Tyrode's solution preheated to 38°.

The apparatus employed and the procedures involved in the preparation and perfusion of the placentas, in recording and maintaining the perfusion pressure, and in measuring the inflow and outflow volumes of the perfusate have been described in previous papers (12, 19). In 26 successful placental preparations, each lasting 1–4 hr., a total of 30 experiments were performed. The results obtained from 4 placentas were discarded because the response to a test dose of serotonin was erratic.

Throughout this investigation the agonist, serotonin, was administered before the various antagonists for the purpose of establishing a standard response to its vasoconstrictor effect; the antagonists were administered 5 min. after the pressor action of serotonin subsided. Responses to subsequent doses of serotonin, after the various antagonists, were then compared to the initial response to serotonin at the start of each experiment. The per cent decrease at maximal antagonism of the pressor effect of serotonin was calculated and used to compare the relative antagonistic capability of the compounds employed. The average onset of maximal antagonism, as well as the time interval (duration of action in Table I) before subsequent doses of serotonin would produce pressor responses that approximated half that of the initial standard response, were also used as bases of comparison. The doses of serotonin, administered after the antagonist, were injected at approximately 8–10-min. intervals and were based on those doses used in previous investigations in this laboratory (12,

19), either 25 or 50 mcg. In the later perfusions the dose of 50 mcg. was adhered to because this appeared to give more consistent responses.

One objective of the investigation was to observe the relative antagonism of the compounds employed utilizing the smallest dose which exhibited serotonin antagonism. This dose, for the antagonists, was not always the same in every placenta. Also, because the antagonists varied widely in their inherent ability to antagonize the pressor action of serotonin, they could not be compared on an equidosage basis and still show antiserotonin activity.

The following known serotonin antagonists were injected into the arterial side of the perfusion, in a volume of distilled water not exceeding 2.0 ml., except where noted: 5-hydroxytryptamine creatinine sulfate (serotonin), 0.01%; chlorpromazine hydrochloride,[1] 0.025%; promethazine hydrochloride,[2] 0.05%; promazine hydrochloride,[3] 0.05%; cyproheptadine hydrochloride,[4] 0.01%; D-lysergic acid diethylamide-25[5] (LSD-25), 0.01%; diphenhydramine hydrochloride,[6] 1.0%; dibenamine hydrochloride,[7] 0.4% in 95% U.S.P. alcohol. In addition, 95% U.S.P. alcohol was injected alone to observe the effect of this vehicle on the placental vessels.

RESULTS

The following results, which are summarized in Table I, were obtained on the vasculature of full-term human placentas perfused at pressures between 60 and 108 mm. Hg. This range of perfusion pressures corresponds to inflow rates of 58 to 72 ml. of perfusion fluid [Tyrode's solution modified by the addition of 0.525% polyvinylpyrrolidone (Plasdone C)] per min.

Chlorpromazine.—In doses of 0.5–1.0 mg., chlorpromazine caused a maximum decrease of 52.0 to 85.0% (average 67.8) compared to the standard pressor effect of an initial 25.0-mcg. dose of serotonin. In the 3 experiments performed, the maximum antagonism of serotonin occurred an average of 20 min. (range 10–28) after the administration of chlorpromazine. Approximately 21–79 min. elapsed before further doses of serotonin gave an increase in pressure approximately equal to half the pressure increase produced by the initial dose of serotonin (28.0–119.2 mm. Hg) (Fig. 1). In 2 additional preparations, subsequent doses of serotonin failed to produce pressure increases that even approximated half that caused by initial doses of serotonin.

Promazine.—In a total of 5 experiments, 0.5–1.0 mg. of promazine produced an average maximum antagonism of serotonin of 38.2–72.2% (average 47.4). The antagonistic effect of promazine became maximal at an average of 14 min. (range 9–19) after administration and lasted 9–46 min. before a standard dose of serotonin (25.0–50.0 mcg.) caused an increase in pressure in the placental vessels that was about half that caused by the same dose of serotonin initially (11.0–123.6 mm. Hg) (Fig. 2).

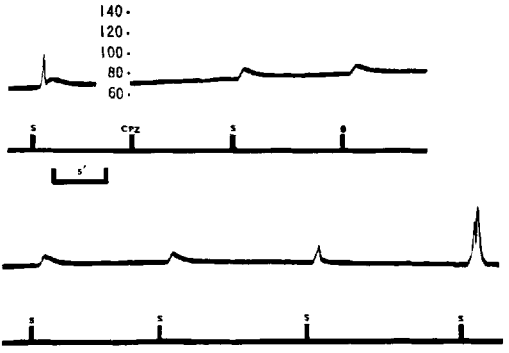

Fig. 1.—Antagonism of serotonin by chlorpromazine (top and bottom). Key: S, serotonin (25 mcg.); CPZ, chlorpromazine (1.0 mg.).

Promethazine.—Promethazine, in doses of 0.5–2.0 mg., produced an average maximum decrease to the pressor effect of 25.0–50.0 mcg. of serotonin of 52.7% (range 16.7–80.1). The maximum antagonism became evident at an average of 16.2 min. (range 11–30) after promethazine was given and lasted from 11–49 min. before the same dose of serotonin gave a response approximately half that of the initial dose (4.8–258.0 mm. Hg). The results presented above were obtained from 6 experiments on 5 separate placental preparations (Fig. 3).

LSD.—Doses of 100.0–200.0 mcg. of LSD reduced the pressor effect of 50.0 mcg. of serotonin by an average of 75.6% (range 28.3–100.0) at maximal antagonism. This effect of the antagonist was observed to reach a maximum at an average of 10.8 min. (range 6–16) after administration and lasted from 11–30 min. before subsequent doses of serotonin produced increases in pressure equal to about half those produced by initial doses (7.8–74.8 mm. Hg). In 4 of the 6 experiments performed, LSD produced an increase in pressure itself equivalent to 1.2–4.4 mm. Hg (Fig. 4).

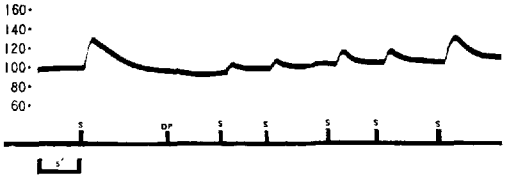

Fig. 6.—Antagonism of serotonin by diphenhydramine. Key: S, serotonin (50 mcg.); DP, diphenhydramine (10 mg.).

Cyproheptadine.—In 3 experiments 100.0 mcg. of cyproheptadine produced an average of 86.2% (range 82.7–92.4) maximum decrease in comparison to the pressor effects of 50 mcg. of serotonin. The maximum serotonin antagonism of cyproheptadine was noted at an average of 11 min. (range 10–12) after administration and lasted 17–28 min. before the administration of another dose of serotonin gave pressure increases equivalent to about half those produced by the control dose (13.6–53.8 mm. Hg) (Fig. 5). In one perfusion, 50.0-mcg. doses of serotonin subsequent to the administration of 100.0 mcg. of cyproheptadine failed to produce an increase in pressure about equal to half that produced by the initial dose of the agonist.

Diphenhydramine.—Diphenhydramine, in a dose of 10.0 mg., produced an average 68.9% decrease (range 63.6–71.4) to the pressor effects of serotonin at maximal antagonism. In the 3 experiments performed, the average maximal antagonism occurred an average 31.7 (range 14–49) min. after administration and lasted 24–63 min. before subsequent doses of serotonin gave responses equivalent to about half the original pressure increase (19.8–46.2 mm. Hg) caused by the initial 50-mcg. dose of serotonin. In 2 of the 3 preparations, diphenhydramine elicited an initial decrease in pressure ranging from 3.1–6.6 mm. Hg (Fig. 6).

Dibenamine.—In a total of 4 experiments, 2.0 mg. of dibenamine caused an average maximum decrease in the response to serotonin of 46.4% (range 14.2–92.8). The average maximum antagonism occurred 26.3 min. (range 7–52) after administration and lasted from 17–52 min. before subsequent doses of serotonin produced about half the pressure increase caused by the control dose of 50 mcg. (7.0–47.0 mm. Hg). In all of the experiments performed, the administration of dibenamine alone caused an increase in pressure ranging from 2.0–5.0 mm. Hg. The administration of a volume of 95% U.S.P. ethyl alcohol (0.5 ml.), equal to that used to dissolve a 2-mg. dose of dibenamine hydrochloride, caused a comparable increase in pressure in 4 separate experiments. In 2 of the 4 experiments utilizing dibenamine, it was noted that the first dose of serotonin subsequent to the antagonist elicited a pressure increase greater than the control response at the beginning of the perfusion. However, all other injections of serotonin resulted in diminished responses.

DISCUSSION

When the antagonists, utilizing their smallest effective dose, were compared on the basis of the per cent that they decreased the pressor response of the placental vessels to serotonin at maximal antagonism, their ability to antagonize the vasoconstrictor effect of serotonin, in decreasing order of effectiveness, was: cyproheptadine, LSD, diphenhydramine, chlorpromazine, promethazine, promazine, and dibenamine. As can be seen from Table I, the onset of maximal antagonism for most of the compounds tested was between 10 and 20 min. after administration, with only diphenhydramine and dibenamine having a more prolonged onset. The range of duration of action, based upon the previously stated criterion, varied greatly, with chlorpromazine being by far the longest acting, as would be expected from the known localization of this compound in body tissues (20). Cyproheptadine, while the most effective antiserotonin agent tested, had the shortest duration of action. Chlorpromazine, in 2 perfusions, and cyproheptadine, in 1, blocked serotonin's vasoconstriction so effectively that subsequent doses never elicited pressor responses that approximated half those produced by the initial standard doses of serotonin during the biological life of the preparation. In all of the perfusions performed the phenomenon of tachyphylaxis to the pressor action of serotonin was never observed. In most instances the effect of the antagonist reached a maximum after 10–31 min.; subsequently the pressor response

to successive doses of serotonin began to approximate half that of the control response.

In a preliminary investigation, leading to the present study, no dose-response relationship to serotonin could be demonstrated in the perfused placental preparation. Consequently, it was not possible to classify the compounds employed as specific or nonspecific antagonists.

Because previous investigations (12, 21) have alluded to the concept that placental vessels contain both α- and β-adrenergic receptors, according to Ahlquist's classification (22), and because it has been postulated that the α receptors are stimulated by serotonin (12), the vasoconstrictor effect of this agonist, as well as the actions of the various antagonists, can be interpreted in the light of these observations, as well as by the well-known stimulant effect of serotonin on most smooth muscle. The phenothiazines used in this investigation, chlorpromazine, promazine, and promethazine, possibly owe their antiserotonin action to a blockade of the α-adrenergic receptors in the placental vessels, since they have been shown to possess adrenergic blocking properties (23). Dibenamine and possibly LSD share this mechanism with the phenothiazines, and a similar interpretation can be applied to the understanding of their antiserotonin action in this preparation. LSD, however, has been shown to have a structural similarity to serotonin, notably the indole configuration, and thus it may compete with serotonin for receptor sites in the smooth muscle (24). In addition, LSD has a stimulant effect on smooth muscle similar to that of serotonin (24) which again may be attributed to its structural similarity to serotonin. This was probably the case in this investigation, as LSD produced pressure increases equivalent to 1.2–4.4 mm. Hg in most of the experiments performed. Cyproheptadine (25) and diphenhydramine (26) both have a negative musculotropic action in other systems, and it is plausible to credit their antiserotonin action in the placental vessels to a similar mechanism. Diphenhydramine and cyproheptadine were both shown to be strong serotonin antagonists in this investigation, being more potent than dibenamine and the phenothiazines which acted predominantly on receptor sites. In fact, diphenhydramine, in 2 of the 3 perfusions, caused a decrease in pressure immediately after it was injected which varied between 3.1 and 6.6 mm. Hg.

In 2 of the 4 perfusions performed using dibenamine, doses of serotonin, subsequent to this antagonist, gave pressor responses greater than the original control response, indicating that the dibenamine was potentiating the vasoconstrictor action of serotonin. However, dibenamine has been shown to possess serotonin-like actions in other preparations, such as its antidiuretic effect in the rat (13); therefore, a similar effect in the placental vessels cannot be disregarded at this time. The administration of dibenamine in a vehicle of 95% ethyl alcohol always caused an initial increase in pressure, ranging from 2.0 to 5.0 mm. Hg; this is due to the vasoconstrictor effect of the alcoholic vehicle since in this, and previous investigations (27), alcohol has been shown to cause vasoconstriction of the placental vessels.

By following the procedures outlined in this investigation, we have evaluated the relative effectiveness of several agents that are antagonistic to serotonin. Consequently, we can hypothesize that those agents which were found to be the most effective serotonin antagonists in this organ may have some therapeutic efficacy in the diseases in which abnormal amounts of serotonin play a significant role in their pathologic manifestations as well as their etiology. The primary example of such a disease is toxemia of pregnancy since the clinical manifestations of this malady are thought to be the result of the vasoconstrictor effect of serotonin on the blood vessels of the placenta (14, 15).

Azulene Analogs of Pharmacologic Agents

By TULLY J. SPEAKER* and GLENDEN D. REDMAN

The synthesis of a series of azulene-1-carboxylic acid esters is described. These esters are to be screened for pharmacologic activity.

AZULENE, with a resonance energy of about 46 Kcal./mole can be classified as aromatic with respect to resonance stability (1, 2) and is the only known bicyclic nonbenzenoid hydrocarbon of this type. Azulene has been unequivocally shown to undergo electrophilic substitution at the 1-position (3).

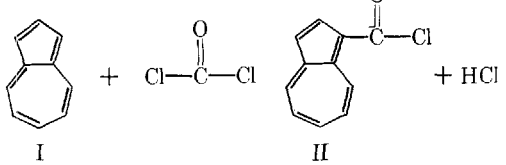
Until the development of an efficient method for the preparation of azulene in 1956 by Ziegler (4), utilization of this nonbenzenoid nucleus was severely restricted, at least in part by economic factors.

Investigation of the pharmacodynamic activity of azulene and azulene derivatives, principally hydrocarbons, has to date been restricted in the main to examination of the antiphlogistic (5, 6), antiallergic (7), and bacteriostatic (8) properties of these compounds or mixtures of them obtained from chamomile and similar oils.

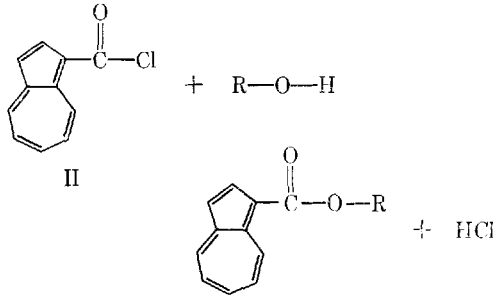
It seemed of importance, therefore, to undertake a systematic study of the effects of replacing benzenoid nuclei in structures known to exhibit pharmacologic activity with the nonbenzenoid aromatic nucleus of azulene.

Because the aromatic portions of local anesthetics are essential to a high level of local anesthetic activity, it seemed reasonable to initiate this study by preparing several azulene compounds which might be expected to be local anesthetics were their aromatic portions benzenoid rather than nonbenzenoid.

The room temperature reaction of azulene (I) with phosgene in the absence of Friedel-Crafts catalysts described by Triebs *et al.* conveniently provided the acid chloride of azulene-1-carboxylic acid (II), and this acid chloride on reaction with appropiate alcohols afforded the corresponding esters (III) in yields averaging about 90% of theoretical, based on azulene.



I II

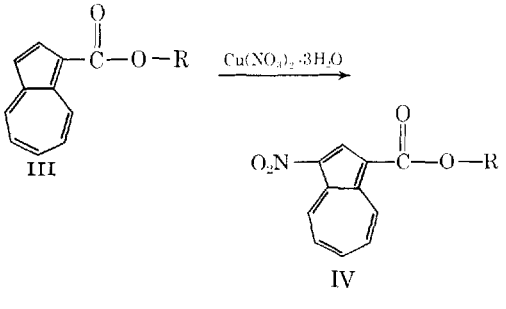


II III

The high π-electron density of the 1- and 3-positions of the azulene nucleus calculated by the linear combination of atomic orbitals-molecular orbital method of Hückel (10) suggests that a 3-substituent corresponds closely in electronic behavior to a *para* substituent in a phenyl nucleus.

Accordingly, it was of interest to prepare several 3-substituted esters for this study.

Treating an azulene-1-carboxylic acid ester with cupric nitrate in a mixture of acetic acid and acetic anhydride after the method of Anderson (11) provided a route to the corresponding 3-nitro ester (IV) and reduction of the 3-nitro



III IV

esters yielded the relatively unstable 3-amino esters (V).

Attempts to chlorocarboxylate 1-nitroazulene were unfruitful.

Some esters substituted in the alcohol-derived portion are poorly stable under even these mild nitration conditions, but the relative stability of the Ω-haloalkanol esters to these nitration conditions offered a method for introduction of more labile groups into the alcohol-derived portion of the 3-substituted esters.

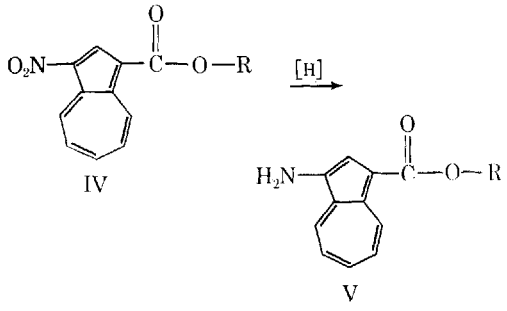
This investigation was supported in part by grant RG 7885 from the U. S. Public Health Service, Bethesda, Md.
* Present address: School of Pharmacy, University of Connecticut, Storrs.



EXPERIMENTAL

Azulene for this study was at first prepared in this laboratory after the method of Ziegler (4) and was later obtained from Terra Chemicals, Inc.

Alcohols available from Distillation Products Industries, Division of Eastman Kodak Co., were obtained from that source. The others were prepared in this laboratory.

All melting points were determined using a Fisher-Johns melting point apparatus and are corrected.

All spectral data were obtained using a Beckman DB spectrophotometer and Distillation Products Industries spectro grade methanol as solvent.

Gases were obtained from the Matheson Co., Inc.

Chromatographic alumina was Fisher Scientific Co. No. A540.

Esters of Azulene-1-carboxylic Acid.—Each of the esters of unsubstituted azulene-1-carboxylic acid was prepared by the following procedure adapted from Triebs *et al.* (9). A solution of 1.282 Gm. (0.01 mole) of azulene in 50 ml. of dry toluene was saturated with phosgene while cooled in a bath of running tap water and allowed to stand 1 hr. (Failure to cool the solution increased the amount of tarry material formed and significantly lowered yields of ester.) During this time the solution changed from a dark blue color to a dark red-violet color. The excess phosgene was removed by gentle refluxing under a slight vacuum for about 30 min.

A solution of 0.010 mole of the appropriate alcohol in dry toluene was added dropwise to this solution of azulene-1-carboxylic acid chloride. The reaction mixture was allowed to stand 30 min., treated with 20 ml. of dilute ammonium hydroxide, and transferred to a separator. The reaction vessel was rinsed with an additional 10 ml. of toluene and the rinsings were added to the funnel. The reaction mixture was successively extracted with 10-ml. portions of ammonium hydroxide until the aqueous portion showed no blue color. The wet toluene was allowed to evaporate spontaneously in a stream of cool air. (Early experiments suggested that yields fall drastically if the esters are heated at steam bath temperatures.)

The residue was triturated with approximately 5 Gm. of alumina and packed above an alumina chromatography column (1.8 × 15 cm.), and the chromatogram was developed first with ligroin to remove any unreacted azulene and then with toluene. The red-violet eluates were collected, and solvent was allowed to evaporate spontaneously as before. Most of these esters were oils.

Alkanolamine esters were converted to their corresponding hydrochlorides in the usual manner. The amine hydrochlorides were hygroscopic.

3-Nitroazulene-1-carboxylic Acid Esters.—Each of the 3-nitroazulene-1-carboxylic acid esters was prepared by the following procedure adapted from the work of Anderson *et al.* (11). Increasing the quantity of reagents by a factor of 10 introduced no new difficulties.

A chilled slurry of 0.241 Gm. (0.001 mole) of finely powdered cupric nitrate, $Cu(NO_3)_2 \cdot 3H_2O$, in 3 ml. of acetic anhydride was added to a mechanically stirred solution of 0.001 mole of an azulene-1-carboxylic acid ester in a mixture of 5 ml. of acetic acid and 1 ml. of acetic anhydride maintained at temperatures below 5°. The transfer of the slurry was facilitated by the use of an additional 2 ml. of chilled acetic anhydride.

The mixture was stirred for 10 min. and poured into 50 ml. of ice water and extracted with three 10-ml. portions of chloroform. The combined chloroform extracts were washed 3 times with 10-ml. portions of water, evaporated to dryness in a stream of cool air, and the residue was triturated with about 5 Gm. of alumina.

This triturate was packed above an alumina chromatography column (1.8 × 15 cm.). Elution with toluene removed the unreacted ester as a red-violet band and slowly displaced an orange band from a closely following dark brown region. The column was extruded and the orange region packed above a fresh alumina column. The new column was eluted with 20% ether in toluene and evaporation of the orange eluate in a stream of cool air gave orange to red needles of the 3-nitro esters.

3-Aminoazulene-1-carboxylic Acid Esters.—Each of the 3-aminoazulene-1-carboxylic acid esters was prepared by the following procedure adapted from that of Anderson *et al.* (3). Over a 5-min. period 0.5 Gm. of zinc dust was added to a stirred solution of 0.001 mole of the appropriate 3-nitroazulene-1-carboxylic acid ester and 0.2 Gm. of sodium acetate in 10 ml. of acetic acid. The mixture was stirred 1 hr. and diluted with 30 ml. of distilled water. The resulting blue mixtures were decanted from any unreacted zinc and extracted with three 20-ml. portions of ether. The emerald-green ether extracts were combined and washed with aqueous sodium hydroxide (5% w/v) until free of acid. The ether solution was extracted with dilute hydrochloric acid until the aqueous extracts were colorless.

The combined acid extracts were neutralized with ammonium hydroxide and extracted with two 20-ml. portions of ether. The ether was allowed to evaporate spontaneously, and the residue was triturated with about 5 Gm. of alumina. The triturate was packed above an alumina chromatography column and eluted with 20% ether in toluene. It gave only a single red band. Spontaneous evaporation of the eluate in a stream of cool air gave the free 3-aminoazulene-1-carboxylic acid esters. The amines were converted to their hydrochlorides in the usual manner.

Alkanolamine Ester of 3-Nitroazulene-1-carboxylic Acid.—The Ω-halo ester of 3-nitroazulene-1-carboxylic acid was converted to the corresponding *N,N*-dialkylaminoalkanol ester of 3-nitroazulene-1-carboxylic acid by the following procedure.

A solution of 0.073 Gm. (0.001 mole) of diethylamine in 10 ml. of ether was added dropwise to a

mechanically stirred solution of 0.279 Gm. (0.001 mole) of the 2-chloroethanol ester of 3-nitroazulene-1-carboxylic acid in 20 ml. of ether, and the mixture was heated at reflux temperature for 1 hr. The ether was decanted from the resulting gummy blue solid, and the residue was dissolved in 20 ml. of distilled water. The solution was transferred to a separator, and the solution was made alkaline with ammonium hydroxide. The solution was extracted with 20-ml. portions of ether, and the combined ether extracts were washed with a little water. The ether extract was allowed to evaporate spontaneously, and the residue was triturated with about 3 Gm. of alumina. The triturate was packed above an alumina chromatography column and eluted with 20% ether in toluene. Only a single red-orange band appeared. It was eluted and spontaneous evaporation of the solvent in a stream of cool air gave the *N,N*-diethylamino derivative, which was converted to the corresponding hydrochloride in the usual manner.

The results are reported in Table I together with some of the physical properties of these new compounds.

Upon preliminary pharmacologic testing some of these compounds were found to exhibit local anesthetic activity.

Increasing Dissolution Rates and Gastrointestinal Absorption of Drugs *Via* Solid Solutions and Eutectic Mixtures II

Experimental Evaluation of a Eutectic Mixture: Urea–Acetaminophen System

By ARTHUR H. GOLDBERG*, MILO GIBALDI, and JOSEPH L. KANIG

The binary system of APAP and urea was found to be a simple eutectic mixture with negligible formation of solid solutions. Solubility studies indicated that urea increased significantly the solubility of APAP. Dissolution rate studies were conducted with APAP alone, and in fused and physical mixtures with urea. An unusual dissolution phenomenon was found to exist in the system and is considered. In all cases the presence of urea enhanced the dissolution rate of APAP by virtue of a microenvironmental solubilization. The fused mixture at the eutectic composition was found to give similar, but prolonged enhancement of dissolution rate as compared to the physically mixed sample.

It is well established that dissolution is frequently the rate-limiting step in the gastrointestinal absorption of a drug from a solid dosage form. The relationship between solution rate and absorption is particularly distinct when considering drugs of low solubility. Consequently, numerous attempts have been made to modify the dissolution characteristics of certain drugs in an effort to attain more rapid and more complete absorption.

Bruner and Tolloczko (1) were the earliest workers to demonstrate that dissolution rate was a function of the surface area exposed to the dissolution medium. Accordingly, a drug will dissolve more rapidly when its specific surface area is increased, *i.e.*, when its particle size is decreased.

Levy (2) has considered a number of methods by which a drug may be presented to the gastrointestinal fluids in finely divided form. The most direct method is the utilization of microcrystalline or micronized particles which may be administered in any one of a number of dosage forms. A second method involves the administration of solutions from which, upon dilution with gastric fluids, the dissolved drug will precipitate in the form of very fine particles. A more unique way of obtaining microcrystalline dispersions of a drug in gastrointestinal fluids has been recently suggested by Sekiguchi *et al.* (3, 4). This approach involves the administration of a eutectic mixture composed of the drug and a substance which dissolves readily in water.

Sekiguchi and co-workers (3, 4) have proposed that when the eutectic mixture is exposed to the gastrointestinal fluids, the soluble carrier dissolves rapidly, leaving the insoluble drug in an extremely fine state of subdivision. More recently Goldberg *et al.* (5) presented theoretical arguments which attempted to demonstrate that the results obtained by Sekiguchi (3, 4) were due to the formation of solid solutions rather than simple eutectic mixtures. The existence of solid solutions in the eutectic mixture precluded a direct evaluation of the role of particle size reduction in the enhancement of dissolution. Owing to the physical-chemical characteristics of a solid solution, a very rapid rate of dissolution is to be expected when an insoluble drug is dissolved in a soluble carrier (5).

The purpose of this investigation was to compare the dissolution rate of a *simple eutectic mixture*, composed of the drug and a readily dissolving substance, with the dissolution rate of the drug alone. A study of a eutectic mixture, uncomplicated by the presence of solid solutions, permits a more realistic evaluation of the utility of the eutectic system in enhancing dissolution.

EXPERIMENTAL

A study was initiated to find a poorly soluble drug that would form a simple eutectic mixture with a water soluble carrier. The carriers investigated met the following criteria: (*a*) soluble in water; (*b*) physiologically inert; (*c*) a melting point of not more than 200°; (*d*) thermal stability up to its melting point; (*e*) a relatively low vapor pressure.

A number of drugs were employed that met the following criteria: (*a*) poor water solubility; (*b*) therapeutically significant; (*c*) thermal stability up to its melting point; (*d*) relatively low vapor pressure; (*e*) melting point of not more than 250°.

Screening Procedure.—In order to select combinations which would lend themselves to more detailed investigation, an initial screening procedure

Received October 11, 1965, from the College of Pharmacy, Columbia University, New York, N. Y.
Accepted for publication January 27, 1966.
Previous paper: Goldberg, A. H., Gibaldi, M., and Kanig, J. L., *J. Pharm. Sci.*, **54**, 1145(1965).
* Research fellow under a grant from the Bristol-Myers Co., New York, N. Y. Present address: University of Michigan, Ann Arbor.

was developed to permit rapid evaluation. Equal quantities (3 Gm.) of carrier and drug were physically mixed and placed, along with a thermometer, into a test tube. The tube was immersed into a temperature controlled silicone[1] bath, preset to the temperature of the melting point of the lower melting component. The mixture was constantly stirred to facilitate distribution of heat and the temperature of the silicone bath was slowly raised, if necessary, until complete melting occurred. The following observations were made during each such screening procedure: (*a*) temperature at which mixture started to melt; (*b*) temperature at which discoloration, gas evolution, or fumes occurred (if such phenomena did occur); (*c*) temperature at which complete melting was effected; and (*d*) the number of distinct phases present in the melted mixture.

The fused liquid was then immediately poured onto Ferrite plates[2] and the following evaluations made: (*a*) length of time for crystallization to occur; (*b*) physical state of mass (crystalline or amorphous); and (*c*) length of time required for the amorphous mixtures to change to a crystalline form.

Solid-Solid Interaction.—On the basis of results obtained in the screening procedure, the combination of APAP[3] and urea was selected for further study. This mixture formed a homogeneous liquid when fused, exhibited a melting point lower than that of the lower melting component, and recrystallized to a crystalline solid immediately upon quenching in air under ambient conditions.

A phase diagram of APAP–urea was made using the cooling curve method, employing blends of APAP and urea in the following mole fractions: 0.9–0.1; 0.8–0.2; 0.7–0.3; 0.6–0.4; 0.5–0.5; 0.4–0.6, and 0.2–0.8. The blended mixtures were placed into the inner tube of a Beckman molecular weight apparatus with the stirring loop, thermometer, and stopper in place. The tube was then immersed into a temperature controlled silicone bath. The temperature was slowly raised to effect fusion, and to allow the temperature of the melt to rise to about 10° above its melting point. The entire inner tube was then placed into the outer jacket of the Beckman apparatus which was immersed in a water bath maintained at 60°. The top of the stirring loop was attached to the arm of a U.S.P. tablet disintegration apparatus, which raised and lowered the stirring loop at the rate of 30 times per minute within the fused drug-carrier combination.

During the cooling process, temperature was plotted *versus* time, and two discontinuities in the curve were noted. The first change of slope (at the higher temperature) is comparable to the melting point of that component in the mixture which is in excess of the eutectic composition, and the second change in slope (at the lower temperature) corresponds to the eutectic temperature. The critical temperatures thus obtained were plotted *versus* composition on a second graph.

A second phase diagram of urea–APAP was prepared using a microthermal technique.[4] Various ratios of the materials were weighed, intimately mixed, and placed on a microscope slide. The slide was covered with a cover slip, and sealed with silicone grease,[5] to minimize any possible loss due to sublimation. This preparation was heated until fusion occurred, and then allowed to cool. The cooled crystalline mass was then reheated at the rate of 4°/min. by means of a heating stage attached to a microscope fitted with polarizing lenses. Using 100 magnification power, observations were made of the melt.

The first change noted occurs at the eutectic temperature. At this point the solid appears to disappear partially, and small liquid areas become apparent. These areas of liquid continue to increase in size until all of one component dissolves in the eutectic melt. The crystals remaining constitute that component which is present in excess of the eutectic composition. As the temperature increases, the component in excess slowly disappears from view. The temperature at which the last bit of crystal disappears is taken as the melting point of the component in excess. A phase diagram was constructed by plotting both temperatures (where melting first appears, and the final melting point) *versus* ratio of components (per cent w/w).

Interaction in Aqueous Solution.—To determine any possible interaction between drug and carrier in aqueous solution, solubility studies were performed. An excess amount of drug was placed in 60-ml. test tubes equipped with screw caps and containing 30 ml. of an aqueous solution of the carrier in varying concentrations. The content of each tube was equilibrated at 37° in a Gyrotory incubator shaker.[6]

At the end of this period, 1-ml. samples were withdrawn by means of a filter pipet. Each milliliter was diluted to 100 ml. with water, and 0.5 ml. of this dilution was added to 0.5 ml. of distilled water, and diluted to 10 ml. with acidified methanol (1% v/v solution of 0.1 *N* HCl in methanol). The absorbance of each diluted sample was determined at 242 mμ using a recording spectrophotometer.[7] A blank of 10% water in acidified methanol was employed. The absorbance was read and the amount of APAP present was determined by dividing the absorbance by the slope (obtained by the method of least squares) of a previously constructed Beer's law curve. Preliminary investigation had indicated that urea in no way interfered with the assay procedure.

Dissolution Studies.—The dissolution studies were conducted using the tape method (6). This method employs a strip of plastic adhesive,[8] tautly affixed to a metal frame. The powdered sample to be evaluated is dusted on the adhesive surface in a monoparticulate layer. The entire frame is then immersed below the surface of the dissolution medium which is stirred by a paddle attached to an overhead, constant speed motor rotating at 53.5 r.p.m.

TABLE I.—APAP SAMPLES EMPLOYED IN DISSOLUTION STUDIES

Sample	Compn., mg. APAP	Urea	Mesh Size	Method of Prepn.
1	30	...	50–60	Fusion
2	30	...	100–120	Fusion
3	30	23.8	50–60	Fusion
4	30	23.8	50–60	Physical mixture
5	30	35.7	50–60	Physical mixture

Table I lists the various APAP samples used in the dissolution studies. Samples 1–3 were prepared by fusing APAP or a blend of APAP and urea. When complete liquefaction occurred, the homogeneous melt was immediately cast on Ferrite plates under ambient conditions. The congealed solid was then crushed using a mortar and pestle. The resulting powder was subsequently classified by means of a Syntron shaker operated at 90 v. for 2 min. The desired fraction was then collected. Samples 4 and 5 were prepared by first fusing, congealing, and sizing the individual components and then blending the two materials in the indicated proportions.

The dissolution fluid consisted of 400 ml. of distilled water maintained at 37° in a 600-ml. beaker which was immersed in a constant-temperature water bath. The particles to be tested were weighed and dusted onto the tape. The frame was then positioned in the dissolution apparatus and, at time zero, dropped below the surface of the dissolution fluid. One-milliliter samples were withdrawn at 1-min. intervals for 5 min. Each sample was diluted to 10 ml. with acidified methanol and assayed spectrophotometrically as previously outlined.

RESULTS AND DISCUSSION

Solid-Solid Interactions.—The phase diagrams obtained by the cooling curve method and the microthermal technique closely coincided. An analysis of the phase diagram presented in Fig. 1 (which was prepared by the microthermal technique) reveals the existence of a binary system which closely approximates a theoretical eutectic mixture. No solid solubility was detected. Figure 1 shows the eutectic composition to be 52% APAP and 48% urea, and the eutectic temperature to be 115°.

The phase diagram prepared by the cooling curve method indicated a eutectic composition of 55.7% APAP and 44.3% urea. The eutectic temperature was found to be somewhat lower (110°) than the temperature observed when employing the microthermal technique. This finding is probably the result of supercooling. The small discrepancy in eutectic composition between each method of phase diagram preparation is attributable to the sublimation of urea from the open system employed in the cooling curve technique.

Interaction in Aqueous Solution.—Equilibrium solubility experiments were conducted to determine the extent of interaction between drug and carrier in solution. As may be noted in Fig. 2, urea was found to interact strongly with APAP in aqueous solution. This interaction was manifested by a linear increase in the solubility of APAP to the

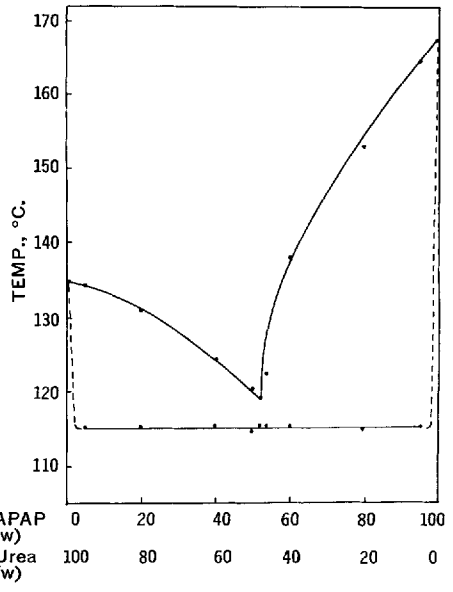

Fig. 1.—Phase diagram for urea–APAP system prepared by a microthermal technique.

extent of 0.23 Gm./Gm. of urea. The significance of the solubilization effect will be considered in the discussion of dissolution rates which follows.

Dissolution Studies.—According to the Noyes-Whitney equation, the dissolution rate of a solid is a function of the surface area presented to the dissolution medium as well as the concentration gradient existing between the solid–liquid interface and the bulk of the dissolution medium (7). Under conditions of constant surface area, as is observed in the dissolution of a material from a planar surface, the dissolution rate should follow zero-order kinetics

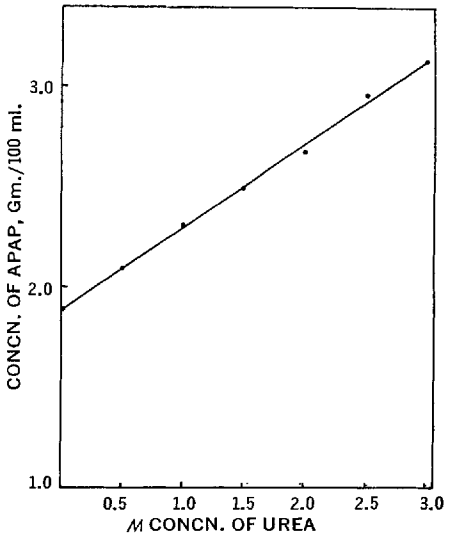

Fig. 2.—Aqueous solubility of APAP as a function of urea concentration.

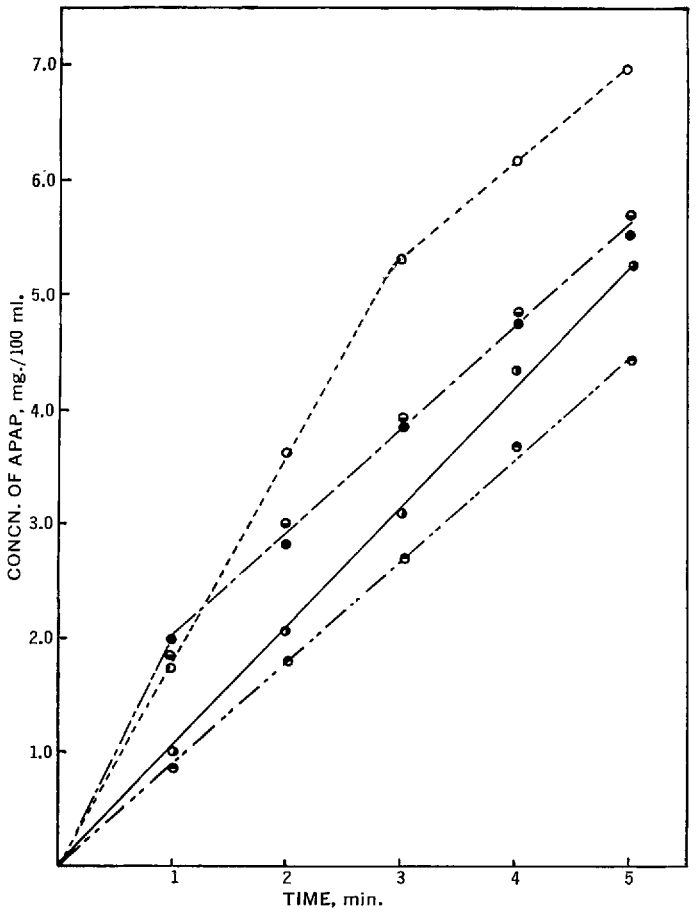

Fig. 3.—Dissolution rates of APAP and APAP–urea as determined by the tape method. Key: ◓, APAP, 50 60 mesh; ◑, APAP, 100–120 mesh; ●, APAP–urea, physical mixture at eutectic composition; ◒, APAP–urea, physical mixture, urea present in excess of eutectic composition; O, APAP–urea, fused eutectic.

provided the concentration gradient is maintained essentially constant by keeping the dissolution medium sufficiently dilute. On the other hand, in those situations where only the concentration gradient may be maintained constant, *e.g.*, in particulate dissolution, the dissolution rate is proportional to the surface area. Accordingly, the dissolution of particulate solids has been found to adhere to the "cube root law" which represents a mathematical model to account for the decrease in surface area during the dissolution process (8).

The results of the dissolution studies in this investigation appeared to differ considerably from theoretical expectations. Previous studies (6), utilizing the tape method, showed reasonable agreement with the "cube root law" indicative of particulate dissolution. Dissolution of the APAP samples, however, seemed to agree with a planar surface dissolution model. As may be noted in Fig. 3, dissolution curves were of two distinct types: either linear for the entire experimental period or biphasic, consisting of two linear segments. Both samples of pure APAP followed pseudo-zero kinetics over the 5-min. period. When the data obtained with the pure APAP were tested for fit to the "cube root law," it was found that the coarser sample (50–60 mesh) showed reasonably good agreement while the 100–120 mesh sample demonstrated significant curvature and deviation. Based on these observations, it was concluded that particulate density, *i.e.*, the number of particles per unit area of tape, exerted an influence on the dissolution process.

It has been theorized that the dissolution process involves the formation of a thin layer or film of saturated solution at the solid-liquid interface and the diffusion of molecules from this layer to the bulk solution (1). Applying this concept to the dissolution of particulates from the tape, it is apparent that as long as the particles are farther apart than the thickness of the diffusion layer, the "cube root law" would be obeyed. However, if the particulate density is increased so that the diffusion layer of each particle "overlaps" with that of its neighboring particle, it is reasonable to expect dissolution to approach a planar surface model. The latter situation was observed with the 100–120 mesh APAP.

When particles of pure APAP were physically mixed with particles of urea, a biphasic dissolution curve was obtained (Fig. 3). Theoretically, in a system measuring only particulate dissolution the urea would not influence the dissolution rate of the APAP since each particle would dissolve independently. However, the initial dissolution rate of APAP (from time zero to 1 min.) from both physically mixed samples was significantly greater than the dissolution rate of APAP alone. These findings further support the possibility that the diffusion layers of the urea and APAP particles

"overlap." When the sample is first introduced into the dissolution medium, the urea rapidly goes into solution and quickly attains a very high microenvironmental concentration in the "mixed" diffusion layer of both particles. The presence of urea increases the solubility of APAP in the diffusion layer and thereby increases the dissolution rate of the drug. When the eutectic mixture was studied, a biphasic dissolution curve again resulted, demonstrating an increased initial dissolution rate of APAP.

These findings coupled with the results obtained with the pure APAP samples indicate that the dissolution process, under these experimental conditions, adheres to a mixed mathematical model, *i.e.*, intermediate to a planar surface dissolution model and a particulate dissolution model. This rather unusual situation does not, however, negate the value of the system for comparing the relative dissolution rate of APAP from the various samples. In each case, with the exception of the pure APAP (100–120 mesh), the quantity of the drug, the particle size of the sample, and the approximate monolayer density were maintained constant. Moreover, the mechanism of dissolution remained the same regardless of the sample tested, as manifested by the pseudo zero-order kinetics observed in part or *in toto* in each dissolution run. It should nevertheless be noted that the use of the tape method for determining true particulate dissolution is dependent on maintaining a small monolayer area in relation to the area of tape on which the particles are placed.

The results of the dissolution studies permitted the calculation of pseudo zero-order rate constants. (Table II.) The pure APAP sample (50–60 mesh) yielded a rate constant of 0.89 mg./min. while the 100–120 mesh sample of pure drug showed a rate constant of 1.07 mg./min., showing an increase of approximately 20%. The physically mixed sample of APAP and urea, corresponding to the eutectic composition, demonstrated an initial rate constant (0–1 min.) of 1.99 mg./min., about twice that of pure APAP of comparable particle size. The second phase of this dissolution curve showed a rate constant of 0.90 mg./min. This second rate constant is the same as that of pure APAP of equal particle size (0.89 mg./min.). This suggests that urea has left the microenvironment at about 1 min. Verification of this conclusion was provided by microscopic examination of the sample; after 1 min., the tape is depleted of urea and only APAP particles remain.

When the amount of urea in the physically mixed sample is increased beyond the eutectic composition an initial rate constant (0–1 min.) of 1.85 mg./min. is found, comparing favorably to the initial rate constant found with the other physically mixed sample. The second phase of the dissolution (1–5 min.) had a rate constant of 0.83 mg./min., again quite close to that of pure APAP of equal mesh size. The urea concentration in the mixed diffusion layer is apparently close to the saturation level since initial dissolution rates were essentially independent of the quantity of urea in the sample. In addition, once the urea is completely depleted from the diffusion layer, APAP particles of equal size remain on the tape and dissolution is identical to the dissolution of pure APAP.

The fused eutectic mixture shows an initial rate constant (0–3 min.) of 1.72 mg./min., reasonably close to the initial rate constants found with the physically mixed samples. The second phase of the dissolution curve yielded a rate constant of 0.81 mg./min., again in close agreement with the rate constant of pure APAP particles of 50–60 mesh.

These results indicate that particle size reduction of APAP by eutectic formation with urea does not increase the dissolution rate of the drug. It has been observed in the present dissolution system that decreasing the particle size 50% yields a 20% increase in the dissolution rate of APAP. According to Findlay (9), the APAP in the eutectic should appear as fine-grained crystals. However, no evidence of any significant particle size reduction was observed. The initial rate of dissolution of APAP from the eutectic was found to be the same or slightly less than that of the physical mixture. The major difference between the physical mixture and the eutectic was one of duration of effect. It apparently required a longer period for the urea to diffuse completely from the eutectic than from the physical mixture, thereby increasing the duration of the solubilizing effect of the urea on the APAP.

Table II.—Pseudo Zero-Order Dissolution Rate Constants for APAP Alone and in Fused or Physical Mixtures with Urea

Sample	Description	Initial Rate Constant	Time Interval, min.	Second Rate Constant	Time Interval, min.
1 APAP	Fused, 50–60 mesh	0.89	0–5	...	...
2 APAP	Fused, 100–200 mesh	1.05	0–5	...	...
3 APAP–urea	Fused mixture, eutectic composition	1.72	0–3	0.81	3–5
4 APAP–urea	Physical mixture, eutectic composition	1.99	0–1	0.90	1–5
5 APAP–urea	Physical mixture, urea present in excess of the eutectic composition	1.85	0–1	0.83	1–5

A second major reason for believing that particle size reduction was not achieved in the eutectic is provided by the second rate constant, which approximated the rate constant for the 50–60 mesh APAP. This result suggests that the urea is leached from the mixed eutectic particle leaving a matrix of APAP with an effective surface area comparable to that of a 50–60 mesh particle of APAP. Therefore, the value of eutectic formation as a means of enhancing dissolution rate still remains somewhat dubious. An enhancement of dissolution rate by virtue of simple eutectic formation alone is yet to be demonstrated.

Increasing Dissolution Rates and Gastrointestinal Absorption of Drugs *Via* Solid Solutions and Eutectic Mixtures III

Experimental Evaluation of Griseofulvin–Succinic Acid Solid Solution

By ARTHUR H. GOLDBERG*, MILO GIBALDI, and JOSEPH L. KANIG

The phase diagram for the griseofulvin and succinic acid system showed a eutectic mixture with considerable solid solubility of griseofulvin in succinic acid. Evaluation of the dissolution rates of critical samples indicated that the solid solution dissolved 6.5–7 times faster than the pure material.

THE UTILIZATION of finely subdivided or micronized particles as a means of increasing the rate of dissolution of a drug has been considered frequently (1–4). Various methods of achieving particle size reduction have been reviewed by Levy (5). Sekiguchi *et al.* (6, 7) have suggested that particle size reduction, as a means of increasing gastrointestinal absorption of a drug, may be achieved through eutectic formation between a poorly soluble drug and a rapidly soluble carrier. Goldberg *et al.* (3, 4) have proposed that the increased absorption and dissolution rates found by Sekiguchi *et al.* were a function of the solid solutions present in the samples tested, rather than eutectic formation *per se*. Goldberg *et al.* (3) have also noted that the dissolution rate of a poorly soluble drug from a solid solution with a soluble carrier should be considerably faster than any other physical form of the drug, including the soluble eutectic and micronized forms. The purpose of this study was to evaluate experimentally the role of solid solutions in increasing dissolution rates.

The contents of each tube were equilibrated at 37° in a Gyrotory incubator shaker.[2]

At the end of this period, 1-ml. samples were withdrawn by means of a filter pipet. The griseo-

TABLE I.—COMPOSITION OF GRISEOFULVIN SAMPLES USED IN DISSOLUTION STUDIES

Sample	Compn.	Amt., mg.	Form	Particle Size, μ
1	Griseofulvin[a]	10.0	Crystalline	250–300
2	Griseofulvin	10.0	Eutectic	250–300
	Succinic acid	5.2		
3	Griseofulvin	10.0	Physically mixed	250–300
	Succinic acid	5.2		250–300
4	Griseofulvin	10.0	Solid soln.	250–300
	Succinic acid	40.0		
5	Griseofulvin	10.0	Physically mixed	250–300
	Succinic acid	40.0		250–300
6	Griseofulvin	10.0	Micronized	1–10

[a] Particle size enlargement of pure griseofulvin was obtained by crystallization from methanol. All other samples were fused. Griseofulvin, however, showed signs of decomposition upon heating to its melting point.

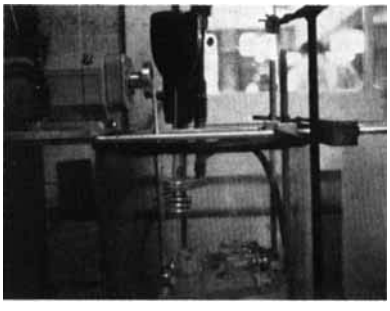

Fig. 1.—Oscillating bottle apparatus used for determining dissolution rates.

fulvin–succinic acid sample was diluted to 10 ml. with methanol and assayed spectrophotometrically at 292 mμ using a recording spectrophotometer.[3] A blank of 10% water in methanol was employed. The absorbance was read and the amount of griseofulvin present was determined by dividing the absorbance by the slope (obtained by the method of least squares) of a previously constructed Beer's law curve. Preliminary investigation had indicated that succinic acid did not interfere with the assay procedure. No shift in the absorbance peak was observed and solutions containing succinic acid gave the same absorbance as solutions containing an equal quantity of griseofulvin alone in the solvent.

The dissolution rate studies were conducted by 2 different methods. The apparatus used for one study is shown in Fig. 1. The various samples listed in Table I were screened, weighed, and placed into 10-ml. multiple-dose vials, sealed with an elastomer stopper, and capped with a metal ferrule having a hole in the center, exposing a portion of the top of the elastomer. Ten milliliters of water at 37° was injected by syringe through the stopper at time zero. The vial was immediately placed on the oscillating platform assembly in the water bath. The platform, in motion, described a 15° arc, 14 times per minute. Destructive sampling was used for the assays at 3, 5, 10, 15, and 20 min. after introduction. A sample was withdrawn by means of a syringe and rapidly filtered under vacuum using a Millipore[4] filter assembly. A 2-ml. sample of the filtrate was diluted to 10 ml. with methanol and assayed spectrophotometrically as previously described. A minimum of 2 experiments were conducted with each sample at each time interval.

The second method employed for evaluating the comparative dissolution rates was the tape method (8). This procedure involves accurately weighing and quantitatively transferring the screened material to be tested to a taut, adhesive surface and, in turn, introducing the resulting monoparticulate layer to the dissolution medium. Four hundred milliliters of distilled water, maintained at 37°, served as the dissolution fluid. Stirring rate was maintained at 130 r.p.m. by means of a constant speed motor. The stir paddle employed was 2 times the width of the stir paddle previously reported (8). The increased speed and wider stir paddle was necessitated by the extremely low solubility of griseofulvin.

Samples 1, 2, 4, and 5 of Table I were evaluated by the tape method. Sampling times were 0.5, 1.5, 3.0, 5.0, and 10 min. At each time interval 10-ml. samples were withdrawn by means of a filter pipet and immediately replaced with 10 ml. of dis-

tilled water preheated to 37°. Griseofulvin concentration was determined spectrophotometrically. All values were corrected to account for drug removed by prior sampling.

RESULTS AND DISCUSSION

The phase diagram obtained with the griseofulvin–succinic acid mixtures is shown in Fig. 2. The diagram clearly indicates the existence of a significant solid solution region consisting of griseofulvin and succinic acid. Little solubility of succinic acid in griseofulvin in the solid state is evidenced. Further inspection of the phase diagram reveals that the mixture exhibits a well-defined eutectic point. The eutectic mixture has a composition of 0.71 mole of succinic acid and 0.29 mole of griseofulvin, corresponding to about 55% griseofulvin and 45% succinic acid.

The eutectic mixture consists of 2 physically separable phases. One phase is almost pure griseofulvin, while the other phase is a saturated solid solution of griseofulvin in succinic acid. The composition of the saturated solid solution is 10 moles per cent griseofulvin and 90 moles per cent succinic acid. This corresponds to about 25% griseofulvin dissolved in succinic acid. Because the ratio of griseofulvin to succinic acid at the eutectic point is thermodynamically fixed, it can be shown by simultaneous equations that the eutectic mixture is composed of 60% solid solution and 40% of almost pure griseofulvin. Since the solid solution is 25% griseofulvin, 15 parts of the 55 parts of griseofulvin found in 100 parts of eutectic mixture is in the form of a solid solution. This corresponds to 27.3% of the griseofulvin.

It has been our experience that when 2 compounds exhibit solid state interactions they frequently demonstrate interaction in aqueous solution. This phenomenon has been observed with *N*-acetyl-*p*-aminophenol and urea (4), niacinamide and ascorbic acid (9), and in sulfathiazole–urea and chloramphenicol–urea systems (10). Similarly, griseofulvin and succinic acid were found to display

Griseofulvin, Succinic acid	Fused, solid soln.	6.9	6.7

a solution phase interaction manifested by a linear increase in the solubility of griseofulvin with increasing concentration of succinic acid. The solubility data are presented in Fig. 3.

As noted in the experimental section of this report, 2 methods were employed to evaluate the relative dissolution rates of the various samples listed in Table I. The results obtained using the oscillating vial method are shown in Fig. 4 and Table II. Table II contains relative dissolution rate data which were calculated by determining the amount of griseofulvin dissolved from a particular sample and dividing this figure by the amount of griseofulvin dissolved from the pure crystalline sample at the same time interval. At 3 min., the ratio of griseofulvin solid solution to that of the control is almost 7, indicating that the initial rate of dissolution of griseofulvin from a solid solution containing 20% griseofulvin is in the order of 7 times greater than griseofulvin alone.

The amount of dissolved griseofulvin from the solid solution at 5 min. was 2.4 times the equilibrium solubility. It is well known that reducing the particle size of a material to a very fine state of subdivision often results in supersaturation (11). Theoretically, griseofulvin is released from the solid solution in a molecular state and it is reasonable to expect such supersaturation.

It is not possible to attribute the observed increased dissolution rate to a local effect since the dissolution rate of all physical mixtures of succinic acid and griseofulvin was about the same as that of pure griseofulvin. In addition, no sample contained a sufficient amount of succinic acid to produce a bulk solubilizing effect. The increased dissolution rate of the micronized form as compared to the crystalline form of griseofulvin can be related to only one factor: decreased particle size and increased surface area. It may be concluded that since the solid solution dissolves twice as fast as the micronized form, the griseofulvin must be released in a particle size that is much smaller than the

micronized particles theoretically approaching molecular size.

The eutectic mixture, at 3 min., dissolved 4.2 times faster than the crystalline griseofulvin, and 1.2 times faster than the micronized powder. This result is expected from the predictions of Sekiguchi *et al.* (6, 7). However, since the eutectic mixture is composed of 60% of the solid solution, it is reasonable to assume that the increased dissolution rate is attributable primarily to the presence of this solid solution in the eutectic sample. If decreased particle size does exert an effect, this effect appears inconsequential as compared to the effect of solid solution formation.

Although it may be fortuitous, the eutectic mixture which consists of 60% solid solution shows a rate at 3 min. which is just 60% that of the solid solution. Since it has been shown (4) that formation of a eutectic mixture *per se* may not increase the rate of dissolution, it is interesting to speculate that this is not just coincidental, but a physically meaningful result.

The results of the dissolution rate studies conducted with the tape method are shown in Fig. 5 and Table III. Inspection of the data indicates excellent correlation between the 2 dissolution methods. The griseofulvin from the solid solution was again found to dissolve 6–7 times faster than the pure material.

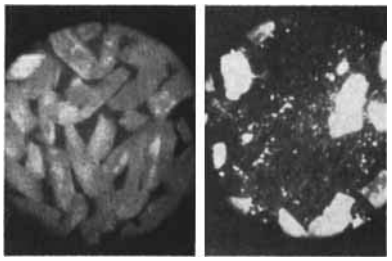
When employing the tape method in an earlier study (4), with a physical mixture of APAP and urea, a distinct local effect of the urea on the APAP was noted. In the present investigation, despite the solubilizing effect of the succinic acid on griseofulvin, no local effect was noted. The supersaturation that was found when using the vial method was absent from the data obtained with the tape method. This may be the result of differences between the 2 methods in the amount of drug excess and in the type of agitation employed.

The use of the tape method permitted the preparation of photomicrographs of the particles before and after the dissolution study. A light microscope, equipped with polarizing lenses, was employed at a magnification of 150×, in conjunction with a Polaroid Land camera.

Figure 6, *A*, shows the particles of pure griseofulvin before dissolution. Figure 6, *B*, shows the same particles after a 26-min. exposure to the dissolution medium. The only difference seems to be the disappearance of the microcrystals that appear to be associated with the griseofulvin crystals in Fig. 6, *A*.

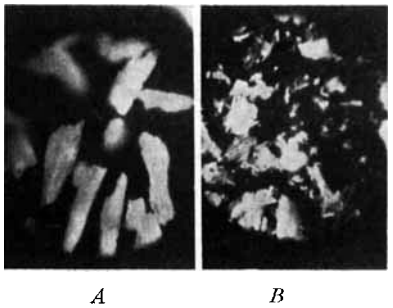
Figure 7, *A* and *B*, are photomicrographs of the griseofulvin–succinic acid eutectic mixture before and after a 26-min. dissolution study. Fragmentation of the particles is evident in Fig. 7, *B*. This is probably the result of preferential loss of the more soluble components of the individual particulates.

Figure 8, *A*, shows the particles in a physical mixture of griseofulvin and succinic acid. The striking similarity between the two crystals may be observed. After a 26-min. period in the dissolution medium (Fig. 8, *B*) only the griseofulvin crystals appeared to remain on the tape with little or no



A B

Fig. 8.—Photomicrographs of a physical mixture of griseofulvin and succinic acid present in a ratio corresponding to the solid solution composition. *A* shows both crystals; *B* shows the same area of the tape after a 26-min. exposure to the dissolution fluids; only the griseofulvin crystals remain on the tape.



A B

Fig. 9.—Photomicrographs of the griseofulvin–succinic acid solid solution before (*A*) and after (*B*) exposure to the dissolution medium.

change in size or shape. Figures 9, *A* and *B*, are photomicrographs of the solid solution containing 20% griseofulvin. Before dissolution the particles appeared somewhat more elongated and irregular than the other samples considered. After exposure to the dissolution fluids (Fig. 9, *B*) the particles seem to be sintered and greatly reduced in size.

The photomicrographs serve to support graphically the quantitative findings of the dissolution rate studies. The most rapidly soluble forms of griseofulvin, *i.e.*, the solid solution and the eutectic mixture, manifest the most dramatic alterations in their crystalline nature after exposure to the dissolution medium.

The therapeutic advantages of the griseofulvin–succinic acid solid solution are presently under investigation in our laboratories. Extrapolation of the *in vitro* findings suggests the possibility that this form will provide more rapid and complete absorption of the drug, permit a reduction in dosage, and conceivably provide a more uniform therapeutic response. Of greater significance is the fact that this investigation has demonstrated a method of physical modification which could prove more important than micronization in enhancing the absorption and therapeutic effect of many water-insoluble drugs.

The Antitumor Agent, 1,3-Bis(2-chloroethyl)-1-nitrosourea

By TI LI LOO*, ROBERT L. DION, ROBERT L. DIXON†, and DAVID P. RALL

The new potent antitumor agent, 1,3-bis(2-chloroethyl)-1-nitrosourea (BCNU), is most stable at pH 4. In acid and in solutions above pH 7, it decomposes rapidly. In plasma, BCNU has a half-life of 20 min. *in vitro*, and less than 15 min. *in vivo*. Its alkylating action is not caused by the slow hydrolysis of the chlorine. BCNU is 80 per cent bound to human plasma protein at 0°. When administered intravenously to the dog, it enters the cerebrospinal fluid (CSF) readily and disappears speedily from the plasma and the CSF. The total amount of unchanged drug excreted in the urine in 4 hr. is less than 0.1 per cent of the dose. Heating at 43° for 5 hr. converts BCNU partly into 1,3-bis(2-chloroethyl)urea.

STUDIES OF the antitumor activity of derivatives of nitrosoguanidine (2) and nitrosourea (3) have led to the discovery of 1,3-bis(2-chloroethyl)-1-nitrosourea (BCNU), a potent cancer chemotherapeutic agent of a novel type. BCNU is remarkable in that it is highly effective not only in intraperitoneal L1210 leukemia, but also in intracerebral L1210 leukemia (4), a distinct feature seldom found in most conventional agents. Unfortunately, clinical application of BCNU is limited because of unusual delayed toxicity in animals and man (5–7).

Chemically, although considered to be an alkylating agent, BCNU differs from typical derivatives of 2-chloroethylamine in having several reaction sites in addition to the carbon–chlorine bond which are potentially liable to attack by a variety of reagents under normal physiological conditions. Besides, the resultant transient chemical species may undergo further extensive biotransformations. These interesting considerations have prompted the authors to undertake a study on some of the chemical and pharmacological properties of BCNU. The present paper summarizes the results of these studies.

EXPERIMENTAL

BCNU.[1]—A sensitive and reproducible colorimetric method for the determination of BCNU has been described (8). The rate of decomposition was calculated by measuring the amount of unchanged BCNU after incubation with buffers or biological fluids. For the recovery of BCNU, buffers were treated the same way as biological fluids. Also, at pH above 8, the very fast rate of decomposition of BCNU necessitates the continuous direct measurement of absorbance at 230 mμ, the $\lambda_{max.}$ of BCNU. However, because of low molecular extinction (about 6,000), the direct measurement of absorbance is far less sensitive than the colorimetric method. In the range of 10–50 mcg./ml., a satisfactory linear relationship was found to exist between the concentration of BCNU and its absorbance at 230 mμ. However, the absorbance at 230 mμ assigned to $\pi \rightarrow \pi^*$ transition (9) could be attributed to the excitation of —N=N— as well as to that of —N=O. The decrease in absorbance at 230 mμ is a measurement of not only BCNU, but also its primary rearranged product (namely, the diazoester, see below). The colorimetric method is devoid of such ambiguities.

Determination of Chloride.—Microtitration of chloride was performed with an automatic Cotlove titrator (10). Nitrite anion derived from the nitroso group of BCNU was found not to interfere with the titration.

Protein Binding.—Protein binding was determined by ultrafiltration using the Toribara apparatus (11). The experiments were carried out at 0° because of the extreme instability of BCNU in plasma. A solution of BCNU in human plasma was prepared. An aliquot was kept at 0° throughout the duration of the experiment as a control. A measured volume of the remaining solution was placed in a cellulose sac (Visking Corp.) in the Toribara apparatus and spun at 2,200 r.p.m. for 2.5 hr. Further prolongation of centrifugation did not affect the results. After centrifugation, the BCNU in the control plasma, the plasma in the cellulose sac, and the ultrafiltrate were determined.

Plasma Level and Urinary Excretion in the Dog.—While under anesthesia with sodium pentobarbital,[2] female mongrel dogs weighing 10–16 Kg. received BCNU *via* the femoral vein, 10 mg./Kg., in a minimal volume of 50% ethanol. Samples of blood, 5 ml. each, were drawn from the opposite femoral artery with syringes wetted with heparin solution. Plasma was separated by centrifugation at 0°. Urine samples were collected by catheterization. Cerebrospinal fluid (CSF) (1.5 ml.) was sampled *via* the cisterna magna. All biological fluids were immediately frozen in a dry ice bath until analyzed. It is often desirable to prepare plasma and urine standards of the same animal as previously explained (8). Triplicate determinations were run whenever possible.

To achieve a constant plasma level, constant drug infusion was performed after an intravenous priming dose of 10 mg./Kg. The infusion solution was prepared by dissolving an appropriate amount of BCNU in a minimal volume of 95% ethanol and diluting with 0.2 *M* acetate buffer of pH 4.1. The latter was chosen because it is nearly isotonic and because BCNU is most stable (see below) at pH 4. The concentration of the infusion solution was such that the animal received 20 mg. of BCNU/Kg./hr. at a constant infusion rate of 0.5–1 ml./min.

Paper Chromatography.—Solutions of BCNU were applied to strips of Whatman No. 3 mm. paper and developed, ascending flow, by either 0.1 *M* sodium acetate buffer of pH 4.4 or petroleum ether of b.p. 100–115°. The instability of BCNU limits the solvent system to the above. Depending on BCNU concentration, the spots could be made visible on the dried paper by any of the following procedures. (*a*) Direct illumination with ultraviolet light of 254 mμ. (*b*) Spraying first with a solution of 50 mg. of sulfanilamide in 0.2 *N* hydrochloric acid, and 5 min. later with a solution of 0.3 Gm. of *N*-(1-naphthyl)ethylenediamine dihydrochloride in 100 ml. of 95% *n*-butanol. (*c*) Spraying with a diphenylamine–palladium chloride reagent (12) consisting of 5 parts of 1.5% diphenylamine in ethanol and 1 part of 0.1% palladium chloride and 0.2% sodium chloride in water, followed immediately by irradiation with ultraviolet light of 254 mμ.

In acetate buffer system, BCNU gave an R_f value of 0.73 and in petroleum ether, 0.78.

Attempted Isolation of BCNU Metabolite from Dog Urine.—Following an intravenous injection of BCNU at 10 mg./Kg., the urine of a dog was collected for 3 hr. It was extracted 6 times with ether, using one-third its volume of ether each time. The combined ether extracts were dried over anhydrous magnesium sulfate and concentrated in an atmosphere of nitrogen at 0°. The presence of BCNU in the residual oil was confirmed by paper chromatography. However, other spots on the chromatogram were not identified. The oil resisted attempts at crystallization.

Thermal Decomposition of BCNU in Petroleum Ether.—BCNU, 500 mg., was dissolved in 50 ml. of petroleum ether (b.p. 30–60°) and refluxed at 43° (internal temperature) for 5 hr. The solvent was removed by vacuum distillation in a water bath at room temperature. After refrigeration overnight, the yellowish semisolid was triturated with ether and centrifuged. The supernatant was discarded and the residual solid was recrystallized twice from 30 ml. of ether containing 3 ml. of methanol. The fine colorless leaflets had an m.p. of 127–1:8°, undepressed by authentic 1,3-bis(2-chloroethyl)urea (13). The yield was 50 mg., 38%.

Anal.—Calcd. for $C_5H_{10}Cl_2N_2O$: C, 32.45; H, 5.45; Cl, 38.32; N, 15.14. Found: C, 32.52; H, 5.39; Cl, 37.97; N, 14.86.

RESULTS AND DISCUSSION

Stability of BCNU.—Table I summarizes the authors' results. The stability of BCNU is profoundly influenced by the pH of the solution. It is evident that BCNU is most stable in petroleum ether or in aqueous solution at pH 4. In acetate buffer of pH 4 at room temperature, its half-life exceeds 8 hr.

In strong acid (pH below 1), the rate of decomposition is too fast to measure. In fact, the ready

liberation of nitrous acid by BCNU in strong acidic solution constitutes the basis for its colorimetric determination. Between pH 1 and pH 4, the decomposition is first order with respect to BCNU. Its relative stability at pH 1 (half-life longer than 3 hr.) agrees with the observation that BCNU is effective by mouth.

From pH 4.4 to pH 7.8, the decomposition still follows first-order kinetics; however, as explained below, the mechanism is probably not the same as in the more acidic media. The results of some typical experiments are graphically represented in Fig. 1. In the pH range of 4 to 9 the rate varies directly with pH,[3] but it is independent of the nature and concentration of the buffer. It is naturally affected by temperature: at room temperature (25°) the rate of decomposition is about 35% slower than at body temperature (37°). Also, at pH above 9.3, or even at pH 8, but at 37° instead of 25°, the decomposition of BCNU becomes complex kinetically, and the rate is not only very fast, but also no longer first order. Its half-life at pH 10 is not much more than 5 min.

In urine, BCNU is about as stable as in water of comparable pH. But with plasma, the case is entirely different. It decomposes at a rate 3 times faster than in phosphate buffer of pH 7.4, and its *in vitro* half-life in plasma is about 20 min. Although fast, the decay still obeys first-order kinetics, in distinct contrast with the *in vivo* situation. In the latter case, the decay of BCNU is not only somewhat faster, but follows complex kinetics because of biotransformation and excretion. In Ringer's solution, however, the decomposition is unremarkable. Clearly, plasma accelerates the destruction of BCNU *in vitro*.

[3] A rate expression could be empirically derived,

$$-\frac{d(\text{BCNU})}{dt} = k(\text{BCNU})/(\text{H}^+)^{0.3}$$

at 25° for the range pH 4 to pH 9.

The stability of BCNU was also studied in two organic solvents, namely, methanol and petroleum ether (b.p. 100–115°) by direct spectrophotometry. In the former at 50°, the decomposition of BCNU is rapid and the kinetics is complicated. On the

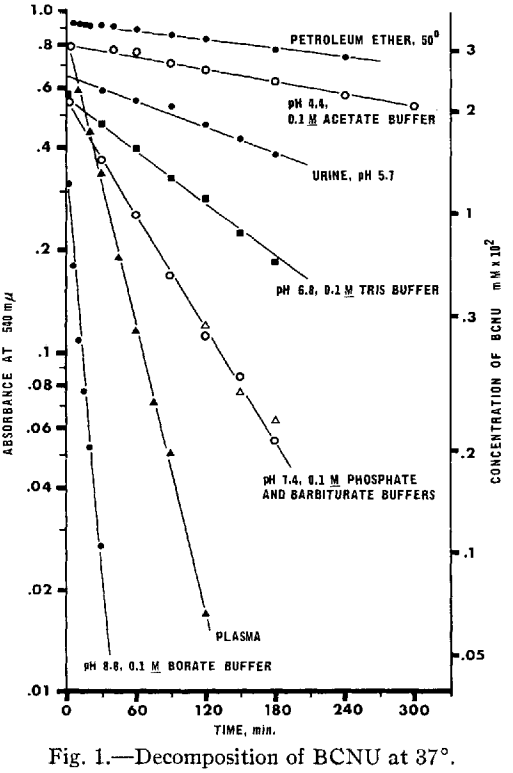

Fig. 1.—Decomposition of BCNU at 37°.

other hand, BCNU appears to be relatively stable in the latter even at 50°, and the decay obeys first-order law.

Alkaline Hydrolysis of BCNU.—It is difficult, perhaps impossible, to ascertain meaningfully the true rate of hydrolysis of the chloro- group in BCNU because of the extreme instability of BCNU in alkaline solution. However, since BCNU is generally considered an alkylating agent, we undertook a study of the rate of release of chloride ion by BCNU in order to compare it with other well-known alkylating agents. As expected, a semilog plot of either chloride liberated or fractional BCNU unhydrolyzed *versus* time fails to reveal any kinetic trend. The rate of hydrolysis is relatively slow; no more than 22% of the theoretical amount of chlorine was set free by incubation of BCNU at 25° for 90 min. in 0.1 *M* borate buffer of pH 9.8 at concentrations ranging from 0.187 m*M* (40 mcg./ml.) to 2.34 m*M* (500 mcg./ml.). At 37° in 0.1 *M* phosphate buffer of pH 7.4, a 2.34 m*M* solution of BCNU showed 31.6% of hydrolysis after more than 5 hr. The same solution exhibited 87% hydrolysis only after heating at 50° for 24 hr. As stated above, these rates could not really pertain to BCNU because under the experimental conditions BCNU has a half-life of about 5 min. to less than 1 hr. Obviously, in spite of the common biochemical effects (14) and cross resistance shared by BCNU and other alkylating agents (4, 15, 16), BCNU does not belong to the group of alkylating agents such as bis(2-chloroethyl)methylamine. If it is an alkylating agent at all, it must owe the alkylating action to one of its degradation products.

Protein Binding.—With a solution of 9.36×10^{-5} *M* of BCNU in human plasma, the results of a typical experiment are shown in Table II.

The percentage of BCNU bound to plasma protein is: (0.760–0.170)/0.760 × 100 or 78%, and the percentage recovery is: (0.760 × 4.5) + (0.170 × 0.5) × 100/(0.784 × 5.0) or 109%. On the basis of three experiments, the average extent of binding of BCNU with human plasma protein is about 80% at 0°.

The fraction of plasma protein involved in drug binding usually is albumin. Assuming an albumin concentration of 5×10^{-4} *M* in human plasma (17, 18), and also there is only one single binding site for BCNU per molecule of human plasma protein, the association constant, *K*, of the plasma protein–BCNU complex is easily estimated:

$$K = \frac{(P \cdot \text{BCNU})}{(P_f)(\text{BCNU})} = \frac{0.80 \times 9.36 \times 10^{-5}}{(5 \times 10^{-4} - 0.80 \times 9.36 \times 10^{-5})(0.20 \times 9.36 \times 10^{-5})}$$

$$= 9.4 \times 10^{3}\ M^{-1} \text{ at } 0°$$

which is comparatively small.

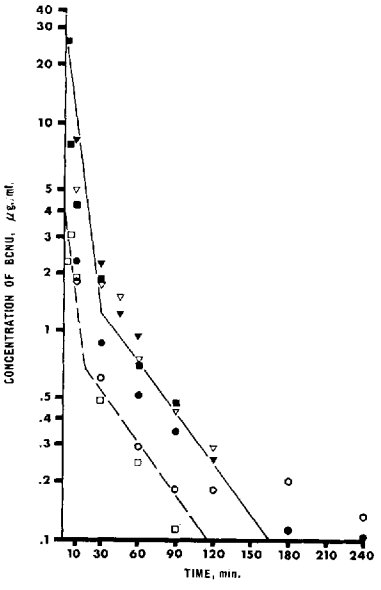

Fig. 2.—Plasma and CSF levels of BCNU in the dog. Key: ○, dog 1; □, dog 2; ▽, dog 3. (Solid symbols indicate plasma; open symbols indicate CSF.)

Plasma Level and Urinary Excretion in the Dog.—The rapid decline of BCNU in the plasma of the dog after a single intravenous injection is shown in Fig. 2. For the first 30 min. the fall of plasma levels in the three animals does not deviate too much from an exponential pattern and the half-life in plasma seems to be less than 15 min. Although protein binding by BCNU appears extensive, the association constant is relatively small. Consequently, even

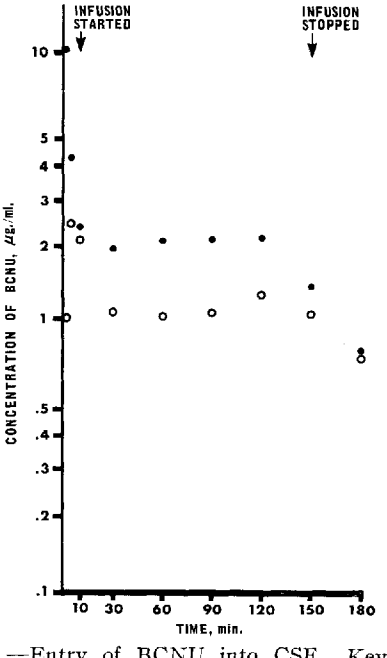

Fig. 3.—Entry of BCNU into CSF. Key: ●, plasma; ○, CSF.

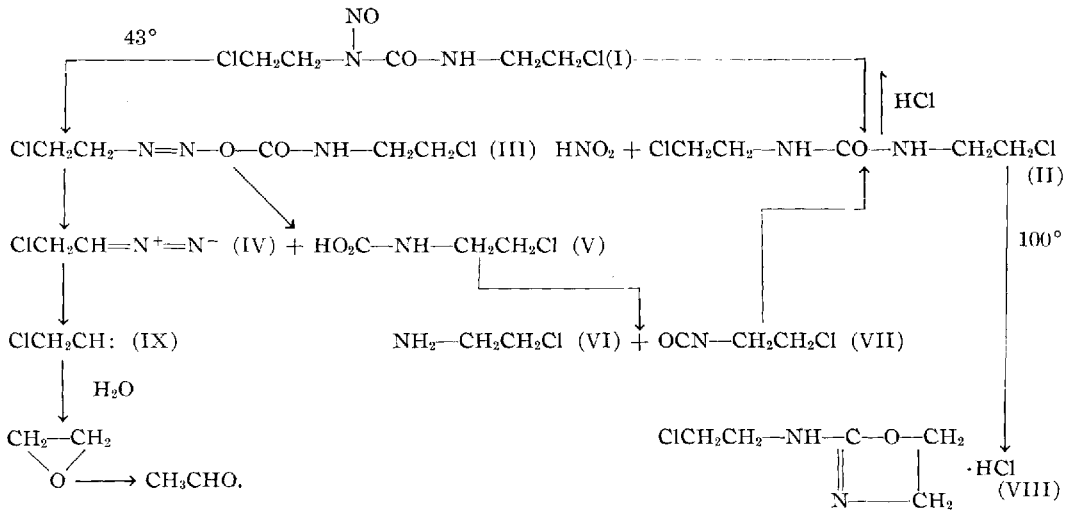

Scheme I

though an increased proportion of drug would be bound as the total amount of BCNU decreases, this estimation of half-life in plasma is essentially correct (17). Extrapolation to zero time gives a zero time plasma level of about 30 mcg./ml. Since the dose of BCNU in these experiments was 10 mg./Kg., the volume of distribution is therefore 33% of body weight, in other words, somewhat larger than the volume of extracellular water. This is unexpected because BCNU, being highly soluble in lipids, appears to penetrate cellular membranes freely. In fact, BCNU makes its appearance in the CSF and the blood stream simultaneously. Furthermore, its concentration in the former falls at about the same rate as in the latter.

In view of the exceptional chemical reactivity of BCNU, it is necessary to maintain a steady plasma level by infusion before a meaningful estimate of the extent of entry into the CSF could be made. Figure 3 illustrates the results of such an experiment. After a constant plasma level of the drug has been achieved, the CSF level of BCNU reaches about 48% that of plasma (average of three experiments), confirming the screening data and clinical experience that BCNU readily penetrates the blood-brain barrier. At first sight this ratio appears to be higher than the percentage of free BCNU in plasma (20%). However, it should be recalled that protein binding was determined with human plasma at 0° and besides, the cellulose sac used is only a crude facsimile of cell membrane.

Ten minutes after a single intravenous injection, BCNU begins to appear in the urine. The excretion reaches a peak at about 2 hr. and then gradually tapers off until 3 hr. later when a detectable amount of the drug was present. Nevertheless, in no case is the total amount of unchanged BCNU excreted in 4 hr. in excess of 0.1% of the dose.

That the colorimetric method actually measures unchanged BCNU in plasma, CSF, and urine is supported by paper chromatography. When applied on Whatman No. 3 mm. paper and developed by the systems described above, the ether extracts of these biological fluids exhibit spots with R_f values identical to those obtained from ether extracts of the same fluid after the addition of authentic BCNU.

Doubtlessly BCNU undergoes extensive catabolism in the body since the percentage of unchanged BCNU recoverable from urine is so low. Although its biotransformation must await further studies, some indications could be gleaned from its thermal decomposition.

Thermal Decomposition of BCNU in Petroleum Ether.—The authors chose to undertake the study in a nonpolar solvent, namely, petroleum ether, so as to minimize secondary reactions. The isolation of 1,3-bis(2-chloroethyl)urea (II), after heating BCNU at 43° for 5 hr., suggests the postulated sequence of events in Scheme I.

The proposed 4-centered thermal rearrangement of BCNU (I), a nitrosamide, to the diazoester (III), is well known (19, 20). This is perhaps also the first step in the decay of BCNU in aqueous solutions above pH 4. The diazoester (III), incapable of but a fleeting existence, at once decomposes by an α-elimination analogous to the case of *N*-(*n*-butyl)-*N*-nitrosotrimethylacetamide (21) to give the diazoethane (IV) and the carbamic acid (V). The fate of the diazoethane (IV) cannot be defined by this experiment. However, the isolation of acetaldehyde from an aqueous solution of BCNU after refluxing (22) implies that the acetaldehyde originates from an analogous ephemeral intermediate, 2-chloroethyldiazoic acid, $ClCH_2CH_2N{=}NOH$, *via* ethylene oxide. Possibly, therefore, in this work the diazoethane (IV), on losing nitrogen, becomes transformed into the reactive carbene (IX) which also hydrolyzes to acetaldehyde. In aqueous solution, the intermediate steps would be similar.

It is not clear exactly how 1,3-bis(2-chloroethyl)-urea (II) is derived from the carbamic acid (V); the over-all reaction, nevertheless, must result from 2 moles of V through the loss of 1 mole each of water and carbon dioxide. The authors suggest 2-chloroethyl isocyanate (VII)[4] as a possible inter-

[4] Dr. R. E. Larson independently made the same suggestion that 2-chloroethyl isocyanate might be one of the intermediate biotransformation products of BCNU.

mediate not only because the addition of 2-chloroethylamine (VI) to the postulated 2-chloroethyl isocyanate (VII) explains very well the formation of 1,3-bis(2-chloroethyl)urea (II), but also because the delayed hepatoxicity of BCNU strongly resembles that of α-naphthyl isocyanate. In any event, the thermal decomposition of BCNU (I) to afford the original unnitrosated 1,3-bis(2-chloroethyl)urea (II) cannot be explained by the simple loss of a nitroso group directly from BCNU for the following reasons: first of all, such a homolysis is unprecedented; second, and most important, when 1-(2-chloroethyl)-1-nitroso-3-cyclohexylurea undergoes a like reaction in petroleum ether (b.p. 66°–75°) at 67° overnight, the product is 1,3-dicyclohexylurea [m.p. 224°, identical to an authentic sample (23) in every respect] and not 1-(2-chloroethyl)-3-cyclohexylurea, m.p. 130°–132° (24).

It has also been shown that 1,3-bis(2-chloroethyl)-urea (II) readily cyclizes in boiling water to 2-(2-chloroethylamino)-2-oxazoline (hydrochloride) (VIII) (25). However, we have no evidence that this has occurred at 43° in petroleum ether. Whether this is true *in vivo* remains to be seen.

SUMMARY

1. BCNU is most stable at pH 4. In acid as well as in aqueous solutions of pH greater than 7 it is shortlived. Its half-life in plasma is about 20 min. *in vitro* and less than 15 min. *in vivo*.

2. The release of Cl^- by hydrolysis of BCNU is too slow to account for its alkylating action.

3. BCNU is 80% bound to human plasma protein at 0°.

4. In the dog, after a single intravenous injection, BCNU enters the CSF immediately and then disappears rapidly from both the blood stream and the CSF. No more than 0.1% of unchanged drug is excreted in 4 hr. Nothing is known concerning its biotransformation *in vivo*.

5. Refluxing of BCNU at 43° in petroleum ether for 5 hr. converts it partly into 1,3-bis(2-chloroethyl)urea. The mechanism of this reaction is discussed.

Retention, Excretion, and Distribution of 2,3,5-Triiodobenzoic Acid and Its Metabolites in the Rat

By R. D. ICE, C. E. BRECKINRIDGE, JR., and J. E. CHRISTIAN

The synthesis of 2(^{131}I),3,5-triiodobenzoic acid (TI*BA), starting with 2-amino-3,5-diiodobenzoic acid and sodium iodide (^{131}I) is described. The rate of excretion, biological half-life, and metabolites of this compound in rats were studied. Four metabolites and TIBA were found in the urine.

In soybeans, TIBA affects plant morphology and flowering response (1, 2). When properly used it increases bean production through a better utilization of photosynthate (3). Since soybeans are used for animal and human consumption, the question arises as to the environmental health hazards of TIBA and its metabolites.

TIBA was originally synthesized by Wheeler and Johns (4). Anthranilic acid was reacted with iodine monochloride and the resultant product diazotized and reacted with potassium iodide. The synthesis of TI*BA has been de-

Received December 13, 1965, from the School of Pharmacy and Pharmacal Sciences, Institute for Environmental Health Studies, Purdue University, Lafayette, Ind.

scribed by Munakata and Nakai (5). They followed the procedure of Wheeler and Johns substituting sodium iodide (^{131}I) for potassium iodide.

Saz *et al.* (6–8) have reported that oral doses have been given to man without apparent toxic effects and were still being excreted 10 days after administration. Goldberg *et al.* (9) have reported the LD_{100} for white mice to be 1.25 Gm./Kg. The LD_{50} was 0.70 Gm./Kg. Crismer (10) reported a recovery of 40% in the bile and 12% in the urine of TIBA given i.v. to dogs. Knoefel and Huang (11) have reported that TIBA exerts its toxic action through its protein binding capacity and that TIBA was reabsorbed from the glomerular filtrate.

EXPERIMENTAL

Apparatus and Materials.—A large volume liquid scintillation detector, the Purdue University Small Animal Counter (PUSAC), described by Dunavant and Christian (12), was employed for whole body counting. Crystal scintillation counting, using a 2-in. thallium activated, sodium iodide, well crystal, was used for feces, urine, and tissue counting. All activity determinations were corrected for background, counter efficiency, and decay as required.

Thin-layer chromatograms were made 250 μ thick with a model 200 (L-2) spreader.[1] Five plates, 20 × 20 cm., were prepared from 15-Gm. Silica Gel G[2] mixed with 37 ml. of water. The chromatograms were heated 0.5 hr. at 110° before use. Solvent chambers lined with Whatman No. 1 filter paper were used. Each chamber was saturated with solvent before use.

Thick-layer chromatograms, 1.0-mm. thick, were prepared using a model 200-11[1] variable thickness spreader. Five chromatograms were prepared from 85 Gm. of Silica Gel G and 150 ml. of water. The plates were activated at 110° for 1 hr. prior to use. Three solvents systems were used. They were as follows: (*a*) normal propanol–ammonium hydroxide (28%)–water (10:1:1), (*b*) normal butanol–acetic acid–water (4:1:1), (*c*) methanol–water (75:25).

All solvent systems were prepared fresh, except for solvent system (*b*) in which metabolite analyses were done with the solvent system 30 or more days old. Each solvent was allowed to proceed 12–15 cm. on the chromatogram.

Unlabeled TIBA was located with bromocresol green spray[3] (0.1% in *n*-butanol). All labeled compounds were identified from autoradiograms using No Screen medical X-ray film. After exposure, the film was developed using Kodak liquid X-ray developer and fixed with Kodak liquid X-ray fixer[4] following the manufacturer's recommendations. Reagent grade chemicals were used. Sodium radioiodide was purchased from Iso/Serve, Inc., Cambridge, Mass.

Synthesis of TI*BA.—Following a procedure described by Breckinridge *et al.* (13), which is a modification of the method used by Olivier and Combe (14), 2.5 Gm. of 2-amino-3,5-diiodobenzoic acid[4] was dissolved in 10 ml. of sulfuric acid with continual cooling to 0°. One gram of sodium nitrite was added slowly. The reaction was stirred for 2 hr. This mixture was poured over 33 Gm. of ice and air was bubbled through the solution for 1 hr. While cold, it was filtered through Whatman No. 1 filter paper by gravity. Sodium iodide (^{131}I), 54.5 mc., in 1 ml. of NaOH was added. A carrier solution of 1 Gm. NaI in 1 ml. of water was used to rinse the isotope container and this was added to the mixture. The solution was heated for 30 min. Free iodine was neutralized with sodium hydrogen sulfite. The resultant precipitate was separated by filtering by suction with a Büchner funnel and a double layer of Whatman No. 1 filter paper. The precipitate was dissolved with a minimum amount of hot ethanol. Crystallization was accomplished by adding distilled water to the warm alcoholic solution with stirring until a saturation point was obtained. The solution was reheated to effect complete solution, covered, and set aside for crystallization. Needle shaped, light orange crystals with a melting point of 223.6–225.5° were obtained. The specific activity was 9.80 mc./mmole. Yields of 80–86% of theoretical were obtained.

Radio-Compound Purity.—Dilutions of synthesized TI*BA in 10 μl. of ethanol, prepared to give a total of 10^8 disintegrating atoms during a 15-hr. period, were chromatographed using thin-layer chromatography and solvent system (*b*), made fresh. Only one labeled compound, R_f 0.69, appeared on the autoradiograph and this gave an R_r value of 1.0 when compared with TIBA. Thin-layer chromatography with solvent system (*a*) gave three separate labeled compounds. The R_f of TIBA was 0.60 and the two impurities were located at R_f 0.39 and R_f 0.73. Successive recrystallization decreased the amounts of the impurities significantly, but the impurities could not be completely removed, probably because of continued decomposition resulting from the recrystallization procedure. Repeated thin-layer chromatograms of the synthesized TI*BA compared with a radioiodide ion standard indicated an R_r of 1.0 for the impurity at R_f 0.73. The impurity at R_f 0.39 was not identified.

Purification was accomplished using a thick-layer chromatographic technique. Thirty-six spots of the synthesized TI*BA and unlabeled TIBA control were placed across a thick-layered chromatogram 1.5 cm. from the base of the plate. Each spot contained 3 mg. of TI*BA in 100 μl. of ethanol. After developing, the control TIBA was located with bromocresol green spray. The Silica Gel G in the corresponding area to the control presumed to contain pure TI*BA was scraped off and extracted with four 10-ml. portions of hot ethanol, and filtered through a sintered-glass funnel. The ethanolic solution was chromatographed using the thin-layer technique and solvent system (*a*). Only one labeled compound (R_f 0.60) appeared on the autoradiogram of the chromatogram. To further prove the identity of the labeled compound, 250 mg. of unlabeled TIBA was added and the mixture, dissolved in hot ethanol, filtered through a sintered-glass filter and recrystallized. The crystals melted at 223–225° (the known melting point of TIBA) and contained the radioactivity. Accordingly, the

[a] Per cent of administered dose. [b] Same rat group conditions as listed in Table I.

purified TI*BA was considered to be free of labeled compound impurities.

Whole Body Retention and Excretion.—Three groups of rats were studied. All doses were oral using an oral administration needle. Each rat was given a dose of 0.2 μc. representing 0.10 mg. of TI*BA per 0.5 ml. All doses were in a 50% ethanol and distilled water solution. The results were tabulated in per cent retained and appear in Table I. The data suggest two exponential components. A short biological half-life component is indicated from 11.8–17.9 hr. This may represent blood concentration of TI*BA. A long biological half-life component, 395–403 hr., was also indicated. This component may indicate thyroid involvement. Excretion studies were run concomitantly with whole body retention studies using the same rats and groupings. The feces was collected at 12-hr. intervals and the urine was collected at 4–12-hr. intervals. Results are shown in Table II. Urinary excretion was the primary mode of excretion, accounting for 70–78% of the administered dose. Fecal excretion accounted for 3–4% of the administered dose.

Distribution Study.—Two groups of six rats each were starved for 24 hr. prior to and during the study. An oral dose of TI*BA, as before, was administered. Immediately after administration a whole body count was made. Four hours later the rats were anesthetized with ether and a 1-ml. blood sample was obtained from the tail. The animals were sacrificed by over-anesthetizing with ether and the thyroid and kidneys completely excised. An aliquot of muscle tissue (from the right rear leg) and liver was also obtained. Each sample was weighed immediately after removal and a radioactivity determination made in the crystal scintillation counter. Table III presents the data on the distribution of TIBA in the blood, liver, kidney, thyroid, and muscle tissue.

The distribution study clearly indicates thyroid concentration of the labeled iodine atoms. Table III indicates the thyroid concentration was 12–18 times the concentration found in the blood. This probably is due to a partial breakdown of the TIBA to iodide ion which in turn is taken up by the thyroid. However, TIBA itself or other metabolites may be concentrated in this particular tissue.

Metabolite Studies.—A total of 12 Holtzman rats were given orally 6.75 μc. representing 2.9 mg. of TI*BA in 50% ethanol and distilled water solution. The rats were not permitted food or water

0.39	11.6	±1.8

[a] Thick-layer chromatographic separation with *n*-butanol–acetic acid–water (4:1:1). [b] Standard error of the mean as determined from 10 separate determinations, five from each of the two separate urine samples collected from two separate groups of five animals each.

24 hr. prior to or during the experiment. A 60-μl. aliquot of whole urine collected over a period of 18 hr. was spotted on each of three thick-layer chromatographic plates along with standards of TI*BA and radioiodide ion. The remaining urine was acidified with 1 *N* HCl using litmus paper as the indicator, allowed to stand for 30 min., and then a 60-μl. aliquot was spotted on chromatography plates.

A chromatogram was developed in each of the three solvent systems. In solvent system (*b*) (30 days old) four metabolites plus TIBA were found. Radioiodide ion standard gave an R_r of 1.0 with a spot located at R_f 0.52. TI*BA standard gave an R_r of 1.0 for the spot at R_f 0.77. The spot at R_f 0.48 disappears in the hydrolyzed urine indicating a possible conjugate of TIBA. The spots at R_f 0.39 and R_f 0.81 were not identified.

A separation occurred in solvent system (*a*) indicating three metabolites plus TIBA. An R_r of 1.0 for TIBA at R_f 0.60 was obtained. An R_r of 1.0 for iodide ion at R_f 0.73 was obtained. A metabolite at R_f 0.45 disappeared upon acid hydrolysis indicating a possible conjugate of TIBA. The third metabolite was at R_f 0.52 and was not identified.

In solvent system (*c*) three metabolites were indicated plus a heavy concentration at R_f 0.83. Iodide ion and TI*BA standards had R_r values of 1.0 at R_f 0.83. The other three metabolites occurred at R_f's of 0.81, 0.77, and 0.73.

The metabolite experiment described above was repeated using 10 animals to obtain a quantitative evaluation of the metabolites present in the urine. The urine collected over a period of 18 hr. was pooled into two separate groups representing five animals in each group and chromatographed as previously described using solvent system (*b*). The separated labeled compounds were located on the chromatogram by autoradiography and the Silica Gel G containing each metabolite was quantitatively transferred to separate vials for counting in the well crystal scintillation counter. The relative percentage of each metabolite, based on the total activity found on the chromatogram, was calculated. The data are presented in Table IV.

SUMMARY AND CONCLUSIONS

1. Radioactive labeled 2(^{131}I),3,5-triiodobenzoic acid was synthesized and purified free of other radio-labeled compounds by thick-layer chromatographic separation followed by hot ethanolic extraction.

2. Whole body retention studies of TIBA showed a two component system—one with a biological half-life of 11.8–17.9 hr. and the second 395–403 hr.

3. Excretion studies showed that the primary route of excretion was urinary. Of the administered dose, 70–78% was excreted through the urine while only 3–4% was excreted through the feces.

4. Distribution studies in the blood, liver, kidney, muscle tissue, and thyroid after 4 hr. indicated an average thyroid concentration of 15 times the average blood concentration.

5. Metabolite studies using thick-layer chromatography indicated 4 metabolites plus TIBA in the urine. One of the metabolites was identified as iodide ion. Quantitative determination showed 31.3% TIBA and 10.4% iodide ion. Three unidentified metabolites were found to be present in the quantity of 26.3, 20.4, and 11.6%.

Rapid, Sensitive Colorimetric Method for the Determination of Estrogens

By TIBOR URBANYI and C. R. REHM

A colorimetric method has been developed for the routine determination of estrogens in pharmaceutical preparations. The method is based on the formation of an azo dye from the condensation of diazotized 4-amino-6-chloro-*m*-benzene disulfonamide with estrogens which contain a phenolic hydroxyl group. The condensation product exhibits a red color with an absorption maximum at 500 mμ in alkaline solution. The most reproducible results are obtained when coupling is carried out at pH 5 buffered solution. The color formation obeys Beer's law over a range of 0.05–0.25 mg. of estrogens per ml. of sample solution. Optimum conditions for the color formation have been determined, and the application of this procedure to pharmaceutical products is given.

THE OFFICIAL U.S.P. procedure for the determination of ethinyl estradiol, estradiol benzoate, estradiol dipropionate, and estrone are based on the Kober reaction in which a violet color is developed on reaction of the estrogens in a sulfuric acid–phenol–iron reagent (1). The Kober reaction, in spite of many modifications over the years, still leaves much to be desired in an analytical procedure. The method is time-consuming, and the color development is critically dependent upon reagent composition, reaction time, and temperature. Furthermore, interference by other nonphenolic steroids can occur (2).

Colorimetric methods, based on the coupling of the phenolic hydroxyl group with diazotized amines, have been reported for a number of the estrogens. These include coupling with diazotized *p*-nitroaniline (3), with diazotized sulfanilic acid (4, 5) and its derivatives (6), and with tetrazotized dianisidine (7). These methods have been used primarily in the determination of estrogens in biological samples.

It has been observed in these laboratories that diazotized 4-amino-6-chloro-*m*-benzene disulfonamide couples with phenolic compounds to form products with extremely stable colors (8). The suitability of this reagent for the determination of a number of estrogens has been investigated. As a result of these studies, a rapid and sensitive colorimetric method for the determination of ethinyl estradiol, estradiol, estradiol esters, and estrone has been developed.

EXPERIMENTAL

A Beckman model DU spectrophotometer was used to determine the absorbance values reported. A Cary model 11 recording spectrophotometer was used to obtain the spectra presented.

Received January 25, 1966, from the Research Department, Ciba Pharmaceutical Co., Summit, N. J.
Accepted for publication March 21, 1966.

Determination of Ethinyl Estradiol and Other Phenolic Estrogens

Reagents and Solutions.—4-Amino-6-chloro-*m*-benzene disulfonamide, 0.2% methanolic solution; sodium nitrite, 1% aqueous solution; hydrochloric acid, 1 *N;* sulfuric acid, 18 *N;* sodium acetate, 2 *N* solution; sodium hydroxide, 0.1 and 1 *N* aqueous solutions; sodium hydroxide, 10% aqueous solution; sodium hydroxide, 10% in 80% methanol–water.

Standard Estrogen Solution.—Weigh accurately about 50 mg. of the estrogen into a 50-ml. volumetric flask and dissolve it in methanol. Make up to volume with methanol, then dilute 10.0 to 100 ml. with 0.1 *N* sodium hydroxide. Concentration: approximately 0.1 mg./ml.

Preparation of Assay Solutions.—*Solid Dosage Forms.*—Extract an accurately weighed sample of the powder or powdered tablets equivalent to about 5 mg. of the estrogen with three 10-ml. portions of methanol. Centrifuge each portion and filter the methanol extracts into a beaker and evaporate the methanol to dryness. Transfer the contents of the beaker quantitatively with 0.1 *N* sodium hydroxide to a 50-ml. volumetric flask and dilute to volume with additional 0.1 *N* sodium hydroxide. This is the assay solution

Oil Solutions.—Pipet 5.0 ml. of 10% sodium hydroxide solution in 80% methanol–water into a 40-ml. centrifuge tube. Accurately pipet a volume of the oily sample solution containing approximately 5 mg. of estradiol or estradiol esters and shake mechanically for a minimum of 15 min., add 20 ml. of petroleum ether and 5 ml. of 10% aqueous sodium hydroxide, shake for 2 min., and centrifuge. Remove the lower layer with a syringe equipped with a blunt, 14-gauge needle and filter the solution through a paper filter into a 50-ml. volumetric flask. Add 10 ml. of 10% sodium hydroxide to the centrifuge tube, shake 2 min., centrifuge, and filter the lower layer to the flask as before. Add sulfuric acid dropwise until the solution is approximately neutral (test with indicator paper, pH between 6 and 8). Dilute the solution to volume with 0.1 *N* sodium hydroxide. This is the assay solution.

Color Development.—Into separate 10-ml. volumetric flasks pipet successively 1.0 ml. each of 4-amino-6-chloro-*m*-benzene disulfonamide, sodium nitrite, and hydrochloric acid solutions, and mix well. Allow to stand 1–2 min. and add 2.0 ml. of the stand-

ard solution, 2.0 ml. of the assay solution, and 2.0 ml. of 0.1 *N* sodium hydroxide solution to separate flasks. Add 2.0 ml. of sodium acetate solution to each flask and allow to stand exactly 6 min. Dilute each flask to volume with 1 *N* sodium hydroxide and determine the absorbance of the standard and sample solutions at 500 mμ in 1-cm. cells against the blank, using a suitable spectrophotometer.

DISCUSSION

The absorption spectra of alkaline solutions of the coupled products, resulting from the reaction of ethinyl estradiol, estradiol, estradiol dipropionate after saponification, and estrone with diazotized 4-amino-6-chloro-*m*-benzene disulfonamide are shown in Fig. 1. It is seen that similar spectra are obtained

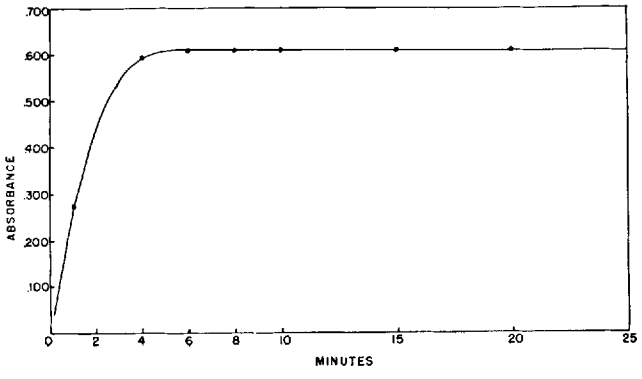

Fig. 3.—Absorbance of final solution *vs.* coupling reaction time for estradiol; coupling reaction carried out at pH 5.0.

[a] Average of duplicate determinations.

for the four compounds, each exhibiting a broad absorption maximum at 500 mμ. Esters of estradiol exhibit spectra identical to that of estradiol when coupled with the reagent after saponification, as shown in Fig. 1. Saponification of mono- and diesters of estradiol proceeds rapidly in alkaline solution at room temperature and is complete in 10 min. or less in aqueous media which is 0.1 *M* or stronger in hydroxyl ion. The structure of the coupled products has not been determined; however, it is logical to assume that coupling occurs in one of the positions *ortho* to the phenolic hydroxyl group.

The molecular absorptivities of these four estrogens as calculated from the curves in Fig. 1 are listed in Table I.

It can be seen from these data that the molar absorptivities of the four compounds are nearly identical within experimental error.

The pH dependency of the absorption spectrum of the reaction product of estradiol with diazotized 4-amino-6-chloro-*m*-benzene disulfonamide is shown in Fig. 2.

It can be seen from these spectra that the red color of the coupled product is produced only in a highly alkaline medium (pH > 12). At pH 5 or below, the coupled product in solution exhibits a yellow color, the absorption spectrum exhibiting a shoulder at 450 mμ. At pH values between pH 5 and 12, varying shades of orange are produced. The absorption band at 500 mμ increases in intensity up to a pH of about 13; at pH values above this no further increase in intensity occurs. The spectra exhibit an isosbestic point at about 450 mμ as shown in Fig. 2. The absorption spectra of the coupled products of ethinyl estradiol and estrone with the diazotized disulfonamide exhibit similar pH dependencies.

The initial reaction between nitrous acid and 4-amino-6-chloro-*m*-benzene disulfonamide appears to be somewhat more complex than a simple diazotization reaction since it has been observed that approximately 2 moles of nitrous acid are consumed by the compound (8). Conditions for diazotization of the disulfonamide do not appear to be critical. Diazotization of the disulfonamide in 1 *N* hydrochloric acid is complete in 2 min. in the presence of excess nitrous acid. Destruction of the excess nitrous acid was not found to be necessary since no interference in the subsequent color development and measurement was observed. Coupling of the estrogens studied with diazotized 4-amino-6-chloro-*m*-benzene disulfonamide does not proceed readily in acid solution but was found to proceed rapidly when carried out at pH 5 or above. The most reproducible absorbance values were obtained when coupling was carried out at about pH 5. When coupling was carried out in alkaline solution, it was found that the resulting absorbance (color intensity) was critically dependent upon the rate of addition of alkali. This indicated a rapid destruction of the diazotized disulfonamide in highly alkaline solution. By coupling at pH 5, however, this problem is avoided and day to day variation in color intensity never exceeded 2%. This is consistent with the observation of Rehm and Smith, who found that coupling of the reagent with chromotropic acid under similar conditions of pH also gave highly consistent absorbance values (8). The effect of coupling time at pH 5 before the addition of alkali upon the absorbance of the final solution at 500 mμ is shown in Fig. 3. It is seen that color intensity increases during the first 6 min. and then remains constant over a period of at least 25 min. This indicates that the resulting diazo compound is quite stable at this pH.

The extreme stability of the red color as measured at 500 mμ is shown by the data in Table II. These data indicate no significant changes in absorbance of the final solution over a 4-hr. period in the dark and under normal laboratory illumination. An increase of about 3% in absorbance is noted after 2 hr. for solutions placed in direct sunlight.

The relationship between absorbance at 500 mμ and concentration was found to be quite linear for ethinyl estradiol, estradiol, estradiol dipropionate, and estrone as shown in Fig. 4.

The specificity of the method for these compounds in the presence of several frequently encountered excipients is demonstrated by the data shown in Table III. Recoveries of 98–100% were obtained for the various estrogens in the presence of lactose, starch, and sesame oil. Other phenols will, of course, interfere in the determination of these estrogens by this method as they would in the case of the Kober reaction; however, such interferences would not normally be expected.

The reproducibility, sensitivity, and rapidity of this procedure represent a considerable improvement over the presently used Kober reaction for the determination of these estrogens.

The application of this reaction to the determination of other compounds of pharmaceutical interest

containing phenolic hydroxyl groups such as pyridoxine will be presented in a future report.

SUMMARY

Diazotized 4-amino-6-chloro-*m*-benzene disulfonamide has been found to couple with various estrogens containing a phenolic hydroxyl group to yield a stable red color in alkaline solution.

This reaction is the basis of a rapid, sensitive, and reproducible method for the determination of estrogens such as estradiol, ethinyl estradiol, estrone, and estradiol dipropionate.

Commonly encountered excipients such as lactose, starch, and sesame oil were found not to interfere in the determination of these estrogens.

Effects of Adsorbents on Drug Absorption II

Effect of an Antidiarrhea Mixture on Promazine Absorption

By DONALD L. SORBY and GRACE LIU

An antidiarrhea mixture containing attapulgite and citrus pectin was studied for its potential effect on the absorption of promazine from the human gastrointestinal tract. Test conditions were established so that results would have maximum applicability to the clinical use situation. Drug and adsorbent were not equilibrated prior to administration. Under these conditions, the antidiarrhea mixture decreased the rate and extent of absorption of the test drug. An *in vitro* adsorption study established that the antidiarrhea mixture had a strong affinity for the test drug. Results are in general agreement with the previous report in this series.

A PREVIOUS report (1) showed that activated charcoal and activated attapulgite both altered the absorption of promazine from the gastrointestinal tract. Prior to administration to human subjects, a 50-mg. quantity of promazine was equilibrated with the particular adsorbent material. The resulting test doses contained 38.5 mg. of the total 50-mg. quantity of promazine adsorbed to activated attapulgite or 24.7 mg. bound to activated charcoal. Under these conditions, activated attapulgite slowed the rate of absorption; however, it had no significant effect on the total availability of the drug. Activated charcoal, on the other hand, appeared not to release any of the adsorbed drug while within the gastrointestinal tract and only promazine, which was free in solution in the test dose at the time of administration, was absorbed. *In vitro* studies of desorption rates from adsorbates demonstrated that promazine release was rapid from activated attapulgite and very slow from activated charcoal.

Several pharmaceutical products containing adsorbent materials are intended to control diarrhea by exerting their action within the gastrointestinal tract. In this respect they are thought to adsorb certain toxic amines produced by putrefaction or as by-products of bacterial metabolism, and thus prevent their undesirable actions on the human body (2). The question arises concerning whether the presence of such adsorbent materials within the gastrointestinal tract might also interfere with absorption of amine-type drugs, many of which are known to be strongly adsorbed *in vitro* by the materials included in antidiarrhea preparations (2–6).

The observed effects of adsorbents on drug absorption (1) are applicable only to the situation where drug and adsorbent are equilibrated before administration to test subjects. The question concerning whether the same effects will be obtained if drug and adsorbent do not meet until both are within the confines of the gastrointestinal tract was left unanswered.

The purpose of this research was to determine whether the presence of an adsorbent antidiarrhea mixture within the gastrointestinal tract would interfere with the absorption of an amine-type drug. Promazine hydrochloride (50

containing phenolic hydroxyl groups such as pyridoxine will be presented in a future report.

SUMMARY

Diazotized 4-amino-6-chloro-*m*-benzene disulfonamide has been found to couple with various estrogens containing a phenolic hydroxyl group to yield a stable red color in alkaline solution.

This reaction is the basis of a rapid, sensitive, and reproducible method for the determination of estrogens such as estradiol, ethinyl estradiol, estrone, and estradiol dipropionate.

Commonly encountered excipients such as lactose, starch, and sesame oil were found not to interfere in the determination of these estrogens.

Several pharmaceutical products containing adsorbent materials are intended to control diarrhea by exerting their action within the gastrointestinal tract. In this respect they are thought to adsorb certain toxic amines produced by putrefaction or as by-products of bacterial metabolism, and thus prevent their undesirable actions on the human body (2). The question arises concerning whether the presence of such adsorbent materials within the gastrointestinal tract might also interfere with absorption of amine-type drugs, many of which are known to be strongly adsorbed *in vitro* by the materials included in antidiarrhea preparations (2–6).

The observed effects of adsorbents on drug absorption (1) are applicable only to the situation where drug and adsorbent are equilibrated before administration to test subjects. The question concerning whether the same effects will be obtained if drug and adsorbent do not meet until both are within the confines of the gastrointestinal tract was left unanswered.

The purpose of this research was to determine whether the presence of an adsorbent antidiarrhea mixture within the gastrointestinal tract would interfere with the absorption of an amine-type drug. Promazine hydrochloride (50

mg.) was used as the test drug. The antidiarrhea mixture contained in each 30-ml. vol. activated attapulgite (3 Gm.), activated attapulgite, colloidal (0.9 Gm.), and citrus pectin, 0.3 Gm.[1]

EXPERIMENTAL

Determination of Adsorption Isotherm.—Adsorption of promazine by activated attapulgite was reported previously (1). The antidiarrhea mixture contained additional ingredients, however, and it was thus necessary to study the interaction between promazine and the specific product.

The antidiarrhea mixture was diluted with a quantity of distilled water equal to twice its own weight. While the resulting suspension was vigorously stirred, 20-ml. aliquots were pipeted into 50-ml. glass-stoppered test tubes.

Visking cellulose dialysis casings ($^{18}/_{32} \times 8$ in.) were pretreated by soaking in distilled water at 90° for 10 hr. The water was changed several times during this period. The inside of each casing was then flushed with distilled water and the casings were returned to a warm water soak for an additional half hour. Just prior to use, excess water was expressed, and a knot was tied in one end of each casing to form a small bag.

A 10-ml. quantity of a solution containing either 10, 20, 30, 40, or 50 mg. of promazine hydrochloride in distilled water was pipeted into each dialysis bag, and a knot was tied to close the open end. Four bags were prepared for each concentration of promazine hydrochloride. Two of the four bags were placed into tubes containing the diluted antidiarrhea mixture. The remaining two bags were placed into tubes containing 20 ml. of distilled water. The tubes were stoppered and sealed with paraffin wax to prevent passage of water along the stoppers by capillary action. All tubes were placed in a rocker-shaker device totally immersed in a constant-temperature bath at 25.0°. Shaking proceeded for 5 days. Equilibrium was established by the end of this time period.

The dialysis bags were removed from the tubes and dried lightly with tissue. An appropriate aliquot of the solution inside the bag was removed, and the amount of promazine remaining in solution was determined by the method described previously (3). Control experiments showed that the antidiarrhea mixture contained no interfering materials at the levels of dilution used to assay for promazine. For systems containing only distilled water as the phase outside the dialysis bag, both external and internal solutions were assayed for promazine content.

The amount of material disappearing from solution in the systems containing no adsorbent was plotted *versus* the concentration of material remaining. This served as a calibration curve to provide a "dialysis cell adsorption value" for the samples containing adsorbent. The apparent amount of promazine adsorbed in systems containing the antidiarrhea mixture was calculated from the difference between the amount of promazine added initially and the amount present in solution at the end of the experiment minus the amount adsorbed by the dialysis cell.

Twenty-milliliter aliquots of the diluted suspension were pipeted into tared dishes, weighed, evaporated to dryness, and reweighed. From these data, it was possible to calculate the amount of water contributed to the dialysis system by the antidiarrhea mixture and also the weight of solids which it contained. This experiment also showed that there was a high degree of reproducibility in pipeting the diluted antidiarrhea mixture, even though there was some hold-back of material within the pipet.

The data obtained from the adsorption experiments were treated according to the Langmuir equation. Figure 1 shows the experimental values and the regression line calculated by the method of least squares. The constants for the Langmuir equation were calculated from the reciprocals of the slope and intercept values of the regression equation.

In Vivo Tests.—*In vivo* testing was conducted using an adult, male human, 31 years of age, weighing 80 Kg., and in apparent good

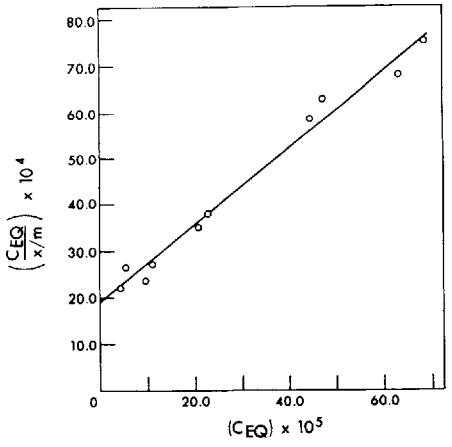

Fig. 1.—Langmuir isotherm for adsorption of promazine at 25.0° by the antidiarrhea mixture. C_{EQ} denotes the molar concentration of promazine in solution at equilibrium; x/m, the millimoles of promazine adsorbed per gram of solids in the antidiarrhea mixture.

[1] The antidiarrhea mixture was procured from a local source and was representative of the product as it appears in commerce.

health. The subject had participated in previous experiments (1) where he was designated as subject *A*.

The subject was assigned the various test doses in a random order determined through use of a table of random numbers. At least 1 week elapsed between administration of consecutive test doses. During the course of the study, there was no appreciable change in the amount of background material in the urine which was sensitive to the assay procedure. Thus, the 1-week delay between tests appeared to be adequate to avoid carryover effects between consecutive doses.

On the day prior to each experiment, the subject collected three separate urine samples to serve as blanks in the assay. Upon arising the morning of the test day, the subject voided his bladder, consumed 4 fl. oz. of water and, after waiting 0.5 hr., collected a urine sample also to be used as a blank in the assay. The subject immediately consumed the test preparation, rinsing the bottle with a small portion of water to insure complete transfer of the test dose. Urine samples were collected over the time intervals shown in Table I. No further food or drink was consumed for at least 1 hr. Consumption of food and water was *ad libitum* for the remainder of the test period. Immediately after collection, the volume of each urine sample was measured and recorded. An aliquot of the sample was frozen for assay at a later time. At the conclusion of each experiment, the frozen samples were returned to the laboratory, and after reaching room temperature they were assayed for their content of promazine excretion products.

When the experiment involved measurement of the effects of the antidiarrhea mixture, the subject consumed 1 fl. oz. of the undiluted preparation at bedtime the night before the test. Upon arising the next morning, the subject consumed an additional 1 fl. oz. of the antidiarrhea mixture. Finally, 0.5 hr. later, he took another 0.5 fl. oz. A solution containing 50 mg. of promazine hydrochloride in 45 ml. of distilled water was immediately consumed. Experiments were also carried out to measure excretion characteristics following doses of 25 mg., 37.5 mg., and 50 mg. of promazine hydrochloride in distilled water and with no antidiarrhea mixture present in the gastrointestinal tract. Data obtained from the various experiments are shown in Table I.

Analysis of Urine Samples.—Urine samples were analyzed by a procedure similar to the method used before (1). It was found previously that the yellow-colored urine pigments cause some interference with the assay procedure. This interference introduces a systematic but variable error into each assay since the intensity of the yellow color varies from sample to sample. The assay procedure was further modified in this experiment to better correct for this interference in order to obtain higher precision.

A relationship exists between the transmittance at 420 mμ of urine samples containing no promazine and the intensity of color developed at 515 mμ in these same samples when assayed by the method for determining promazine content of the urine. The assay procedure was thus modified in the following fashion. Four urine blanks were collected prior to each experiment. The transmittance of all samples, as well as urine blanks, was determined at 420 mμ before assay for promazine content.[2] The samples and blanks

[2] Per cent transmittance at 420 mμ was measured on the diluted urine sample immediately prior to passing it through the ion-exchange column.

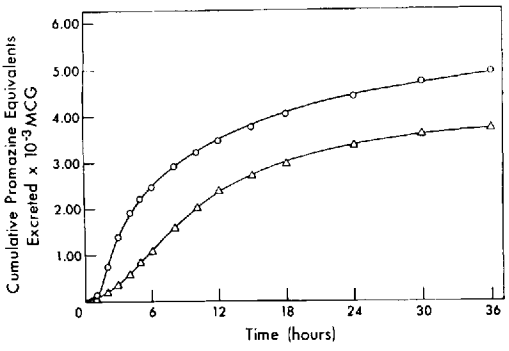

Fig. 2.—Cumulative amounts of promazine equivalents excreted in the urine following administration of promazine hydrochloride (50 mg.) in simple aqueous solution. Key: O, promazine administered alone; △, promazine administered immediately following antidiarrhea mixture. Points on each curve represent means from five separate experiments.

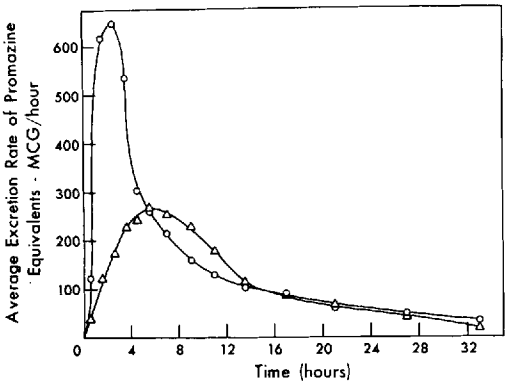

Fig. 3.—Average urinary excretion rate of promazine equivalents following administration of promazine hydrochloride (50 mg.) in simple aqueous solution. Key: O, promazine administered alone; △, promazine administered immediately following antidiarrhea mixture. Points on each curve represent means from five separate experiments.

were then assayed as described previously (1) for their apparent content of promazine excretion products. A blank correction curve was prepared by plotting the per cent transmittance at 420 mμ against per cent transmittance at 515 mμ after assay for each of the urine blanks. A blank correction was made for each test sample by comparing its per cent transmittance at 420 mμ with the correction curve. The probable color intensity at 515 mμ contributed by blank was therefore obtained for each test sample.

As discussed previously (1), due to the nonspecific nature of the assay procedure, it is necessary to express the results of assays on the basis of promazine equivalents. A promazine equivalent is defined as representing the amount of promazine hydrochloride which, if carried through the assay procedure, would give the same color intensity at 515 mμ as the urine sample in question. The excretion products in urine samples were quantitated by comparing their per cent transmittance at 515 mμ to a standard curve prepared by assaying known amounts of promazine hydrochloride dissolved in distilled water. The promazine equivalent representing the blank for a particular sample was subtracted from the assay value to obtain the actual amount of excretion product.

Treatment of Excretion Data.—Methods for treating urinary excretion data were described previously (1). Cumulative amounts of promazine equivalents excreted up to the end of each time interval and the average excretion rates during each time period were calculated. Statistical comparisons of data were made by a t test for independent sample means. Two-tail t values were used in assessing the level of significance of all data. The results of the various calculations are presented in Figs. 2, 3, and 4 and in Tables I and II.

DISCUSSION

Adsorption of promazine by the contents of the antidiarrhea mixture appears to conform to the Langmuir equation (Fig. 1). The equation for the regression line shown in Fig. 1 is

$$\frac{C_{EQ}}{x/m} = 8.31\ C_{EQ} + 1.90 \times 10^{-3}$$

where C_{EQ} is the concentration of promazine

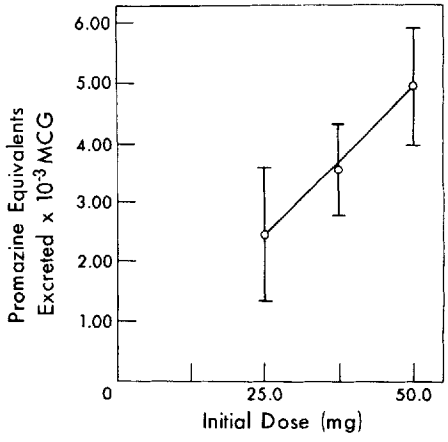

Fig. 4.—Relationship between initial dose of promazine hydrochloride and cumulative promazine equivalents excreted in the urine after 36 hr. Points represent means of five separate experiments for the 50.0 and 37.5 mg. doses and four separate experiments for the 25.0-mg. dose. Bars denote 95% confidence intervals about means. Differences between means are significant at the $P = 0.05$ level by the t test.

remaining in solution at equilibrium, and x/m is the amount of promazine adsorbed per unit weight of adsorbent, *i.e.*, the specific adsorption. The reciprocal of the slope yields a Langmuir adsorption constant which predicts the maximum amount of promazine which can be adsorbed. At that point, the surfaces of all adsorbing materials in the preparation supposedly are saturated with the adsorbed substance. The value of this constant is 0.120 mmole/Gm. of solids in the antidiarrhea mixture.[3] This amount corresponds to 38.5 mg. of promazine adsorbed per gram of solids. While the extent of adsorption is not always directly proportional to the total adsorbent in a system (7), it appears that the usual 1-fl. oz. dose of the antidiarrhea mixture would be capable of adsorbing nearly all of a 50-mg. dose of promazine hydrochloride. It should be pointed out that the degree of dilution by gastric fluids and by water in the test dose, as well as the effects of the various gastrointestinal contents, could make the adsorption characteristics quite different in the *in vivo* situation. These *in vitro* data do show, however, a high potential for adsorption of promazine by the antidiarrhea mixture. The quantity of antidiarrhea mixture consumed by the test subject would be more than adequate to adsorb all of the test dose under conditions similar to the *in vitro* experiment.

Data presented in Tables I and II and in Figs. 2 and 3 amply demonstrate the fact that the antidiarrhea mixture interferes with absorption of the test drug from the human gastrointestinal tract. Both the absorption rate and the over-all extent of absorption, as judged by urinary excretion data, are modified when the antidiarrhea mixture is present. The delay in the time of peak urinary excretion rate (Fig. 3) suggests that, for a period of time, the apparent absorption rate constant for promazine is altered. Such an effect was also seen previously (1) when promazine pre-equilibrated with activated attapulgite was administered to test subjects. These results differ from those obtained previously in that the total amount of drug absorbed is also significantly decreased. This may be seen in both Figs. 2 and 3. Judged by the 36-hr. cumulative excretion, the relative availability of promazine was 76% after administration with the antidiarrhea mixture. The same value can also be arrived at independently by comparing the 36-hr. cumulative excretion after the antidiarrhea mixture to Fig. 4. This amount of excretion product would be obtained from an initial dose of 38 mg. of promazine hydrochloride in solution, again 76% of the actual dose.

Data shown in Fig. 4 add proof to the validity of test methods employed here and previously (1) for studying the effects of adsorbents on the absorption of the model amine. While the assay method is indeed nonspecific and will determine only a portion of total drug metabolites excreted (1, 8), Fig. 4 shows that a direct relationship exists between the initial dose of promazine and the amount of excretion product collected over a 36-hr. period. While not presented here, similar plots of data for other collection periods are also linearly related to initial dose. Differences between the three doses with respect to the mean cumulative excretion products at each collection period were significant in every case at the $P = 0.05$ level as well. It is thus established that the differences between excretion curves found both here and previously (1) reflect differences in the amount of test drug absorbed.

[3] No attempt was made to distinguish between adsorbing and nonadsorbing solids in the antidiarrhea mixture. It is likely that only a portion of the total solids present after evaporating the mixture to dryness possess adsorbent power.

The decision to perform the experiments in replicate with one subject rather than by using a test panel of different subjects was based on several factors. Between subjects variability with respect to elimination of the test drug is quite high (1). This reduces the sensitivity of the experiment with respect to its ability to detect adsorbent effects. Replicate experiments in one individual should be subject to less variability. The data show that even with one subject, variability is high but it is not so great as was obtained previously (1). Data in the literature (9–12) point out the importance of urine flow rate and urine pH to the excretion rate of various amines. It was not considered to be desirable to attempt to control urine pH since this would involve administration of materials which might alter the local environment within the gastrointestinal tract at the time of administering the test dose. It was thought that by using a single test subject, patterns of diet and fluid intake would be less varied and would result in a more constant influence of urine pH and flow rate on promazine excretion. The difficulty of securing cooperation of test subjects in an experiment where many samples are collected and several tests are to be performed was another factor behind use of a single test subject. Others have also employed a single test subject in cases where precise and careful subject cooperation was required (13).

Of course it may be argued that the responses of one individual cannot be extrapolated to the general population of subjects. This would certainly be true in many cases and indeed one must proceed with caution in interpreting the results of this experiment. In this case, however, the human subject is used to provide a suitable environment to study uptake and release of the test drug from the adsorbent material. A more precise estimation of these effects may be obtained where the data are not subject to the additional variables arising from differences in the way individuals metabolize and excrete the drug once it is absorbed. In a sense the human subject provides an experimental instrument which no *in vitro* apparatus can be made sufficiently refined to do, *viz.*, to provide a system containing all of the variables usually met within the human gastrointestinal tract. It is also necessary to study the adsorption phenomenon where it is subject to the influence of the dynamic situation which is provided by constant removal of drug from solution in the gut through absorption. Obviously, there will be quantitative differences in the magnitude of adsorbent effects between different individuals. Between subject differences with respect to gastric and intestinal pH, gastrointestinal motility, ionic content of the gastrointestinal fluids, presence of food, the adsorbent dose, and even the disease state may all alter the magnitude of the adsorbent effect in a given individual. It is considered, however, that the results of this experiment amply demonstrate the potential effect of an adsorbent on drug absorption. In showing that this potential exists, the results should be applicable to the general population of subjects.

SUMMARY

It is apparent, on the basis of evidence presented, that the presence of the antidiarrhea mixture within the gastrointestinal tract is sufficient to retard absorption of the model amine drug. While availability was retarded in this case, the results still compare qualitatively with those obtained previously (1) for attapulgite-promazine adsorbates. Considering the overwhelming excess of adsorbent present, and its affinity for the drug *in vitro*, the degree of interference with absorption is more remarkable for the fact that it does not occur to a greater extent rather than for the fact that it does occur. It has already been shown *in vitro* (1) that desorption is facilitated in acidic media. It was also found for other clay-type adsorbents (14) that acidic media retard adsorption of various phenothiazine derivatives. In the gastrointestinal tract, therefore, the affinity between drug and the antidiarrhea mixture may be considerably less than found *in vitro*.

The results of this study have important clinical implications. While it has not been established whether adsorbent effects determined here and previously (1) are applicable to other amine-type drugs, it is probably true that effects would be similar for amines of similar basicity and adsorbability *in vivo*. If this is the case, a potential exists for interference with the absorption of many drugs when the gastrointestinal tract is "loaded" with an antidiarrhea mixture. In view of the somewhat questionable merits of these preparations as adjuncts to controlling diarrhea (15), their use in a given situation should be carefully weighed against potential harmful effects on the absorption of certain more therapeutically important drugs which the subject might be taking concurrently.

Further studies now in progress should provide more information concerning the general applicability of these results to other amine-type drugs. Also in progress are studies aimed at establishing correlations between *in vitro* adsorption studies and *in vivo* effects of adsorbents on drug absorption.

Microcrystalline Cellulose in Tableting

By GEORGE E. REIER* and RALPH F. SHANGRAW

The development of microcrystalline cellulose has made available to the pharmaceutical industry an extremely valuable tableting agent. It was found that tablets of plain microcrystalline cellulose will tend to soften and swell when exposed to humid conditions, but the effect is reversed upon the removal of increased humidities. Elevated temperatures have no effect on these tablets. Microcrystalline cellulose tablets will disintegrate very slowly in solvents of a relatively low polarity. It is postulated that tablets of this material are a special form of cellulose fibril in which the individual crystallites are held together largely by hydrogen bonding. Tablet disintegration is merely the breaking of the intercrystallite bonds by the disintegrating medium. No significant separation of components was found during the compression of a microcrystalline cellulose-containing formulation. The release of amphetamine sulfate and sodium phenobarbital from tablets containing microcrystalline cellulose is excellent. Determinations after 10 weeks at various environments indicate that no release problems exist. When the cellulosic compound was used as a dry binder–disintegrator in the direct compression of formulations of ephedrine hydrochloride, quinine sulfate, and a low melting steroid, tablets of outstanding quality were produced.

THE SUCCESSFUL application of direct compression as a tableting procedure is dependent upon the development of suitable materials which in themselves are both highly fluid and cohesive. Spray-dried lactose exhibits these characteristics and has enjoyed considerable success as a tableting agent in direct compression. However, it has the disadvantage of browning under certain conditions (1–3) and there is a limiting hardness to tablets produced from spray-dried lactose which, if exceeded, results in capping. This pressure sensitivity occurs at lower tablet hardnesses than usually encountered with granulations of conventional lactose.

studies of disintegrants in direct compression systems (9, 10).

There can be no doubt that microcrystalline cellulose is a unique material and a more detailed study of the following appeared warranted: (*a*) the effect of elevated temperature and humidity on plain microcrystalline cellulose tablets; (*b*) the disintegration time in media of varying polarities of plain microcrystalline cellulose tablets; (*c*) the extent of hopper segregation occurring during tableting; (*d*) the extent of irreversible adsorption of drugs of different ionic character onto microcrystalline cellulose; and (*e*) the further investigation of microcrystalline cellulose as a dry binder.

EXPERIMENTAL

Throughout the investigation, tablets were evaluated with respect to weight, hardness, disintegration time, and friability. All hardnesses were measured by means of a hand operated Strong Cobb hardness tester. Disintegration times were determined by means of the U.S.P. disintegration apparatus, utilizing distilled water at 25° as the immersion fluid.

TABLE II.—THE EFFECT OF PROGRESSIVE CHANGES IN CONDITIONS ON WEIGHT AND HARDNESS OF PLAIN MICROCRYSTALLINE CELLULOSE TABLETS

4	60° C.	0.141	10.7
6	Ambient conditions[b]	0.146	11.6
8	60° C.	0.143	12.3
10	75% R. H.	0.151	8.0
12	Ambient conditions[b]	0.147	11.5

[a] Strong Cobb units. [b] Ambient conditions are approximately 25° and 40% relative humidity.

Effects of Temperature and Humidity.—A study of variations in hardness and weight caused by environment was conducted on tablets compressed to a constant thickness by means of a hand operated single punch Erweka tablet machine using $^{5}/_{16}$-in. dies and flat-faced punches. In order to vary hardness while keeping thickness constant, it was necessary to change the die fill and, consequently, the average tablet weight between batches. The tablets were stored at a high relative humidity (75%) or high temperature (60°) for 1 week and changes in weight, hardness, and thickness noted. These results can be seen in Table I. Tablets were also cycled through temperature and humidity changes. These results are summarized in Table II.

Influence of the Polarity of the Disintegration Medium on Tablet Disintegration.—Flat-faced $^{5}/_{16}$-in. plain microcrystalline cellulose tablets having an average weight of 0.15 Gm. and hardness of 6 were produced on a hand operated press. The effect of the polarity of the disintegration medium on the disintegration of these tablets was studied by determining the time for disintegration in media of different dielectric constants. One tube from the U.S.P. basket rack assembly was suspended in a 250-ml. graduated beaker containing the disintegration medium at room temperature. The tube was raised and lowered according to U.S.P. specifications but disks were not used. Table III shows the results of this study.

Determination of Component Separation During Compression.—A formula containing 30% red spray-dried lactose was chosen since it was thought that spherically shaped particles in such an amount could easily "settle through" the microcrystalline cellulose when the powder blend was subjected to vibration. The colored material was utilized so that the degree of separation could be estimated by extraction of the dye from the tablet. Amphetamine sulfate was also included in a concentration such that each tablet of the mixture would contain

[a] Percentage strengths refer to aqueous solutions (v/v). [b] Reported in "Handbook of Chemistry and Physics," 39th ed., Chemical Rubber Publishing Co., Cleveland, Ohio, 1957, pp. 2331–2335. [c] Tablet softened, lateral cracks observed but no flaking off. [d] Some flaking occurred, tablet soft but not disintegrated. [e] A few small pieces flaked off.

5 mg. No lubricant was necessary in the compression of the formulation. The total composition was:

Amphetamine sulfate.....	75 Gm. (1.7%)
Red spray-dried lactose.....1350 Gm.	(30.0%)
Microcrystalline cellulose...3075 Gm.	(68.3%)

Tablets were produced on a Colton model 216 rotary press fitted with $^{7}/_{16}$-in. standard concave punches. Die fill and pressure were adjusted at the beginning of the run to produce tablets of about 300 mg. in weight and 6–7 Strong Cobb units in hardness. Three different machine speeds were used during the course of the study: 600, 860, and 1120 tablets/min.

Tablet samples were taken at intervals that varied with the speed of the machine. These tablets were assayed by a spectrophotographic method which allowed for the separate determination of amphetamine sulfate and red spray-dried lactose. The means of the assay results for each sample were calculated, and the per cent deviations of the sample means from the over-all mean are shown in Table IV. The disintegration times of all tablet samples were less than 30 sec. while friability ran from 0.1–0.25% weight lost.

Amphetamine Sulfate and Sodium Phenobarbital Release from Tablets of Microcrystalline Cellulose.—Since the acidity or basicity of the therapeutic agent must be taken into account, an ionic drug from each category was included in this study. The tablets were placed at three storage stations. The determination of drug release was carried out by placing the tablets, previously weighed, into 1-oz. dry square bottles and adding 25 ml. of distilled water prewarmed to 37°. The bottle and contents were placed in a 37° water bath and rotated end-over-end at 20 r.p.m. At the end of the desired time, the mixture was quickly filtered, and a sample collected for further dilution and spectrophotometric assay. The tablets were compressed using flat-faced $^{13}/_{32}$-in. tooling and the mg. per tablet formulas were as follows:

Amphetamine sulfate	15.0	...
Sodium phenobarbital	...	15.0
Spray-dried lactose	75.0	75.0
Microcrystalline cellulose	158.8	157.5
Magnesium stearate	1.2	2.5

The results of this experiment are shown in Tables V and VI.

Microcrystalline Cellulose as a Dry Binder–Disintegrator.—Ephedrine hydrochloride and quinine sulfate have long posed problems in regard to disintegration and until recently were allowed to possess unusually long disintegration times (11). For this reason, these materials were chosen for use in further evaluating the binding and disintegration properties of microcrystalline cellulose in direct compression.

An androstane-type steroid (under clinical investigation by the National Institutes of Health) was also included in this part of the work. The steroid melts at 60° and liquefies under pressure, thus microcrystalline cellulose was utilized as an adsorbent as well as a dry binder–disintegrator in order that tablets of a uniform surface appearance might be produced by direct compression.

In all cases it was necessary to slug the powder blend. The slugs were passed through a No. 16 screen and additional lubricant added before recompression on a rotary tablet machine. The mg. per tablet formulas were as follows:

Ephedrine Tablet	
Ephedrine hydrochloride.....	30.0
Spray-dried lactose.....	37.5
Microcrystalline cellulose.....	112.5
Calcium sulfate.....	187.5
Magnesium stearate.....	7.5

Magnesium stearate	12.5

Attempted recompression of the steroid product resulted in considerable "picking." However, freezing of the granulation by placing it in a container with dry ice for a short period of time immediately prior to compression eliminated this difficulty. The success of this procedure would suggest that further studies should be conducted on the effect of low temperatures on compaction. The characteristics of the tablets produced in this study are shown in Table VII.

DISCUSSION

Mechanism of Compaction and Disintegration.—As may be seen from Table I, plain microcrystalline cellulose tablets after storage at 75% relative humidity for 1 week exhibit an increase in weight and a decrease in hardness. The latter result is consistent with that noted in an earlier report (6). In addition, tablet thickness appears to increase. The mean thicknesses of the group before and after exposure to increased humidity were tested by means of Student t test (12). While the changes in thickness appear quite large, they are not statistically significant at the 95% confidence level. This lack of significance can be attributed to the relatively high variance found in the group. However, the consistent increase in thickness for the batches studied certainly is indicative of a swelling effect. Similar tablets stored at 60° for 1 week exhibit a uniform weight loss but no change in thickness. A slight decrease in hardness may be noted, but it was not large enough to even consider a test for significance.

The changes in plain microcrystalline cellulose tablets brought about by storage in various environmental conditions are not permanent as evidenced by the data in Table II. Loss of hardness of microcrystalline cellulose tablets at increased humidities may be explained by the adsorption of water onto the surfaces of the cellulose crystals. The adsorbed water molecules interrupt the bonding between particles thus causing a softening of the tablet and a tendency to swell. When humid conditions are removed, the equilibrium moisture content is lowered in the tablet, and it resumes its original hardness and thickness. At elevated temperatures, there is a slight weight loss due to the driving off of water, but this appears to have no appreciable effect on hardness.

As the mechanism of disintegration of microcrystalline cellulose tablets has been attributed to hydrogen bonding and its interruption (6), a study of disintegration times in media of variable polarities should and did give interesting results. Table III shows the variation of tablet disintegration time with the dielectric constant of the disintegrating medium. The dielectric constant is a measure of a solvent's polarity or ability to form dipoles and is,

consequently, a measure of a compound's ability to hydrogen bond, since this phenomenon is a particular kind of dipole–dipole interaction. As the dielectric constant decreases, the medium becomes less able to hydrogen bond with the individual crystals of cellulose. The result is that the crystals remain bonded to each other and tablet disintegration does not occur.

Because of the extreme ease of compression of microcrystalline cellulose into hard tablets, apparently very little elastic deformation occurs within the microcrystals during tablet formation (13). In fact, it is even doubtful that significant amounts of plastic slip and crystal fusion take place. Undoubtedly, a much more important factor contributing to the compaction of this material is hydrogen bonding. A microcrystalline cellulose tablet may be visualized as a special form of cellulose fibril in which the crystals are compacted close enough together so that hydrogen bonding between them can occur.

Problems in Tableting.—Due to the small particle size of microcrystalline cellulose as well as its fluidity, hesitancy to assume a charge, and lack of aggregation, blending with other substances does not appear to offer difficulty. While one might expect these mixtures to separate when subjected to vibration, the results in Table IV do not so indicate even though the formulation studied was designed to point up segregation. The initial high reading for spray-dried lactose in the first sample can be ascribed to a small quantity of the higher density lactose separating from the mixture during the period of free fall when the hopper was loaded. The effect rapidly disappeared and deviation from the average appears relatively random until the end of the experiment where some increase in drug concentration did occur. However, none of the variations found can be considered serious.

Because of the large surface area of microcrystalline cellulose and its adsorptive capacity (5), tablets composed largely of this material might not exhibit complete release of the therapeutic agent contained therein. The data in Tables V and VI show the effects of various environmental conditions on the release of amphetamine sulfate and sodium phenobarbital from tablets containing microcrystalline cellulose and spray-dried lactose as the fillers. Immediately following manufacture, full drug release was achieved within 3 min. After 10 weeks storage at 75% relative humidity and room temperature, the release of the amphetamine sulfate product was slightly decreased. However, the full amount of drug was available after 30 min. No slowing of release was found at the other storage stations.

In the case of the sodium phenobarbital tablets, the same slight decrease in drug release was found in those tablets stored at 75% relative humidity and room temperature as well as at 60° and ambient humidity. Those tablets stored under ambient conditions showed a considerably greater reduction in the amount of drug released within 3 min. However, all sodium phenobarbital tablets exhibited complete drug release at the end of 30 min. thus indicating no drug–binder interaction.

While the usefulness of microcrystalline cellulose as a dry binder-disintegrator has previously been reported (6), the results in Table VII serve to emphasize the uniqueness of the material when used in such a manner. The properties of the ephedrine hydrochloride and quinine sulfate products illustrate the outstanding tablet quality routinely available through the use of microcrystalline cellulose as a dry binder–disintegrator. It would certainly appear that microcrystalline cellulose should be given serious consideration by tablet formulators as a dry binder, particularly in direct compression.

SUMMARY AND CONCLUSIONS

1. It was found that increased humidities caused a softening and a tendency to swell of plain microcrystalline cellulose tablets. Neither tablet change is permanent since they disappear upon removal of the humid conditions. Elevated temperatures do not affect tablets of this material.

2. The disintegration time of such tablets is markedly influenced by the polarity of the disintegrating medium. From the environment and disintegration observations, it was postulated that a plain microcrystalline cellulose tablet is a special form of cellulose fibril which is held together largely by hydrogen bonding.

3. Hopper segregation was studied. The results of the experiment indicate that no significant separation need be anticipated.

4. Amphetamine sulfate and sodium phenobarbital tablets prepared utilizing a blending of spray-dried lactose and microcrystalline cellulose as a filler exhibited no problems in respect to dissolution of active ingredients.

5. The characteristics of tablets produced with microcrystalline cellulose as a dry binder–disintegrator were outstanding.

Effect of Physical Activity on the Absorption Rates of Procaine Penicillin G Implants

By BERTON E. BALLARD

The pellet implantation technique was used to estimate quantitatively the effect of rat body movement on solid drug absorption rate. Animals placed in a rodent activity cage and rotated at 2.81 and 3.83 r.p.m. showed significantly greater mean absorption rates per mean area for procaine penicillin G pellets than nonrotated controls.

To DATE no study has appeared in the literature which shows the possible quantitative relationship that may exist between drug pellet absorption rate and degree of animal physical activity (1). Such a study would have theoretical as well as practical significance, because the intensity of the pharmacological, toxicological, and therapeutic response to an implanted solid drug may be directly related to the magnitude of the absorption rate of the drug.

MATERIAL AND METHODS

Implants.—Commercially available procaine penicillin G was the model drug used in these studies. After it was recrystallized from water and dried in a desiccator for 48 or more hr., it was compressed at 2.81×10^3 Kg./cm.^{2} on a Carver laboratory press designed to allow use of standard tableting machine punches and dies. The mean diameter of the disks was 0.639 cm. and their mean initial weight was 66.9 mg. (range 51.8 to 86.9 mg.). The mean apparent density of the disks was 1.167 Gm./cm.^{3}. No binders, excipients, diluents, or lubricants were added.

Implantation.—Female Sprague-Dawley rats having a mean weight of 228 Gm. (range 182 to 298 Gm.) were used in these tests. Animal weight was not rigidly controlled, because it was obvious by inspection that no correlation could be found between disk absorption rate and animal weight for any given rotational velocity. The animals were anesthetized with ethyl ether, and a ventral midline incision of about 1-cm. length was made in the abdominal skin in an anatomical region that has been defined before (2). The subcutaneous connective tissue lateral to the incision was teased apart to provide sites for the implantation of 2 preweighed disks, one to either side of the midline incision. The incision was sutured closed following the implantation of the disks. After the "rest" and exercise periods, the animals were reanesthetized and the implants removed. The disks were briefly washed with distilled water and placed to air dry for 24 hr. or more on pieces of filter paper. The disks were reweighed and the mean absorption rate per mean area, $\bar{R}/\bar{A}$, was calculated by methods previously described (3), except that no correction for the proteinaceous "ghost" weight was made, because of the short implantation times used.

Activity.—After implantation of the 2 disks, the animals were allowed to recover ("rest") from effects of anesthesia in their cages for about 2 hr. They then were placed in a rodent activity cage[1] for varying periods of time, depending in part upon the rotational velocity of the cage. The cage has a circumference of 1.13 M., and was rotated at a constant angular velocity by means of a dual shaft electronic controlled mixer[2] fitted with a small pulley having an outside diameter of 2.1 cm. A piece of laboratory rubber tubing about 140 cm. long and 8 mm. in outside diameter with the ends stapled together was wound around part of the circumferences of the pulley and cage. The revolutions per minute (r.p.m.) shown in Table I were read at the end of each exercise period from a counter attached to the wheel.

Calculation.—Because periods of rest (r) and exercise (e) varied from animal to animal and from one rotational velocity to another, Eq. 1 was used to account for these variables.

$$(\bar{R}/\bar{A})_e = \frac{[(\bar{R}/\bar{A})_t \cdot T_t] - [(\bar{R}/\bar{A})_r \cdot T_r]}{T_e} \quad \text{(Eq. 1)}$$

where $(\bar{R}/\bar{A})_e$ is the mean absorption rate per mean area attributed to the exercise period in the activity cage; $(\bar{R}/\bar{A})_t$ is the mean absorption rate per mean area for the total implantation time, T_t; the term $(\bar{R}/\bar{A})_r$ is the mean absorption rate per mean area for the rest period; T_r is the total time an implanted animal was "resting" or outside the activity cage and is the sum of the times after implantation and before exercise and after exercise up to the time of implant removal; and T_e is the time that the implanted animal was "exercising" in the activity cage.

3.83 (7)	2.00	3.26	519	2.57 (0.03)	$0.001 < p < 0.005$

[a] Weighted mean revolutions of activity cage per minute. Number of animals is in parentheses. [b] Mean time for exercise in activity case. [c] Mean time an implanted animal was "resting" or outside the activity cage. [d] Mean absorption rate per mean area attributed to the exercise period in the activity cage as calculated by Eq. 1. The value for zero r.p.m., included for comparison purposes, is actually $(\bar{R}/A)_r$. The 95% confidence limits appear in parentheses. [e] The p value from the 2-tail t test when comparing the mean absorption rate per mean area for zero r.p.m. with rates at another r.p.m. The values at 1.04 and 2.05 r.p.m. should be considered as not significant.

RESULTS AND DISCUSSION

The results of this experiment summarized in Table I showed that when the animals' activity was substantially increased over normal values there was also a significant increase in the magnitude of the mean disk absorption rate per mean area. The present findings tend to substantiate the unverified suggestion made by Kearns (4) that the absorption rate of an implanted pellet (a steroid) could be increased if the patient would massage daily the skin area over the drug.

The results also show that the degree of dispersion about the mean values of $\bar{R}/\bar{A}$ (as reflected by the 95% confidence limits) is much broader for the animals "resting" than it is for those moving at a constant velocity on the activity wheel. The broader dispersion seen in the mean values for the "resting" animals might be expected because there was a wide variation in the intensity of body movement brought on by the use of ether as the anesthetic.

Some clinicians (5, 6) have studied the correlation between physical activity and the magnitude and duration of penicillin serum levels following an intramuscular injection of procaine or benzathine penicillin G. Elevations in penicillin serum levels observed by these investigators after vigorous exercise could be explained by the results of this experiment. If human physical activity increased the dissolution rate of the depot penicillin salt crystals, then elevations in the drug serum level should logically follow, assuming that drug elimination mechanisms remained unchanged before and after exercise.

Cholinesterase Activity and Sulfonamide Absorption in Rats

By VERNON A. GREEN, THOMAS M. GLENN, SAMUEL J. STRADA, and GONZALO MEDINA

Rats administered, orally, a combination of neostigmine methylsulfate and sulfonamide showed an increased 4-hr. blood sulfonamide level as compared to animals administered only sulfonamide. Blood cholinesterase activity, 4 hr. after treatment, was determined and compared with that of control animals.

OVER A half-century ago Barbour and Abel (1) found that physostigmine increased the rate of diffusion of acid fuchsin in frogs. Lewis (2), in 1916, reported the same to be true for trypan red in dogs. Twenty-two years later Cole and Curtis (3) showed that acetylcholine increased the permeability of the marine organism *Nitella*. In the last decade there have been reports of the potentiation of the action of morphine in cats (4), streptomycin in rats (5), and barbital in mice (6) by pretreating with cholinesterase inhibitors. Other reported changes in drug activity brought about by anticholinesterases include the potentiation of the anesthetic activity of a given dose of phenobarbital and pentothal (7) and a lengthening of the duration of the anesthesia.

The increased permeability of *Nitella* in the presence of acetylcholine and the like phenomena seen in *P. vulgarus*, *S. typhosa*, and *P. aeruginosa* with

eserine (8) would indicate a possible relationship between cholinesterase or acetylcholine and membrane permeability in these species.

Cholinesterase and acetylcholine are found throughout the body of higher animals. Alteration of either could affect the tissue permeability which would influence drug absorption. Neostigmine methylsulfate-induced increases of absorption of sulfisoxazole from everted sacs of guinea pig ileum (9) are indicative of the above.

In this work the *in vivo* absorption of sulfonamides in the presence of an anticholinesterase was studied and a comparison made with the sulfonamide absorption in animals with sulfonamide alone. Blood cholinesterase activity was determined 4 hr. after treatment to ascertain the anticholinesterase activity of the neostigmine methylsulfate.

EXPERIMENTAL

Cholinesterase Depression.—In order to correlate any change in sulfonamide absorption with the depression of the esterase, the activity of the enzyme was determined in untreated rats and rats receiving 6 mcg./Kg. of neostigmine methylsulfate 4 hr. prior to withdrawal of blood sample. Blood was removed by cardiac puncture; the enzyme determination was made immediately and expressed in units.[1] The depression was determined to be approximately 20% as shown in Table I.

Sulfonamide Determination.—Sulfacetamide, sulfanilamide, and sulfaguanidine were administered, 400 mg./Kg. orally, to randomly sexed Sprague-Dawley rats weighing 225–275 Gm. Twenty animals were used in each group. A similar number of animals was used for the same sulfonamides administered at the same dose but in combination with 6 mcg./Kg. of neostigmine methylsulfate.

Four hours after the administration of the sulfonamide, 2 ml. of blood to be used for the total sulfonamide determination was removed by cardiac puncture. Samples that clotted before being mixed with the buffer or that may have been diluted with tissue fluid were discarded.

The method used to determine the sulfonamide concentration was the colorimetric method for measuring free and total sulfonamides in tissue used by Bratton and Marshall (10).

Neostigmine methylsulfate increased the blood levels with all three sulfonamides. (Table II.)

DISCUSSION

From the data obtained in this study, it appears that neostigmine methylsulfate increased the absorption of the sulfonamides from the gastrointestinal tract. The observed increase in blood sulfonamide is in agreement with that reported earlier for sulfisoxazole in guinea pigs (9).

It appears probable that the inhibition of cholinesterase, by some mechanism, alters the permeability of the intestinal tract to allow for greater absorption of the drug. It is possible that the anticholinesterase by some combination with the enzyme as a part of cell membrane may change the characteristics of the membrane to allow for greater permeability. Furthermore, it may be that the acetylcholine accumulates in sufficient quantities to change the permeability as it does in *Nitella*. If vasodilation due to the accumulation of acetylcholine is the basic factor in the increased permeability, it should be blocked by atropine. The failure of atropine to block this phenomenon has been shown earlier by Green (7). It appears that cholinesterase–inhibitor combination is the most likely explanation for the observed increases in absorption.

SUMMARY

In this study, rats receiving neostigmine–sulfonamide combinations, orally, showed higher blood levels of the sulfonamides than animals receiving sulfonamide alone. The neostigmine methylsulfate-treated animals showed a 20% depression of blood cholinesterase activity.

Numerous drug agents have anticholinesterase activity. If esterase activity affects absorption, increased absorption of the inhibitor-drug or other drugs used in combination could be a factor in creating undesirable responses. The investigators feel that these findings warrant further investigation.

[1] A unit of cholinesterase, as used in this study, is defined as the number of milliliters of 0.1 *M* acetic acid derived from 3 ml. of 0.1 *M* acetylcholine bromide solution by the cholinesterase activity in 1 ml. of blood at pH 8.

Repeated Test of Mice in the Photocell Activity Cage After Different Time Intervals

By NATHAN WATZMAN, HERBERT BARRY, III, WILLIAM J. KINNARD, JR., and JOSEPH P. BUCKLEY

A total of 384 mice, given 2-hr. tests twice in the photocell activity cage under the same conditions, showed lower activity scores (with square root transformation) in the second test. This behavioral carry-over effect was greater for subgroups given the second test at an interval of 1 or 3, instead of 7 or 14 days, after the first. Chlorpromazine produced a greater decrement in activity in the first 0.5 hr. of the second test than of the first. In both tests, aggregations of five, rather than single animals, showed a greater drug decrement in the first hour and some recovery from the drug effect in the last 0.5 hr. The most stable data were obtained in the first 0.5 hr. A high correlation between tests, especially with a 1-day interval, indicated that a repeated-test design can provide a sensitive measure of drug effects.

IT IS HIGHLY desirable to give repeated tests to the same animals when evaluating the effects of psychotropic agents on behavior. Not only is it an economic advantage, but a more sensitive test is obtained, because the consistency of individual performances usually found in repeated tests means a small variation in scores against which the effects of drugs can be measured.

The disadvantage of repeated tests on the same animals is that both drug and behavioral carry-over effects may occur from one test to the next, especially when there is a short time interval between sessions. In order to assess this disadvantage, it is necessary to measure the degree of this carry-over effect at different intersession intervals, with the experimental conditions held constant in both sessions. This was the purpose of the study reported in the present paper.

The photocell activity cage, which has been used extensively to study the depressant properties of chlorpromazine (1–3), was used as the test apparatus.

METHOD

Subjects.—The subjects were 384 male, Swiss-Webster mice (Taconic Farms, N. Y.) weighing approximately 18–20 Gm. Housing and testing were in separate rooms, both with the temperature controlled between 73 and 75°F. Food and water were available *ad libitum*.

Apparatus.—The experimental work was performed in four 6-beam photocell activity cages, circular in shape (Actophotometers, Metro Industries, Inc.). The electronic circuits of each cage are designed so that a single digital counter (General Controls, Des Plaines, Ill.) is activated whenever an animal blocks, or moves through any beam, regardless of whether any of the other beams are interrupted. Therefore, an animal continuously blocking a single beam could not preclude the registration of counts emanating from the other beams. The experimental room was sound attenuated, and was effectively shielded from the noise of the counters which were placed in an adjoining room.

Experimental Design.—Each animal, or group of animals, was tested in 2 sessions, both 2 hr. in duration. Several experimental conditions were varied in a complete factorial design, so that all levels of each variable were equally represented as follows.

Intersession Interval.—1, 3, 7, and 14 days.

Drug Condition.—Chlorpromazine (4 mg./Kg.) or placebo (saline, 0.1 ml./10 Gm. body weight), given orally 30 min. before the start of the session. Each animal was assigned to the same condition (drug or placebo) in both tests.

Test Aggregation.—Singly, or in groups of five mice. They were housed during the intersession interval under the same aggregation conditions as during testing.

Different Units.—Four activity cages operated simultaneously.

Replication.—The complete design was repeated once.

This experimental design resulted in 128 different combinations of conditions, divided equally between single animals and groups of five.

Statistical Treatment of Data.—Normalization of skewed frequency distributions by means of data transformation is an acceptable statistical technique in research. Extremely high raw scores are likely to lead to a misinterpretation of relative magnitudes, if they are farther from the median values than the lowest scores. Logarithmic, or square root, transformation of data may provide a nonskewed, normal distribution of scores by reducing the magnitude of the high scores more than the low ones. The parametric tests of statistical significance, including the analysis of variance, depend on the assumption that the frequency distribution of scores is nonskewed.

A comparison of the raw, square root, and logarithmic forms of these experimental data indicated that the raw scores were skewed in a positive direction, with the extreme high scores being much farther from the median than were the extreme low scores, whereas the logarithmic scores were skewed in the opposite, negative direction. The square root scores were skewed to the least degree (positive direction), especially in the first hour of the 2-hr. session. Also, activity appeared to be the most consistent and correlations between the two sessions highest for the scores in square root form. Irwin (4) has used square root transformation of data on locomotor activity in the treadwheel.

Received January 10, 1966, from the Department of Pharmacology, School of Pharmacy, University of Pittsburgh, Pittsburgh, Pa.

Accepted for publication January 28, 1966.

This investigation was supported by grant MH-06540 from the National Institute of Mental Health, U. S. Public Health Service, Bethesda, Md.

The computer analysis was done at the University of Pittsburgh Computation and Data Processing Center, supported by grant G-11309 from the National Science Foundation, Washington, D. C.

Mr. Jerome V. Lisovich provided the programing of the data analysis for the IBM 7090 computer.

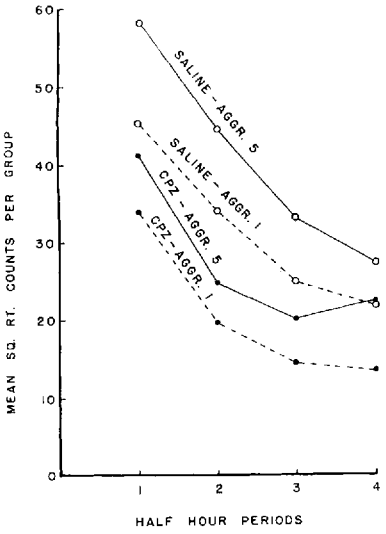

Fig. 1.—The effects of chlorpromazine and aggregation on the spontaneous activity of mice.

In the present study, the number of counts for each 0.5 hr., hour, and the 2-hr. total in both sessions were punched on IBM cards, converted to square root scores by the IBM 7090 computer, and tested for statistical significance by the BMD 02V analysis of variance program on the same computer. Each fixed factor (drug, aggregation, intersession interval) was tested for statistical significance in relation to the pooled interactions, which included the interaction of the randomly selected variables (test units with replication) and either or both variables with one or more of the fixed variables (5). Since each animal was tested in both sessions, the pooled interaction term for testing the difference between the sessions, and interactions of any other variables with sessions, included the session variable. Correlations between the first and second session for all the animals, and for each level of the selected variables, were computed by the BMD 03D program. Stability of performance within the same session was computed according to the split-half method (6), for 0.5-hr. intervals, utilizing a specialized program written for the IBM 7090 computer. This method correlates the performance of an animal, or aggregation of animals, in the even-time segments (second and fourth 0.5-hr. periods) with the scores recorded in the odd-time segments (first and third 0.5-hr. periods). The test of statistical significance for the difference between correlation coefficients was that described by Edwards (7).

RESULTS

Figure 1 shows the effects of two variables (drug and aggregation) on activity in each 0.5-hr. period, with scores for the other experimental variables averaged together. In the first 0.5 hr., there was a highly significant difference between the chlorpromazine and saline conditions ($F = 174$, $df = 1,117$, $p < 0.01$) and between animals tested singly and in groups of five ($F = 90$, $df = 1,117$, $p < 0.01$). There was also a significant interaction between drug and aggregation, indicating that chlorpromazine had a greater effect on the activity of aggregated than single mice for the first 0.5 hr. ($F = 5.76$, $df = 1,117$, $p < 0.05$). This interaction was also significant for the second 0.5 hr. ($F = 5.31$, $df = 1,117$, $p < 0.05$), but not for the last two 0.5-hr. periods. These findings confirm results reported previously by Watzman *et al.* (2), utilizing raw scores.

In the last 0.5 hr. of the session, the animals tested in groups of five showed some recovery from the depressant effects of the drug. Out of 32 groups of aggregated animals under chlorpromazine, 25 showed higher activity in the fourth than in the third 0.5 hr., and only seven groups were lower. This recovery from the depressant effects of the drug was statistically significant ($\chi^2 = 9.0$, $df = 1$, $p < 0.01$) and is in contrast with the lower activity in the fourth than third 0.5-hr. period found with each of the other three conditions shown in Fig. 1. In general, all of these experimental effects decreased in statistical significance in the later 0.5-hr. periods, due to a decrease in stability of the scores. However, the difference between animals tested singly and in groups of five continued to be highly significant, even in the last 0.5-hr. period ($F = 25$, $df = 1,117$, $p < 0.01$).

The replication showed no consistently significant difference from the original experiment. There was a significant difference among the four test units ($F = 9$, $df = 3,117$, $p < 0.01$) for the entire 2 hr., but no consistently significant interaction between this variable and any of the others.

The main subject of interest in the present experiment is the comparison between the first and second test session, shown in Fig. 2. The activity counts were preponderantly lower in the second session ($F = 48$, $df = 1,112$, $p < 0.01$ for the total 2 hr.). This decrement in second-session performance was greater for the groups tested at shorter time intervals (1 and 3 days). This difference, generally, persisted throughout the second session, but was statistically significant for the first 0.5 hr. only, measured by the interaction of sessions with the four intervals ($F = 3.06$, $df = 3,112$, $p < 0.05$). When the test for linearity of the scores is applied, with the assumption that the 1, 3, 7, and 14-day intervals represent a progressive function, the interaction between tests and intervals is statistically significant

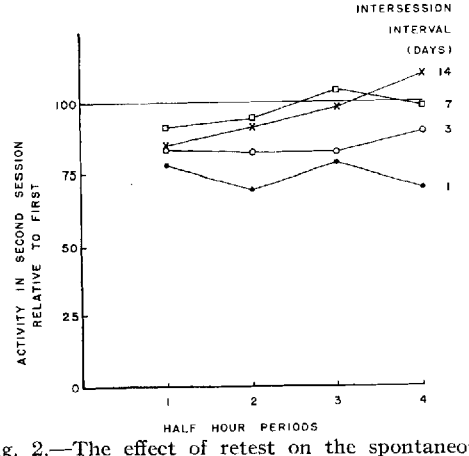

Fig. 2.—The effect of retest on the spontaneous activity of mice at 1, 3, 7, and 14-day intervals.

($p < 0.05$) in each of the 0.5-hr. periods, except the third ($F = 4.6$, 6.0, 3.7, and 6.5, respectively, $df = 1,112$).

In the first 0.5 hr., chlorpromazine produced a 23% decrement in activity in the first session and a 32% decrement in the second session. This difference was statistically significant, as indicated by the interaction between sessions and drug conditions ($F = 4.68$, $df = 1,112$, $p < 0.05$). This difference was approximately equal for the groups given the two tests at different intervals ($F < 1$ for the three-way interaction among drug conditions, sessions, and intervals). In the last three 0.5-hr. periods, the drug-induced decrement in activity was approximately equal in the two sessions, as indicated by the absence of any significant interaction between sessions and drug conditions. The other variables did not interact significantly with the two sessions, and therefore showed similar patterns in both tests.

There was a high degree of stability of performance within each session, with the split-half correlation being 0.75 for session *1* and 0.74 for session *2*. The over-all correlation between the two sessions, pooling all of the other parameters together, was 0.74 for the total 2 hr. As would be expected, the correlation between sessions was greater for the shorter intersession intervals, with the stability scores for the total 2 hr. being 0.84, 0.78, 0.80, and 0.61, respectively, for the groups given the second session 1, 3, 7, and 14 days after the first. The correlation between sessions was highest in the first 0.5 hr. of the session (0.73) and lowest in the fourth 0.5 hr. (0.35), and this difference was statistically significant at the 1% level. For the total 2 hr., this stability score showed little difference between saline (0.62) and drug treatment (0.57), but in the first 0.5 hr., the saline scores were significantly more stable, with correlations between the sessions of 0.68 for saline and 0.46 for chlorpromazine ($p < 0.05$). In the first 0.5 hr., the correlation between sessions was higher for the animals tested in groups of five (0.74) than those tested singly (0.60), but this difference was not statistically significant.

DISCUSSION

The present experiment clearly shows a behavioral carry-over effect from one session to the next for both saline and chlorpromazine animals. After an interval of 1 or 3 days between tests, activity in the second session was substantially lower than in the first, in all four 0.5-hr. periods. Even at the 7 and 14-day intervals, the recovery of the original activity level was not complete, as shown by significantly lower activity in the first 0.5 hr. for these two groups pooled together ($F = 20$, $df = 156$, $p < 0.01$.)

The dosage of chlorpromazine used (4 mg./Kg., orally) greatly decreased the activity of mice under all the experimental conditions tested. However, the magnitude of this drug effect was somewhat altered by certain experimental conditions. The greater decrement produced by chlorpromazine in the first two 0.5-hr. periods, for animals tested in groups of five rather than singly, confirms findings previously reported (2). Since the present experiment used square root transformations which produced normally distributed scores, this interaction between drug condition and aggregation appears to be a general phenomenon, not depending on the skewed distribution of the raw scores used in the prior study. The present experiment also showed that the aggregated condition, which produced a greater decrement under the drug in the first hour, produced an earlier recovery from the drug effect, indicated by the statistically significant increase in activity from the third to the fourth 0.5 hr. The stimulating aggregation situation, in which activity was decreased to a greater degree by chlorpromazine, apparently caused a more rapid recovery from the depressant effects of the drug.

The present experiment also demonstrated a greater depressant effect of chlorpromazine on activity in the first 0.5 hr. of the second session than of the first session. Adler (8), also utilizing the photocell activity cage, found a greater depressant effect of tetrabenazine on the motor activity of rats in the second of two tests with a 1-week intertrial period. Rushton *et al.* (9) found different magnitudes of drug effect on exploratory activity of rats, depending on whether the drug test was on their second rather than first exposure to the test situation, and also depending on whether the drug test was preceded by a drug or placebo test in the same situation. The stimulating effect of an amphetamine–barbiturate mixture was apparently greater in the second test, when the same drug was given in both tests. In the present experiment, and in Adler's study (8), the animals were given the same drug, or placebo, condition in both tests, so that it is not possible to determine whether the greater depressant drug effect in the second test was due solely to a greater familiarity with the test situation, or to the prior administration of the drug associated with this test situation. However, this effect was clearly not due to accumulation of the drug from the first session, because the greater drug effect was found in the second session after the 14-day interval, as well as after the 1-day interval.

The behavioral and drug carry-over effects, from the first to the second session, indicate that the experimenter should be careful when using the same animals more than once in tests of drug effects. It is obviously necessary to counterbalance the sequence, giving placebo first to half the animals and the drug first to the other half. On the other hand, the high over-all correlation in activity between the first and second sessions, especially in the early part of the sessions, shows that the use of repeated tests on the same animal can increase the sensitivity of the test of drugs, or other conditions which are experimentally varied in the different test sessions. With the factorial design as used in the present experiment, the advantages of repeated testing can be fully obtained, even when there is a decrement in performance in the second session and a different magnitude of drug effect in the two sessions. It should be emphasized that, in the present experiment, these differential effects in the two sessions were fairly small, relative to the magnitude of the over-all drug effects and to the effects of other conditions, such as aggregation and 0.5-hr. intervals. The same general pattern of depressant drug effects was found in both sessions. Therefore, the effects of the drug could be tested adequately with a greatly reduced number of animals by the use of the repeated test design, giving chlorpromazine in one session and placebo in the other, at least for this dosage of this compound and under these conditions.

The most stable data were obtained in the first

0.5 hr. of the test, and with the shortest interval between sessions. These conclusions are based on the higher correlations between the two tests for the first 0.5 hr. and for the 1-day interval. The disadvantage of the greater decrement in activity after the shortest intersession interval is offset by the generally higher correlations between the first and second sessions found for the 1-day group, as well as by the practical advantage of using a shorter interval. These findings may be of use to experimenters in selecting the optimum conditions for testing the effect of chlorpromazine on the activity of mice in the photocell cage.

Preliminary Investigations of *Heracleum mantegazzianum*

By EUGENE C. LEE, PHILIP CATALFOMO, and LEO A. SCIUCHETTI

Preliminary investigations of the air-dried roots of *Heracleum mantegazzianum* grown under greenhouse conditions were conducted. Seed germination requires moist cold treatment. The germination rate appears to be directly related to the length of the moist cold period. Gibberellin seed treatment did not substitute for the cold requirement. Thin-layer chromatography revealed the presence of 6 coumarins which were tentatively identified as bergapten, isobergapten, pimpinellen, isopimpinellen, sphondin, and umbelliferone. Results also indicate that the plant can cause photosensitization.

EXCELLENT reviews concerning the distribution, chemistry, or pharmacological properties of the naturally occurring coumarins are available (1–5); included are phytochemical studies revealing the presence of coumarins in a number of *Heracleum* species. A notable aspect is the involvement of furocoumarins in certain cases of phytophotodermatitis; several of them occur in *Heracleum* species. The distribution of photodynamically active furocoumarins were recently reviewed by Pathak *et al.* (6). Although phytochemical investigations of the coumarins of *Heracleum* species has been extensive, the species *Heracleum mantegazzianum* Somm. et Lev. is a noteworthy exception. However, during the course of this investigation, a report by Beyrich (7) revealed the presence of phellopterin and other coumarins in this species, but the results are not entirely consistent with those reported in this investigation. Since *H. mantegazzianum* has been reported to evoke phytodermatitis, a preliminary investigation was undertaken to determine the presence of photosensitizing coumarins and related compounds.

To obtain sufficient plant material for this and subsequent studies the plant was propagated under greenhouse conditions. Seeds of the *Umbelliferae* have been noted for germination difficulties, and germination standards for cultivated members of this order have been set much lower than those of other plants (8). The seeds of some *Heracleum* species have a requirement for after ripening in moist cold (9). Attempts have also been made to obviate the cold requirement in the dormancy of certain seeds by chemical means, especially with the gibberellins (10). Since no report could be found in the literature concerning the cold requirement of the effects of gibberellic acid on seed germination of *H. mantegazzianum*, preliminary germination studies were also conducted.

EXPERIMENTAL AND RESULTS

Germination Studies.—Preliminary studies were designed to compare the effect of cold treatment *versus* treatment with gibberellic acid on the germination rate of the seeds. Three groups of seeds (39 per group) were planted in flats containing a mixture of 1 part sand and 2 parts sandy loam plus 50 Gm. of complete fertilizer.[1] Group *A* was pretreated by storage at 2–5° for 74 days; group *B* was soaked for 20 hr. in a solution of gibberellic acid (100 p.p.m.); and group *C*, soaked in distilled water, was considered the control group. The flats were maintained under normal greenhouse conditions and germination was allowed to occur at a temperature range of 18–27° for 38 days. Ger-

mination did not occur in group *B* or group *C;* however, 4 seeds in group *A* germinated. Although this is a low germination rate (10.3%), it was apparent that cold treatment is required for germination. Based on these results, 1000 selected seeds were soaked for 36 hr. and refrigerated at 2–5° for 294 days. This treatment resulted in a 55% germination.

Preparation of Root Material.—To obtain root material for subsequent investigations, seeds were cold treated and germinated on moist blotting paper in Petri dishes. After germination occurred, they were transplanted in peat pots containing the soil mixture previously described. After 92 days the plants (average height 33.5 cm.) were harvested, the roots washed free of soil, and separated from the plant. The roots were allowed to dry at room temperature for 8 weeks. The dried material was milled to a No. 20 powder in a Wiley mill and the powder placed in air-tight colored glass containers until utilized in subsequent analyses.

Extraction of Coumarins.—Approximately 13.5 Gm. of dried powdered root was placed in a Soxhlet-type apparatus and extracted to exhaustion with 100 ml. of ethyl ether. The extractive was filtered and the filtrate evaporated on a steam bath to a syrupy residue. The residue was washed 3 times with 2-ml. portions of petroleum ether and redissolved in a mixture containing equal parts of ethyl ether and alcohol to a total volume of 10 ml. in a volumetric flask. The extract was stored in a refrigerator until subjected to chromatographic analysis.

Chromatographic Analysis.—Tentative identification of the coumarins was accomplished by employing two-dimensional thin-layer chromatography on Silica Gel G. The extract was applied in 20-μl. portions to thin-layer plates, 200 mm. on each side. The plates were developed in ethyl acetate–xylene (1:1) in the first direction and hexane–ethyl acetate (2:1) in the second direction. The solvent front was allowed to proceed a distance of 100 mm. in each direction. Solutions of known coumarins which were chromatographed singly, in mixture, and in combination with extracts, were compared to chromatoplates of extracts without additions. The coumarins were detected by examining the plates under ultraviolet light. This procedure revealed the presence of 7 principal spots which were tentatively identified as bergapten, isobergapten, pimpinellin, isopimpinellin, sphondin, and umbelliferone. The seventh spot, which fluoresced blue, was not identified, but co-chromatography indicated that it was not imperatorin.

DISCUSSION

The germination studies indicated that seeds of *H. mantegazzianum* will germinate only after extended cold treatment since no seeds germinated in the group where this procedure was omitted. Seeds exposed to moist cold for 74 days showed a germination rate of 10.3%. When the cold period was extended to 294 days, the germination rate increased to 55%. It appears, therefore, that the germination rate may be directly related to the period of moist cold treatment. An attempt to overcome this requirement by soaking in a solution of gibberellic acid met with no success. Similar attempts by Stuart and Cathey (10), but with sweet cherry and peach, indicated that gibberellic acid only partially substituted for cold treatment. Although gibberellins have been credited with substituting for other germination conditions, *i.e.*, light requirement, they do not adequately substitute for the cold treatment (10).

Thin-layer chromatographic analysis of the ether extract of air-dried root revealed the probable presence of 6 coumarins: bergapten, isobergapten, pimpinellin, isopimpinellin, sphondin, and umbelliferone, the last being the only nonfurocoumarin. A seventh spot, which fluoresced blue, was not imperatorin. A preliminary report by Beyrich (7), who investigated the fruits of *H. mantegazzianum*, showed the presence of pimpinellin and isopimpinellin in addition to the following furocoumarins: angelicin, xanthotoxin, imperatorin, and phellopterin. Since he examined a different plant part, direct comparison of results is precluded.

The plant under investigation has been shown to evoke phytophotodermatitis (6). The furocoumarins, especially bergapten and xanthotoxin, cause dermatitis. Since these compounds in all probability appear to exist in *H. mantegazzianum*, as well as others possibly having similar biological activity, this plant should be considered a photosensitizing species.

Stability of the Folin Phenol Reagent

By ROBERT C. PETERSON

A comprehensive study has been made of the stability of the Folin phenol reagent as the initial acidic concentrate. Even though refrigerated, an apparent continuing and linear decomposition of about 2 per cent per month occurs which should be considered in the determination of mcg. amounts of protein.

DURING work in which it was attempted to determine the specific activity of trypsin, the protein content of electrophoretically fractionated zones was determined with the Lowry (1) modification of the Folin-Ciocalteu (2) reagent.

A satisfactory standard curve could be prepared for protein concentration, but when a known sample was referred to it at a later time, the sample value was always low. It was found that the low values were produced by a slow but consistent deterioration of the Folin reagent whether it was from commercial sources[1] or prepared in our laboratory according to Folin-Ciocalteu (2). This deterioration occurred even though the reagent was refrigerated (6°) immediately after preparation and removed only when portions were desired for dilution in the protein tests.

The Folin phenol reagent is known to be rapidly destroyed by an alkaline solution (1), but this writer is not aware of any comments in the literature regarding its instability as the initially prepared acid.

Since this reagent is continually used, it seemed worthwhile to acquire more knowledge concerning its stability. It was felt that reagent prepared in the laboratory and used shortly thereafter would give the greatest response, and so a preparation was made as mentioned above and immediately refrigerated. The reagent titrated as 2.5 *N* acid with 0.5 *N* NaOH in the presence of phenol red; Fisher reagent gave the same value under these conditions. The laboratory reagent was tested approximately once a month for 6 to 7 months.

METHODS AND MATERIALS

The standard protein was N.F. Trypsin Crystallized Reference Standard, lot 6040 (3). A new solution, 5 mg. in 100 ml. of water, was made up for each test. A second standard was L-tyrosine.[2] A new solution, 3 mg. in 100 ml. of water, was made up for each test.

The phenol reagent was tested for optimal response according to Oyama and Eagle (4) and their Lowry reagent modifications were used. Reagent *A* consisted of 20 Gm. of Na_2CO_3, 4 Gm. of NaOH, and 0.2 Gm. of $K_2C_4H_4O_6 \cdot 1/2\ H_2O$ made to 1 L. with water. Reagent *B* was 0.5 Gm. of $CuSO_4 \cdot 5H_2O$ made to 100 ml. with water. Reagent *C* was made freshly before each test series from reagents *A* and *B*:50 to 1 by volume. For each test 0.5 ml. of each standard was diluted to 1 ml. with water and this solution was reacted with 2.5 ml. of reagent *C* for 10 min. Folin reagent, 0.25 ml., at various dilutions with water (4) was jetted in and mixed thoroughly. The absorbance was determined at 750 mμ every 30 min. for 2 hr. with a Beckman model DU spectrophotometer. For each test the optimum response of the Folin reagent was considered to be the absorbance value from the phenol reagent dilution which gave the greatest stability of color, *i.e.*, the absorbance values produced a plateau. These absorbance values, determined at approximately 1-month intervals, gave an indication of the stability of the phenol reagent.

With L-tyrosine, 15 mcg. per test, the curve in Fig. 1 was obtained when absorbance was plotted against time elapsed since preparation of the reagent. Figure 2 presents similar data for 25 mcg. of trypsin per test.

DISCUSSION

In all cases it was found that the 1 to 2 dilution of phenol reagent gave optimum response.

The continual deterioration of the phenol reagent is obvious. With trypsin this is a decrease in absorbance of 0.0044 every 30 days. With L-tyrosine, the decrease is greater.

For accurate quantitative use of the Folin phenol reagent, either its response as related to a standard decomposition curve must be considered or its activity must be correlated with a known amount of standard protein or amino acid.

It follows that to get sensitivity with the reagent with microgram quantities of protein, the state of decay of the reagent must be known. If deterioration is sufficiently great, either fresh reagent must be used or the quantity must be increased.

Nuclear Magnetic Resonance Spectra of Amines II. Identification of *N*-Phenyl Amines

By R. J. WARREN, W. E. THOMPSON, J. E. ZAREMBO, and I. B. EISDORFER

The effects of a strongly acidic solvent on the chemical shift and spin-spin splitting of the phenyl protons in *N*-phenyl amines are characteristic for this functional group. These effects provide the basis for the identification of the *N*-phenyl group in primary, secondary, and tertiary amines.

THE EFFECT of protonation of amines containing *N*-methyl groups has been recently reported by these laboratories (1). The authors wish to report on the *N*-phenyl group as characteristically identified by examination of the NMR spectrum of free base in deuterated chloroform and the spectrum in trifluoroacetic acid.

EXPERIMENTAL

All NMR spectra were recorded on a Varian A-60 spectrometer using Varian sample tubes. Deuterated chloroform and trifluoroacetic acid were used as solvents. Spectra were obtained on samples at room temperature at a concentration of 50 mg./ml.

The *N*-phenyl amines used were Eastman organic chemicals as purchased from Distillation Products Industries, Rochester, N. Y., or K and K chemicals as purchased from the K and K Laboratories, Plainview, N. Y.

RESULTS AND DISCUSSION

The pronounced change in the aromatic proton pattern of an *N*-phenyl amine free base on conversion to the amine cation is illustrated in Fig. 1, curve A, diphenylamine in deuterated chloroform, and curve B, diphenylamine in trifluoroacetic acid. This phenomenon, the collapse of a complex A_2B_2C aromatic pattern into a simple peak (or narrow band of peaks), is general for any protonatable *N*-phenyl group with no other substituents on the *N*-phenyl ring. The collapse of this pattern can be attributed to equalization of the chemical shifts of the phenyl protons. The principal cause of inequality of chemical shifts for the phenyl protons in an amine free base is conjugation of the amine group with the phenyl ring. Protonation of the amine blocks this conjugation and results in nearly uniform chemical shifts for the protons on the benzene ring. The reduction of conjugation of an *N*-phenyl amine on formation of the amine cation is well established in the theory of ultraviolet spectra for anilines (2).

The authors have found the collapse of the A_2B_2C spectral pattern of the *N*-phenyl group useful for determining whether one or more *N*-phenyl groups in an unknown compound have other substituents on the *N*-phenyl ring. For example 3-chloro-*N*-phenyl aniline shows 2 species of protons in trifluoroacetic acid due to the *meta* substituted benzene ring.

The NMR data for 5 representative *N*-phenyl reference compounds are listed in Table I. It should be noted that acidic solvents, such as aqueous hydrochloric and sulfuric acids, all influence the NMR absorption pattern of the *N*-phenyl group in the same fashion, regardless of whether the amine is primary, secondary, or tertiary.

If the *N*-phenyl group is close to another aromatic ring, the asymmetric magnetic field generated by the second aromatic ring may prevent observation of collapse of the A_2B_2C pattern on cation formation. For example, the NMR spectra for *N*-methyl-*N*-phenyl-benzylamine (Fig. 2) show a more complex pattern for the ion (Fig. 2, B) than for the free base (Fig. 2, A). The authors have observed a similar

For accurate quantitative use of the Folin phenol reagent, either its response as related to a standard decomposition curve must be considered or its activity must be correlated with a known amount of standard protein or amino acid.

It follows that to get sensitivity with the reagent with microgram quantities of protein, the state of decay of the reagent must be known. If deterioration is sufficiently great, either fresh reagent must be used or the quantity must be increased.

Nuclear Magnetic Resonance Spectra of Amines II. Identification of *N*-Phenyl Amines

By R. J. WARREN, W. E. THOMPSON, J. E. ZAREMBO, and I. B. EISDORFER

The effects of a strongly acidic solvent on the chemical shift and spin-spin splitting of the phenyl protons in *N*-phenyl amines are characteristic for this functional group. These effects provide the basis for the identification of the *N*-phenyl group in primary, secondary, and tertiary amines.

THE EFFECT of protonation of amines containing *N*-methyl groups has been recently reported by these laboratories (1). The authors wish to report on the *N*-phenyl group as characteristically identified by examination of the NMR spectrum of free base in deuterated chloroform and the spectrum in trifluoroacetic acid.

EXPERIMENTAL

All NMR spectra were recorded on a Varian A-60 spectrometer using Varian sample tubes. Deuterated chloroform and trifluoroacetic acid were used as solvents. Spectra were obtained on samples at room temperature at a concentration of 50 mg./ml.

The *N*-phenyl amines used were Eastman organic chemicals as purchased from Distillation Products Industries, Rochester, N. Y., or K and K chemicals as purchased from the K and K Laboratories, Plainview, N. Y.

RESULTS AND DISCUSSION

The pronounced change in the aromatic proton pattern of an *N*-phenyl amine free base on conversion to the amine cation is illustrated in Fig. 1, curve A, diphenylamine in deuterated chloroform, and curve B, diphenylamine in trifluoroacetic acid. This phenomenon, the collapse of a complex A_2B_2C aromatic pattern into a simple peak (or narrow band of peaks), is general for any protonatable *N*-phenyl group with no other substituents on the *N*-phenyl ring. The collapse of this pattern can be attributed to equalization of the chemical shifts of the phenyl protons. The principal cause of inequality of chemical shifts for the phenyl protons in an amine free base is conjugation of the amine group with the phenyl ring. Protonation of the amine blocks this conjugation and results in nearly uniform chemical shifts for the protons on the benzene ring. The reduction of conjugation of an *N*-phenyl amine on formation of the amine cation is well established in the theory of ultraviolet spectra for anilines (2).

The authors have found the collapse of the A_2B_2C spectral pattern of the *N*-phenyl group useful for determining whether one or more *N*-phenyl groups in an unknown compound have other substituents on the *N*-phenyl ring. For example 3-chloro-*N*-phenyl aniline shows 2 species of protons in trifluoroacetic acid due to the *meta* substituted benzene ring.

The NMR data for 5 representative *N*-phenyl reference compounds are listed in Table I. It should be noted that acidic solvents, such as aqueous hydrochloric and sulfuric acids, all influence the NMR absorption pattern of the *N*-phenyl group in the same fashion, regardless of whether the amine is primary, secondary, or tertiary.

If the *N*-phenyl group is close to another aromatic ring, the asymmetric magnetic field generated by the second aromatic ring may prevent observation of collapse of the A_2B_2C pattern on cation formation. For example, the NMR spectra for *N*-methyl-*N*-phenyl-benzylamine (Fig. 2) show a more complex pattern for the ion (Fig. 2, B) than for the free base (Fig. 2, A). The authors have observed a similar

lack of collapse for the *N*-phenyl protons of *N*-phenylbenzylamine.

CONCLUSION

The difference between the NMR spectrum of the *N*-phenyl amine free base and that of the *N*-phenyl amine ion is a useful diagnostic tool for structure determinations of these compounds. This difference makes it possible to establish the presence of the *N*-phenyl structures in primary, secondary, and tertiary amines. Interference with identification of the *N*-phenyl group may occur from other aromatic rings in the molecule. It is conceivable that long-range effects of any functional group possessing magnetic anisotropy could cause some interference; however, no examples of this effect were noted in this study.

Interaction Between Pharmaceuticals and Sodium Polyethylenesulfonate

By G. LEONARDI, M. SOLINAS, and C. BOTRÉ

Several drugs, mainly in the field of local anesthetics, were studied with a synthetic polyelectrolyte, sodium polyethylenesulfonate, by means of membrane equilibrium dialysis measurements. Data on equilibrium constants of the association between the drugs considered, as hydrochlorides, and the polyelectrolyte are reported.

THE STUDY of interactions between drugs and macromolecules has received increasing interest recently (1–5).

The result of such interaction, in general, is the formation of association complexes between the drug and the macromolecule, which may lead to unusual features, both from physicochemical and biological points of view.

In some cases, for instance, the pharmacological activity of the complex is improved with respect to the single drug, either in the sense of the intensity and/or the duration of action.

This paper reports data about the interaction observed between several local anesthetics and a synthetic polyelectrolyte, *i.e.*, sodium polyethylenesulfonate.

This study was performed mainly by means of membrane equilibrium dialysis according to a procedure proposed by Klotz *et al.* (6).

The equilibrium constants of associations between drugs and the polyelectrolyte are reported.

EXPERIMENTAL

The sample of sodium polyethylenesulfonate (NaPES) was prepared according to Breslow and Kutner (7). Its molecular weight was about 7,000. The dissociation degree (α) of the NaPES was determined potentiometrically in an aqueous solution by using a cationic glass electrode (Beckman catalog No. 39728) and saturated calomel electrodes connected to the solution by means of an agar bridge. The procedure and the apparatus were extensively described in a previous paper (8). The experimental value of α was 0.25, in good agreement with the theoretical value calculated according to Oosawa (9).

All the pharmaceuticals were used as hydrochlorides. They are listed in Table I together with the wavelength corresponding to a maximum of absorbance. Table I also reports association constants and pKa values at 25° (10).

Conductivity measurements were performed in a thermostatic bath at 25 ± 0.02° using a WTW bridge model LF 3.

The dialysis experiments were carried out with cellophane bags (HMC type). These were previously treated with boiling water for about 5 min., washed with cold water, wiped, filled with a known volume of the NaPES solution, and then dipped into a known volume of drug solution.

Received March 1, 1965, from the Istituto di Chimica Farmaceutica e Tossicologica, Universita di Roma, Centro Nazianale di Chimica del Farmaco del CNR, Rome, Italy.
Accepted for publication February 2, 1966.

The polymer concentration was 10^{-3} *M;* the drug concentration was 10^{-4} *M*. The equilibrium across the membrane was reached at room temperature after about 48 hr. No change in volume inside or outside the bag was observed.

The concentration of the drug in solution was determined with a grating spectrophotometer (Hitachi, Perkin-Elmer, model 139). The measurements of the absorbance were performed in each case at the wavelength corresponding to the maximum value of the absorption of the drug. Quartz cells, 1 mm. optical path, were employed.

At each concentration a blank test was set up. In this case, water was placed inside the bag instead of polyelectrolyte solution. The amount of drug bound to the polyelectrolyte was determined by measuring the concentration of the solution outside the bag containing the polyelectrolyte as well as the outside concentration of the drug in the blank.

RESULTS AND DISCUSSION

In order to prove that in the range of concentration considered no aggregation takes place in solution of the drugs considered, specific conductivity was measured at different concentrations. In each case the plots of specific conductivity *versus* the concentration gave straight lines. On the other hand, it was shown that when aggregation of drug molecules in solution occurs, a break in the plot of specific conductivity *versus* concentration may be detected (2).

The data obtained from the membrane equilibrium dialysis were treated according to the method of Klotz *et al.* (6). Such treatment, in fact, may be applied to a general association equilibrium between a polyelectrolyte (P) and a drug (D), for which

$$P + D \rightleftharpoons PD \qquad \text{(Eq. 1)}$$

The equilibrium constant for the ith association, K_i, is:

$$K_i = \frac{n - (i - 1)}{i} k \qquad \text{(Eq. 2)}$$

When $i = 1$, first equilibrium constant, Eq. 2 reduces to

$$K = nk \qquad \text{(Eq. 3)}$$

where n = number of sites available along the polymer
K = equilibrium constant
k = constant which depends on the nature of the anion

The relationship which correlates the number of sites available along the polymer to the interaction with the molecules of the drug can be written as follows:

$$\frac{1}{r} = \frac{1}{n\,k\,D} + \frac{1}{n} \qquad \text{(Eq. 4)}$$

where r is the ratio between the number of moles of bound drug and total moles of polymer.

By plotting $1/r$ *versus* the reciprocal of nonbound

TABLE I.—ASSOCIATION CONSTANTS FOR DRUG–POLYELECTROLYTE SYSTEM

Hydrochlorides of	Formula	λ mμ	Association Constant $K \times 10^{-4}$	pK_a at 25°
Amylocaine		232	7.94	8.40
Benzocaine	$H_2N—C_6H_4—COOC_2H_5 \cdot HCl$	235	...	2.43
Diphenhydramine		250	6.52	9.00
d-Ephedrine		210	25.00	9.55
Parethoxycaine		260	6.25	...
Tripelennamine		305	7.60	8.96
Procaine		290	3.33	8.95
Promethazine		248	16.95	8.65
Pramoxine		224	5.91	...

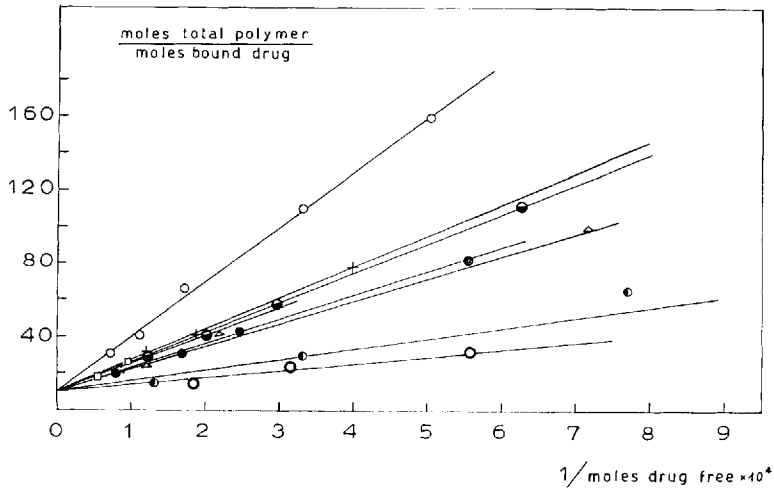

Fig. 1.—Ratio between total moles of polymer and moles of bound drug *vs.* the reciprocal of free drug molecules. Key: ○, procaine; ◐, promethazine; +, pramoxine; ○, *d*-ephedrine; ●, tripelennamine; ◒, parethoxycaine; △, amylocaine; □, diphenhydramine.

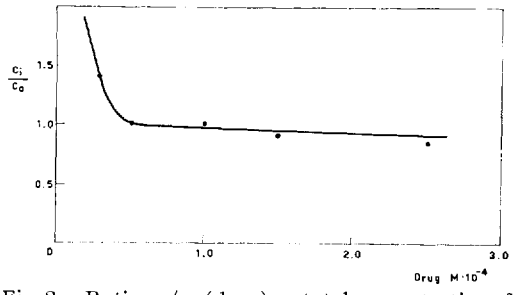

Fig. 2.—Ratio, c_i/c_0, (drug) *vs.* total concentration of the drug.

By solving the system one obtains,

$$(0.5\,a_0 - a_i)x_0^2 + (Da_i - Pa_i + a_0a_i - 0.5\,a_0^2)x_0 + (DPa_i - Da_0a_i) = 0 \quad \text{(Eq. 5)}$$

By substituting in Eq. 5 the values of D, P, a_0, and a_i, respectively, the values of x_0 and x_i are obtained.

In Fig. 2, the ratio between inside molar concentration of the drug, c_i, and outside molar concentration, c_0, is plotted against the total concentration of the drug. Figure 3 reports the ratio, c_i/c_0, respective to the chloride ions as a function of the total concentration of the drug.

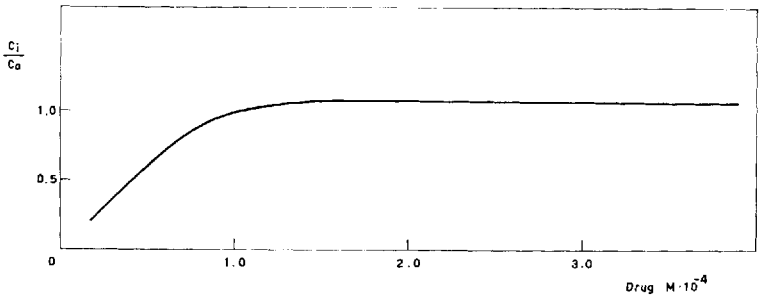

Fig. 3.—Ratio, c_i/c_0 (chloride ion) *vs.* total concentration of the drug.

moles of drug (Fig. 1), straight lines are obtained, showing that the electrostatic effect can be neglected with respect to the statistical effect. This is reasonable since the concentration of the solution is very low. The number of free sites of the polymer was, under our conditions, roughly 10 times the concentration of the drugs considered.

Under the experimental conditions of this work, the Donnan effect may be neglected, since we have

$$\begin{cases} \dfrac{x_i}{v_i} \cdot \dfrac{a_i}{v_i} \cdot \dfrac{y_i}{v_i} = \dfrac{x_0}{v_0} \cdot \dfrac{a_0}{v_0} \cdot \dfrac{y_0}{v_0} \cdot \\ \dfrac{y_0}{v_0} = \dfrac{1}{v_0}(a_0 - x_0) \end{cases}$$

and

$$\begin{cases} \dfrac{D - x_0}{v_i} \cdot \dfrac{a_i}{v_i} \cdot \dfrac{P - y_0}{v_i} = \dfrac{x_0}{v_0} \cdot \dfrac{a_0}{v_0} \cdot \dfrac{y_0}{v_0} \\ y_0 = a_0 - x_0 \end{cases}$$

where D = mmoles of total drug
P = mmoles of polymer (inside)
a_0 = mmoles of chloride outside
a_i = mmoles of chloride inside [this value was obtained by Kennon *et al.* (11)]
x_0 = mmoles of drug outside
x_i = mmoles of drug inside
v_0 = outside volume of solution (20 ml.)
v_i = inside volume of solution (10 ml.)
v_i/v_0 = 0.5
y_0 = mmoles of sodium outside
y_i = mmoles of sodium inside

The trend of the values, c_i/c_0 *versus* the concentration of the drug, shows that in the considered range of concentrations, they may be considered roughly constant and near unity. Therefore, under the above-mentioned conditions the Donnan effect can be neglected.

The association constants between the drugs and polyelectrolyte reported in Table I are approximately higher for monomethyl derivatives (*d*-ephedrine), followed by dimethyl and diethyl derivatives, while no significant differences can be observed in their respective pKa values.

Further studies are in progress to evaluate the role of the steric hindrance on such interactions.

Evaluation of *N*-Haloacyl Analogs of α,α-Diphenyl-4-piperidinemethanol Against Ehrlich Ascites Carcinoma in Mice

By WILLIAM D. ROLL

The antitumor activity of 8 haloamide derivatives of α,α-diphenyl-4-piperidinemethanol was studied in C3H agouti mice against the Ehrlich ascites carcinoma. The preliminary screening studies would seem to indicate that the chemotherapeutic effect of these compounds is potentially significant. There seems to be a definite correlation between structure and activity within the propionamide and acetamide analogs in that within each group of compounds the iodoamides have the highest order of activity; the bromoamides have intermediate activity; and the chloroamides have the least activity. The haloacetamide analogs seem to be more toxic than the corresponding halopropionamide derivatives.

In a previous paper (1) the synthesis and potential antitumor activity of a series of *N*-haloacyl derivatives of α,α-diphenyl-4-piperidinemethanol were reported. A continuation of the antitumor screening study shows that the compounds (Table I) have significant activity against Ehrlich ascites tumor in C3H mice.

EXPERIMENTAL[1]

Experiments were performed on 5–10-week-old C3H agouti mice purchased from the R. B. Jackson Memorial Laboratory, Bar Harbor, Maine. The testing procedure used was similar to that described by Linder (2) and Hauschka *et al.* (3).

Transplantation of the tumor was carried out by aseptically withdrawing ascites fluid from a donor mouse bearing a 7-day ascites tumor. Each experimental animal was inoculated i.p. with 2×10^6 ascites cells. Ten animals were used as controls and 10 animals for treatment. Mice were distributed into groups of comparable weight and treatment was begun 24 hr. after tumor implantation. The compounds were administered in peanut oil (1%) and control animals received corresponding volumes of peanut oil alone. Change in body weight was noted as a measure of the accumulation of tumor cells and ascitic fluid. Cell counts were used as a measure of the inhibition of tumor cell growth. The dosages recorded in Table II were administered in single intraperitoneal injections per day commencing 24 hr. after transplantation of the tumor and continuing for 3 days. The results recorded in Table II were determined on the sixth day after intraperitoneal transplantation of the tumor.

RESULTS

The chemotherapeutic activity of the halopropionamide analogs (I, IV, VII) against ascites tumor showed that the iodopropionyl derivative (VII) exhibited the greatest inhibition, and the relative activity within this group of compounds was VII > IV > I. The same order of activity was noted with regard to the haloacetamide analogs: iodoacetamide > bromoacetamide > chloroacetamide. The toxicity of haloacetyl derivatives was greater than that of the halopropionyl analogs. (See *Footnote c*, Table II.)

Saccharin Derivatives VIII. Hypotensive Agents

By GLENN H. HAMOR

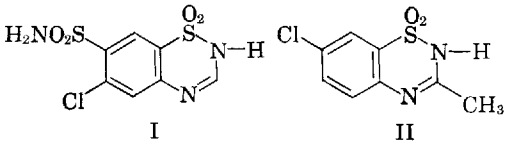
Saccharin analogs of chlorothiazide have been reported to possess diuretic activity. This paper relates the synthesis of 6-chloro-2-methylsaccharin, which is structurally similar to 7-chloro-3-methyl-1,2,4-benzothiadiazine 1,1-dioxide (diazoxide), a non-diuretic, hypotensive benzothiadiazine. The 6-chloro-2-methylsaccharin along with some 9 related saccharin derivatives, which had been synthesized earlier in a continuing study of saccharin chemistry, were screened for pharmacological activity. Preliminary results indicate hypotensive effects in cats and dogs, with little diuretic response. In fact, 2-ethyl-4-nitrosaccharin showed antidiuretic properties. In addition to producing a moderate transient hypotension in the anesthetized dog, 6-chloro-2-methylsaccharin produced CNS stimulation in rats.

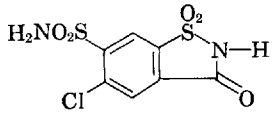
THE DIURETIC activity of compounds related to 6-chloro-7-sulfamoyl-1,2,4-benzothiadiazine 1,1-dioxide (chlorothiazide) (I) is well known (1). Certain of them also show hypotensive activity and are used clinically in the treatment of mild hypertension (2). Several recent papers describe closely related substances lacking the sulfamoyl group, exemplified by 7-chloro-3-methyl-1,2,4-benzothiadiazine 1,1-dioxide (diazoxide) (II), as possessing antihypertensive but not diuretic activity (3–6).

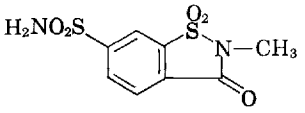
The saccharin analogs, 5-chloro-6-sulfamoylsaccharin (III) (7) and 2-methyl-6-sulfamoylsaccharin (IV) (8), are reported to exhibit diuretic activity.[1] This paper relates the results of preliminary pharmacological testing of some 9 saccharins corresponding to the hypotensive 1,2,4-benzothiadiazines in not containing an extranuclear sulfamoyl group. The synthesis of 6-chloro-2-methylsaccharin (V) is described. The remaining 8 saccharin derivatives had been prepared earlier in a continuing study of saccharin chemistry (9–11).

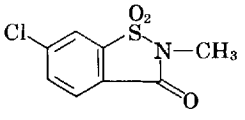
Because Topliss *et al.* (4) had reported most of the hypotensive activity of the benzothiadiazines to be retained if the chlorine at position 7 were replaced by nitro, various nitrosaccharins and related compounds were selected for testing (Table I). The 6-chloro-2-methylsaccharin was synthesized by chlorosulfonation of 4-chlorotoluene, followed by treatment with aqueous ammonia, which gave 4-chlorotoluene-2-sulfonamide. Oxidation of this compound succeeded by a Williamson reaction of the resulting 6-chlorosaccharin with methyl iodide gave the desired 6-chloro-2-methylsaccharin.

Preliminary pharmacological results[2] indicate these compounds to possess hypotensive effects, on intravenous injection in cats and dogs, of primarily a transient nature. The 4-nitro-2-*n*-propylsaccharin (compound *4*) shows some evidence of autonomic ganglionic blocking. These substances possess little diuretic response. In fact, 2-ethyl-4-nitrosaccharin (compound *3*) showed antidiuretic properties. In contrast, 2-methyl-6-sulfamoylsaccharin (IV), the diuretic compound, produced transient pressor effects in the cat after doses of 0.5–10.0 mg./Kg. intravenously. In addition to producing a moderate transient hypotension following administration of 5 and 10 mg./Kg. i.v. in the dog, 6-chloro-2-methylsaccharin (V) caused CNS stimulation in rats orally at 300 mg./Kg. It may be of interest to note that this saccharin compound (V) is tasteless, as have been other *N*-substituted saccharins in our experience.









EXPERIMENTAL

6-Chloro-2-methylsaccharin (V).[3]—In a 200-ml. round-bottom flask fitted with a reflux condenser and heating mantle were placed 5.0 Gm. (0.023 mole) of 6-chlorosaccharin,[4] m.p. 217° [reported m.p. 218° (12)], 1.3 Gm. (0.012 mole) of sodium carbonate, and 100 ml. of dimethylformamide. To this was added 7.3 Gm. (0.051 mole) of methyl iodide. The solution was refluxed for 1 hr. and then poured into approximtely 700 ml. of ice water. The mixture was cooled for 30 min., then filtered and washed with 2 portions of cold water to give 3.2 Gm. (60%) of white solid, m.p. 174–175.5°.[5] Recrystallization

Thin-Layer Chromatography of Cardiac Glycosides

By EUGENE J. JOHNSTON and ALLEN L. JACOBS

A rapid thin-layer chromatographic procedure for the separation and identification of the common cardiac glycosides is presented. A benzene–ethanol solvent is used for development and a perchloric acid spray for visualization.

THIN-LAYER chromatography has proven to be more rapid and sensitive than paper chromatography for the identification and purity determination of many drugs. A number of solvent systems and sprays useful for cardiac glycosides have been published (1–4). This paper reports the development of a relatively simple technique which has certain advantages over these approaches.

Received January 10, 1966, from the Analytical Research Department, Sandoz Pharmaceuticals, Hanover, N. J.
Accepted for publication February 21, 1966.

EXPERIMENTAL

Thin-Layer Plates.—A 0.25-mm. layer of Silica Gel G (E. Merck, Darmstadt) is applied to the plates. The plates are air dried for 10 min., then heated in an oven for 45 min. at 120°. The plates are stored in a desiccator and used without further activation.

Solvent System.—Benzene–95% ethanol (7:3 v/v).

Spray Reagent.—Fifteen milliliters of 70% perchloric acid added to 100 ml. of water.

Preparation of Samples.—The substances are dissolved in a suitable solvent, usually methanol. For purity studies, 100 mcg. of substance is spotted on

Thin-Layer Chromatography of Cardiac Glycosides

By EUGENE J. JOHNSTON and ALLEN L. JACOBS

A rapid thin-layer chromatographic procedure for the separation and identification of the common cardiac glycosides is presented. A benzene–ethanol solvent is used for development and a perchloric acid spray for visualization.

THIN-LAYER chromatography has proven to be more rapid and sensitive than paper chromatography for the identification and purity determination of many drugs. A number of solvent systems and sprays useful for cardiac glycosides have been published (1–4). This paper reports the development of a relatively simple technique which has certain advantages over these approaches.

Received January 10, 1966, from the Analytical Research Department, Sandoz Pharmaceuticals, Hanover, N. J.
Accepted for publication February 21, 1966.

EXPERIMENTAL

Thin-Layer Plates.—A 0.25-mm. layer of Silica Gel G (E. Merck, Darmstadt) is applied to the plates. The plates are air dried for 10 min., then heated in an oven for 45 min. at 120°. The plates are stored in a desiccator and used without further activation.

Solvent System.—Benzene–95% ethanol (7:3 v/v).

Spray Reagent.—Fifteen milliliters of 70% perchloric acid added to 100 ml. of water.

Preparation of Samples.—The substances are dissolved in a suitable solvent, usually methanol. For purity studies, 100 mcg. of substance is spotted on

TABLE I.—CHROMATOGRAPHIC DATA

Substance	R_f	Fluorescence
Acetyl digitoxin	0.82	Red
Digitoxin	0.72	Red
Digoxin	0.62	Blue
Lanatoside A	0.52	Red
Lanatoside B	0.41	Red
Lanatoside C	0.36	Blue
Desacetyl lanatoside C	0.27	Blue
Ouabain	0.09	Yellow-green

the plate, although for simple detection 1 mcg. is sufficient.

Visualization.—The plates are sprayed, then placed in a 100° oven for a few minutes. The perchloric acid produces a charring effect and a fluorescence which is visible under long-wave ultraviolet light (366 mμ.).

DISCUSSION

The sensitivity of detection by fluorescence is augmented by the visualization of the spots in ordinary light. Good separation of the common cardiac glycosides can be obtained (Table I). The presence of certain contaminants is easily detected. The system has the advantages of simplicity, speed (approximately 0.5 hr.), efficiency of separation, and avoids the use of hazardous spray reagents, such as antimony trichloride.

Good results can also be obtained using a spray consisting of 0.5 ml. of *p*-anisaldehyde in 50 ml. of glacial acetic acid and 1 ml. of concentrated sulfuric acid (5). After heating the plate for a few minutes at 100°, the glycosides appear as blue spots with the exception of ouabain which appears as a yellow spot.

Determination of Organically-Bound Iodine in Pharmaceuticals

By GERALD J. YAKATAN* and MURRAY M. TUCKERMAN

Eight official iodinated compounds with iodine contents from 50 to 66 per cent were assayed by the methods official in U.S.P. XVI and N.F. XI, by reduction with zinc in alkali, and by a standard procedure using oxygen flask combustion. An additional four compounds, formerly official, with iodine content as low as 23 per cent were also examined. The results indicate that the suggested standard procedure is equal or superior to the other methods in recovery of iodine and generally equivalent in reproducibility. The alkaline zinc reduction method is suggested for those compounds having an electronegative substituent *ortho* or *para* to the iodine atoms on the aromatic ring. The oxygen flask combustion is suggested for all other iodinated compounds and as a general method. The suggested standard procedure consists of combustion by the oxygen flask method, absorption of the combustion products in an alkaline sulfite solution, and titration of the acidified solution of iodide with standard silver nitrate using a silver-calomel electrode pair for potentiometric determination of the end point.

THE QUANTITATIVE determination of iodine in organic compounds has long proved a source of difficulty for the analytical chemist. This is reflected in the numerous proposals for the determination of iodine in organic substances. An assay procedure for the determination of iodine in an organic compound actually involves two problems. First, the organic compound must be decomposed to liberate the iodine, and then the iodine must be quantitatively determined. By far the more difficult of these problems is finding an efficient method for the decomposition of the organic compound which will not result in the loss of any of the iodine present.

* National Science Foundation Summer Fellow, 1964. Present address: College of Pharmacy, University of Florida, Gainesville.

EXPERIMENTAL

Reagents.—All reagents employed were reagent grade chemicals. All standard solutions employed were prepared and standardized according to the official compendia.

Methods.—*A. Parr Bomb Method* (*1–3*).—The organic matter is oxidized by fusion with sodium peroxide in a bomb and the halide present is converted to sodium halide.

B. Alkaline Permanganate Method (*4*, *5*).—This assay is based on the conversion of organically-bound iodine to iodide by the action of permanganate in alkali and reduction with bisulfite.

C. Zinc–Sodium Hydroxide Method (*6*).—In this method the organic iodine is replaced with hydrogen generated in the nascent form by the reaction of zinc and sodium hydroxide.

D. Oxygen Flask Combustion Method (7–9).—This is an extremely rapid, simple, and inexpensive technique for combustion analysis of organic materials in oxygen. The procedure converts organic materials into soluble combustion products which are then analyzed.

Methods *A*, *B*, and *C* were official in U.S.P. XVI and N.F. XI, and the complete procedures may be found in the compendia in the monographs for the various compounds used in this study.

Preliminary testing indicated that, of the official methods, method *C* offered the best possibility of a general assay method. All compounds used in this study were assayed by the official method, by method *C*, and by the proposed general method, method *D*, which is given in detail under *Proposed General Method*. Table I shows a comparison of the four methods.

Proposed General Method

Apparatus.—Five-hundred-milliliter oxygen combustion flask (Arthur H. Thomas Co., Philadelphia, Pa.), 10-ml. buret, pH meter, silver and calomel electrodes, magnetic stirrer.

Reagents.—Sodium hydroxide solution (1 in 100), sodium bisulfite solution (1 in 100), approximately 1 *N* nitric acid solution, oxygen, 0.01 *M* $AgNO_3$ solution prepared by weighing as primary standard, low-ash filter paper (Whatman 42).

Combustion Method.—Weigh the sample accurately on a piece of the filter paper and fold the paper to enclose the sample. Place the sample, together with a filter paper fuse-strip, in the platinum wire loop fused into the flask stopper. Place 5 ml. of the sodium hydroxide solution and 2 ml. of the sodium bisulfite solution in the flask. Flush the air from the flask with a stream of rapidly flowing oxygen, moisten the stopper joint with water, and ignite the fuse strip. Immediately plunge the sample holder into the flask, and hold the stopper firmly in place. After combustion is complete, shake the flask vigorously, inverting and rotating the flask to absorb all of the iodine vapor, and allow the flask to stand for 3 min.

Completion Method.—Place a few drops of water around the stopper joint and twist the stopper to loosen it. Rinse the stopper and sample holder with water and transfer the flask contents to a 250-ml. beaker, washing the flask several times with a total of about 70 ml. of water. Add 2 ml. of the nitric acid solution, and if the solution turns a pale yellow, add 1 or 2 drops of the bisulfite solution to decolorize. Titrate potentiometrically with 0.01 *M* silver nitrate using a silver indicator electrode and a calomel reference, adding titrant in 1-ml. increments until the potential is about −100 mv. Now add titrant dropwise, taking a reading after each addition until the meter shows a change of 150–200 mv. This maximum potential change occurs at about 0 mv. and is evidenced by a slow drift in the meter pointer. The volume of titrant is recorded. The meter pointer will stabilize in a few minutes and the addition of 1 drop of excess titrant will result in a potential change of about 40 mv. The end point is further shown by the coagulation of the silver iodide particles. The silver electrode may be cleaned by immersing it in a 50% nitric acid solution until the electrode gases freely.

DISCUSSION

Some of the assay methods for iodinated compounds in the U.S.P. XVI and N.F. XI can produce low results and be quite time-consuming. Because the zinc–sodium hydroxide method requires no elaborate equipment and utilizes a simple procedure, it was hoped at the onset of this work that this method might be applicable to all of the compounds studied. In proving this, all of the compounds used in this study were analyzed by this procedure. The data reveal that the method is acceptable for those compounds which have a carboxyl or sulfonic acid group attached directly to the ring structure with the iodine atoms being *ortho* or *para* to the acid groups. In those compounds in which the acid function is separated from the ring structure by one or more carbons, the results with this method are a few per cent lower than those obtained with other methods. In compounds without an acid group present, the zinc–sodium hydroxide method will not work.

These observations can be explained on the basis of electron densities in the ring systems. The carboxyl group, a *meta* director, decreases the electron densities in the *ortho* and *para* positions, thus decreasing the strength of the carbon-iodine bonds in these positions and allowing dehalogenation to take place readily. When the carboxyl function is sep-

arated from the ring, a decrease in electron density is effected to a lesser extent, possibly explaining the lower results obtained with compounds of this type. In the hydroxyquinoline compounds, the hydroxyl group, an *ortho-para* director, increases the electron density at the *ortho* and *para* positions, strengthening the C-I bond, thus resulting in the failure of the zinc–sodium hydroxide method.

Tetrabromophenolphthalein ethyl ester (0.1% in glacial acetic acid) is the adsorption indicator used in the official compendia for the titration procedure following decomposition by zinc–sodium hydroxide. In the course of this work, it was noticed that the indicator was stable only for a period of 3–4 weeks. This is believed due to hydrolysis of the ester linkage, since refrigeration of the indicator prolonged the stability by several weeks. The freshly prepared indicator produces a sharp color change at the end point, but the sharpness of this change decreases as the indicator solution ages. It is important, therefore, to follow the U.S.P. XVII requirement that the indicator be freshly prepared.

The oxygen flask procedure produced values closer to the theoretical values than were obtained with any of the other methods used except the longer, more involved Parr bomb procedure. No difficulty was encountered from loss due to the transfer of the absorbing medium to another container prior to the titration procedure. Many of the compounds used in the study contained over 60% I and not a single case of incomplete combustion was enountered, probably because of the small sample size.

The potentiometric titration technique was employed because of the difficulties mentioned with tetrabromophenolphthalein ethyl ester and because of the difficulty in visual detection of the equivalence point at low iodide concentration. The validity of the titration method was shown by the recovery of 100.0% of potassium iodide from seven different samples having iodide concentrations equivalent to that obtained from the combustion procedure.

The suggested technique differs from that official in U.S.P. XVII and N.F. XII in that the iodine is converted into iodide and titrated with silver nitrate as is required for iodochlorhydroxyquin U.S.P. The official method converts iodine to iodide, then to iodate by oxidation with bromine in an acetate-buffered medium, removal of excess bromine by formic acid, removal of oxygen by displacement with nitrogen, conversion of iodate to iodine by treatment with iodide solution, and titration of the liberated iodine with standard sodium thiosulfate.

The official procedure has the advantage of producing six equivalents of iodine for each atom of iodine originally present, and is not subject to interference by chloride. The sample size allows titration volumes of about 30 ml. of 0.02 *N* thiosulfate.

The suggested procedure eliminates the need for further chemical treatment after combustion, but produces only one equivalent of iodide for each atom of iodine originally present. The sample size requires about 9 ml. of 0.01 *N* silver nitrate. The potentiometric end point prevents interference by chloride.

The choice between the two methods is certainly open to debate. The official method requires more handling, more reagents, a cylinder of nitrogen, use of a hazardous bromine solution, storage of standard sodium thiosulfate whose normality must be frequently checked and which is a secondary standard, and use of starch T.S. indicator which must be freshly prepared. In contrast, the suggested method uses the solution from the combustion and a stable solution of primary standard for titration, but does require the less common 10-ml. buret and silver electrode as well as a pH meter capable of use as a millivoltmeter. The official method might be best for a laboratory which routinely uses 0.02 *N* thiosulfate for iodine determinations, whereas the suggested method might be better for laboratories with a low volume of iodine titrations but with adequate instrumentation.

In several instances the data obtained by all methods is at least 4% lower than the theoretical values for the compound. In all cases where this is true, the compound is not official as the powdered material supplied to the authors for this investigation, but as the injection. The data obtained do not reflect on the validity of the assay methods; in many cases it is the manufacturers' policy to assay the powdered material for iodine content and then prepare the injection to meet the standards of the official compendia.

CONCLUSIONS

The proposed method utilizing the oxygen flask combustion is in all cases superior to or equal to other methods in recovery of iodine and generally equivalent in reproducibility. With the procedure suggested, an analyst with a minimum of practice can complete an analysis in 20 min., far faster than any of the presently official methods. The method is so rapid and simple that a technician could obtain excellent results in routine laboratory work.

Despite the general applicability of the suggested method, it is recommended that the alkaline zinc method be retained for appropriate compounds because of its case, absence of hazard, use of common equipment, and an indicator end point.

Quantitation of the PVA–Borate–Iodine Complex

By CARL A. PANNUTI, VINCENT DEPAUL LYNCH, ANTHONY J. MONTE-BOVI, and JOHN J. SCIARRA

While the PVA–borate–iodine complex is shown to be suitable for the qualitative determination of boric acid, attempts to adapt this to a colorimetric procedure were of no avail. A possible explanation is suggested as a dilution phenomenon.

IN A PREVIOUS publication (1), it was reported that the PVA–borate–iodine reaction was suitable for the detection of boric acid in urine. At the same time it was inferred that this test might be adaptable to a quantitative determination of boric acid, on the basis of the fact that the authors were able to detect as little as 0.3 mg. of that substance. The fact that this reaction involved the development of a color as an end point might also lead one to believe that variation in the color produced by different concentrations of boric acid could be used as the basis for a colorimetric assay.

In a series of experiments conducted along those lines in these laboratories, the following facts were ascertained.

(*a*) Simple dilution with water caused the typical blue-black color to be discharged. The resultant color was either yellow or red-brown. The intensity of the dilute color could not be related to differences in the concentration of any of the components of the reaction mixture. Colorimetric determinations were carried out using a Spectronic 20 colorimeter.

(*b*) The discharge of color could not be attributed to alteration in pH. It was determined that an optimum pH of 4.0 was necessary for initial color development, but that subsequent dilution caused the color to discharge even though the optimum pH was maintained throughout the series of dilutions.

Received March 4, 1966, from the College of Pharmacy, St. John's University, Jamaica, N. Y.
Accepted for publication March 28, 1966.

(*c*) A variety of water-miscible, organic solvents was tested to determine whether the discharge of color could be caused by the available excess hydroxyl or hydronium ions. A spectrum of glycols and alcohols caused color discharge. In addition, color loss was also noted with the addition of dioxane, acetone, and ethyl acetate. This seems to indicate that the change in color from blue to yellow is a dilution phenomenon not related to either excess hydroxyl or hydronium ions.

(*d*) In the case of dilution with absolute ethyl alcohol, it was noted that the yellow color which developed could be related to the concentration of boric acid. Using a Beckman model DB recording spectrophotometer, a linear relationship was established for concentrations of boric acid down to 10.0 mg. Below this concentration, only erratic readings were obtained. The developed color was discharged on standing. Decoloration was hastened when heat was applied. It was shown subsequently that the yellow color represented an excess of iodine.

(*e*) The above observations lead us to believe that this test, in all probability, will have to remain qualitative.

It must be concluded that the color developed in the PVA–borate–iodine reaction is dependent upon the optimum concentration of reactants in an optimum volume of solvent. The nature of the solvent is important to the extent that all reactants must be mutually soluble in it. The initial color is probably not due to a production of a color pigment in the complex formation, but rather to the ability of that specific concentration of substances to exhibit spectral absorbance within the blue range.

Preparation of Some Cyanoalkylpiperidines

By MORRIS FREIFELDER

Selective conversion of the pyridine ring was accomplished without attack of the nitrile group when some alkyl cyanoalkylpyridinium halides were hydrogenated in the presence of platinum oxide or rhodium on carbon catalyst.

CATALYTIC hydrogenation of a ring system is more difficult to achieve than reduction of a functional group. In the pyridine series the difficulty is due to the poisoning effect of the ring nitrogen or more likely to the effect of the resultant more basic piperidine nitrogen atom. Nevertheless, a number of examples have been cited where the ring was preferentially attacked when a methylene bridge separated it from a ketone group (1). In general this took place when the ring was quaternized. There are only a few examples of selective conversion when the carbonyl group is adjacent to the ring. Lyle and Warner converted 3-benzoylpyridine hydrochloride and methyl 3-benzoylpyridinium iodide to the corresponding benzoylpiperidines in 35–40% yield (2); Freifelder obtained 70% of 3-acetyl-1,4,5,6-tetrahydropyridine and 7% of 3-acetylpiperidine

from the hydrogenation of 3-acetylpyridine (3). Other investigators report selective conversion of the carbonyl group or concurrent reduction in such instances.

1-Methyl-3-cyanomethylpiperidine was obtained from the reduction of methyl 3-cyanomethylpyridinium iodide in the presence of platinum oxide or rhodium on carbon. The instability of 2- and 4-cyanomethylpyridines prevented any work on subsequent quaternization and reduction to obtain the isomeric 2- and 4-cyanomethylpiperidines. 1-Benzyl-3-cyanomethylpiperidine was also prepared and subjected to hydrogenolysis to yield 3-cyanomethylpiperidine.

Attempts were made to reduce 3-cyanomethylpyridine to the piperidine selectively in aqueous alcoholic hydrochloric acid or in glacial acetic acid. In all cases the nitrile group was perferentially attacked.

It had been postulated that the selective conversion of the ring which occurs when a quaternary compound is reduced is due to the existence of a single species incapable of reversibility as compared to the equilibrium existing between the base and the ionic form of an acid salt (1). The unsuccessful conversions in aqueous acidic media were probably due to water competing for protonation. In glacial acetic acid protonation apparently was not complete enough for selective ring reduction. When the hydrogenation of 2-(2-cyanoethyl)pyridine was carried out in trifluoroacetic acid selective conversion of the ring did not take place. On the other hand

reduction of the methiodide in 50% aqueous alcohol yielded 1-methyl-2-(2-cyanoethyl)piperidine in fairly good yield.

EXPERIMENTAL[1]

The following procedure was used to prepare the quaternary salts listed in Table I.

Methyl 3-Cyanomethylpyridinium Iodide (I).—A mixture of 11.8 Gm. (0.1 mole) of 3-cyanomethylpyridine and 21.3 Gm. (0.15 mole) of methyl iodide in 60 ml. of dry benzene was heated in a 183-ml. stainless steel rocker type bomb for 12 hr. at 100°. After cooling, the solid product in the reactor was filtered, washed with anhydrous ether, and dried.

Hydrogenation of the quaternary compounds was carried out in the following manner.

1-Methyl-3-cyanomethylpiperidine (IV).—A solution of 20.8 Gm. (0.08 mole) of I in 200 ml. of 90% aqueous alcohol was hydrogenated (3 Atm.) in the presence of 0.6 Gm. of platinum oxide.[2] Uptake for 0.24 mole was complete in 4 hr. The catalyst was removed by filtration. It was washed with 25 ml. of water and the combined filtrate and washings concentrated to dryness under reduced pressure. The residue was dissolved in a small amount of water and the solution, kept below 15°, was made strongly basic with 40–50% sodium hydroxide solution. The mixture was extracted thoroughly with benzene and the extract dried over anhydrous magnesium sulfate. The solution was then concentrated and the residue distilled. Gas-liquid chromatography of the distilled product as well as the other amines (V and VI) showed each to be a single component. Infrared examination gave no evidence of the presence of primary or secondary amine but did show the characteristic C≡N band at 4.46–4.48 μ. It was difficult to get good carbon, hydrogen, and nitrogen values unless the bases were analyzed immediately after distillation because they absorbed carbon dioxide so rapidly. Some were additionally characterized as salts. (See Table II.)

3-Cyanomethylpiperidine (VII).—A solution of 32.8 Gm. (0.153 mole) of V in 100 ml. of 95% ethanol containing 0.153 mole of dry hydrogen chloride was hydrogenated in the presence of 5.0 Gm. of 5% palladium on carbon at room temperature and 2 Atm. pressure. Hydrogen uptake was interrupted at 90% of theory to insure selectivity. After removal of catalyst, the solution was concentrated to dryness under reduced pressure. The residue was dissolved in 50–75 ml. of water and cooled to about 10–15° and kept cold while adding an excess of 50% sodium hydroxide solution. The oily layer was extracted with benzene, dried over anhydrous magnesium sulfate, and concentrated after filtration from the drying agent. The residue was distilled, b.p. 125° (15 mm.); n_D^{25} 1.4791; yield, 53%.

Anal.—Calcd. for $C_7H_{12}N_2$: C, 67.69; H, 9.74. Found: C, 67.79; H, 9.95.

The base picks up carbon dioxide rapidly and must be analyzed immediately. The found nitrogen value continued to drop after each analysis.

A hydrochloride melted at 140–142°. It was found to be a hemihydrate.

Anal.—Calcd. for $C_7H_{13}ClN_2 \cdot 0.5H_2O$: C, 49.55; H, 8.35; N, 16.52. Found: C, 49.39; H, 8.00; N, 16.58.

On further drying at 100° under reduced pressure for 8 hr. the salt appeared to stabilize at 0.25 H_2O.

Anal.—Calcd. for $C_7H_{13}ClN_2 \cdot 0.25H_2O$: C, 50.90, H, 8.24; Cl, 21.45; N, 16.96; O, 2.45. Found: C, 50.75; H, 8.35; Cl, 20.79; N, 16.98; O, 1.87.

Attempts to dry the salt at 130° *in vacuo* caused loss of hydrogen chloride.

Hydrogenation of 3-Cyanomethylpyridine in Acidic Media.—A solution of 11.8 Gm. (0.1 mole) of 3-cyanomethylpyridine in 50–75 ml. of water containing 1.0 to 1.2 moles of hydrogen chloride was hydrogenated in the presence of 0.350 Gm. of platinum oxide. Only 2 molar equivalents of H were absorbed. After removal of catalyst, concentration of the filtrate and basification, as in previous experiments, the crude product on infrared examination showed that the C≡N band was no longer present. The presence of the pyridine ring C=N, and the presence of primary or secondary amine was noted. On distillation about a 10% yield of 3-(2-aminoethyl)pyridine was obtained. The residue was a tarry formation.

In a reduction in glacial acetic acid containing 0.1% of concentrated sulfuric acid, 30% of the same amine was obtained. We never were able to show more than trace amounts of VII by gas-liquid chromatography in these or other experiments in various acidic media.

[1] Microanalyses were carried out by O. F. Kolsto and his group, infrared examination by A. Kammer and W. Washburn, gas-liquid chromatography by Mrs. Taimi Anderson. The author is grateful to these people for their assistance and to Miss Evelyn Schuber for the preparation of 2-(2-cyanoethyl)pyridine.

[2] A 15–20% ratio of 5% rhodium on carbon to substrate may be substituted. Both catalysts are available from Engelhard Industries, Newark, N. J.

In Vitro Determination of Defoaming Inactivation of Silicone Antacid Tablets

By MORTON REZAK

A simple and inexpensive *in vitro* test was utilized to evaluate the defoaming activity of a silicone defoamer in tablet combination with a number of commonly used antacid materials. The results covered the complete range of defoaming action.

THE USE OF silicone defoamers with routine antacid therapy has come into common practice where gas formation has been implicated as a difficulty in effective antacid therapy (1), and where gaseous distention is a factor in patient distress (2–4).

A study conducted in this laboratory indicated that the silicone defoaming action in an antacid-defoamer tablet was not stable, and seemed to reduce with aging. The objectives of this study were to (*a*) compare the defoaming activity of a silicone defoamer in tablet combination with commonly used antacids, (*b*) determine the stability of the above products.

EXPERIMENTAL

Selection of Antacids.—The antacids selected as representative of the antacids in use today were calcium carbonate, sodium bicarbonate, sodium citrate, aluminum hydroxide, magnesium trisilicate, magnesium hydroxide, magnesium carbonate, glycine, magnesium carbonate–aluminum hydroxide coprecipitate, magnesium peroxide, and bismuth subcarbonate. The silicone used is simethicone (Antifoam A, Dow Chemical Co.), an activated silicone.

Composition and Manufacture of the Tablets.—The following ingredients were used (mg./tablet): antacid, 400; cornstarch, 30; mannitol, 100; simethicone, 25; polyoxyl 40 stearate,[1] 3; lactose, 50; PVP, 80; microcrystalline cellulose,[2] 35; and magnesium stearate, 7; totaling 730.

Procedure.—The antacid, starch, and mannitol are blended. The simethicone and polyoxyl 40 stearate are melted together and added to the lactose. All the above materials are blended and granulated with an aqueous solution of the PVP. The granulation is wet and dry milled, blended with the cellulose and stearate, and compressed.

Both granulation and tablet were placed on stability at 45°.

PROCEDURES

Materials to be Tested.—The tablet to be tested was passed through a No. 20 screen. The granulation was tested as a granulation.

Foam.—The foam was generated by dissolving 200 mg. of a commercial laundry detergent in 100 ml. of purified water at 37°. The solution was placed in a 250-ml. graduated cylinder, and shaken vigorously until 150 ml. of foam was produced.

Defoaming Rate.—The material to be tested was placed into the graduated cylinder; the cylinder was then stoppered and inverted quickly 5 times to place the granules in contact with both foam and liquid. The clock was started and at each 15-sec. interval, the volume of remaining foam was noted, and the cylinder inverted once again. The test was considered complete after 2 min. or when all the foam disappeared, leaving the original 100 ml. of water in the cylinder.

Prolonged Defoaming Rate.—A defoaming rate was run as above, extending the time to 5 min. Tablets and pure simethicone were tested to obtain some estimate of free simethicone remaining in the tablets. The simethicone was spread out on micro-

crystalline cellulose at a concentration of 25 mg./Gm. to facilitate testing.

RESULTS AND DISCUSSION

The speed of action of a gastrointestinal defoaming agent may be an indication of its efficiency in dispersing gas *in vivo* (5). This can be demonstrated by its defoaming action. The results listed in Table I indicate that there is a wide variation of defoaming action depending upon the antacid used in a silicone defoamer-antacid tablet.

There is also an apparent aging effect on these tablets, as some of the tablets exhibited a decrease in defoaming activity with storage at 45°. These test results can be seen in Table II.

It is significant that those antacids which most inactivate the simethicone (Antifoam A) did so independently of whether or not the material was compressed. In Table III it is evident that the simethicone inactivation is just as pronounced in these granulations as in the compressed tablets.

An attempt was made to correlate the defoaming activity of the tablets with the defoaming activity of the pure simethicone. In Figs. 1 and 2, the foam reduction as a function of time is shown.

The complete defoaming range of the tablets is shown in Fig. 1. The calcium carbonate tablet releases the simethicone almost immediately, so that

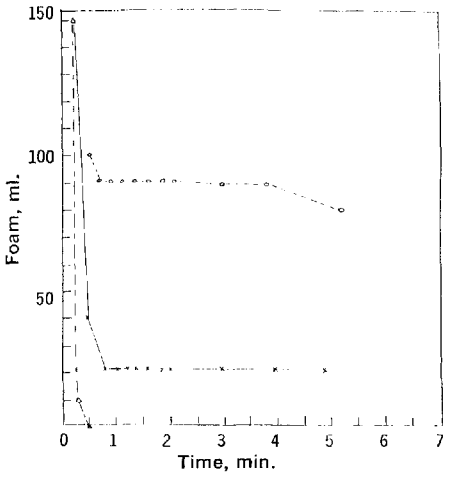

Fig. 2.—Foam depression of simethicone. Key: O, 5 mg.; ×, 10 mg.; Δ, 15 mg.

the foam disappears in 30 sec. The magnesium carbonate–aluminum hydroxide coprecipitate retards the simethicone, so that the foam drops after a 90-sec. delay. The aluminum hydroxide adsorbs the simethicone to a significant degree, so that a very slow reduction in foam height takes place.

In Fig. 2, a 15-mg. dose of plain simethicone approximates the calcium carbonate tablet curve in Fig. 1. The calcium carbonate tablet is at least equivalent to 15 mg. of free simethicone. Smaller doses of the simethicone quickly reduce smaller amounts of the foam, and do not approximate the simethicone-antacid tablet curves of Fig. 1.

There appears to be a gross correlation of the amount of foam reduction with the amount of free simethicone. In Fig. 2, we can see that 5 mg. of simethicone will reduce 60 ml. of foam, 10 mg. of simethicone will reduce 130 ml. of foam, and 15 mg. of simethicone will reduce at least 150 ml. of foam. Therefore, after 5 min., the aluminum hydroxide tablet had released the equivalent of approximately 7.5 mg. of free simethicone.

SUMMARY

An *in vitro* evaluation of the defoaming ability of antacid-silicone tablets was conducted. It was demonstrated that there are marked differences among the antacids tested with regard to their effect of the activity of the silicone defoamer.

The role of the amount of silicone defoamer was studied and correlated with foam depression. Stability studies indicate that some antacids will adsorb the silicone over a period of time.

REVIEWS

Atmospheric Oxidation and Antioxidants. By GERALD SCOTT. American Elsevier Publishing Co., Inc., 52 Vanderbilt Ave., New York, N. Y. 10017, 1965. x + 528 pp. 17 × 24.5 cm. Price $26.

This book is concerned with the oxidative degradation of organic compounds. Particular emphasis is placed on underlying mechanisms of autoxidation and antioxidant action. It is a well-written book containing an abundance of clear figures (174) and tables (172). More than 1200 references are listed, almost half of which are less than 10 years old. A particularly useful feature is the designation of general review references and others that are complementary to text discussion. The well-arranged table of contents and extensive (over 1400 entries) subject index enhance the value of the book as a reference source.

The first part (Chapters 1–5) deals with fundamental studies in simple systems and the classification of antioxidants by their mechanisms. Modes of breakdown of peroxides are considered in relation to the autoxidative process. Data from kinetic studies are used to give information on reaction intermediates of the oxidative free radical chain mechanism. Effective use is made of illustrative thermo-chemical calculations in discussing reactivity of hydrocarbons toward oxygen.

The various mechanisms by which antioxidants interrupt the autoxidative chain are discussed on the basis of chemical and kinetic evidence. The author distinguishes two mechanistically distinct classes of antioxidants: (*a*) radical chain-breakers that remove species in the propagation step; (*b*) preventive agents that remove sources of free radicals (peroxide decomposers). Synergistic effects obtained by combining both kinds of antioxidants in a system are considered.

Chapters 6 to 10 demonstrate the application of concepts to technological systems of oils, polymers, and rubbers. Behavior of oxidizable materials and the techniques used in measurement of deterioration are described in terms of mechanisms. Stabilization of oxidizable hydrocarbons, plastics, and unsaturated compounds is described in detail. A brief review of vitamin autoxidation includes an interesting discussion of coupled oxidation of vitamin A acetate in methyl linoleate.

The critical discussion of accelerated aging tests for evaluating rubber is especially noteworthy in Chapter 9. It is pointed out that accelerated tests of materials that undergo oxidative degradation do not always reflect stability under actual use conditions.

This excellent book is remarkably free of errors. It is recommended highly to all who wish to learn more about atmospheric oxidation and antioxidants.

The Mast Cells. By HANS SELYE. Butterworth, Inc., 7235 Wisconsin Ave., Washington, D. C. 20014, 1965. xxix + 498 pp. 17.5 × 25 25 cm. Price $19.75.

Dr. Selye provides, in a single volume, a detailed survey of the existing data and some previously unpublished observations on the mast cells. Much of the literature—more than 2500 references—published since discovery of the mast cell until the present has been abstracted and organized into 10 chapters: History, Definition and Terminology, Histology, Embryology, Comparative Anatomy, Agents Affecting Mast Cells, Diseases, Biochemistry, The Blood Basophil, and Theories. These chapters are subdivided into more specific sections.

The style of the book is such that it can be used to locate a specific point or to gain a general view of current knowledge. The author's critical evaluation of the literature and his own observations appear in narrative form at the beginning of the sections. The abstracts follow and are presented individually; they are further differentiated from the narrative by being printed in smaller type.

Among the author's unpublished work included in this book are his observations on organotropic mast-cell dischargers, the newly discovered phenomenon of "mastopexis" (the binding of foreign materials, especially metals, by mast cells), and the participation of mast cells in anaphylactoid inflammation, calciphylaxis, and calcergy.

Kinetic Methods of Analysis

By J. GORDON HANNA and SIDNEY SIGGIA

KINETIC CONSIDERATIONS always have been of prime importance to the analytical chemist in the development and use of his procedures. Because he can be satisfied with no less than quantitative recoveries, he must utilize optimum experimental conditions for his reactions. He uses these conditions not only to produce the desired stoichiometric reaction in the minimum time but also to obtain a specific reaction with the least interference from side or parallel reactions. Analytical chemists have gone a step further and are applying the kineticists' reaction rate techniques directly to the solution of analytical problems. This has yielded methods which give quantitative results based on reactions which are not necessarily complete. In fact, some methods require the occurrence of only a small fraction of the reaction. Also, procedures have been developed for the determination of traces of materials based on their catalytic effect on the rates of suitable reactions. Another result is the production of methods for the differential determination of two or more compounds in a mixture which are reacting concurrently but at different rates with a common reagent. These developments in the use of reaction rate approaches are considered in this review.

KINETIC METHODS FOR A SINGLE REACTIVE SPECIES

The application of kinetic principles to analysis renders possible the use of reactions which normally do not produce quantitative conversions because of the establishment of unfavorable equilibria or because of the necessity for impractically long reaction times. The concentration of a single reactive species can be determined in some cases based on an accurate knowledge of the rate constant and the measurement of the rate of reaction of the sample. A near quantitative conversion is not required because a measurement of the fraction of the material which has reacted during a specified time interval can be related directly to the original concentration. For example, if the reaction is first order, the integral form of the rate expression is

$$kt = 2.303 \log \frac{a}{(a - x)} \qquad \text{(Eq. 1)}$$

Then, if the reaction is run under carefully controlled conditions, and if x, which represents the amount of the initial concentration, a, which has reacted in time, t, is measured, a can be calculated using Eq. 1. The same technique can be used for second-order reactions, in which case the integral form of the rate expression is

$$kt = \frac{2.303}{(b - a)} \log \frac{a(b - x)}{b(a - x)} \qquad \text{(Eq. 2)}$$

Here b is the initial concentration of the reagent which must be known. If $a = b$, the integral form is then

$$kt = \frac{1}{(a - x)} - \frac{1}{a} \qquad \text{(Eq. 3)}$$

In practice, it sometimes is more convenient to

Received from the Olin Research Center, Olin Mathieson Chemical Corp., New Haven, Conn.

refer the rate found for the sample to a calibration curve prepared from data obtained using known amounts of the pure compound.

Blaedel and Petitjean (3) investigated the possibility of developing kinetic methods based upon measurements of the rate of a reaction at several times during the early stages of the reaction. They carried out a preliminary study of the utility of the approach using the alkaline hydrolysis of ethyl acetate. The reaction vessel was part of a tuned circuit of a high frequency oscillator and conductance changes in the solution as the reaction proceeded caused changes in the frequency of the loaded oscillator. The amount of organic compound in the sample being analyzed was then determined by referring the measured rates of frequency change, f/t, to a working curve plotted from data obtained with known amounts of the substance being determined. The results obtained with ethyl acetate indicated that the method yielded highly precise determinations of single constituents in samples free of interferences. They then applied the developed method successfully to acetylacetone determinations by measurement of the reaction rate of the ketone with hydroxylamine hydrochloride. This particular oximation reaction does not reach substantial completion in a practical period of time and, therefore, presents problems in the usual straightforward procedures. These investigators concluded that data obtained during the first 5 or 10 min. of a reaction are capable of yielding results accurate to 0.3% for simple systems.

The same principle has been used to determine glucose in serum plasma or blood, based on the enzyme-catalyzed oxidation of the sugar to gluconic acid and hydrogen peroxide. Guilbault and co-workers (27) followed the rate of peroxide production by recording the potential difference between two platinum indicator electrodes polarized with constant current. The potential changes are proportional to the glucose concentration. Malmstadt and Piepmeier (47) used a pH stat to maintain the pH stationary at a preselected value with continuous neutralization of the gluconic acid formed during the reaction. The instrument which they described provides direct digital readout of initial rate data that are proportional to the concentration of glucose present. Results reproducible within 1–2% in the 50–250 p.p.m. range were obtained. Use also has been made of the color produced by the action of the peroxide formed on *o*-tolidine (2, 68) or on *o*-dianisidine (45). The elapsed time for the production of a definite absorbance change is proportional to the initial rate and to the concentration of glucose. The peroxide produced during the reaction has been determined also by its rapid molybdate-catalyzed oxidation of iodide and the glucose oxidation followed by measuring the iodine formed potentiometrically (46, 58), spectrophotometrically (2, 41), and amperometrically (56).

Pardue and Frings (60) used autometric amperometric control equipment to provide a direct readout of the time required for a definite amount of iodine to be produced from iodide as the result of the enzyme-catalyzed oxidation of galactose to peroxide. This amperometric method was further extended to furnish digital readout in concentration units (61). Frings and Pardue (23) also used an automatic spectrophotometric measurement of the peroxide produced by the enzymatic reaction by measuring the color produced by the oxidation of *o*-dianisidine. A similar arrangement was used to obtain automatic direct readout of p.p.m. cystine based on potentiometric measurement of the rate of an azide–iodine reaction (57, 59, 62).

Malmstadt and Hadjiioannou (42) reported a similar technique for the determination of alcohol in blood. The time required for a small fixed change in absorbance as a result of the selective enzyme-catalyzed oxidation of the alcohol was measured in the early stages of the reaction, and this value related directly to the alcohol concentration. The method was used to determine alcohol in the range 0.015–0.300 Gm./100 ml. of blood with a relative error of 2–3%. Sample sizes ranged from 0.1–0.25 ml. and the time of measurement ranged from a few seconds to 2 min.

Malmstadt and Hadjiioannou (43) determined some L-amino acids by an automatic spectrophotometric reaction rate method based on the coupled enzyme reaction in which oxidative deamination is specifically catalyzed by L-amino acid oxidase to form hydrogen peroxide. The time required, from a few seconds to about 2 min., for the reaction to produce a small fixed amount of colored product as a result of the reaction of the resultant peroxide with *o*-dianisidine was related to the initial amino acid concentration. The concentration range determined was 4–50 p.p.m. with a relative error of about 2%.

A pH stat with digital readout of data collected early in the hydrolysis of urea in the presence of urease was used by Malmstadt and Piepmeier (47). The pH was maintained constant by adding dilute hydrochloric acid to neutralize the ammonia formed. The increments of acid added during a preset time interval, about 2.5 min., was counted. The count was directly proportional to the urea concentration. The procedure was

tested in the 2- to 10-p.p.m. range, and the results were reproducible within 1–2%.

The relationship between the concentration of the catalyst and the rate of the catalyzed reaction often is used to quantitatively estimate the catalyst. The approach is not new, but new and revised procedures based on it continue to appear because, where applicable, it is one of the most sensitive techniques devised to determine minute traces of materials. Some of these methods are cited here as illustrations.

The catalytic effect of copper on the oxidation of cysteine to cystine and the subsequent measurement of oxygen evolved in a specified time has been used to determine copper in blood (82) and in milk (9). The reduction of ceric ion by arsenite in an acid medium is catalyzed by soluble iodides. Sandell and Kolthoff (71) measured the time required for this reaction to go to completion and found a linear relationship between the reciprocal of that time and the quantity of iodine present. The reduction of the yellow ceric to colorless cerous ion was followed colorimetrically. The change in absorbance was recorded continuously, and the slope of the recorded curve was related to the iodine concentration by Chaney (14). Lein and Schwartz (39) used the first-order velocity constant as a function of the iodine concentration. Malmstadt and Hadjiioannou (44) noted the time, 10–100 sec., required for the reaction to consume a small fixed amount of ceric ions, and, therefore, the absorbance to decrease by a preselected amount, measured automatically, and related this directly to the iodine concentration. The latter investigators reported the determination of iodine in the range of 0.015–0.45 mcg. with a relative error of about 1–2%. Hadjiioannou (28) used this procedure to determine iodine in common salt and in natural waters. This same reaction system was used for the determination of labile organic-bound iodine by Zak and Baginski (86). Yatsimirskii and co-workers (84) determined micro amounts of iodides by their catalytic action on the oxidation of thiocyanate with ferric iron and with nitrate. Changes in the extinction of the thiocyanate complex of iron were evaluated. The sensitivity of this method was reported to be 0.001 mcg./ml. and the error of a single determination was about 2%.

Underwood, Burrill, and Rogers (81) determined submicrogram quantities of silver using the catalytic action of silver on the persulfate oxidation of manganous ion to permanganate. Spectrophotometric measurement at 525 mμ after a specified time was related to a calibration curve prepared using standard silver solutions. The practical lower limit of the method was reported to be about a millimicrogram of silver.

Vanadium operates as a catalyst in the oxidation of *p*-phenetidine citrate by potassium chlorate in the presence of phenol as an activator yielding a colored product. Bontschev (10) determined 0.1 mcg. of vanadium by means of the linear relationship between the extinction at 510 mμ and the time of heating. Fishman and Skongstad (19) used the catalytic effect of vanadium on the rate of oxidation of gallic acid by persulfate in acid solution to determine vanadium in water. The absorbance at 415 mμ was determined and compared with standard solutions treated in an identical manner. The procedure is applicable for concentrations of vanadium in the range 0.1–8.0 mcg./L. and shows a standard deviation of 0.2 or less.

Alizarin is oxidized only slowly by hydrogen peroxide but in the presence of cobalt chloride in alkaline solution, the rate is increased in proportion to the concentration of alizarin and the cobalt. The color of the alizarin is destroyed by the oxidizing action of the peroxide, and then if the extinction of the solution is measured at intervals after the addition of the cobalt solution, the rate of reaction can be determined. A calibration curve was used (64) to determine cobalt in concentrations ranging from 0.001–0.0066 mcg./ml. Bognar and Jellinek (5) determined as little as 0.002 mcg. of cobalt with an accuracy of ±10% by measuring the rate of reaction of diphenylcarbazone and hydrogen peroxide in the presence of iron. They measured the time interval to the attainment of a specific extinction by the reaction mixture.

Yatsimirskii and Raizman (85) utilized the catalytic effect of zirconium and hafnium on the oxidation of iodide by hydrogen peroxide to determine the concentrations of these catalysts.

Bulgakova and Zalubovskaya (13) followed amperometrically the rate of iodide oxidation with hydrogen peroxide as a method to determine molybdenum in cadmium sulfide and in lithium fluoride crystals.

Pantaler (52) determined tungsten and molybdenum based on the catalytic oxidation of rubeanic acid by hydrogen peroxide in 0.1 *N* hydrochloric acid. He plotted absorbance against time and obtained the amount of tungsten or molybdenum by comparing the slope of the line with slopes given by standard solutions. He reported the method satisfactory for 0.1 mcg. of either metal in 25 ml. of reaction mixture.

Babkin (1) followed the rate of the manganese-catalyzed permanganate–oxalate reaction to determine concentrations of manganese in the

0.01–0.6 mg. range. The results were obtained from a calibration curve constructed for the relationship between reaction time and amount of manganese. Fernandez, Sobel, and Jacobs (18) used the oxidation of leucomalachite green with periodate in the presence of manganese for the determination of submicrogram amounts of manganese in human serum. The progress of the reaction was followed photometrically, and the slope of the rate curve was compared with the slope for a standard curve to calculate the manganese content.

Bognar and Sarosi (6) investigated the effect of osmium tetroxide on the kinetics of oxidation of hydroquinone, orcinol, and 1,3-dihydroxynaphthalene by hydrogen peroxide and found they could determine as little as 0.001 mcg. of osmium tetroxide in 5 ml. of solution. (Ethylenedinitrilo) tetraacetic acid (EDTA) does not interfere with the catalytic reaction so that this compound could be used to increase the selectivity of the method. The same workers (7) also determined osmium tetroxide based on its catalytic effect on the oxidation of 3,3′-dimethylnaphthidine by potassium chlorate. The formation of the violet-red colored product was followed spectrophotometrically.

Michalski and Wtorkowska (50) established the optimum conditions for the determination of sulfide and thiosulfate (51) from the catalytic effects on the iodine–azide reaction. The rate was determined from the changes in iodine concentration which was followed amperometrically with a rotating platinum indicator electrode. The value of the potential which should be applied to provide the limiting current, proportional to concentration, was found from polarographic measurements. Sulfide was determined in the range 10^{-15} to 10^{-18} Gm./ml. with a deviation from the mean of less than 10%.

The catalytic activities of acids and bases in selected reactions can be used for the determination of the concentrations of these species. For example, Clibbens and Francis (15) and Francis and Geake (22) found the decomposition of nitrosotriacetonamine into nitrogen and phorone to be a function of the catalytic activity of hydroxyl ion. The original concentration of nitrosotriacetonamine was known and the rate of decomposition found by measuring the nitrogen produced as a function of time. A relationship between the first-order velocity constant for the reaction and the hydroxyl ion was determined and used. Duboux (17) used a proportionality between the hydrogen ion concentration and the velocity constant for the acid-catalyzed inversion of sugar to determine acidity.

The general enzymatic reaction rate method can be used also to determine enzyme activity. Hadjiioannou and Santos (29) determined serum lactic dehydrogenase from the effect of this enzyme on the rate of oxidation of lactic acid in the presence of diphosphopyridine nucleotide to form a species absorbing in the ultraviolet. An automatic potentiometric method for the determination of glucose oxidase activity similar to the procedure used to determine glucose has been demonstrated (63). The direct electrochemical measurement of peroxide produced has been used also to determine glucose oxidase (27). The same electrochemical technique has been used to determine cholinesterase and acetylcholinesterase based on the rate of enzymatic hydrolysis of thiocholine ester by the enzyme sample (36). The method has been extended to the analysis of some highly toxic organophosphorous compounds which act as anticholinesterase compounds where the decrease in rate of the cholinesterase–butyrylthiocholine ester hydrolysis is linearly related to concentration of the organophosphorous compound (26).

Magerum and Steinhaus (40) introduced an interesting kinetic method for the determination of ultratrace concentrations of metals. They used a coordination chain reaction involving the exchange of triethylenetetramine–nickel II (trien–Ni II) and (ethylenedinitrilo)tetraacetocuprate II (EDTA–Cu II). The presence of free ligand, which can originate from the pure complexes or can be added separately, greatly accelerates the reaction. The bright blue color of trien–Cu II produced is used to follow the progress of the reaction. A metal at 5×10^{-8} *M* concentration can react with free ligand (EDTA) reducing the exchange rate. The metal ion detected in this manner need have no connection with the reactant metals, but only be capable of reacting with EDTA. The reaction is first order with respect to the EDTA concentration and was followed for at least half-life, normally 10–15 min. A calibration curve was prepared of the rate constant against concentration of EDTA used. Experimental results were given down to 10^{-8} *M*.

DIFFERENTIAL REACTION RATES TO ANALYZE MIXTURES

The differential reaction rate approach is effective for the analysis of mixtures of two or more compounds, each of which reacts at a different rate with a common reagent, resulting in products which are either identical or are indistinguishable by the analytical method used.

The rate of disappearance of the reagent or the appearance of a product is monitored to obtain data for the total reaction of the components. Usually a graphical analysis or an equivalent mathematical treatment of the data based on the appropriate rate law is then applied to quantitatively resolve the mixture. The process normally requires a prior knowledge of the reaction order. The applicable graphical plot for a mixture of two reactive components shows a linear portion arising from the reaction of the slower component after substantially complete consumption of the faster component has occurred. The extrapolation of this linear portion to zero time provides data which can be used to calculate the original composition of the mixture.

Thus, for a first-order reaction log $(a - x)$ is plotted against t, based on Eq. 1. In this case, a represents the total concentration of the reactive components of the mixture and is determined by an independent method or by permitting the rate reaction to go to completion. For a two-component mixture, $a = a_1 + a_2$, if a_1 and a_2 are the concentrations of the faster and slower reacting constituents, respectively. When the final linear portion of the plot is extrapolated to $t = 0$, $x = a_1$ and $a - x = a - a_1 = a_2$, and sufficient data are then available to calculate the composition of the mixture. This process is illustrated in Fig. 1. If P is the value at the intercept $t = 0$, then from Eq. 1

$$\log a_2 = P \qquad \text{(Eq. 4)}$$

The concentration of the remaining component, a_1, is obtained by difference from a.

In some cases, it may be more convenient to transform a second-order reaction, one that is first order with respect to the reactant to be determined and first order with respect to the reagent, into one that is pseudo first order. To achieve this, the reagent is used in sufficient excess that its concentration can be considered constant. In this event, the data are treated according to the normal first-order rate laws. However, in most situations, if a large excess of reagent is

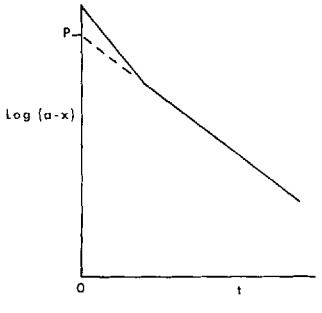

Fig. 1.—Graphical extrapolation procedure for a first-order reaction.

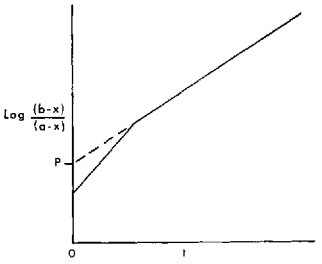

Fig. 2.—Graphical extrapolation procedure for a second-order reaction.

present, the reaction becomes so rapid that it is not manageable.

The procedure is based on Eq. 2 for a second-order reaction if the total concentration of the reactants and the concentration of the reagent are unequal. The initial concentration of the reagent, b, and the total initial concentration of reactants must be known and log $[(b - x)/(a - x)]$ is plotted against time. Extrapolation of the final linear portion is performed as described for the first-order reactions and is illustrated in Fig. 2. For the second-order case, at the intercept, $t = 0$,

$$\log [(b - a_1)/(a - a_1)] = P \qquad \text{(Eq. 5)}$$

Eq. 5 is solved for the concentration of the faster reacting constituent, a_1, and a_2 is determined by difference from a.

A plot of $1/(a - x)$ against t is used for the special second-order rate situation where $a = b$ (Eq. 3). At the intercept of the extrapolated final portion of the plot with the zero time axis

$$1/a_2 = P \qquad \text{(Eq. 6)}$$

Eq. 6 can then be solved for a_2, and a_1 obtained by difference. This procedure based on the equivalency of the total concentration of the components of the mixture determined and the reagent concentration is more convenient in some cases and simplifies the computations. If there is not a precise match of a and b, however, a small error in the slope of the linear portion can result in a large error in the calculation of a_2, particularly if a_1 is relatively large. Also, if the imbalance is quite significant, the latter portion of the curve will not be linear. Reilley and Papa (66) rearranged Eq. 3 and obtained the form indicated in Eq. 7.

$$x = k_2 a_2 (a - x)\, t + a_1 \qquad \text{(Eq. 7)}$$

Here k_2 represents the rate constant for the slower reacting component. When x is plotted against $(a - x)t$, a straight line is obtained after substantially all a_1 has reacted. The slope of this straight line portion is then $k_2 a_2$, and a_1 is the intercept at $t = 0$.

A scheme has been presented for differential rate analysis for second-order reactions applicable to mixtures of organic compounds which react with differing stoichiometry (8). It involves the introduction into Eq. 2 of a term indicating the number of moles of a polyfunctional compound which reacts with the reagent. It is illustrated by application to the hydrolysis of mixtures of cyclotrimethylenenitramine and cyclotetramethylenenitramine by sodium hydroxide. However, such systems usually can be handled easily on the equivalency basis rather than on the mole basis without resorting to special equations.

ANALYSES BASED ON SINGLE AND DOUBLE POINTS

It is possible to calculate the concentration of each component in a binary mixture based on a single determination after a measured reaction time if the rate constant for the reaction of each component and the total original concentration of the components are known. If measurements are made at two separate times, it is also possible to calculate the original composition without the use of rate constants.

Lee and Kolthoff (38) expressed the first-order rate law as shown in Eq. 8.

$$a - x = a_1 e^{-k_1 t} + a_2 e^{-k_2 t} \qquad \text{(Eq. 8)}$$

The rate constants for the two components are k_1 and k_2. Therefore, if $(a - x)$ is measured and k_1, k_2, and t are known, then the values of a_1 and a_2 can be found from a calibration curve prepared from the analysis of known mixtures or from calculations based on Eq. 8. The calibration curve is the linear plot obtained from values of $(a - x)/a$ *versus* a_1/a. Garmon and Reilley (24) proposed a double point method also based on Eq. 8. They determined the amount of reaction at two different time intervals, substituted the known and measured values into Eq. 8, and solved the two equations simultaneously to obtain values for a_1 and a_2.

Reilley and Papa (66) based a single point method for second-order reactions on Eq. 3. To make this equation applicable they arranged the concentration of the reagent equal to the total concentration of the components in the mixture being determined, *i.e.*, they used the conditions that $a = b$. In addition to the value of x measured at a single time, the rate constant must be known. The rate constants need not be known if x is measured at two different times and the resulting two equations are solved simultaneously.

The single and double point methods have been extended so that it is not necessary to have the condition of equivalency of the reagent concentration and the total sample concentrations (54). In this case, Eq. 2 is used with the requirement that the value for x is obtained after complete reaction of a_1, and the rate constant for the reaction of the slower component of the mixture is known. Again this process can be expanded to a double point method obviating the need for the rate constant if the process of solving simultaneous equations is used.

Roberts and Regan (67) proposed a somewhat different approach for the analysis of mixtures. They changed a normally second-order reaction to pseudo first order by having the concentration of the sample mixture in large excess relative to the reagent. Then they represented the first-order rate constant, k, by

$$k = k_1 a_1 + k_2 a_2 \qquad \text{(Eq. 9)}$$

Because $a_1 = a - a_2$, Eq. 9 can be rewritten to obtain

$$a_1 = \frac{k - k_2 a}{k_1 - k_2} \qquad \text{(Eq. 10)}$$

If k_1 and k_2 are separately determined for pure compounds, a is determined and k is measured for experimental mixture, then Eq. 10 can be solved for a_1, and a_2 can be obtained by difference from a.

Greinke and Mark (25) used the Roberts and Regan approach but followed the reaction in two different solvent mediums and obtained two different over-all pseudo first-order rate constants. Then by proper substitution in Eq. 9 and simultaneous solution of the two resulting equations, they were able to resolve binary mixtures.

APPLICATIONS OF DIFFERENTIAL KINETIC ANALYSIS

The differential kinetic approach has proven quite general and has been applied to the analyses of most of the organic functional groups. Siggia and Hanna (73) used the second-order graphical method involving extrapolation to the zero time intercept to analyze mixtures of hydroxyl-containing compounds. They monitored the reaction with acetic anhydride and determined primary alcohols in the presence of secondary alcohols, primary hydroxyl groups in polyhydric alcohols also containing secondary hydroxyl groups, and an alcohol in the presence of its next higher homolog as well as in the presence of one further separated in the series. Reilley and Papa (66) applied the graphical approach based on Eq. 7 and also the single and double point methods with the condition that $a = b$ to analyze mixtures of *n*-butanol and *sec*-butanol. Hanna and Siggia

(32) determined the primary hydroxyl group content of polyglycol ethers by graphical extrapolation of the kinetic data obtained by reaction of the hydroxyls with both acetic anhydride and phenyl isocyanate. Budd (12) substituted phthalic anhydride as the reagent for the same system when aldehydes or phenols were present. Hendrickson (33) used an infrared method to determine primary hydroxyl groups in polyglycol ethers. He used trityl chloride as the reagent, followed the disappearance of the hydroxyl band, and performed a graphical analysis of the kinetic data. Willeboordse and Critchfield (83) followed the disappearance of the NCO band in the infrared spectrum as the hydroxyl groups of mixtures of alcohols including polyglycol ethers reacted with phenyl isocyanate. They showed the applicability of the graphical approach and the single and double point methods to their process. They also analyzed ternary mixtures of alcohols based on the equations worked out by Schmalz and Geiseler (72). These equations require two data points and the rate constants, but become very involved and impractical for more than three component mixtures. Mark (48) published data showing that enzyme catalyzed reactions can be applied to the analyses of mixtures of ethanol and *n*-propanol by a kinetic method involving double points. He used alcohol dehydrogenase to catalyze the oxidation of the alcohols at different rates and followed the reactions spectrophotometrically.

Garmon and Reilley (24) analyzed mixtures of glycolic and diglycolic acids by measuring the color produced with 2,7-dihydroxynaphthalene at two different reaction times and used the double point technique to calculate the concentrations. Roberts and Regan (67) analyzed mixtures of carboxylic acids based on the rates of reaction with diphenyldiazomethane. They applied their technique of having the concentration of the carboxylic acid mixture in large excess relative to the concentration of the reagent and based the calculations on Eq. 10.

Lee and Kolthoff (38) analyzed mixtures of esters by comparing the amount of saponification after a selected time interval with a calibration curve prepared using known concentration mixtures.

Lee and Kolthoff (38) also analyzed mixtures of carbonyl compounds in the same manner based on the rates of decomposition of the bisulfite addition products. Only aldehydes and a few reactive ketones can be determined with this reaction. Fowler, Kline, and Mitchell (20, 21) determined aromatic aldehydes in mixtures with aromatic ketones by their rates of reaction with hydroxylamine hydrochloride. They used calibration curves to relate the amount of reaction after a specified time to the original concentration. Siggia and Hanna (73) applied the second-order graphical approach to the oximation reaction and analyzed mixtures of an aldehyde and a ketone, and mixtures of two aldehydes and mixtures of two ketones. They followed the reaction by maintaining the pH constant by titrating the hydrochloric acid as it was liberated from the reagent. Papa and co-workers (55) followed the course of the oximation reaction with a direct reading conductance meter. They made the reaction pseudo first order by adding the reagent in large excess and then compared the time interval for the reaction of a preselected fraction of the mixture and a predetermined calibration curve. Greinke and Mark (25) employed this same indicating technique but used two different alcohol–water concentration mediums to obtain data for their evaluation of mixtures of ketones based on Eq. 9. Sihtola, Neimo, and Sumiala (80) applied the second-order graphical approach to analyze the carbonyl groups in cellulose and were able to classify six different carbonyl groups present according to reactivity. They determined the slowest component first from the intersection of its extrapolated line with the zero time axis as usual. Then they subtracted the contribution of the slowest component from *a* and *b*, made a new plot, and performed the extrapolation again to obtain the value for the concentration of the next slowest component. They repeated this procedure until all components were evaluated. Papa, Mark, and Reilley (53) applied both single and double point methods to analyze fructose and glucose in aqueous media and in blood. They measured the rate of formation of molybdenum blue from Mo VI and also analyzed mixtures of sucrose and fructose and of sucrose and glucose. Mark and co-workers (49) used 2,3,5-triphenyl-2H-tetrazolium chloride as a reagent for the determination of mixtures of reducing sugars. A red formazan was formed which was measured spectrophotometrically to follow the reaction. The double point method and the solution of simultaneous equations were used in the calculations. Krivis and Supp (37) demonstrated the use of polarography combined with a graphical handling of the data to evaluate mixtures of Δ^4-3-ketosteroids and $\Delta^{1,4}$-3-ketosteroids. The mixtures were reacted with semicarbazide and hydrocortisone–prednisolone and cortisone–prednisone mixtures were differentiated.

Hanna and Siggia (30) adapted the reaction of amines with phenyl isothiocyanate to the differential kinetic analysis of mixtures of primary and

secondary amines, mixtures of homologous primary and of secondary amines, and mixtures of aliphatic and aromatic amines. The reaction to form thiourea is a second-order process and the graphical extrapolation technique was applied.

Siggia, Hanna, and Serencha (78) measured the rate of evolution of ammonia as a result of alkaline hydrolysis to analyze mixtures containing both a nitrile and an amide as well as binary mixtures of each of these compounds. Standard first-order rate plots were made from the data obtained and the linear portion extrapolated to zero time to calculate the composition of the mixture.

Siggia, Hanna, and Serencha (75) used both bromination with free bromine and catalytic hydrogenation with hydrogen gas followed by graphical extrapolation of the rate curves to resolve qualitatively mixtures of unsaturated compounds. The decrease in bromine content of the bromination reaction mixture was followed colorimetrically with time and showed a second-order rate process. In the hydrogenation process, the hydrogen was present in a large excess causing the reaction to proceed in a pseudo first-order pattern. Polgár and Jungnickel (65) described a method to measure the amount of substitution realized when bromine was added to unsaturated linkages. Several additional determinations were made at times in excess of that needed for complete saturation of the compound. They plotted the results against time and extrapolated the final linear portion to zero time to obtain the correct value for the addition reaction. Kolthoff and Lee (35) and Saffer and Johnson (69) applied the rates of reaction of perbenzoic acid with olefinic double bonds as a basis for differential analysis. They found the reaction valuable to distinguish between the amounts of internal and external double bonds in polymers. Reference of the amount of reaction after a specified time was related to calibration curves to determine the compositions of mixtures. Schmalz and Geiseler (72) also used the perbenzoic acid reaction to analyze mixtures of unsaturated compounds. They determined the rate constants for the components based on a single reaction of a mixture. Their calculations were based either on the differential equations, using graphically determined values of the derivatives, or on the integrated rate laws, using the area under the experimentally determined reaction rate curves. The derivated rate constants were then used to calculate the composition of the sample mixtures. Connor and Wright (16) used the difference in rates of the addition of mercuric acetate to double bonds to determine the *cis–trans* concentration ratio in isomer mixtures, specifically for the analysis of mixtures of ethyl oleate and ethyl elaidinate.

Salzman and Gilbert (70) differentiated natural smog oxidants into components by following the rate of oxidation of potassium iodide colorimetrically. The reaction showed a pseudo first-order rate process because the iodide was present in a large excess. They applied the graphical method to resolve the mixtures.

Hass and Weber (34) found a linear relationship between the second-order rate constants for the reaction of mixtures of the monochlorides of *n*-pentane and isopentane and the composition. Brown and Fletcher (11) used the slope and zero time intercept of the first-order rate plot of the hydrolysis of mixtures of isomers of diethyl-*tert*-butylcarbinyl chloride for analysis.

Siggia, Hanna, and Serencha (77) measured the rate of liberation of nitrogen from diazonium compounds in the presence of cuprous chloride to analyze mixtures of these compounds. They found the decomposition followed a first-order pattern and applied the graphical extrapolation procedure.

Block, Morgan, and Siggia (4) combined the graphical differential reaction rate technique with the micro-Dumas method to analyze mixtures of nitrogen-containing compounds. The reactions studied were first order with respect to the nitrogen-containing compound.

Special approaches available to monitor rapid reactions should provide the mechanics for the performance of the differential rate analyses of mixtures of inorganic compounds. Hanna and Siggia (31) demonstrated that continuous flow techniques can be applied to the analysis of mixtures of iodate and bromate, periodate and bromate, and dichromate and bromate. These analyses involved the observance of the point of appearance of the starch–iodide color in the flow tube as a result of the reaction with potassium iodide. Various measurement techniques can probably be applied for other reactions; therefore, the scope of the flow systems for differential analysis is potentially wide.

Siggia, Hanna, and Serencha (76, 79) demonstrated that for analytical purposes, data obtained from the rates of distillation of mixtures, the rates of effusion of mixtures of gases through a small orifice, and the dialysis of mixtures under specific conditions could be treated in a manner similar to the treatment of data from chemical reactions. The distillation procedure was applied to mixtures of organic acids, mixtures of alcohols, mixtures of carbonyl compounds, and mixtures of aromatic compounds. The effusion method was applied to mixtures of both inorganic and organic gases. The dialysis method was found

applicable to mixtures of inorganic salts, of salts of organic acids, of inorganic acids, of organic acids, of amines, of sugars, and of amino acids.

Siggia and Hanna (74) have pointed out that in the case of some binary mixtures the effect of the presence of the faster reacting component is to decrease the rate of reaction of the slower component. When the graphical approach is used, this effect works to an advantage because the experimental differences between the slopes are more pronounced than are expected from theoretical plots. Methods that rely on rate constants obtained using pure materials for the final calculations, however, can give significant errors. The effect was noted particularly for mixtures of some ketones determined by the oximation procedure and mixtures of oleates determined both by bromination and hydrogenation.

Kinetics of Reactions Involved in Penicillin Allergy I

Mechanism of Reaction of Penicillins and 6-Aminopenicillanic Acid with Glycine in Alkaline Solution

By MICHAEL A. SCHWARTZ and GAY-MAY WU

The principal antigenic determinant of penicillin allergy, penicilloyl-protein, may be formed either by direct reaction of penicillin with protein, or through penicillenic acid, a rearrangement product of penicillin. As part of a study of the mechanism of the direct reaction, the kinetics of reaction of glycine with a series of penicillins and 6-aminopenicillanic acid has been investigated. The aminolysis of penicillins by glycine is general base catalyzed, while the reaction with 6-APA is uncatalyzed. The latter is probably due to intramolecular general-base catalysis. The rates of reaction with glycine of all the penicillins studied are of the same order of magnitude. This is in contrast to the rates of penicillenic acid formation which are highly dependent upon the nature of the penicillin side chain. The pertinence of these results to the mechanism of formation of penicillin antigen is discussed.

It is generally agreed that the principal antigenic determinant of penicillin allergy is the penicilloyl group covalently bound to body protein, probably through ϵ-amino groups of lysine residues (1, 2). As shown in Scheme I, there are two pathways by which the antigen may form. One involves the known rearrangement of penicillin to penicillenic acid (II) which is known to react rapidly with amines. The other is a direct reaction of protein with penicillin. The latter will produce the α-diastereoisomer of the penicilloamide while the penicillenic acid route requires isomerization of the asymmetric carbons (marked with asterisk in Scheme I) of the β-lactam ring to produce a mixture of diastereoisomers.

The evidence for the penicillenic acid route was recently summarized by Levine (3). (*a*) Penicillenic acid has been found in penicillin preparations (4); (*b*) while penicillin does react rapidly with ϵ-aminocaproic acid at pH 11.5, this reaction would be slow at physiological pH; (*c*) penicillenic acid is a very reactive compound chemically (5); (*d*) studies on the nature of antibody to penicillin G indicated specificity toward the mixture of diastereoisomers of the benzylpenicilloyl haptenic group rather than for the α-diastereoisomer alone (6).

On the other hand, evidence has been accumulated to show that the direct reaction of penicillin with protein may play a more important role than previously thought. Thiel, Mitchell, and Parker (7) found that the sera of most of 114 patients allergic to penicillin contained antibody specific for the α-diastereoisomer of penicilloamide. This is in direct contrast to Levine's results cited above (6). More recently two groups (8, 9) have found that penicillins can indeed combine with protein at neutral pH at 37° *in vitro*. These included penicillins which were known to produce penicillenic acid at relatively low rates. Also included was 6-aminopenicillanic acid (6-APA), the nucleus common to all penicillins, which cannot form a penicillenic acid. It is known that 6-APA is antigenic in rabbits, and it has been suggested as an agent causing penicillin allergy (10).

The present work was undertaken to investigate the rates and mechanisms of reactions of penicillin which may be involved in penicillin allergy. Rather than a complex protein, glycine was selected as a model amine for study because of its ready availability in high purity, and its high solubility. The rate of penicillenic acid formation as a function of pH has also been measured for several penicillins.

Formation of Penicillin Antigen

Scheme I

EXPERIMENTAL

The penicillins were all commercial products.[1] Glycine and mercuric chloride were Fisher certified reagent, as were the other reagents used.

The rates of formation of penicillenic acid from penicillin were measured by following the increase in absorbance at 322 mμ as a function of time. This wavelength is characteristic of the penicillenic acid chromophore. The rates were determined in a series of buffers extending over the pH range 1–4 at 34° on a Beckman DB recording spectrophotometer with thermostated cell compartment. Mercuric chloride was added to the buffer in a concentration equal to the initial penicillin concentration. It was known that mercuric chloride stabilizes the penicillenic acid (11). The authors' preliminary studies showed that mercuric chloride had no effect, however, upon the *rate* of penicillenic acid formation.

The rates of reaction of the penicillins with glycine were determined by following the changes in optical rotation accompanying opening of the β-lactam ring of the penicillin (12) with a Perkin-Elmer model 141 photoelectric polarimeter using a mercury vapor source with filter for 365 mμ. The glycine itself acted as buffer and maintained pH within less than 0.1 unit during a single determination. Ionic strength of the buffers was brought to 0.5 by addition of potassium chloride. Initial penicillin concentration was 0.001 or 0.002 *M*. The temperature in these studies was maintained at 50° by water circulating through the polarimeter cell from a thermostated bath.

The pH of the buffers was measured at 50° with a Beckman expanded scale pH meter. The pKa′ of glycine at 50°, ionic strength 0.5, was determined from the pH of the buffers to be 9.10 ± 0.02.

The rates of alkaline hydrolysis of the penicillins in the absence of glycine were determined at 50° by measurement of the rate of acid production on a Radiometer TTT-1 titrator-pH stat equipped with SBR-2, SBU-1 recorder. Ionic strength in these runs was brought to 0.5 by addition of KCl. The rates for each penicillin were measured at several pH's.

RESULTS

Penicillenic Acid Formation.—The first-order rate constants for penicillenic acid formation were calculated by dividing the initial slope of a plot of absorbance at 322 mμ *versus* time by the initial concentration of penicillin.

$$k_{obs.} = \frac{\text{initial slope}/26{,}600}{\text{initial concn. of penicillin}}$$

The factor 26,600 is the molar absorptivity of penicillenic acid (5). Figure 1 shows these rate constants as a function of pH. These curves follow the same pattern previously observed for penicillin G (13) where the rate of penicillenic acid formation was found to be dependent upon the concentration of undissociated penicillin acid (HP):

$$\frac{d\,(\text{penicillenic acid})}{dt} = k_{obs.}\,(\text{HP}) = \frac{k_E(\text{H}^+)}{(\text{H}^+) + Ka}\,(\text{P})_{total}$$

where k_E represents the specific pH-independent rate constant. At high pH where $(H^+) \ll Ka$, the observed first-order rate constant will be directly proportional to (H^+) and, as shown in the dashed lines of Fig. 1, will decrease rapidly with increasing pH, and approach very low values at physiologic pH. There is a large difference in the magnitude of these rates for the various penicillins, the rate for methicillin being about 20 times that for oxacillin and about 50 times that of penicillin V. It is known that penicillin G fits in between oxacillin and methicillin, and much closer to the latter (13). Ampicillin produces penicillenic acid even more slowly than penicillin V (11).

Reaction of Penicillins with Glycine.—The optical rotation was followed until no further change

[1] The authors are grateful to Eli Lilly and Co., Indianapolis, Ind., for a supply of potassium penicillin V and to Bristol Laboratories for the other penicillins and 6-APA used in this work.

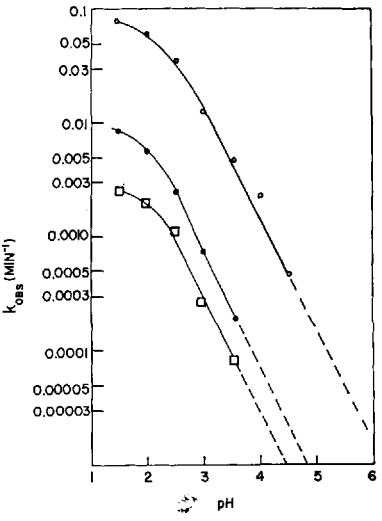

Fig. 1.—Rate of formation of penicillenic acid as a function of pH. Key: ○, methicillin; ●, oxacillin; □, penicillin V.

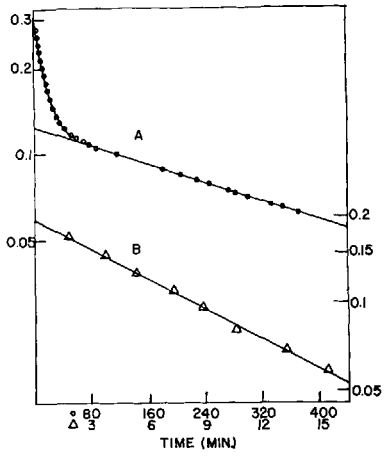

Fig. 2.—First-order plot for reaction of methicillin with 0.3 *M* glycine buffer, pH 9.47 at 50°. Key: ●, $(R - R_\infty)$ *vs.* *t*, left ordinate; △, residuals, right ordinate. Ordinates are log scale.

occurred and this value was designated R_∞. Plots of log $(R_t - R_\infty)$ against time were expected to show apparent first-order kinetics since the concentration of glycine was in large excess over that of penicillin. As seen in Fig. 2, curve A, large deviations from linearity were observed. This particular curve depicts the reaction of methicillin with 0.3 *M*, pH 9.48 glycine buffer, but is typical of all the studies.

It is known that reaction of penicillin with amines yields the α-penicilloamide which can undergo mutarotation to a mixture of diastereoisomers. The mixture is known to have a lower specific rotation than the α-diastereoisomer and the specific rotation of the penicillin is higher than that of the α-diastereoisomer (14). Essentially the following is the situation:

$$A \xrightarrow{k_1} B \xrightarrow{k_2} C \qquad \text{(Eq. 1)}$$

where *A* represents the original penicillin, *B* the α-diastereoisomer, and *C* the mixture of diastereoisomers. The apparent first-order rate constants are k_1 and k_2.

In this system:

$$A = A_0 e^{-k_1 t} \qquad \text{(Eq. 2)}$$

$$B = \frac{k_1 A_0}{k_2 - k_1}(e^{-k_1 t} - e^{-k_2 t}) \qquad \text{(Eq. 3)}$$

$$C = A_0\left[1 + \frac{1}{k_1 - k_2}(k_2 e^{-k_1 t} - k_1 e^{-k_2 t})\right] \qquad \text{(Eq. 4)}$$

Let r_A, r_B, r_C represent the molar rotations of the respective species. The rotation at any time during the course of the reaction, R_t, will be the sum of the rotations of the individual species:

$$R_t = r_A(A) + r_B(B) + r_C(C) \qquad \text{(Eq. 5)}$$

$$R_t = r_A A_0 e^{-k_1 t} + \frac{r_B k_1 A_0}{k_2 - k_1}(e^{-k_1 t} - e^{-k_2 t}) + r_C A_0\left[1 + \frac{1}{k_1 - k_2}(k_2 e^{-k_1 t} - k_1 e^{-k_2 t})\right] \qquad \text{(Eq. 6)}$$

Combining terms with the same exponential:

$$R_t = \left[r_A A_0 + \frac{r_B k_1 A_0}{k_2 - k_1} + \frac{r_C A_0 k_2}{k_1 - k_2}\right] e^{-k_1 t} - \left[\frac{r_B k_1 A_0}{k_2 - k_1} + \frac{r_C A_0 k_1}{k_1 - k_2}\right] e^{-k_2 t} + r_C A_0 \qquad \text{(Eq. 7)}$$

At infinite time $R = r_C A_0 = R_\infty$

$$R_t - R_\infty = \left[r_A A_0 + \frac{r_B k_1 A_0}{k_2 - k_1} + \frac{r_C A_0 k_2}{k_1 - k_2}\right] e^{-k_1 t} - \left[\frac{r_B k_1 A_0}{k_2 - k_1} + \frac{r_C A_0 k_1}{k_1 - k_2}\right] e^{-k_2 t} \qquad \text{(Eq. 8)}$$

Since k_1 is faster than k_2, at some time where $e^{-k_1 t}$ approaches zero there will remain a term in $e^{-k_2 t}$ and the plot of $\ln(R_t - R_\infty)$ *versus* time will be linear with slope $-k_2$. This linear portion of the curve may be extrapolated to zero time and the values of $(R_t - R_\infty)$ along this portion of the line represent the contribution of the term in $e^{-k_2 t}$ to the over-all value. Thus subtraction of this term from the observed $(R_t - R_\infty)$ will leave only the term in $e^{-k_1 t}$. Then a plot of logarithm of these residuals against time should be linear with slope $-k_1$, and this is shown as curve B in Fig. 2.

The rate constant k_1 was determined for each penicillin and 6-APA, and was corrected for alkaline hydrolysis in the absence of buffer:

$$k_C = k_1 - k_{OH}(OH^-) \qquad \text{(Eq. 9)}$$

It was found, for the penicillins, that k_C was not a linear function of glycine concentration at constant pH but was a linear function of the square of the glycine concentration as shown in Fig. 3. These particular lines represent reaction of ampicillin but are typical of those observed with all of the penicillins studied. In the case of 6-APA, on the other hand, there *was* a linear relationship between rate constant (k_C) and concentration of glycine as shown in Fig. 4.

The slopes of the lines in Fig. 3 represent the proportionality constant between k_C and the square of

the total glycine concentration and are designated k_G. It can be seen that k_G increases with increasing pH implicating the glycine anion, $NH_2CH_2COO^-$, as the reactive species. Figure 5 shows the direct dependence of k_G on the square of the fraction of the total glycine which exists as anion:

$$k_G = k_G^-(f_G^-)^2 \qquad \text{(Eq. 10)}$$

Thus the entire rate may be attributed to a third-order reaction with no second-order term in evidence.

In the case of 6-APA the slopes of the lines in Fig. 4 were found to be proportional to the fraction of the total glycine existing as anion:

$$k_G = k_G^-(f_G^-) \qquad \text{(Eq. 11)}$$

Table I gives both k_G and k_G^- for all the penicillins studied and 6-APA. Also included are the rate constants for alkaline hydrolysis. Each of the latter represents the average of 3 or 4 determinations.

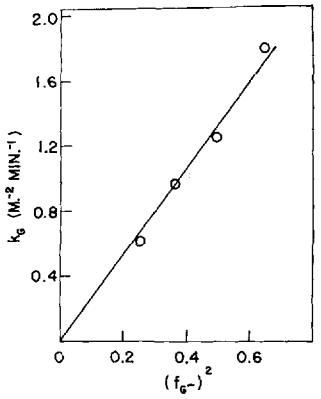

Fig. 5.—Plot showing glycine anion as reactive species.

DISCUSSION

The requirement of 2 molecules of glycine anion for reaction with the penicillins is indicative of a general base-catalyzed nucleophilic attack of glycine on the β-lactam carbonyl. General base-catalyzed aminolysis of esters (15, 16) and δ-thiolvalerolactone (17) have been reported. In the case of aminolysis of phenyl acetate by glycine (16) both general base-catalyzed and an uncatalyzed reaction were detected. In the present study an uncatalyzed aminolysis could not be detected, although one would suspect that such a reaction should occur in an aqueous medium. Probably the rate of such a reaction is so small that its contribution to the over-all rate could not be observed.

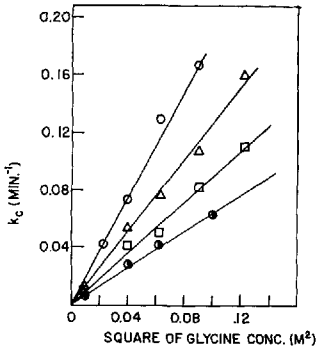

Fig. 3.—Dependence of rate of reaction of ampicillin with glycine upon the square of the glycine concentration. Key: O, pH 9.70; △, pH 9.48; □, pH 9.29; ◑, pH 9.10.

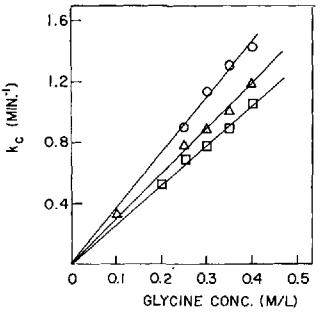

Fig. 4.—Dependence of rate of reaction of 6-APA upon glycine concentration. Key: O, pH 9.70; △, pH 9.48; □, pH 9.29.

Also absent from the rate law for reaction of penicillins with glycine was a term indicating general acid-catalyzed aminolysis as was noted with δ-thiolvalerolactone (17) in addition to the general base-catalyzed reaction. Again this might make too small a contribution to the over-all rate to be noticed or might be absent entirely.

A mechanism for general base-catalyzed aminolysis of penicillin may be described schematically as follows:

$$P + G^- \underset{k_{-3}}{\overset{k_3}{\rightleftarrows}} PG^-$$

$$PG^- + G^- \xrightarrow{k_4} G^{\pm} + \text{product} \qquad \text{(Eq. 12)}$$

where P represents penicillin, G^- the glycine anion, and $G^{\pm}$ the zwitter ion. The intermediate produced in the first reaction could be a tetrahedral addition product or a complex. The driving force in the second step is the removal of a proton from the intermediate by the second glycine anion. Assuming a steady state in the intermediate:

$$\frac{d(PG^-)}{dt} = k_3(P)(G^-) - [k_{-3} + k_4(G^-)]\,PG^- = 0 \qquad \text{(Eq. 13)}$$

$$(PG^-) = \frac{k_3(P)(G^-)}{k_{-3} + k_4G^-} \qquad \text{(Eq. 14)}$$

$$K_C = \frac{1}{P}\frac{dP}{dt} = \frac{k_4k_3(G^-)^2}{k_{-3} + k_4(G^-)} \qquad \text{(Eq. 15)}$$

when $k_{-3} \gg k_4(G^-)$

$$K_C = \frac{k_4k_3}{k_{-3}}(G^-)^2 \qquad \text{(Eq. 16)}$$

At sufficiently high (G^-) it might be thought from Eq. 15 that the rate would reduce to first order in

glycine anion. This was not observed at concentrations up to 0.3 *M*, as would be expected for the rapid equilibration between reactants and intermediate which would take place in this case.

In the case of 6-APA only over-all second-order kinetics was observed. This might be due to intramolecular general base catalysis by the free amino group on the carbon adjacent to the β-lactam carbonyl, or a relatively large contribution by the uncatalyzed aminolysis, or both.

From these results one might speculate that compounds containing both general base and nucleophilic groups on the same molecule, diamines for example, would react much more rapidly with penicillin than glycine. This is currently under investigation, and preliminary results indicate that this is indeed the case. The results of these experiments will be the subject of a future communication (18). Intramolecular general base catalysis could provide a rationale for rapid reaction of penicillin with proteins at physiological pH, which is pertinent to the question of penicillin antigen formation. On protein molecules there could be many sites where intramolecular general base catalysis of aminolysis could occur at rates rapid enough to compete with the elimination of penicillins from the body where the half-life is about 30–60 min.

Also of pertinence to the mechanism of penicillin antigen formation is the fact that the rates of reaction of all these penicillins with glycine are of the same order of magnitude, a factor of about 2.3 separating the slowest (methicillin) from the most rapid (penicillin V). This shows a lack of influence of the side chain upon reactivity toward nucleophiles of the β-lactam carbonyl. This is also apparent in the values for k_{OH}. On the other hand, the side chain has a great effect on the rates of penicillenic acid formation from penicillins. Although clinical experience with some of these penicillins is rather limited, allergic reactions to all the penicillins have been reported (19). Even though many of these are probably due to cross-reaction with antibody to penicillin G, the new penicillin must still combine covalently with protein to provide an antigen. From the relative rates reported here it would seem more likely that the direct reaction between penicillin and protein is taking place rather than the penicillenic acid route.

While the side chain (R in I) appears to have little influence on reaction of penicillins with small molecules, the situation with proteins might be quite different where steric effects of the side chain might play a role. Such effects are observed in the relative affinities of the various penicillins for the enzyme penicillinase. Methicillin and oxacillin have very little affinity for the enzyme while penicillin G, penicillin V, and ampicillin are relatively tightly bound. Only a hint of steric effect was seen in the present work where the rate constant for reaction of oxacillin with glycine is slightly higher than that of penicillin G, while the reverse is true of the k_{OH} values. Oxacillin has the bulky phenyl group on the carbon adjacent to the point of attachment which might interfere somewhat with the approach of the glycine more than with hydroxyl ion. The magnitude of the differences is too small, however, to draw definite conclusions and further studies of steric effects are contemplated.

In contrast to the potentially relatively rapid rates of reaction of penicillins with proteins are the very low rates of penicillenic acid formation calculated for neutral pH. For example, the half-life for penicillenic acid formation from methicillin at pH 7.4 at 34° would be about 1000 days. It would seem then that if the penicillenic acid route to antigen is of any consequence the penicillenic acid would have to be present in a preparation *prior* to parenteral administration. This is possible as a result of decomposition under normal storage conditions particularly in liquid dosage forms. Since acid is produced upon hydrolysis of penicillins the pH will be lowered, thus increasing the rate at which penicillenic acid is formed. It would seem important, therefore, that parenteral penicillin preparations be buffered to minimize this route of degradation. With oral preparations penicillenic acid is probably formed quite rapidly in the acid stomach. The limiting factor would then become the absorption of penicillenic acid. Since oral administration of penicillins has produced the least number of clinical allergy problems of any route, this might be considered relatively unimportant.

Polarographic Study of Pteridines

By MILTON LAPIDUS and MARVIN E. ROSENTHALE

The electronegativity of the half-wave potentials of a series of pteridine congeners was found to be related to the substituent groups. The 2,4,7-triaminopteridines, 7-substituted 4-amino-2-aryl-6-pteridinecarboxamides, and 4,7-diamino-2-aryl-6-pteridinecarboxamides were characterized, in that order, by decreasingly lower electronegative half-wave potentials.

A NUMBER of attempts have been made to correlate pharmacological activity with the oxidation-reduction potentials of a homologous series of compounds (1). Relationships have seldom been demonstrated; however, there is a report that acridines with reduction potentials (E°_{h}) more negative than -0.400 v. have greater antiseptic activity (2) than those with less negative potentials. That study showed the active acridines to have reduction potentials so electronegative that no physiological system could reduce (inactivate) them. Evidently, with the acridines, the maintenance of the oxidized configuration is necessary for biological activity. Another study showed that the degree to which members of two homologous series of acridine antimalarials inhibit the diamine–oxidase enzyme system parallels the values of the reduction potential of the compounds (3). However, no evidence was found that inhibition of diamine–oxidase is necessary to antimalarial action (4).

The possible importance of the oxidation-reduction potential prompted the authors to determine it for a large number of pteridines which have been under pharmacological review. Some of these pteridines are useful diuretic agents (5–8).

Received January 14, 1966, from Wyeth Laboratories, Inc., Radnor, Pa.
Accepted for publication March 31, 1966.

METHOD

Material.—The pteridines studied were synthesized by Osdene *et al.* (9).

Polarographic Analysis.—A Leeds and Northrup recording polarograph equipped with a dropping mercury electrode was used for determining reduction potentials. The H-type electrolysis cell consisted of a saturated calomel half-cell connected to the test solution through an agar bridge and a fritted-glass diaphragm. Under a potential of -0.50 v. the dropping mercury electrode delivered 2.43 mg. of Hg/sec. with a drop time of 4.31 sec. All measurements were made at 25°. Unless otherwise noted, the solutions for polarographic analysis contained 5×10^{-4} *M* pteridine, 0.1 *M* phosphate buffer (pH 2.0), and 0.005% gelatin. The calibrating solution, which contained zinc chloride (1×10^{-3} *M*) in place of the pteridine, gave an $E^{1}_{1/2}$

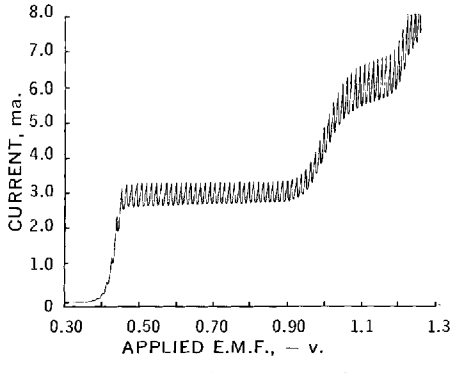

Fig. 1.—Polarographic reduction of Wy-4437 (pH 2.0).

Polarographic Analysis.—A Leeds and Northrup recording polarograph equipped with a dropping mercury electrode was used for determining reduction potentials. The H-type electrolysis cell consisted of a saturated calomel half-cell connected to the test solution through an agar bridge and a fritted-glass diaphragm. Under a potential of -0.50 v. the dropping mercury electrode delivered 2.43 mg. of Hg/sec. with a drop time of 4.31 sec. All measurements were made at 25°. Unless otherwise noted, the solutions for polarographic analysis contained 5×10^{-4} *M* pteridine, 0.1 *M* phosphate buffer (pH 2.0), and 0.005% gelatin. The calibrating solution, which contained zinc chloride (1×10^{-3} *M*) in place of the pteridine, gave an $E^{1}_{1/2}$

of −1.075, a value in agreement with the literature (10). Replicate samples varied ±0.015 v.

RESULTS

The pteridines gave well-formed 2-step polarographic waves (Fig. 1). The half-wave potentials, designated $E^1_{1/2}$ and $E^2_{1/2}$, were determined by expolation from the current (ma.) *versus* applied voltage (v.) record (11). Characteristic half-wave potentials, $E^1_{1/2}$, were found for each of the 3 general classes of pteridines at pH 2.0.

Class I.—*4,7-Diamino-2-aryl-6-pteridinecarboxamides.*—In this group the compounds had half-wave potentials of −0.390 to −0.460 (Table I).

Class II.—*7-Substituted 4-Amino-2-aryl-6-pteridine Carboxamides.*—Substitution in the 7 position resulted in an increase in the electronegativity of the half-wave potential ($E^1_{1/2}$ from −0.470 to −0.565, Table II).

Included in class II pteridines was a polarographic study investigating the influence of the N—N intra-

nuclear distance in the carboxamide structures in the 6 position of a homologous series of pteridines (Fig. 2). The half-wave reduction potential of this series was found to be a function of the N—N intranuclear distance as well as the pH. A methylene bridge of 5 carbons gave the maximal electronegative half-wave potential at pH 7.0 and 7.5.

Class III.—*2,4,7-Triamino-6-arylpteridines and 2,4,7-Triamino-6-pteridinecarboxamides.*—The electronegative potentials found in this general group were from −0.570 to −0.690 (Table III). The reduction potential of the 6-arylpteridines was more electronegative than the 6-pteridinecarboxamides.

Within each of the three general classes, the reduction potential of the pteridines increased in electronegativity with the increase in pH from 2.0 to 7.4. A typical half-wave potential *versus* pH curve is shown in Fig. 3.

DISCUSSION

Polarographic and spectrographic evidence has established that reduction of the pyrazine ring in folic acid and related pteridine structures occurs at the 5–6 and 7–8 double bonds. The reduction occurs in two steps and has been shown to be pH-dependent and to involve 2 electrons per step (12, 13). The authors compared the reduction record of 4,7-diamino-*N*-(4-dimethylaminobutyl)-2-phenyl-6-pteridinecarboxamide (class I, Wy-4437) with that of folic acid at the same molar concentration and pH and found the same 2-step reduction and the same limiting current. The authors consider this to be evidence for a 2-electron-per-step reduction mechanism for both structures (14).

Substitution on the pteridine nucleus had an over-all effect on the reductive process occurring at the 5–6 and 7–8 double bonds. The gain of electrons by the pteridine ring at the dropping mercury electrode and the simultaneous introduction of H+ occurred at voltages which were characteristic for each of the substituted pteridines. One can assume that the more difficult it is for a pteridine to gain electrons and be reduced, the more electronegative the applied voltage has to be. This effect, the ease or difficulty of reduction, involves not only the pteridine nucleus but the substituents as well.

The comparative electronegativity of the half-wave potential of the 3 general classes of pteridines studied was: class III > class II > class I. The substitution of a 2-phenyl group (Wy-1843) for the 2-amino group (Wy-1840) resulted in a decrease in electronegativity of the half-wave potential (Table IV). This decrease may be due to a withdrawal of electrons from the site of reduction by the phenyl group. The result of this resonance effect is to permit reduction to occur at a lower potential. The replacement of a primary amino group (Wy-1843) by a secondary amino group (Wy-5120) at position 7 resulted in an increase in electronegativity of the half-wave potential, indicating that the 2-diethylaminoethyl structure on the 7-amino group must act as an electron donor.

A polarographic study of the effect of pH on a homologous series of 4,7-diamino-2-*m*-chlorophenyl-6-pteridinecarboxamides (Fig. 2) revealed that an increase in the N—N intranuclear distance within the carboxamide tended to raise the electronegative half-wave potential. At acid pH's the protonation of amino and heterocycle nitrogen limited the resonance and inductive effects, but this leveling effect was minimized as the pH was increased. At neutrality the maximal reduction potential was recorded for a methylene chain length of 5 carbons.

Moisture Stress Tests in Stability Programs

By J. THURØ CARSTENSEN, E. SERENSON ARON, D. C. SPERA, and J. J. VANCE

Although the effect of moisture in solid dosage forms is qualitatively recognized, the severity of this parameter is often much greater than anticipated. Quantization of interaction of moisture with active components is often possible and an apparent order of reaction can be established rather easily. The higher the order the more severe the effect of moisture content and the closer this variable must be controlled in stability programs. Vitamin A is used to exemplify these points.

TARDIF in a recent publication (1) touched on the effect of moisture on vitamin A stability in solid dosage forms. The moisture sensitivity of vitamin A is greatly affected by the presence of antioxidants, and as will be demonstrated below, can be exaggerated considerably depending on (*a*) the presence of antioxidants in the vitamin A beadlet and (*b*) the tablet base used. The sucrose base employed by Tardif is moderately severe. In our investigations we have found lactose to be a severe interacting substance that lends itself well to artificial testing of (*a*) the quantitative nature of the interaction of vitamin A with moisture and (*b*) as a screening agent for vitamin A beadlets of different matrix composition.

Higuchi and Reinstein (2) at an early date studied the order of reaction of vitamin A with water in hydroalcoholic systems and found the reaction order to be second order with respect to ethanol at high ethanol concentration, slowly approaching first order as the ethanol concentration was decreased. The order with respect to water was found to be complex, changing from much less than 1 in solvent containing 2% water, increasing to 1 at 5% water content, and then to 2 at 20% water content.

The authors have reported their findings in the lactose solid state system, which is a much cruder system than the systems employed by Higuchi and Reinstein.

Theory.—If vitamin A degrades by functional dependence of water content, then a $(1 + a)$ order reaction rate may be expressed as

$$dC_A/dt = -K \cdot C_A \cdot C^a_{H_2O} \qquad \text{(Eq. 1)}$$

where C denotes concentration and the subscripts denote vitamin A acetate and water. If the water is in sufficient excess, Eq. 1 will degenerate to the pseudo first order:

$$dC_A/dt = -K' \cdot C_A \qquad \text{(Eq. 2)}$$

or log (% retained) $= -K' \cdot$ (time) $+ 2$, where

$$K' = K \cdot C^a_{H_2O} \text{ or}$$
$$\log K' = \log K + a \cdot \log C_{H_2O} \qquad \text{(Eq. 3)}$$

"a" will appear as the slope of K' *versus* log C_{H_2O} plots regardless of whether Naperian or non-Naperian rate constants and logarithms are used. Non-Naperian data will be employed in the following.

EXPERIMENTAL

Samples of tablets were made of the following composition: 427.5 mg. of lactose, 5.0 mg. of calcium stearate, and 17.5 mg. of vitamin A acetate beadlets (containing no antioxidant).

The materials were predried at 37° for 24 hr. and various amounts of moisture were added to subparts of the granulation which was then compressed on a Stokes E machine using $^{13}/_{32}$ in. standard concave punches, the thickness being about 10.3 mm. The tableting of the wetter samples was not particularly satisfactory from a mechanical point of view.

The samples were stored in well-sealed bottles at 5, 25, 55, 70, and 85° and assayed at the periods shown in Table I.

Samples of vitamin A palmitate beadlets were incorporated in the same base. The vitamin A palmitate beadlets all contained antioxidants as opposed to the experimental lots of vitamin A acetate beadlets used. The results from storage testing of these are shown in Table III.

RESULTS

Table I yields storage results in terms of units of vitamin A/Gm. of tablet weight.

The table purposely omits longer term data to illustrate the rapidity and utility of the procedure. The use of longer periods is also questionable in view of recent findings (5) regarding equilibrium aspects of vitamin A beadlets, in particular in dryer formulations.

Extracting the K' values (in units of days^{-1}) from Table I yields the data in Table II. The $\log_{10}$ of K' is shown rather than K' to allow treatment by Eq. 3.

The data in Table II are shown graphically in Fig. 1, and analysis by the method of least squares show the lines (*a*) not to differ significantly with respect to slope and (*b*) to yield a best estimate of $a = 2.0 - 3.0$.

Received March 4, 1966, from Hoffmann-La Roche, Inc., Nutley, N. J.

E	2	3.762–4	3.348–4		2.497–4	2.394–4	1.3–1

[a] It is assumed that the moisture present prior to water addition is bound; the water "concentration" is taken as moisture added.

The assays from 3 different lots of vitamin A palmitate with different beadlet composition are shown in Table III at the 2% moisture level, as an example of the screening aspects of the procedure. It should be noted that the beadlets referred to in Table III are all vitamin A *palmitate* beadlets containing antioxidants, whereas the beadlets referred to in Table I are vitamin A *acetate* beadlets containing no antioxidants.

DISCUSSION

It is apparent from the data that lactose plus moisture is a severe test for vitamin A. It hence may serve as a good agent for evaluating vitamin A beadlets made by various processes and compositions.

The data of Table II have been plotted graphically in Fig. 1 and yield the information that the over-all apparent interaction order is 4 ($a = 3$).

This is a relatively high order. For stability programs, therefore, there appears to be a need for preliminary determination of interaction order since the stability must be viewed in light of the moisture content. Such information should be secured early in the program.

Determination of the interaction order is rapidly obtained. Examplewise, data in Table I (which suffice for this purpose) were secured in about 1 month. The actual calculation of the a-value can be done graphically simply by determining the slope of the plot of log K' *versus* log (H_2O). For instance, the 25° data of Table II, taking points B and D would yield a slope (a-value) of $(2.340 - 0.938)/(1.175 - 0.700) = 2.96$.

Most of the data may be treated by Arrhenius plotting although in the case of the samples in Table I with high moisture contents, elevated temperatures give unreasonably high degradation rates and would have to be extrapolated differently (3) if such extrapolating were needed. The utility of the procedure outlined in stability programs and evaluations is quite apparent.

If the apparent order of the reaction is known it can be established whether losses are solely due to moisture or whether other factors are involved. If, for instance, one tablet formulation contained 2% moisture, another 1%, and the K-values depended on, *e.g.*, $K' = K \cdot C_{H_2O}^2$ then it may be con-

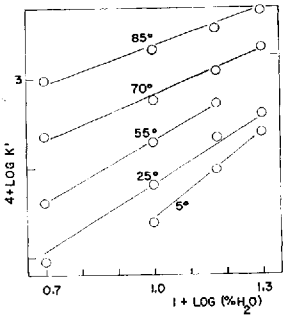

Fig. 1.—Vitamin A acetate-lactose tablets. Plot of the logarithm of the apparent first-order rate constant, K', as a function of amount of water added.

cluded that if K' (2%) = 4 K' (1%) the difference in K' values is solely due to moisture. Such a conclusion could not have been reached without knowledge of the apparent (third) order of reaction.

SUMMARY

1. Vitamin A acetate has been used as an example to demonstrate "order of interaction" in solid dosage forms.

2. Since moisture is a variable seldomly controlled within extremely narrow limits in stability programs, it may prove useful, in many cases, to establish the "order of interaction" between moisture and active component(s).

3. Screening bases for such studies can be selected by choosing the worst offenders in preliminary compatibility programs (4).

4. If a high-order interaction is established, stringent moisture control data should be obtained in the stability program.

5. The study of "order of interaction" may be carried out in a relatively short span of time (30 days).

New Pharmacologic Aspects of β-Diethyl-aminoethyl 2,2-Diphenylpentanoate

By RICHARD A. CARRANO* and MARVIN H. MALONE

In a comparison with atropine and structurally related adiphenine using a gross *in vivo* screen in rats, β-diethyl-aminoethyl 2,2-diphenylpentanoate (SKF 525-A) appeared to act peripherally as a parasympatholytic and/or sympathomimetic. SKF 525-A apparently has some selective activity on the central nervous system (blepharoptosis, hypothermia) indicating a capacity to cross the blood-brain barrier. Drug–receptor interactions were studied on the isolated rat jejunum using furtrethonium as the agonist. SKF 525-A was primarily a noncompetitive antagonist with a competitive component and qualitatively different from the activities of atropine, adiphenine, and papaverine. The respective pA_2 and pD'_2 values are reported. The SKF 525-A receptor appears composed of the cholinergic receptor plus another spasmogen receptor. SKF 525-A did not inhibit the action of acetylcholinesterase, but was a potent inhibitor of monoamine oxidase at physiological concentrations.

MUCH OF the work previously reported on β - diethyl - aminoethyl 2,2 - diphenyl pentanoate (SKF 525-A) has been concerned with its ability to act as a multipotent inhibitor of various liver microsomal degradation reactions (1). The original observations made for SKF 525-A concerning potentiation of barbiturates and other central nervous system depressants (2–5) suggested possible potentiation by CNS mediation; however, Brodie (1) demonstrated that this agent was able also to prolong the activity of the central stimulant, amphetamine. This study was prompted by the chemical similarity between SKF 525-A and adiphenine, and also by the lack of comprehensive screening in the literature.

Received February 9, 1966, from the Division of Pharmacology, University of Connecticut, Storrs.
Accepted for publication March 21, 1966.
Preliminary report: *Federation Proc.*, **24**, 388(1965).
The SKF 525-A and furtrethonium were provided courtesy of the Smith Kline & French Laboratories, Philadelphia, Pa., while adiphenine was generously supplied by the Ciba Pharmaceutical Co., Summit, N. J.
* Fellow of the American Foundation for Pharmaceutical Education.

EXPERIMENTAL

In Vivo Hippocratic Screening.—In accordance with the method of Malone and Robichaud (6), nonfasted albino rats (Wistar strain) in the weight range of 150–250 Gm. were injected intraperitoneally with 5 logarithmetically spaced doses of each drug tested (1 lethal, 1 essentially ineffective dose, and 3 effective log-dosages between those two). Observations were made using the standard worksheet (6) at 5, 10, 15, 30, and 60 min. postinjection, 2, 4, and 24 hr. postinjection, and 2, 4, and 7 days postinjection.

Mechanism of Drug-Receptor Interaction.—Using the methods of Ariëns (7), van Rossum (8), and van Rossum and van den Brink (9), cumulative dose-response curves were made utilizing rat jejunum and furtrethonium iodide as the reference agonist. The bath solution was standard Tyrode's oxygenated with 95% oxygen and 5% CO_2 and containing the calcium disodium salt of ethylenediaminetetraacetic acid in a concentration of 1×10^{-5} Gm./L. The jejunum was mounted in the bath (37.5°) using a modified Magnus technique. All drug concentrations were calculated in terms of drug base. When an antagonist was tested it was

cluded that if K' (2%) = 4 K' (1%) the difference in K' values is solely due to moisture. Such a conclusion could not have been reached without knowledge of the apparent (third) order of reaction.

SUMMARY

1. Vitamin A acetate has been used as an example to demonstrate "order of interaction" in solid dosage forms.

2. Since moisture is a variable seldomly controlled within extremely narrow limits in stability programs, it may prove useful, in many cases, to establish the "order of interaction" between moisture and active component(s).

3. Screening bases for such studies can be selected by choosing the worst offenders in preliminary compatibility programs (4).

4. If a high-order interaction is established, stringent moisture control data should be obtained in the stability program.

5. The study of "order of interaction" may be carried out in a relatively short span of time (30 days).

EXPERIMENTAL

In Vivo Hippocratic Screening.—In accordance with the method of Malone and Robichaud (6), nonfasted albino rats (Wistar strain) in the weight range of 150–250 Gm. were injected intraperitoneally with 5 logarithmetically spaced doses of each drug tested (1 lethal, 1 essentially ineffective dose, and 3 effective log-dosages between those two). Observations were made using the standard worksheet (6) at 5, 10, 15, 30, and 60 min. postinjection, 2, 4, and 24 hr. postinjection, and 2, 4, and 7 days postinjection.

Mechanism of Drug-Receptor Interaction.—Using the methods of Ariëns (7), van Rossum (8), and van Rossum and van den Brink (9), cumulative dose-response curves were made utilizing rat jejunum and furtrethonium iodide as the reference agonist. The bath solution was standard Tyrode's oxygenated with 95% oxygen and 5% CO_2 and containing the calcium disodium salt of ethylenediaminetetraacetic acid in a concentration of 1×10^{-5} Gm./L. The jejunum was mounted in the bath (37.5°) using a modified Magnus technique. All drug concentrations were calculated in terms of drug base. When an antagonist was tested it was

allowed to incubate with the tissue for 10 min. prior to the production of the cumulative dose-response curve.

In Vitro Acetylcholinesterase Inhibition Studies.—The manometric techniques of Umbreit *et al.* (10) were used for this study with acetyl-β-methylcholine (0.03 *M*) as the substrate for acetylcholinesterase. Physostigmine was used in concentrations ranging from 10^{-6} to 10^{-9} *M* as a standard acetylcholinesterase inhibitor. SKF 525-A was used in concentrations ranging from 10^{-3} to 10^{-6} *M*. The inhibitor and acetylcholinesterase were incubated (37°) together for 20 min. prior to mixing with the substrate. The total flask volume was 3 ml. and pH was kept at 7.4 with Krebs-Ringer bicarbonate buffer. Molar I_{50} and I_{80} values were calculated. All drug concentrations were expressed in terms of drug base.

In Situ Monoamine Oxidase Inhibition Studies.—Rat liver MAO activity was determined by the spectrophotometric disappearance of the substrate kynuramine (11). Iproniazid was used as the reference MAO inhibitor. All concentrations were calculated in terms of the drug base.

Radiometric determinations were carried out using the method of Wurtman and Axelrod (12) with incubations at 37° in 15-ml. glass-stoppered centrifuge tubes for 20 min. A young male rat was sacrificed by decapitation, and 200 mg. of liver rapidly excised and homogenized thoroughly with 10 ml. of cold isotonic KCl. One milliliter of this homogenate was diluted to 10 ml. with isotonic KCl and rehomogenized so that a final concentration of 2 mg./ml. was obtained. The total volume of each incubation tube was 3 ml. made up of the appropriate ingredients. At the termination of the incubation, 0.2 ml. of 2 *N* HCl was added to each tube followed by 6 ml. of toluene. The ^{14}C derivative was extracted into the toluene layer by shaking and the two layers separated by centrifugation. Four milliliters of the toluene layer was taken from each tube and placed into a liquid scintillator vial containing 10 ml. of liquid scintillator solution (0.5 Gm. POPOP, 4 Gm. PPO, add 1 L. of toluene), and counted for 10 min. in a Packard tricarb counter. Counting efficiency of each vial was determined by the internal standard method. A wide range of log-concentrations was used for each agent with concentrations expressed in terms of drug base.

RESULTS AND DISCUSSION

In Vivo Hippocratic Screening.—Dosages of 32, 56, 100, 178, 316 mg./Kg. were injected for each of the following: SKF 525-A, structurally related adiphenine, and atropine. The qualitative nature of the observable symptoms which exhibit dose-response relationships permit an estimate of possible mechanism of action (6).

Atropine produced excellent dose-response activity for the following acute effects: mydriasis, decreased skeletal muscle coordination and tone, lowering of rectal temperature, tremors and convulsions coupled with xerostomia, and decreased lacrimation. An increase in blood pressure was suggested by the presence of exophthalmos. The well-known parasympatholytic activity appeared to be detected by the screening technique and all activities were in agreement with reports in the literature. At 100–316 mg./Kg. dosages, there was an apparent blockade of transmission at the level of the motor end plate of skeletal muscle. The dosage of 316 mg./Kg. was lethal within 30 min. Recovery from 178 mg./Kg. of atropine was essentially complete by +24 hr.

Adiphenine produced effects very similar to those observed with atropine. However, mydriasis was not as pronounced and stimulation of both salivation and lacrimation was noted at doses of 100 and 178 mg./Kg. Lack of xerostomia suggests a different mechanism of action at these higher dosage levels, possibly indicating a decreased affinity of the adiphenine molecule to the parasympathetic receptor, and possibly the extension of its action to another closely related receptor or receptor system.

SKF 525-A was found to be a strong mydriatic but not as powerful as atropine. It had the ability to decrease motor activity, although paralysis of skeletal muscle and loss of screen grip (6) were not seen. Fine tremors of skeletal muscle were pronounced at the two lower dosages. Lacrimation was greatly increased. The most striking effect of SKF 525-A and with an excellent dose-response relationship was hypothermia (−6.9° at +1 hr. with a dosage of 178 mg./Kg.). At the lowest dosage level of 32 mg./Kg., SKF 525-A produced a hypothermia (−3.3° at +1 hr.) equivalent to that noted with 178 mg./Kg. of atropine and adiphenine. Associated with hypothermia was an effect of palpebral ptosis and enophthalmos. The dosage of 316 mg./Kg. was lethal within 30 min. and was accompanied by convulsions. The animals receiving 178 and 100 mg./Kg. died within 60 and 95 hr. of dosing and death was associated with increased skin plasticity, pilomotor erection, and profound loss of body weight. Since only 1–2 rats per dosage are required for the Hippocratic screening (6), it is a qualitative technique whereby the evaluation of the activity of the test material is based on the complete log-response profile of the entire animal population receiving the 5 log-dosages rather than on one animal or on one selected log-dosage. The Hippocratic technique is used as an initial directive screen to suggest avenues for further more specific pharmacologic evaluation. In considering the total profile of acute symptoms produced by SKF 525-A, one could postulate either parasympatholytic or sympathomimetic activity. Increased lacrimation and mydriasis accompanied by skeletal muscle tremors suggest sympathomimetic activity. Salivation was not stimulated concurrent with lacrimation. The hypothermia appeared due to a selective CNS activity—this was suggested considering two factors. First, the "true" palpebral ptosis indicative of possible hypothalamic depression was correlated directly with the period of strong hypothermic activity; and second during the ptotic effects the animals were obviously conscious. Since death with SKF 525-A came on slowly accompanied by weight loss, this agent could produce general metabolic inhibition.

It was evident from this gross *in vivo* screen that SKF 525-A may have important pharmacologic actions independent of metabolic inhibition and actions quite different from those seen with atropine and adiphenine. In general, the data indicated a decrease in parasympatholytic activity stepwise

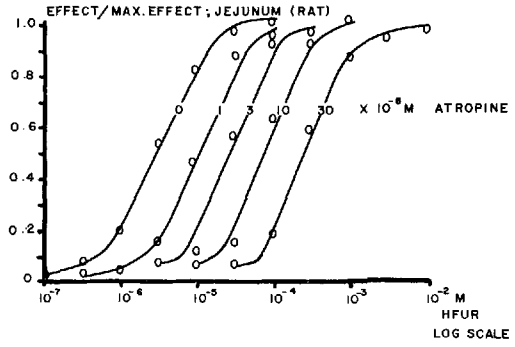

Fig. 1.—Cumulative log-concentration curves of furtrethonium (HFUR) in the presence of atropine.

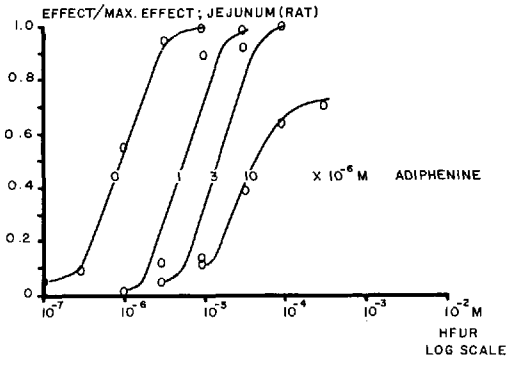

Fig. 2.—Cumulative log-concentration curves of furtrethonium (HFUR) in the presence of adiphenine.

from atropine to adiphenine to SKF 525-A. A shifting of mechanism of activity or site of action may be pertinent to this structural progression.

Drug Receptor Interactions.—The results for SKF 525-A were compared with those for atropine, adiphenine, and papaverine. Figure 1 illustrates the cumulative dose-response curves for furtrethonium in the presence of increasing log-increments of atropine. A constant level of atropine was maintained for each dose-response curve of furtrethonium. The conclusion that must be drawn is that atropine is a pure competitive antagonist of furtrethonium for the cholinergic receptor of rat jejunum. There is a concentration-related decrease in the affinity of the furtrethonium molecule for the cholinergic receptor. The influence of atropine can be overcome by an increase in the concentration of furtrethonium and eventually furtrethonium occupies all receptors, thus producing a maximal effect. The complementarity between the cholinergic receptor site and the atropine molecule is similar to that between furtrethonium and the cholinergic receptor site, but not equivalent since atropine has no intrinsic activity.

Figure 2 illustrates similar cumulative dose-response curves with adiphenine as the antagonist. Here the competitive nature of the drug–receptor interactions can also be seen. However, with a concentration of 10×10^{-6} *M* for adiphenine, the maximum response obtainable for the furtrethonium cumulative dose-response curve is reduced. This implies not only a decrease in the affinity, but also a decrease in the intrinsic activity of the furtrethonium molecule for the cholinergic receptor. A noncompetitive component has been introduced into adiphenine's action. This noncompetitive component may be the determinate factor responsible for the decrease in gross parasympatholytic activity (as compared to atropine) noted in the *in vivo* screening data.

Figure 3 demonstrates the furtrethonium dose-response curves in the presence of increasing log-increments of the musculotropic antagonist papaverine. A "pure" noncompetitive antagonism is illustrated. The papaverine molecule and the cholinergic receptor do not have any degree of complimentarity; however, the interaction of papaverine with components (7) of the contractile mechanism of the muscle has a blocking influence on the action produced by furtrethonium on the cholinergic receptor of the jejunum.

Figure 4 illustrates that SKF 525-A, in part, appears to be a noncompetitive antagonist of furtrethonium on the cholinergic receptor. It is not correct to assume that SKF 525-A acts in the same way as papaverine on this biological preparation. Examination of the curves in Fig. 4 reveals that there is a shift in the dose-response curves for furtrethonium occurring along the log-dose axis

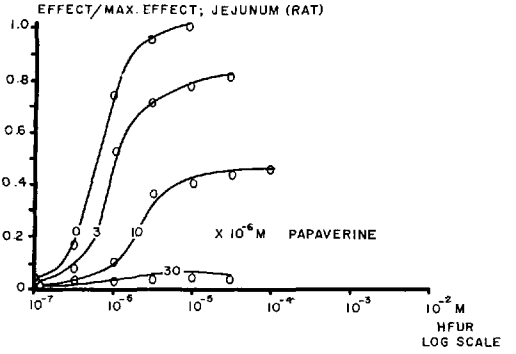

Fig. 3.—Cumulative log-concentration curves of furtrethonium (HFUR) in the presence of papaverine.

TABLE I.—PARAMETERS OF PARASYMPATHETIC AGENTS TESTED ON ISOLATED RAT JEJUNUM (10 min. INCUBATION) WITH FURTRETHONIUM AS THE AGONIST

	Intrinsic Activity	Log Affinities		
		pD_2	pA_2	pD'_2
Furtrethonium[a]	1	5.90 (5.90)[b]	...	...
Atropine	0	...	8.42 (8.80)[b] (8.37–8.77)[c]	...
Adiphenine	0 (−1)	...	6.69 (6.80)[b]	4.58[d] (4.70)[e]
SKF 525-A	?[f]	...	...	6.06
Papaverine	−1	...	...	5.00 (4.80)[b]

[a] While all calculations are in terms of the base molecules, furtrethonium iodide and atropine sulfate were the respective salts used with all other agents as hydrochloride salts. [b] Parenthetical value was reported by van Rossum and van den Brink (9); the incubation time was not listed. [c] Parenthetical values were reported by Schild (17, 18) for a 2 and 14-min. incubation time, respectively. [d] Incubated at 1×10^{-5} *M* concentration. [e] Parenthetical value was reported by Ariëns and van Rossum (13); the incubation time was not listed. [f] See text for discussion.

prior to the depression of maximal effect. This is not demonstrated in Fig. 3 with papaverine. According to Ariëns and van Rossum (13), van Rossum (8), and Ariëns (7), when a noncompetitive antagonist interferes with the induction of the stimulus its presence may result in a shift of the dose-response curves of the agonist followed by a decline of the maximum attainable effect. In such a case the antagonist may be expected to exhibit a certain specificity with respect to the agonist. A reserve in receptors for the agonist may be the cause of this shift. Since SKF 525-A is a reversible antagonist, the small shift noted is significant. Therefore, SKF 525-A although noncompetitive in action like papaverine acts by way of a different mechanism. Papaverine's action is nonspecific whereas SKF 525-A has a certain specificity with respect to the furtrethonium molecule and the cholinergic receptor and, therefore, may be considered to interfere with the actual induction of the stimulus itself. Table I gives the values for the log-affinities calculated according to the method of van Rossum and van den Brink (9). An examination of Table I shows that the values obtained in this laboratory are in agreement with those reported by others. Atropine has the greatest affinity (pA_2) for the cholinergic receptor, even greater than furtrethonium. However, since its intrinsic activity is equal to zero it cannot cause an effect. The pronounced affinity of atropine to the cholinergic receptor is understood in light of the fact that it is effective in concentrations around 1×10^{-8} *M*. Furtrethonium produces its effects at about 3×10^{-6} *M*; but since it has an intrinsic activity, it is capable of eliciting a stimulus and a subsequent response of the biologic object. Adiphenine has an affinity (pA_2) to the cholinergic receptor less than atropine but greater than furtrethonium. The inability of adiphenine to produce a stimulus is due to a molecular configuration that destroys its intrinsic activity. The affinity of SKF 525-A to the cholinergic "neighboring" receptor site (pD'_2) is higher than both papaverine and adiphenine. The value for the affinity is indirectly related to the effective concentrations. Table I lists a question mark for the intrinsic activity of SKF 525-A. As a strong noncompetitive antagonist with some competitive characteristics, it may have two intrinsic activities of 0 and −1, as does adiphenine. On several occasions when SKF 525-A was introduced into the bath, it initiated a stimulus and produced an effect which rapidly subsided. Whether this stimulatory effect was induced by interaction with receptors is questionable. However, such a response was never noted for any of

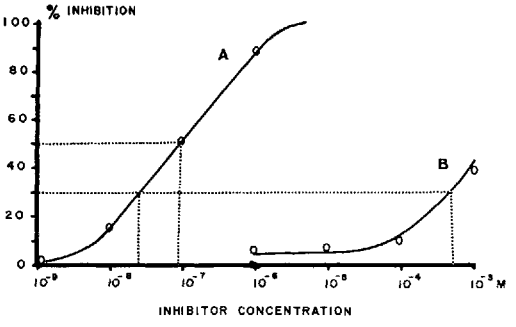

Fig. 5.—Acetylcholinesterase inhibition by physostigmine and SKF 525-A. Key: A, physostigmine ($M\ I_{50} = 9.50 \times 10^{-8}\ M$; $M\ I_{30} = 2.65 \times 10^{-8}\ M$); B, SKF 525-A ($M\ I_{30} = 8.25 \times 10^{-4}\ M$).

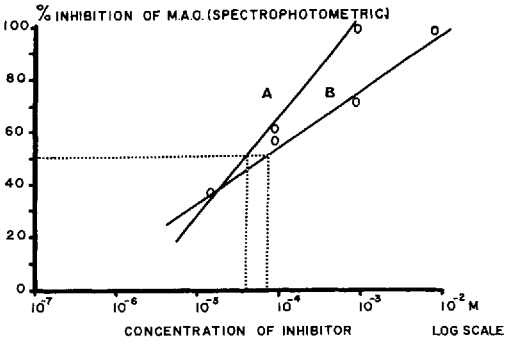

Fig. 6.—Spectrophotometric determination of $M\ I_{50}$ for iproniazid ($8.5 \times 10^{-5}\ M$) and SKF 525-A ($5.3 \times 10^{-5}\ M$) on monoamine oxidase. Key: A, SKF 525-A; B, iproniazid.

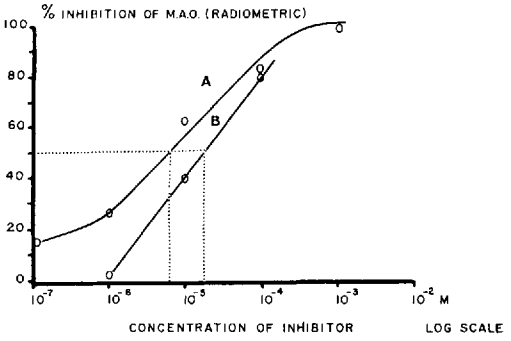

Fig. 7.—Radiometric determination of M I_{50} for iproniazid (7.5×10^{-6} M) and SKF 525-A (1.9×10^{15} M) on monoamine oxidase. Key: A, iproniazid; B, SKF 525-A.

the other antagonists utilized. Important implications may be derived from these observations in connection with the rate theory proposed by Paton (14). In reference to this theory, Paton has suggested that if the rate of occupation of the receptor is an important factor for the intrinsic activity, it may be expected that not only the mimetics but also the lytics will induce an initial response (contraction) before acting as a blocking agent. The unique action of SKF 525-A in blocking the interactions of furtrethonium with the cholinergic receptor is strong indication that the receptor site for SKF 525-A is composed of certain components of the cholinergic receptor and another spasmogen receptor.

In Vitro Acetylcholinesterase Inhibition.—Since SKF 525-A is considered to be a multipotent enzyme inhibitor and since most of the antiacetylcholinesterases, especially the reversible ones, are structurally related to acetylcholine, the action of SKF 525-A on acetylcholinesterase was compared with physostigmine. Figure 5 shows that SKF 525-A was not an effective acetylcholinesterase inhibitor at physiological concentrations. The data for the standard inhibitor, physostigmine, were in excellent agreement with that reported in the literature (15).

In Situ Monoamine Oxidase Inhibition.—The possibility of sympathomimetic effects due to MAO inhibition was considered to be possible in light of the Hippocratic screening. Figure 6 illustrates the data obtained from the spectrophotometric method and shows that SKF 525-A has a lower molar I_{50} than the standard, iproniazid. Figure 7 illustrates the results from the radiometric technique for SKF 525-A and iproniazid. The molar I_{50} values for both procedures are in good general agreement. The concentrations used are in the physiological range. The radiometric method is regarded generally to be the more sensitive and more reliable of the two assays. Allmark (16) demonstrated that large doses of isoniazid and related compounds (iproniazid) prolonged the sleeping time of barbiturates. This provides a correlation between SKF 525-A activity and MAO inhibition since the first major action of SKF 525-A that was studied was its capacity for barbiturate potentiation. In any case it is possible that inhibition of MAO may account for the sympathomimetic effects seen when SKF 525-A alone is administered to intact unanesthetized rats.

Pyrimidine Derivatives VIII

5-Arylazopyrimidines and Their Inhibitory Effects Against Transplantable Mouse Tumors

By MERVYN ISRAEL, HERBERT N. SCHLEIN*, CHARLOTTE L. MADDOCK, SIDNEY FARBER, and EDWARD J. MODEST

Twenty-five substituted 5-arylazopyrimidine derivatives have been prepared as potential "small molecule" antagonists of folic acid *via* reaction of 5-unsubstituted pyrimidines with appropriate diazotized aniline derivatives. The antineoplastic activity of 19 of these compounds has been examined *in vivo* by means of a primary screening program utilizing five transplantable mouse tumors. At nontoxic dosages, several of these agents showed effective tumor growth inhibition, as evidenced by reduction in mean tumor size. Histopathological examination of mice treated with 2,4-diamino-6-hydroxy-5-phenylazopyrimidine revealed intestinal irritation and evidence of nephrotoxicity, as well as incomplete absorption of the drug.

THE EFFECTIVENESS of aminopterin (4-aminopteroylglutamic acid) against acute leukemia in children (1) has led to the synthesis of a variety of folic acid antagonists as potential tumor inhibitory substances. Included among these are the so-called "small molecule" antifolics (*i.e.*, compounds less closely related to the structure of folic acid but retaining antifolic activity),[1] which are represented by the following examples: the 2,4-diamino-5-arylpyrimidines (I) (2), the 2,4-diamino-5-aryloxypyrimidines (II) (3), the 2,4-diamino-5-benzylpyrimidines (III) (4), and the 2,4-diamino-5-aryl-*as*-triazines (IV) (5), all synthesized by Hitchings and his collaborators, and the 4,6-diamino-1-aryl-1,2-dihydro-*s*-triazines (V) (6), prepared in these laboratories. These antimetabolites all approximate the 2,4-diamino-5-arylpyrimidine structure. A more complete comparison of these "small molecule" antifolic structures has already appeared elsewhere (7). Various substituted 5-arylazopyrimidines (VI), which structurally resemble the aforementioned compounds, have been prepared by us for evaluation as potential antitumor agents. Preliminary communications on the synthesis (8) and microbiological activity (9) of these compounds have appeared; the latter report was published simultaneously, by mutual arrangement, with that of Timmis and co-workers (10), whose independent studies paralleled our own. At about the same time, Tanaka and his colleagues also described the biological activity of some 5-arylazopyrimidines (11), and various reports have since appeared concerning the antifolic and tumor inhibitory activity of this type of compound (12–15). The authors now describe the synthesis of some hitherto unreported derivatives of this series and summarize their experimental antitumor properties.

DISCUSSION

The 5-arylazopyrimidines prepared during this investigation (Tables I and II) were obtained by reaction of a 5-unsubstituted pyrimidine with an appropriate diazotized aniline derivative. Compounds *1–14* represent a series of derivatives of 2,4-diamino-6-hydroxypyrimidine with modification in the arylazo substituent (R_4). In this series, the coupling reaction was accomplished at pH 5.0–5.5 in 10% sodium acetate, following essentially the conditions of Benson, Hartzel, and Savell (16); the yields varied from 50–100%. With other pyrimidines, no general pH optimum was found for diazo coupling. Some pyrimidines (*e.g.*, 2,4-diamino-6-chloropyrimidine) coupled best at a slightly acid pH; others (*e.g.*, 2,4-diamino-6-mercaptopyrimidine) required an alkaline pH for coupling. In some instances (*e.g.*, 2,4-diaminopyrimidine), coupling did not occur at any pH tried. In two instances (compounds *19* and *21*), the coupling reaction was most efficient when the pH was kept constant during the entire course of the reaction by means of a buffered system. It appears, therefore, that optimal conditions for diazo coupling represent a compromise between the solubility of the pyrimidine and its relative reactivity toward electrophilic substitution, on the one hand, and the concentration of the diazonium salt and its rate of decomposition on the other.

The crude products were purified initially by thorough washing with alcohol, water, and ether, and then, if they contained hydroxy or mercapto substituents, by precipitation from alkaline solution by the addition of dilute acid; material purified to this stage was sufficiently pure for biological evaluation. Analytically pure samples were obtained by one of three general methods: sublimation, recrystallization, or reprecipitation. The method of choice, wherever applicable, was high vacuum sublimation; this technique afforded analytically pure, anhydrous material directly. Second choice was recrystallization. Arylazopyrimidines are, in general, insoluble in most common organic solvents. However, a limited few were crystallizable from hydrophilic solvents such as ethanol or 2-ethoxyethanol. The third choice was repeated precipitation either from basic solution by the addition of acid or from acetone solution by the addition of water. This procedure usually returned hydrates of variable composition which retained

[a] See under *Experimental*. [b] Percentage yield figures for compounds *1–14*, *19*, *20*, *22*, *24*, and *25* are based upon material which had been once purified by precipitation at pH 4–5 from an alkaline solution; yields for the remaining compounds are based on product purified according to the method indicated under *Purification*. [c] Purification procedure used to obtain the analytical sample. Crystallization solvents: A, 95% ethanol; C, cellosolve (2-ethoxyethanol); C-W, cellosolve–water; E, ether; W, water; S, sublimation in high vacuum (sublimation temperature in °C. in parentheses); P, precipitation at pH 4–5 from alkaline solution. [d] Previously reported as a hydrate (16). [e] Cited in Parker, R. P., and Webb, J. S., U. S. pat. 2,543,333 (Feb. 27, 1951); however, no analytical values are given. [f] The sesquihydrate is obtained on drying at 85° for 48 hr. *in vacuo*; drying at 140° for 72 hr. afforded the hemihydrate. [g] Free acid previously reported by Hartzel, L. W., and Benson, F. R., *J. Am. Chem. Soc.*, **76**, 2263(1954). [h] Containing 5% sodium chloride. [i] *Reference 19*. [j] Also prepared by Timmis *et al.* (10). [k] Reported (10) m.p. 262°. [l] *Reference 21*.

[a] Transplantable mouse tumors employed: L1210 ascitic lymphatic leukemia in the BDF/1 hybrid; P1534 lymphatic leukemia in the DBA/2 inbred strain; C1498 myelogenous leukemia in the C57BL/6 inbred strain; DBRB mammary adenocarcinoma in the DBA/1 inbred strain; S180 spindle cell sarcoma in the CAF/F1 hybrid. Dosages are in mg./Kg./day. A suspension of the agent in 10% polysorbate 80 was administered i.p. once daily starting with the first post-tumor inoculation day and continuing until the death of the last animal. *S*, per cent change in mean survival of treated mice compared with controls; *I*, per cent change in mean tumor size of treated mice compared with controls. Numbers in parentheses indicate day of tumor measurement. [b] Significant survival increase ($S > +20\%$). [c] Significant tumor inhibition ($I > +50\%$). [d] Toxic dose ($S < -25\%$).

water tenaciously; extreme drying conditions were then necessary to obtain anhydrous material.

Nineteen of the 25 compounds reported here were examined for antineoplastic activity against transplantable mouse tumors following the standard assay procedures employed at this foundation (17). (Table III.) All 19 were evaluated against the L1210 ascitic lymphatic leukemia in the BDF/1 mouse and against as many other primary screen tumors as availability of sample would permit. These include the following mouse tumors: P1534 lymphatic leukemia in the DBA/2 inbred strain, C1498 myelogenous leukemia in the C57BL/6 inbred strain, DBRB mammary carcinoma in the DBA/1 inbred strain, and S180 spindle cell sarcoma in the CAF/1 hybrid. The agent was administered intraperitoneally as a suspension in 10% polysorbate 80[2] once daily starting with the first post-tumor inoculation day; injections were continued until the death of the last experimental animal.

At nontoxic dosages,[3] only one agent (compound *16*) showed significant activity against the L1210 leukemia as evidenced by an increase in mean survival time. A number of agents effected moderate to marked tumor inhibition in the other assay systems, but few showed a concomitant increase in mean survival time. These data are summarized in Table III.

[2] Marketed as Tween 80 by Atlas Chemical Industries, Inc., Wilmington, Del.

[3] A dose level was regarded as toxic if the mean survival time of mice administered this dose was 25% or below the mean survival time of control mice.

Tanaka and his associates have claimed that positions 2, 4, and 6 of the pyrimidine ring of VI should all be substituted with amino groups for maximum activity against mouse tumors (14). However, the authors' results (Table III) indicate that, although the 2,4,6-triamino derivatives are active (compounds *17* and *18*), the 2,4-diamino-6-hydroxy derivatives (compounds *1*, *7*, and *9*) and the 2,4-diamino-6-chloro derivatives (compounds *15* and *16*) are more active. A more accurate but nevertheless tentative generalization might be that the 2,4-diamino-5-arylazopyrimidine configuration is required for experimental antitumor activity.

When compound *1* was administered at 20, 40, and 80 mg./Kg./day × 20 i.p. to mice bearing the P1534 leukemia, and compound *24* at 31.25, 62.5, and 125 mg./Kg./day × 12 i.p. to mice bearing the C1498 leukemia, gross inspection at autopsy performed 1 day later in these groups of mice revealed incomplete absorption of compound from abdominal cavities. In addition, compound *1* at the 2 higher doses, and compound *24* at all 3 doses produced intestinal irritation, as manifested by adhesions between surfaces of peritoneal viscera (liver, spleen, and kidney), and capsular thickening. Compound *24*, at the 2 higher dose levels, showed histological evidence of nephrotoxicity, with hyaline casts in dilated proximal and distal convoluted tubules, and degenerating renal epithelium.

In an acute oral toxicity experiment, compound *1* was administered to normal BAF/1 mice by gavage at single doses of 500, 750, and 1000 mg./Kg. The mice were sacrificed 4 days later and, on autopsy, the agent was still evident in the stomachs of the treated animals. The kidneys were pale and enlarged; histology indicated that pigment casts were present in both collecting and convoluted tubules. Additional casts of an amorphous, pink-staining material with dilatation of convoluted tubules pointed to nephrotoxicity.

As mentioned earlier, the compounds have also been examined for antimetabolic activity in microbiological systems and have been found to exhibit antifolic and antipurine properties (9). These results and a detailed analysis of the structure-activity correlations will be the subject of the next paper in this series.

EXPERIMENTAL[4]

Starting Materials.—The aromatic amines were Eastman Kodak white label grade and were used without purification, except for aniline, which was redistilled from zinc prior to use.

The pyrimidines were obtained as follows: (*a*) 2,4-diamino-6-hydroxypyrimidine, 2,4-diamino-6-chloropyrimidine,[5] 2,4-diamino-6-mercaptopyrimidine,[5] and 4-amino-2,6-dihydroxypyrimidine by procedures recently described (19); (*b*) 2,4,6-triaminopyrimidine by the method of Traube (20) from malononitrile and guanidine free base; (*c*) 2,4-diamino-6-methylthiopyrimidine by methods developed in these laboratories (21); (*d*) 4,6-diamino-2-hydroxypyrimidine by hydrolysis of 4,6-diamino-2-mercaptopyrimidine with chloroacetic acid following the procedure of Bendich, Tinker, and Brown (22); (*e*) 4,6-diamino-2-methylthiopyrimidine from Dougherty Chemical Co., Richmond Hill, N. Y., and barbituric acid from Matheson Coleman and Bell, East Rutherford, N. J.

Preparation of 5-Arylazopyrimidines.—The compounds listed in Table I were prepared by the following methods. Although many of the arylazopyrimidines can be made by more than one of the procedures indicated in Table I, the method specified for each compound is the optimal method found during this study. In particular, compounds *7* (*Method E*), *15* and *16* (*Method D*), *19* (*Method F*), and *21* (*Method G*) are best prepared by the specific procedures indicated. Analytical data for the new compounds prepared are given in Table II.

Method A.—This is essentially the method of Benson, Hartzel, and Savell (16). The diazotized aromatic amine in hydrochloric acid solution was added to a cold, stirred solution of an equimolar amount of the pyrimidine in 10% sodium acetate; the pH at the end of the reaction was 5–6. For alkali-soluble products, the work-up was modified to include an initial purification step: the crude product was dissolved in warm 1 *N* sodium hydroxide, the solution filtered free of tarry or insoluble impurities, and the product precipitated at pH 5 by the addition of acetic acid.

Method B.—This procedure differs from *Method A* in that the diazonium intermediate was added to a suspension of the pyrimidine (0.05 mole) in 450 ml. of 10% sodium acetate. The mixture was stirred for 1 hr. at room temperature and the product collected by suction filtration, washed, and dried.

Method C.—In this modification, 0.1 mole of the aromatic amine in 100 ml. of 6 *N* hydrochloric acid was diazotized and coupled with 2,4-diamino-6-hydroxypyrimidine (0.1 mole) dissolved in 500 ml. of 10% sodium carbonate.

Method D.—A diazotized amine solution, prepared in the usual manner and freed of excess nitrous acid by the addition of urea, was added to a cold, stirred solution of the pyrimidine in 3 *N* acetic acid. Immediately after admixture, solid sodium hydroxide was added to adjust the pH to 4; the pH was then brought to 5.5 by the addition of a large quantity of solid sodium acetate. The reaction mixture was stirred for at least 3 hr., the temperature gradually rising to room temperature. The product was collected, washed with water, and dried.

Method E.—A suspension of 0.2 mole of diazotized sulfanilic acid (23) was added at room temperature to a solution of 0.2 mole of 2,4-diamino-6-hydroxypyrimidine in 160 ml. of 1 *N* sodium hydroxide. A bright yellow precipitate formed instantaneously and the resulting suspension was stirred for 15 min. The final pH was 5.0. The product was collected, washed sparingly with cold water, and dried for 17 hr. at 60° *in vacuo*. Isolation of the sodium salt of compound *7* was accomplished by addition of an equal volume of absolute ethanol to a solution of 20 Gm. of the crude material in 600 ml. of 1% aqueous sodium bicarbonate.

[4] Melting points were taken by the capillary method at a rate of heating of 2°/min. in a modified Wagner-Meyer melting point apparatus (18) and are uncorrected. Drying of analytical samples was carried out at 70–100° for 17 hr. *in vacuo* over phosphorus pentoxide. Analyses were performed by Dr. Stephen Nagy and his associates, Microchemical Laboratories, Massachusetts Institute of Technology, Cambridge, Mass., and by the Scandinavian Microanalytical Laboratory, Herlev, Denmark.

[5] Larger quantities of this material were obtained through the courtesy of the Cancer Chemotherapy National Service Center, National Cancer Institute, National Institutes of Health, Bethesda, Md., and were prepared by Aldrich Chemical Co., Milwaukee, Wis., according to the procedures outlined in *Reference 19*.

Method F.—The coupling reaction was achieved at a constant pH of 9.6 in an ammonium hydroxide–ammonium chloride buffer following the procedure recently described (19).

Method G.—Coupling was accomplished at constant pH of 5.0 in a citric acid–disodium phosphate buffer; this procedure is described in *Reference 21.*

Effects of Pentobarbital, Acetylsalicylic Acid, and Reserpine on Blood Pressure and Survival of Rats Subjected to Experimental Stress

By JOSEPH P. BUCKLEY, EUGENE E. VOGIN*, and WILLIAM J. KINNARD

Sodium pentobarbital, 20 mg./Kg. *per os* daily, and acetylsalicylic acid (ASA), 100 mg./Kg. *per os* daily, failed to prevent the development of hypertension in rats subjected to experimental stress. ASA enhanced the lethal effects of the stressors and potentiated the effects of the stress conditions on gastric mucosa. Reserpine phosphate, 0.1 mg./Kg. (base) i.p. daily, administered after the animals had been subjected to the stress conditions for 6 weeks, did lower the blood pressure to control levels.

THE DEVELOPMENT of hypertension in animals exposed to experimental stress has been reported by numerous investigators (1–5). Buckley *et al.* (5) found that reserpine phosphate, 0.1 mg./Kg. i.p., and chlorpromazine hydrochloride, 4 mg./Kg. i.p., administered 1 hr. prior to subjecting rats to a 4-hr. variable stress program not only failed to decrease the pressor effects induced by the stressors over a 27-week period but also appeared to potentiate the lethal effects of the stressors. This present study was undertaken to investigate the effects of pentobarbital and acetylsalicylic acid (ASA) on animals subjected to chronic variable stress programs, and the effects of reserpine phosphate[1] administered to the experimental animals after physiological effects of stress exposure were evident.

EXPERIMENTAL

The stress chambers utilized were semisoundproof rooms designed by the Industrial Acoustics Co., New York, N. Y. (5). The stress program consisted of (*a*) flashing 150-w. spotlights (installed in each corner of the cage) which were on for $^1/_4$ sec. and off for $^3/_4$ sec. (in alternate pairs); (*b*) audiogenic stimulation at 5-min. intervals for 0.5-min. periods produced by amplifying a tape recording of noxious sound so that the intensity was approximately 100 decibels at the center of the cage; and (*c*) oscillation at the rate of 140/min. A simple conditioned avoidance response program utilizing automatic pole climbing units (4) was also utilized in the stress program. The cycle was initiated every 2.75 min. and consisted of a low tone for 15 sec., followed by the delivery of an electric shock (3 ma.) to the grid

Method F.—The coupling reaction was achieved at a constant pH of 9.6 in an ammonium hydroxide–ammonium chloride buffer following the procedure recently described (19).

Method G.—Coupling was accomplished at constant pH of 5.0 in a citric acid–disodium phosphate buffer; this procedure is described in *Reference 21.*

floor for 30 sec. or until the animal leaped onto the Plexiglas pole. Control blood pressures were obtained twice weekly in both studies, utilizing a photoelectric tensometer (Metro Industries, Long Island, N. Y.) and the animals acclimated to this apparatus over a 4-week pre-experimental training period.

Study 1.—Fifty-nine male Wistar rats, weighing approximately 175 Gm., were randomly divided into 6 groups. The groups to be stressed contained 15 rats each and received the following treatment: group *A*, distilled water, 1 ml./Kg.; group *B*, sodium pentobarbital, 20 mg./Kg.; and group *C*, acetylsalicylic acid (ASA), 100 mg./Kg. Three unstressed control groups were divided as follows: group *D*, 5 animals treated with distilled water, 1 ml./Kg.; group *E*, 5 rats receiving sodium pentobarbital, 20 mg./Kg.; and group *F*, 4 rats receiving ASA, 100 mg./Kg. The animals receiving pentobarbital and distilled water were treated by oral intubation 0.5 hr. prior to subjecting the animals to the 4-hr. stress program. Acetylsalicylic acid was suspended in 1% carboxymethylcellulose and was administered by gastric intubation 1 hr. prior to subjecting the animals to the stress.

The stressors were applied singly or in combination, and the stressor schedule altered daily to prevent acclimation to the stimuli. The animals were stressed 4 hr./day, 6 days/week, from weeks 1–17 and 6 hr./day, 6 days/week, from weeks 18–30. The blood pressure of each animal was obtained once a week prior to administering drugs and subjecting the animals to the stress chamber. The animals in the 3 stressed groups were subjected to ten 2.75-min. cycles in the avoidance response pole climbing apparatus once weekly starting with the twelfth week. These animals were not exposed to the stress chamber on that particular day and received water or drug treatment prior to being subjected to the avoidance-escape situation.

Study 2.—A second study was conducted utilizing 68 male albino Wistar rats, which were divided as follows: group *A*, 24 rats treated with 0.1 ml./Kg. of saline i.p.; group *B*, 25 rats treated with 0.1 ml./Kg. of saline i.p., weeks 1–6; and reserpine phosphate, 0.1 mg./Kg. (base) i.p., 0.5 hr. prior to the experiment, from week 7 on; group *C*, 9 rats treated with saline, 0.1 ml./Kg. i.p.; and group *D*, 10 rats treated with saline, week 1–6 and reserpine phosphate, 0.1 mg./Kg. (base) i.p., from week 7 on. The animals in groups *A* and *B* were subjected to 2 hr. of variable stress daily, 6 days/week; and starting with the tenth week were also subjected to the pole-climbing stress once weekly. Groups *C* and *D* were utilized as nonstressed controls. Blood pressures and body weights were obtained once weekly on all animals prior to treatment and subjection to stress.

RESULTS

Study 1.—The effects of the stressors on blood pressures of the experimental animals are summarized in Fig. 1. The blood pressures of the stressed animals rose steadily reaching maximum values during the sixteenth and seventeenth week (group *A*, 158 mm. Hg ± 3.08; group *B*, 154 mm. Hg ± 2.25; and group *C*, 154 mm. Hg ± 2.0), whereas the mean blood pressures of the nonstressed animals ranged from 118–124 mm. Hg. When these data were subjected to the Student *t* test, the differences between the mean blood pressures of the stressed group and the nonstressed control group were highly significant ($P < 0.01$).

Increasing the duration of stress from 4 to 6 hr. during the eighteenth week did not appear to induce a further increase in blood pressure. At the end of the thirtieth week, none of the stressed rats of group *A* were dead, whereas the mortality rate was 13% for the pentobarbital treated stressed rats and 67%

for the ASA-treated stressed rats. The majority of deaths occurred at night between stress sessions. All of the animals in group *C* (ASA treated) which died during the stress session had marked ulceration of the stomach and small intestines with evident bleeding of the gastric mucosa. There was also a marked difference in the behavior of the various groups. The animals in each group were initially docile and very easy to handle; however, by the fifteenth week, the rats in group *A* (treated with distilled water) were extremely difficult to handle and demonstrated a high degree of activity. The animals in group *B* (pentobarbital treated) appeared to be more docile than those in group *A* but did show signs of irritability and became more aggressive during the latter portion of the study. The animals in group *C* (ASA treated) demonstrated the greatest change in that they were extremely difficult to handle and fought the feeding tube continuously. All of the animals in this group had pronounced diarrhea, excessive salivation, and appeared to be extremely sensitive to touch. The nonstressed controls remained fairly docile throughout the experimental period; however, group *F* which received daily administration of ASA appeared to be more excitable than the other two control groups, and most of the animals in this group had periods of diarrhea throughout the study.

Study 2.—The blood pressures of the animals in the two stressed groups gradually increased and by the sixth week of stress averaged 20 mm. Hg higher than initial blood pressures, whereas the blood pressures of the two control groups increased by less than 8 mm. Hg (Fig. 2). Reserpine phosphate, administered once daily starting with the seventh week produced mild diarrhea and ptosis in the animals of groups *B* and *D*. The mean blood pressure of the animals in group *B* dropped from 122 mm. Hg in week 6 to 105 mm. Hg in week 8, and ranged from 101–110 mm. Hg throughout the remainder of the experiment. The blood pressure of the saline-treated stressed group reached a maximum of 125 ± 2.9 mm. Hg during the seventeenth week of the experiment, whereas the reserpine-treated stressed animals in group *B* had a mean blood pressure of 104 ± 1.4 mm. Hg ($P < 0.05$). The number of deaths occurring in this study was relatively low in comparison to previous studies (4% in group *A*, 12% in group *B*, 11% in group *C*, and 20% in group *D*), and the hypertensive effect occurring during the chronic exposure to the stressors was also much less than has

Table I.—Conditioned-Avoidance Response in Male Albino Rats Subjected to Experimental Stress

25	8.3 ± 1.06	14.7 ± 1.23
26	8.1 ± 0.99	15.1 ± 1.06

previously been obtained. The response latencies of the saline and reserpine-treated stressed animals in the avoidance-escape test are summarized in Table I. The response time of the reserpine-treated animals was always much greater than the saline-treated animals; however, there was a gradual decrease in response time over a 12-week period from 36 sec. to slightly over 15 sec.

DISCUSSION

The hypertensive effects induced by exposure to the stressors in the first study were similar to those previously obtained in this laboratory (3-5). The responses obtained in the second study, however, were relatively mild; and after reaching a peak in the seventeenth week, the animals appeared to be acclimated to the experimental conditions as demonstrated by a plateauing of the blood pressure over the next 10 weeks. Several additional studies have since been conducted, and this variation in the blood pressure response has also occurred. The physiological response of the animal to the experimental stressors appears to vary among samples obtained from the same strain and from an identical source at different times, but there is only a slight variation in the response of animals within a particular sample.

In the first study, pentobarbital and ASA failed to protect the experimental animals from the effects of the stressors. The stressors apparently potentiated the toxicity of ASA, an effect which was most apparent on the gastrointestinal tract. The oral administration of single doses of ASA (100–500 mg./Kg.) has been reported to cause small gastric mucosal erosions to fasted guinea pigs within 30 min. of dosing; however, they appeared to heal within 24 hr. (6). Many investigators have also associated ingestion of ASA with the development of gastric mucosal erosions in mice (7, 8). Selye (9) has reported that exposure of rats to one or more stressors will induce gastric ulceration. The intensity of the stressors utilized in this current study have been controlled so that gastric ulceration would not occur in untreated stressed rats. The data indicate that the effects of ASA on gastric mucosa are greatly enhanced by environmental stress. Selye (10) has suggested that stressors induce the discharge of ACTH which stimulates the release of both mineral corticoids and glucocorticoids from the adrenal cortex, and Timmer (11) has reported a marked increase in free plasma corticosterone of rats subjected to severe acute stress. Salicylates have also been reported to increase the plasma level of 17-hydroxycorticosteroids in rats (12), and it is, therefore, possible that this assumed increase in plasma corticosteroids may be responsible for the gastric ulceration. However, it appears more likely that the observed ulcerations were due to a combination of the local effect of the ASA on the gastric mucosa and an increase in free plasma corticosteroids.

Reserpine phosphate did reverse the effects of the experimental stressors on the blood pressure of rats (*Study 2*). These data are opposite to those obtained in a previous study (5) in which reserpine, 0.1 mg./Kg. i.p., not only failed to protect the rats from the pressor response induced by chronic stress but potentiated the lethal effects of the stressors. Epstein *et al.* (13) investigated the effects of reserpine on the stress of reduced barometric pressure in rats and also found that rather than protect the rats against the stress of altitude reserpine acted as an added stress factor. The experimental design in the previous study was different than the one presently being reported. In the present study, reserpine was not administered until the seventh week of stress to allow for the development of the stress reaction; whereas in the previous study, reserpine treatment was initiated immediately. These data suggest that the effects of reserpine and, for that matter, almost any compound may vary greatly, depending upon the time interval following the initiation of the stress program that treatment is started. However, it is also possible that the relatively mild physiological response to the stressors was responsible for the effect observed with reserpine.

Micromeritics of Granular Pharmaceutical Solids II

Factors Involved in the Sieving of Pharmaceutical Granules

By DALE E. FONNER, JR., GILBERT S. BANKER, and JAMES SWARBRICK

This report deals with basic studies concerned with the use of sieving as an accurate means of classifying granular pharmaceutical solids. Attention was focused on the effects of sieve shaker speed, initial load and particle size distribution of the granulation on the rate of particle size reduction and the cumulative per cent of material passing a sieve. The size and concentration of the smaller-than-mesh particles were shown to exert a profound influence on the equilibrium time of a sieve. Using a nest of sieves, an equilibrium time technique was developed to obtain the particle size distribution and permit calculation of various statistical parameters dependent on the observance of the log-normal law. An equilibrium time procedure such as developed here permits the quantitative classification of granular pharmaceutical solids by sieving, with a better assurance that separation has been achieved with the minimum of attrition.

THERE ARE few reports in the literature concerning the sieving of granular pharmaceutical solids for the purposes of classification or size analysis. It would appear that, in the past, such important considerations as size of the initial load, the sieve shaker speed, time of sieving, and the hardness, particle size distribution, and shape of the material being sieved have either been left to chance or substantially neglected. Such fundamental parameters as the type of particle size distribution and the magnitude of various statistical diameters on a weight or count basis have also not been applied to pharmaceutical granulations.

Since sieving is the easiest technique available for classifying particles in the size range of granular pharmaceutical solids, it finds wide industrial application. However, sieving errors can arise from a number of different variables. According to Herdan (1), the most predominant are variations in sieve loading, duration of sieving, random orientation of particles, fluctuation through sampling, errors of observation and experiment, and the effect of different equipment and operations. Consequently, if sieving is to be applied as an accurate, quantitative technique for classification, it is necessary to obtain more information as to the effect of the parameters previously enumerated on both the sieving process and the particle size distributions obtained.

Whitby (2) has carried out an extensive study of the physical laws which govern the sieving of fine particles. It was shown that the sieving curve under nonsteady-state conditions can be divided into two distinctly different regions, with a transition region between. The sieving curve was obtained by plotting the cumulative per cent by weight passing the sieve against time on either log-log or log-probability paper. A typical example of the former case is shown in Fig. 1. Whitby found that the rate at which the material passes a sieve in region 1 is a constant closely following the relationship:

$$\% \text{ material passing} = at^b \qquad \text{(Eq. 1)}$$

where t is the sieving time, b is a constant very nearly equal to 1, and a is a sieving rate constant. Region 2 was found to follow the log-normal law. In this region all the particles much smaller-than-mesh size have already passed the sieve; consequently, the particles now passing the sieve are of a constant mesh size. For all practical purposes the sieve is considered to be at equilibrium at that time when the second linear portion (region 2) begins, since the slight positive slope of the line is due mostly to the attrition of larger-than-mesh size particles (Fig. 1).

The purpose of this report is to (*a*) present useful techniques and theories developed in other fields of study for the computation of various statistical diameters, (*b*) investigate the magnitude of particle size reduction which occurs on a vibrating sieve, (*c*) investigate the effects of load, shaker speed, and particle size distribution on the cumulative per cent of material passing a sieve, and (*d*) suggest a method for determining the sieving time for a nest of sieves.

EXPERIMENTAL

Preliminary Controls.—Brass screens[1] constructed to A.S.T.M. specifications were used in all cases. A Cenco-Meinzer[2] sieve shaker was employed with the speed setting at position 5, except for those studies concerned with the effect of varying the sieve

shaker speed. A nylon brush was used to clean the sieves. Each granulation batch was gently mixed prior to sampling by placing the granulation on a sheet of paper and lifting the corners in sequence toward the center of the sheet. The preparation and properties of all granules used have been described elsewhere (3).

Particle Size Reduction on a Single Sieve.—Granules prepared using a hand screen and an oscillating granulator were examined (3). No sieve cuts were used and the initial load for sieve analysis was 100 Gm. The cumulative per cent by weight passing a No. 16 sieve was plotted against time on log-probability paper over an extended shaking period.

Effect of Load and Shaker Speed on Granule Breakdown.—Granules produced from an oscillating granulator (3) were employed. A 16-mesh sieve was used and no sieve cuts were taken. The effect of varying the initial load was studied between the limits of 50 and 150 Gm. The effect of altering the speed setting was studied using a standard load of 100 Gm. and varying the speed between the limits of positions 2 and 8 on the shaker speed control.

Particle Size Reduction on a Nest of Sieves.—The effect of shaking time on the estimation of the geometric mean diameter on a weight basis, $\bar{M}$, was determined using 16, 20, 40, and 60 screens in a nest. An initial 100-Gm. load of granules prepared using the hand screen was used and no sieve cuts were taken. The particle size distributions obtained at various shaking time intervals were plotted on log-probability paper. The values for $\bar{M}$ were then plotted against time on log-log paper.

Influence of Particle Size on the Equilibrium Time of a Sieve.—This investigation was carried out using a No. 20 mesh sieve and a commercially prepared calcium sulfate base granulation.[3] Three systems of granulations were studied. System *1* consisted of 12/16 mesh particles together with various concentrations of 40/60 mesh particles over the range from 12.5–100% by weight. System *2* contained 12/16 mesh particles and 30/40 mesh particles in concentrations ranging from 25–100% by weight. System *3* was composed of 12/20 mesh particles plus various concentrations of 20/40 mesh particles ranging from 12.5–100% by weight. The equilibrium times were obtained, from log-log plots of the cumulative per cent passing the sieve as a function of time, as that time at which the second linear portion of the plot began. This is shown as E.T. in Fig. 1. (See also Fig. 6.)

Characterization of Particle Size Distribution.—Various statistics were computed from the distribution of particle sizes obtained using two techniques.

Standard Procedure.—The standard procedure consisted of sieving a 200-Gm. sample of the lactose granulation (3), prepared using the hand screen, for 10 min. on a nest composed of a No. 16, 20, 30, 40, 60, and 80 mesh sieve. The cumulative per cent less-than-stated size was plotted against stated size on log-probability paper.

Equilibrium Time Procedure.—The equilibrium time procedure was based upon a sequential analysis developed from the equilibrium time values of the individual sieves in the nest. This approach was necessary because the upper sieves in a nest will unload their smaller-than-mesh particles before those sieves near the bottom of the nest. Consequently, the equilibrium time for a sieve in a nest can only be computed when the smaller mesh screens are at nonsteady-state conditions. Therefore, the sieve immediately below the sieve whose equilibrium time was being determined was covered with a sheet of paper. The material collected after the upper sieve had come to equilibrium was then used as the sample for the previously covered sieve; the next lower sieve in the nest was covered in this case. The equilibrium times for the individual sieves, obtained from log-log plots of the cumulative per cent passing the sieve as a function of time, are presented in Table I.

On the basis of these results, the following procedure was used to obtain the particle size distribution of 200 Gm. of the lactose granulation (3). The same nest of sieves was employed but no sieves were covered. The No. 16 sieve was removed after 90 sec. of shaking and its contents weighed. It was then emptied and returned to the nest. After 150 sec. of shaking, the 20- and 30-mesh sieves were removed and their contents weighed. The screens were emptied and then returned to the nest. Finally, the last three screens were removed and weighed after a total of 200 sec. of shaking (this time was obtained by adding the individual equilibrium times together). Selection of the times for removal of the sieves is not highly critical, although the selected time must *not* be less than the computed equilibrium time for the sieve being removed.

RESULTS AND DISCUSSION

Particle Size Reduction on a Sieve.—The data from extended shaking time studies performed on particles from the oscillating granulator were found to follow the log-normal law as predicted by Whitby (2), for sieving times beyond the equilibrium time value previously defined. Figure 2 represents a plot of cumulative per cent passing *versus* time on log-probability paper. It is evident that a considerable number of particles are still passing the sieve after 140 min. of shaking. Since it is not likely that undersize particles would take this long to reach the classification area, it must be assumed that particle size reduction is occurring.

Table I.—Equilibrium Times for the Individual Sieves in a Nest[a]

Mesh size	16	20	30	40	60	80
Equilibrium time, sec.	45	30	25	20	36	44

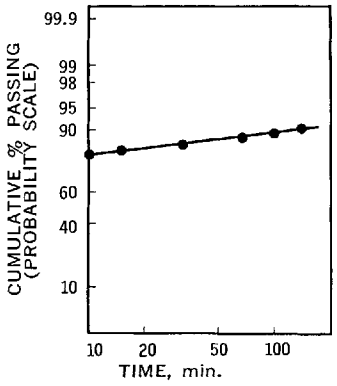

Fig. 2.—Log-probability plot of the rate of attrition of particles from the oscillating granulator. Load: 100 Gm.; speed setting: 5; sieve size: 16 mesh.

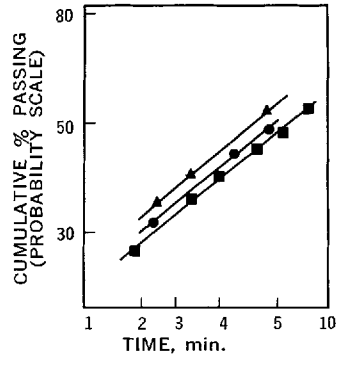

Fig. 3.—Effect of initial load upon the rate of attrition of particles from the oscillating granulator. Speed setting: 5; sieve size: 16 mesh. Key: ▲, 50 Gm.; ●, 100 Gm.; ■, 150 Gm.

Effect of Load on Granule Breakdown.—Figure 3 illustrates the results obtained for the three different initial loads studied. Since the curves for each initial load are virtually parallel, the attrition rate constant is apparently unaffected by the initial load over the range of values studied. However, it is evident from Fig. 3 that the cumulative per cent passed at any one time increases as the initial load decreases over the range of values studied. This means that the smaller loads have passed a greater percentage of their particles at equilibrium time than have the higher loads, *i.e.*, the smaller the load, the more efficient is the sieving process. This phenomenon is probably due to less "blinding" on the sieve and greater maneuverability of the particles at these smaller loads.

Effect of Shaker Speed on Granule Breakdown.—The results obtained from this portion of the study are plotted in Fig. 4. Since the actual vibration rates of the shaker at the various speed settings could not be determined, it was not possible to plot attrition rate as a function of vibration rate. Nevertheless, it is apparent from Fig. 4 that higher speeds of shaking may markedly influence the reduction in size of particles on a sieve.

Effect of Sieving Time on the Geometrical Mean Diameter by Weight.—Plots of the geometrical mean diameter by weight, $\bar{M}$, for particles from the oscillating granulator, at various sieving times are shown in Fig. 5. These data were obtained from studies on the particle size reduction on a nest of sieves.

It is apparent from Fig. 5 that much care must be exercised when selecting a sieving time, especially if the ultimate objective is to characterize the distribution of particle sizes. The mean particle size by weight obtained from sieve analysis will continually decrease as the sieving time increases. Similar data were obtained for particles prepared from the hand screen; however, the slopes of the two lines were different. Thus, the slope of the sieving curve for particles from the oscillating granulator was 0.096 μ/sec. and the slope for particles from the hand screen was 0.174 μ/sec. This implies that the particles prepared from the oscillating granulator are harder than those from the hand screen, a finding which is in agreement with the hardness index values determined for these granulations in earlier work (3).

Influence of Particle Size on the Equilibrium Time of a Sieve.—The effects of different proportions by weight of three sieve fractions of smaller-than-mesh size calcium sulfate granules on the equilibrium time of a 20-mesh sieve are shown in Fig. 6. Each point on the curve represents the mean of two equilibrium

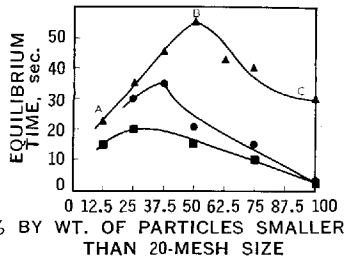

Fig. 6.—Effect of various particle size fractions upon the equilibrium time of a 20-mesh sieve using a commercial calcium sulfate granulation. Load: 200 Gm.; speed setting: 5. Key: ■, system *1* (12/16 and 40/60-mesh fractions); ●, system *2* (12/16 and 30/40-mesh fractions); ▲, system *3* (12/20 and 20/40-mesh fractions).

times. These were obtained graphically and, in most cases, were identical. System *3* was chosen because it contained many particles at, or near, mesh size.

From Fig. 6, it can be seen that the equilibrium times go through a maximum which is displaced to a lower percentage of smaller-than-mesh size particles as these smaller particles decrease in size. At the same time, the height of the peak decreases. In this particular study, all the variables were held constant with the exception of the per cent by weight of particles smaller-than-mesh size. The time taken for all the smaller-than-mesh size particles to pass the sieve is obviously a function of the number of these particles as well as the number of particles too large to pass which will hinder the passage of the smaller particles. Thus,

$$\text{E.T.} = f(n_u, n_0) \qquad \text{(Eq. 2)}$$

where E.T. is the equilibrium time in seconds, n_u is the number or weight of particles which can pass the screen, and n_0 is the number or weight of the greater-than-mesh size particles.

Increasing n_u while keeping n_0 constant would be expected to increase E.T. because of the increased number of particles which must now pass through the larger-than-mesh size particles and the sieve. On the other hand, holding n_u constant and decreasing n_0 would permit the smaller-than-mesh size particles to pass more rapidly through the sieve because the hindrance effect of the larger-than-mesh size particles is being progressively reduced.

In the system under discussion, we are increasing the weight concentration of the smaller-than-mesh size particles at the expense of the larger-than-mesh size particles, *i.e.*, n_u is increasing and n_0 is decreasing simultaneously. This reasoning may now be applied to the results shown in Fig. 6. Thus, it is postulated that over the region AB, the E.T. is increasing because the increase in n_u is of more significance than the decrease in n_0. However, at B, the effect of increasing n_u (tending to increase E.T.), and the effect of decreasing n_0 (tending to decrease E.T.), are equal and a maximum point is obtained. Over the region BC, the value for E.T. falls because the decreasing n_0 is now the controlling factor. We would expect, furthermore, the point at which the equilibrium time begins to decrease, after reaching the maximum B, to occur at lower concentrations of the smaller sized component, as the size of the latter decreases. This is because the hindrance of the smaller-than-mesh size particles by the larger particles decreases as the size of the former decrease. This is shown to occur in Fig. 6.

It is also evident from Fig. 6 that the maximum equilibrium time increases as the smaller-than-20-mesh particles increase in size. This is presumably due to the fact that the movement of the smaller sized particles through the void spaces in the granular bed becomes more difficult as the size of the smaller particle fraction increases. The large increase in equilibrium time for system *3* (12/20 mesh and 20/40 mesh particles), is most likely due to "blinding," since this system contained many particles at, or near, mesh size. Particles in this size range will reduce the effective open area of the sieve. Therefore, when selecting a sieving time, much thought should be given not only to the size of the smaller-than-mesh particles, but also to the *concentration* of such particles.

It is interesting to note the 100% point on the curves for the three systems shown in Fig. 6. At this point, there are no particles larger than mesh size present on the sieve. Therefore, an equilibrium time near zero is to be expected. This was not the case for system *3*, containing 20/40 mesh particles, where 6.7% of the granules by weight were still on the sieve after 15 min. of shaking. This phenomenon was checked by resieving the bulk sample of 20/40 mesh particles and running the determination again. The moisture content of the granules was checked before resieving and immediately following the 15 min. shaking period; it was constant at 1.6%. The same result was obtained, *i.e.*, approximately 7% by weight of the initial load of 200 Gm. did not pass. It is postulated that reduction in the

TABLE II.—STATISTICAL PARAMETERS CALCULATED FROM SEIVING STUDIES[a]

Parameter	Eq. Used (4)	Sieving Procedure: Std., 10 min.	Sieving Procedure: Equilibrium Time
Geometric mean diam. by wt., $\bar{M}$	50% of stated size from plot on log-probability paper	840 μ	900 μ
Geometric S.D., σ_g	$\frac{84.13\%\text{ stated size}}{50\%\text{ stated size}}$ from plot on log-probability paper	3.67	4.12
Geometric mean diam. by count, d_g	$\log d_g = \log \bar{M} - 6.908 \log^2 \sigma_g$	5.13 μ	2.19 μ
Mean surface diam. by count, d_s	$\log d_s = \log \bar{M} - 4.605 \log^2 \sigma_g$	28.73 μ	16.29 μ
Mean vol. diam. by count, d_v	$\log d_v = \log \bar{M} - 3.454 \log^2 \sigma_g$	66.81 μ	44.40 μ
Arithmetic mean diam. by count, d_{av}	$\log d_{av} = \log \bar{M} - 5.757 \log^2 \sigma_g$	12.36 μ	5.97 μ
No. of particles/Gm., N	$\log N = \log \frac{1}{\rho \alpha_v} - \log d_g^3 - 10.362 \log^2 \sigma_g$	1.369×10^7	4.661×10^8

[a] 200 Gm. of the lactose granulation prepared by the hand screen method was used.

effective open sieve area, due to the large number of near-mesh-size particles present, was probably the major cause of this unexpected result.

Comparison of Various Statistical Diameters.—Using the standard and equilibrium time procedures for sieve analysis, it was possible to make a comparison of various statistical diameters. These were computed from the respective plots of size distribution by weight on log-probability paper shown in Figs. 7 and 8. In both cases, the distributions closely follow the log-normal law. Table II summarizes the results obtained from Figs. 7 and 8.

Owing to the increased duration of sieving, it was expected that those statistical diameters obtained by sieving for 10 min. would be smaller than those using the equilibrium time procedure. However, this was only true for the diameter calculated on a weight basis, $\bar{M}$. The expected order of statistical diameters by count was reversed because of the high value for σ_g in the equilibrium time analysis. (See Table II.) From this portion of the study, it can be concluded that although diameters on a weight basis will always decrease with increasing sieving times, those calculated diameters by count cannot always be assumed to decrease with increasing sieving times. In actuality, these parameters do decrease, but the computed values are arrived at from a consideration of the entire range of particle sizes. Since sampling of particle sizes was possible only over a finite range, the error in σ_g arising from lack of data at the very small sizes was probably responsible for the results shown in Table II.

Particle size reduction has been shown to occur when sieving is continued well beyond the equilibrium time, and this probably accounts for the widely varying values of $\bar{M}$ and σ_g shown in Table II. Therefore, to lessen the error introduced by particle breakdown, the equilibrium time procedure is suggested for the characterization of size distribution of pharmaceutical granular solids. Such an approach automatically takes account of the variable equilibrium times observed for the separate sieves. (See Table I.)

CONCLUSIONS

Basic studies on the sieving mechanism were carried out. It was found that particle size reduction occurred during sieving and was markedly influenced by the sieve shaker speed setting. The rate of particle size reduction was apparently independent of the initial load; however, the efficiency of the sieving operation is influenced by the initial load, as evidenced by Fig. 3. The equilibrium time of a sieve was found to be markedly dependent on the particle size of the sample used. This was particularly so when the size of the particles approach the mesh size of the sieve. Also shorter equilibrium times were observed when the concentration of smaller-than-mesh size particles was either fairly high or low in comparison to the greater-than-mesh size particles. At intermediate concentrations of the smaller-than-mesh particles, the equilibrium times can be expected to increase.

Comparative studies, using two different techniques to obtain particle size distribution curves, showed that the computed statistical diameters were influenced by the time of sieving. It is recommended that the equilibrium time procedure be used for the characterization of granular pharmaceutical solids by sieving. This in turn must entail prior knowledge of the equilibrium times of each individual sieve since, as is seen in Table I, these vary with screen mesh size. Only by the use of the equilibrium time method can the operator be confident that particle breakdown has been kept to a minimum and that equilibrium conditions on each sieve in the nest have been attained.

Increasing Dissolution Rates and Gastrointestinal Absorption of Drugs *Via* Solid Solutions and Eutectic Mixtures IV

Chloramphenicol–Urea System

By ARTHUR H. GOLDBERG*, MILO GIBALDI†, JOSEPH L. KANIG, and MICHAEL MAYERSOHN

The dissolution rates of a number of chloramphenicol–urea samples were studied. Solubility studies indicated that urea increased significantly the solubility of chloramphenicol; this resulted in a large increase in the initial dissolution rate of chloramphenicol from physically mixed samples of the drug with urea. The α solid solution of chloramphenicol in urea was found to dissolve twice as rapidly as a physical mixture of the same composition, and almost 4 times as rapidly as the pure drug.

THE IMPORTANCE of particle size reduction as a means of increasing dissolution rates is well established. The methods by which a drug may be presented to the gastrointestinal fluids in finely divided form has been reviewed by Levy (1). Among the various ways to obtain microcrystalline dispersions *in vivo* is to administer a eutectic mixture composed of the drug and a substance which readily dissolves in water (2). This approach has been employed to enhance the dissolution rate of chloramphenicol (3). The results of this study were explained on the basis of particle size reduction of chloramphenicol in the drug–urea fused mixture (3).

Goldberg *et al.* (4) have raised a number of theoretical questions concerning the proposed mechanism of this phenomenon. Alternatively, these authors suggested that the enhanced dissolution rate was attributable to the presence of solid solutions in the system rather than simple eutectic formation. Indeed, the sample prepared by Sekiguchi *et al.* (3) at the eutectic composition manifested no enhancement in the dissolution rate of chloramphenicol as compared to the pure drug. An increase in dissolution rate became apparent only when a sample containing urea in excess of the eutectic composition was investigated.

The failure of the chloramphenicol–urea eutectic mixture to display increased dissolution of the antibiotic drug raises doubts concerning the general utility of the simple eutectic mixture in modifying dissolution. These doubts are heightened by a recent study by Goldberg and co-workers (5) on acetyl *p*-aminophenol–urea mixtures. This binary system showed practically no solid solubility. Examination of the results of this investigation indicated that particle size reduction in the eutectic mixture played a negligible role in enhancing dissolution. Conversely, a subsequent study (6) convincingly demonstrated the importance of solid solutions in modifying dissolution characteristics. The griseofulvin–succinic acid solid solution was found to dissolve 6–7 times faster than the pure drug.

The purpose of this present investigation was to examine the dissolution properties of various mixtures of chloramphenicol and urea in order to elucidate the mechanism involved in the reported enhancement of the rate of solution of chloramphenicol from these mixtures.

EXPERIMENTAL

Sample Preparation.—The fused mixtures of chloramphenicol[1] and urea were prepared by adding the powdered blend to a stainless steel crucible immersed in a temperature-controlled silicone fluid bath preheated to the melting point of the mixture. The mixture was constantly stirred until a homogeneous liquid resulted. The molten material was then cast immediately on chrome-plated stainless steel plates and allowed to congeal. The solidified mass was crushed with a mortar and pestle and then sieved through standard screens using a Syntron shaker.[2] Those particles passing through a No. 50 standard screen but retained on a No. 60 screen were used in the dissolution studies. The particle size of pure chloramphenicol was increased in the same manner. The samples investigated are listed in Table I. The chloramphenicol content of each sample was verified by spectrophotometric analysis.

Urea	74		

Solubility Studies.—The solubility of chloramphenicol as a function of urea concentration was studied in aqueous solution. An excess of chloramphenicol was added to 30 ml. of distilled water containing various concentrations of urea, in 60-ml. screw-top vials. The vials were then placed in an incubator shaker[3] and maintained at 37° until equilibrium was established.

Solubility studies were also conducted with sample *F* (α solid solution) and sample *G* (a physical mixture corresponding in composition to the α-solid solution). An excess of each sample was placed in 30 ml. of water and incubated until the system reached equilibrium. This experiment was conducted to insure that fusion did not result in decomposition of the active ingredient.

Dissolution Rate Studies.—The dissolution rate of chloramphenicol from each of the samples listed in Table I was determined by means of the tape method (7). The quantity of material dusted on the adhesive surface varied with the individual sample but in each case corresponded to 10 mg. of chloramphenicol. The choice of a constant amount of drug is based on the assumption that if no interaction occurs, then the drug crystallizes from the melt to form particulates, within the mass, of approximately the same size regardless of urea concentration. If this hypothetical situation did exist, then all fused samples should show the same dissolution rate since the urea rapidly dissolves and leaves behind about 10 mg. of drug in the form of equal-sized particulates, having the same surface area. Under such conditions it would not be reasonable to maintain sample size constant since the apparent dissolution rate would decrease as the concentration of diluent increases and the corresponding effective surface area decreases.

The dissolution fluid consisted of 400 ml. of distilled water maintained at 37° in a 600-ml. beaker which was immersed in a constant-temperature water bath. The stir paddle was rotated in the fluid at a constant rate of 53.5 r.p.m. After immersion of the tape frame, 1-ml. samples were withdrawn at 3 and 5 min.

Assay Procedure.—Chloramphenicol concentration was determined spectrophotometrically. Each sample was diluted suitably with distilled water and the absorbance determined at 274 mμ using a Beckman DB recording spectrophotometer. Concentrations were calculated from a previously prepared Beer's law plot.

RESULTS AND DISCUSSION

Phase Diagram.—As noted by Goldberg *et al.* (4) the chloramphenicol–urea system exhibits a great deal of solid solubility. This is manifested by the existence of regions α and β in the phase diagram depicted in Fig. 1. At the eutectic point the mixture contains 76% chloramphenicol which is present as part of 2 distinct saturated solid solutions. The saturated α solid solution contains 30% chloramphenicol, while the saturated β solution contains

[a] Refer to Table I for description of samples.

90% of the drug. The eutectic mixture actually consists of 23% α and 77% β solid solution. The α and β solid solutions account for 7 and 69 parts, respectively, of the total 76 parts of chloramphenicol present in the eutectic mixture.

Solubility Studies.—The data presented in Fig. 2 clearly demonstrate the significant effect of urea on the solubility of chloramphenicol. A greater than sevenfold increase in the solubility of the drug was observed over the urea concentration range studied.

The solubility of the α solid solution was found to be identical with that of a physical mixture of the same composition. This finding is indicative of the absence of chemical reaction between the drug and carrier which could occur during the fusion process. Therefore, the samples differ only with respect to their physical state.

Dissolution Rate Studies.—The results of the dissolution studies are shown in Table II. Inspection of each of these rates reveals a number of interesting relationships as well as an insight to the complexities involved in the dissolution of chloramphenicol from the fused binary mixtures.

The chloramphenicol–urea eutectic was found to dissolve somewhat faster than the pure drug with a comparable particle size. Sekiguchi *et al.* (3) were unable to detect differences in the dissolution rate of the eutectic mixture and the pure drug. The experimental discrepancies between the former study and the present work may be ascribed to differences in the method of determining dissolution rate. The method employed by Sekiguchi and coworkers involved a higher degree of agitation than employed in this investigation. The use of high shear in *in vitro* dissolution investigations tends to obviate differences arising from microenvironmental factors which would be significant *in vivo*. Three individual (or possibly concerted) factors are involved in the dissolution of chloramphenicol from the eutectic. These include local solubilization, particle size reduction, and the presence of a significant amount of the rapidly soluble α solid solution.

The importance of the microenvironmental effect of urea on the dissolution of chloramphenicol may be appreciated by considering the dissolution rate of the physically mixed chloramphenicol–urea sample. As noted in Table II, the relative dissolution rate of the drug from sample *G* is almost twice as rapid as from the pure chloramphenicol. The solubility of chloramphenicol is significantly higher in the microenvironment (which approximates a saturated solution of urea) than in the bulk and the drug dissolves rapidly.

The significance of solid solution formation in the enhancement of dissolution can be realized by comparing the results obtained from samples *F* and *G*. Both samples are identical with respect to composition but differ in that sample *F* is a fused mixture and is actually composed of a homogeneous solid solution of chloramphenicol in urea. One would anticipate that the local effect of urea would be approximately the same in both samples or perhaps somewhat lower in the fused sample where urea exists in a more hydrophobic solid environment and conceivably dissolves at a slower rate. Despite this seeming equality, the initial dissolution rate of chloramphenicol from the α solid solution is more than twice that of the physical mixture and almost 4 times greater than the rate of solution of the pure drug. These differences may only be ascribed to the physical state of the chloramphenicol in the fused sample.

In a previous paper (4), Goldberg *et al.* theorized that the β solid solution of urea in chloramphenicol may demonstrate a strong crystal lattice. The results of dissolution studies conducted with the β solid solution indicate that despite the presence of a significant quantity of urea in the sample the solution rate is approximately equal to that of the pure drug. This is rather surprising in that the mere presence of a material as soluble as urea in the crystal would tend to increase the wetting of the particle and in this manner alone increase effective surface area and thereby increase dissolution rate. The inability to demonstrate this effect may perhaps be attributable to the formation of a crystal lattice in which the chloramphenicol is bound at least as tightly as in the pure crystal.

Comparison of the results obtained with samples *B*, *C*, *D*, *E*, and *F* reveals an interesting relationship. These samples range in α solid solution content from 0% (pure β solid solution) to 100% (pure α solid solution). The rate of dissolution of chloramphenicol from these mixtures was found to be a direct function of the α solid solution content of the sample. With an increase in the per cent α solid solution in the sample there was a corresponding increase in the rate of solution of the drug.

The findings of these investigations once again point out the potential importance and biopharmaceutical significance of solid state molecular dispersions in the enhancement of dissolution rate.

Dermatitic Effect of Nonionic Surfactants I

Gross, Microscopic, and Metabolic Changes in Rabbit Skin Treated with Nonionic Surface-Active Agents

By M. MEZEI, R. W. SAGER, W. D. STEWART*, and A. L. DERUYTER†

Nonionic surface-active agents were applied to rabbit skin daily in an attempt to determine the physiological properties and irritative potential of some selected surfactants. Three methods of evaluation were used: gross examination, microscopical examination, and measurement of the respiratory metabolic activity of the treated skin. The gross and microscopical evaluations of these tests both indicated that the greatest irritation was produced by the polyoxyethylene ethers. These substances produced gross inflammation in even short periods of time (3 days) in the weakest dilutions (1 per cent) in which they were tested. Polysorbates caused more irritation than sorbitans. The metabolic measurements indicated a two, three, and fourfold increase in the oxygen consumption of the inflamed, treated skin sample, depending on the length of the treatment and the type of agent used.

IN THE PAST 20 years there has been a considerable increase in the utilization of synthetic surfactants as household and industrial cleansing products, and as solubilizers and emulsifiers in both pharmaceutical and cosmetic preparations. Consequently, because of this frequency of contact among the general population, the effects on the human skin of these surfactants become of extreme importance.

At present a literature survey presents a wide variety of results. In 1963, Treon (1) conducted standard patch tests with a large number of nonionic surfactants, including those that were used in the present experiment. He reported no irritation with human skin and only mild irritation on rabbit skin in the cases of sorbitan trioleate,[1] polysorbate 80,[2] and polyoxyethylene esters 52, 56, and 72.[3] The other nonionic surfactants caused no irritation in rabbit skin. The same year Choman (2) published observations on the effects of aqueous nonionic surfactants on excised calf and human skin, in which he indicated that irritation or cellular structural alteration did not occur.

Contrary to these reports there are several studies claiming carcinogenic effects of some of the same nonionic surfactants in *in vivo* mouse skin experiments (3–9).

Received April 16, 1965, from the School of Pharmacy, Oregon State University, Corvallis.
Accepted for publication March 23, 1966.
This project was initiated by the senior author while at the University of British Columbia, Vancouver, B. C., Canada. A preliminary report was presented at the Eleventh Canadian Conference on Pharmaceutical Research, Halifax, N. S., Canada, August 15, 1964.
This work is supported by the Medical Research Council of Canada, gr. MA-1623, by the Canadian Foundation for the Advancement of Pharmacy, and by the Oregon State University Research Council.

This presentation will consider the gross anatomic, histological, and metabolic changes of rabbit skin caused by the daily application of selected nonionic surface-active agents.

EXPERIMENTAL

Three main groups of nonionic surface-active agents were selected for this study: (*a*) partial esters of sorbitan fatty acids, sorbitan series; (*b*) partial esters of polyoxyethylene sorbitan fatty acids, polysorbate series; and (*c*) polyoxyethylene ethers.[3]

A detailed list of these surfactants is in Table I. These surfactants were used both in undiluted and in diluted forms, using distilled water, hydrophilic

ointment U.S.P., hydrophilic petrolatum U.S.P., and white petrolatum U.S.P. as diluents. The diluents were also applied alone as controls.

Increasing concentrations from 1–100% of the above surfactants were prepared and applied to the trunks of New Zealand white rabbits. Each trunk, clipped free of hair by an electric clipper (Oster model A2), provided 8 test areas. On each rabbit, one area was untreated and one area was treated with only an ointment base, to act as control sites. Fifty rabbits were used in this investigation, providing 400 separate areas. About 0.3 Gm. of each different preparation was evenly applied and then gently rubbed in for 3 sec. with a hard rubber spatula to the appropriate area, once a day. For the evaluation of histological changes biopsy specimens were taken from representative sites after application for 10 and 30 days and at the completion of the experiment. After each biopsy, that area was discontinued for use as an experimental site. With forceps, the skin was elevated, and a full thickness biopsy was taken by scissors. The specimens were kept in a 10% formol–saline solution until routine histological slides were prepared, stained with hematoxylin and eosin, and examined microscopically.

The oxygen consumptions of the treated and control skin samples were determined by the direct Warburg method (10). The animals were killed by fracturing the neck. The test areas were washed with water quickly to remove the remainder of the substances previously applied, and the samples were taken with the aid of the Castroviejo keratotome (11) set to cut 0.2 mm. thickness of skin. The skin slices were cut to small pieces with cold scissors and were immediately weighed on an analytical balance (referred to as wet weight), then transferred to Warburg flasks containing 3.0 ml. of Kreb's Ringer phosphate–glucose solution (10) and 0.2 ml. of 20% KOH solution in the center well. The measurement was carried out at 37°, after a 30-min. equilibration period. Room air was used as the gas phase. At the end of the measurement the samples were removed from the flasks, rinsed in distilled water, and placed in preweighed crucibles. Dry weights of the samples were obtained by drying overnight in an oven at 105°. The oxygen consumption was calculated in microliters per milligram of skin (dry) per hour: this value is the QO_2.

RESULTS AND DISCUSSION

The samples were evaluated by three methods: (*a*) direct inspection, (*b*) histological examination, and (*c*) measurement of the respiratory metabolic activity of the treated skin.

Gross observations were made and recorded daily, but representative tables are made up for intervals of 3 days and 10 days after starting applications. After 3 days of application, the first gross changes, namely erythema and edema, resulting in a hard induration began to appear where certain of the polyoxyethylene ethers were being applied, even in a dilution of 10%. Irritation was also observed, but to a lesser degree (Table II), where 100% concentrations of polysorbates were applied. At the sites of application of 10% concentrations of polysorbates, only a slight erythema was noticeable. With the exception of sorbitan monolaurate[4] and sorbitan trioleate, no changes were seen at the sorbitan areas. As the treatment continued, a de-

Fig. 2.—Control skin, plain hydrophilic ointment application only (−).

gree of irritation became apparent in most treated areas. The skin treated with polyoxyethylene ethers of all concentrations showed scaling and thickening, with marked induration and fissuring. A type of crust formation, shown microscopically to consist of necrotic and sloughing epidermis, often developed after 1 week of treatment with various concentrations of polyoxyethylene ether, (as illustrated by Fig. 1). Area 1 (polyoxyethylene ether 56, 5%) and area 3 (polyoxyethylene ether 30,[5] 10%) showed considerable irritation. Area 4, the untreated skin, showed no sign of irritation. The inflamed necrotic and irreversibly damaged epidermis sloughed off after 2 or 3 weeks of polyoxyethylene ethers application, but reepithelialization of the surface followed rapidly.

Table II illustrates the gross evaluations after 3 days of treatment. It is evident from this table that the surfactants belonging to the polyoxyethylene ether series produced irritation even after 3 days of application, and in a dilution of 1%. Table III records observations made after 10 days of application, where even the areas treated with surfactants belonging to the sorbitan series begin to show some irritation. An interesting observation was the increased rapidity of hair growth, chiefly in areas of application of the polysorbates. New skin was formed satisfactorily from remaining epidermal appendages in almost all the areas which had sloughed off after treatment with the polyoxyethylene ether-type of surfactants.

The microscopic appearances in the treated areas paralleled the degree of gross irritation observed. Figures 2, 3, 4, and 5 illustrate the degrees of inflammation and irritation after 10 days of application. The microscopic changes which were observed are illustrated by Tables IV and V.

The respiratory metabolic activity of selected samples of surfactant-treated skin was studied using oxygen consumption measured by the Warburg method. It has been reported (12–14) that in *in vitro* tests the surfactants influence enzymatic reactions, damaging the function of the respiratory chain. The authors found that the surfactant-treated skin consumed 2, 3, or 4 times as much oxy-

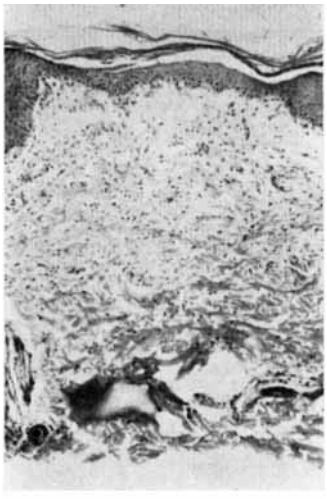

Fig. 3.—Polysorbate 80 in 100% concentration; there is irregular acanthosis of the epidermis and edema and inflammation in the dermis (2+).

Fig. 4.—Polyoxyethylene ether 52 in 5% concentration. There is acanthosis and hyperplasia of the epidermis, together with some edema and inflammation of the dermis (3+).

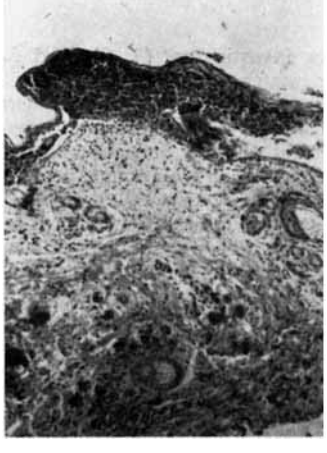

Fig. 5.—Polyoxyethylene ether 30 in 60% concentration; the epidermis is destroyed. It is replaced by eosinophilic staining material filled with many polymorphonuclear leucocytes. These cells extend to the dermis and in some instances dip down into the sebaceous glands and hair follicles. There are scattered polymorphonuclear leucocytes and indication of edema in the dermis (4+).

gen as the control skin, depending on the length of time of the treatment and on the type of agent used. The results are illustrated by Figs. 6 and 7.

Figure 6 represents the QO_2 values of the control and treated skin samples obtained from 13 rabbits at a period of 3- to 15 days (1 rabbit a day) after starting application. Figure 7 illustrates the QO_2 values of skin samples taken from the second group of rabbits, 15 in number, within the period of 30–81 days after starting application. During this period the samples were taken 30, 31, 40, 42, 43, 44, 45, 50, 51, 52, 55, 58, 77, 78, and 81 days after starting the application.

A specific explanation for the increased respiration rate due to the topical application of surfactants has not yet been found. The surfactants can directly influence enzymatic reactions as reported (12–14). On the other hand, the permeability changes of cell membranes induced by the surfactants could also be the source of the altered respiratory activity. The effect of these surfactants on the cell membranes, and in a smaller scale, on the membrane of the mitochondrion is very probable, due to their hydrophilic and lipophilic properties. By these properties they might be able to disturb the balance of the cell system, *e.g.*, they can weaken the hydrophobic bond, which is a key to the structure and function of the membrane of the mitochondrion, consequently causing alteration in the oxidative metabolism.

One of the difficulties in measuring skin respiration is to provide samples containing mainly the epidermis and relatively small amounts of dermis. The oxygen consumption of the epidermis, which is ordinarily actively proliferating, is significantly higher than that of the dermis. Usually, skin respiratory results refer to milligrams of dry skin or milligrams of tissue nitrogen. While the dry weight is a rather poor standard, due to the possible variations in amounts of epidermis, dermis, or physiologically inert constituents present, no other standard has been shown to be superior. Tissue nitrogen varies directly with the dry weight and is, in addition, more time consuming. With the aid of the Castroviejo keratotome samples were obtained containing relatively uniform structural components of the skin. The definite pattern in the authors' results, and the reproducibility of repeated measurements during these investigations, indicate that with this technique, the dry weight (imperfect as it may be) is the most practicable standard of reference.

A number of rabbits, of which the gross and histological skin-change data were presented above, were being treated with surfactants for several months in a long-term study to ascertain whether any carcinogenic effect can be observed arising from application of the above surfactants, as has been reported in mouse skin experiments (3–9). The authors found no gross or microscopic signs of carcinogenic effect of these agents in 3 rabbits which were treated with sorbitans and polysorbates for a period of 5 months and of 22 rabbits which were treated for more than 2 months.

The authors' results are in conflict with previous reports regarding the irritative potential of these substances.

In these reports (1, 2), no irritation was reported caused by sorbitan monolaurate, sorbitan mono-

stearate,[6] sorbitan monooleate,[7] polysorbate 20,[8] polysorbate 60,[9] polysorbate 80; and polyoxyethylene ethers 30 and 92;[10] and only mild irritation caused by sorbitan trioleate, polysorbate 85,[11] and polyoxyethylene ethers 52 and 72. The difference in the degree of irritation, which in our case was extreme, and in some instances, resulted in complete destruction of the epidermis, may be due to the different methods by which the surfactants were applied. The above investigators (1, 2) used *in vitro* tests and/or patch tests. The authors' method was an attempt to reproduce the frequent application of dermatologic and of cosmetic preparations by the general public. It is not always advisable to apply the results of animal experiments to humans and the fact that these evidences of irritation have been produced in rabbits must be kept in mind in assessing their significance.

The closed patch test applied for 48 hr. is less desirable as a measure of capacity of a primary irritant than a daily application of the test material for a period of at least 10 days.

Studies have not proved that synthetic detergents are entirely responsible for the reported increase in primary irritant dermatitis and "housewife's dermatitis" cases (15–18). Evidence has been presented that surface-active agents cause denaturation of keratin (19) and produce harmful

effects on the horny layer as defatting agents by removal of the lipids and other substances (20–23). The surface-active agents are usually present in cosmetic and dermatological preparations in concentrations varying from 1–10%. Considering the above studies (15–23) and these results, the possibility arises that, if the increased number of cases of hand dermatitis in females cannot be explained by the increased use of synthetic household detergents then the surfactants present in hand lotions and other cosmetic or dermatological preparations could possibly be one factor in some of the cases of hand dermatitis in the female population. There are, as yet, only animal tests to prove that a number of polyoxyethylene ether surfactants, a common component of hand lotions, have a distinct potential to irritate the skin. Certain other surfactants, namely the polysorbates and sorbitans, also have undesirable influences on the skin, if used in daily applications for a longer period.

Occurrence of Amanita Toxins in American Collections of Deadly Amanitas

By V. E. TYLER, JR., R. G. BENEDICT, L. R. BRADY, and J. E. ROBBERS*

Chromatographic examination of *Amanita phalloides* carpophores collected in the Pacific Northwest revealed the presence of relatively large amounts (1.5–1.9 mg./Gm. dry wt.) of β-amanitin but lesser concentrations (trace to 0.93 mg./Gm.) of α-amanitin. It was concluded that these represent a distinct chemical race of *A. phalloides*, apparently restricted in its occurrence to the states of Washington, Oregon, and California. Other species investigated included *Amanita bisporigera*, the most toxic yet found in the United States, containing 2.25–5.0 mg. of α- and β-amanitins per Gm. *Amanita verna* specimens contained variable amounts of the two toxins (0 to 1.7 mg./Gm.), but very small quantities (0 to <0.1 mg./Gm.) of α-amanitin only were detected in samples of *Amanita virosa*.

CONFUSION ABOUNDS in the literature pertaining to the identity and toxicity of *Amanita* species. In the United States this is particularly true of *Amanita phalloides* (Fr.) Secr. and related species (so-called deadly amanitas); in fact, all literature prior to the last decade or two must be carefully evaluated to determine, if possible, the identity of the mushroom which was actually studied under a particular designation.

Until 1918, all species of deadly amanitas occurring in the U. S. were generally referred to *A. phalloides*, which was considered to represent a single polymorphic species. For example, Murrill (1), referring to *A. phalloides* in 1916, wrote of "The variety of colors assumed by this species—white, yellow, green, gray, brown, blackish . . ." In 1918, Atkinson (2) recognized that the most common *Amanita* species in the eastern U. S., usually interpreted as a dark brown form of *A. phalloides*, was actually a different species. He subsequently described it and assigned the name *Amanita brunnescens* Atk. The various color forms were gradually sorted out with the passing years, the white forms being identified as *Amanita verna* (Fr.) Vitt. s. Boud., *Amanita virosa* Secr., or *Amanita bisporigera* Atk., the yellow or green as *Amanita citrina* S. F. Gray, and the blackish or gray as *Amanita porphyria* (Fr.) Secr. Finally, none remained which could actually be designated *A. phalloides*.

Changes in nomenclature are generally accepted with reluctance; thus, *A. phalloides* is still frequently referred to in the popular press and even in scientific writings. As late as 1955, the term "brown *A. phalloides*" was used to designate *A. brunnescens* (3). Disregarding this use of antiquated nomenclature, mycologists began to assume that authentic *A. phalloides* did not occur in the U. S. (4).

In 1958, Smith (5) reported that the species did occur rarely in California, but details were not presented. A year later, specimens were found in Ashland, Ore., which greatly resembled *A. phalloides*, and analysis of them revealed the presence of β-amanitin (6) as well as a smaller amount of α-amanitin (7). A fatal case of mushroom poisoning with symptoms identical to those

Occurrence of Amanita Toxins in American Collections of Deadly Amanitas

By V. E. TYLER, JR., R. G. BENEDICT, L. R. BRADY, and J. E. ROBBERS*

Chromatographic examination of *Amanita phalloides* carpophores collected in the Pacific Northwest revealed the presence of relatively large amounts (1.5–1.9 mg./Gm. dry wt.) of β-amanitin but lesser concentrations (trace to 0.93 mg./Gm.) of α-amanitin. It was concluded that these represent a distinct chemical race of *A. phalloides*, apparently restricted in its occurrence to the states of Washington, Oregon, and California. Other species investigated included *Amanita bisporigera*, the most toxic yet found in the United States, containing 2.25–5.0 mg. of α- and β-amanitins per Gm. *Amanita verna* specimens contained variable amounts of the two toxins (0 to 1.7 mg./Gm.), but very small quantities (0 to <0.1 mg./Gm.) of α-amanitin only were detected in samples of *Amanita virosa*.

CONFUSION ABOUNDS in the literature pertaining to the identity and toxicity of *Amanita* species. In the United States this is particularly true of *Amanita phalloides* (Fr.) Secr. and related species (so-called deadly amanitas); in fact, all literature prior to the last decade or two must be carefully evaluated to determine, if possible, the identity of the mushroom which was actually studied under a particular designation.

Until 1918, all species of deadly amanitas occurring in the U. S. were generally referred to *A. phalloides*, which was considered to represent a single polymorphic species. For example, Murrill (1), referring to *A. phalloides* in 1916, wrote of "The variety of colors assumed by this species—white, yellow, green, gray, brown, blackish . . ." In 1918, Atkinson (2) recognized that the most common *Amanita* species in the eastern U. S., usually interpreted as a dark brown form of *A. phalloides*, was actually a different species. He subsequently described it and assigned the name *Amanita brunnescens* Atk. The various color forms were gradually sorted out with the passing years, the white forms being identified as *Amanita verna* (Fr.) Vitt. s. Boud., *Amanita virosa* Secr., or *Amanita bisporigera* Atk., the yellow or green as *Amanita citrina* S. F. Gray, and the blackish or gray as *Amanita porphyria* (Fr.) Secr. Finally, none remained which could actually be designated *A. phalloides*.

Changes in nomenclature are generally accepted with reluctance; thus, *A. phalloides* is still frequently referred to in the popular press and even in scientific writings. As late as 1955, the term "brown *A. phalloides*" was used to designate *A. brunnescens* (3). Disregarding this use of antiquated nomenclature, mycologists began to assume that authentic *A. phalloides* did not occur in the U. S. (4).

In 1958, Smith (5) reported that the species did occur rarely in California, but details were not presented. A year later, specimens were found in Ashland, Ore., which greatly resembled *A. phalloides*, and analysis of them revealed the presence of β-amanitin (6) as well as a smaller amount of α-amanitin (7). A fatal case of mushroom poisoning with symptoms identical to those

Received March 10, 1966, from the Drug Plant Laboratory, College of Pharmacy, University of Washington, Seattle, and the *College of Pharmacy, University of Houston, Houston, Tex.
Accepted for publication April 1, 1966.
Presented to the Medicinal Chemistry Section, A.PH.A. Academy of Pharmaceutical Sciences, Dallas meeting, April 1966.
This investigation was supported in part by grant GM 07515-06 from the U. S. Public Health Service, Bethesda, Md.

Fig. 1.—*Amanita phalloides* carpophore collected in Seattle, Wash.

produced by amanita toxins was reported from California in 1965 (8). The species responsible was identified as *A. phalloides*, but botanical details were not presented. In October 1965, Mrs. Betty Dorland collected specimens on Mercer Island, Seattle, Wash., which were identical to the 1959 collection from Oregon. The carpophores (Fig. 1), found growing in sandy grass-covered soil under old birch trees, were identified as *A. phalloides*[1] (Table I).

This discovery of specimens of deadly amanitas in the Pacific Northwest prompted the present study with its dual objectives: (*a*) to determine if the specimens of *A. phalloides* collected in the U. S. were similar in their toxin content to specimens of European origin and (*b*) to evaluate the quality and quantity of toxins in other American collections of deadly amanitas.

EXPERIMENTAL

Analysis of Washington A. phalloides.—Dried carpophore tissue (550 mg.) was exhaustively extracted with methanol in a Soxhlet apparatus and the resulting extract (*A*) concentrated to a volume of 2.0 ml. To insure complete extraction, the dried marc was subsequently re-extracted with 70% ethanol, and this extract (*B*) was evaporated to dryness, and the residue redissolved in 1.0 ml. of 70% ethanol.

Quantities of these extracts ranging from 1–10 μl. were spotted on thin-layer plates prepared with Silica Gel G and were chromatographed in a solvent mixture composed of methanol–methyl ethyl ketone (1:1), as described by Sullivan *et al.* (9). For reference, α- and β-amanitin[2] were chromatographed concurrently and in admixture with the extracts. Spraying the chromatograms with 1% cinnamaldehyde in methanol followed by exposure to hydrochloric acid vapor revealed the amanita toxins as violet-colored spots. As little as 0.3 mcg. of pure α- or β-amanitin could be detected with certainty by this procedure. The results, including average R_f values and approximate quantities determined by visual comparison of the size and intensity of the spots with those of the reference standards, are summarized in Table II.

Quantities (< 20 μl.) of both extracts *A* and *B* and of the reference compounds were also chromatographed on Silica Gel G plates with *n*-butanol–acetic acid–water (4:1:1) as described by Benedict *et al.* (10) and on Whatman No. 1 and No. 3 filter papers with methyl ethyl ketone–acetone–water–*n*-butanol (20:6:5:1) as recommended by Block *et al.* (3). In all of these systems extract *A* yielded relatively large amounts of β-amanitin; extract *B* contained a very small amount of β-amanitin and a trace only of α-amanitin.

Analysis of Other Deadly Amanitas.—Additional *Amanita* species which have been suspected of containing amanita toxins include *A. bisporigera*, *A. tenuifolia* Murr., *A. verna*, and *A. virosa* (11). Of these, samples of *A. tenuifolia* and *A. verna* were examined chromatographically by Block *et al.* (3); the former was found to contain only β-amanitin but the latter both α- and β-amanitin. However, several specimens identified as *A. verna* contained no amanita toxins.

For their studies the authors were able to obtain several samples of *A. bisporigera*,[3] *A. phalloides* (European origin), *A. phalloides* (Oregon origin), *A. verna*,[3] and *A. virosa*. Details of these collections are presented in Table I. One-hundred-milligram samples of *A. bisporigera* and 500-mg. samples of *A. phalloides*, *A. verna*, and *A. virosa* were extracted with methanol in a Soxhlet apparatus and quantities of the concentrated extracts were spotted and chromatographed in the methanol–methyl ethyl ketone system as previously described. The amanitins were detected with cinnamaldehyde spray and verified, in doubtful cases, with Pauly's reagent (12). R_f values and estimated quantities of toxins detected are described in Table II.

RESULTS AND DISCUSSION

Chromatographic examination of extracts of the specimen of *Amanita* collected in the fall of 1965 in Seattle, Wash., revealed the presence of amanita toxins. The results were similar but not identical to those obtained by analysis of a similar specimen collected in Oregon in 1959 (6). β-Amanitin predominated in both samples, but only traces of α-amanitin could be detected with difficulty in the Seattle specimen following a second extraction of the carpophore with aqueous ethanol. A somewhat larger amount of α-amanitin was present in the Oregon mushroom. Although the total concentrations of these two amanitins (1.9–2.43 mg./Gm.)

approximated that detected in a typical European collection of *A. phalloides* (2.0 mg./Gm.), the unusually high proportions of β- to α-amanitin (1.9/trace, 1.5/0.93) are quite different from that detected in European specimens (about 2/3).

However, since morphological differences between the Pacific Northwest collections and European specimens of *A. phalloides* are essentially nonexistent, it appears most useful to describe the former as members of a chemical race of *A. phalloides* in which β-amanitin is the predominant amanitin. Until large numbers of single carpophores of the European species can be investigated for their content of both α- and β-amanitin, it is not possible to determine if this chemical race was transferred relatively recently to the Pacific coast together with the various introduced trees (*Betula, Populus*), under which it has been found and with which it probably forms mycorrhizal associations, or if it is a race originating in the Pacific Northwest and restricted there in its occurrence. In any event, the evidence indicates conclusively the existence of a chemical race of *A. phalloides* distinguished by a high proportion of β-amanitin, specimens of which are rare in Washington, Oregon, and presumably California.

It is apparent from the data in Table II that *A. bisporigera* is the most toxic American mushroom yet examined. Its total content of α- and β-amanitins was found to range from 2.25–5.0 mg./Gm. in contrast to 1.9–2.43 mg./Gm. for the native *A. phalloides*, 0–1.7 mg./Gm. for *A. verna*, and 0–<0.1 mg./Gm. for *A. virosa*. Singer (13) does not classify *A. bisporigera* in section 6, *Euamanita*, of subgenus II, *Euamanita*, together with other amanita toxin-containing species, but instead lists it under section 5, *Amidellae*. On the basis of its high concentration of α- and β-amanitin, as well as its botanical affinities to *A. virosa* (14), it would seem that the species should properly be classified in section 6, *Euamanita*.

The finding of variable concentrations of toxins in *A. verna* was not unexpected. Although the complete absence of toxins from collection No. 5362 may

be attributed to its excessive age and prolonged storage (31 years) preceding analysis, failure to detect toxins in the more recent collection No. B1 must be due to natural variablility. Block *et al.* (3) report similar results from their study of toxin-containing *Amanita* species in which several specimens identified as *A. verna* produced no toxic symptoms in mice nor could toxins be detected in them chromatographically. It is not clear whether the differences observed by Block *et al.* and by the authors are due to environmental conditions, ontogenetic considerations, or genetic factors, but it must be concluded that the amanita-toxin content of *A. verna* carpophores is extremely variable and, in general, appreciably less than that of *A. bisporigera* or *A. phalloides*.

No amanitins were detected in one sample of *A. virosa* (Tla), but another carpophore (Tlb) collected at the same time from the same site contained a very small amount of α-amanitin (<0.1 mg./Gm.), as did another, more recent collection (T4). Although standard reference works (15, 16) all refer to *A. virosa* as a deadly poisonous species, apparently the only previous experimental work on the subject was that of Ford (17). He found an extract to be toxic to guinea pigs and concluded that the toxins of the species were identical to those of *A. phalloides*. Identification of small amounts of α-amanitin in two carpophores from different collections confirms this earlier finding. However, as in the case of *A. verna*, the effects of environment, ontogenesis, and genetics must all be investigated before a definite explanation can be given for the irregular low-level occurrence of toxins in *A. virosa*.

Kinetics and Mechanisms of Action of Antibiotics on Microorganisms V

Chloramphenicol and Tetracycline Affected *Escherichia coli* Generation Rates

By EDWARD R. GARRETT, GEORGE H. MILLER, and M. R. W. BROWN*

Total and viable count methods were used to study *Escherichia coli* generation rates at various temperatures and tetracycline and chloramphenicol concentrations. The negative dependence of apparent first-order generation rate constants on concentrations of these antibiotics was determined for all temperatures. The coincidence of the heat of activation for *E. coli* growth in antibiotic-free media and for the inhibitory rate constants was observed. The facile reversibility of antibiotic effects to predictable rates of *E. coli* generation in the subinhibitory concentration ranges of these antibiotics was demonstrated. A quantitative model consistent with the observed concentration dependencies and observed reversibilities is proposed which relates antibiotic partitioning from the media, a critical value for protein synthesis that results in microbial generation, and the present concept that these antibiotics compete for ribosomal binding sites and so inhibit the function of messenger RNA in protein synthesis.

THE CLINICAL importance of chloramphenicol and tetracycline has resulted in many investigations of their biochemical mode of action (1–4) and is generally ascribed to the inhibition of protein synthesis which has been principally observed under conditions of complete inhibition of growth. A more complete understanding of the action of these antibiotics could be realized if the kinetics of bacterial generation was more completely elucidated in antibiotic concentrations less than those that result in complete growth inhibition, *i.e.*, subinhibitory concentrations.

Previous reports from this laboratory (5–8) have established methods for the determination of population growth rates of *Escherichia coli* by viable and/or total cell count methods in the presence of these antibiotics either alone or in combination and have demonstrated the linear dependency of such growth rates upon antibiotic concentration. This was a general inhibition of growth rate at 37.5° rather than kill superimposed on an uninhibited growth at subinhibitory antibiotic concentrations. At higher antibiotic concentrations a definite organism kill occurred where kill was defined as a loss of the ability to produce colonies when a diluted sample was incubated on an agar plate.

Fassin *et al.* (9) have reported some work on the temperature dependency of chloramphenicol action using inhibitory and subinhibitory antibiotic concentrations. A more complete kinetic knowledge of the effect of temperature on the kinetics of antibiotic inhibited *E. coli* growth and the derived apparent heat of activation, ΔH, of inhibition are needed to gain insight into the energy requirements of such inhibition.

A lag period in *E. coli* growth after removal of the bacteria from a medium containing inhibitory concentrations of chloramphenicol has been indicated (10). Since the subinhibitory concentrations of chloramphenicol are thought to stimulate RNA synthesis more than higher concentrations (11, 12), a more detailed knowledge of the reversibility of the inhibition of population growth rates at these concentrations is necessary for the formulation of a kinetic mechanism of action.

EXPERIMENTAL

Organism.—All experiments were carried out with *E. coli* strain B/r, a strain that had been employed in previous experiments in this laboratory (5–8).

Medium.—Peptone broth (U.S.P. XVII) was used as the culture broth and combined with agar for colony counts.

Materials.—Assayed samples of tetracycline hydrochloride were supplied by courtesy of The Upjohn Co., Kalamazoo, Mich., and chloramphenicol by courtesy of Parke, Davis and Co., Detroit, Mich.

Temperature Studies.—A broth culture was allowed to grow for 12 hr. at 37.5°, diluted into fresh broth, and the growth rate determined by turbidimetric measurements with a Klett-Summerson colorimeter. When exponential growth had been established, sufficient inoculum to achieve a concentration of 10^6 *E. coli*/ml. was added to fresh broth to make 20-ml. replicate cultures. The cultures were maintained at either 25, 30, 31, 34, 35, 37, 37.5, 41, 43, or 45° on different days in constant-temperature water baths equipped with a shaker. Sufficient antibiotic was added after 90 min. to the cultures to achieve concentrations of 0.0, 1.04, 2.08, 3.12, or 4.16×10^{-7} *M* tetracycline or 1.17, 2.33, 3.50, or 4.66×10^{-6} *M* chloramphenicol.

The number of *E. coli*/ml., N, present in the cultures was determined by a viable (colony) count method and/or a total count method at appropriately spaced time intervals (5–8). For total counts, the Coulter counter (Coulter Electronics, Hialeah, Fla.) was used. Apparent specific growth rate constants, $k_{app.}$ in sec.$^{-1}$, were obtained from the least squares slopes of a plot of log N *versus* time in accordance with the apparent first-order expression,

$$\log N = (k_{app.}/2.303)t + \log N_0 \quad \text{(Eq. 1)}$$

where N_0 is the number of *E. coli*/ml. at $t = 0$, and t is in sec. Regression analysis was performed by an IBM 720 digital computer.

Reversibility Studies.—Three replicate culture flasks were inoculated with sufficient *E. coli* to yield initial concentrations of 10^6 *E. coli*/ml.

Sufficient antibiotic to achieve concentrations of 0.00 and 4.16×10^{-7} *M* tetracycline and 4.66×10^{-6} *M* chloramphenicol was added to the cultures after 90 min. of growth. After 200 min. of growth, a tenfold dilution of the cultures was achieved by adding 2 ml. of the cultures to 18 ml. of fresh broth. The number of *E. coli* present in the cultures was determined by total counts at approximately equally spaced time intervals.

Three replicate culture flasks were inoculated with sufficient *E. coli* to yield an initial concentration of 10^6 *E. coli*/ml. Sufficient antibiotic to achieve concentrations of 0.00 and 1.04×10^{-7} *M* tetracycline and 1.17×10^{-6} *M* chloramphenicol was added after 90 min. of growth. Final concentrations of 0.00 and 1.04×10^{-7} *M* tetracycline and 4.16×10^{-6} *M* chloramphenicol were achieved with the addition of more antibiotic after 150 min. of growth. The number of *E. coli* present in the cultures was determined at appropriately spaced time intervals by total counts.

Viable Count Method.—One milliliter of appropriately diluted (with 0.85% saline) 0.5-ml. samples of the culture was pipeted onto each of 5 replicate agar plates within 15 min. of sampling. Previous experiments (7) have shown the necessity of completing plating within this time interval.

Total Count Method.—One-half milliliter samples of culture were diluted with 0.86% saline which had been previously filtered through a double thickness of type HA Millipore filter paper. A drop of formaldehyde was added, and the total number of organisms was counted with a model A Coulter counter equipped with a 30-μ orifice. The conditions were: an aperture current of 5, a gain of 6, and a threshold setting of 10. When necessary, formaldehyde-inhibited culture aliquots were stored in the freezer for periods not longer than 4 hr. before counting. This procedure does not materially affect total counts (7).

RESULTS

Temperature Studies.—Apparent first-order generation rate constants as per Eq. 1 for the growth of *E. coli* in the presence of tetracycline and chloramphenicol at various temperatures are given in Table I. When the tetracycline concentration is

[a] Derived from viable counts by colony counter. [b] Derived from total counts by Coulter counter. [c] Averaged from several total and viable studies. [d] The 95% confidence limits of these k values were ±0.06–0.10. All others were ±0.02–0.03.

below 4.16×10^{-7} M (0.2 mcg./ml.) or the chloramphenicol concentration is below 4.66×10^{-6} M (1.5 mcg./ml.), a net growth is observed; *i.e.*, $k > 0$. A coincidence of total and viable cell counts was observed during this reduced but exponential growth of the population in the presence of chloramphenicol. A typical example of such plots is given in Fig. 1. The mode of action at 37.5° has been shown to be an inhibition of population growth rate rather than kill superimposed on growth in similar experiments for tetracycline (7). Thus, the mode of action appears to be independent of the temperature range studied and similar for both chloramphenicol and tetracycline (Table I).

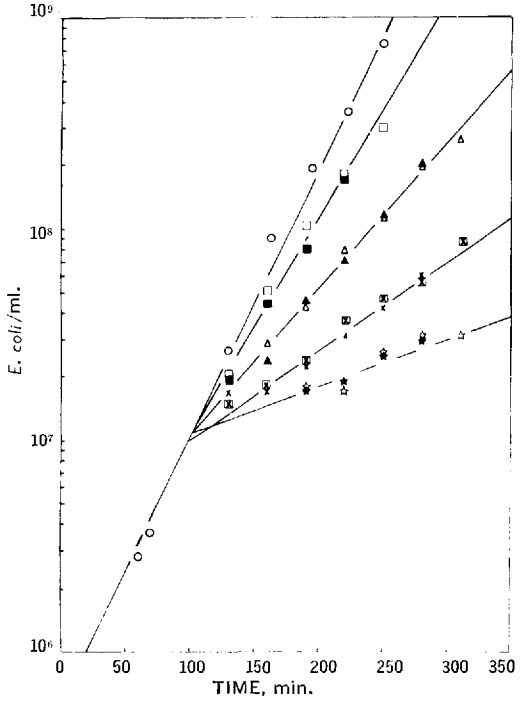

Fig. 1.—Example of coincidence of viable (open symbols) and total (solid symbols) counts for the logarithmic growth of *E. coli* in the presence of various concentrations of chloramphenicol at 41°. Key: ○, 0.00×10^{-6} M chloramphenicol; ■ and □, 1.17×10^{-6} M chloramphenicol; ▲ and △, 2.33×10^{-6} M chloramphenicol; × and ⊠, 3.50×10^{-6} M chloramphenicol; ★ and ☆, 4.66×10^{-6} M chloramphenicol.

It has been shown (5–8) that the specific growth rate constants obtained at 37.5° are linearly dependent upon the concentrations of tetracycline or chloramphenicol, A,

$$k_{app.} = k_0 - k_a A,\ k > 0 \qquad \text{(Eq. 2)}$$

where k_0 is the population growth rate constant in the absence of antibiotic. The inhibitory coefficient, k_a, may be obtained from plots of generation rate constants *versus* antibiotic concentration (Fig. 2). This linear relationship was found to hold over the entire temperature range studied, and the inhibitory coefficients are summarized in Table II.

The Arrhenius equation for the dependence of reaction rate constants upon temperature is

$$\log k = \log P - (\Delta H/2.303R)\ (1/T) \qquad \text{(Eq. 3)}$$

where R is 1.987 cal./mole and T is in degrees Kelvin. A typical Arrhenius plot for *E. coli* growth in the absence of antibiotics is shown in Fig. 3. The heat of activation is 20.8 ± 1.6 Kcal./mole for the linear portion. A similar temperature dependence is exhibited by the inhibitory coefficients, k_a, of Eq. 2. The heats of activation for k_a are 20.6 ± 1.5 Kcal./mole for tetracycline HCl and 23.7 ± 0.4 Kcal./

mole for chloramphenicol. The coincidence of total and viable count methods are clearly demonstrated in the plots.

Reversibility.—Evidence that the inhibition of growth rates caused by these antibiotics is reversible in the subinhibitory range is shown in Fig. 4 for the chloramphenicol case. Cultures inhibited by the antibiotics, chloramphenicol and tetracycline, revert to population growth rates coincident with those found in the presence of very small concentrations of these antibiotics when they are diluted into fresh broth (Table III). Alternatively (Fig. 5), cultures inhibited by low concentrations of these antibiotics may be further inhibited by the addition of more antibiotic to give growth rates with the predictable rate constants (Table IV). Therefore, the inhibition of the growth rates caused by these antibiotics in the subinhibitory concentrations under study is reversible, at least to the same extent as for cultures in antibiotic-free media on dilution.

DISCUSSION

An operational model for the interference of antibiotic with protein synthesis in the individual cell can be constructed

$$A \rightleftarrows A' + R \underset{k_2}{\overset{k_1}{\rightleftarrows}} (A'R) \qquad \text{(Eq. 4)}$$
$$K_1 \qquad K_2$$

A basic postulate is that the concentration of the antibiotic A in the media is readily partitioned into the cell with an equilibrium constant K_1, where A′ is the antibiotic concentration within the cell. There are R unreacted receptor sites within the cell

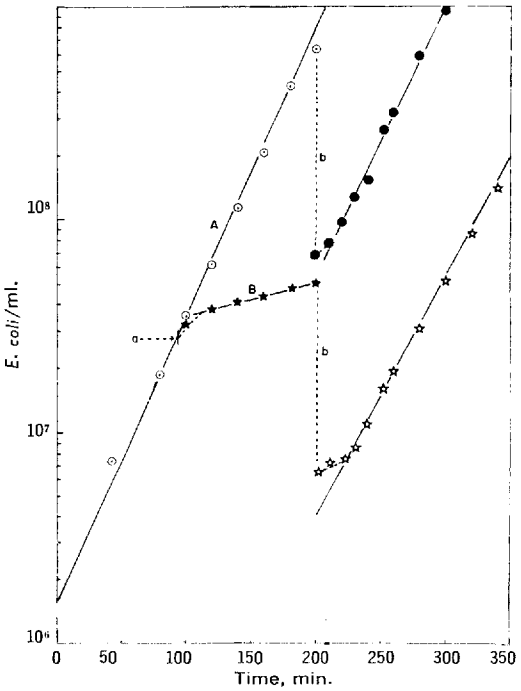

Fig. 4.—Example of reversibility of *E. coli* growth rate on dilution of chloramphenicol concentration. Curve A represents the logarithmic growth phase of an antibiotic-free culture. At time *a*, 4.66×10^{-6} moles/L. chloramphenicol are added to maintain the apparent first-order growth rate represented by line B. At time b, both the antibiotic-free culture, A, and the chloramphenicol culture, B, are diluted tenfold to demonstrate rapid reversibility of culture growth rates on dilution of antibiotic concentration in the subinhibitory antibiotic concentration range. Key: ⊙ = 0, chloramphenicol; ● = 0, chloramphenicol; ★ = 4.66×10^{-6} moles/L. chloramphenicol; ☆ = 4.66×10^{-7} moles/L. chloramphenicol.

that when interacted with the antibiotic in a reversible equilibrium, K_2, inhibit protein synthesis.

The subsequent development will consider that the rate of protein synthesis is proportional to unbound receptor sites. In order to account for the lack of direct proportionality between the rates of protein synthesis and the rates of reproduction of microorganisms, it will be necessary to introduce the concept that a minimum rate of protein synthesis is necessary for microbial generation. The rate of population increase will then be considered as proportional to this net rate of protein synthesis and to the number of organisms in the balanced-growth growth culture. Although total protein synthesis will be considered in the model, it is plausible that the diminution in reproductive rates may involve selective inhibition in the synthesis of specific proteins. The development will then be evaluated against the experimental information of this paper and the data available in the literature.

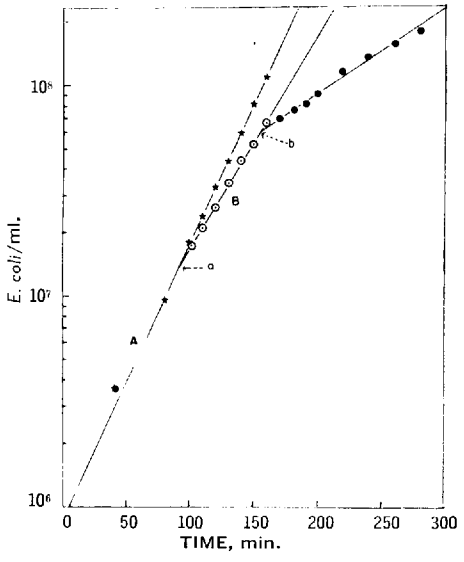

Fig. 5.—Example of rapid dependence of apparent generation rate constants of *E. coli* growth on increased amounts of antibiotic concentration. At times a and b, amounts of tetracycline were added to adjust the antibiotic concentrations to subinhibitory antibiotic concentrations specified. Key: ★ = 0, tetracycline; ⊙ = 1.04×10^{-7} moles/L.; ● = 4.16×10^{-7} moles/L.

The simplest postulate to make is that if Θ is the fraction of receptor sites reacted with antibiotic, the rate of protein synthesis, dP/dt, in a bacterium is proportional to the fraction, $1 - \Theta$, of receptor sites that are free.

$$dP/dt = k_P\,(1 - \Theta) \qquad \text{(Eq. 5)}$$

An implicit assumption in this postulate is that the numbers of receptor sites in a single bacterium are constant and independent of the mass of the cell or a time dependency of protein synthesis. Possible cases where this is not assumed are considered in the *Appendix*.

The equilibrium constant, K_2, for the antibiotic-site interaction of Eq. 4 may be defined by

$$K_2 = k_2/k_1 = (A'R)/[R_T - (A'R)](A') = (A'R)/(R)(A') \qquad \text{(Eq. 6)}$$

where (A'R) is the number of reacted sites, R is the number of unreacted sites, and R_T is the total number of sites whether reacted or unreacted. Thus, one may define the fraction, Θ, of sites reacted with antibiotic on appropriate rearrangement of Eq. 6 as

$$\Theta = (A'R)/R_T = K_2A'/(1 + K_2A') \qquad \text{(Eq. 7)}$$

Thus, Eq. 5 becomes

$$dP/dt = k_p - k_pK_2A'/(1 + K_2A') \qquad \text{(Eq. 8)}$$

where k_p is the steady-state rate of protein synthesis in the absence of antibiotic.

The concentration of antibiotic, A', in the cell may be related to the concentration, A, in the media by

$$A' = K_1A \qquad \text{(Eq. 9)}$$

It follows that the rate of protein synthesis by a

TABLE IV.—THE EFFECT OF ANTIBIOTIC ADDITION ON APPARENT GENERATION RATE CONSTANTS OF *E. coli* CULTURES INHIBITED BY ANTIBIOTICS AT 37.5°

11.7 (chloramphenicol)	3.87	3.98 ± 0.11	46.6 (chloramphenicol)	0.92	1.05 ± 0.03
1.04 (tetracycline)	4.06	3.80 ± 0.07	41.6 (tetracycline)	1.60	1.48 ± 0.05

[a] Calculated from $k = k_0 - k_a$ [antibiotic]. [b] 95% confidence limits of rate constant included.

single bacterium is related to the antibiotic concentration A in the media by

$$dP/dt = k_p - k_pK_1K_2A/(1 + K_1K_2A) \quad \text{(Eq. 10)}$$

This rate of protein synthesis is associated with the generation time for a single organism, but not necessarily directly since it is reasonable to assume that a large fraction of the protein synthesized is consumed in sustaining processes for the maintenance of vitality and that a certain excess is necessary for reproduction.

If the minimum rate of protein synthesis necessary for reproduction division is k_p', the net rate of protein synthesis that results in reproductive division of a single cell is

$$dP'/dt = dP/dt - k_p' \quad \text{(Eq. 11)}$$

which in the absence of antibiotic is $k_p - k_p'$.

If it is postulated that the rate of population increase of N organisms is proportional to this net rate of protein synthesis and to the number of organisms in the balanced growth culture, it follows that

$$dN/dt = q(dP/dt - k_p')N \quad \text{(Eq. 12)}$$

where the proportionality constant q has dimensions of bacteria per unit of protein. Equation 10 may be substituted into Eq. 12.

$$dN/dt = [q(k_p - k_p') - qk_pK_1K_2A/(1 + K_1K_2A)]N \quad \text{(Eq. 13}a\text{)}$$

$$= [k_0 - k_aA/(1 + k_bA)]N \quad \text{(Eq. 13}b\text{)}$$

$$= k_{app.}N \quad \text{(Eq. 13}c\text{)}$$

where

$$k_a = k_b(k_0 + qk'_p) \quad \text{(Eq. 14)}$$

where the apparent first-order generation constant, $k_{app.}$, is observed in the presence of a constant antibiotic concentration, A. The inconsistency of derived equations with experiment when the need for a net rate of protein synthesis is ignored is considered in the *Appendix*.

When

$$k_bA \ll 1 \quad \text{(Eq. 15)}$$

i.e., when complete inhibition of microbial generation is effected by reaction of only a small fraction of total receptor sites, Eq. 13*b* reduces to

$$dN/dt = [k_0 - k_aA]N = k_{app.}N \quad \text{(Eq. 16)}$$

or

$$N = N_0e^{k_{app.}t} \quad \text{(Eq. 17)}$$

or

$$\log N = \log N_0 + (k_{app.}/2.303)t \quad \text{(Eq. 18)}$$

where

$$k_{app.} = k_0 - k_aA \quad \text{(Eq. 19)}$$

which is equivalent to Eq. 2.

In accordance with Eq. 18, the plots of the logarithm of numbers of organisms against time for any concentration of antibiotic that permits a net growth should give a straight line and is confirmed in the typical data for chloramphenicol plotted in Fig. 1.

The apparent first-order generation rate constants, $k_{app.}$, are obtainable from the slopes of such linear plots and are given in Table I for the several temperatures studied and can be obtained with a high order of precision.

If inhibition of the population growth rate is the mechanism for subinhibitory concentrations of the antibiotic rather than kill superimposed on normal growth, viable and total counts of *E. coli* with time should be coincident and the derived rate constants, $k_{app.}$, should be coincident for both total and viable count data. This has been shown to be true in the case of tetracycline (7) at one temperature and is now shown to be so for chloramphenicol and tetracycline for the several temperatures (Fig. 3 and Tables I and II). The coincidence of the plots of total and viable counts for *E. coli* population growth in the presence of graded concentrations of chloramphenicol are apparent from Fig. 1. The coincidence of the calculated $k_{app.}$ values from both count methods at various temperatures is apparent from Table I.

If the contingency of Eq. 15 is valid, it is predicted that a plot of the apparent first-order population growth rate constant in the presence of the antibiotics tetracycline and chloramphenicol should be reasonably linear when plotted against the concentration of the antibiotics. This has been shown to be the case for tetracycline and chloramphenicol (5) at one temperature and is demonstrated by the typical plots in Fig. 2 for several temperatures. The data of Table II include the apparent k_a values obtained from the slopes of such plots.

The proposed model is subject to test by the consistency of experiment with the several hypotheses. The reversible equilibria K_1 and K_2 of Eq. 4 should be quickly established. Literature evidence is confirmatory but has not been obtained at subinhibitory concentrations. The evidence in Fig. 4 and Tables III and IV clearly shows that addition and dilution of chloramphenicol concentrations in media containing a reproducing *E. coli* culture causes rapid changes in apparent population growth rates that are consistent with their linear dependence on antibiotic concentration (Eqs. 2 and 19). The rate transitions are no slower than that which occurs in diluting a control without antibiotic. Similar studies (Fig. 5, Tables III and IV) demonstrate the same phenomena for tetracycline.

Binding should have small energy requirements since it does not involve covalent bonding. The heat of activation, ΔH_a, of the population growth of *E. coli* can be estimated from the negative slope of logarithm of the generation rate constant, $\log k_0$, in the absence of antibiotic against the reciprocal of the absolute temperature, $1/T$ (Fig. 3) in accordance with the logarithmic Arrhenius expression of Eq. 3. The temperature for maximum *E. coli* growth rates can be noted from the maxima of the curves in Fig. 3.

When the derived inhibitory coefficients, k_a (Eq. 19) as given in Table II, are similarly treated, the ΔH_a values for the tetracycline and chloramphenicol inhibitory coefficients are the same as for the population growth rate constants of *E. coli* as can be observed from the parallelism of the slopes of Fig. 3. The consistency of total and viable counts with the Arrhenius relation can be also observed in Fig. 3. The parallelism of the Arrhenius

plots for the inhibitory coefficients and the growth rate constant in the absence of antibiotics is strongly indicative that the k_a is related to the k_0 as is indicated in Eqs. 13*a–c* and 13*A–C*. For example, consider

$$\log k_a = \log K_1K_2k_0 = \log k_0 + \log K_1 + \log K_2 = \log \text{constant} - \{[(\Delta H_a)_{k_0} + (\Delta H_a)_{K_1} + (\Delta H_a)_{K_2}]/2.303R\}\,(1/T) \quad \text{(Eq. 20)}$$

since each of the logarithmic values can be described by an Arrhenius expression similar to Eq. 3. Since, the heat of activation for k_a is within 1–2 Kcal./mole of that for k_0, the energies of partition and binding for K_1 and K_2 must be extremely small as would be expected if this model reflected reality.

A linear equation can be derived for the general case of Eq. 13 where the simplifying premise of Eq. 15 is not necessary and

$$1/(k_0 - k_{\text{app.}}) = (1/k_a)(1/\text{A}) + k_b/k_a \quad \text{(Eq. 21)}$$

When the reciprocal of the experimentally observed differences between the generation rate constants in the absence, k_0, and presence, $k_{\text{app.}}$, of antibiotics is plotted against the reciprocal of the antibiotic concentration, A, for the various data of Table I and previous data (7), reasonable linearity is obtained with intercepts passing close to or through the origin. This is to be expected if Eq. 19 is true. In several cases, a finite intercept could be ascertained whose reciprocal was of the order of magnitude $k_a/k_b > 10k_0$.

If the assumption were valid that the population growth was directly proportional to the rate of protein synthesis (Eqs. 13*A–15a*, *Appendix*) k_a/k_b should equal k_0. (See Eq. 15*a*, *Appendix*, Eq. 18.) This is not so. The postulate that population growth rate is proportional to a net rate of protein synthesis (Eqs. 11–14) is consistent with the observed facts where

$$k_a/k_b = k_0 + qk_p' > k_0 \quad \text{(Eq. 22)}$$

The fact that $k_a/k_b > 10k_0$ implies that it is only necessary to affect less than about 10% of the available protein synthesizing sites to completely inhibit population increase.

The interesting observation that cell-free preparations demonstrate chloramphenicol inhibition of protein synthesis regardless of whether they are derived from chloramphenicol resistant microorganism strains (13) is strongly indicative that the basic difference among strains is in the process by which the compound reaches the site of action or in the permeability of the cells. In this model, this is directly related to the magnitude of K_1 in Eq. 4.

Most of the data available on substrate incorporation on bacterial synthesis are for superinhibitory concentrations of chloramphenicol and tetracycline (11–15) where this refers to concentrations in excess of those minima necessary for complete inhibition of population increase. There are some data that can be interpolated from the literature, however, that are confirmatory when one considers that in the authors' *E. coli*, B/r system about 2–2.5 mcg./ml. of chloramphenicol completely inhibits generation at 37.5°. Chloramphenicol at 100 mcg./ml. inhibits 20–60% of various amino acid incorporation in *Staphylococcus aureus* (11). For *E. coli*, strain B, there is 50% inhibition of $^{35}SO_4$ incorporation and no inhibition of [^{14}C] uracil incorporation at 2 mcg./ml. of chloramphenicol (15). There is less than 20% inhibition of ammonia assimilation and oxygen consumption in the presence of about 2.5 mcg./ml. of chloramphenicol (12).

In cell-free systems of several *E. coli*, 2.5 mcg./ml. of chloramphenicol inhibited amino acid incorporation 30–50% and at 1.3 mcg./ml., the inhibition was 18–35% (13). This is optimum efficiency since partition of chloramphenicol (K_1 in Eq. 4) into the microorganism does not completely reflect the concentration of the antibiotic in the media and the actual inhibition of protein syntheses in the bacteriostatic region of chloramphenicol action, *i.e.*, 1.5 mcg./ml., will be much less than this 35%. The only data available in the appropriate concentration region for tetracycline are the demonstrations of 10–25% inhibition of amino acid incorporation in cell-free systems for various strains of *E. coli* at 2.5 mcg./ml. (13). In this case the authors have complete bacteriostasis at less than 0.2 mcg./ml. of tetracycline which certainly would correspond to a very low value of inhibition of protein synthesis.

These values are consistent with the necessary model that only a small fraction of protein synthesis inhibition is concomitant with bacteriostasis.

The most rational hypothesis to account for the action of chloramphenicol and tetracycline is that they inhibit the function of messenger RNA by blocking its attachment to ribosomes through competition for ribosomal binding sites (3). It has also been noted that the variation in chloramphenicol binding by ribosomes is in agreement with the ability of the antibiotic to inhibit protein synthesis in cell-free systems (16). These observations and data are consistent with the proposed model, the binding of the receptor sites on the ribosomes by these antibiotics to lower protein synthesis.

Although significant increases in both total and viable numbers of bacteria in cultures of *E. coli*, B/r, have been reported in the presence of "bacteriostatic concentrations" (these concentrations of 50 mcg./ml. are really superinhibitory) of chloramphenicol (17), no such significant increases were observed in the studies reported here in the subinhibitory concentration ranges of chloramphenicol up to the 2.5% mcg./ml. where total inhibition of population growth rate was observed. This was also true for tetracycline in comparable subinhibitory concentrations in these and previous studies (7). A change in the overt mechanism of action of these antibiotics in the sub- and superinhibitory ranges is indicated; from a truly bacteriostatic agent functionally dependent on the first power of chloramphenicol and tetracycline concentration where inhibition is additive on a kinetic basis (5, 8), to a bactericidal agent with a more complex functional dependency on these antibiotic concentrations (5, 6).

The proposed model explains the bacteriostatic effects and the functional dependencies on the premise of diminution of protein synthesis below the critical level necessary for generation; the bactericidal effects may be explained by the further inhibition of protein synthesis below that minimum necessary for survival and for regaining of generation capabilities.

APPENDIX

Variation of Receptor Sites with Time.—An implicit assumption in the postulated Eq. 5 is that the numbers of receptor sites in a single bacterium are constant and independent of the mass of the cell or a time dependency of protein synthesis. This is not necessarily so. The rate constant k_p of Eq. 5 includes the intrinsic synthesizing activity $(k_p)_0$ associated with each site and the numbers, R, of such sites so that

$$k_p = (k_p)_0 R \qquad \text{(Eq. 5}a\text{)}$$

If R at a time, t, is R_0, and the numbers of such sites exponentially increase with time with a rate constant, k_r, then

$$k_p = (k_p)_0 R_0 e^{k_r t} \qquad \text{(Eq. 5}b\text{)}$$

A possible simplifying assumption, is that proliferation of such synthesizing sites is associated with protein synthesis and proceeds at the same rate so that if $k_p \sim k_r$, the result is the transcendental equation

$$k_p = (k_p)_0 R_0 e^{k_p t} \qquad \text{(Eq. 5}c\text{)}$$

An alternate modification which was considered later in the development of the model was that a constant rate of protein synthesis is needed to sustain metabolic processes. Thus, only the excess rate characterized by $k_p - k_p'$ can be utilized in manufacturing synthesizing sites so that Eq. 5c may be modified to

$$k_p = (k_p)_0 R_0 e^{(k_p - k_p')t} \qquad \text{(Eq. 5}d\text{)}$$

where $k_p = (k_p)_0$ immediately after division at $t = 0$ of the generation time and k_p is a maximum at $t = t_{max.}$, the generation time for a single cell under the stated conditions. Since balanced growth cultures are being considered, a weighted mean k_p for the entire culture would be approximately constant averaged over all the organisms in the statistically distributed phases of growth between $t = 0$ and $t = t_{max.}$ If the increase in the numbers of sites is reasonably linear with time, Eq. 5b may be given as

$$k_p = (k_p)_0 (R_0 + k_r t) \qquad \text{(Eq. 5}B\text{)}$$

Nonpostulation of a Minimum Rate of Protein Synthesis for Reproduction Division.—If the hypothesis of a minimum rate of protein synthesis necessary for reproduction is not made, it is considered only that the rate of population increase of N organisms is directly proportional to the rate of protein synthesis in a single cell and the number of organisms. Then

$$dN/dt = [q'k_p - q'k_p K_1 K_2 A/(1 + K_1 K_2 A)]\ N \qquad \text{(Eq. 13}A\text{)}$$

$$= [k_0 - k_a A/(1 + k_b A)]N \qquad \text{(Eq. 13}B\text{)}$$

$$= k_{app.} N \qquad \text{(Eq. 13}C\text{)}$$

where

$$k_a = k_b k_0 \qquad \text{(Eq. 14}a\text{)}$$

It follows from Eqs. 13B, 13C, and 14a that

$$1/(k_0 - k_{app.}) = (1/k'_b k_0)(1/A) + 1/k_0 \qquad \text{(Eq. 15}a\text{)}$$

Thus, when the reciprocal of the experimentally observed difference between the generation rate constants in the absence, k_0, and presence, $k_{app.}$, of antibiotics are plotted against the reciprocal of the antibiotic concentration, A, the intercept of the presumed straight line should be $1/k_0$. It was shown that this is not the case, that the reciprocal of the intercept significantly exceeds the experimental k_0 value.

Thus, the hypothesis that the generation rate is proportional to a net rate of protein synthesis above that minimum necessary for maintenance of viability is preferable.

Effects of Shear Processing and Thermal Exposure on the Viscosity-Stability of Polymer Solutions

By DAVID R. POWELL, JAMES SWARBRICK, and GILBERT S. BANKER

The effects of high-shear processing and thermal exposure on the molecular weight and solution viscosity stability of selected polymers were studied. Aqueous solutions of two molecular weight grades of hydroxyethyl cellulose (HEC) were subjected to high-shear rates using a high-shear mixer and two colloid mills. Extremely rigorous shearing conditions were required to alter the viscosity. The viscosity stability of the two grades of HEC was studied under prolonged thermal treatment at 70°. Viscosity degradation was found to follow a first-order reaction rate, the viscosity half-life for the higher grade being considerably less than that for the lower molecular weight grade. Number-average molecular weights for the HEC's were determined by the osmotic pressure technique and related to viscosity-average molecular weights through intrinsic viscosity data. The correlation between the two types of molecular weights was high, implying that bond-scissions and hydrolysis were the cause of viscosity degradation.

THE PHYSICAL nature of most pharmaceutical dispersed systems necessitates the use of viscosity imparting agents or dispersing aids to reduce phase separation tendencies, thereby enhancing medicament distribution. Virtually all such agents are polymeric in structure and fall under the general categories of natural gums, resins, and synthetic polymers. The latter group finds the most application in present-day suspension technology. The viscosity imparted to a system by the presence of these solvated polymeric agents is dependent on their spacial configurations in colloidal solution which is primarily a function of molecular weight, and to some extent, the degree of substitution or branching along the polymer chains.

Various physicochemical forces are capable of randomly rupturing the long chain structure of high molecular weight polymers (1). Two physical forces which may initiate depolymerization and subsequent viscosity loss in high polymer systems are mechanical shear and thermal energy. Studies (2–4) have shown that mechanical depolymerization of polymers in solution may occur and that this phenomenon is difficult to quantify. In most instances, the degradation reactions approximate the first-order rate law. Factors contributing to this mechanical phenomenon include (*a*) shear rate, (*b*) the average molecular weight of the polymer, (*c*) polymer–solvent interactions, and (*d*) the stereochemistry of the polymer and solvent. With polymer systems containing suspended particles, the concentration and particle size characteristics of the suspended material may affect the total shear within the system to provide an added factor influencing mechanical depolymerization (5).

The effect of temperature upon the viscosity stability of aqueous solutions of several hydrophilic polymers has been studied (6–8). While some workers (9, 10) suggest that viscosity reduction with prolonged heating is due to actual depolymerization or hydrolysis, Caldwell and Watters (11) contest the occurrence of any structural changes. A permanent viscosity decrease of a polymer solution should not be taken as absolute evidence of depolymerization, since this effect may be due to deaggregation and/or desolvation of the polymer.

This study was initiated to investigate the viscosity stability of certain hydrophilic polymers under conditions allied with the manufacture and production of pharmaceutical dispersions.

EXPERIMENTAL

Polymer Selection and Solution Preparation.—Two molecular weight grades of hydroxyethyl cellulose,[1] HEC-250G and HEC-250H, were used in this investigation. According to the manufacturer, the approximate molecular weights are 80,000 and 210,000, respectively; however, the method by which these values were obtained was not stated. These polymers were used as received from the manufacturer. The moisture content was determined and used in calculating the necessary weight of material to be used for preparing the required solutions.

Aqueous solutions (w/v) were prepared by dispersing the finely powdered polymers in distilled water at 5° with the aid of a magnetic stirrer. Stirring was then continued until the dispersions reached room temperature and solution had occurred. Generally 4–8 hr. were required. The solutions were made up to volume and allowed to hydrate for a minimum of 24 hr. before being used.

Received March 21, 1966, from the Industrial Pharmacy Department, School of Pharmacy and Pharmacal Sciences, Purdue University, Lafayette, Ind.

Accepted for publication April 8, 1966.

Presented to the Medicinal Chemistry Section, A.PH.A. Academy of Pharmaceutical Sciences, Dallas meeting, April 1966.

Abstracted from a thesis submitted by David R. Powell to the Graduate School, Purdue University, Lafayette, Ind., in partial fulfillment of Master of Science degree requirements.

TABLE I.—MILLING OPERATIONS ON HEC SOLUTIONS

Viscosity Grade	Concn., %, w/v	Vol. Milled, ml.	Power Equip.	r.p.m. and Gap	Shear Rate,[a] sec.$^{-1}$	Shear Time, min.
250H	1.0	1000	EHM[b]	8500–9000	...	5.5
250H	1.0	1000	EHM	11,000–11,500	...	5.0
250H	1.0	850	MGCM[c]	18,000 0.001 in.	1.88×10^6	90[e]
250H	1.0	1500	THCM[d]	11,000 0.002 in.	6.87×10^5	One pass
250G	2.0	900	EHM	8650–8950	...	5.0
250G	4.0	900	MGCM	18,000 0.002 in.	9.44×10^5	12.0

[a] The approximate shear rate for colloid mills was determined by the following equation given by Kostenbauder *et al.* (12): S = rotor peripheral velocity/rotor-stator clearance. [b] Eppenbach Homo mixer, model 1-L, Gifford Wood Co., New York, N. Y. [c] Manton-Gaulin colloid mill, model 2B, Manton-Gaulin Manufacturing Co., Everett, Mass. [d] Tri-Homo colloid mill, Tri-Homo Corp., Salem, Mass. [e] The temperature of the solution was maintained at 20°.

Viscosity Analysis.—Intrinsic viscosities were determined for both grades of HEC using a Cannon-Fenske No. 200[2] capillary viscometer at a constant temperature of 25 ± 0.01°. The viscometer was standardized with a 20-ml. sample of distilled water, and the mean solvent efflux time was determined. Efflux times for 20-ml. samples of five dilute solutions of HEC-250G (0.04–0.2 Gm./100 ml.) and HEC-250H (0.01–0.1 Gm./100 ml.) were determined and the respective relative viscosities (η rel.) calculated. By converting (η rel.) to reduced specific viscosities (η sp/c), and plotting these values against concentration, the intrinsic viscosities were obtained by extrapolation to infinite dilution.

Pseudoplastic rheograms of the HEC solutions at 25° were obtained using a Ferranti-Shirley[3] plate and cone viscometer. The instrument was calibrated with N.B.S. oil M[4] using the 2.75-in. diameter cone throughout.

Molecular Weight Determination.—Number-average molecular weights for both grades of HEC were determined in water at 25 ± 0.01° using a Stabin-Immergut[5] bi-membrane osmometer. Regenerated cellulose films No. 300[6] were used as the semipermeable membranes. Five different concentrations of each polymer were used to determine osmotic pressures which were corrected for membrane asymmetry. Corrected pressures were converted to reduced osmotic pressures which were plotted against concentration. The graphs were extrapolated to infinite dilution and the molecular weights were calculated by the following equation:

$$M\bar{n} = \frac{RT}{(\pi/c)_{c=0}} \qquad \text{(Eq. 1)}$$

where $M\bar{n}$ = number-average molecular weight,
R = gas constant (L. Atm. mole^{-1} degree^{-1}),
T = absolute temperature,
$(\pi/c)_{c=0}$ = reduced osmotic pressure at infinite dilution.

Shear Depolymerization.—Aqueous polymer stock solutions were subjected to varying degrees of agitation and hydrodynamic shear imparted by the use of power equipment common to the pharmaceutical industry (Table I.)

Thermal Depolymerization.—The effects of thermal exposure on the viscosity and molecular weight of 2.0% HEC-250G and 1.0% HEC-250H in solution were investigated. The viscosity stability of solutions of the polymer samples at room temperature was also observed.

Six 135-ml. samples of each polymer stock solution were placed individually in 8-oz. dark glass bottles which were then tightly sealed and placed in a dry air oven at 70 ± 1°. Samples were periodically removed from the oven over a 12–13-day interval and assayed viscometrically. A 1000-ml. sample of HEC-250G (2.0%) was treated at 70° for 48 hr. In addition to assaying this sample viscometrically, the number-average molecular weight was determined.

RESULTS

Mechanical Shear Effects.—Viscosity and molecular weight loss were indicated in only the 90-min. milling operation where a 1.0% HEC-250H solution was allowed to recycle through the rotor-stator mechanism of the Manton-Gaulin colloid mill (Table I).

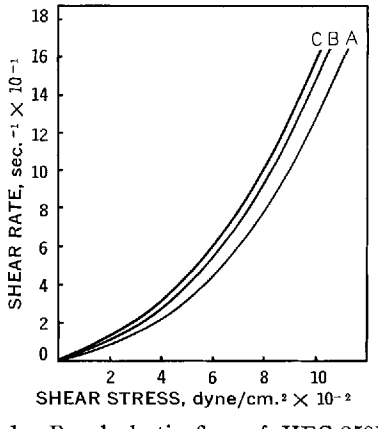

Fig. 1.—Pseudoplastic flow of HEC-250H (1% w/v) milled for 90 min. in the Manton-Gaulin colloid mill. Key: A, initial; B, 30, 45, and 60-min. samples; C, 75 and 90-min. samples.

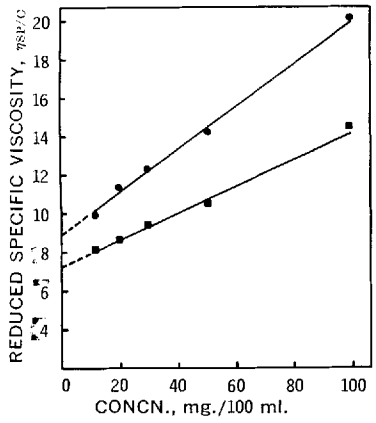

Fig. 2.—Reduced specific viscosity of HEC-250H before and after 90 min. of milling. Key: ●, initial $[\eta]$ = 8.7; ■, after 90 min. $[\eta]$ = 7.5.

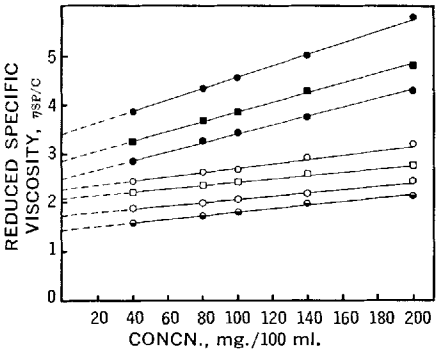

Fig. 3.—Reduced specific viscosity of HEC-250G solutions (2% w/v) thermally degraded at 70°. Key: ●, initial; ■, 24 hr.; closed hexagon, 48 hr.; ○, 94.5 hr.; □, 144 hr.; ⬡, 192 hr.; ◒, 300 hr.

Samples were removed after 30 min. and at 15-min. intervals thereafter and evaluated on the Ferranti-Shirley viscometer (Fig. 1). The reduction in shear stress at a shear rate of 1.66×10^3 sec.$^{-1}$ was 6% for the 30, 45, and 60-min. samples and 9.1% for the 75 and 90-min. samples. The bulk solution remaining after 90 min. was used to determine intrinsic viscosity (Fig. 2). The reduction in intrinsic viscosity was 15%.

Thermal Exposure Effects.—Preliminary studies indicated that the intrinsic viscosity of HEC-250G (2.0%) did not vary over an 18-day period at room temperature. Therefore, any change in the intrinsic viscosity of HEC solutions at elevated temperatures would be solely a function of the heat conditions used as opposed to any spontaneous viscosity change at room temperature.

The effects of temperature with time on the viscosity of HEC are given in Figs. 3 and 4. The method of least squares was used to obtain the slopes and intrinsic viscosities which are given in Table II. The slopes were approximately proportional to the square of their respective intrinsic viscosities, conforming to the equation derived by Huggins (13):

$$\eta_{sp/c} = [\eta]_{c=0} + K'[\eta]_{c=0}\, C \qquad \text{(Eq. 2)}$$

where $\eta_{sp/c}$ = reduced specific viscosity,
$[\eta]_{c=0}$ = intrinsic viscosity,
C = concentration (gramarity),
K' = constant for a homologous series of polymers in a given solvent.

The mean K' value for 35 reduced specific viscosities for HEC-250G was found to equal 1.236 ± 0.430. For the 35 reduced specific viscosities of HEC-250H, the mean K' value was found to equal 1.241 ± 0.458. The fair agreement between mean K' values indicated the validity of the viscosity data obtained. The over-all constant for HEC in water is 1.238 ± 0.444.

Pseudoplastic rheograms for thermally degraded HEC-250G and HEC-250H as a function of time are shown in Figs. 5 and 6, respectively. In each case, the pseudoplasticity of the material diminished with a trend toward Newtonian flow. There was no change in the rheograms of the samples stored at room temperature over the 300-hr. storage.

Molecular Weight–Intrinsic Viscosity Correlation.—The number-average molecular weights determined by osmotic pressure analysis for HEC-250G and HEC-250H were 4.73×10^4 and 1.325×10^5, respectively. The intrinsic viscosities of HEC were related to the corresponding number-average molecular weights by the Kuhn-Houwink (14) empirical equation. Thus,

$$[\eta]_{c=0} = KM^a \qquad \text{(Eq. 3)}$$

where $[\eta]_{c=0}$ = intrinsic viscosity,
M = molecular weight,
K and a = polymer–solvent interaction constants.

The constants K and a, valid only for linear polymers, were found to equal 1.445×10^{-4} and 0.9338, respectively. For HEC, therefore, the Kuhn-Houwink equation becomes:

$$\log[\eta]_{c=0} = 0.9338 (\log M\bar{n}) + \log 1.445 \times 10^{-4} \qquad \text{(Eq. 4)}$$

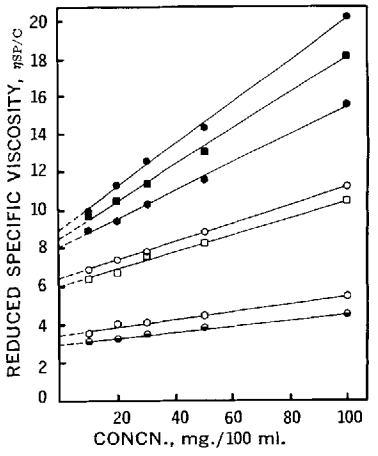

Fig. 4.—Reduced specific viscosity of HEC-250H solutions (1% w/v) thermally degraded at 70°. Key: ●, initial; ■, 24 hr.; closed hexagon, 48 hr.; ○, 96 hr.; □, 147.5 hr.; ⬡, 233 hr.; ◒, 306 hr.

TABLE II.—VISCOSITY DATA OF HEC SOLUTIONS TREATED AT 70°

HEC-250G, 2.0%			HEC-250H, 1.0%		
hr., 70°	$[\eta]_c = 0$	Slope	hr., 70°	$[\eta]_c = 0$	Slope
0	3.35	11.2	0	8.85	112.7
24	2.90	10.0	24	8.56	94.9
48	2.55	9.1	48	8.07	74.7
94.5	2.30	4.3	96	6.36	47.7
144	2.05	3.3	147.5	6.02	44.0
192	1.75	3.4	233	3.65	19.0
300	1.40	4.0	306	3.25	12.7

The validity of the interaction constants was tested by determining the intrinsic viscosity of an HEC-250G solution maintained at 70° for 48 hr. The molecular weight, calculated using Eq. 4, was 4.15×10^4; the observed molecular weight from osmotic pressure analysis was 4.199×10^4. The interaction constants, K and a, for HEC in water were, therefore, assumed to be valid.

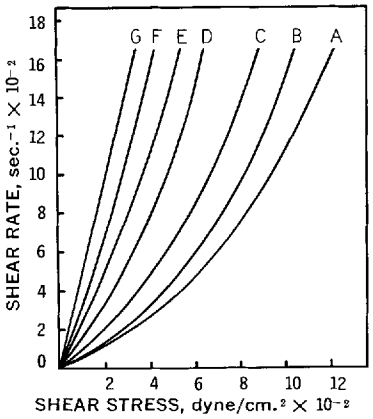

Fig. 5.—Pseudoplastic rheograms of 2% w/v HEC-250G solutions thermally degraded at 70°. Key: A, initial; B, 24 hr.; C, 48 hr.; D, 94.5 hr.; E, 144 hr.; F, 192 hr.; G, 300 hr.

Degradation Rate and Viscosity Half-Life.—The thermal viscosity degradation of HEC in water was found to best approximate a first-order reaction rate (Fig. 7). Viscosity degradation parameters are given in Table III along with the linear correlation coefficients.

The reaction rate constant for the degradation of HEC-250H is approximately 1.5 times greater than that of HEC-250G. This would indicate that the higher molecular weight 250H is more prone to thermal degradation than 250G, even though the concentration of HEC-250H was half that of HEC-250G and the initial pseudoplastic rheograms were nearly identical (Figs. 5 and 6).

DISCUSSION

The mechanical degradation study indicates that the two molecular weight grades of HEC are capable of withstanding intensive hydrodynamic shear rates. Only under the most rigorous conditions where a shear rate of 1.88×10^6 sec.$^{-1}$ was maintained for 90 min. was HEC-250H (1.0%) found to degrade. Analysis showed that a 15% reduction in molecular weight and intrinsic viscosity had been affected. These findings are in accordance with other investigations (2, 3), where it was noted that mechanical shear had little effect on polymers, in this case noncellulosics, of molecular weights less than 5×10^5.

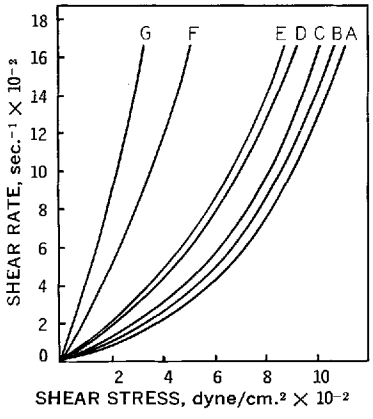

Fig. 6.—Pseudoplastic rheograms of 1% w/v HEC-250H solutions thermally degraded at 70°. Key: A, initial; B, 24 hr.; C, 48 hr.; D, 96 hr.; E, 147.5 hr.; F, 233 hr.; G, 306 hr.

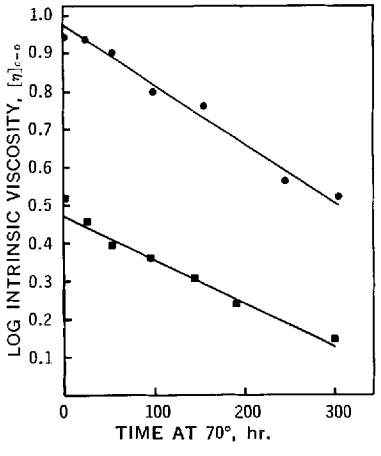

Fig. 7.—Degradation rate curves of aqueous HEC solutions at 70°. Key: ●, HEC-250H (1% w/v); ■, HEC-250G (2% w/v).

TABLE III.—VISCOSITY DEGRADATION DATA FOR HEC SOLUTIONS TREATED AT 70°

Mol. Wt. Grade	Reaction Rate Constant, hr.$^{-1}$	Slope	Viscosity Half-Life, hr.	Linear Correlation Coefficient
HEC-250G	2.58×10^{-3}	-1.12×10^{-3}	268.5	0.992
HEC-250H	3.64×10^{-3}	-1.58×10^{-3}	190.8	0.974

The mechanism associated with the thermal degradation and subsequent reduction in viscosity and molecular weight of HEC solutions is believed to be random hydrolysis of the glycosidal linkages. This proposed mechanism is in accordance with other degradation studies (6, 9, 10) involving cellulose derivatives. Hydrolytic cleavage of hydroxyethyl side chains or pyranose rings may also occur but is not likely to cause the marked viscosity changes found in this study. The extensive release of hydroxyethyl units would decrease the polymer solubility by conversion to cellulose; however, no turbidity was noted in the degraded samples. Rupture of the pyranose rings would not effectively alter chain length or molecular weight.

The relative viscosity stability and degradation rates of the two molecular weight grades of HEC at 70° indicates that when viscosity control is necessary, it is advantageous to employ a higher concentration of lower molecular weight polymer. It was shown that the pseudoplasticity of a 2% HEC-250G solution was nearly identical to that of a 1% HEC-250H solution, but that the viscosity half-life of the lower molecular weight 250G was 1.5 times greater than the 250H.

SUMMARY

A study was undertaken to determine the viscosity stability of two molecular weight grades of HEC. Polymers in aqueous solutions were subjected to processing conditions allied with the manufacture of pharmaceutical dispersed systems.

The intrinsic viscosity, pseudoplasticity, and molecular weight of two grades of HEC were not affected by the more moderate shearing operations used. In one case, under extremely rigorous shearing conditions, the higher molecular weight grade (HEC-250H) showed a significant viscosity and molecular weight reduction.

It was hypothesized that the decrease in viscosity at 70° was due to hydrolysis of glycosidal linkages; this was supported by number-average molecular weight analysis.

Good correlation between intrinsic viscosity and number-average molecular weight enabled calculation of the interaction constants in the Kuhn-Houwink equation. The constant of the Huggins equation relating dilute viscometry slope to the square of intrinsic viscosity was also calculated.

Thermally induced degradation of HEC was found to approximate a first-order rate law with high linear correlation.

The viscosity degradation rate for 1% HEC-250H was approximately 1.5 times that of 2% HEC-250G. This indicated that the higher molecular weight grade was more prone to thermal degradation than the lower molecular weight grade.

Spectrophotometric and Chemical Studies of 5-Mercaptouracil, 5-Mercaptodeoxyuridine, and Their *S*-Substituted Derivatives

By THOMAS J. BARDOS and THOMAS I. KALMAN

5-Mercaptouracil (I) and 5-mercaptodeoxyuridine (II), structural analogs of thymine and thymidine, respectively, are effective growth inhibitors in various biological systems and under study as potential antineoplastic and antiviral agents. Both compounds were found to be extremely unstable in aqueous solutions as they undergo rapid autoxidation to the corresponding disulfides. Determination of the ultraviolet spectra and pKa values of the thiols was possible only by special techniques, using dithiothreitol (DTT) as a "protecting" agent. Both I and II have very low pKa's, and their anionic forms show characteristic absorption maxima in the 330-mμ region. These results are discussed in comparison with the spectra and ionization equilibria of related compounds including some new *S*-substituted derivatives of I and II. DTT was found to be also a uniquely suitable reagent for the preparation of pure I and II by stoichiometric reduction of the corresponding disulfides. A special technique was developed for the quantitative determination of the free thiols.

A STRUCTURAL analog of thymine (1), 5-mercaptouracil (I), has been under biological and preclinical investigation during the last few years as an experimental antineoplastic agent (2). Its 2′-deoxyriboside (II) was recently synthesized enzymatically (3) and chemically (4), and it was shown to have high inhibitory activity in various biological test systems (3). Both compounds, however, undergo rapid autoxidation in aqueous solution, and this property has presented a major problem in their preparation and biological testing. In fact, the autoxidation of I in dilute aqueous buffer solutions proceeds so rapidly that the ultraviolet spectrum originally reported (1) for this compound was actually that of the corresponding disulfide (III). In view of the continuing interest in the biological activities and possible chemotherapeutic applications of these compounds, a careful study was undertaken to determine their correct spectra and dissociation constants, and to establish the conditions of their stability to autoxidation.[1] This study was greatly aided by two recent developments, *i.e.*, (*a*) the availability of Cleland's reagent (5), dithiothreitol (DTT), and (*b*) the excellent method of Klotz and Carver (6) for the determination of sulfhydryl groups.

EXPERIMENTAL

Materials.—5-Mercaptouracil (I) and 5-uracilyl-disulfide (III) were prepared by previously described methods (1, 7). Both compounds were purified by repeated crystallizations from water, and the free thiol content of each preparation was determined by the titrimetric method described below. 5-Mercaptodeoxyuridine disulfide[2] (IV) was a sample of the enzymic preparation (3). The synthesis of 5-methylmercaptouracil (V) and 5-acetylmercaptouracil (VI) will be reported.[3]

Reagents.—DTT (dithiothreitol, Cleland's reagent)[4] and glutathione (reduced)[5] were used as indicated. Mersalyl acid (*o*-{[3-(hydroxymercury)-2-methoxypropyl]carbamyl}-phenoxyacetic acid)[6] was dissolved at 10^{-3} *M* concentration in 0.2 *M* phosphate buffer, pH 6.3, containing 8×10^{-3} *M* NaCl. Indicator dye, pyridine-2-azo-*p*-dimethylaniline,[7] was dissolved in absolute EtOH and used at 10^{-3} *M* concentration. Both the mercurial and the dye solutions were stored in the refrigerator and freshly prepared after 3 days.

Buffers.—The following buffers were used: between pH 3 and 5, 0.025 *M* acetate buffers; between pH 5 and 8, 0.015 *M* phosphate buffers; between pH 8 and 12, Sorensen's glycine buffers. Below 3 and above 12, dilute HCl and NaOH solutions were used, respectively.

Ultraviolet Absorption and pKa Determinations.—Stock solutions of compounds having sulfhydryl groups (I, II) were prepared in the following manner to prevent their rapid air oxidation. I was dissolved in 5×10^{-4} *N* HCl (0.250 mg./ml.) in the presence of 1.0 mg./ml. of DTT. The disulfide (IV) was reduced to II at 0.500 mg./ml. concentration (pH 7–9) by the addition of DTT (1 mg./ml.), then the pH was adjusted to 3–4 with HCl. Stock solutions of the other compounds were freshly prepared in distilled water, except for the disulfide (III) which was dissolved in 0.01 *N* NaOH.

A Leeds and Northrup pH indicator was used for the pH measurements.

Received February 4, 1966, from the Departments of Medicinal Chemistry and Biochemical Pharmacology, School of Pharmacy, State University of New York at Buffalo.

Accepted for publication April 12, 1966.

Abstract submitted for presentation to the Medicinal Chemistry Section, A.PH.A. Academy of Pharmaceutical Sciences, Dallas meeting, April 1966.

This investigation was supported by grant CA-06695 from the National Cancer Institute, U. S. Public Health Service, Bethesda, Md.

[1] A study of the kinetics of autoxidation and its dependence on several variables will be presented in a subsequent publication.

[2] The authors are grateful to Mrs. K. Baranski for a sample of this compound.

[3] The authors thank Mr. M. Kotick for the preparation of these compounds.

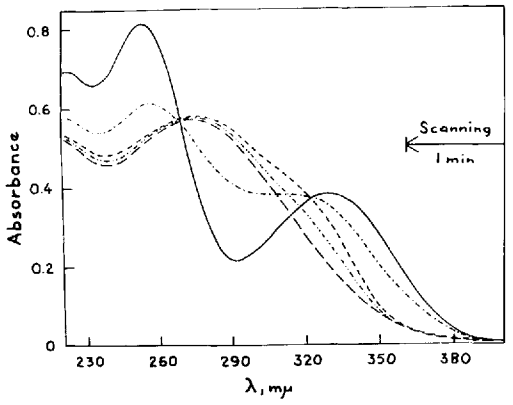

Fig. 1.—Change of ultraviolet absorption spectrum of 8.68×10^{-5} *M* solution of 5-mercaptouracil (I) at pH 7.4 (in 0.05 *M* phosphate buffer). Time lapse: from the dilution of the stock solution with the buffer until the beginning of the recording. Key: – · – · – ·, 2 min.; – – – –, 8 min.; — · · — · ·, 16 min.; — — —, 60 min.; ——, stabilized control (contains DTT). The scanning speed is indicated in the graph.

The ultraviolet absorption curves were obtained on a Beckman DB recording spectrophotometer, but a Gilford model 2000 photometer was used for the accurate determination of the $\lambda_{max.}$, $\lambda_{min.}$, ϵ, and pKa values. Aliquots of stock solutions were pipeted and diluted with buffers directly in the cells (10 mm. light path) to a final concentration of 12.5 or 25 mcg./ml.

Absorbance values measured at fixed wavelengths when plotted against pH gave the pKa values as midpoints of the curves. These pKa values were compared to the calculated ones obtained by the following formula (after Gage) (8):

if $A(a) < A(b)$:

$$\text{pKa} = \text{pHx} + \log \frac{A(b) - A(x)}{A(x) - A(a)}$$

if $A(a) > A(b)$:

$$\text{pKa} = \text{pHx} - \log \frac{A(a) - A(x)}{A(x) - A(b)}$$

where $A(a)$ is the absorbance value of the acidic (unionized) form, $A(b)$ is the value of the basic (ionized) species, and $A(x)$ is the value measured at a pH close to the apparent pKa. The pKa values obtained from the curves and by calculation agreed within 0.1 pH unit.

Reduction of the Disulfide with DTT.—The disulfide (III) (recrystallized from H_2O), 65 mg., and DTT, 130 mg., were dissolved in 30 ml. of 10^{-2} *N* NaOH and brought to pH 8. After a few minutes of stirring under N_2, the solution was acidified with HCl to pH 1.6, then 10 ml. of absolute ethanol was added, and the product was allowed to crystallize at −5 to −10°. The crystals were washed with 1:3 ethanol–water mixture (adjusted to pH 2 with hydrochloric acid), followed by absolute ethanol and, finally, by a few drops of acetone, then they were dried *in vacuo* at 110°. The infrared spectrum of the product showed a sharp peak at 2550 cm.$^{-1}$, characteristic for the S-H bond, and quantitative sulfhydryl group determination by the method described below proved that the reduction of the disulfide to the free thiol was complete.

Sulfhydryl-Group Determination.—Essentially, the method of Klotz and Carver (6) was employed with some modifications. An excess of the mercurial was immediately added in order to effect rapid and quantitative combination with the very unstable mercapto compounds. This was followed by the addition of a known excess of glutathione which was then titrated with additional portions of the mercurial in the described manner. Weighed samples were dissolved in 10^{-2} *M* HCl under N_2, from which aliquots were pipeted into a 18 × 150 mm. test tube. After 5 ml. of 10^{-3} *M* mersalyl acid was added and mixed, 0.1 ml. of 5×10^{-2} *M* glutathione and 0.6 ml. of indicator were added. The mixture was titrated with 10^{-3} *M* mersalyl acid, the color change was followed with a Bausch & Lomb photometer at 550 mμ, and the end point of the titration was determined as described (6).

RESULTS AND DISCUSSION

Figure 1 shows the rapid change of the absorption spectrum of I in a dilute aqueous solution (8.68×10^{-5} *M*) buffered at a neutral pH. Even when the spectrum was taken immediately after dissolving the compound in the buffer, it already showed a vast shift in comparison to the spectrum of a "stabilized" solution of I (*i.e.*, a freshly prepared solution containing DTT, see below) and within 16 min. became nearly identical with that of the disulfide (III). The same process was observed to occur at a comparable rate under alkaline conditions, while acid pH decreased the rate of oxidation, and the compound appeared to be relatively stable at pH < 3.7. Thus, solutions of I in 5×10^{-4} *N* hydrochloric acid did not show appreciable change within several hours and could be used as stock solutions in the spectrophotometric studies. (See *Experimental.*)

DTT was found to be an effective protecting

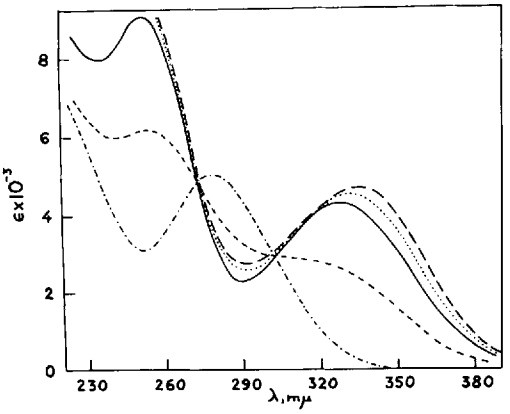

Fig. 2.—Ultraviolet absorption spectra of 5-mercaptouracil (I) stabilized by the addition of DTT (see text) at various pH values. Key: – · – ·–, pH = 2.0; – – – – –, pH = 5.3; ——, pH = 7.7; . . . . . , pH = 10.6; — — —, pH = 11.8.

TABLE I.—SPECTROPHOTOMETRICALLY DETERMINED, APPARENT pKa VALUES[a]

Compd.	pKa_1	pKa_2	pKa_3

II	5.0	10.5	..
III	8.0	>13	..
IV	8.1	>13	..
V	8.5	>13	..
VI	>8[b]	...	..

[a] Limits of accuracy: ±0.05 pH units. [b] Hydrolysis occurs at pH > 8.

agent by virtue of its low redox-potential (5). This compound not only prevented the air oxidation of I, but it was also capable of reducing, rapidly and quantitatively, the disulfides (III and IV) to the corresponding thiols (I and II), respectively. Thus, in the presence of excess DTT, it was possible to determine the ultraviolet absorption spectra of the free thiols at various pH values and to estimate their dissociation constants by spectrophotometric methods. (See *Experimental.*) The ultraviolet absorption of DTT itself interfered with the spectra of I and II only at pH > 9, and then only in the range below 260 mμ. The spectra of I at various pH values in the presence of DTT are shown in Fig. 2; in the pH 2-7 range, two isosbestic points appear, at 273 and 302 mμ.

The apparent pKa values of I and its derivatives are given in Table I. The pKa_1 values corresponding to the first acid dissociation equilibria of I (5.3) and II (5.0), respectively, are considerably lower than the pKa of thiophenol (7.76) (9). 5-Nitrouracil has a similarly low pKa_1 as I, and in the case of the former this is due to the powerful electron-attracting inductive and conjugative effects of the nitro group both of which promote the ionization of the N-1 hydrogen (10). The relatively small, electron-releasing conjugative effect of the divalent sulfur (11) is essentially inoperative from the 5-position of the uracil nucleus (*meta* to both ring-nitrogens) (12) and the inductive (−I) effect of the C → S bond prevails. This would cause only a moderate increase in the acidity of the N-1, or N-3 hydrogen, corresponding to lowering of the pKa_1 value only by about 1 unit, as seen by comparison of the pKa_1 values (8.0–8.5) of the *S*-substituted derivatives, III, IV, V, and VI (Table I), with that of uracil (9.45) (10). Therefore, the much lower pKa_1 values of I and II clearly correspond to the dissociation of the sulfhydryl group, and the high acidity of this group must be attributed to the electron-attracting effect of the uracil nucleus. This effect seems to be slightly larger in the case of II. (Scheme I.)

Table II summarizes the spectrophotometric data of compounds I–V. The free thiols (I and II) are readily distinguished from their disulfides and other *S*-substituted derivatives by their characteristically large bathochromic shifts in neutral or basic solutions (*i.e.*, in their ionized forms). Compound II shows slightly higher wavelength and greater intensity absorption than I in both the "neutral" (*a*) (pH 2) and "mono-anionic" (*b*) (pH 7.7) form.

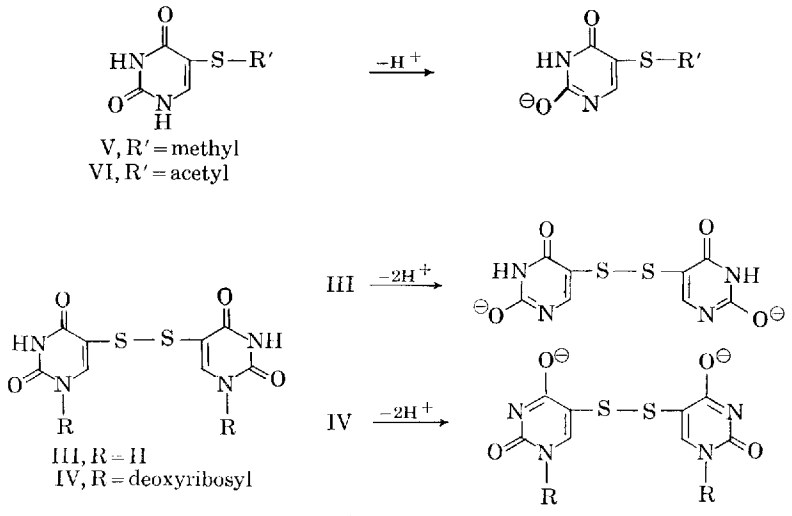
VI	2.0	269.5	7.4	242	3.8

[a] Absorption maxima and minima, wavelength in mμ. [b] Molar absorptivities at given wavelength. [c] Presence of DTT prevents correct reading below 260 mμ.



Scheme III

Ionization of the second proton (pH 11.8 in Table II) increases both the wavelength and the intensity of the absorption band in the 330 mμ region in the case of I, and decreases both values in the case of II; however, the dianions of I and II have of necessity different structures. (Scheme II.)

The *S*-substituted derivatives, III, V, and VI, show much smaller acid-base shifts in their ultraviolet spectra than the free thiols and rather resemble thymine in their spectral behavior (10), indicating that their first ionization involves the N-1 hydrogen. The disulfide (IV), in which both the sulfhydryl group and the N-1 position are blocked, shows no acid-base shift, being in this respect similar to 1-methyl-uracil (10) or thymidine (13). (Scheme III.)

Since the ionizations of the symmetrical disulfides (III and IV) probably proceed in two steps, *i.e.*, giving rise to intermediate structures in which only one of the pyrimidines is ionized, the spectra of these compounds do not give real "isosbestic points" (Fig. 3), and their pKa_1 values actually represent averages of *two* pKa's which are very close and cannot be clearly distinguished from each other.

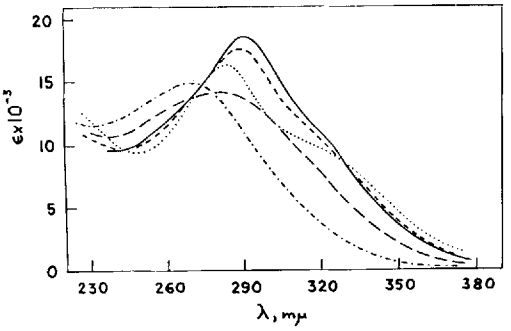


Fig. 3.—Ultraviolet absorption spectra of 5-uracilyl-disulfide (III) at various pH values. Key: -·-·-·, pH = 2.0; ———, pH = 7.7; ——, pH = 10.6; - - - - - -, pH = 13.0; . . . . . , pH = 14.0.

DTT was found to be a useful reducing agent for the preparative conversion of the disulfide (III) to the free thiol (I). (See *Experimental.*) This conversion was accomplished previously by a much less convenient procedure (using zinc and sulfuric acid) (1, 7), which cannot be applied to the reduction of the deoxyriboside (IV).

For the determination of the free thiol content of various preparations, the method of Klotz and Carver (6) was employed in a somewhat simplified form, without the elaborate precautions recommended for the exclusion of air. This, however, gave variable results in the case of 5-mercaptouracil since a considerable portion of the sample oxidized during the titration procedure. Glutathione, on the other hand, was found to be quite stable under the same conditions. Taking advantage of this fact, an "indirect method" was developed. (See *Experimental.*) The results[8] are given in Table III.

TABLE III.—SULFHYDRYL GROUP ANALYSIS

Compd.	Free SH/S × 100[a] Direct[b]	Indirect[c]
I[d]	55–85	98
I[e]	. . .	98–100
III	<2	<2
Glutathione	100	100
DTT	. . .	98–100

[a] Per cent of total sulfur present in the form of free sulfhydryl-group. [b] As determined by direct titration with mersalyl acid (6). [c] As determined by the modified, indirect procedure. (See *Experimental.*) [d] Recrystallized and stored in the desiccator for a period of over 12 months. [e] Prepared from III by reduction with DTT. (See *Experimental.*)

The results indicate that I is quite stable for a period of at least 1 year when stored in solid dry state. It is also seen from Table III that the reduction of the disulfide (III) to the free thiol (I) by DTT has proceeded in a quantitative manner.

[8] The authors acknowledge the technical assistance of Mr. Peter Forgach in these determinations.

Absorption, Distribution, and Elimination of a Long-Acting Vitamin B_{12} Preparation

By KNUD KRISTENSEN* and TAGE HANSEN

The prolonged effect of various long-acting vitamin B_{12} preparations has been examined on rabbits regarding absorption, distribution, and elimination after intramuscular injection.

RECENT investigations (13) have shown that patients with pernicious anemia have considerably greater requirements for vitamin B_{12} than have previously been assumed. More recently, there has been considerable interest in preparations that can meet the requirements more adequately and in a more satisfactory way than the aqueous solutions of vitamin B_{12} used previously. The authors have investigated the characteristics of various preparations made on the basis of various principles. A preparation containing cyanocobalamin–tannin complex suspended in aluminum monostearate oil gel[1] was studied in detail.

The clinical value of this preparation is reflected in papers by Bastrup-Madsen *et al.* (4, 5), Schwartz *et al.* (19, 20), Meulengracht (14, 15), an editorial (8), Nielsen and Vedsø (16), Schrumpf (18), and Gough *et al.* (10).

EXPERIMENTAL

Materials and Methods

Preparations A–G were investigated (Table I). After intramuscular injection (i.m.) in rabbits, the following were investigated: (*a*) liberation of vitamin $B_{12}{}^{60}Co$ from the site of injection; (*b*) absorption of vitamin $B_{12}{}^{60}Co$ by the liver; and (*c*) excretion of vitamin $B_{12}{}^{60}Co$ in urine and feces.

For preparations F and G the investigations were supplemented by radioactivity counts and microbiological determinations of vitamin B_{12} in liver, kidney, and femoral muscle about 3 months after the start of trial.

Preparations

A number of preparations were made using vitamin B_{12} labeled with ^{60}Co. Their composition is shown in Table I. The products were prepared according to methods described in a British patent (6).

The distribution and excretion of vitamin B_{12} after parenteral administration of preparation B and of aqueous solutions of cyanocobalamin were investigated in rats and in healthy subjects by Davis *et al.* (7), Thompson and Hecht (22), Astudillo *et al.* (3), and Glass *et al.* (9), but no records have been found of investigations on patients with pernicious anemia. The authors have not investigated any preparations of vitamin B_{12} suspended in oil or vitamin B_{12} suspended in 2% monostearate oil gel; the latter was described by Arnold *et al.* (1, 2), Sobell *et al.* (21), and Heinrich and Gabbe (11). It does not appear to possess any retarded action of interest for clinical use.

Preparations F and G correspond to a marketed suspension of cyanocobalamin–tannin complex in aluminum monostearate oil gel,[1] except that labeled vitamin B_{12} (^{60}Co) was used instead of ordinary cyanocobalamin. Spectrophotometric and microbiological checks were made on the preparations. The radiochemical purity of the labeled compounds was confirmed by paper chromatography and subsequent counts and by microbiological determinations of the vitamin B_{12} activity on agar plates with *Lactobacillus leichmannii*, as described by Winsten and Eigen (23), among others.

Animal Material.—Twelve white male rabbits were used. The initial weights were from 2.7 to 3.0 Kg. The rabbits were anesthetized with sodium amobarbital (30 mg./Kg.) supplemented by ether during the radioactivity counts.

Standards and Methods of Measurement.—The radioactivities above the site of injection and above the liver were determined on a scintillation detector shielded by 5 cm. of lead with a 30-mm. round opening upon which the object to be measured was placed. Feces and organs were homogenized before

counting. A scintillation detector with a well-type crystal was used for counting radioactivity in urine and liquid samples of feces and organs.

The microbiological vitamin B_{12} activity was determined by the *L. leichmannii* method (12) as modified by Noer (17).

Before and after each measurement the scintillation detector was checked against a standard and corrected accordingly.

In order to determine the absolute content of radioactive vitamin B_{12} in samples of urine, feces, and organs, a known quantity of the injection preparation in question was added after the samples had been counted. Thus, the counts of the samples and of the standards were carried out under the same conditions.

Trial Methods.—Blank values were determined on urine and feces collected for 24 hr. from the rabbits in specially constructed metabolism cages. After being anesthetized, the rabbits were strapped to the counting table with the right femoral muscle above the detector.

After the background had been counted, the preparation to be tested was injected intramuscularly into the right femoral muscle directly above the detector. The doses employed are shown in Table I. Immediately afterward, the radioactivity at the site of injection was screened at various sites around the injection site, and the counts were carried out at the site of highest activity. Immediately afterward, the radioactivity in the hepatic region was determined in the manner described above.

Counts of the activity at the site of injection and in the hepatic region were carried out at irregular intervals for 3 months, and their relative values, as percentages of the initial count, were calculated.

During the first 3–4 days after the injection, urine and feces were collected as 24-hr. samples.

In the tests made with preparations F and G, the rabbits were killed with ether after the test period of about 3 months; liver, kidney, and femoral muscle were dissected free, and their contents of radioactive material were determined. In addition to the organs mentioned above, the spleen, heart, bladder (containing urine), small intestine (duodenum, jejunum, ileum), large intestine (cecum, including vermiform appendix, colon, rectum), and contents of both large and small intestine were collected from rabbit *3*. (See Table II.) Liver, kidneys, and muscle from the right femur were taken from the control rabbit, which had been kept on the same diet as the test animals for 3 months, in order to obtain a basis of comparison and a standard for the content of vitamin B_{12}. A microbiological determination of vitamin B_{12} was carried out on all homogenates of liver, kidney, and femoral muscle.

RESULTS

Measurement Above the Site of Injection.—Figure 1 shows the increase of prolonged effect obtained by combining the different principles. It will be seen that a clearly prolonged effect is only obtained by suspending a vitamin B_{12} compound in

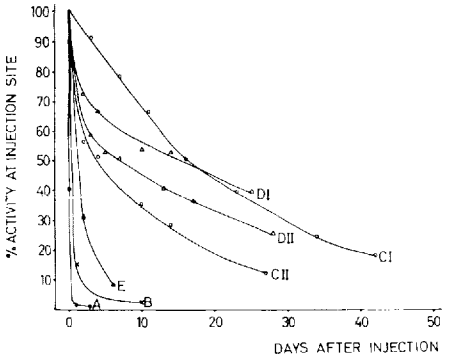

Fig. 1.—Absorption of radioactive vitamin B_{12} from the site of injection. Key: A, aqueous solution of vitamin B_{12}; B, aqueous suspension of B_{12}–zinc–tannate; C_I and C_{II}, B_{12}–zinc–tannate suspended in a 2% aluminum monostearate oil gel; D_I and D_{II}, B_{12}–tannate suspended in a 2% aluminum monostearate oil gel; E, B_{12}–tannate suspended in oil.

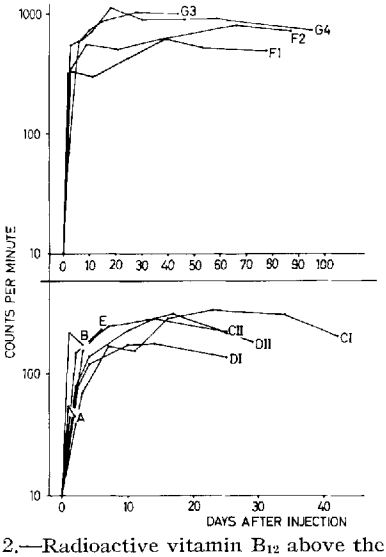

Fig. 2.—Radioactive vitamin B_{12} above the liver. Key: (bottom) A, aqueous vitamin B_{12} solution; B, aqueous suspension of B_{12}–zinc–tannate; C_I and C_{II}, B_{12}–zinc–tannate suspended in a 2% aluminum monostearate oil gel; D_I and D_{II}, B_{12}–tannate suspended in a 2% aluminum monostearate oil gel. E, B_{12}–tannate suspended in oil. Key: (top) F_1 and F_2, B_{12}–tannate suspended in a 2% aluminum monostearate oil gel; G_3 and G_4, B_{12}–tannate suspended in a 2% aluminum monostearate oil gel.

aluminum monostearate oil gel. Table II shows the prolonged effect of two preparations of vitamin B_{12}–tannate in aluminum monostearate oil gel (F and G). Rabbit *3*, which died during narcosis about 1.5 months after the beginning of the investigation, differed from the other three. During the period of investigation the rabbit did not move about much. This could have been the reason for the small liberation of vitamin B_{12} from its intramuscular depot.

Measurement Above the Liver.—Figure 2 gives an impression of the storage of vitamin B_{12} in the liver, obtained by combining the different principles. The graphs for preparations F and G show considerably higher counts because of the larger amount of radioactivity injected (see Table I).

The counts shown in Fig. 2 were obtained by deducting the value expressing a scattered radiation from the depot of the femoral muscle from the counts corrected for background. The value of scattered radiation decreases in proportion to the activity at the site of injection; accordingly, the correction will be:

(corr. counts per minute above liver immediately after injection) × (% activity at site of injection on the day in question) divided by 100.

Because of the somewhat inaccurate method of measurement, only the shapes of the graphs, not the absolute values should be compared.

Excretion in Urine.—Table III shows the difference in excretion in urine after administering the various preparations. The difference in urinary excretion between preparation D and preparations F and G may be explained partly by the larger quantity of F and G injected, and partly by a minute amount of free vitamin B_{12} in the preparations.

Excretion in Feces.—The excretion in the feces was <1%/24 hr.

Content of Vitamin B_{12} in Liver, Kidneys, and Femoral Muscle.—At the time when the rabbits were killed the vitamin B_{12} contents of liver, kidneys, and femoral muscle were measured, both by radioactivity measurements and by microbiological determinations. Table IV shows the results. The counts immediately show that the content of vitamin B_{12} in liver and kidneys of rabbits treated with preparations F and G has increased compared with that of the control rabbit. The content of vitamin B_{12} in the right femur is due to vitamin B_{12} not yet liberated from the site of injection, and a reasonable agreement with the results obtained by radioactivity measurements above the site of injection was found. The difference between vitamin B_{12} measured microbiologically and vitamin B_{12} determined by radioactivity gives us the level of vitamin B_{12} in the rabbits before the injection and is of the same order of magnitude as those obtained microbiologically from the control rabbit.

Radioactive Vitamin B_{12} Content in Other Organs and Tissues (Rabbit 3).—*Spleen.*—No measurable vitamin $B_{12}{}^{60}Co$ (<1% of dose administered).

Heart.—No measurable vitamin $B_{12}{}^{60}Co$ (< 1% of dose administered).

Contents of Intestine.—Less than 1% of dose administered.

DISCUSSION

These investigations on rabbits clearly reveal that preparations of B_{12}–tannate or B_{12}–zinc–tannate in a 2% aluminum monostearate oil suspension release vitamin B_{12} from an intramuscular depot over a much longer period of time than does B_{12}–zinc–tannate in an aqueous suspension or B_{12}–tannate in an oil suspension or vitamin B_{12} in a water solution (Fig. 1).

Vitamin B_{12} preparations in a 2% aluminum monostearate oil suspension can release vitamin B_{12} for the body for more than 1 month compared with a few days for the other types of preparations investigated.

By this prolonged release one avoids the urinary excretion that always follows injections of vitamin B_{12} in excess of serum vitamin B_{12} binding capacities. This also means that vitamin B_{12} is available for storage in vitamin B_{12} depots over a longer period of time (Fig. 2). Due to the techniques used, only the shapes of the curves are comparable. A more detailed study of 2 different vitamin B_{12} preparations in a 2% aluminum monostearate oil suspension showed vitamin B_{12} was released from the intramuscular depots for more than 2 months, with some of the injected material still left at the injection site as vitamin B_{12} as determined by microbiological methods. Table IV shows there is good agreement between direct measurements above the site of injection and measurements of the dissected femoral muscle.

Furthermore, it is shown (Table IV) that the released vitamin B_{12} was deposited in the liver and kidneys, as could be expected, and that the liver and kidneys from rabbits injected with B_{12}–tannate in a 2% aluminum monostearate oil suspension contained a considerably greater amount of vitamin B_{12} in comparison with the control.

SUMMARY

By investigations carried out on rabbits, the properties of various vitamin B_{12} preparations with prolonged effect are demonstrated, including the liberation from intramuscular depots and the storage in the natural depots of the body. After intramuscular injection of B_{12}–tannate in aluminum monostearate oil gel the observations were: (*a*) a prolonged liberation of vitamin B_{12} from the depot injected into the muscle; (*b*) an increased vitamin B_{12} activity in liver and kidneys, taken as a sign of storage in the natural depots of the body; and (*c*) minimum excretion in urine.

Mechanism of Action of Starch as a Tablet Disintegrant I

Factors that Affect the Swelling of Starch Grains at 37°

By JAMES T. INGRAM and WERNER LOWENTHAL

A study was initiated to determine if starch grains swell at 37° and what environmental conditions may influence swelling. To determine the extent of swelling which starch undergoes in various media, individual grain dimensions were measured microscopically. Full factorial experiments were conducted, and analyses of variance were calculated to determine whether significant differences in the mean grain sizes could be demonstrated when environmental conditions were changed. Potato, corn, and amioca starches and moisture content showed significant swelling in distilled water and simulated gastric fluid U.S.P. This was postulated as due to initial size difference of the grains being maintained during the experiment. Variation in pH had very little effect on swelling; however, evidence was obtained to show that the less acid medium produced more swelling than the media of lower pH. Salts did affect swelling, and results indicated that salts of polyvalent cations produced more swelling than the salts of monovalent cations. Analysis of the effect of time on swelling indicated that any swelling of the starch grains is apparently instantaneous.

IT IS DESIRABLE that a tablet, when used, disintegrate as rapidly as possible. Ideally, the process of tableting should not alter the therapeutic action of a drug or the time in which this action is produced. The same effect should be produced in essentially the same time when a tablet is swallowed as when the drug is taken in powder form.

The rate at which a physiological effect is produced from a drug taken orally is dependent upon the rate of absorption from the gastrointestinal tract. Before a drug in tablet form may be absorbed, it must first be released from the tablet by disintegration of the tablet. The usefulness of a tablet, therefore, arises almost wholly from its ability to disintegrate upon contact with liquid.

Compressed tablets are ordinarily manufactured containing substances to accelerate or aid their disintegration. Cornstarch has long been the standard disintegrant for compressed tablets. The mechanism by which starch functions as a tablet disintegrant has been assumed to be that the starch grains swell when in contact with moisture, causing the tablet to break open.

Knowledge of the exact mechanism of action of starch as a tablet disintegrant would be useful in the development of more efficient disintegrating agents.

DISCUSSION

Review of Pertinent Literature.—Little work has been reported on the exact mechanism of action of starch as a disintegrating agent. After an extensive literature search, all references which had been located state that starch acts as a disintegrant by swelling, but no data or proof are presented or referred to indicate that starch swells sufficiently *in vivo* or *in vitro* to cause disintegration (1, 2).

Curlin (3) tested the disintegration of aspirin tablets in cold water and found by microscopic examination that the starch grains were not swollen after disintegration.

Billups and Cooper (4) reviewed the proposed theories explaining the mechanism of action of tablet disintegration. They indicate that the most widely held view is that disintegration is caused by absorption of water by the disintegrating agent and development of pressure within the tablet by swelling or expansion of the disintegrating agent. In their study on the correlation of water absorption with tablet disintegration time, they concluded that while water absorption is a common qualitative characteristic of many disintegrating agents, it is not a quantitative measure of their effectiveness. Disintegrating agents with the highest rates of water absorption did not produce the fastest disintegration times. Some evidence supported the view that disintegrating agents with the highest rates of water absorption produced the longest disintegration times. Their results also showed that the amount of water absorbed by cornstarch, dried to a constant weight, after exposure to 98% relative humidity, was only 0.5% w/w in 50 min.

Crossland and Favor (5) employing a viscous water-binding dispersion medium (sodium alginate and high viscosity type carboxymethylcellulose), showed by means of viscosity measurements the stages of swelling. In the starch–alginate–water system, the first indications of swelling are observed at about 55°.

Leach, McCowen, and Schoch (6) evaluated swelling of various starches over a range of pasting temperatures (about 50–95°) and found that the swelling pattern was greatly influenced by the species of starch. Cornstarch showed a limited two-stage swelling, whereas potato starch underwent very

Received March 4, 1966, from the School of Pharmacy, Medical College of Virginia, Richmond.
Accepted for publication April 26, 1966.
Presented to the Industrial Pharmacy Section, A.PH.A. Academy of Pharmaceutical Sciences, Dallas meeting, April 1966.

rapid and unrestricted swelling at about 55°. The swelling of the grains was determined from the weighing of starch after submersion in water and correcting the value for solubles.

Hellman, Boesch, and Melvin (7) compared swelling of starch grains to water absorbed from atmospheres of different moisture content by following the dimensional changes of individual starch grains microscopically at a temperature of 25.10° over a period of 8–24 hr. At 100% relative humidity cornstarch showed a 9.1% increase in diameter over the diameter of vacuum dried starch. The corresponding increases for other starches examined under similar conditions were 12.7% for potato starch, 28.4% for tapioca starch, and 22.7% for waxy cornstarch.

Variation in the effect of different salt solutions on initial gelatinization of starches was shown by Sandstedt, Kempf, and Abbott (8). They showed that salt solutions change not only the temperature of initial gelatinization but also the initial temperature of each stage of gelatinization, length of transition period between stages, and rate or amount of gelatinization in each stage of the entire course of gelatinization. These changes were not correlated with each other. Their data indicated that each change in the course of gelatinization was due to a different property of the salt.

Abbott *et al.* (9) determined *in vitro* disintegration time of several commercial tablets in simulated gastric juice and human gastric juice and showed that disintegration is prolonged in human gastric juice. There is some correlation between prolongation of disintegration and gastric mucoid content. A high mucoid content in gastric juice may increase the rate of disintegration more than 16 times. *In vitro* disintegration is prolonged in simulated gastric juice if the tablets are first exposed to mucoidal material from human gastric juice.

EXPERIMENTAL

This study was planned to determine if starch grains swell at 37° and what environmental conditions may influence the swelling of starch grains at 37°. The following variables were studied: (*a*) time, (*b*) pH, (*c*) effect of ions and ionic concentration, (*d*) starch species, and (*e*) simulated gastric fluid U.S.P. (SGF). Evanson and DeKay (10), in a study of tablet disintegration, reported inconsistent results when distilled water was compared with artificial gastric juice with respect to time. For this reason distilled water was included as a submersion medium in this study to allow comparisons with other submersion media.

Procedure.—To determine the extent of swelling, if any, which starch undergoes in various media, microscopic examination was used and individual grain dimensions were measured. For the measurements of corn and amioca starches, an oil immersion 97× objective and 5× ocular micrometer were used. For the measurements of potato starch, a 43× objective and a 5× ocular micrometer were used, and measurements were mathematically converted to 485 magnification. Owing to the spherical and ellipsoidal shapes of the grains, the apparent grain length changed with position of focus. To achieve uniformity, each grain was measured at that depth of focus producing maximum diameter. The starch samples were slurried in the appropriate media at 37° and maintained at that temperature until a sample was removed at the appropriate time, placed on a slide, and covered with a cover slip. One hundred or 200-grain measurements were made from each slide. A mechanical stage was used and as the field of view was moved horizontally, each starch grain crossing the micrometer scale was measured. Each scale division on the micrometer represents 1.80 μ when using the 485 magnification.

Commercial grades of corn, potato, and amioca (waxy corn) starches were chosen for the initial investigation. To determine the effect of moisture content on swelling, both low and high moisture content forms of each starch were examined. For the high moisture content, the commercially available starches[1] were used. For the low moisture content, each starch was dried at 93° until a constant moisture content was obtained as determined on a moisture balance.[2] Moisture contents obtained were as follows: cornstarch, 2.25% w/w; potato starch, 2.25% w/w; and amioca starch, 2.88% w/w. In addition to these dried starches, a commercial redried cornstarch[3] (P-825) containing 1.5% maximum moisture was examined.

RESULTS AND DISCUSSION

In examining the factors influencing the swelling of starch grains, full factorial experiments were designed, and analyses of variance were calculated to determine whether significant differences in the grain sizes could be demonstrated when environmental conditions were changed. Preliminary experiments showed that the method of measurement was reproducible.

Distilled water and SGF were compared as submersion media by varying the type of starch, moisture content, and time in two 2 × 3 × 3 factorial designs. The mean grain sizes are shown in Table I for the distilled water and in Table II for SGF. In each experiment the only single effect producing a significant difference in grain size was the type of starch. In each case, the type of starch was significant at the 0.5% level and was shown by Duncan's multiple range tests (11) to be due to the potato starch. No significant difference was shown between corn and amioca starches.

The mean grain size of potato starch is approximately 29 μ while that of cornstarch is approximately 10.5 μ and that of amioca is approximately 9.5 μ. The large difference in mean grain sizes between the potato and the cornstarches would result in a larger error mean square term in the analyses of variance. This is due to the fact that the variances are proportional to the mean grain sizes. Because of this, the analyses of variance were recalculated omitting the potato starch data. This was done to obtain a more sensitive comparison between corn and amioca starches, whose mean grain sizes were more nearly the same. Moisture content and time became significant at the 2.5%

[a] One scale division = 1.8 μ.

level in the distilled water experiment and at the 10 and 5% levels, respectively, for the SGF experiment. Duncan's multiple range tests showed in each case that the difference in grain size was between unsubmerged starch (zero time) and starch which had been submerged. No significant difference in grain diameter was observed in the starches which had been submerged between 5 and 30 min. Preliminary experiments had shown that submersion time was not significant but no comparisons were made to unsubmerged starch.

Starch moisture content effect was probably significant because the initial size differences between the high and low moisture content of the starches were maintained throughout the experiment.

To investigate further the effect of moisture content and submersion time on swelling, a 3 × 6 factorial experiment was designed using three low moisture content starches and SGF as the submersion medium. The starches were slurried and the diameters measured at various time intervals up to 3 hr. The data are given in Table III. The analysis of variance showed that the only significant difference observed was in the type of starch. This was again shown by Duncan's multiple range test to be due to the potato starch; the two forms of cornstarch were not significantly different.

The analysis of variance was recalculated, omitting the potato starch, and a significant difference was shown between the two cornstarches at the 10% level. This difference is again most likely due to the initial differences in the grain sizes which was maintained up to 120 min.

A 3 × 6 factorial experiment was designed to determine the effect of pH and time of submersion on swelling. Commercially dried cornstarch[3] was used for this experiment. The mean grain sizes are presented in Table IV. The analysis of variance showed that pH was significant at the 10% level, and a breakdown of this effect showed that at a pH of 5.3 the swelling that occurred was significantly greater than that at pH 1.3 or 3.3. The significance of the swelling at pH 5.3 could be due to onset of starch hydrolysis. Starch will hydrolyze at an alkaline pH. Unsubmerged starch (zero time) was included in this experiment to allow better comparisons between pH and time, but no significant difference was demonstrated between the measurements at the various time intervals.

To investigate the effect of salts on swelling of untreated starch grains, a 2 × 2 × 3 × 4 factorial experiment was designed. Unsubmerged starch

		0.9	5.482	6.054	5.652

[a] One scale division = 1.8 μ.

was included as zero time in the experiment to allow comparisons between salt effect and time. Table V shows the variables investigated and the mean grain sizes. The analysis of variance showed that the single effects of type of starch, time submersed, and submersion medium, each produced a significant difference at the 0.5% level. Concentration of the salt in the submersion medium was not significant. Three-factor interactions were not significant. All statistical two-factor interactions involving time produced a significant difference in grain diameters at the 10% level or less. Duncan's multiple range tests showed in each case that the mean grain sizes of the unsubmerged starch (zero time) were significantly different from those of the submerged starch. Duncan's multiple range tests performed on the time-submersion medium interaction and on the single effect of submersion medium showed a significant difference at the 10% level between the salts with polyvalent cations ($MgCl_2$ and $AlCl_3$) and the salts with monovalent cations (Na_2SO_4 and NaCl), $MgCl_2$ and $AlCl_3$ producing greater diameter changes.

SUMMARY AND CONCLUSIONS

The literature pertaining to swelling of starch grains was reviewed, and a procedure for determining swelling of starch grains in various environmental conditions is described.

Corn and amioca starches and the moisture content of these starches showed a significant difference in grain sizes when submersed in distilled water or simulated gastric fluid U.S.P. This was postulated as due to the initial size differences of the starches. It was observed that initially high moisture content starches had larger mean grain sizes than low moisture content starches and that this difference was maintained throughout the time of the experiments. The initial differences in mean grain sizes of the corn and amioca starches was also maintained throughout the experiments.

The two cornstarches submersed 5 to 30 min. in simulated gastric fluid U.S.P. had greater increase in grain sizes over those submersed in distilled water.

Changes in pH had little effect on swelling. However, evidence was obtained to show that starch grains may swell more at a pH of 5.3 than in lower pH media.

Salts affected the swelling of starch grains, with polyvalent cationic salts ($MgCl_2$ and $AlCl_3$) producing more swelling than monovalent cationic salts (NaCl and Na_2SO_4). Ionic concentration did not show any effect on swelling.

There was no significant difference in swelling of starch grains demonstrated between the various time intervals. However, when unsubmerged starches were included in the analyses of variance, significant size differences were shown between the unsubmerged starches and the starches slurried for 5 min. and longer. No significant additional increase in mean grain size was found after 5-min. submersion, indicating any swelling that occurs is apparently instantaneous.

The swelling of the starch grains observed was in the order of 5 to 10% increase in mean grain size. At present, this does not seem to be a large enough change to cause tablets to rupture. Further work is in progress to determine other factors that may influence the swelling of starch grains, and to determine whether the observed increases in mean grain diameter are sufficient to rupture tablets.

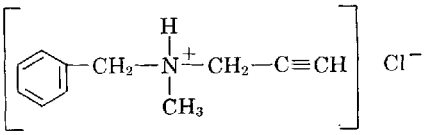
Qualitative and Quantitative Tests for Pargyline Hydrochloride

Provisional, unofficial monographs are developed by the Drug Standards Laboratory, in cooperation with the manufacturers of the drug concerned, for publication in the *Journal of Pharmaceutical Sciences*. The ready availability of this information affords discriminating medical and pharmaceutical practitioners with an added basis for confidence in the quality of new drug products generally, and of those covered by the monographs particularly. Such monographs will appear on drugs representing new chemical entities for which suitable identity tests and assay procedures are not available in the published literature. The purity and assay limits reported for the drugs and their dosage forms are based on observations made on samples representative of commercial production and are considered to be reasonable within expected analytical and manufacturing variation.

N-Methyl-*N*-(2-propynyl)-benzylamine hydrochloride; $C_{11}H_{13}N \cdot HCl$; mol. wt. 195.69. The structural formula of pargyline hydrochloride may be represented as



Physical Properties.—Pargyline hydrochloride occurs as a fine white crystalline powder having a characteristic odor, m.p. 158–162° (U.S.P., class I). It is very soluble in water and freely soluble in alcohol. Pargyline hydrochloride sublimes slowly when maintained at temperatures approaching its melting range.

Identity Tests.—A 1 in 2,500 solution of pargyline hydrochloride in 0.1 *N* hydrochloric acid exhibits ultraviolet absorbance maxima at about 251, 257, 262 [absorptivity (a) about 1.55], and 268 mμ, and absorbance minima at about 229, 253, 259, and 266 mμ. The spectrum is shown in Fig. 1.

The infrared spectrum of a 0.5% dispersion of pargyline hydrochloride in potassium bromide, in a disk of about 0.82 mm. thickness is shown in Fig. 2.

Dissolve about 50 mg. of pargyline hydrochloride in 3 ml. of water, add ammonia T.S. until basic, and filter. Acidify the filtrate with diluted nitric acid and add 1 ml. of silver nitrate T.S.: a white precipitate forms, which is insoluble in diluted nitric acid, but soluble in ammonia T.S. (presence of chloride).

Purity Tests.—Determine the water content of pargyline hydrochloride by the titrimetric (Karl Fischer) method: not more than 1% is found.

Char about 1 Gm. of pargyline hydrochloride, accurately weighed, cool the residue, add 1 ml. of sulfuric acid, heat cautiously until evolution of sulfur trioxide ceases, ignite, cool, and weigh: the residue does not exceed 0.2%.

Determine the heavy metals content of pargyline hydrochloride by the U.S.P. heavy metals test, method II: the heavy metals limit for pargyline hydrochloride is 20 p.p.m.

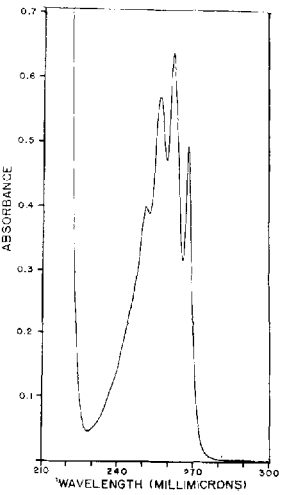


Fig. 1.—Ultraviolet absorption spectrum of pargyline hydrochloride in 0.1 *N* hydrochloric acid (400 mcg./ml.); Beckman model DK-2A spectrophotometer.

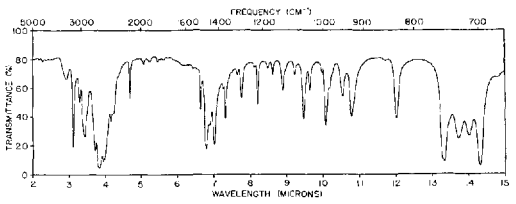

Fig. 2.—Infrared spectrum of pargyline hydrochloride in potassium bromide disk (0.5%); Perkin-Elmer model 21 spectrophotometer, sodium chloride prism.

Received September 26, 1965, from the Drug Standards Laboratory, American Pharmaceutical Association Foundation, Washington, D. C.
Accepted for publication March 21, 1966.
Abbott Laboratories, North Chicago, Ill., has cooperated by furnishing samples and data to aid in the development and preparation of this monograph.

A solution of pargyline hydrochloride in water (1 in 10) is colorless and clear, except for some mechanical impurities which may remain in suspension.

Assay.—*Acetylenic Group.*—Transfer about 200 mg. of pargyline hydrochloride, accurately weighed, to a tall-form 200-ml. beaker and dissolve in 20 ml. of alcohol. Add 25 ml. of 0.1 *N* alcoholic silver nitrate (prepared by dissolving 8.5 Gm. of silver nitrate in 20 ml. of water and diluting to 500 ml. with alcohol), 50 ml. of 0.2 *M* alcoholic trishydroxymethylaminomethane (THAM), and mix. Titrate the mixture potentiometrically with 0.1 *N* alcoholic potassium hydroxide using glass and calomel electrodes. Each milliliter of 0.1 *N* alcoholic potassium hydroxide is equivalent to 9.785 mg. of $C_{11}H_{13}N \cdot HCl$. The amount of pargyline hydrochloride found is not less than 98.0% and not more than 102.0%.

Amine Group.—Transfer about 400 mg. of pargyline hydrochloride, accurately weighed, to a tall-form 200-ml. beaker, and dissolve in 50 ml. of glacial acetic acid. Add 10 ml. of mercuric acetate T.S. and titrate potentiometrically with 0.1 *N* acetous perchloric acid. Alternatively, add 2 drops of crystal violet T.S. and titrate to a green end point.[1] Each milliliter of 0.1 *N* perchloric acid is equivalent to 19.57 mg. of $C_{11}H_{13}N \cdot HCl$. The amount of pargyline hydrochloride found is not less than 98.0% and not more than 102.0%.

DOSAGE FORMS OF PARGYLINE HYDROCHLORIDE

Pargyline Hydrochloride Tablets

Identity Tests.—Transfer to a 100-ml. volumetric flask an amount of powdered tablets equivalent to about 40 mg. of pargyline hydrochloride. Add about 50 ml. of 0.1 *N* hydrochloric acid and shake mechanically for 15 min. Dilute to volume with 0.1 *N* hydrochloric acid, mix, and filter: the filtrate exhibits ultraviolet absorbance maxima and minima at the same wavelengths as a solution of pargyline hydrochloride reference standard in the same medium.

Assay.—*Amine group.*—Weigh and finely powder not less than 20 tablets. Transfer to a 125-ml. separator an amount of powder, accurately weighed, equivalent to about 40 mg. of pargyline hydrochloride. Add 30 ml. of water and 1 ml. of sodium hydroxide T.S. and extract with four 20-ml. portions of chloroform. Wash the combined chloroform extracts with 10 ml. of water and discard the water phase. Filter the chloroform extract through a pledget of purified cotton into a tall-form 200-ml. beaker and wash the cotton with 10 ml. of chloroform. Add 25 ml. of acetonitrile and titrate potentiometrically with 0.01 *N* perchloric acid in dioxane. Each milliliter of 0.01 *N* perchloric acid is equivalent to 1.957 mg. of $C_{11}H_{13}N \cdot HCl$. The amount of pargyline hydrochloride found is not less than 90.0% and not more than 110.0% of the labeled amount.

[1] If the indicator method is used, perform a blank titration and make any necessary correction.

DISCUSSION

U.S.P. and N.F. terminology for solubility, melting range, reagents, etc., have been used wherever feasible.

Pargyline hydrochloride[2] is a nonhydrazine monoamine oxidase inhibitor which acts as an antihypertensive.

Identity Tests.—The ultraviolet absorption spectrum of the extract obtained from commercial 10-mg. tablets compared qualitatively with that of Fig. 1 in the region of from 250–270 mμ. Extraneous absorbance, due to unidentified tablet constituents, was present throughout the ultraviolet range but did not obscure the distinctive features of the pargyline hydrochloride spectrum.

Quantitative Methods.—The assay based on the acetylenic group in pargyline hydrochloride is similar to the assays provided in the N.F. XII monographs on ethchlorvynol and ethinamate. In the present assay, however, the titration with 0.1 *N* alcoholic potassium hydroxide determines the bound hydrochloric acid in addition to the acid released on formation of the silver acetylide. The bound acid may be determined independently by titration of a sample to which no silver nitrate has been added. Titration of the sample without the addition of THAM buffer results in extreme darkening of the solution as the titration progresses. This effect, which is believed to be due to a darkening of the precipitated silver chloride as well as the deposition of some silver oxide, is minimized in the buffered medium. The assay of pargyline hydrochloride gave an average value of 100.6 ± 0.5%.[3]

Caution is to be observed in disposing of completed titration mixtures since silver acetylides are explosive when dry. The titration vessel should be flushed with water thoroughly prior to disposal. Occluded precipitates should be dissolved with nitric acid.

Attempts to employ this method for the direct determination of pargyline hydrochloride in the tablets proved unsuccessful. The voltage change in the vicinity of the end point was gradual, and the results obtained tended to be high (about 110% of label claim).

The nonaqueous titration of pargyline hydrochloride with perchloric acid gave an average value of 99.4 ± 0.1%.[3] With crystal violet indicator, the color change from turquoise to a definite green corresponded to the midpoint of the inflection in the potentiometric titration curve. Generally, the visual titration is not as advantageous as the potentiometric determination due to the fading of the indicator in the presence of the precipitate which forms during the titration. An additional drop of crystal violet T.S. as the end point is approached will aid in identifying the desired indicator change.

Extraction of the powdered tablets with chloroform followed by titration of the free base with perchloric acid gave an average value of 99.8 ± 0.4%[3] of the labeled amount of pargyline hydrochloride.

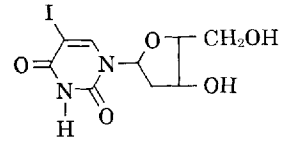
Qualitative and Quantitative Tests for Idoxuridine

Provisional, unofficial monographs are developed by the Drug Standards Laboratory, in cooperation with the manufacturers of the drug concerned, for publication in the *Journal of Pharmaceutical Sciences*. The ready availability of this information affords discriminating medical and pharmaceutical practitioners with an added basis for confidence in the quality of new drug products generally, and of those covered by the monographs particularly. Such monographs will appear on drugs representing new chemical entities for which suitable identity tests and assay procedures are not available in the published literature. The purity and assay limits reported for the drugs and their dosage forms are based on observations made on samples representative of commercial production and are considered to be reasonable within expected analytical and manufacturing variation.

5-IODO-2′-DEOXYURIDINE; $C_9H_{11}IN_2O_4$; mol. wt. 354.10. The structural formula of idoxuridine may be represented as



Physical Properties.—Idoxuridine occurs as a white, odorless, crystalline powder. In a melting point capillary it darkens and then decomposes with evolution of iodine fumes at 180–185° (U.S.P., class I*a*). It is slightly soluble in water and in alcohol, and is practically insoluble in chloroform and in ether. A 1% solution in 1 *N* NaOH is dextrorotatory.

Identity Tests.—Heat about 100 mg. of idoxuridine in a porcelain crucible over a free flame: violet vapors of iodine are evolved.

Dissolve 100 mg. of idoxuridine in 100 ml. of a 1 in 4 solution of isopropylamine in methanol. To 5 ml. of this solution add 5 ml. of chloroform and 0.2 ml. of a freshly prepared 1 in 100 solution of cobaltous acetate in methanol: a violet to blue-violet color is produced.

A 1:50,000 solution of idoxuridine in 0.1 *N* sodium hydroxide exhibits an ultraviolet absorbance maximum at about 280 mμ [absorptivity (*a*) about 16.0] and a minimum at about 253 mμ. The spectrum is shown in Fig. 1.

The infrared spectrum of 0.5% dispersion of idoxuridine in potassium bromide, in a disk of about 0.82-mm. thickness, is shown in Fig. 2.

Purity Tests.—Char about 1 Gm. of idoxuridine, accurately weighed, cool the residue, add 1 ml. of sulfuric acid, heat cautiously until evolution of sulfur trioxide ceases, ignite, cool, and weigh: the residue does not exceed 0.5%. Retain the residue for the heavy metals test.

Dissolve the sulfated ash obtained from 1 Gm. of idoxuridine in a small volume of hot nitric acid and evaporate to dryness on a steam bath. Dissolve the residue in 2 ml. of diluted acetic acid, dilute to 25 ml. with water, and determine the heavy metals content of this solution by the U.S.P. XVII heavy metals test, method I: the heavy metals limit for idoxuridine is 20 p.p.m.

Assay.—*Iodine.*—Transfer about 75 mg. of idoxuridine, accurately weighed, into a large nickel crucible. Add 1 Gm. of anhydrous potassium carbonate powder and mix thoroughly with the sample using a dry glass rod. Gently tap the crucible to compact the mixture. Overlay the mixture with 12 Gm. of anhydrous potassium carbonate powder and again tap the crucible to compact the material. Ignite the contents of the uncovered crucible for 30 min. at 525° in a muffle furnace preheated to that temperature. Cool the crucible and transfer the contents to a 400-ml. beaker, rinsing the crucible with several portions of water, and adding the rinsings to the beaker. Add about 50 ml. of water to the beaker, heat gently, and break up the melt with the aid of a stirring rod. Filter the suspension through paper,

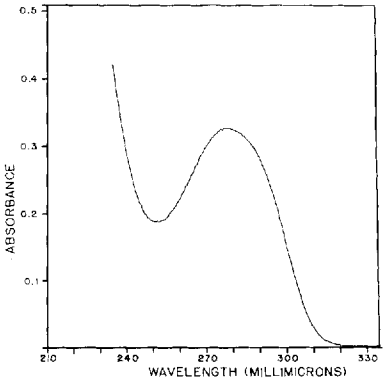


Fig. 1.—Ultraviolet absorption spectrum of idoxuridine in 0.1 *N* sodium hydroxide (20 mcg./ml.); Beckman model DK-2A spectrophotometer.

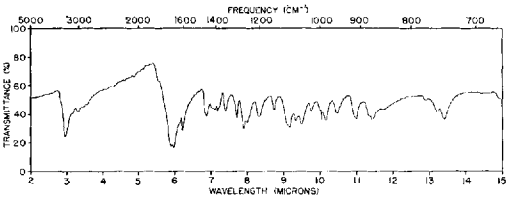

Fig. 2.—Infrared spectrum of idoxuridine in potassium bromide disk (0.5%); Perkin-Elmer model 21 spectrophotometer, sodium chloride prism.

Received May 19, 1964, from the Drug Standards Laboratory, American Pharmaceutical Association Foundation, Washington, D. C.

Accepted for publication March 7, 1966.

Alcon Laboratories, Fort Worth, Tex., Allergan Pharmaceuticals, Santa Ana, Calif., and Smith Kline & French Laboratories, Philadelphia, Pa., have cooperated by furnishing samples and data to aid in the development and preparation of this monograph.

collecting the filtrate in a 250-ml. volumetric flask. Wash the beaker and filter paper with hot water until near the mark. Cool to room temperature, dilute to volume with water, and mix well. Pipet a 50-ml. aliquot of this solution into a 500-ml. conical flask and add 150 ml. of water. Add methyl orange T.S., then add phosphoric acid to produce a definite pink color. Add 10 ml. of bromine T.S. (sufficient amount to impart a definite yellow color to the solution) and several glass beads and heat to boiling. Boil the solution until it is colorless, rinse the inside walls of the flask with water, and boil an additional 5 min. Stopper the flask loosely, and cool to room temperature in a cold water bath. Add 5 ml. of phenol solution (1 in 20), again rinse the walls of the flask, and allow to stand 5 min. Add 5 ml. of potassium iodide solution (1 in 10) and titrate immediately with 0.05 *N* sodium thiosulfate, adding 3 ml. of starch T.S. as the end point is neared. Perform a blank determination and make any necessary correction. Each milliliter of 0.05 *N* sodium thiosulfate is equivalent to 1.058 mg. of iodine (I). The amount of iodine found is not less than 34.7% and not more than 36.6% of the weight of the sample taken.

Idoxuridine.—Dissolve about 500 mg. of idoxuridine, accurately weighed, in 40 ml. of dimethylformamide which has been previously neutralized to thymol blue T.S. Titrate with 0.1 *N* sodium methoxide to a blue end point. Each milliliter of 0.1 *N* sodium methoxide is equivalent to 35.41 mg. of $C_9H_{11}IN_2O_5$. The amount of idoxuridine found is not less than 98.0% and not more than 101.0% of the weight of the sample taken.

DOSAGE FORMS OF IDOXURIDINE

Idoxuridine Ophthalmic Solution

A sterile solution of idoxuridine in water. The solution may be rendered isotonic by addition of appropriate agents.

Identity Tests.—Evaporate 5 ml. of idoxuridine ophthalmic solution to dryness with the aid of a stream of air, add 2 ml. of alcohol, and again evaporate to dryness. To the residue add 5 ml. of a 1 in 4 solution of isopropylamine in methanol. If the residue is not completely soluble in this solution, the use of a stirring rod will aid in dissolving the idoxuridine present. Add 5 ml. of chloroform and 0.2 ml. of a freshly prepared 1 in 100 solution of cobaltous acetate in methanol: a violet to blue-violet color is produced.

Purity Tests.—To about 10 ml. of idoxuridine ophthalmic solution add a few drops of starch T.S.: no blue color is produced (absence of free iodine).

Assay.—To 4 Gm. of purified siliceous earth in a 4-oz. glass mortar add 4 ml. of water and incorporate by kneading thoroughly with a flexible spatula blade until the mixture is fluffy. Transfer to a chromatographic tube (19 × 200 mm.) equipped with a Teflon stopcock, and tamp gently to compress the material to a uniform mass. Transfer 2 Gm. of purified siliceous earth to the glass mortar, add 2.0 ml. of idoxuridine ophthalmic solution, mix as before, and transfer to the tube without tamping. Transfer 2 Gm. of purified siliceous earth to the same mortar, add 2 ml. of water, mix well, transfer about half of the mixture of the tube, and tamp down gently until the column appears uniform. Transfer the remaining portion of the tube, tamp as before, and cover with a small pledget of glass wool. Elute with chloroform–*n*-butanol (5:1) at a flow rate of approximately 1 ml./min., discarding the first 15–20 ml. of eluant. Collect the next 80 ml. of eluant in a 100-ml. volumetric flask, dilute to volume with the eluting solvent, and mix. Concomitantly determine the absorbance of this solution and of a standard solution of idoxuridine,[1] in the same medium, at a concentration of about 20 mcg./ml., in 1-cm. cells, at 292 and at 310 mμ, with a suitable spectrophotometer, using chloroform–*n*-butanol (5:1) as the blank. Calculate the quantity, in mg., of $C_9H_{11}IN_2O_5$ in the volume of ophthalmic solution taken by the formula $0.1C \times (A_{u292} - A_{u310})/(A_{s292} - A_{s310})$ in which C is the exact concentration of the standard solution, in mcg./ml., A_u is the absorbance of the sample solution, and A_s is the absorbance of the standard solution. The amount of idoxuridine is not less than 90% and not more than 110% of the labeled amount.

DISCUSSION

U.S.P. and N.F. terminology for solubility, melting range, reagents, etc., have been used wherever feasible.

Idoxuridine,[2] synthesized by Prusoff (1), is an antiviral agent indicated in the treatment of corneal erosions caused by the herpes simplex virus. The effectiveness of idoxuridine in the treatment of herpes simplex keratitis has been attributed to its similarity of structure to thymidine; idoxuridine differs from thymidine only in the substitution of an iodine atom for a methyl group in the carbon-5 position of the uracil moiety. Administration of idoxuridine in the form of an ophthalmic solution results in a competition with thymidine for incorporation in the synthesis of deoxyribonucleic acid (DNA), the genetic material of herpes simplex virus which determines its ability to infect and reproduce. Incorporation of idoxuridine in the DNA synthesis results in the production of a "faulty" DNA, inhibiting reproduction of the invading virus.

Identity Tests.—Idoxuridine reacts with cobalt salts in nonaqueous alkaline medium to produce a colored complex. This color reaction is rather specific for compounds possessing the —CONHCO— or —CONHCS— group (2). Barbiturates, hydantoins, and xanthines are typical classes of compounds which produce colored complexes under similar conditions. The method may be adapted for quantitative determination of idoxuridine in the ophthalmic solution. The presence of isotonic agents such as sodium chloride which are relatively insoluble in the reaction solvents decreases the reproducibility of the method. The ultraviolet absorption spectrum may be run alternatively in acid solution with a maximum absorbance at about 288 mμ [absorptivity (a) about 21.5] and a minimum at about 248 mμ. These tests together

[1] Prepare a methanolic solution of idoxuridine in a concentration of 2 mg./ml. Dilute 1.0 ml. of this solution to 100.0 ml. with chloroform–*n*-butanol (5:1).

[2] Marketed as Dendrid by Alcon Laboratories, Fort Worth, Tex., as Herplex by Allergan Pharmaceuticals, Santa Ana, Calif., and as Stoxil by Smith Kline & French Laboratories, Philadelphia, Pa.

with the identity test based upon the evolution of iodine vapor and comparison of the infrared spectrum provide a satisfactory identification of idoxuridine.

Purity Tests.—Thin-layer or paper chromatographic procedures may be included for testing the purity of bulk idoxuridine. Comparison of idoxuridine to a reference standard is made by examination of developed chromatograms using an ultraviolet light and/or color producing reagents, *i.e.*, cysteine–sulfuric acid. The idoxuridine spot should be equivalent in position to the reference standard spot for idoxuridine, and no other spots at other positions should be visible. The spotting of control solutions containing the degradation products of idoxuridine (5-iodouracil, uracil, and deoxyuridine) will aid in detecting the position of extraneous spots on the chromatograms.

Quantitative Methods.—The quantitative determination of the iodine content of idoxuridine is similar to the official assay for sodium liothyronine (3) and gave an average value equivalent to 36.1 ± 0.1%[3] iodine. A rapid, precise measure of the iodine content may also be determined by the oxygen flask method (4–6). Nonaqueous titration of idoxuridine with sodium methoxide gave an average value of 99.8 ± 0.6%.[3] Azo violet indicator may also be used for the end point detection of the titration. Analysis of the sterile ophthalmic solutions by column partition chromatography was based on the procedure of Simpson and Zappala (7). Acid washed Celite 545 was used as the supporting phase without prior treatment. Celite 545 may be used as the adsorbant by prewashing an acidified column with organic solvents to remove extractable impurities. The organic solvents are then removed by oven drying. Incorporation of water or 0.1 *N* hydrochloric acid in the preparation of the Celite columns gave comparable results representing an average recovery of 97.4 ± 5.7%[3] of the theoretical amount of idoxuridine in the ophthalmic solutions.

The volume of eluting solvent included for the assay of idoxuridine ophthalmic solution gave quantitative recoveries with the Celite used. However, it should be noted that the elution rate for idoxuridine may vary from lot to lot of Celite which then necessitates a minor change in the volume of eluate collected. This should be demonstrated for each batch of Celite by a satisfactory recovery of a standard aqueous idoxuridine solution subjected to the column procedure.

Technical Articles

Automated Nephelometric Determination of Rat Liver Glycogen in Adrenal Steroid Bioassays

By WILLIAM F. BEYER

An automated procedure for the nephelometric determination of rat liver glycogen is described. Alkaline liver digests are mixed with 57.5 per cent alcohol and heated at 45°. Samples are analyzed at a rate of 60/hr. using an automatic sampler and analyzer (Technicon AutoAnalyzer) in conjunction with a commercially available fluorometer. The coefficient of variation for the automated procedure is approximately 1 per cent.

RAT LIVER glycogen is used as the criterion of response in the bioassay for endocrine principles of the adrenal cortex and also for synthetic steroids. The assay is based on the method of Pabst *et al.* (1) and is currently an official procedure for adrenal cortex injection as directed by N.F. XII (2). For the assay, livers of adrenalectomized rats, previously injected with test samples, are digested in hot 30% potassium hydroxide. After standing overnight at room temperature, the alkaline liver digests are diluted with water and glycogen is determined.

An automated procedure for glycogen has been described by Singer *et al.* (3) requiring manual deproteination with trichloroacetic acid. Glyco-

with the identity test based upon the evolution of iodine vapor and comparison of the infrared spectrum provide a satisfactory identification of idoxuridine.

Purity Tests.—Thin-layer or paper chromatographic procedures may be included for testing the purity of bulk idoxuridine. Comparison of idoxuridine to a reference standard is made by examination of developed chromatograms using an ultraviolet light and/or color producing reagents, *i.e.*, cysteine–sulfuric acid. The idoxuridine spot should be equivalent in position to the reference standard spot for idoxuridine, and no other spots at other positions should be visible. The spotting of control solutions containing the degradation products of idoxuridine (5-iodouracil, uracil, and deoxyuridine) will aid in detecting the position of extraneous spots on the chromatograms.

Quantitative Methods.—The quantitative determination of the iodine content of idoxuridine is similar to the official assay for sodium liothyronine (3) and gave an average value equivalent to 36.1 ± 0.1%[3] iodine. A rapid, precise measure of the iodine content may also be determined by the oxygen flask method (4–6). Nonaqueous titration of idoxuridine with sodium methoxide gave an average value of 99.8 ± 0.6%.[3] Azo violet indicator may also be used for the end point detection of the titration. Analysis of the sterile ophthalmic solutions by column partition chromatography was based on the procedure of Simpson and Zappala (7). Acid washed Celite 545 was used as the supporting phase without prior treatment. Celite 545 may be used as the adsorbant by prewashing an acidified column with organic solvents to remove extractable impurities. The organic solvents are then removed by oven drying. Incorporation of water or 0.1 *N* hydrochloric acid in the preparation of the Celite columns gave comparable results representing an average recovery of 97.4 ± 5.7%[3] of the theoretical amount of idoxuridine in the ophthalmic solutions.

The volume of eluting solvent included for the assay of idoxuridine ophthalmic solution gave quantitative recoveries with the Celite used. However, it should be noted that the elution rate for idoxuridine may vary from lot to lot of Celite which then necessitates a minor change in the volume of eluate collected. This should be demonstrated for each batch of Celite by a satisfactory recovery of a standard aqueous idoxuridine solution subjected to the column procedure.

Automated Nephelometric Determination of Rat Liver Glycogen in Adrenal Steroid Bioassays

By WILLIAM F. BEYER

An automated procedure for the nephelometric determination of rat liver glycogen is described. Alkaline liver digests are mixed with 57.5 per cent alcohol and heated at 45°. Samples are analyzed at a rate of 60/hr. using an automatic sampler and analyzer (Technicon AutoAnalyzer) in conjunction with a commercially available fluorometer. The coefficient of variation for the automated procedure is approximately 1 per cent.

RAT LIVER glycogen is used as the criterion of response in the bioassay for endocrine principles of the adrenal cortex and also for synthetic steroids. The assay is based on the method of Pabst *et al.* (1) and is currently an official procedure for adrenal cortex injection as directed by N.F. XII (2). For the assay, livers of adrenalectomized rats, previously injected with test samples, are digested in hot 30% potassium hydroxide. After standing overnight at room temperature, the alkaline liver digests are diluted with water and glycogen is determined.

An automated procedure for glycogen has been described by Singer *et al.* (3) requiring manual deproteination with trichloroacetic acid. Glyco-

gen determinations are then made automatically by measuring the intensity of the glycogen–iodine complex. This report gives details for an automated assay of rat liver glycogen using a fluorometer adapted for nephelometry. The method, based on a previously described procedure (4), depends upon the cloud produced by glycogen from alkaline liver digests in 55% alcohol. Technicon instruments and a commercially available fluorometer equipped with a square quartz flow cell are used in the analyses, permitting glycogen determinations at a rate of 60 samples/hr.

MATERIALS AND METHODS

Instrument and Equipment.—(*a*) Automatic sampler,[1] proportioning pump, flow through door for fluorometer, recorder, chart reader, double mixing coils, and assorted glass fittings and tubing. (*b*) Fluorometer[2] with Wratten 2A-12 primary and secondary filters and blue lamp, permitting measurements at approximately 510 mμ. (*c*) Square quartz flow cell, 3 mm. i.d. × 5-mm. o.d. with 12-mm. masked adapter insert.[3] (*d*) Water bath operated at 45°.[4]

Reagents.—(*a*) Potassium hydroxide, 3.6% and 30%. (*b*) Alcohol, 57.5%, (v/v). (*c*) Test rat liver digests. Adrenalectomized rats are injected with adrenal steroid preparations as directed by N.F. XII. Livers are removed, digested in 12 ml. of hot 30% potassium hydroxide, and diluted to 100 ml. with water after standing overnight at room temperature. (*d*) Pooled livers of adrenalectomized uninjected rats (blank pool). Prepared in the same manner as liver digests of test rats for each series of glycogen determinations. (*e*) Standard rat liver glycogen. Prepared according to van der Vies (5). (*f*) Standard solutions of rat liver glycogen. Fresh solutions of glycogen standard are prepared in the blank pool. For a standard curve, solutions in the range of 0.06 to 1.2 mg./ml. are adequate. To check instrumental and reagent changes, a 0.5-mg./ml. standard is used.

Method.—The sample line is placed in the blank

pool and all other lines in proper reagents as shown in the manifold flow diagram of Fig. 1. Sensitivity of the fluorometer is positioned at 10× and 2A-12 filters are used for both primary and secondary filters. With all instruments operating, a zero base line is established. The 0.5-mg./ml. glycogen standard is placed in duplicate cups initially and singly thereafter at regular intervals following a group of test samples. The analyses are made at a rate of 60/hr. using 3.6% potassium hydroxide in the rinsing system of the automatic sampler.

Calculations.—The quantity of glycogen in each rat liver is calculated using the formula:

$$Gu = \frac{Nu}{Ns} \times Gs \times V$$

where, Gu = milligrams glycogen per liver; Gs = milligrams glycogen standard per milliliter of blank pool; Ns = nephelometric reading of glycogen standard on transmission scale; Nu = nephelometric reading of test sample on transmission scale; and V = milliliters of liver digest.

To correct for changes in the automated system average readings of standards on either side of a group of test samples are used with appropriate liver digests.

Alternatively, the chart reader and a standard curve for rat liver glycogen may be used. Liver glycogen values of test samples are adjusted in accordance with nephelometric readings of the 0.5-mg./ml. standard placed at regular intervals.

RESULTS AND DISCUSSION

Following preliminary experiments with various manifold systems and temperatures, optimum operating conditions and manifold design were determined. The 0.025-in. sample line (Fig. 1), delivering 0.23 ml./min., dilutes the 57.5% alcohol carried by two 0.110-in. lines at a rate of 6.78 ml./min., to 55%. This concentration of alcohol was found to effectively form the glycogen cloud.

Nephelometric responses to liver glycogen concentrations when plotted were linear over the range of 0.06 to 1.2 mg./ml. (6 to 120 mg./liver) and had a zero intercept. An upper limit was not established; however, the concentration of liver glycogen encountered in the bioassay of adrenal steroids normally does not exceed 120 mg./liver. Although glycogen values may vary by a factor of 10 in glycogen deposition assays, sample carry over with the automated procedure is minimal. Figure 2 shows that very similar readings are recorded for duplicate samples of glycogen standard even though preceded by a standard having either high or low nephelometric readings.

Figure 3 gives a typical recorder tracing of unknown test liver digests and glycogen standard showing the variation in liver glycogen that is encountered normally. A portion of the recording, extreme right, shows continuous sampling of the 0.5-mg./ml. glycogen standard and duplicate sampling of the same standard.

Recovery studies were carried out using the automated procedure on samples of glycogen standard added to varying quantities of test liver digest. Table I shows that satisfactory recovery was obtained, with results varying from 98.9–101.1% for the six samples tested.

The reproducibility of the procedure was determined by sampling repeatedly two test liver digests. Table II gives the results: a coefficient of variation of 0.81% was obtained for 14 analyses and 1.07% for 16 subsequent analyses carried out at a later date.

No significant differences in liver glycogen determinations occurred for the manual procedure (4) and the automated method. Table III gives the results of a representative adrenal cortex assay with glycogen determined by both methods on parallel samples of liver digests. It can be noted that only small differences occurred in individual glycogen values; consequently, statistical results are very similar. A comparison of seven additional liver glycogen deposition assays is shown in Table IV. In all cases, comparable potencies and log-confidence intervals were obtained, indicating that the automated procedure is suitable for rat liver glycogen determinations in the glycogen deposition assay of adrenal steroids.

Analog Computer in Drug Dosage and Formulation Design

By EDWARD R. GARRETT and HOWARD J. LAMBERT

Methods have been described which utilize the analog computer as a laboratory aid in the preparation of drug formulations with improved therapeutic efficacy. Five basic dosage models were used to show the versatility of the computer and the variety of programs that are possible. These included single dosage, repetitive dosage, and three different types of sustained and delayed-release mechanisms. The analog computer may be used to predict which combination of existing formulas should be combined to give the desired response or may be used to provide specific information on the desirable physical characteristics of such formulas in advance of their manufacture. The major information needed for such predictions are the pharmacokinetic parameters specific to the drug in question. The analog computer provides an inexpensive means of predicting formulation requirements and may perform, in a matter of hours, work that might take weeks or months by normal laboratory screening methods.

IN AN ERA where both public opinion and federal legislation demand increased proof of drug efficacy and drug safety, the "art" of drug dosage and formulation design is being supplanted by the sophistications of advanced science and technology. Qualitative evaluations of drug potency and action are no longer adequate. Instead, the many transfer processes and reactions undergone by a drug during its release from the dosage forms and its passage through the body should be quantitatively described by mathematical models when reliable analytical data can be obtained. Models, originally formulated by Teorell (1), Dominguez (2), and others allow the description of a drug's action by listing certain numerical values obtained by mathematical treatment of experimental data. These values include rate constants for dissolution, absorption, tissue distribution, metabolism, and excretion. Such mathematical constants then become the focus of attention, an abstraction one level above the observed data (3). Also provided are quantifiable concepts that are extremely useful, such as metabolic half-lives and compartmental volumes of distribution which yield a pharmacokinetic profile or "fingerprint" for a drug. The work of Swintosky (4) on the drug sulfaethylthiadiazole is an excellent illustrative example. At best, however, the direct application of such analytical mathematical techniques is most approximate and difficult. The complexity of the mathematics involved leads to simplification of complex models and only sequential or parallel drug transferences are the models considered.

Received December 20, 1965, from the College of Pharmacy, University of Florida, Gainesville.

Accepted for publication March 31, 1966.

Presented in part to the Annual Pharmacy Congress, College of Pharmacy, St. Johns University, New York, N. Y., March 17, 1965.

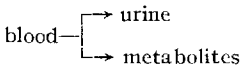
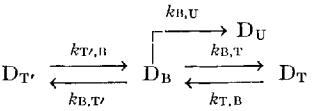
tablet → gastrointestinal tract →



DISCUSSION

The basic premises behind all such models include: (*a*) rapid equilibration of drug between blood and (*b*) other body tissues, fluids, or compartments.



The amount of drug in the blood (D_B) supposedly reflects and is proportional to the amount of drug in tissues T and T′ (D_T and $D_{T'}$) provided that the equilibration is extremely rapid. Furthermore, the rates of transfer must be invariant functions of the amounts of drug in each of these compartments (*i.e.*, first-order kinetics are followed). This implies that the compartmental sizes are limitless and the distribution model is independent of the magnitude of the dose. The slow rate-determining step must be either the elimination of the drug from the body or its metabolism, where these rates are proportional to the amount in the blood.

If both of these conditions are satisfied, then Eq. 1 will hold,

$$\log D_B = \frac{-k_e t}{2.303} + \text{constant} \qquad \text{(Eq. 1)}$$

and a plot of the logarithm of the blood concentration (D_B) *versus* time will result in a straight line with a slope of $-k_e/2.303$. In addition, the biological half-life, defined as that period of time needed for any blood concentration (after tissue equilibration is established) to reach one-half its value, will be constant for any blood level or dose chosen,

$$t_{0.5} = \frac{2.303 \log 2}{k_e} = \frac{0.693}{k_e} = \text{constant} \qquad \text{(Eq. 2)}$$

The k_e referred to here is the rate constant derived from the plotting of Eq. 1. It should be realized that this is not $k_{B,U}$ (the rate constant for urinary and/or metabolic elimination), but rather, is de-

pendent upon the ratios of other distribution rate constants (12).

$$k_e = \frac{k_{B,U}}{1 + \frac{k_{B,T}}{k_{T,B}} + \frac{k_{B,T'}}{k_{T',B}}} \quad \text{(Eq. 3)}$$

If the transfer of drug between one compartment, *e.g.*, T′, and the blood is an extremely slow process, for example, the slow release of thiopental from fatty tissues (5), or the deeper compartment for psicofuranine (13), this reaction then becomes rate determining and deviations from apparent first-order kinetics occur. A similar situation develops when a nonlinear Langmuir-type binding occurs, *e.g.*, the binding of sulfonamides to plasma proteins (6). When such phenomena occur, the "biological half-life" varies with the dose and loses its value as a descriptive entity since Eq. 2 no longer holds.

Another instance where the biological half-life concept may fall down is when one of the distribution compartments is of limited size. With increasing dose, the amount of drug stored in this compartment will increase until a saturation point is reached. At this point, nonlinear discontinuities will occur in the first-order kinetic distribution pattern.

These phenomena are difficultly described by available analytical mathematics. The advent of computers has provided a pharmaceutical research tool to handle such complex problems with efficiency and reliability.

The Analog Computer.—The analog computer is an extraordinary tool for the elucidation of the mechanisms and rates of transformations and distribution of drugs in *in vivo* and *in vitro* systems. It permits the determinations of models for absorption from the site of administration into the blood, diffusion into tissues, and other volumes of distribution (*i.e.*, lymph, cerebrospinal fluid, red blood cells, etc.), metabolic pathways, and excretion processes. Such determinations are carried out by programing the computer for any sequential, or parallel, changes in drug amount in the various depots of an organism. The "read-out" can be obtained as plotted curves of drug amount *versus* time for any selected compartment in the model chosen.

The theory and details of analog computer programing are presented in many excellent texts and brochures (7–12). In general, the analog computer can simulate postulated physiological models by a dynamic electrical network. Employing a set of linked integrators, the output from each integrator can represent the time-variable amount (drug concentration times the apparent volume of distribution) of the drug distributed in a particular biological compartment. The integrators are connected by rate setting potentiometers and summing amplifiers so as to simulate the distribution of the drug on the basis of the chosen model. Dosage is introduced by applying an initial condition voltage to either the "stomach" integrator or the "blood" integrator depending on whether oral or intravenous modes of administration are to be simulated.

Typical examples of such analog computer applications are found in the literature for the distribution of the nucleoside antibiotic psicofuranine (13) and for ^{47}Ca dynamics in the dog (14, 15). An elementary handbook for the practical application of analog computer methods to pharmacokinetics has also been presented (16).

Dosage Form Design.—A dosage form for oral administration has several prerequisites. (*a*) The dosage form (a tablet or a capsule) must disintegrate in the gastrointestinal tract and the powders or granules released must dissolve in the surrounding fluids. (*b*) The drug in solution must be absorbed by the gastrointestinal mucosa and be transferred into the blood. (*c*) If the blood level of the drug is proportional to its therapeutic response, the blood level achieved should be within the therapeutic concentration range for the desired duration of action. With many pharmacological agents, it is not necessarily true that blood levels directly reflect pharmacological activity. However, these discussions will be restricted to those cases where this is so. Blood levels in the subthreshold therapeutic range will result in ineffective biological activity, whereas concentrations above those eliciting the optimum response may yield toxic manifestations. For these reasons, drugs with a high therapeutic ratio (LD_{50}/ED_{50}) are normally used. (*d*) The duration of the therapeutic blood level should be optimum for the desired therapy. (*e*) The pharmacokinetic parameters which describe the absorption, distribution, metabolism, and excretion of the drug in the human should be known. They can be determined by definitely programed acute studies on intravenous and oral administration by methods which have been previously cited in the literature (13–15). This assumes that there is no change in the metabolic rate with continued administration as there is with barbiturates and many other drugs.

Theories of disintegration and dissolution have been covered in the recent pharmaceutical literature by Wagner (17), Higuchi (18), and others (19–21). Since this literature is both extensive and thorough, these theories will not be discussed herein.

The pH-partition theory of drug absorption through biological membranes has been discussed by Schanker in several review articles (22). The basic premises are that a drug will not be absorbed unless it is unionized and can be partitioned into a lipid-like membrane. These rules hold for drugs which are "passively" rather than "actively" transported in biological systems and permit estimates of ease of absorption. However, absorption rates can be quantified and used whether they are active or passive since, not withstanding the mechanism, they are largely concentration dependent.

Methods of prolonging blood levels, such as using enzyme poisons to slow drug metabolism or drugs to compete for excretory transport systems [*e.g.*, the use of probenecid to block the tubular secretion of penicillin (23)] have been used. These are objectionable both because of their lack of specificity of action and because of their tendency to alter the physiological *status quo*.

The study of the relationship between the physical and chemical properties of drugs and their administered dosage forms and the resultant biological effects has been called biopharmaceutics. The proper use of pharmacokinetic and biopharmaceutical techniques should achieve optimal therapeutic response from a given dose of drug.

Means by which such goals may be obtained are by systematic variation of the following factors: (*a*) the form of the drug (*i.e.*, free acid or base, ester, salt, complex, etc.); (*b*) the physical state (crystal or powder), particle size, and surface area; (*c*) the

presence or absence of other materials with the drug in the dosage form; (*d*) the type of dosage form in which the drug is administered; (*e*) the processes encountered during the manufacture of the dosage form. These alterations usually affect the absorption rate of the compound by controlling its rate of dissolution from the dosage form and into the gastrointestinal fluids. Since these methods alter only the time availability of the drug and not the biological system, they are obviously the methods of choice.

Application of Computer Techniques.—The purpose of this paper is to show how the analog computer may be programed to give information on how to improve the therapeutic efficiency of a drug formulation. Such information may be obtained in two ways. First, having a knowledge of the pharmacokinetics of the drug the proper dose and dissolution rate constants which will give optimum therapy may be ascertained. Second, using knowledge of the physical characteristics of available formulations, which combinations will provide the desired effect can be predicted.

With either or both of these methods, information can be provided faster, more accurately, and at lower cost than by the sole use of the *in vivo* and *in vitro* testing available. It must be stressed, however, that the ultimate test of therapeutic efficacy of drug formulations is in biological systems.

RESULTS AND DISCUSSION

The basic model used in these present computer studies on optimization of drug dosage forms was

$$GI \xrightarrow{k_{GI,B}} B \xrightarrow{k_{B,U}} U \qquad \text{(Eq. 4)}$$

where GI is the gastrointestinal compartment; B, the body compartment; U, the sum of excretory compartments (urine, metabolism, feces, etc.); $k_{GI,B}$ is the first-order rate constant for absorption of drug from the gastrointestinal tract into the blood; and $k_{B,U}$ is the sum of the first-order rate constants for loss (*i.e.*, glomerular filtration, metabolism, etc.) of the free, therapeutically active drug moiety from the body compartment.

This model was chosen for its simplicity since drug formulation rather than complex pharmacokinetics was being investigated. It should be remembered, however, that the computer can be used for any model where the kinetic patterns have been established. Indeed it may be only with the use of a computer that such complex models can be verified in the first place (13–15).

The assumptions that are inherent in the choice of this simple model are that (*a*) the sequential transfers from GI → B → U are by first-order processes and are therefore dependent on the drug amount in each compartment; (*b*) the drug used is nonionic in character and shows no variation in absorption due to pH changes along the length of the gastrointestinal tract; (*c*) the drug is completely absorbed; and (*d*) instantaneous equilibration of the drug occurs between all tissues permeable to the drug and the blood. At any time, therefore, the blood concentration of drug mirrors the concentrations in all drug-containing tissues.

The rate constants for absorption and elimination were held constant throughout the course of the experiment and had the following values:

$$k_{GI,B} = 4.60 \text{ hr.}^{-1}$$

$$k_{B,U} = 1.15 \text{ hr.}^{-1}$$

These values closely approximate those which may be calculated for an oral dose of 400,000 units of potassium penicillin V from the data of Holland *et al.* (24). The high absorption rate constant permits all (100%) of the dose to be absorbed in 1.5 hr., while the elimination rate constant allows the drug a biologic half-life of 0.6 hr.

A computer plot of the gastrointestinal, body, and urinary amounts of drug (labeled D_{GI}, D_B, and D_U, respectively) as fractions of an initial 10 units of drug given in solution or as a rapidly dissolving tablet, with time, is given in Fig. 1.

Certain clinical parameters are needed for proper design of dosage forms. For a given dose the threshold level for this drugs' action is considered to be 2.5 units of the total dose in the blood compartment with a maximum effect noted at 3.5 units (the upper and lower dashed lines of Fig. 1 demonstrate these values). It is interesting to note that only 14% of the dosage was used in the therapeutic range, 21% was expended in D_B levels above 3.5, and 65% at subthreshold levels.

The differential equations and analog computer program which describe the basic model are found in the *Appendix* under *Model I* (Eqs. 1*a*–1*c* and Fig. 2).

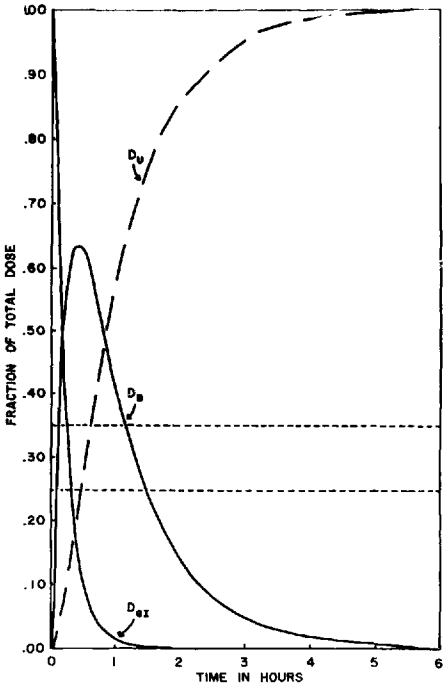


Fig. 1.—Analog computer plot of compartmental distribution of a single 10 unit dose of drug. D_{GI} = amount of drug in the gastrointestinal tract, D_B = amount of drug in the body, and D_U = amount of drug eliminated from the body. The interval between the dashed lines indicates the desired therapeutic range.

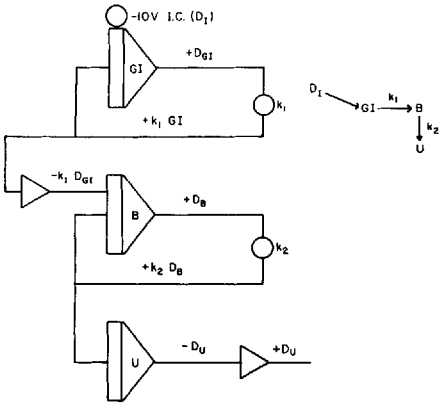

Fig. 2.—Analog computer program for a single 10-unit dose of drug administered in solution into the GI compartment (*Model I*).

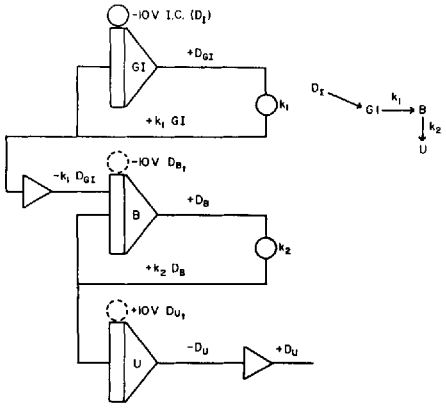

Fig. 4.—Analog computer program used for investigation of a multiple dosage regimen (5 units of drug every 1.2 hr.) (*Model II*).

A logical approach to maintain therapeutic levels with greater drug efficiency is multiple dose therapy. When a drug is administered on a multiple dose regimen with a constant dosage interval, the blood levels of the drug reach a steady state condition after several doses. This steady state is evidenced by the blood levels in a given dosage interval being essentially the same as those in the preceding and following intervals. For the authors' drug, the computer was dosed with half the original dose of Fig. 1 (5 units) at zero time followed by equal doses at consecutive 1.2 hr. intervals (2 half-lives) until 8.4 hr. The typical compartmental profile for such multiple dosing is seen in Fig. 3. The equations used for this approach are the same as those used for the basic model (*Model I*, Eqs. 1*a*–1*c*). The computer program involves only minor modifications of the one used for single dosing and is seen in *Model II* (*Appendix*) and Fig. 4. It is readily apparent that adjustments of dosage amounts and times are easily accomplished by slight modifications of the computer program to graphically evaluate optimum choices. In Fig. 3 therapeutic blood levels are maintained for the better part of 9 hr. The need for dosage form optimization is evident, however, to supplant the repetitive dosing regimen as well as to moderate the undesirable rising and falling of the body compartment levels.

Sustained and Delayed-Release Models.—The desirable qualities of oral sustained or delayed-release formulations have been listed by Rowland and Beckett (25) and include an initial and a maintenance dose to give and maintain blood concentrations of drug which elicit the desired therapeutic effects.

The benefits would be to reduce the frequency of drug administration compared with conventional dosage forms and to give a more uniform biological response with a reduced incidence and intensity of side effects.

In general, the total dose used in a sustained-release dosage form is the sum of the amount in the initially fast dissolving portion (D_I) and that present in the more slowly dissolving maintenance form

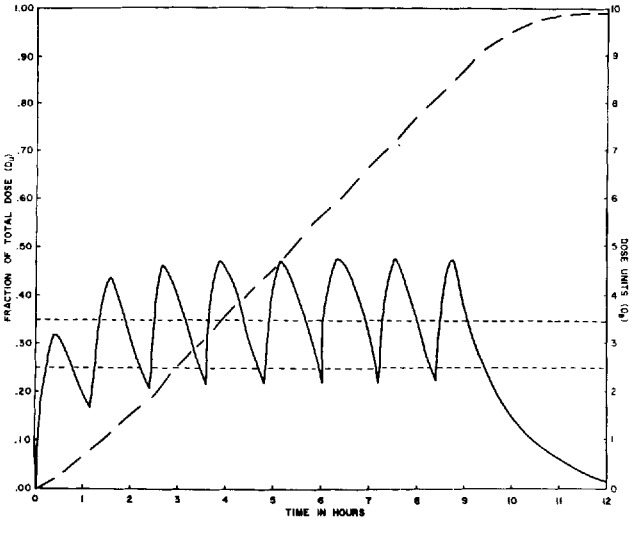

Fig. 3.—Compartmental levels of drug using a repetitive dosage regimen (5 units of drug every 1.2 hr.). The ordinates for blood level are given on the right in terms of units of drug. Key: – – – –, D_U; ———, D_B.

(D_M). As ideally postulated, the "loading" dose (D_I) will bring the drug amount in the body to its therapeutic level, while the D_M will maintain this level for the prescribed period of time.

The major prerequisite for the "loading" dose, D_I, is that it dissolve rapidly and completely. This end is normally achieved by either placing the drug in solution as an initial dose or formulating a conventional, fast disintegrating and dissolving tablet which, in essence, achieves the same goals. For the authors' purposes, D_I was placed on the computer as an initial condition on the GI compartment integrator (see *Appendix*). What this accomplishes is to have 100% of D_I in solution and ready for absorption at time zero.

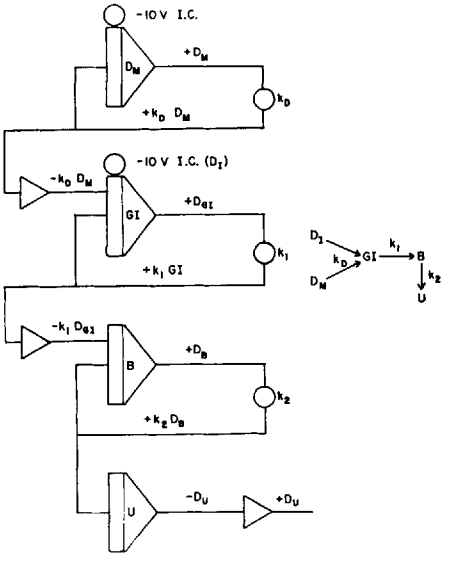

Fig. 5.—Analog computer program used for evaluation of first-order sustained-release dosage formulations (*Model III*).

The formulation and programing of the "maintenance" or slowly releasing form, D_M, is a problem of greater complexity. Three basic models for sustained and delayed-release formulations have been chosen.

First-Order Release.—Both Wiegand and Taylor (26) and Wagner (17) have shown that per cent released *in vitro versus* time data reported in the literature for the dissolution of many sustained-release preparations give linear pseudo (or apparent) first-order rates from about 0.5 hr. to the time the test was completed. Literature data subsequent to these papers have confirmed these observations and include: (*a*) drug embedded in an insoluble tablet matrix (27), (*b*) drug coated with waxy or polymeric materials (28), and (*c*) drug complexed with cation exchange resins (29). Since these preparations make up the predominant number of available sustained-release products, it was decided to investigate the programing of a first-order release rate for D_M as a method for prolonging the blood level of the drug under investigation.

The equations and program which describe this model are found in the *Appendix* under *Model III*, Eqs. 3*a*–3*d*, and Fig. 5.

An infinite number of first-order disappearances of D_M can be obtained by systematic alteration of the potentiometer corresponding to k_D (the rate constant for dissolution of D_M).

Using these k_D's and various combinations of D_I and D_M, the computer was then programed to determine the set of conditions which yield the maximum therapeutic benefit.

Figure 6 shows the type of sustained release obtained in a typical case with such a first-order loss from D_M. In this case, 10% of the total dose (which was twice the dose used in Fig. 3) is present as D_I, while 90% is D_M. The dissolution rate constant (k_D) for D_M was chosen as 0.375 hr.$^{-1}$.

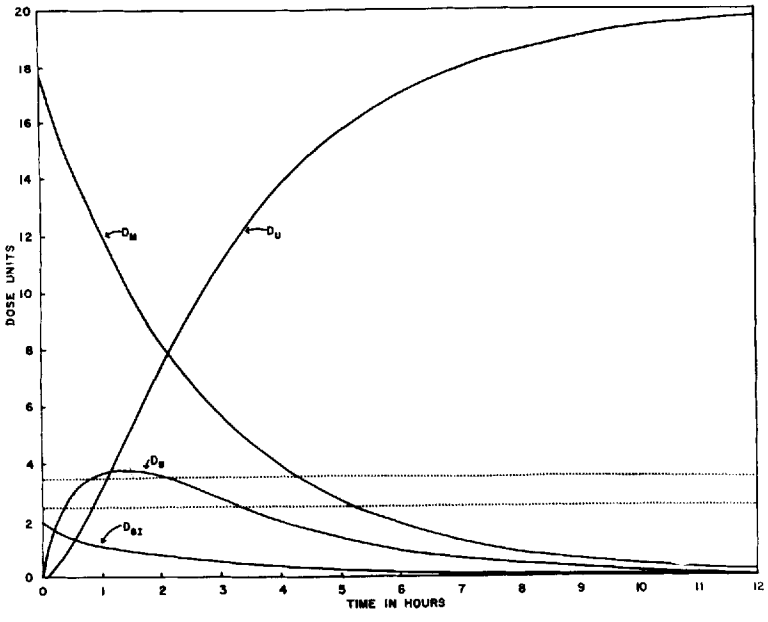

Fig. 6.—Effect of a first-order sustained-release maintenance dose (D_M) on compartmental drug levels. This formulation was programed to yield a drug-free system after 12 hr. D_I = 2 units; D_M = 18 units.

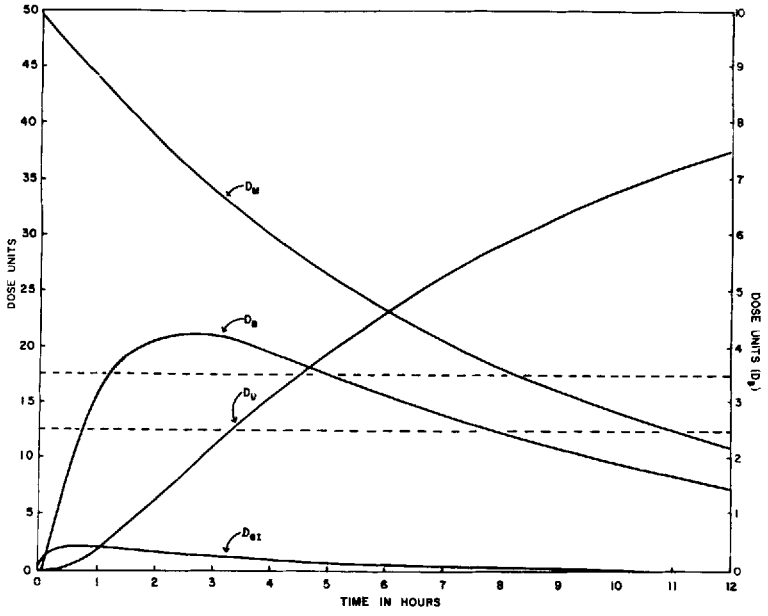

Fig. 7.—Effect of increasing amount of drug in D_M and decreasing k_D. No time limit was set here on the maintenance of drug in the body. The ordinates for blood level are given on the right. Key: D_M = 50 units; D_I = 0.

It would seem, at least for this drug, that a first-order mechanism for the release of the maintenance dose offers no significant improvement over multiple dosing. The optimum increase in blood level duration for twice the amount of drug is twice that obtained for the original dose. Other combinations of k_D, D_I, D_M lead to the same conclusions. When the dose or k_D is increased, drug levels in the body are increased. The only apparent advantage of such a sustained-release dosage design is the reduction in times of oral administration; there is no apparent increase in the efficient usage of the drug amounts. An illustration of this point is Fig. 7, where 5 times (50 units) the dose used in Fig. 1 is given with a k_D of 0.125 hr.$^{-1}$. The increased duration of blood level is only 5 times that observed for 10 units of drug.

Release from Coated Pellet Formulations.—Many companies now supply products in the form of a hard gelatin capsule containing round candy pellets upon which has been deposited a fixed amount of drug. Coated over the drug are one or more thicknesses of a waxy or polymeric coating, whose dissolution rate has been evaluated in both *in vitro* and *in vivo* systems.

When either the thickness or the type of coating substance is varied, it is possible to obtain several different populations of drug pellets. If the appearance of drug in solution is measured with time, the drug will only appear after the protective coating has been ruptured, dissolved, or digested away.

If the situation was ideal, and all members of a given population of pellets had exactly the same coating thickness, *i.e.*, the variance among pellets was zero, the drug in solution *versus* time plot should show a lag period (equal to that amount of time necessary to rupture, dissolve, or digest the protective coating) followed by a steep, almost instantaneous, appearance of all the drug from this population of pellets into solution. This would be a direct simulation of the repetitive dosage regimen we have previously considered in *Model II* and Fig. 3.

What is far more likely, however, is that a finite wide variance does indeed exist within a chosen population of pellets. This being the case, the dissolution of the population of pellets is not instantaneous, but rather normally distributed with mean $\bar{t}$ and variance, σ^2. Integration of the area under the normal curve, number of pellets ruptured, or releasing drug *versus* time, will give the amount of drug in solution. A plot of this integral *versus* time will yield a symmetrical sigmoid curve whose midpoint is $\bar{t}$.

In accordance with the authors' postulated model, the release of drug from the pellet types occurs at separated intervals with a Gaussian distribution of release about the mean of this interval. The amount of drug which is to be released at each interval is a function of the numbers of pellets so formulated. The release of drug from each pellet is relatively instantaneous; the release of total drug for that pellet type is normally distributed about the mean time of release of that pellet population. If a dosage form is produced with 100 or more populations of effective thicknesses with each containing equivalent total amounts of drug an over-all zero-order release can be simulated.

Figure 8 demonstrates a typical compartmental profile using a pellet-type formulation; the D_I = 5 dose units and the D_M consisted of 4 populations of pellets (each containing 5 units of drug) with different mean times of release. The standard deviation about these mean times of release was considered to be the same for each population in this case. The D_B and D_{GI} are plotted in terms of dose units in the respective compartment while D_U is shown on scale as 0.4 times the actual dosage units excreted.

Several studies in the literature (30–32) have demonstrated a simulation of t.i.d. dosing with coated pellet sustained release. Per cent release data for 5 bulk pellet groups, presented in one paper (30), support the normal distribution postulate.

The rather unique equations and programs used to simulate the normally distributed pellet popula-

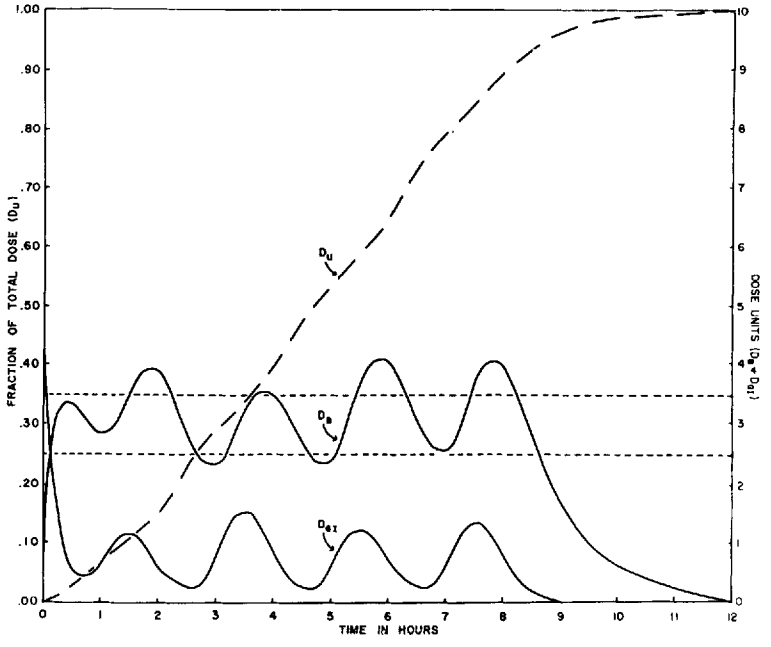

Fig. 8.—A simulated repetitive dosing compartmental profile obtained after a single dose of a coated pellet formulation. Four pellet populations, each containing 5 units of drug, with the same standard deviation but different mean times of dissolution were used in addition to 5 units of immediately dissolving D_I.

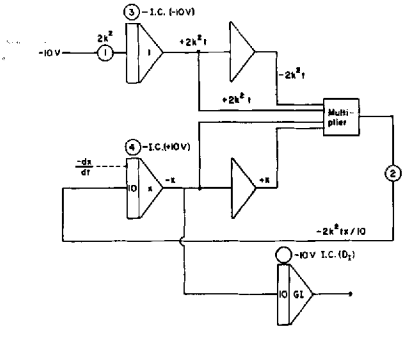

Fig. 9.—Analog computer program for the generation and integration of a Gaussian type distribution (coated pellet type of sustained release). The remainder of the program is the same as in Fig. 2 (*Model IV*).

tions (33) are found in the *Appendix* under *Model IV*, Eqs. 9–12, and Fig. 9, respectively.

Zero-Order Release.—The ideal mechanism to maintain a constant blood level is to release drug from D_M by zero-order kinetics (*i.e.*, at a constant rate independent of concentration).

To achieve optimum therapy, the rate of change of drug in the blood (D_B) with time should be zero. Since this rate is the difference between the rate of absorption and the rate of excretion

$$dD_B/dt = k_{GI,B}D_{GI} - k_{B,U}D_B = 0 \quad \text{(Eq. 5)}$$

it follows that the amount of drug in the gastrointestinal tract, D_{GI}, should be a constant for a desired blood level, D_B, since from Eq. 5,

$$D_{GI} = \frac{k_{B,U}}{k_{GI,B}} D_B \quad \text{(Eq. 6)}$$

It also follows that the amount of drug in the gastrointestinal tract, D_{GI}, should remain invariant with time

$$dD_{GI}/dt = dD_M/dt - k_{GI,B}D_{GI} = 0 \quad \text{(Eq. 7)}$$

From Eqs. 6 and 7 the rate of release from the maintenance dose should be

$$\frac{dD_M}{dt} = \frac{k_{B,U}}{k_{GI,B}} \cdot k_{GI,B}D_B = k_{B,U}D_B \quad \text{(Eq. 8)}$$

Thus, the rate of release from the maintenance dose D_M must be constant and equal to the rate of loss of drug from the blood at a blood level corresponding to D_B. This rate is given by Eq. 8.

Zero-order release may be feasible in *in vivo* situations when the drug has a limited solubility in the gastrointestinal fluids. Under the circumstances, the drug will initially dissolve at a rate proportional to the amount of drug remaining in the tablet until a saturated solution is formed in the gastrointestinal fluids. Afterward, the drug should dissolve at the same rate as it is absorbed with a net result of a constant dissolution rate.

Figure 10 demonstrates the compartmental profile for a formulation containing $D_I = 4$ units and $D_M = 6$ units (solid line) and $D_I = 4$ units, $D_M = 16$ units (dashed line). The solubility (D_S) was chosen at 4.0 drug units. The improvement in therapeutic effect over those conditions used in Fig. 1 can be observed here where the desired blood level has a duration of 1.9 hr. compared to the 1.4 hr. noted with a conventional dosage form.

The equations used to predict the k_D required for the D_M of Fig. 10 as well as those describing the model are found under *Model V* (*Appendix*). The computer program for zero-order release is Fig. 11.

APPENDIX

Model I.—*Computer Simulation of a Single, Rapidly Dissolving Dose.*—A single dose, in solution

$$D \longrightarrow GI \xrightarrow{k_{GI,B}} B \xrightarrow{k_{B,U}} U$$

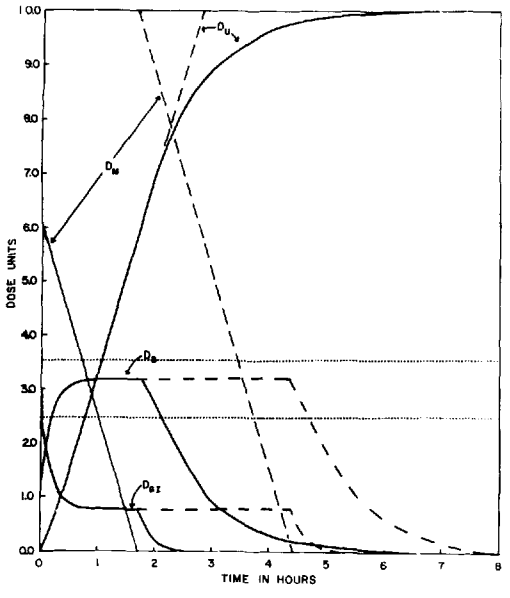

Fig. 10.—Effect of a zero-order sustained-release dosage form on compartmental drug levels. The solid lines are for a formulation containing $D_I = 4$ units and $D_M = 6$ units, while the dashed lines are for $D_I = 4$ units and $D_M = 16$ units of drug.

in the GI compartment at time zero is absorbed into, and lost from, the blood at a rate proportional to the residual drug concentration.

$$-\frac{dD_{GI}}{dt} = k_{GI,B}D_{GI} \qquad \text{(Eq. 1}a\text{)}$$

$$-\frac{dD_B}{dt} = k_{B,U}D_B - k_{GI,B}D_{GI} \qquad \text{(Eq. 1}b\text{)}$$

$$\frac{dD_U}{dt} = k_{B,U}D_B \qquad \text{(Eq. 1}c\text{)}$$

The computer program resulting from these equations is seen in Fig. 2.

Model II.—*Computer Simulation of Repetitive Dosing Regimen.*—One-half of the dose used in

$$D \longrightarrow GI \xrightarrow{k_{GI,B}} B \xrightarrow{k_{B,U}} U$$

Model I is administered at time zero followed by the same dose every 2 half-lives (1.2 hr.). The equations describing repetitive dosing are identical to Eqs. 1*a*–1*c*. The computer program, Fig. 4, is essentially the same, differing only by the presence of initial condition potentiometers on the blood and urine integrators. At the beginning of each dosage interval the computer is stopped and these potentiometers are used to place the amount of drug remaining from the previous dosing in each compartment. For example, referring to Fig. 3, the amount of drug placed on the blood potentiometer at $t = 1.2$ hr. ($t = 0$ for dose 2) was 1.7 dose units.

Model III.—*Computer Simulation of First-Order Sustained Release.*—Dosage forms:

$$\begin{matrix} D_I \longrightarrow \\ D_M \overset{k_D}{\longrightarrow} \end{matrix} GI \xrightarrow{k_{GI,B}} B \xrightarrow{k_{B,U}} U$$

A combination of immediately soluble D_I and slowly releasing D_M is given at time zero. The rate of release of D_M is proportional to the amount of D_M remaining in the dosage form.

$$-\frac{dD_M}{dt} = k_D D_M \qquad \text{(Eq. 3}a\text{)}$$

$$-\frac{dD_{GI}}{dt} = k_{GI,B}D_{GI} - k_D D_M \qquad \text{(Eq. 3}b\text{)}$$

$$-\frac{dD_B}{dt} = k_{B,U}D_B - k_{GI,B}D_{GI} \qquad \text{(Eq. 3}c\text{)}$$

$$\frac{dD_U}{dt} = k_{B,U}D_B \qquad \text{(Eq. 3}d\text{)}$$

The computer program used to predict the optimum D_M and k_D for sustained therapeutic blood levels is seen in Fig. 5.

Model IV.—*Computer Simulation of a Coated Pellet Type of Sustained Release.*—Several populations of pellets, whose dissolution pattern follows a normal distribution, are combined to yield, upon administration of a single dose, a compartmental profile similar to that obtained with repetitive dosing.

A unique method was found (33) for computer simulation of a normal distribution and is as follows.

The frequency distribution which describes the normal distribution (Gaussion errror function) is

$$f(\gamma) = \frac{1}{\sqrt{2\pi}\sigma} e^{-(\gamma-\mu)^2/2\sigma^2} \qquad \text{(Eq. 9)}$$

or

$$x = Ae^{-k^2t^2}$$

where

$$A = \frac{1}{\sqrt{2\pi}\sigma}, \; k = \frac{1}{\sqrt{2}\sigma}, \text{ and } t = \gamma - \mu \qquad \text{(Eq. 10)}$$

The first derivative of Eq. 10 is

$$\frac{dx}{dt} = -2Ak^2te^{-k^2t^2} \qquad \text{(Eq. 11)}$$

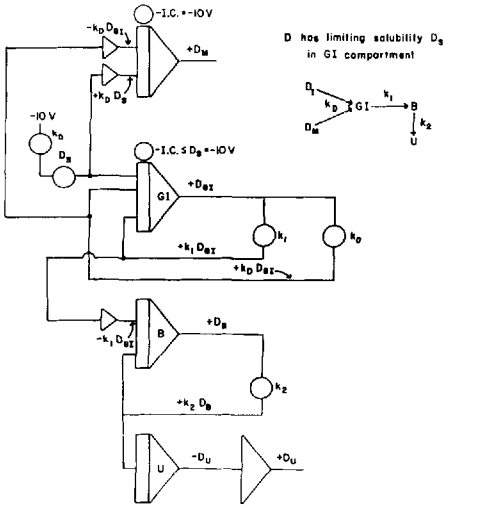

Fig. 11.—Analog computer program for evaluation of solubility limited, zero-order sustained-release dosage formulations (*Model V*).

Substituting Eq. 11 into Eq. 10 one obtains

$$\frac{dx}{dt} + 2k^2tx = 0 \qquad \text{(Eq. 12)}$$

The analog computer program for Eq. 12 is seen in Fig. 9. The plotted output of the x integrator gives the bell-shaped curve expected for the Gaussion error function. Integration of the area under this curve gives the amount of drug released into the gastrointestinal tract (D_{GI}). The remainder of the program (for D_{GI}, D_B, and D_U) is the same as in Fig. 2.

Model V.—*Computer Simulation of a Zero-Order Sustained-Release Mechanism.*—Let drug D have a

$$\begin{matrix} D_I \longrightarrow \\ D_M \text{---}\rfloor \end{matrix} GI \xrightarrow{k_{GI,B}} B \xrightarrow{k_{B,U}} U \qquad k_D$$

finite, limiting solubility (D_S) in the gastrointestinal tract. Let the initial dose, D_I, present as an initial condition in the GI compartment be equal to or less than D_S. As saturation is approached, the release of D_M will become constant.

The equations used for this program are

$$-\frac{dD_M}{dt} = k_D(D_S - D_{GI}) \qquad \text{(Eq. 4}a\text{)}$$

$$-\frac{dD_{GI}}{dt} = k_{GI,B}D_{GI} + k_DD_{GI} - k_DD_S \qquad \text{(Eq. 4}b\text{)}$$

$$-\frac{dD_B}{dt} = k_{B,U}D_B - k_{GI,B}D_{GI} \qquad \text{(Eq. 4}c\text{)}$$

$$\frac{dD_U}{dt} = k_{B,U}D_B \qquad \text{(Eq. 4}d\text{)}$$

The program corresponding to these equations is seen in Fig. 11.

The calculations used to predict the exact k_D required are as follows. Since Eq. 4*c*

$$-\frac{dD_B}{dt} = k_{B,U}D_B - k_{GI,B}D_{GI}$$

For a sustained blood level, $\frac{dD_B}{dt} = 0$, and the D_{GI} necessary is

$$D_{GI} = \frac{k_{B,U}}{k_{GI,B}} D_B \qquad \text{(Eq. 13)}$$

for D_{GI} to be constant, $dD_{GI}/dt = 0$ and, from Eq. 4*b*

$$k_{GI,B}D_{GI} = k_D(D_S - D_{GI}) \qquad \text{(Eq. 14)}$$

and, since D_S, D_{GI}, and $k_{GI,B}$ are known, the necessary k_D can be calculated

$$k_D = \frac{k_{GI,B} \cdot D_{GI}}{D_S - D_{GI}} \qquad \text{(Eq. 15)}$$

Species Differences in Lipid and Endocrine Gland Responses to a Stilbene Derivative

By T. S. DANOWSKI, N. R. LIMAYE, R. E. COHN, B. J. GRIMES, J. V. NARDUZZI, and C. MOSES

A stilbene derivative, α-(*o*-anisyl)-β,β-diphenylacrylic acid, administered to healthy male adults did not affect, as it did in certain experimental animals, food intake, body weight, serum lipid levels, thyroid activity, adrenocortical function, or the other endocrine indices tested.

A DERIVATIVE of the stilbenes, α-(*o*-anisyl)-β,β-diphenylacrylic acid,[1] at dosages of 10 mg./Kg./day or higher, exerts a hypocholesterolemic effect in the mouse, rat, and dog, but not in the monkey (1). Studies in experimental animals have also demonstrated that ingestion of the compound is accompanied by an absolute or relative decrease in seminal vesicle and prostate weights and increases in pituitary, thyroid, and adrenal size. The adrenomegaly in such animals is associated with decreased adrenocortical function, judging from a delayed excretion of a water load, decreased tolerance to cold stress, and diminished corticogenesis *in vitro* in adrenals from rats pretreated with this derivative. Estrogenic effects have also been observed during such therapy and in the rat the compound has been found to inhibit the ovarian hypertrophy which follows unilateral ovariectomy. This derivative exerted a profound anorexigenic effect in the mouse, adult rat, and rabbit resulting in a marked loss of weight, but this was not evidenced in the dog or monkey. It has been suggested that the hypocholesterolemic effect in animals may be related to decreased food intake and that the compound probably exerts antithyroid, antiadrenocortical, and antigonadotropic actions (1).

The studies reported here indicate that in healthy adult males comparable dosages, up to 800 and 1600 mg./day for 1 month or longer, neither affected body weight, serum cholesterol, triglycerides, or other solutes, nor did it produce changes in indices of the thyroid, adrenocortical, adrenomedullary, or other endocrine gland function.

MATERIALS AND METHODS

The derivative of stilbene was administered *per os* to 14 healthy adult male prisoners in increasing dosages: 50 mg. daily for 3 weeks, followed by 100 mg. daily for 3 weeks, 200 mg. daily for 3 weeks, 400 mg. daily for 4 weeks, and 800 mg. daily for 4 weeks. In another group of four men 1600 mg. was administered daily for 4 weeks.

Blood and serum solutes (venous blood sugar and NPN) and serum CO_2, Cl, Na, K, albumin, globulin, calcium, inorganic phosphorus, uric acid (2), creatinine (3), total and α- and β-lipoprotein cholesterol and triglycerides (4–7), NEFA (8), and protein bound iodine (9) were measured in samples obtained at 6:30 to 7:00 a.m. during the fasting state on two occasions 1 week apart prior to therapy. The same studies were repeated at the end of each dosage period.

Urinary 17-ketosteroids (10), Porter-Silber chromogens (11), 11-desoxycortisol metabolites (12), pressor materials as measured by aortic strip assay (13), and gonadotropins (14) were determined in 24-hr. refrigerated specimens of urine prior to and during the administration of 400, 800, and 1600 mg. per day.

Plasma 17(OH) corticosteroids (15) were measured at weekly intervals prior to and during therapy in samples of venous blood obtained between 6:30 and 7:00 a.m.

The response of plasma 17(OH) corticosteroids to exogenous ACTH [80 units (Parke-Davis) in 500 ml. of 5% dextrose in water] administered by intravenous infusion during a 6-hr. period was examined before and during therapy with the compound at 400 mg./day for 4 weeks and 1600 mg./day for 4 weeks. The plasma corticosteroid levels were measured in samples of blood obtained just before the infusion and just at the end of the infusion.

The effects of intravenously administered rapidly acting insulin (0.1 unit/Kg. of body weight injected intravenously) upon venous blood sugar and serum inorganic phosphorus levels, were assessed prior to and during the 12th week of therapy when the dosage had reached 400 mg./day.

Certain hepatic indices (serum bilirubin, cephalin flocculation, thymol turbidity, alkaline phosphatase in addition to serum albumin, globulin, and lipids already cited) were obtained before and during therapy. Renal status was evaluated by means of routine urine analyses and creatinine clearance on two occasions prior to and two others during therapy. The hemoglobin and relative blood cell volume (hematocrit) were also measured on the above schedule.

RESULTS

The drug was taken without evoking any symptoms or signs. Body weights were of the same order of magnitude prior to and during therapy. Therapy

Received February 17, 1966, from the Department of Medicine, University of Pittsburgh, and the Medical Center and Shadyside Hospitals, Pittsburgh, Pa.

Accepted for publication April 19, 1966.

This investigation was supported in part by grants from the John A. Hartford Foundation, Inc., the Medical Research Foundation, Inc., and the U. S. Department of Health, Education, and Welfare, Washington, D. C.

[1] Supplied by Smith Kline & French Laboratories, Philadelphia, Pa., as SK&F 16046.

was not associated with any change in the venous blood sugar or NPN or the serum CO_2, Cl, Na, K, Ca, inorganic phosphorus, albumin, globulin, and uric acid. The serum total cholesterol and triglycerides and their respective α and β lipoprotein fractions remained unchanged. Serum PBI levels were not altered during therapy. The excretion of urinary 17-ketosteroids, Porter-Silber chromogens, and 11-desoxycortisol metabolites expressed in mg./day/1.0 Gm. of creatinine was essentially the same before and during ingestion of this compound. During therapy the fasting a.m. levels of plasma 17(OH) corticosteroids did not differ significantly from the values recorded during the control period.

The plasma 17(OH) corticosteroid responses to intravenous ACTH prior to and during administration of the compound were of the same order of magnitude. Therapy for 12 weeks was not accompanied by significant alteration in the hypoglycemic or hypophosphatemic effects of intravenously administered rapidly acting insulin. The urinary excretion of gonadotropins, urinary pressor activity (aortic strip assay), serum creatinine, and creatine clearances and routine urine analysis were unchanged at the end of the treatment period. Hepatic indices and the hematocrit and hemoglobin remained within the pretherapy range during ingestion of this agent.

DISCUSSION

None of the effects of this derivative of the stilbenes, variously observed in some but not all species of experimental animals tested (1), could be discerned in the trials in healthy male adults described here. Thus, anorexia, weight loss, and hypocholesterolemia (perhaps related to decreased food intake) did not occur. Also indices of pituitary, thyroid, adrenocortical, adrenomedullary, and gonadotropic and other endocrine gland function were not affected. Blood sugar responses to intravenous insulin were not changed. The compound did not alter the hepatic indices tested. In other words, effects of this stilbene derivative, observed in certain species of experimental animals, were not evident in healthy male adults receiving this compound in comparable dosages.

Effects of Certain Preservatives on the Aging Characteristics of Acacia

By OSCAR E. ARAUJO

The rheological characteristics of acacia solutions of various concentrations were examined. Based on the results, a series of 25 per cent acacia solutions using five different preservatives and two combinations of preservatives were studied for a period of 1 year. Rheological, pH, and organoleptic data were obtained in order to describe the aging characteristics of the solutions. In each case, the results showed a reduction in pH and viscosity, which was most pronounced in the unpreserved control solution. Possible reasons for the decrease, as well as for the rate at which it occurred, are discussed.

ACACIA HAS been in use for at least 4000 years and yet comparatively little quantitative research appears in the literature (1). Curiously, in spite of the popularity enjoyed by this polysaccharide as a protective colloid and emulsifier in numerous pharmaceutical preparations, only a handful of findings pertaining to its aging characteristics are reported.

Taft and Malm (2) found that bacterial growth appeared in dilute solutions of gum arabic 36–48 hr. after preparation. Osborne and Lee (3) carried out experiments to establish the effect of aging upon preserved and unpreserved acacia mucilages. The preservative used was 0.2% benzoic acid. These investigators reported an initial rise and an eventual decrease in the viscosity of the mucilages. They further observed a considerably greater decrease in the viscosity of the unpreserved mucilage than of the preserved one. Joslin and Sperandio (4) reported that acacia mucilages prepared with boiling water exhibited a reduction in viscosity over a period of 8 weeks. However, the authors stated that this decrease in viscosity was less pronounced than the reduction occurring in those mucilages prepared with water at room temperature. They further noted that the acacia mucilages became slightly more acidic during the aging period.

Recently, Ory and Steiger-Trippi (5) reported the changes in viscosity observed after 1 month's

Received March 30, 1966, from the Department of Pharmacy, College of Pharmacy, University of Florida, Gainesville.
Accepted for publication April 14, 1966.

was not associated with any change in the venous blood sugar or NPN or the serum CO_2, Cl, Na, K, Ca, inorganic phosphorus, albumin, globulin, and uric acid. The serum total cholesterol and triglycerides and their respective α and β lipoprotein fractions remained unchanged. Serum PBI levels were not altered during therapy. The excretion of urinary 17-ketosteroids, Porter-Silber chromogens, and 11-desoxycortisol metabolites expressed in mg./day/1.0 Gm. of creatinine was essentially the same before and during ingestion of this compound. During therapy the fasting a.m. levels of plasma 17(OH) corticosteroids did not differ significantly from the values recorded during the control period.

The plasma 17(OH) corticosteroid responses to intravenous ACTH prior to and during administration of the compound were of the same order of magnitude. Therapy for 12 weeks was not accompanied by significant alteration in the hypoglycemic or hypophosphatemic effects of intravenously administered rapidly acting insulin. The urinary excretion of gonadotropins, urinary pressor activity (aortic strip assay), serum creatinine, and creatine clearances and routine urine analysis were unchanged at the end of the treatment period. Hepatic indices and the hematocrit and hemoglobin remained within the pretherapy range during ingestion of this agent.

DISCUSSION

None of the effects of this derivative of the stilbenes, variously observed in some but not all species of experimental animals tested (1), could be discerned in the trials in healthy male adults described here. Thus, anorexia, weight loss, and hypocholesterolemia (perhaps related to decreased food intake) did not occur. Also indices of pituitary, thyroid, adrenocortical, adrenomedullary, and gonadotropic and other endocrine gland function were not affected. Blood sugar responses to intravenous insulin were not changed. The compound did not alter the hepatic indices tested. In other words, effects of this stilbene derivative, observed in certain species of experimental animals, were not evident in healthy male adults receiving this compound in comparable dosages.

Effects of Certain Preservatives on the Aging Characteristics of Acacia

By OSCAR E. ARAUJO

The rheological characteristics of acacia solutions of various concentrations were examined. Based on the results, a series of 25 per cent acacia solutions using five different preservatives and two combinations of preservatives were studied for a period of 1 year. Rheological, pH, and organoleptic data were obtained in order to describe the aging characteristics of the solutions. In each case, the results showed a reduction in pH and viscosity, which was most pronounced in the unpreserved control solution. Possible reasons for the decrease, as well as for the rate at which it occurred, are discussed.

ACACIA HAS been in use for at least 4000 years and yet comparatively little quantitative research appears in the literature (1). Curiously, in spite of the popularity enjoyed by this polysaccharide as a protective colloid and emulsifier in numerous pharmaceutical preparations, only a handful of findings pertaining to its aging characteristics are reported.

Taft and Malm (2) found that bacterial growth appeared in dilute solutions of gum arabic 36–48 hr. after preparation. Osborne and Lee (3) carried out experiments to establish the effect of aging upon preserved and unpreserved acacia mucilages. The preservative used was 0.2% benzoic acid. These investigators reported an initial rise and an eventual decrease in the viscosity of the mucilages. They further observed a considerably greater decrease in the viscosity of the unpreserved mucilage than of the preserved one. Joslin and Sperandio (4) reported that acacia mucilages prepared with boiling water exhibited a reduction in viscosity over a period of 8 weeks. However, the authors stated that this decrease in viscosity was less pronounced than the reduction occurring in those mucilages prepared with water at room temperature. They further noted that the acacia mucilages became slightly more acidic during the aging period.

Recently, Ory and Steiger-Trippi (5) reported the changes in viscosity observed after 1 month's

storage in solutions containing 7.5% and 20% acacia. Four preservatives were used in concentrations of 2%: sorbic acid, phenyl mercuric borate, a mixture of the sodium salts of the ethyl and propyl esters of *p*-hydroxy benzoic acid, and an arylalkyl quaternary ammonium sulfate. The results indicated that a reduction in viscosity occurred in all solutions except those preserved with phenyl mercuric borate.

The above studies assumed that acacia solutions at the concentrations used behaved as Newtonian systems, and, therefore, the viscosity at only 1 rate of shear was necessary. It appeared reasonable to establish the experimental validity of such an assumption by measuring the viscosity of acacia solutions of various concentrations at several rates of shear. If the rheograms were to show Newtonian behavior, then acacia solutions of an arbitrary concentration would be studied further to determine the effect of a number of preservatives on their aging characteristics.

EXPERIMENTAL

Preparation of Solutions.—All acacia solutions were prepared by placing the proper volume of distilled water previously heated to 60° into a Waring blender. The accurately weighed gum arabic was then added to the surface of the water, permitted to hydrate momentarily, and then blended for 1 min. All percentages reported are on a weight to weight basis. The preservatives used in this study were dissolved in the warm water prior to the blending procedure. Six hours were permitted to elapse after the preparation of the solutions before any measurements were made. This was done to insure complete hydration of the gum and to allow any foam created by the mixing process to subside. All solutions were examined for a period of 1 year. U.S.P. grade acacia taken from the same lot was employed in order to eliminate source variations.

pH Measurements.—A Photovolt electronic pH meter model 110 was used to measure the pH of the solutions at convenient intervals of time.

Rheological Measurements.—A Stormer viscosimeter equipped with the modified cup and bob as suggested by Fischer (6) was used in this investigation. A weight hanger with various slotted weights provided the shearing stress. Calibration curves using castor oil as a standard were constructed periodically throughout the study. The viscosity of castor oil was obtained from standard tables. An average instrumental constant, K_v, was calculated from the data collected according to the expression

$$\eta = K_v \frac{\text{Gm.}}{\text{r.p.m.}} \qquad \text{(Eq. 1)}$$

where Gm. represents the shearing stress and r.p.m. the rate of shear. Once the constant, K_v, vas obtained, the apparent viscosity, η, of any system could be arrived at by means of this equation. All viscosity measurements were carried out at 20 ± 0.1°.

Organoleptic Observations.—A description of the appearance and the odor of the solutions was recorded periodically throughout the investigation.

Preservatives Used.—Five different preservatives were employed in the following concentrations: 0.2% benzoic acid, 0.2% methylparaben, 0.05% propylparaben, 0.5% chlorobutanol, and 0.01% benzalkonium chloride. Combinations of benzoic acid–propylparaben and benzoic acid–chlorobutanol in the above percentages were also used.

RESULTS AND DISCUSSION

Verification of Newtonian Characteristics.—Solutions containing 10, 12.5, 15, 20, 25, 30, 35, 40, and 45% acacia were prepared by the previously described method. The rheological data were obtained within 24 hr. from the time of preparation, thus obviating the addition of preservatives to the solutions. Figure 1 shows representative rheograms of the results. It was clearly seen that Newtonian behavior occurred at the lower concentrations as evidenced by the linearity of the plots. At concentrations of 40% acacia and above, pseudoplastic characteristics were observed, as denoted by a decrease in viscosity with increasing shearing stress.

TABLE I.—pH OF 25% ACACIA SOLUTIONS

Preservative Used	Time Elapsed						
	0 Days	1 Wk.	2 Wk.	6 Wk.	3 Mo.	9 Mo.	1 Yr.
None	4.80	4.78	4.60	4.30	4.20	3.85	3.50
Benzoic acid	4.72	4.70	4.48	4.47	4.30	4.20	3.90
Benzoic acid–chlorobutanol	4.65	4.60	4.55	4.22	4.20	4.20	3.90
Benzoic acid–propylparaben	4.65	4.60	4.52	4.28	4.20	4.20	3.90
Propylparaben	4.79	4.60	4.65	4.35	4.32	4.25	4.00
Methylparaben	4.79	4.70	4.70	4.25	4.20	4.20	4.10
Chlorobutanol	4.80	4.78	4.62	4.34	4.30	4.25	4.00
Benzalkonium chloride	4.79	4.75	4.70	4.32	4.23	4.20	4.00

where F is the shearing stress in Gm., G is the rate of shear in r.p.m., η' is an indicator of viscosity, and N is an index of non-Newtonian behavior, has been used to describe pseudoplastic systems. This exponential expression in its logarithmic form

$$\log G = N \log F - \log \eta' \qquad \text{(Eq. 3)}$$

was applied to the rheological data of the solutions exhibiting pseudoplasticity (40 and 45% acacia). The resulting linear relationships are shown in Fig. 2. The value of N must be greater than unity if the system is pseudoplastic, and its magnitude is proportional to the degree of pseudoplasticity. The calculated value of N for the 40% acacia solution was 1.08 and that for the 45% solution was 1.15. Thus, the degree of pseudoplasticity appeared to increase with increasing concentrations of acacia. This was in line with the concept whereby linear polymers tend to orient themselves along the direction of flow when a shearing stress is applied. At low concentrations, this orientation probably occurs at minimal shearing stresses and the solution behaves as a Newtonian system, where the viscosity is constant. At higher concentrations, it is conceivable that low stresses are not sufficient to rearrange the greater number of polymers present, resulting in pseudoplastic behavior until the force is large enough to produce complete alignment.

Aging Studies—*General.*—It was apparent that it would be considerably easier to characterize a Newtonian system, which has a constant viscosity, than a pseudoplastic one. It was also felt that a solution containing enough acacia to support an appreciable amount of bacterial growth was desirable. With these criteria in mind, solutions containing 25% acacia were prepared, as before, for the aging studies conducted.

The previously mentioned preservatives were added in the amounts earlier stipulated. An unpreserved 25% acacia solution served as a control.

pH Considerations.—The change in pH of the solutions upon standing appeared to follow a definite pattern, as seen in Table I.

A sharp decrease in pH occurred in the first 6 weeks, ranging from 0.25 pH units for the benzoic acid preserved solutions to 0.54 units for the solution containing methylparaben. These values represented 30 and 78%, respectively, of the total drop in pH occurring after 1 year's storage time for each of these solutions. The mean drop in pH after 6 weeks for all solutions studied, expressed as a per cent of the decrease observed after 1 year on the shelf, was 53%.

These results seemed to indicate some manner of bacterial attack on the carbohydrate, with a consequent production of acid groups causing a pH lowering. The pH decreased rapidly at first, but after 6 weeks the medium either had become too acid to support the same rate of bacterial decomposition, or there had been a severe depletion of available substrates for bacterial action. The reduction in pH may also have resulted from spontaneous hydrolysis of certain ester linkages of the carbohydrate.

The over-all mean decrease in pH after 1 year for all the preserved solutions was 0.75 units, while that for the unpreserved solution was 1.30. This was expected since the latter should have supported the

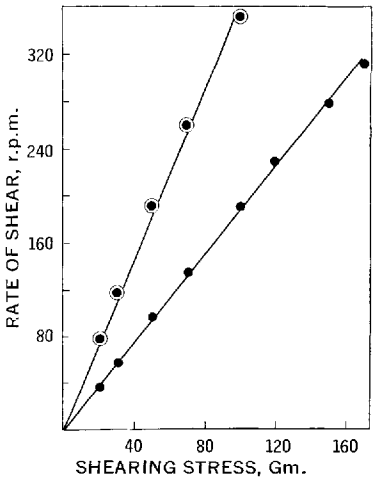

Fig. 3.—Rheograms of unpreserved 25% acacia solutions. Key: ●, 6 hr. after preparation; ◉, 1 year after preparation.

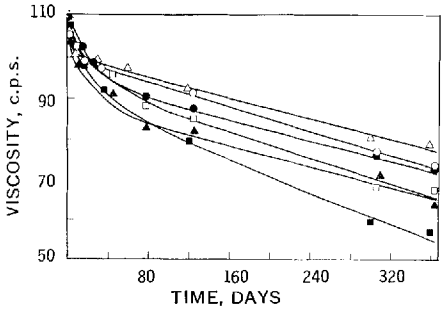

Fig. 4.—The viscosity stability of preserved and unpreserved acacia solutions. Key: △, 0.2% benzoic acid; ○, 0.2% methylparaben; ●, 0.05% propylparaben; □, 0.5% chlorobutanol; ▲, 0.01% benzalkonium chloride; ■, unpreserved.

greatest amount of bacterial decomposition and, consequently, the largest reduction in pH.

Organoleptic Qualities.—None of the solutions showed any visible growth in the first month of storage. Each initially exhibited its characteristic chemical odor, depending on the preservative used. The unpreserved solution had a typical musty odor of gum, which grew unpleasant after 10 days. The solution containing benzalkonium chloride, after only 1 week, gave rise to a pungent, disagreeable odor, which became increasingly offensive as time elapsed. Two months after preparation, mold growth appeared on both the unpreserved solution and the one containing benzalkonium chloride. There appeared to be gas released as the containers were opened, a common occurrence in many types of bacterial action.

After 1 year of shelf life, all the solutions exhibited a slight degree of turbidity and, as before, the unpreserved and benzalkonium chloride solutions gave evidence of the greatest amount of growth and most offensive odors. The reduction in pH of the solutions, due to the aforementioned bacterial attack, provided a good medium for mold growth most apparent in the unpreserved solution where the drop in pH was the greatest.

Rheological Observations.—It was assumed that 25% acacia solutions behaved as Newtonian systems throughout the entire study. This premise was verified by rheograms of the solutions constructed at various storage times. Figure 3 shows representative plots where the linear characteristics can be seen.

The changes in viscosity of the various solutions during the period studied are shown graphically in Fig 4. In order to avoid confusion, the plots for the solutions containing the combinations of preservatives were not included. The data collected, however, would place these graphs immediately below the plot for the solution containing benzoic acid.

A comparison of the rheological results with the pH observations previously discussed revealed certain similarities. First, a definite reduction in viscosity was observed in all solutions. Second, as expected, the unpreserved solution showed the greatest decrease in viscosity at the end of 1 year. Finally, a sharp decrease in viscosity occurred during the first 6 weeks on the shelf. The same rationale used in explaining the reduction in pH would apply here.

It is interesting to note that, unlike the pH observations, the viscosity drop after 6 weeks, expressed as a per cent of the total reduction over a 1-year period, ranged only from 30% for the solution containing methylparaben to 42% for the propylparaben preserved solution. Therefore, at least from a viscosity stability standpoint, it makes little difference whether the acacia solutions are preserved. It is obvious, however, as can be seen from the organoleptic qualities described, that other factors have to be considered.

The rate of reduction in viscosity became essentially linear for all solutions following the pronounced drop seen in the first 6 weeks. The degradation of most linear polymers has been reported to be primarily first order (8), while that of tragacanth has been described as zero order (9).

It was apparent from the results of this investigation that the viscosity stability curves for the initial 6-week period fit neither a first nor a zero-order process. It could be argued, however, that after 6 weeks the essentially linear nature of the data throughout the remaining shelf life suggests a zero-order degradation.

The results of this investigation appeared to indicate that, when all aging characteristics were considered, benzoic acid was the most effective preservative used. Furthermore, when benzoic acid was combined with two of the other preservatives used, little difference was seen in the behavior of the solutions.

SUMMARY

1. The rheograms of a series of acacia solutions ranging in concentration from 10–45% were constructed. Newtonian behavior was observed in all except the 40–45% solutions, which showed pseudoplastic characteristics.

2. A series of 25% acacia solutions using various preservatives were studied for a period of 1 year.

3. The pH of all these solutions decreased rapidly in the first 6 weeks, then tapered off. The largest reduction in pH occurred in the unpreserved control solution.

4. The appearance and odor of the solutions during a 1-year period were noted and various degrees of growth and turbidity were observed, along with a variety of fermented and unpleasant odors.

5. The viscosity of the solutions was calculated at various intervals of time, and viscosity–stability curves were shown. All the solutions revealed a decrease in viscosity with age. The benzoic acid preserved solution exhibited the smallest reduction, while the unpreserved solution revealed the greatest drop in viscosity.

Mechanism of Action of Anticonvulsant Drugs III. Chlordiazepoxide

By JOHN H. MENNEAR and ALLAN D. RUDZIK

The anticonvulsant activity of chlordiazepoxide in mice was found to be antagonized by pretreatment with reserpine or Ro4-1284 but not by α-methyl dopa or α-methyl tyrosine. This antagonism of chlordiazepoxide by reserpine was reversed by the administration of α-methyl dopa, *d*-amphetamine, or 5-hydroxytryptophan. The failure of α-methyl tyrosine to antagonize chlordiazepoxide suggests that the anticonvulsant action of chlordiazepoxide is not mediated through the release of biogenic amines. Similarly, the reserpine antagonism of chlordiazepoxide appears to be mediated through some mechanism other than catecholamine depletion.

EARLIER communications from these laboratories have described the effects of various amine-depleting agents on the anticonvulsant properties of diphenylhydantoin (1) and acetazolamide (2). These reports have confirmed the findings of earlier workers (3, 4) that reserpine antagonizes the anticonvulsant activities of both diphenylhydantoin and acetazolamide. In addition, however, the authors have demonstrated that this action is not specific for reserpine, but that the benzoquinolizine derivatives, tetrabenazine and Ro4-1284[1] also antagonize both anticonvulsants. Furthermore, acetazolamide was found to be antagonized by all agents which deplete brain biogenic amines, whereas diphenylhydantoin was not. These results suggest that the anticonvulsant action of acetazolamide is mediated, in some manner, through brain amines. The action of diphenylhydantoin is probably not mediated through brain amine release.

The experiments reported in this communication were conducted to compare the action of chlordiazepoxide, which has been reported by Randall *et al.* (5) to possess anticonvulsant activity in mice, to the anticonvulsant activities of acetazolamide and diphenylhydantoin.

EXPERIMENTAL

Male albino mice (Harlan Industries) weighing 18–22 Gm. were used in all experiments. Each animal was used only once. Prior to experimentation the mice were housed in groups of 50 with free access to food and water. All drugs were administered intraperitoneally and doses and pretreatment times are shown in Tables I and II.

Maximal seizures were produced by the method of Swinyard *et al.* (6) employing a current of 50 ma. and 0.2-sec. duration delivered *via* corneal electrodes. The criterion for protection against maximal electroshock was abolition of the hind leg extensor component of the seizure.

The anticonvulsant potency of chlordiazepoxide was compared in groups of mice treated with various amine-depleting agents by determining the dose of chlordiazepoxide which protected 50% of the mice against the electroshock. The ED_{50} values were estimated and compared for significance of differences by the method of Litchfield and Wilcoxon (7).

Chlordiazepoxide was always the last drug to be administered and was followed in 30 min. by electroshock. Unless otherwise stated, mice were housed in individual plastic cages prior to electroshock. In one experiment the animals were aggregated, in groups of 10, in stainless steel cages.

RESULTS

The effects of the various amine-depleting agents on the ED_{50} value of chlordiazepoxide in the maximal electroshock test are shown in Table I. Both reserpine, at 5.0 mg./Kg., and Ro4-1284, at 100 mg./Kg., antagonized the anticonvulsant effect of chlordiazepoxide as evidenced by a significant increase in the ED_{50} value ($p < 0.05$). Neither α-methyl tyrosine nor α-methyl dopa, at doses of 400 mg./Kg., altered the ED_{50} value of chlordiazepoxide.

TABLE I.—EFFECTS OF AMINE-DEPLETING AGENTS ON THE ANTICONVULSANT POTENCY OF CHLORDIAZEPOXIDE

Treatment	i.p. Dose, mg./Kg.	Pretreatment Time, hr.	ED_{50} of Chlordiazepoxide,[a] mg./Kg.
Saline	...	4	23(19–28)
Reserpine	5.0	24	88(64–121)[b]
Ro4-1284	100	4	66(58–75)[b]
α-Methyl tyrosine	400	4	19(16–22)
α-Methyl dopa	400	4	22(18–26)

[a] 95% confidence limits shown in parenthesis. [b] Significantly different from saline controls ($p < 0.05$).

In order to test the ability of various agents to reverse the effects of reserpine on the anticonvulsant potency of chlordiazepoxide, a series of experiments were performed in which reserpinized mice (5.0 mg./Kg.) received a single dose of the test compound 1 hr. prior to electroshock. This was followed in 30 min. by varying doses of chlordiazepoxide. The ED_{50} values for chlordiazepoxide, in combination with the various compounds, were determined 30 min. later. The results of this experiment are shown in Table II. α-Methyl dopa (400 mg./Kg.), *d*-amphetamine (5.0 mg./Kg.), and 5-hydroxytryptophan (500 mg./Kg.), when administered 30 min. prior to chlordiazepoxide, significantly reduced the ED_{50} value of chlordiazepoxide in reserpinized mice ($p < 0.05$). The 400 mg./Kg. dose of dopa, when administered to reserpinized mice in the isolated situation failed to alter the ED_{50} value of chlordiazepoxide. When this dose of dopa was administered to aggregated mice, however, a significant reduction in the ED_{50} value was produced ($p < 0.05$).

DISCUSSION

The results of this study demonstrate that the effects of amine-depleting agents on the anticonvulsant properties of chlordiazepoxide more closely resemble the effects of similar interactions for diphenylhydantoin than for acetazolamide which have been reported earlier (1, 2). With respect to the effects of reserpine and Ro4-1284, chlordiazepoxide resembles both diphenylhydantoin and acetazolamide in that the anticonvulsant effects of all three of these agents are antagonized by these amine depletors. In the case of interaction with α-methyl dopa, chlordiazepoxide closely resembles diphenylhydantoin in that the anticonvulsant effects of both were unchanged by this amine depletor. The failure of amine depletion by α-methyl dopa to antagonize either diphenylhydantoin or chlordiazepoxide might be explained on the basis of the metabolic fate of α-methyl dopa. α-Methyl dopa is metabolized to α-methyl norepinephrine (8). This metabolite may serve as a false neurotransmittor, an effect which could prevent the antagonism of the anticonvulsants by amine depletion *per se*. This seems unlikely, however, since the authors have found that α-methyl dopa antagonizes the anticonvulsant action of acetazolamide (2). Also, amine depletion by α-methyl tyrosine, which is not metabolized to a catecholamine-like structure (9) is without effect on either diphenylhydantoin (1) or chlordiazepoxide but was found to antagonize acetazolamide (2).

Further similarities between chlordiazepoxide and diphenylhydantoin in these experiments are that the administration of 5-hydroxytryptophan, α-methyl dopa, or *d*-amphetamine to reserpinized mice antagonized the effect of reserpine on the anticonvulsant effects of both chlordiazepoxide and diphenylhydantoin. Since dopa failed to antagonize the reserpine effect in isolated mice the authors studied this interaction in aggregated animals. Dopa has been shown to antagonize the effect of reserpine on the anticonvulsant action of acetazolamide in aggregated but not isolated mice (2). This effect of aggregation may be due to an increased uptake of dopa into the central nervous system. It has been shown by other workers that amphetamine is concentrated in the central nervous system to a greater extent in aggregated than in isolated mice (10).

It appears that the mechanism of the antagonism of the anticonvulsant effect of chlordiazepoxide by reserpine and Ro4-1284 is probably not the result of amine depletion, nor does the anticonvulsant effect of chlordiazepoxide appear to be mediated through brain catecholamines since (*a*) neither of the amine depletors, α-methyl dopa nor α-methyl tyrosine, was effective in antagonizing chlordiazepoxide and (*b*) the reserpine antagonism of chlordiazepoxide was reversed by *d*-amphetamine. On the basis of the results of the present study as well as earlier work from these laboratories (1, 2) the anticonvulsant effect of chlordiazepoxide appears to resemble that of diphenylhydantoin rather than acetazolamide.

Solubility of Some Steroids in Water

By PETER KABASAKALIAN, ELI BRITT, and MILTON D. YUDIS

The solubility of 21 steroids in water at 25° was determined and compared with previous data whenever available.

SCATTERED data have been reported in the literature for the solubility of a number of steroids (1–8) in water. However, there seems to be no single collection of such information nor is there sufficient data, particularly for the C_1-dehydro corticosteroids, which have gained widespread use in pharmaceutical and medical practice during the past 10 years. A greater need for this kind of information stems from the increased interest in the dependence of drug activity upon solution concentration, which in turn is often related to drug solubility in water. A further application for such data is useful in the design of dissolution rate studies.

It is believed, therefore, that the water solubility of a number of steroids in clinical use should be reported.

EXPERIMENTAL

Finely ground U.S.P. grade or material of equivalent quality was used for all solubility determinations. For each substance excess steroid at two initial solute concentrations, about 1 and 3 mg./ml., and 20 ml. of distilled water were added and sealed in 50-ml. glass ampuls. Each suspension was stirred for 48 hr. at 25 ± 0.1° using a Vibro-Mixer (Chemapec, Inc., Hoboken, N. J.) stirrer, which is known to effect rapid equilibration. A portion of the solution was withdrawn from the equilibrated suspension free of all solid material with a pipet fitted with a washed glass wool filter plug. The filtered solution was diluted appropriately with distilled water depending upon the quantity of substance in solution and was assayed spectrophotometrically at about 240 mμ for the conjugated A-ring ketosteroids and at about 280 mμ for the estrogenic steroids. Reference absorptivity constants were determined in a solution containing 10% methanol–90% water (v/v).

DISCUSSION

The water solubility of 21 steroids has been determined, each at two initial suspension concentrations. In all cases, the solubility for the suspension at the lower concentration was equal to or less than that for the higher concentration. In those cases where a difference was observed, the solubility reported was calculated by extrapolation to zero suspension concentration. The coefficient of variation for replicate measurements made in this study was equal to or less than 10%. The results are summarized in Table I. Available literature data for these substances are also included.

Some generalizations can be drawn from the available data. Steroids possessing the $C_{17,21}$-dihydroxy-C_{20}-keto side chain, such as cortisone, hydrocortisone, prednisone, and prednisolone, show the greatest solubility in water while the solubility of the corresponding C_{21} acetate esters is markedly reduced; the C_{21} primary hydroxyl moiety must function importantly in the solvation process. Nevertheless, the alcoholic function of C_{17} also contributes to solvation as the solubility of the $C_{20}C_{21}$-ketoalcohol, deoxycorticosterone is less than that of the dihydroxyketo analogs. The solubility of the C_{16}-methyl-9-α-fluoroderivatives, dexamethasone and betamethasone, is considerably less than prednisolone and is attributed to reduction of solvation about the side chain due to steric effects of the methyl substituent. The enhancing effect of the C_{11} and C_{17} hydroxyl group is indicated by comparing the solubility of hydrocortisone *versus* cortisone, prednisolone *versus* prednisone, and testosterone *versus* testosterone propionate.

TABLE I.—SOLUBILITY OF STEROIDS IN WATER

Compd.	Solubility in Water, mcg./ml., 25° This Work	Lit.

Crystal Structure of 2,4-Diselenouracil

By ELI SHEFTER*, MICHAEL N. G. JAMES, and HENRY G. MAUTNER

The crystal structure of 2,4-diselenouracil has been determined to provide some quantitative molecular information about the nature of hydrogen bonding exhibited by this compound in solution. The crystal is monoclinic, with space group P $2_1/c$, with a = 4.41 Å., b = 14.90 Å., c = 10.69 Å., and β = 108.4°. The observed density is 2.42 Gm. cm.$^{-3}$ and that calculated for four molecules in the unit cell is 2.33 Gm. cm.$^{-3}$. The structure was determined by the heavy atom technique and refined by block diagonal least squares to an R value of 0.136. The compound was found to exist primarily in a zwitterionic amidic configuration rather than the keto form. The seleniums formed relatively strong hydrogen bonds of the form N(H)···Se with distances of 3.47 and 3.75 Å.

VARIOUS EXPERIMENTAL observations (1, 2) have indicated that selenium analogs of pyrimidine and purine bases are able to form relatively strong hydrogen bonds in solution. Many of these seleno-bases have also been shown to be pharmacologically active antineoplastic agents (3, 4). It has been implied (5) that this activity may be attributable to the "formation of unusually strong hydrogen bonds when incorporated into deoxynucleic acids." The present X-ray investigation of one of these seleno-derivatives, 2,4-diselenouracil, was primarily undertaken to obtain structural information about the nature of the intermolecular hydrogen bonding.

EXPERIMENTAL

Diselenouracil crystallizes from ethanol–water solutions as yellow dichroic prisms, which exhibited twinning along the (100) plane. Many batches of recrystallized material were examined for the presence of a "single" crystal, but all crystals appeared to be twinned. It was found necessary to use a crystal from which the twin had been dissected for the collection of intensity data. The fragment used showed excellent extinction under the polarizing microscope, but photographs indicated that a small amount of the twin remained; this was estimated to be less than 10% from oscillation photographs.

Oscillation and Weissenberg photographs taken about the a and b axes using Cu radiation (λ = 1.5418 Å.) showed the crystal to be monoclinic, with unit cell dimensions of a = 4.41 Å., b = 14.90 Å., c = 10.69 Å., and β = 108.4° (with estimated standard deviations of 0.5%). The space group, as determined from Weissenberg photographs and confirmed by the determination and refinement of the structure, is P $2_1/c$. The density measured by flotation in a mixture of tetrabromoethane and chloroform was found to be 2.42 Gm./cm.^{3}, and that calculated for a unit cell containing four molecules of diselenouracil was 2.33 Gm./cm.^{3}.

The intensity data were recorded on equi-inclination Weissenberg photographs using multiple film packs. The dissected crystal (dimensions 0.14 mm. along a, 0.04 mm. along b, and 0.02 mm. along c) was first mounted about the a axis for collection of layers h = 0, 1, and 2, and it was then cut in half perpendicular to a and remounted about b to obtain the layers k = 0 and 1. The intensities were estimated visually and corrected for Lorentz polarization effects. The structure factors for the data about the two axes were put on the same scale by comparing common reflections. There were 649 unique reflections that gave measurable values; this represents approximately 55% of all unique reflections in the Cu sphere.

Determination and Refinement of Structure.—The positions of the two selenium atoms were easily located from an unsharpened Patterson synthesis, and the atoms comprising the pyrimidine ring were then found in a Fourier synthesis phased on the seleniums. The atomic identity of the six ring atoms was obtained by electron density calculations at the atomic sites. The refinement of the positional and isotropic thermal parameters of the molecule was carried out by block diagonal least squares, using a program described by Mills and Rollett (6). The weighing scheme used in the refinement was similar to that of Hughes (7). During the final cycles of refinement it was necessary to give zero weight to 36 weak reflections, as they appeared to be significantly influenced by the presence of the twin. The refinement was considered to be complete when the parameter shifts were less than one-third of their estimated standard deviations, which were calculated from the diagonal elements of the normal matrix. The positional and thermal parameters obtained are listed in Table I. The final R value (equals $\Sigma||F_0| - |F_c||/\Sigma|F_0|$) was 0.136 for all 649 reflections. A list of the observed and calculated structure factors can be obtained from the authors. The atom form factors used in the above calculations for carbon and nitrogen were those of

This investigation was supported in part by Fellowship 1-F2-GM-22,830-01 to Eli Shefter from the U. S. Public Health Service, Bethesda, Md.

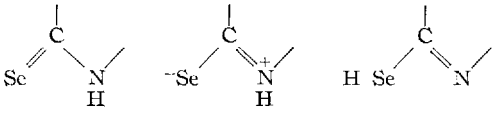
The authors are indebted to Professor D. C. Hodgkin, FRS, for her interest, to Professor S. Ramasashen for his discussions, and to the computing center of Oxford University for use of their facilities.

* Present address: Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo.

Berghuis *et al.* (8), and for selenium those of Thomas and Umeda (9) were used after being corrected for anomalous scattering. All computations were done on a Ferranti mercury electronic computer, using many of the programs described by Mills and Rollett (6).

RESULTS AND DISCUSSION

From X-ray studies on uracil (10) and various uracil containing compounds (11–14) it has been shown that in the solid state it exists primarily in the diketo form rather than the enol configuration. The C(2)-Se(2) and C(4)-Se(4) bond lengths of 1.89 and 1.99 Å. (E.S.D. 0.05 Å.), respectively, suggests that the electronic structure around the seleniums would be predominantly a zwitterionic amidic configuration (II) rather than I.



I II III

The enol form (III) was eliminated as a possible configuration, as this structure was found to be isomorphous with the crystal structure of dithiouracil (17), for which hydrogen atoms were found attached to the nitrogens. The presence of the amidic configuration rather than the enolic one is also consistent with the dipole moment, ultraviolet spectra, and ionization measurements (2, 18) made on 2-pyridselenone and its *N*-methyl derivative. The sum of the covalent bond radii for Se and C is 1.94 Å. for the single bond and 1.74 Å. for the double bond (15). These results are not surprising in the light of the studies of Mautner (1), which showed that Se has a greater ability than S and O to withdraw electrons from N in pyridine and pyrimidine derivatives.

The E.S.D.'s given above for the Se bonds is twice that calculated from the diagonal elements of the normal matrix, as it is felt that this is a more reasonable approximation to the errors. Relatively large standard deviations for the pyrimidine ring bonds (0.1 Å.) makes it impossible to assess their bond orders and, therefore, precludes any discussion of this part of the molecule.

Though selenium compounds are not usually thought of as hydrogen bond participants, in diselenouracil the seleniums appear to form such interactions. The short Se · · · N distances of 3.47 and 3.75 Å. and the angles around the nitrogen atoms indicate that the seleniums are forming relatively strong hydrogen bonds (Fig. 1). These hydrogen interactions are attributable to the electronic configuration and seem to be a function of the amount of polarization in the C-Se bonds. In the structure of *N*-phenyl-*N'*-benzoylselenourea (16) a Se · · · N hydrogen bond of 3.83 Å. was found, and it could

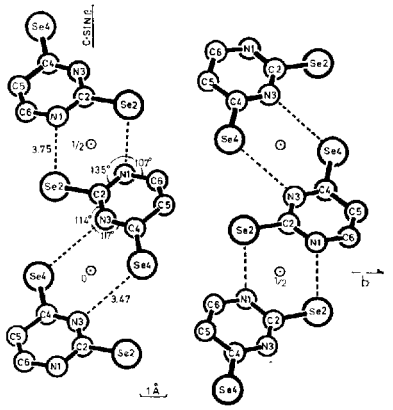


Fig. 1.—Packing diagram of 2,4-diselenouracil as viewed down the *a* axis. Probable hydrogen bonds are indicated by broken lines.

also be attributed to the electron-withdrawing property of the selenium. The importance of such bonding is best realized in connection with the postulate (5) that the antineoplastic activity of selenium derivatives of purine and pyrimidine bases may be related to their ability to form strong hydrogen bonds with their complement base within the helical deoxyribonucleic acid (DNA).

The least squares plane through the eight atoms, indicated they are coplanar; *i.e.*, the deviation of any atom from this plane is less than an E.S.D. of its positional parameter along the normal to the plane. This observation is consistent with the results on uracil and thymine.

Pharmaceutical Sciences—1965

A Literature Review

By ROBERT E. DEMPSKI and GERALD P. POLLI

CONTENTS

Received from the Pharmaceutical Research and Development Department, Merck, Sharp and Dohme Research Laboratories, West Point, Pa.

THIS REVIEW is a continuation of an annual series originated by McKeehan (1). It represents a comprehensive cross-section of the research and development efforts in various disciplines of the pharmaceutical sciences. Numerous periodicals and *Chemical Abstracts*' Pharmaceuticals and Pharmacodynamics sections published during 1965 were searched and selectively abstracted.

Some of the literature related to the pharmaceutical sciences has been reviewed on an annual basis in other publications and is omitted here. For such associated papers in analytical chemistry, antibiotics, bacteriology, biochemistry, biology, cancer, medicine, medicinal chemistry, microbiology, organic chemistry, pharmacology, physical chemistry, physiology, and plant physiology, the reader is referred to reviews in these areas of study. The "Advances in . . . " series,

the "Annual Review of . . . ." series, and the "Progress in . . . " series are particularly pertinent. In order to maintain continuity with previous pharmaceutical science reviews of *J. Pharm. Sci.*, their general format was retained.

GENERAL PHARMACY

The literature continues to abound with articles of interest to investigators involved in all areas of the pharmaceutical sciences. One paper by O'Reilly listed and discussed many of the pharmaceutical reviews published from June 1963 to June 1964 (2). Vice President Hubert Humphrey described the problems in keeping up with drug literature in a survey performed by the National Library of Medicine (3). Two other surveys attempted to outline the problems associated with the collection, distribution, and effective utilization of the vast amount of drug literature (4, 5). The proper procedure for the approval of a new drug or drug cosmetic has been discussed in an outline of current regulation procedures (6). Kass reviewed the type and scope of information an inspector is entitled to receive upon FDA inspection (7). An article written by a group of four physicians explained the practical aspects of drug therapy from the standpoint of the pharmacist, clinician, researcher, and teacher (8).

One review was concerned with how and why generic and trade names are assigned to new drugs (9); Ansel commented on the qualities of a desirable trade name and the intricacies of determining its legal availability, subsequent registration, and protection (10). The utilization of drugs in aerospace medicine was summarized (11). The chemistry and uses of antifungal (12), anthelmintic (13), and antimalarial (14) drugs were presented in three different articles which contained many useful references. The outlook for dimethylsulfoxide, a new drug from lignin, as a therapeutic agent has been described (15). A paper on historical studies of camphor was also published (16). Kuttel recommended a simple and practical design for aseptic compounding in dispensaries (17). Additional surveys considered the preparation and properties of ophthalmic solutions (18, 19) and some aspects of toiletry technology (20).

Preservatives.—The preservation of ophthalmic products was reviewed in a paper with 68 references (21). In another study, many types of preservatives were evaluated for their antibacterial and antifungal properties (22). Evans applied the Ferguson principle to systems of mixed preservatives to ascertain that biological activity is proportional to the degree of saturation of the aqueous phase (23); the same principle was used to determine and correlate the activity of three quaternary ammonium salts against *M. aureus*, *E. coli*, and *C. albicans* with the surface properties of these compounds (24). Propylene glycol exhibited antimicrobial activity when used topically (25). Thoma carried out galenic and analytical studies on the effect of several cellulose derivatives and alginates on the activity of several antiseptics (26). Alkaline glutaraldehyde has been suggested as a general disinfectant for instruments and apparatus that cannot be sterilized by autoclaving (27). Two studies were concerned with the mechanism of action of phenolic disinfectants. One investigated the effects on induction of and accessibility of the substrate to β-galactosidase in *E. coli* (28), and the other explored the effect of 2,4-dichlorophenol on the incorporation of labeled substrates by *E. coli* (29). Another paper assessed the importance of metal ions and the toxic properties of the formyl group in determining the bactericidal activity of various phenols and salicylaldehydes (30). One other report presented data on the hemolysis of erythrocytes by a series of quaternary ammonium salts (31).

Foster published two different articles on the preservation of ophthalmic solutions (32, 33). Test procedures and test organisms suitable for shortening the time required for the selection of an adequate preservative have been disclosed (34). The use of antimicrobial agents in parenteral products was reviewed in a paper containing 22 references (35). Another summary with 38 references on the activity of antibacterials in a two-phase system was presented (36). Krowczynski and co-workers suggested a preservative for aqueous heparin solutions (37). Also, 8-hydroxyquinoline sulfate was satisfactory as a preservative for tuberculin PPD (38). This agent was effective against two yeasts, three molds, *P. aeruginosa*, and *S. aureus*.

Flavor, Aroma, and Color.—A review has been compiled on the use of flavors in the United States, the various methods used for flavor testing, and the difficulties encountered for the taste correlation of drugs (39). Tilgner proposed a flavor dilution profilogram for characterizing the detailed aroma or flavor sensations of a product in dilution steps between the threshold and some standard extract of the undiluted product (40). A combined electrophysiological and sensory test revealed that the gustatory effect of substances which show taste as sour or salty was reinforced by inhibition of cholinesterase on the tongue (41). No changes were observed for bitter or sweet tastes. Taste sensitivities to quinine and 6-*n*-

propylthiouric acid were determined (42). Five new principles for flavoring antitussives have been developed (43). Sorbitol, saccharin, and *N*-cyclohexylsulfamic acid were found to be effective synthetic sweetening agents in pharmaceutical preparations (44). In addition, Edwards commented on the flavor constituents of citrus oils (45).

The philosophy of and methods for the identification of odor and flavor constituents were reviewed by Wick (46). The theory of odor and the relationship between the odor and the chemical properties of flavors have been surveyed in another paper (47). A review of pioneers in aldehydes and ketones was presented (48), and the synthesis, physiochemical properties, and economic factors of lavender were summarized (49). One status report listed all currently approved U. S. certified colors (50); another outlined the current FDA status of all color additives for cosmetic use (51). The effects of grain size and moisture content have been studied with the Pulfrich photometer against 120 color standards (52). A method was described for classifying and describing colors formed when the concentrations of several dyes and carbon black in compressed tablets were evaluated (53). One other paper discussed the physiology and psychology of color sensation (54).

Adjuvants.—The properties and compatibilities of two dextrans with molecular weights of 40,000 and 70,000 were tabulated by Smith (55). Another investigator assessed the effect of heat on aqueous solutions of dextran by measurements of viscosity and reducing power (56). The use of cation exchangers as carriers of drug components for the improvement of their palatability has been described (57). The application of polyethylene glycols in pharmaceuticals was outlined (58). Anomalies in some of the physical properties of spray-dried lactose and granulated magnesium oxide were traced to the presence of fines which could be removed by washing with selected organic solvents (59). A silicone fluid proved useful as a lubricant for artificial eyes (60); it did not adhere to tissue, was insoluble in water, was stable over a wide temperature range, and did not support bacterial growth. The properties of neutrality, inertness, low surface tension, easy viscosity control, miscibility with eye secretions, and a low tendency to support bacterial growth, all contributed to making methylcellulose a valuable agent for preparing an aqueous vehicle for pilocarpine nitrate ophthalmic solutions (61). Polyvinylpyrrolidone has been recommended for use as a binder in tablet making (62). The characteristics of Neen gum, a polyelectrolyte which behaves as a lyophilic colloid, were disclosed (63). Experimental data were also presented on a new gum prepared by fermentation from glucose that could be used for thickening highly concentrated electrolyte solutions (64). Some of the practical aspects of colloids were commented on by Smith (65). The viscosity control of liquids and the forced flow of solids were accomplished by the use of silicas (66). One worker collected data on the common properties of some clays including dispersion, aggregation, and the difference between clays and other mineral colloids with particular reference to exchange capacity (67). Other researchers conducted an infrared study on structuration in bentonite clays (68).

The importance of propylene glycol as a solvent in dermatology was reported by Barr (69). The attributes of hexadecyl alcohol as a new material for cosmetic and topical formulations have been discussed in detail (70, 71). Another paper described the suitability of higher-boiling fractions of ethoxypolysiloxane oil in ointments and suppositories (72). The formulation of creams, lotions, and ointments with silicones was studied in two different publications (73, 74), and the utility of isopropyl myristate (75) and coconut oil derivatives (76) in cosmetics was also demonstrated. Both cholestanol (77) and germ lecithin (78) were effective emulsifiers in making water-in-oil emulsions. King and Sheffield used the triethanolammonium salts of several alkylsulfuric acids in the formulation of dermatologic vehicles (79). The seed husk of *Plantago ovata* has been evaluated for its emulsifying properties (80); the powder produced poor emulsions, whereas the mucilage gave emulsions that compared favorably with those made with acacia. One investigator proposed microcrystalline cellulose as a new ingredient for the formulation of creams, lotions, and ointments (81). Another researcher outlined the pharmaceutical and cosmetic usage of a new colloidal alumina as a topical formulating agent (82). The synthesis, analysis, and physical properties of several allantoin complexes were determined, and their potential dermatological uses were suggested (83). Other investigators evaluated current problems associated with the effects of synthetic detergents on the skin (84).

Stability.—Current formulation stability problems were discussed in two different review articles (85, 86). Papers by Sawatari (87) and Sabalitschka (88) advocated the use of antioxidants as stabilizers. Another report examined the measurement and prevention of oxidative deterioration in cosmetics and pharmaceuticals (89). The thiobarbituric acid–malonaldehyde

reaction was used to measure antioxidant effectiveness in pharmaceutical oils (90). The oxidation of benzaldehyde and methylbenzaldehyde in hydrous solutions of polyoxethylene glycol ethers was measured by a manometric technique (91). Phenolic antioxidants were found to be quite satisfactory for improving the stability of creams containing vegetable oils (92). The rates of autoxidation of linoleic acid in micellar solution were also studied (93). The influence of heat sterilization and the stability of pharmaceutical solutions were surveyed by Speiser (94). The effect of ultrasonic energy was explored in two different studies; it was used to study the hydrolysis of acetylsalicylic acid solutions at various temperatures and pH values (95), and to evaluate its influence on physical and chemical transformations of purine derivatives (96). In another investigation, the effect of X-rays on dihydrouracil in aqueous solution, with and without the presence of oxygen, was revealed (97).

Acetylcholine bromide solutions were shown to be stable at room temperature for 2.5 months and at 5° for 5 months (98). Optimum stability conditions for adrenaline were achieved by dissolving its bitartrate salt in water containing sodium thiosulfate and boric acid (99). In another stability study, solutions of chlorpromazine were found to develop a precipitate if combined with sodium phenobarbital, sodium bromide, or neospasmin (100). Denoel discovered that ephedrine decomposed rapidly in peanut oil, but was extremely stable in mineral oil (101). Three other investigators tested the effect of self-radiation, pH, temperature, and sunlight on the stability of sodium iodohippurate-^{131}I (102). Experiments were also conducted on the stability of isoniazid and its related compounds (103). Sealing morphine hydrochloride solutions under carbon dioxide or nitrogen gave more protection against decomposition than equivalent solutions sealed under air (104). The effect of aging of aqueous pralidoxime solutions on the assay, toxicity, and antidotal activity has been investigated by Lehman and Bloch (105). Two studies were performed on tetracaine hydrochloride solutions. One study evaluated the effect of an ultraviolet lamp on pH and potency (106); the other examined the effect of sterilization and hydrolysis in the pH range of 4–7 (107). The mechanism of thermal rearrangement and decarboxylation of procaine was disclosed (108). Various methods were suggested for the stabilization of procaine hydrochloride solution. Two papers proposed the addition of carbon dioxide and *p*-aminobenzoic acid as stabilizers (109, 110). The addition of EDTA was observed to prevent solutions of procaine from turning yellow, but it failed to inhibit decomposition of the drug (111). Another local anesthetic, procaine, was stabilized with a mixture of sodium thiosulfate and sodium sulfite (112). The stability of retinol acetate (113) and sodium sulfacetamide has also been investigated (114). A compatibility study with certain sulfonamides indicated that insoluble precipitates were formed with salts of several alkaloids, boric acid, and zinc sulfate (115). Other workers conducted a study on the stability of a 10% solution of sodium sulfadiazine in the presence of copper, iron, and hydrogen peroxide (116). In addition, the stability of triiodothyronine (117) and triiodothyronine-^{131}I (118) was carefully determined under different conditions of storage.

Koshy *et al.* described some of the factors involved in the browning of spray-dried lactose (119). In a similar study, the lactose–amine reaction was discovered to be predominately a primary amine–carbonyl reaction and was similar in nature but distinct from the dextrose-, galactose-, and HMF–amine reactions (120). γ-Rays from ^{60}Co were claimed to accelerate the oxidative decomposition of methyl linoleate mixed with lactose (121). Two compatibility studies have been conducted on powder mixtures. The incompatibility of carbinoxamine maleate (122) and calcium phosphorylcholine hydrochloride (123) with 20 and 84 different powder preparations, respectively, was carefully evaluated. Experiments on powders of dehydroacetic acid revealed that the α-form, which is stable at room temperature, is rapidly converted to the β-form at 80° (124). Diffuse reflectance studies were used to observe solid–solid interactions of oxytetracycline, phenothiazine, anthracene, and salicylic acid with various adjuvants (125). Some of the factors influencing the stability of calcium acetylsalicylate and acetylsalicylic acid tablets have been investigated by Kiss, Rozsondai, and Scholz (126). In a study where acetylsalicylic acid was combined with ascorbic acid in tablets, the effect of water vapor pressure on the moisture sorption and the stability of both components was reported (127). No breakdown of digitoxin was found in tablets, injections, or solutions stored in the dark for 5 years (128). Similarly, no decrease in the alkaloid content of ipecac concentrate was observed after 18 months of storage (129). The sedimentation of thyme tincture was prevented by clarification with talc and cooling to 0 to −5° (130). The stability of helveticoside, a glycoside from strophanthidin, was also studied in a long-term investigation (131).

Stability Kinetics.—Garrett published a review with 198 references discussing the prediction of drug stability in pharmaceutical preparations (132). Two other reviews appeared in the literature. Both of these surveys evaluated the use of chemical kinetics for the prediction of drug stability (133, 134). A nomograph chart was devised in one study to facilitate the analysis of stability data obtained in accelerated testing at elevated temperatures (135). A reciprocal heating machine has been found very useful for investigating single-step stability studies under nonisothermal conditions (136). Other workers used model calculations, based on the statistical-mechanical formulation of isotope effects, to predict how analysis of experimentally measured isotope effects may be used to gain information concerning the differences between the reactants and the transition state in a rate process or between the reactants and the product in an equilibrium process (137).

One paper examined the kinetics of solvolysis of various *N*-alkyl-*N*-nitrosoureas in neutral and alkaline solutions (138). The decomposition of *p*-aminosalicylate was found to be first order while sodium *p*-aminosalicylate was zero order in aqueous solution (139). Pseudo first-order rates of spontaneous degradation were ascribed to apomorphine under varying conditions of temperature and pH (140). The hydrolysis of methyl and ethyl esters of benzoic acid, some sterically hindered acids, and benzonitrile by suspensions of sodium hydroxide in DMSO was 10^4 to 10^5 greater than in hydroxylic solvents (141). Activation energies, frequency factors of the Arrhenius equation, and equilibrium constants between chlorothiazide and its intermediate were calculated from the rate constants on the hydrolysis reaction (142). The rate of autolysis of α-chymotrypsin in the pH region of 7 to 11, in the absence of added salt, has been studied through the rate of acid formation in a pH-stat and through the rate of decrease in enzyme activity (143). Garrett and Notari quantified the kinetics of dehydration of cycloheximide to anhydrocycloheximide in the pharmaceutically useful acetate buffer region (144). Another article compared the rate of hydrolysis of thalidomide, *N*-butylphthalidomide, and phthalimide in sodium hydroxide (145). The degradation of hexamine in aqueous solution was considered to be pseudo first order (146). The solvolysis of 5-iodo-2′-deoxyuridine was revealed as first order over the pH range of 3.9 to 12.0 (147). First-order rate constants were disclosed for the decomposition of molten malonic acid from the volume of carbon dioxide evolved (148). In a stability study on mydeton injection solutions, the rate of decomposition was influenced by pH and temperature (149). Two different papers discussed the rate of hydrolysis of procaine under various conditions of temperature and pH (150, 151). The effects of substitution have been correlated with the acid-catalyzed hydrolysis rates of some oxazolidines (152). Other kinetic studies were carried out on tetracaine, parethoxycaine, leucinocaine, procaine, farmocaine, and larocaine (153). Methyl substitution was demonstrated as providing increased ring stability in a study on the hydrolysis of succinamic acid and succinimides (154). Pseudo first-order rate constants were recorded for the base-catalyzed hydrolysis of urea (155).

Antibiotic Stability.—A buffer solution containing boric acid, sodium borate, and polyethylene glycol did not prevent hydrolysis of chloramphenicol (156). The stability of two antibiotics, cranomycin (157) and erythromycin lactobionate (158), has been studied. Tukamoto, Miyake, and Sato reported on the decomposition of dihydrostreptomycin, chloramphenicol, and tetracycline by drug-fast *E. coli* (159). Other investigators have compared the effect of glycerin, paraffin, propylene glycol, white petroleum jelly, polyethylene glycol, lactose, alcohol, sunlight, and darkness on the stability of hamycin preparations (160). Acid degradation studies were performed on kasugamycin (161). A decrease in the optical rotation of lincomycin showed a direct correlation with microbiological assays (162). One study followed the rates of decomposition of methicillin in aqueous solution (163); another determined the effect of sugars on the browning of neomycin (164).

Several papers were presented on the stability of various penicillins. Losses in potency of 2,6-dimethoxyphenyl penicillin were evaluated iodimetrically, by U.V. absorption, and by microbiological assays on *B. subtilis* (165). The stability of aqueous solutions of certain novel penicillins was observed to be reduced by surfactants, preservatives, and thickening agents (166). The decomposition rates of α-phenoxypropylpenicillin, 2,6-dimethoxyphenylpenicillin, and α-aminobenzylpenicillin have been demonstrated to be first order and obeyed Arrhenius' equations (167). In another study, it was concluded that acacia accelerated the inactivation of penicillin, whereas methylcellulose had no effect (168). Other workers, Olszewski and Grabowska, tested the influence of sodium benzoate on the stability of aqueous penicillin solutions (169). In a physical-chemical study on the relationship between potency and hygroscopicity, the effect of humid-

ity on the potency of four semisynthetic penicillins was investigated (170). Schwartz described the effect of ionic interaction on the catalysis of penicillin hydrolysis by certain catecholamines (171). This investigator also concluded that the degradation of penicillin G involved both the catalyzed hydrolysis of the undissociated molecule and a rearrangement of the penicillin ion following proton attack (172). A different study on some penicillin salts correlated the initial product characteristics and the properties after 3 years by statistical means to predict their shelf-life (173). The catalytic effect of buffers on the degradation of penicillin G in aqueous solution has also been examined (174). Other workers considered the cause of the reddening coloration and pigments in colored solutions of streptomycin (175).

Vitamin Stability.—Elevated temperature storage tests and a graphic method of calculation were used by Tardif to determine thermal degradation rates in three polyvitamin tablet formulations (176). In another vitamin stability study, the same worker found no differences in a polyvitamin suspension that had been stored either in the plant or in the pharmacy (177). In other multiple vitamin stability studies, vitamins A, B_{12}, and ascorbic acid were classified as being the least stable (178). The stability of vitamin A, tocopherol, and unsaturated fatty acids in vitaminized vegetable oil exposed to sunlight was also investigated (179). The stability of vitamin A in concentrates and foodstuffs was determined under various conditions of temperature, atmosphere, and time (180). The effect of material quality and the method of preparation upon the stability of aqueous thiamine injections was the subject of one paper (181); another study examined the effect of salts, vehicles, pH, temperature, and vitamins B_2, B_6, and niacinamide upon the stability of thiamine (182). The effect of cocarboxylase on the hydrolysis of thiamine pyrophosphate was reported (183). Kato claimed that powdered mixtures of thiamine tetrahydrofurfuryl disulfide with sodium bicarbonate and acetylsalicylic acid were completely stable (184). Two separate papers were also presented on the stability of isomers of dihydrothiamine (185, 186). In addition, γ-rays from ^{60}Co were found to accelerate the decomposition of thiamine hydrochloride when mixed with calcium carbonate and dibasic calcium phosphate (187). The stability of riboflavin and its phosphate salt in syrup, propylene glycol, glycerol, 70% sorbitol solution, and water has been assessed (188). Macromolecules, *e.g.*, polyvinylpyrrolidone, polysorbate 80, and sodium decyl sulfate, enhanced the rate of aerobic photobleaching of riboflavin by visible light (189).

The mechanism of color formation, the role of furfural, and the decomposition products of ascorbic acid were delineated (190). In a similar study, the rate of formation of furfural by the hydrogen ion-catalyzed anaerobic degradation of undissociated ascorbic acid was depicted as being equal to the rate of disappearance of the ascorbic acid (191). Another anaerobic study considered the formation of carbon dioxide and furfural by decomposition of ascorbic acid at various pH and temperature conditions (192). Finholt *et al.* also studied the anaerobic degradation of ascorbic acid by following the rate of formation of carbon dioxide (193). Otani detected a linear relationship between the color change and the degradation of ascorbic acid in the pH range 1–7 (194). He presented another paper on the relationship between the color change and the oxidation of ascorbic acid in aqueous solution (195). Additional experimental data compared the stability of ascorbic acid and 2-keto-l-gulonic acid in an aqueous medium (196). Two different manuscripts were concerned with the effect of stabilizers on ascorbic acid. Amino acids improved the stability in liquid formulations (197); rutin retarded the oxidation of ascorbic acid in apple juice (198). Another study analyzed the shelf-life of several liquid formulations with ascorbic acid in different vehicles with and without other vitamins (199). The most stable injectible solutions of ascorbic acid were prepared by using a 5% excess of ascorbic acid, purging with carbon dioxide, and sealing under carbon dioxide (200). In tablets, ascorbic acid remained stable longer if made by dry compression or by using a nonaqueous binder and storing in amber containers without moisture (201). Studies in model systems have indicated that ascorbic acid is more stable in aqueous systems and is a more efficient antioxidant than erythorbic acid (202).

The thiazole moiety of thiamine hydrochloride and selected model compounds had no adverse effect on the cyanocobalamin stability (203). A dose of 9.1×10^4 rads of γ radiation from ^{60}Co destroyed 45% of the vitamin B_{12} under test (204). Steric factors were found to have an important influence on hydrolysis of vitamin B_{12} in aqueous hydrochloric acid–dioxane solution at 50° (205). Hydroxocobalamin in liver extract has been stabilized by the addition of ferric and ferrous sulfate ions (206). Janicki and coworkers conducted a study on the stability of vitamin D_2 in irradiated feed yeasts during storage (207). Thiamine, riboflavin, chlorine, ascorbic acid, manganese sulfate, and calcium hypo-

phosphite were all shown to cause decomposition of folic acid in pharmaceutical preparations (208). The discoloration of isonicotinic hydrazide tablets in tropical climates was attributed to the lactose contained therein (209). Other studies compiled data on the incompatibility of some commercial vitamin K_1 injections (210).

PHARMACEUTICAL TECHNOLOGY

Past, present, and future trends in pharmaceutical product development were summarized by Cooper (211). Two progress reports on solid and solid-fluid systems in pharmaceutical engineering have also been published (212, 213). Some experimental work was conducted on the chemical engineering of foam separation (214). Smith advocated that vibration grinding was a faster process than ball milling (215); he also presented several comments on wet *versus* dry grinding (216). A report was made on some powder properties, their mixing performance, and the development of some new theories of mixing (217). The drying characteristics of three commonly employed tablet excipients have been investigated under vacuum in an instrumented rotary double-cone dryer (218). One review discussed the theory of drying (219); another summary compared the methods used for both batchwise and continuous drying (220). Additional comments on some of the principles and applications of spray drying were also published (221).

Two different papers suggested methods and apparatus for the preparation of gold colloids for medicinal use (222, 223). Another investigator summarized nine different methods for measuring particle size (224). A novel method for evaluating dissolution characteristics of capsules was developed by Paikoff and Drumm (225). The simultaneous mixing and segregation occurring in randomly mixed particulate solid systems subjected to agitation have been investigated (226). Similarly, idealized systems of solid particles as represented by steel and glass spheres were studied with reference to their rates of segregation (227). Four separate papers appeared on the lyophilization of pharmaceuticals. These articles included a study on the effect of certain physical-chemical properties on lyophilization (228), a description of a high-sensitivity resistance bridge for low-conductivity measurements at eutectic temperatures (229), a method for programing a mathematical expression for estimating eutectic temperatures from melting point and solubility parameters (230), and determination of the eutectic temperatures of some inorganic salts (231).

Parenterals.—A review on the formulation of parenterals was published by Parrott (232), while Bedaux outlined various aspects for the preparation of infusion solutions (233). Other researchers recommended the use of demineralized water for the preparation of parenteral solutions (234). A thermoelectric vapor phase osmometer was described for measuring osmotic coefficients, isotonicity values, and sodium chloride equivalents of some univalent electrolytes of pharmaceutical interest (235). Isotonic solution values were tabulated for numerous medicinal agents and adjuvants in three separate publications (236–238). The use of polymers in injectables was surveyed in a discussion with 56 references (239). Also, new formulas were suggested for infusion solutions based on acetates and sorbitol (240). The preparation and development of a chloramphenicol intramuscular injection have been described (241). Pinter reported on a method for the preparation and storage of a citric acid solution for the dissolution of lyophilized plasma (242). Nine commercial parenteral preparations containing calcium salts were mixed with 70 commercial preparations containing salts of organic acids and observed for pH changes and precipitates (243). The same investigators compared the compatibility of thiamine tetrahydrofurfuryl disulfide injection with 136 other commercial parenteral preparations (244). In another compatibility study, 270 unique pairs of medication were tested in 5% dextrose solutions. This test resulted in 23 pairs that were physically incompatible (245). An additional 34 drugs intended for intravenous use were cross-matched to test for physical signs of incompatibility (246). A strain of *Pseudomonas* has been isolated from an injection solution containing 10% bivalent mercury diuretic that was resistant to phenyl mercuric borate and sodium ethyl mercuric thiosalicylate (247). A new disposable hypodermic device, called a hypule, has been evaluated by a biological procedure and tested for compatibility with 117 different parenterals (248).

Sterility.—Advances in sterilization techniques were outlined by Ehrlen (249). Four additional reviews discussed the utilization of gaseous ethylene oxide in sterilization (250–253). A method has been developed for the determination of residual ethylene oxide and ethylene glycol in ethylene oxide sterilized pharmaceuticals (254). The utility of cold sterilization in pharmaceutical products was also disclosed (255). Also, emphasis was placed on the cleaning operation and choice of chemicals and detergents used on metal and rubber parts (256). Sterilization

by radiation was also considered (257); while irradiation of tetracyclines and other antibiotics with ^{60}Co did not diminish their antibiotic power (258). An ultraviolet mercury vapor lamp in a quartz tube was employed for sterilizing water received from an ion-exchange method (259). The addition of small amounts of polymyxin B, benzalkonium chloride, chlorobutanol, or various mercury-containing antiseptics to collyriums prevented bacterial contamination (260). The incorporation of 0.3% phenol and autoclaving for 30 min. at 120° provided a new method for the sterilization of oil solutions (261).

Tablets and Capsules.—Some geometrical considerations concerning tablet design to provide a uniform release rate from solution tablets have been investigated (262). It has been ascertained that half-tablets are poor dosage forms, especially when the dosage must be carefully controlled (263). The influence of many different excipients and lubricants on the chemical and physical stability of several medicinals in tablets was demonstrated by Lachman (264). Other researchers described instrumentation for measuring the sign and magnitude of static charges generated by particles flowing through a tablet hopper (265). They also found that tablet lubricants, such as magnesium stearate, polyethylene glycol 4000, sodium lauryl sulfate, and talc, have the ability to lower the accumulation of static charges resulting from the flow of material through a tablet hopper (266). Tableting difficulties due to the nonwetting of lipophilic and aerophilic substances have been overcome by the addition of detergents to tablets (267). A comparative study was made of the absolute water content with relative dampness and dielectric constants on various granules (268). The equilibrium moisture content of several starches, gums, sugars, and hexamine was determined at different relative humidities and temperatures (269).

Two reports were published on the evaluation of several tablet disintegrating agents (270, 271). The latter article indicated that Moriyo starch was as good as or better than cornstarch and Veegum HV as a tablet disintegrant. An *in vitro* disintegration study was performed on 85 different commercial and 14 different hospital preparations according to the "Danish Pharmacopeia" 48 (272). A comparative evaluation was made on the effect of aging for 24 weeks on seven tablet disintegrants (273). Cornstarch was best. The effect of the viscosity of sodium carboxymethylcelluloses used as binding and disintegrating agents on the rate of disintegration of clay tablets was studied (274). In addition, a study was reported on the properties of experimental granulations produced by using aqueous and alcoholic solutions of celluloses, vinyls, acrylamides, pyrrolidones, oxazolidinones, and ethylene oxide condensation products (275). A technique for determining *in vivo* tablet disintegration has also been proposed (276). Some physicochemical properties, including swelling volume, moisture absorption, particle size distribution, surface area, and ion-exchange properties, of the montmorillonites were examined in relation to their application in tablet making (277).

Kirsop reviewed the fundamentals of tablet compression (278). A comprehensive study on compressed tablets evaluated the effect of the method of granulating, excipient, lubricant, disintegrant, particle size, and pressure on the density, disintegration time, and cohesive force (279). It was discovered that the density of compressible systems may be determined without disturbing the system under study by using a densitometer consisting of a sealed source containing ^{170}Tm and a scintillation detector connected to a preamplifier and pulse-height analyzer (280). A "moving-die" apparatus was described for the investigation of die wall friction during compaction (281). This apparatus was used to determine the die reaction during compression of crystalline acetylsalicylic acid, hexamine, sucrose, sodium chloride, and simple granulations of hexamine and sucrose (282). It was also employed to determine the die reaction following compaction of 100 mesh powders of 11 different lubricants (283). Three different papers reported on the physics of tablet compression. One of these articles, by Seitz and Flessland, was concerned with changes in tablet hardness and friability when the operation of a rotary tableting machine was varied (284). Data collected during the measurement of pressure exerted by various substances on the die wall during and after compression of tablets can be related directly to the ease of formation and ejection of these tablets (285). Another comparative study explored the performance of a food grade dextrose and a spray-dried lactose as excipients in the direct compression of tablets (286).

The form or shape of tablets to be coated was studied and an empirical formula was derived from status analysis for tablet form that would express the ease or difficulty of the coating procedure (287). Coatings prepared from 30% gelatin and 2% methylcellulose mixed in a 1:1 ratio with 1:1 potato starch–talc prevented volatilization of peppermint oil from tablets (288). Some spray-dried formulations of sulfaethylthiadiazole were tested for their prolonged-release action (289). Richman, Fox, and Shangraw prepared nonfriable tablets of glyceryl trinitrate by direct compression

employing microcrystalline cellulose as a tablet matrix (290). Gelatinized starch has been used in the preparation of acetylsalicylic acid tablets (291). In an extemporaneous method of preparing enteric-coated capsules, 29 combinations of polyvinyl acetate resins with plasticizers in various solvents were evaluated along with cellulose acetate phthalate (292). The advantages of direct weighing of filled capsules were compared with the indirect weighing of the capsule content to determine weight variations (293).

Suspensions.—Nash discussed the preparation and properties of suspensions intended for oral, parenteral, or topical use (294). Mean diameters and size distribution curves of aqueous barium sulfate suspensions measured by the sedimentation method were nearly identical to results obtained with the Coulter counter (295). A new method of determining the settling rates of suspensions was studied using a specially constructed absorptiometer and a sealed source of β-excited characteristic X-radiation (296). Guar and colloidal substances from linseeds, in low concentrations, induced flocculation of barium sulfate suspensions but in higher concentration hindered interparticle separation (297). The addition of protalbinic acid, lysalbinic acid, or infusion provided various degrees of dispersion for several bismuth compounds (298). The effect of sodium salts of fatty acids on the thermal stability of aqueous dispersions of kaolinite has been investigated (299). Other studies were conducted on the formulation and stabilization of suspensions containing tetracycline base (300), and suspensions containing alkaloids such as noscapine, papaverine, and methyl ephedrine (301). Particles of clay less than 0.5 mm. in size were found to disperse in water more slowly than particles of a larger diameter, 2–10 mm. (302). The influence of the hydrophile–lipophile balance on oily suspensions was also considered (303).

Emulsions.—A review on the stability of oil-in-water emulsions has been published by Garrett (304). In a unique study, the change in the stability of emulsions according to the number of double bonds in the oil molecule was followed by means of the Lederer equation (305). The kinetic theory of droplet coalescence and its applications to emulsion stability has been discussed by Hill and Knight (306). A γ-globulin fraction was discovered to be responsible for the creaming or complete breakage of intravenous fat emulsions *in vitro* (307). Two studies were carried out on deaggregation in oil-in-water emulsions. In one, the rate of deaggregation of an emulsion system containing 2% hexadecane-in-water stabilized with 0.09% dioctyl sodium sulfosuccinate was studied (308). In the other, the influence of *n*-butanol, *n*-hexanol, *n*-octanol, and dioctyl sodium sulfosuccinate on the deaggregation of 2% hexadecane-in-water emulsions was evaluated (309). Two series of mineral oil-in-water emulsions with varying amounts of sodium dodecyl sulfate or polysorbate 80 were also observed for changes in particle size distribution over a 2-year period (310). Another investigator followed the effect of ethoxylated fatty alcohol combinations on the stability of 4% mineral oil emulsions (311).

The preparation, application, and examination of lotions in dermopharmacy was the subject of a review (312). Lin presented an outline for planning laboratory experiments and interpreting results during the process engineering of cosmetic emulsions (313). He also commented on the advantages of cold emulsification over conventional elevated temperature emulsification procedures (314). Several suggestions were made for determining the role of solubility in the formation of emulsions by using the best solvent for the oil to be emulsified (315). Two methods were described outlining the best technique for using the HLB of emulsifiers (316). The interfacial properties of a glycerin and olive oil emulsion were studied (317). The interfacial tension of various natural and synthetic glycerides did not differ greatly, and none of the glycerides had an interfacial tension sufficiently low to emulsify spontaneously but required additional emulsifiers (318). Paraffin oil-in-water emulsions made with a soap and fatty alcohol complex as an emulsifier were examined microscopically for their physical characteristics (319). A fat emulsion concentrate, transparent and stable to autoclaving and containing very low concentrations of nonphosphatide emulsifiers, has been developed (320). Another publication discussed the emulsification and evaluation of a parenteral contrast medium for lymphography (321). In addition, a report was written on the effect of the dispersed phase (water) content on the structural and thixotropic properties of complex emulsions (322). Muys compiled data on the microbiological quality of edible emulsions during manufacture and storage (323).

Ointments and Creams.—A Hoeppler consistometer was used to measure the effect of temperature variations on the heat stability of ointments and creams (324). Another device was developed for determining the oxidation resistance of both oil-in-water and water-in-oil emulsion vehicles (325). The influence of antioxidant mixtures and physiochemical conditions on the stability of 12 different anhydrous and emulsion-type bases has been investigated (326).

Gretskii examined the stability of water–petrolatum emulsions at −10° and −20° by using 5% pentol, sorbitan oleate, or lanolin and 1–24 hr. freezing time (327). This latter investigator and his co-worker also found that emulsion bases composed of mixtures of petrolatum and pentol or sorbitan oleate gave heat stable emulsions (328). Several formulations for barrier creams (329) and clear gels (330) were suggested. In addition, film-forming bases containing aqueous topical adhesives were discussed (331). One author published two different papers on the use of polyorganosiloxane liquids for ointments and liniments (332, 333). Comparative studies were conducted on the solubility and compatibility of polyethylene glycol, polypropylene glycol, and glycerol–polypropylene glycol ether in various topical preparations (334). Dicarboxylic acid esters were claimed to be suitable additives for increasing water-vapor permeability of ointment bases (335). The hardness of topical creams has been increased by increasing the number of hydroxyl groups of partially acetylated mono- and di-glycerides (336). The addition of quaternary compounds increased the water-holding capacity of petrolatum (337). The ointment pendulum of Fueller and Muenzel was employed to evaluate the smearing properties of water-in-oil and oil-in-water emulsion bases (338).

Suppositories.—Anschel and Lieberman published a two part review on suppository bases (339, 340). An easy method has been proposed for the small-scale production of suppositories by pouring the suppository mass into plastic bottles which terminated in points (341). Experiments on changes in the complete deformation time of suppositories during storage showed that with certain fat vehicles the changes were over 100%; there were no changes with polyethylene glycol suppositories (342). Mixtures of polyethylene oxides were characterized for use in suppositories by their melting point, turbidity point, hardness, viscosity, thermal expansion, and rate of dissolution (343). In another study on suppositories the displacement value was found to decrease by reducing the particle size of the insoluble ingredients (344).

Aerosols.—Five different reviews surveyed the pharmaceutical aspects of aerosols (345–349). Another review summarized the function and application of aerosol packaging in pharmacy and medicine (350). Scriba and Hearn presented an outline on current government requirements for packaging and labeling aerosols (351); the hazards of transporting and storing aerosols and their hazards and toxicity during use have also been discussed (352). Some of the operation and maintenance problems associated with processing aerosols with slow-filling valves with a large propellant charge were disclosed (353). Another paper recommended the application of a statistical quality control procedure to a quality assurance program to improve the efficiency of an aerosol filling operation (354).

A review with 144 references considered the topic of monodispersed aerosols (355). Methods were revealed for selecting the best solvent and propellant for achieving a specific desired effect (356). Johnsen and Haase examined the scope of noncondensable gases as aerosol propellants and the data required for the efficient introduction of such gases by the gasser-shaker method into specific products (357, 358). Another discussion was concerned with the effect of transport and storage on aerosol dispensers, propellants, container construction, dispension methods, and protective covers (359). Additional experimental data have indicated a correlation between aerosol product weight loss from leakage through the valve gasket and the choice of propellant, solvent, valve type, and gasket material (360). At 130° F. the reaction of propellant 11 with water was catalyzed by metal (361). The solubility of some lanolin derivatives decreased but at least one increased with storage in pressurized formulations (362). No direct relation was observed to exist between the dispersion of the aerosol and the surface tension, but the dispersion did depend on the salt concentration and the relative humidity of the compressed air used for atomization (363). Also, it was noted that careful control of the formula, the type of actuator, and valve can be used to adjust the chilling effect of aerosol sprays on the skin (364).

Packaging.—Autian reviewed potential problems of packaging cosmetic products with plastic materials (365). A commentary was also presented on mechanical packaging machines available for use in the hospital pharmacy (366). The merits of polyethylene, the plastic most frequently used in cosmetic and pharmaceutical bottles, were examined in detail (367). Other papers were concerned with the application of aluminum containers for packaging pharmaceuticals (368) and suggested methods for the sampling of acceptable metal containers (369). Various manufacturing, packaging, analysis, and control operations for the continuous production of glass vials by a mechanized process have been delineated (370). Coring, permeability, sorption, and leaching were considered the most pressing problems in present closure applications; comments were offered regarding specific areas of improvement in each of these functions (371). Natural

and synthetic rubber stoppers were tested for turbidity, pyrogens, color, metal content, and reducible materials (372). The sorption and diffusion of formic, acetic, propionic, and butyric acids into nylon 66 has been investigated at a number of temperatures and concentrations (373). A similar binding study of sorbic acid with nylon 66 indicated the interaction is primarily one of hydrogen bonding at the amide linkage (374). Sedova *et al.* compared the effect of some rubber stoppers on the quality of injectable solutions during a 12-month period of storage (375). Two brands of disposable syringes selected at random were examined and found to yield two different types of water-soluble extractives (376). Another study indicated that rubber closures were the source of a precipitate found in physiological saline solutions (377). Other investigators recommended a procedure for screening toxicity of plastic materials based on a tissue culture method using monolayers of strain L 929 mouse cells in modified Eagle's medium (378).

A review, citing 49 references, on investigations and standards pertaining to plastic equipment for the collection, storage, transportation, and administration of blood was published with special reference to toxicity problems (379). Two different investigations designed methods for studying the permeability of films and plastic-coated papers (380), and cellulosic or plastic barrier materials, packages, and closures (381). The permeability to water and the stabilities of ascorbic acid and potassium permanganate in several plastic containers were explored by Kimura and co-workers (382). The stability of an enzyme preparation, amylase, was greatly influenced by its packaging material; the activity at 20° and 90% relative humidity decreased in the order of: glass > glassine paper laminated with polyethylene > paper > waxpaper (383). Fluoride solutions in glass containers of aluminum have been stabilized by the addition of EDTA and aluminum chloride (384). Some unique surface tests were utilized for studying the neutrality of glass ampuls for injectable fluids (385). Aluminum tubes provided better protection for anhydrous and hydrated ointment bases containing vegetable oil than orange glass jars (386). Brown tabulated a list of 17 ultraviolet light absorbers used to stabilize plastic packaging materials (387).

EQUIPMENT

Three separate papers discussed automation in the pharmaceutical industry (388–390). Hill published an article on evolutionary operation (EVOP) as a technique for in-plant optimization (391), while Maatman reviewed some of the factors important in the industrial handling and moving of materials (392). Three other investigators evaluated the Sterilab for dispensing sterile products (393). The operation of a simple liquid flow recorder designed to handle a few drops per minute or 50 ml./min. has been revealed (394). The Littleford-Lodige mixer was studied as a method for achieving high-efficiency solid-solid blending; its application as a wet-formulation device was also briefly investigated (395). One other mixer, a stirred flow reactor type, was also tested for its mixing efficiency (396).

A simple constructed device fabricated from materials common to most laboratories was designed for the control of water baths used for nonisothermal studies (397). Another apparatus was developed which permitted rapid determination of thermal diffusivity in foods. A description of its limitations and sources of error was also included (398). Larkins *et al.* described a new automatic recording multigradient capillary viscometer (399). Other workers invented a simple device for measuring the thickness of agar in a Petri dish (400) and illustrated the construction and use of a versatile hot stage microscope for determining phase diagrams of inorganic mixtures (401). During a study on the surface properties of soybean lecithin, a modification of the Wilhelmy or vertical-type film balance was disclosed which is believed to offer certain advantages over other standard film balances (402). One other apparatus has been described for compressing and expanding insoluble monolayers or films present at an oil-water interface (403). A new design was presented for an improved mass-transport cell for the measurement of electrophoretic mobility of concentrated suspensions of particles (404). In addition, a new counter for emulsion photomicrographs was depicted (405). Two papers discussed automated techniques for determining dissolution and reaction rates of antacids. They provided a rapid and accurate profile of the dissolution and reaction rate in addition to the total acid-consuming capacity of the antacid system (406, 407). A new device, called the Heidelberg capsule, has been proposed to telemeter gastric pH (408). The specifications, operation, and production rate of a new encapsulating machine for soft shell products has also been assessed (409).

PHYSICAL PHARMACY

Many pharmaceutical problems were solved through physicochemical means. The theoretical aspects of solid solutions and eutectic mixtures and their application to pharmaceutical systems were discussed by Goldberg, Gibaldi, and Kanig

(410). Other researchers found that the choice of plastic, weight of drug incorporated in the matrix, solubility of the drug used, matrix additives, and the solvent could markedly affect the release rate of drugs from plastic matrices (411). The diffusion coefficients of several physiologically active compounds have been determined in cross-linked thiolated gelatin films (412). It has been shown that stress relaxation effects of gelatin films cross-linked with oxystarch or difluorodinitrobenzene may be represented by the sum of three exponential rates of stress decay (413). Some viscoelastic properties of keratin and collagen fibers immersed in aqueous media have been measured at frequencies between 1 kc./sec. and 20 kc./sec. and at temperatures between 0 and 100° (414). The penetration of chlorpromazine and chlorpromazine sulfoxide into insoluble monomolecular lipid films depended on the surface characteristics of the lipid, pH, and the ionic strength of the underlying solution (415). Additional studies were concerned with the relation between the diffusion coefficients and the electrolytic properties of membranes (416). Measurements of the tensile strength of dry powders of irregular particle shape have been made using a split tilting-plate apparatus based on that described by Thouzeau and Taylor (417). Johnson and co-workers studied the distribution of phenol between water and carbon tetrachloride and the solubility of water in solutions of phenol in carbon tetrachloride (418). Another paper presented a novel means for achieving a superior degree of carbonation with sodium bicarbonate in various latentiated acidifiers (419). The rate of neutralization of hydrochloric acid by dispersed calcium carbonate powder has been examined as a function of pH, temperature, and particle size (420). A tartaric acid buffer has been shown to form a reactive intermediate in aqueous solution capable of rapidly acylating any nucleophilic compound present (421).

Ionization.—The absence of a primary kinetic isotope effect in DMSO was the subject of a paper on ionization rates of weak acids (422). Another article described the mechanisms for the acid dissociation of vitamin B_{12} (423). The acid-base behavior of ephedrine isomers and their oxazolidine derivatives in aqueous and nonaqueous media has been described in detail (424). Also, a new technique was described for measuring the rates of ionization of carbon acids (425).

Solubility.—Wurster and Taylor reviewed the theory of dissolution and methods of study in a paper with 74 references (426). A novel method was developed for determining dissolution rates of multiparticulate systems (427). One other *in vitro* continuous dissolution rate measuring method has been designed and evaluated for determining the dissolution rates of labeled materials from solid dosage forms (428). Results obtained with this method were compared with dissolution rates of similar dosage forms using the U.S.P. disintegration apparatus and the rotating bottle method. An improved holder for rotational disk dissolution studies has been used to determine the relative intrinsic dissolution rates of caffeine monohydrate, aspirin, salicylamide, and acetaminophen (429). The crystal behavior, solubility, and dissolution rates of two anhydrous and one hydrated form of prednisolone in aqueous solution have been investigated (430). The theory for the dissolution rate of polyphase mixtures was probed and applied to several situations involving simultaneous diffusion and rapid equilibria (431). The rate of dissolution of boric acid in aqueous solutions of polysorbates was examined (432); another study explored the effect of complex formation on the dissolution kinetics of *m*-aminobenzoic acid (433). Danckwerts' penetration model was employed to derive equations to explain the theory for the dissolution of solids in a multiparticulate system (434). The dissolution behavior of a weak acid, 1,1-hexamethylene *p*-tolylsulfonylsemicarbazide, and its sodium salt in phosphate buffers has been evaluated by Higuchi *et al.* (435).

One other new method was described for determining the dissolution rate of fine particles of crystalline hydrocortisone acetate (436). A study relating the *in vitro* dissolution rates and solubilities of 45 different compounds representative of various chemical species supported the theory that the initial rate of dissolution of a compound is directly proportional to its solubility (437). In addition, dissolution studies were conducted on both the one-to-one molecular compound and mechanical mixtures of sulfanilamide and sulfathiazole at 15, 25, and 35° (438). As part of a program on the transport, deposition, and dissolution of cholesterol in aqueous medium, the growth, dissolution rates, and nucleation behavior of this compound in saline have been studied by following changes in particle size with the Coulter counter (439). In a similar study, the Coulter counter was used to test the influence of cholate on the precipitation behavior of cholesterol in aqueous media as a function of pH (440).

A new technique has been proposed for determining the solubility product constant (441). Dielectric constants of water–ethanol–sucrose and water–ethanol–sorbitol systems have been experimentally determined and found to be a complex function of composition expressed as weight per

cent (442). The solubilities of acetanilide, *p*-methylacetanilide, *p*-ethoxyacetanilide, aminopyrine, and antipyrine have been measured in dioxane–water mixtures of known dielectric constants (443, 444). Some solubility anomalies were compiled for actinomycin D (445). The water solubilities of five different barbiturates were ascertained by liquid scintillation counting of ^{14}C-tagged compounds using the technique of phase solubility analysis (446). Four different procedures were employed to determine the solubility of cholesterol in water (447). A critical concentration for the solubility of cholesterol chlorobetainate in aqueous solution was detected by specific conductivity, refractive index, and activity coefficient determinations (448). The solubility of iodine has been studied in a series of solvents (449). Nakatani reported on the solubility of compounds related to orotic acid in amine solutions (450). Tagged ^{14}C-pentaerythritol tetranitrate was utilized in determining the solubility of this compound in water and saline (451). Another presentation compared the solubility of polysorbates in simple syrup, glycerol, and propylene glycol (452). The solubilities of several xanthines, including caffeine, theophylline, and theobromine, were examined in dioxane–water mixtures; the solubility curves that were obtained showed a multiplicity of peak solubility values (453). A different type of study provided data on the solubilities of thin films of polyethylene, polypropylene, and polystyrene in many liquid drugs (454). Other investigators studied the solubility of compressed gases in fluorocarbons (455).

Swarbrick published a review article outlining the physicochemical properties of surface-active agents in solution with particular reference to solubilization of materials of pharmaceutical interest (456). One investigation determined the usefulness of test systems consisting of aqueous solutions of anionic surfactants and an excess of ^{14}C-cyclohexane in studying effects related to solubilization (457). The solubilization of several aliphatic and aromatic acids in aqueous solutions of cyclopentamine hydrochloride, ephedrine sulfate, and propoxyphene hydrochloride has been demonstrated (458). A potentiometric method was applied to a study of the solubilization of benzoic acid in systems containing anionic (459) and nonionic (460) surfactants. Another study was concerned with the interaction of urea in varying concentrations with three isomeric monohydroxybenzoic acids (461). The solubilizing capacities for camphor of one anionic, one cationic, and three nonionic surfactants have been investigated and determined by measuring the areas under ultraviolet absorption peaks (462). The use of Z values was proposed as a method for measuring the polarity of the environment in a study on the solubilization of camphor in polysorbate 20 (463). Sorbitan trioleate increased the solubility of hydrous ephedrine alkaloid in liquid petrolatum (464). The effect of various polysorbates on the solubility of sulfanilamide in several different solvent systems was ascertained by Khawam, Tawashi, and Czetsch-Lindenwald (465, 466). Aqueous solutions of urea, 1-acetyl-3-methyl urea, and 1,3-dimethyl urea were discovered to increase the water solubility of testosterone and some other related steroids if the 17-hydroxyl group of the steroid was free (467). The effect of urea on the aqueous solubility of six different dye compounds in water has also been compared (468). In addition, the solubility of theobromine has been increased and stabilized by the addition of various polysorbates in tragacanth mucilage (469).

Complexation.—The formation of copper complexes of sulfur drugs was discussed by Lee (470). Acid dissociation and copper(II) chelate formation constants were compared for glutamic acid and several of its derivatives (471). Data were presented which suggested that coordination complexes may be of major importance in the biological phenomenon of binding with catecholamines (472). Stability constants for complexes of tetracycline with cupric ion have been published (473). An *in vitro* enzyme kinetic study was used to determine the nature of the inhibition of acetylcholinesterase by cupric chelates of glycine and ethylenediamine (474); also, the inhibition of acetylcholinesterase by 1–1 cupric chelates of ethylenediamine and glycine was analyzed and shown to be essentially a noncompetitive type (475). Complexes formed by adrenaline and related compounds with transition metal ions were studied by Jameson and Neillie (476). The inactivation of tetracycline with a cupric–morpholine complex was investigated in another binding study (477). Gel-filtration, ultra-filtration, and ultra-centrifugation were used to study the nature of an iron–dextran complex (478).

Oxytetracycline was shown to form fluorescent complexes with proteins *in vitro* (479); the binding of sulfonamide to serum albumin was also investigated in a similar study (480). Protein binding of radioactive vitamin D_3 added to serum *in vitro* or present in dog serum after intravenous injection has been studied by a variety of methods (481). The interaction of cortisol with bovine

and human serum albumin was observed by an equilibrium dialysis procedure (482). Protein binding of salicylates by rat liver, kidney homogenates, plasma proteins, globulins, and albumin was tested by Stafford (483). Also, the serum albumin binding of several structurally similar xanthine derivatives was evaluated by a spectrophotometric technique (484).

One investigation was conducted to ascertain the interaction of a group of compounds, used in medical and pharmaceutical practice, with several types of insoluble polyamides used in containers or devices for storing or administering drug products (485). The interaction of parachlorometaxylenol with macromolecules was determined by solubility and dialysis procedures (486). An electrophoretic technique was used to illustrate the interaction occurring between sodium carboxymethylcellulose and both methylcellulose and polyacrylamide (487). The interaction between poly-*N*-vinyl-5-methyl-2-oxazolidinone and certain pharmaceuticals in aqueous solution was reported (488). A complex interaction of potato and arrowroot starches with certain drug pharmaceuticals has been noted by Goudah and Guth (489). The binding of certain benzoic acid derivatives by polysorbate 80 and cetomacrogol 1000 was determined by means of an equilibrium dialysis technique (490). An investigation of the binding of polyethylene glycol to carboxymethylhydroxyethylcellulose was also disclosed (491). The hemolytic activity of phenolic preservatives was prevented by their interaction with polyethylene glycols (492).

The reaction of some salts of rare earth metals with group B vitamins has been revealed (493). Another study assessed the interaction of a series of phenyl-substituted carboxylic acids with Schardinger dextrins (494). The equilibrium reactions of caffeine and nicotinamide with lidocaine and saccharin were studied (495); also, flavins and phenols were found to form 1:1 molecular complexes in neutral solution (496). A spectropolarimetric method of determining stability constants of complexes formed through hydrogen bonding has been developed and applied to a camphor–phenol system (497). Gas chromatography was employed during a complexing study of quinine and quinidine with urea, thiourea, and diethylthiourea (498). The binding of chlorpromazine and thioproperazine to rat liver and human leucocytes was reported by Teller (499). The reaction between pyridoxal phosphate and cycloserine has been evaluated (500). Wadke and Guttman presented evidence to indicate that the complexed form of isoalloxazine was resistent to hydrolytic decomposition (501). Complex formation between chlorpromazine and adenosine triphosphate was believed to occur because the surface tension was lowered in the presence of adenosine triphosphate which is not surface active (502). Complex formation involving *cis* hydroxyls in an axial-equatorial position between carbohydrates and dimethylsulfoxide was revealed by proton magnetic resonance data (503).

A study of adsorption complexes formed by the interaction of sodium dodecyl sulfate with gelatin at pH values below the isoelectric point was described (504). Complexation between 1,3,5-trinitrobenzene and several local anesthetic compounds was demonstrated; it was suggested that the amine group was the primary site of reaction, with the tertiary amine taking precedence when present (505). A dark reaction between citrate and iodine was detected by two investigators (506). In addition, Rodgers followed the interaction of hexylresorcinol and amaranth with quaternary ammonium compounds by a conductimetric titration procedure (507). Other studies were concerned with structural determination of complexes by ultrasonic waves (508).

Surface Phenomena.—A review of the basic concepts involved in wetting and adhesion processes was reported by Gray (509). Another review discussed the theory on coagulation of noninteracting particles in Brownian motion (510). Other surveys covered colloidal dispersions, electrokinetic effects, the concept of ζ potential (511), and the coagulation of colloidal powders (512). Higuchi, Rhee, and Flanagan studied the rates of aggregation of polystyrene and polyvinyltoluene particles in aqueous ionic surfactant solutions (513). Solutions to equations for the kinetics of coagulation were analyzed by other workers (514); a mathematical analysis has also been made of two chemically interacting macromolecules settling in a liquid solvent under one-dimensional electrical and cylindrical centrifugal forces that were sufficiently large to overcome diffuse forces (515). Centrifugation current was used to determine the electrokinetic mobility of several electrolytes in the aqueous phase of water-in-heptane emulsions (516). The streaming potential of sulfisoxazole, sulfadimethoxine, and *N'*-acetylsulfisoxazole was measured with Hazel-type cells in sucrose, sodium chloride solution, and sodium chloride in 10% sucrose solution (517).

Two different reviews on the physical chemistry of nonionic detergents have been published (518, 519). Also, a survey on the evaluation of anionic and nonionic emulsifiers according to HLB values was reported (520). The adsorption of three quaternary ammonium salts, having the same

chain length and counterion but differing in the polar group, was measured at the air–water interface (521). The effect of solvent on micellar properties of nonionic surface-active compounds was investigated (522). A conductimetric method was used for determining the critical micelle concentration of sodium decyl and dodecyl sulfates in the presence of sodium chloride (523). Phares predicted reductions in water–air, oil–air, and water–oil interfacial tension produced by nonionic surfactants by using a form of the Langmuir adsorption equation (524). The influence of the sodium chloride concentration on the adsorption of sodium dodecyl, sodium decyl, and sodium octyl sulfate solutions at an air–water interface has been evaluated (525). The Griffin HLB method was utilized to determine the possibility of emulsifying 10 different emulsifiers having HLB values in the range 8–13 (526). The effect of additives on the foaming properties of very dilute surfactant solutions has been reported (527). Some of the physical properties of a series of nonionic detergents with branched hydrocarbon chains of the general formula, $R_2—CH—CH_2O(CH_2CH_2O)_6H$, were described (528).

The adsorption of water on clays was reviewed in a paper with 151 references (529). The relationship between some electrical and thermodynamic properties of adsorbed water on two montmorillonites, a silica gel, and a window glass powder was studied at room temperature (530). The specific surface area of suspensions of montmorillonite and the average thickness of their diffuse double ionic layer were reported (531). The sorption of methylene blue and methylene violet on Fintia bentonite processed by various methods was investigated (532). Bentonite clays have been activated by treatment with 10% hydrochloric acid while heating to improve their adsorptive and catalytic properties (533). Packham examined the coagulation of dispersed clays with hydrolyzing salts while carefully observing the effect of the nature and concentration of clay, pH, and the presence of various ions (534). The adsorption of water on ion-exchange montmorillonite has been discussed (535). It was noted that the heat of wetting of sodium and potassium bentonite was not greatly affected by the addition of small amounts of polyacrylamides (536). Other results were presented which showed clear evidence of discrete charges on clay surfaces (537). The adsorption properties of bentonite clay with regard to vitamin E were considered (538); the adsorption of phenol, *p*-cresol, *p*-nitrophenol, 2,4-dinitrophenol, and puric acid on Fuller's earth was determined (539). The influence of hydrogen ions on the adsorption potential and surface tension of barbital, aminopyrine, and veramon was disclosed in other studies (540). A summary of the effects of the method of preparation on the surface properties of silicas has been presented (541), and the adsorption properties of silica gel precipitated in the presence of some alkaloids has been investigated (542). The reactivities of the surfaces of muscovite, montmorillonite, and chrysotile-asbestos were also explored (543). In addition, Rohdewald evaluated the effect of glycerol, sorbitol, hydrochloric acid, sodium chloride, anionic, cationic, and nonionic surfactants on the properties of talc suspensions (544).

Blaug and Gross reported on the *in vitro* adsorption of nine different anticholinergic drugs by six antacids (545). Steroid adsorption by polyethylene tubing was noted by other workers (546). The critical micel'e concentrations of oxyethylene-oxypropylene polymers were assessed by surface tension and two different spectral absorption methods (547). Additional studies were conducted on the thermodynamic function of the sorption of vitamin B_{12} by the salt forms of sulfo resins (548). The dispersion of inorganic pigments was improved by surface treatment (549). Polypropylene glycols with molecular weights of about 2000 had the highest surface activity and strongest dye dispersing effect (550). It was concluded that with most hygroscopic materials used in pharmacy, the process of water vapor sorption starts to be active in an atmosphere with 50% relative humidity (551). The measurement of interfacial areas of foams and froths has been carried out by a radiographic technique (552). A technique involving reiterated approximations and a high digital computer was employed to solve the problem of surface tension measurement by the Pendant drop technique (553). The hydrophile–lipophile balance of surface-active substances has been determined by a calorimetric technique (554).

Crystallization.—A review of ultrapurification methods based on zone melting appeared in the literature (555). Nickolics, Bidlo, and Nikolics explored the influence of solvents on crystal structure of resorcinol, sulfathiazole, acetylsalicylic acid, phenacetin, barbital, and phenobarbitol (556). The precise crystal and molecular structure of α-D-glucose by neutron-diffraction analysis was ascertained (557); and the crystal and molecular structure of 1,3-dihydro-1-hydroxy-3-oxo-1,2-benziodoxole was determined by X-ray crystallographic methods (558). Polymorphism in potassium sulfate and thallium sulfate has been reported (559). The physical

properties of various anhydrous and hydrous forms of ampicillin were noted (560). A number of compounds were tested for their inhibitory effect on the needle axis growth rate of sodium acid urate crystal (561). Other data revealed the effect of temperature on the linear crystallization rate of salol, betol, salipyrine, antipyrine, and codeine (562).

Rheology.—A new flow equation for pseudoplastic systems was described by Cross (563). An electrical method has been suggested for determining the areas of hysteresis loops (564). A new viscometer was designed for measurements on dilute polymer solutions but could be equally well used for other liquids (565); also, another new glass rotatory viscometer was recommended for certain rheology studies (566). Hiller reported on the effects of temperature and pressure on the rheological behavior of montmorillonite sols (567). The rheology of silica suspensions was investigated as a function of concentration, particle size, polarity of organic solvents, and the pH and ionic strength of the aqueous phase (568). The factors affecting the rheological properties of clay suspensions were observed in another study (569). The thixotropic behavior of "alki" bentonite suspensions (570) and the physicochemical and technological properties of two kaolin varieties were presented (571). The rheology and suspension characteristics of carboxymethylhydroxyethylcellulose–polyethylene glycol systems, evaluated by means of the power law equation, were outlined (572). The concentration dependence of the steady flow viscosity was discussed for aqueous solutions of high viscosity hydroxyethylcellulose (573). The elastic properties of the particle network in gelled solutions of carboxymethylcellulose have been recorded (574). A treatise was published discussing critical gum solution properties that may be determined through analysis (575). Sugar, when used at high levels, offered a means of providing a delay in the development of the viscosity of guar gum formulations (576).

Procedures and instrumentation have been devised for measuring the stress-relaxation modulus of melts employed as soft gelatin encapsulating formulations (577). Other workers explored the viscosity and stability characteristics of the system ascorbic acid–water–polysorbate 20 (578). The flow properties at 25° of concentrated (30–42%) dicalcium phosphate dihydrate paste suspensions and model systems were determined using a concentric cylinder, cone plate, and capillary extrusion viscosimeter (579); in other studies, the thixotropy and dilatancy in complex emulsions and suspensions were investigated (580). Higuchi and Stehle tested the rheometric properties of silica suspensions in dibutyl phthalate, hexadecane, mineral oil, ethylene glycol, and mixtures with and without different surfactants (581). An apparatus, consisting of a sedimentation tube and capillary viscometer, was designed for particle size determination of suspensions and emulsions (582). In one study, the basis and conclusions for rheological characterizations of some pharmaceutical adjuvants were reported (583). The swelling, hygroscopicity, and viscosity properties of bentonite suspensions caused by water absorption were also evaluated (584).

PHARMACOCHEMICAL ASPECTS

This section of the review considers many of the papers on polymers, antibiotics, and radioisotopes which might be of interest to the pharmaceutical scientist. It is not intended to encompass the vast area of pharmaceutical chemistry concerned with synthesis, structure-activity studies, reaction mechanisms, analysis, etc. These related disciplines are reviewed annually in other publications and are, therefore, omitted from this report.

Polymers.—Rodrigues and Barrosa reviewed the current status of polymers of pharmaceutical interest (585). Good agreement was found between theory and experimental data for the stress cracking of high-density polyethylene in octylphenoxy polyethoxyethanol examined from the viewpoint of critical strain (586). An attempt was made to develop a means of assessing the order in an amorphous polymer from density measurements (587). A discussion has been reported on some of the factors responsible for high thermal stability in polymers along with some results of thermal degradation studies on an aromatic polyimide (588). In another investigation, the melting points of polyethylene crystals and the relation between molecular length and chain folding were presented (589). Also analyzed was the effect of changes in structure on chemical reactivity, the effect of structure on physical properties, and the basic principles of a chain reaction mechanism in polymerization (590). Cooper discussed the toxic dangers and disadvantages of plastic materials used in pharmaceutical systems (591).

The effect of the structure of sulfonated polystyrene ion-exchange resins on the sorption of oxytetracycline and chlortetracycline ions has been investigated (592). Measurements of the swelling ratio and exchange capacity of individual ion-exchange resin beads were used to compare resin samples, to study interparticle differences,

and to help characterize resin degradation (593). Lappas and McKeehan employed several esters of poly(ethylene–maleic anhydride) and poly(vinyl methyl ether–maleic anhydride) as coatings to control the release of drugs upon reaching a specific intestinal pH (594). The use of polyvinyl alcohol as a solvent for pilocarpine ophthalmic solutions was reported in publications by different authors (595, 596). A method for preparing an aqueous colloidal dispersion of organic materials such as β-carotene by using water-soluble polymers like polyvinylpyrrolidone has been revealed (597).

Antibiotics.—Reviews on the chemistry and pharmacology of penimepicilina, a new broad-spectrum antibiotic (598), and on the problems and investigative methods of antibiotic binding by blood serum proteins appeared in the literature (599). The properties of some new antibiotics, cephaloridine (600), kasugamycin (601), and copiamycin (602), were disclosed. Also, the preparation and isolation of anhydroerythromycin (603), antibiotic R-12 (604), neohumidin (605), and lemonomycin (606) have been reported. In addition, a new antifungal antibiotic, trichodermin from *Trichoderma viride* was described (607).

The activity in experimental infections, absorption, and elimination of rifamycin B diethylamide in man have been examined (608); also, the *in vitro* activity, absorption, and excretion of cephalothin in normal subjects have been reported (609). Garrett and Miller showed the generation rate constants for viable counts of *E. coli* were linearly dependent on the concentration of tetracycline and chloramphenicol (610). Definitions, standards of identity, strength, quality, purity, tests, and methods of assay were given for dactinomycin (611). A scheme of classification for the antifungal antibiotics of the pentaene group has been presented (612). Gentamicin was tested *in vitro* against 889 strains of pathogenic bacteria (613).

Radioisotopes.—Radioisotopes in pharmaceutical technology were surveyed (614) along with the production of radioactive isotopes for medical use (615). With the exception of the field of chemical kinetics, a brief survey has been presented of the principles of isotope chemistry and their utility in the ever unfolding panorama of scientific research (616). Another brief review was conducted on the preparation and analytical control of radioactive chemicals of the 16th revision of the U.S.P. and the "British Pharmacopoeia" 1958 (617). The preparation of colloidal solutions of zirconyl phosphate with ^{32}P for radiotherapeutic purposes was described (618). The influence of the sample volume on weak β-counting efficiency at 0° in liquid scintillation counting has been reported (619). The factors influencing the loss of ^{14}C from labeled carbonates were published (620); corrections for grain count in autoradiography were also determined (621).

BIOPHARMACEUTICS

The area of biopharmaceutics considers research efforts directed toward studying the influence of pharmaceutical formulations on the biological activity of drugs. Numerous review articles appeared in the literature. Mann cited 144 references while discussing biological aging and its effect on modification of drug activity (622). The evolution of new concepts on the mechanism of drug action was presented (623). Other topics of review included the absorption of pharmaceuticals by diffusion (624) and transport phenomena in artificial membranes (625). A two-part review covering factors influencing drug distribution in the body and pharmacokinetics also appeared in the literature (626, 627). The mechanism of enzyme and hormone actions was the subject of another review (628). In addition, the theoretical aspects of diuresis and the various therapeutic classes of diuretics were surveyed (629).

The kinetics of drug transfer from a buffered aqueous phase through a lipid phase to another aqueous buffered phase were studied (630). The development of a unified statistical mechanical theory of transport across a membrane model in liquid mixtures and electrolytes was discussed (631). A molecular basis for drug activity was considered (632), while the use of quantum chemistry in drug design was explored by Schnaare and Martin (633). On the assumption that the potassium content of the body cell mass remains constant, it has been possible to estimate body cell mass by measuring ^{40}P activity with a whole-body scintillation counter (634).

Milne discussed the potentiation of excretion of drugs (635). Analog computer studies resulted in an equation that can be used to predict the average asymptotic blood levels during a multiple-dose regimen from basic parameters estimated from single-dose studies (636). A theoretical relationship between dose, elimination rate, and duration of pharmacologic effect of drugs has been suggested (637). The importance of the route of administration was demonstrated in the pharmacodynamics of the antitussive action of codeine and ethylcodeine (638). Three unique, new, highly reactive polymeric compounds of magnesium aluminum oxy hydroxide showed 50–60% more antacid activity than presently known aluminum-magnesium antacids (639).

Effects of Physicochemical Properties.—A review, with 21 references, on physicochemical studies of membrane permeation concerned with absorption and excretion of drugs appeared in the literature (640). It was shown that calcium and pH influence the absorption rate of tetracycline and three of its derivatives (641). The water-insoluble salt, lincomycin hexadecylsulfamate, provided greater absorption and activity than the water-soluble salt, lincomycin hydrochloride (642). Poole, Zeigler, and Dugan demonstrated no significant increase in aluminum blood levels after oral ingestion of a water-soluble aluminum complex, potassium glucaldrate, in normal subjects or in those requiring antacid therapy (643). Certain members of some metal-acid complexes of tetracycline and demethylchlortetracycline resulted in higher blood levels (644). Particle size effects were discussed in relation to formula modifications (645); and the effect of griseofulvin particle size reduction was also determined in relation to drug excretion and absorption (646, 647). The *in vivo* distribution of colloidal chromic radiophosphate having different particle sizes has been studied following intravenous, intramuscular, and intracavitary injection into mice (648). The proportion of a sulfisoxazole dose absorbed did not vary with particle size, but the rate at which this proportion was absorbed did change (649). A correlation between the relative percutaneous absorption of topical corticosteroids and the physical properties of solubility and partition coefficient has been revealed (650). The release of steroids from a topical vehicle was stated to be independent of, and uninfluenced by, the presence of a second noninteracting component (651). Wide individual fluctuations were observed in studies on the influence of the rectal route for the administration of sulfonamides for therapeutic purposes (652). A unique relationship has been discovered between the molecular weight and biological effect of dextran (653). When administered to cats, in quantities representing Hatcher doses, there was a proportionality between the absorption rate and the lipid solubility of various lanata glycosides (654).

Effects of Formulation.—Wurster reviewed some of the factors related to the formulation of medicinals for percutaneous absorption (655). Tablet disintegration and physiological availability of drugs were also surveyed in an article containing 58 references (656). The oral absorption of salicylates was found to be a function of the intrinsic rate of dissolution which was affected by formulation parameters such as particle size, disintegrants, and lubricants (657). Incomplete absorption of aspirin was attributed to an excessively low dissolution rate of the dosage form (658). The importance of dissolution rates in producing effective diazoxide blood levels in man was outlined following administration of solutions, capsules, and tablets (659). A method for the evaluation of antimicrobial activity of a bacteriostatic agent in the presence of a surfactant was described (660). Another study disclosed the relationship between the concentration of a surfactant, polysorbate 80, and the rate of absorption of a drug, salicylamide, from the small intestine (661). Modification of *in vivo* promazine absorption by activated attapulgite and activated charcoal in humans using urinary excretion measurements has been demonstrated (662). Three different dosage forms, namely a liquid concentrate, regular sugar-coated tablets, and substained-release preparations, did not influence thioridazine blood levels (663). Only one-fourth to one-third of orally administered tetracycline was absorbed compared to the amount absorbed after intravenous administration (664). A complex model was presented to illustrate the pharmacokinetic parameters related to the absorption, metabolism, and elimination of nalidixic acid in man (665). The absorption and elimination of salicylic acid was investigated after i.m. injection of aluminum aspirin in a neutral oil (666). Serum salicylate levels were also used to evaluate the relative release rate of aspirin from a commercial aspirin tablet and from a hard gelatin capsule (667). Significant differences in blood levels were found for three different theophylline elixirs (668). Additional studies analyzed the effect of viscosity on the gastric absorption of ethanol and salicylic acid (669).

Indomethacin was absorbed satisfactorily from rectal polyethylene glycol suppositories according to blood level studies (670). A preliminary report on drug absorption from the rectum appeared in the literature (671). Suppository administration of theophylline *p*-aminobenzoate of piperazine provided a rate of absorption equal to, or less than, the rate from an equivalent tablet dosage form (672). The pharmacokinetics of rectal application of 4-sulfanilamido-5,6-dimethoxy-pyrimidine has been published (673). The rectal absorption rates of sulfonamides were reduced by water-soluble bases (674). Nonionic surface-active agents were found to decrease the rectal absorption of sulfonamides; this effect was the result of the micelles being too large to pass through the rectal membrane (675). Comparative studies were carried out on the *in vitro* and *in vivo* release of salicylates from fatty suppository bases (676). Anhydrous lanolin increased drug release when cocoa butter was employed as the

fatty suppository base (677). Cod liver oil and polyethylene glycol bases aided in the penetration of chlortetracycline through intact rabbit skin (678). The percutaneous absorption of an ^{35}S-sulfonated polygalacturonic acid from an oil-in-water emulsion base has been determined *in vivo* by following its disappearance after topical application (679). The cutaneous absorption of *S*-dicarbethoxythiamine was studied from various ointment bases (680). A diffusion study of sulfacetamide and sulfathiazole from three different ointment bases through a membrane into water has been reported (681). Dempski and co-workers discussed an *in vitro* study for testing the relative moisture occlusive properties of several topical vehicles and Saran wrap (682). The percutaneous absorption of heparin from commercial ointments was evaluated (683). A new microbiological "agar tube" method has been developed for measuring the release of antibacterial agents from various ointment bases (684). Several unique factors influencing the topical absorption of idoxuridine were demonstrated by Shell (685). One publication presented the pharmacological evaluation of certain ointment bases (686). The diffusion of neomycin from several ointment bases was examined (687); and the absorption of radioactive salicylic acid from 10 ointment bases was also considered (688). The diffusion of iodine and salicylic acid was studied from 29 different ointment bases by impasting the ointment on an agar-gel disk which contained starch solution or ferric chloride (689). In studies concerning the importance of the vehicle for percutaneous absorption, a small uptake of resorcinol and boric acid was noted, but phenol and salicylic acid were readily absorbed, especially from aqueous solutions (690).

Blaug and Canada observed the relationship of viscosity and contact time on the prolongation of action of methylcellulose-containing ophthalmic solutions (691). The intestinal absorption of certain water-soluble acidic dyes and some of their lipoid-soluble complexes has been investigated (692). An investigation of the effect of solubilization of phenobarbital and several other barbituric acid derivatives on *in vitro* and *in vivo* release rates was discussed (693). Succinic acid was found to promote the absorption of iron from the alimentary tract (694); other authors were concerned with the biological availability of riboflavin solubilized with sodium salicylate (695). The onset of action of tubocurarine has been studied in a program evaluating the skin penetrating properties of drugs dissolved in DMSO and other vehicles (696).

Absorption Control.—*In vitro* dissolution tests were developed which correlated quantitatively with dissolution rate-limited drug absorption in man (697). One investigation was noted on the effect of certain tablet formulation factors on *in vitro* drug release and *in vivo* drug absorption (698). Several authors studied the absorption of aspirin from enteric-coated preparations (699–702). Slow-release tablets of ferrous sulphate showed extremely variable absorption when compared to standard ferrous sulphate therapy (703). A radioisotopic technique for determining the efficiency of an enteric-coated tablet *in vitro* was found to be superior to the U.S.P. method (704).

A review of the effectiveness, safety requirements, rational, and clinical pharmacology of prolonged-release drugs was published (705). Frederik and Cass discussed some principles of the clinical evaluation of sustained-release drugs and suggested clinical methods to determine their duration of action (706). Other researchers observed that the action of procaine, isoniazid, sulfamidochrysoidine, and benzocaine was prolonged by combining them with polymers of dextran (707). Sustained-release aspirin formulations have been evaluated by several researchers (708–710). The sustained-release action of polyvinylpyrrolidinone in tablets containing tetracycline hydrochloride or phenoxymethylpenicillin was examined (711). *In vitro* and *in vivo* evaluations were reported for sustained-release amobarbital tablets (712); and controlled-release nitroglycerin tablets used in the treatment of angina pectoris were also tested (713). A novel system was described in which the dissolution rate of theophylline aminoisobutanol in a prolonged-action system was utilized as a parameter of the blood level concentrations (714). The release rates of sustained-release tablets were followed automatically by employing a photometer (715); another simple apparatus was described that was based on continuous elution for the *in vitro* control of sustained-release preparations (716). By using the half-change method of artificial intestinal and stomach juices, the elution ratio of medically active substances from Bellergot tablets with prolonged action has been investigated (717).

Absorption Mechanism.—Reviews appeared covering the mechanism of absorption of weak acids and alkalies through the lipid barrier (718), and the importance of specific binding, nonspecific binding, and the role of chemical configuration of the effective substance and its receptor (719). Five different models for the transport of methionine and sodium butyrate by intracellular plasma have been described and discussed (720). A discussion of the influence of a drug on its own

absorption was outlined (721). Of particular interest was an article which presented a theoretical study of the potential effect of drug binding by plasma proteins on drug distribution (722). The mechanism of absorption of sulfonamides has been studied by measuring the rectal absorption rate in anesthetized rats (723). The absorption of methyl ethyl ketone under normal, dehydrated, and hydrated skin conditions was investigated by Wurster and Munies (724, 725).

The intestinal absorption of vitamin B_{12} was evaluated by several authors (726–729). Deferrioxamine had no significant influence on the intestinal absorption of hemoglobin iron (730); however, in other studies, desferrioxamine B reduced the intestinal absorption of iron (731). The effect of neostigmine on the intestinal absorption of sulfisoxazole (732) and the effect of acetazolamide on the excretion of sulfisomezole into human parotid saliva were explored (733). Beckett and Rowland examined the urinary excretion kinetics of amphetamine in man and showed that the excretion of the unchanged drug was dependent upon urinary pH (734). The effect of cetrimide and phloridzin on the intestinal absorption of glucose in man was disclosed (735). A significant increase in the excretion rate of sodium salicylate has been observed upon the addition of an equal amount of glucosamine hydrochloride to an orally administered dosage form (736). The modification of protein binding and urinary excretion by the simultaneous use of two drugs was reported (737). The effects of acetazolamide, sodium perchlorate, ouabain, and iodide loading on the processes controlling ^{131}I and inulin-^{14}C distribution in the brain and cerebrospinal fluid were compared in nephrectomized rats (738). Silver proteinate was found to inhibit the absorption of iodine in the rat intestine (739). Benzoyl thiamine monophosphate produced thiamine levels in humans 4 times greater than those produced by thiamine hydrochloride (740). Also, it was noted that chymotrypsin did not augment the absorption or increase the activity of an oral dose of tetracycline (741). In addition, intestinal absorption of glycine was inhibited by phlorizin but not by rutin (742), while fat absorption in rats was delayed by Triton (743).

Kinetic Studies.—The kinetic factors of the digestive absorption of drugs were reviewed in a paper citing 181 references (744). Another article commented on the theoretical aspects of the elimination kinetics for a number of model drugs which have a high affinity for plasma protein (745). Radiophosphorus, ^{32}P, was employed to determine the absorption rate of dibasic sodium phosphate from fatty suppository bases in rabbits (746). In studying the percutaneous absorption of dinitroisopropylphenol in rats, absorption increased with time to reach a maximum after 7 hr. (747). An analog computer program suitable for using blood-level *versus* time data as an input and producing *in vivo* dosage for availability *versus* time pattern as its output was developed and tested by Stelmach, Robinson, and Eriksen (748).

The determination and significance of the biological half-life of pharmaceuticals were surveyed in a review with 63 references (749). In addition, the biological half-life of several drugs appeared in the literature, namely, 140 min. for psicofuranine (750), 9 min. for noscapine (751), and 11.3 hr. for meprobamate (752). Several investigators studied the pharmacokinetics of aspirin metabolism and distribution (753–755). The utility of goldfish as test animals for evaluating biological membrane permeation led to a detailed analysis of the drug transfer kinetics for 4-aminoantipyrine (756). Data were compiled on the excretion, distribution, and metabolism of doxapram after intravenous injection into dogs (757). A new method was presented for calculating per cent absorbed *versus* time plots from metabolite blood level data (758). Also, a relation between the rate of elimination of tubocurarine and the rate of decline of its pharmacological activity was demonstrated by Levy (759).

Drug Absorption.—The influence of certain factors on the absorption and excretion of drugs was reviewed by two different authors (760, 761). Schlagel discussed the comparative efficacy of topical anti-inflammatory corticosteroids in a review article containing 219 references (762). In other studies, the excretion of ^{3}H-labeled dihydromorphine was presented (763) and whole-body liquid scintillation counting was found suitable for testing the kaliuretic properties of diuretic agents (764).

Blood levels from chloramphenicol palmitate compared well with those from chloramphenicol *per se* at equivalent dosage levels (765). After a single dose of chloramphenicol, both the biologically active form and inactive metabolites have been found in human milk (766). The absorption and excretion of erythromycin and monomycin were measured by Lagert (767), while Fischer and Riegelman evaluated the absorption and distribution characteristics of griseofulvin from other blood level data (768). The absorption, diffusion, and excretion of lincomycin has been studied following oral, i.m., and i.v. administration (769). Plasma appearance times and values of ^{47}Ca did not cor-

relate with the absorption of radiocalcium from the intestine (770). A double isotope method for the measurement of intestinal absorption of calcium in man was presented in another publication (771). The absorption, distribution, and utilization of iron in a fat-soluble form was evaluated against similar data for ferrous sulfate and ferrocene (772). In addition, the absorption of ^{59}Fe-hemoglobin has been investigated in iron deficient and iron supplemented rats and compared with the absorption of ^{59}Fe as ferrous sulfate (773).

The absorption of steroid hormones was assessed by measuring the disappearance rate from the human small intestine during steady-state perfusion of aqueous solutions through a transintestinal tube (774). It was reported that when aloxiprin and aspirin were administered orally, they had similar mean rates of excretion, but aspirin provided higher blood levels (775). Cotty *et al.* evaluated aspirin blood levels following the ingestion of commercial aspirin-containing tablets by humans (776). The absorption, distribution, and elimination of 6,7-dimethyl-4-hydroxyquinoline hydrochloride, administered orally and intravenously to animals has been studied (777), and the absorption and distribution of oxafuradene in the dog were also determined (778). By means of urinary excretion studies in man, the absorption and excretion of ^{14}C-bethanidine were measured (779). It has been suggested that the acetylated phenolic laxatives, bisacodyl and diphesatin, became absorbable from the intestines and active, pharmacologically, after deacetylation (780). Data were presented on the absorption, distribution, and elimination of *N,N'*-dimethyl-*N,N'*-bis[3-(3,4,5-trimethoxybenzoyloxy) propyl] ethylenediamine dihydrochloride (781). Another publication ascertained the absorption, excretion, and metabolic fate of ethambutol in man after oral and intravenous administration (782); the absorption, distribution, and excretion of morphocycline in rabbits were also discussed (783). Other data were compiled showing that only a limited amount of riboflavin can be absorbed from the intestinal tract (784). Another investigator carried out research on the gastrointestinal absorption and pharmacokinetics of selected compounds in man (785). The absorption of isoniazid and some of its derivatives has been noted (786). The absorption, metabolism, and elimination of thiabendazole in farm animals, along with a method for its estimation in biological materials, were presented by Tocco *et al.* (787). Peak plasma levels for sulfamethoxydiazine were found in 6–8 hr. after oral administration (788); also, a similar study by the same authors comparing the antibacterial activity and chemical levels of the same chemical in human serum and plasma was published (789). Amundson, Johnson, and Manthey determined the urinary excretion of *d*-propoxyphene hydrochloride in man (790). The absorption and elimination profile of isoproterenol in anesthetized and unanesthetized dogs has been announced (791, 792). The rate of excretion of a new antiviral agent, amantadine hydrochloride, was discovered to be first order (793). The absorption of terephthalic acid through the digestive tract and its excretion in urine of rats were examined (794). The urinary excretion of three oral cholecystographic agents, iopanoate, tyropanoate, and bunamiodyl, has been studied (795). Another investigation was concerned with the absorption of *d*,1-1-(3-hydroxyphenyl)-1-hydroxy-2-ethyl aminoeltane in the gastrointestinal tract (796).

PHARMACOGNOSY[1]

One review was published on the investigation of *Lupinus* alkaloids (797); another surveyed the physical and chemical properties of aromatic acids from crude drugs of the *Umbelliferae* family (798). Other reviews were concerned with aurones (799), a tabulation of 43 alkaloids used in modern medicine (800), recent advances in the chemistry of *Rutaceae* alkaloids (801), the present status of *Cannabis* research (802), and the application and relationship of plant tissue culture to medicinal plant study (803).

The morphine content of opium from poppy plants under cultivation has been examined by two investigators (804). In a study on the stability of erichroside from *Erysimum cheiranthoides*, it was shown that lower pH's caused hydrolysis, whereas higher pH's caused isomerization (805). Sciuchetti and Born reported on the effect of dimethylsulfoxide alone and in combination with *N*-dimethylamino succinamic acid or 2-chlorethyl trimethylammonium chloride on the growth and alkaloid biosynthesis of *Datura tatula* (806). In a study on morphine losses in poppy capsules (*Papaver somniferum*), it has been revealed that the maximum loss of morphine in freshly crushed poppy capsules occurred in the first 8 days of storage at 20° (807). A description of various rhubarb roots used in the drug trade was listed (808). An interesting article on Mexican witchcraft drugs, *Ipomoea violocea* and *Salvia divinorum*, outlining their active principles, appeared in the literature (809). The production and consumption of opium and coca derivatives

[1] The writers thank Dr. G. H. Svoboda for his suggestions concerning the preparation of this section.

TABLE I.—PHARMACOGNOSTIC INVESTIGATIONS

Plant	Ref.
A	
Abies amabilis	(817)
Acacia angustissima	(818)
Acacia confusa	(819)
Aconitum japonicum	(820)
Actinidia polygama	(821)
Aesculus hippocastanum	(822)
Afzelia xylocarpa	(823)
Alangium lamarckii	(824, 825)
Amanita muscaria	(826, 827)
Amaranthus caudatus	(828)
Amaryllidaceen species	(829, 830)
Ammi majus	(831)
Anabasis aphylla	(832)
Angelica hirsutiflora	(833)
Angelica japonica	(834, 835)
Angelica pubescens	(836)
Aniscocyclea grandidieri	(837)
Anthocleista procera	(838)
Apocynum cannabinum	(839)
Araucaria imbricata	(840)
Arctium lappa	(841)
Ardisia macrocarpa	(842)
Argyreia nervosa	(843)
Arisaema ringens	(844)
Artemisia absinthium	(845)
Artemisia taurica	(846)
Artocarpus heterophyllus	(847)
Asarum europaeum	(848)
Asclepias tuberosa	(849)
Asimira triloba	(850)
Aspidosperma dasycarpon	(851)
Aspidosperma species	(852)
Atropa belladonna	(853)
B	
Baccharis rosmarinifolia	(854)
Berberis hauniensis	(855)
Bixa orellana	(856, 857)
Boletaceae species	(858)
Bryophyllum daigremontianum	(859)
Buxus microphylla	(860)
Buxus sempervirens	(861, 862)
C	
Cassia occidentalis	(863)
Catharanthus lanceus	(864)
Catharanthus roseus	(865–867)
Ceanothus americanus	(868)
Cedrus deodara	(869)
Centaurea species	(870)
Chelidonium majus	(871)
Chionographis japonica	(872)
Chondria armata	(873, 874)
Cinnamomum species	(875, 876)
Cissampelos pareira	(837, 877)
Clausena anisata	(878)
Clerodendron infortunatum	(879)
Cochlospermum gossypiune	(880)
Convallaria keiskei	(881)
Convallaria majalis	(882)
Coptis chinensis	(883, 884)
Corydalis species	(885)
Crotalaria species	(886)
Croton cumingii	(887)
Cyclea madagascariensi	(837)
Cymbopogon mortini	(888)
Cymbopogon nardus	(889)
Cynara scolymus	(890)
D	
Dalbergia lanceolaria	(891)
Daphne genkwa	(892)
Daphne papyracea	(893)
Datura callus	(894)
Datura innoxia	(895, 896)
Datura meteloides	(897)
Datura sanguinea	(898)
Datura tatula	(899)
Daucus carota	(900)
Delphinium species	(901)
Desmodium caudatum	(902)
Digitalis ciliata	(903)
Digitalis davisiana	(904)
Digitalis lanata	(905, 906)
Digitalis purpurea	(908–913)
Digitalis species	(907)
Digitalis thapsi	(914)
Doryphora sassafras	(915)
E	
Eledone moschata	(916)
Embelia ribes	(917)
Enantia species	(918)
Erysimum canescens	(919)
Erythroxylon monogynum	(920)
Eschscholtzia californica	(921)
Eucalyptus staigeriana	(922)
Eupatorium semiserratum	(923)
F, G	
Fumaria species	(924)
Gaillardia pulchella	(925)
Genista lusitanica	(926)
Gentiana bellidifolia	(927)
Glycosmis arborea	(928)
Glycyrrhiza glabra	(929)
Gualteria psilopus	(930, 931)
Gutierrezia sarothrae	(932)
Gymnema sylvestre	(933)

Withania somnifera	(1055, 1056)
Yucca glauca	(1057)
Zanthoxylum hamitonianum	(1058)

in France since 1950 were summarized (810). Another report stated the growth of *Atropa belladonna* was strongly inhibited by a heavy water concentration greater than 50% (811). An alfalfa trypsin inhibitor was demonstrated to be thermally stable and also stable in the pH range 2–12 (812). Other studies have been conducted on two sulfur-containing alkaloids from Congo trees (813). The presence of aloin was discovered in *Aloe* species from the section *Anguialoe* Reynolds (814). The effect of dimethylsulfoxide and tributyl 2,4-dichlorobenzylphosphonium chloride on growth and alkaloid synthesis in *Datura ferox* has been described (815). Alkaloid artifacts were difficult to distinguish from active plant alkaloids formed in plant extracts by ammonium hydroxide and acetone (816).

Pharmacognostic Investigations.—This section of the review is primarily concerned with those references pertaining to isolation and identification of plant constituents. Table I lists alphabetically each plant studied, followed by appropriate references to the bibliography.

Methodology.—The pH of the medium and the nature of the organic solvent were the main factors affecting the extraction of alkaloids by organic solvents (1059). A comparison was carried out on turbo-, vibro-extraction, and maceration methods for the preparation of various tinctures in the "Yugoslav Pharmacopeia" II (1060). The extraction of drugs from plants

has been improved by the use of surface-active agents (1061). Laboratory experiments demonstrated the effectiveness of a domestic vibrator for obtaining extracts from various types of plant materials (1062).

Ovadia and Skauen reported that ultrasonic energy had an accelerating effect on the extraction of alkaloids (1063). The kinetics of extraction of alkaloids and other extractables from the rhizome of *Scopolia carniolica* by pressing was studied (1064). Another procedure was described for preparing rye fluid extracts containing 0.05% alkaloids (1065). The properties of clove oils produced under different conditions of distillation from the buds and stems were investigated (1066). Optimum conditions for glycoalkaloid diffusion in the *Solanum laciniatum*–sulfuric acid system were reported (1067), as well as optimum conditions for the extraction of alginic acid from seaweeds on the Saurashtra coast (1068). Various methods for obtaining deterpenated oils were reviewed in a paper with 22 references (1069). In addition, thin-layer chromatographic patterns were noted for Umbelliferous drugs and their adulterants (1070).

In Vivo Pharmacodynamic Evaluation of Oral Dosage Forms by Whole Body Liquid Scintillometry

By GERALD HECHT*, JOHN E. CHRISTIAN, and GILBERT S. BANKER

A large volume liquid scintillation detector was used to determine rates of excretion, absorption, and intercompartmental clearance in ambulatory dogs. A γ-emitting test substance was administered intravenously, orally in aqueous solution, and orally in sustained and delayed-release dosage forms. Unanesthetized female dogs were partially restricted, catheterized, and fasted prior to dosing. Where applicable, plots of log per cent whole body retention as a function of time were resolved into linear components following apparent first-order kinetics. The rate constants of these components were calculated and compared. Sustained-release forms were prepared which exhibited zero-order release characteristics *in vitro* and *in vivo*, and the characteristics of an enteric coated dosage form were compared after *in vitro* and *in vivo* testing. The procedure provided such parameters as absorption, excretion, release, and the effect of formulation techniques and formula variation on the biological availability of the test substance employed without the necessity of excreta and blood sampling and analysis.

THE PROBLEM of evaluating the biological availability and pharmacodynamic properties of any drug, new or old, in a new dosage form, is of increasing importance due to the greater potency and specificity of drugs, the greater complexity of dosage forms, and the increasing demands of the drug laws and new drug application requirements.

Several authors (1–9) have attempted to standardize the *in vitro* testing of various oral dosage forms, not necessarily as a means of simulating the characteristics which would be expected *in vivo*, but rather as a means of insuring control and correlation with data collected *in vivo*.

Many methods for the *in vivo* evaluation of oral dosage forms have been devised, but undoubtedly, those supplying the most pertinent information are concerned with the evaluation of absorption,

blood levels, blood clearance, and excretion rates. Heimlich *et al.* (10, 11) used urinary excretion for the calculation of the half-lives and excretion constants for phenylpropanolamine hydrochloride and trimeprazine in sustained-release dosage forms, and Wagner and Nelson (12–14) used per cent absorbed *versus* time plots to elucidate kinetic models for drug absorption.

Large volume liquid scintillation counters have been employed to measure the parameters of whole body retention and excretion of selected γ-emitting radionuclides in humans (15–20). These procedures involve administering a dose of a γ-emitting test substance and determining the whole body radioactivity at zero time and at succeeding time intervals thereafter. Data of this type have been heretofore primarily expressed as whole body retention and have not been specifically correlated to urinary excretion or rate changes in blood levels for the purpose of describing the pharmacodynamics of a drug or a dosage form. For the system studied, whole body activity appears to be an effective method of picturing total compartmentalization and absorption-distribution-excretion kinetics.

In this study, a model system was devised wherein a γ-emitting radionuclide (sodium ^{131}I-orthoiodohippurate)[1] was administered intravenously and orally in various dosage forms, for the purpose of studying by whole body liquid scintillometry the parameters of absorption, excretion, and intercompartmental clearance of the radionuclide and the effect of variations in formula composition on these parameters.

The method described in this study would be applicable to the investigation of (*a*) any drug or test substance which could be labeled with a γ-emitting radionuclide to illustrate drug pharmacodynamics, (*b*) the factors affecting dosage form release mechanisms and properties *in vivo* according to dosage form design and the physicochemical properties of the radionuclide compound, (*c*) drugs which alter the sodium and potassium content of the body.

EXPERIMENTAL

General Considerations.—Since the evaluation of oral dosage forms was of primary interest in this study, the length of time over which whole body radioactivity determinations are normally made in such an investigation (12 hr. or longer) provides certain requirements of the γ-emitting test substance. These requirements may be listed as follows. (*a*) The test substance must not be concentrated or bound in specific tissues of the body such as the thyroid gland or liver. (*b*) The test substance should be completely eliminated by the kidneys. (*c*) The excretion rate must be rapid enough to clear a major portion of the material from the body in 3 or 4 hr. or less. (*d*) The material should not be degraded in the body to release a radioactive metabolite which would confuse interpretation of the data.

Instrumental Methods.—Whole body activity was determined in the 4 π large volume liquid scintillation counter at Purdue University (21).[2] The instrument was calibrated to differentially count the γ-emissions of ^{131}-iodine having an energy of 0.364 mev. Dosages were adjusted to provide count rates of 150,000 counts per minute or less in order to avoid having to make data corrections for coincidence loss which were found to become significant at about 250,000 counts per minute.

The *in vitro* evaluation of the release of the test material from sustained and delayed-release oral dosage forms, and the evaluation of whole blood disappearance of the test substance, was conducted in a 2-in. Harshaw[3] NaI(Tl) well crystal and appropriate electronics, calibrated to differentially count the γ-emissions of ^{131}-iodine having an energy of 0.364 mev.

In vitro release tests were conducted on a rotating bottle apparatus, as described by Souder and Ellenbogen (9), at 36–38°, and at a speed of 40–45 r.p.m.

Animal Methodology.—Seven adult dogs were utilized in this study. The dogs averaged from 8–10 Kg. in weight, and from 2 to an estimated 8 years of age. The dogs were from two groups of animals, the first group consisting of three mixed breed female animals, ranging in estimated age from 2–8 years of age, and the second group consisting of four female AKC registered beagles ranging from 2–2.5 years of age. All animals were immunized for rabies, distemper, and hepatitis, and were wormed. A maximum of four animals were used in any single experiment. On the day before an experiment was conducted, each participating animal was removed from its run and was placed in a metabolism cage. All food and water were withheld for a period of 12 hr. prior to initiation of each experimental procedure.

Catheterization of the female animals to facilitate repeated bladder emptying immediately prior to each whole body radioactivity determination was accomplished using a No. 14 French scale Bardex[4] indwelling catheter, which was fixed in place immediately prior to dosing and removed immediately after the experimental period. To prevent removal of the catheter by the animal, partial restriction was necessary. To accomplish this restriction, each animal was fitted with a "girdle" formed from pieces of polyethylene sheet 1/8 in. thick, 7–8 in. wide, and as long as necessary to completely surround the thoracic and abdominal areas. The girdle was secured by a leather strip which passed in front of the forelimbs and across the chest.

The animals were dosed immediately after bladder drainage. Immediately prior to the determination of whole body activity at each subsequent interval, the bladder was drained, and rinsed with 50 ml.

of sterile sodium chloride injection U.S.P. The urine so collected, the rinse, and washings from the collection graduate were placed in 1-L. polyethylene bottles,[5] brought to 1-L. volume with water, and placed in the geometrical center of the whole body scintillation counter for determination of cumulative excretion values.

So that the animals would not move about unduly to produce geometry errors while in the whole body counter, they were placed in a cylindrical fiber drum[6] of 8-gal. capacity. All counts collected on a single animal at each time interval were averaged and corrected for background, decay, and variation of counter efficiency. Each urine sample was similarly treated, with the exception that decay corrections were unnecessary since the activity of a urine phantom containing an amount of test substance identical to that administered the animals was determined each time a urine sample was counted.

A time span of not less than 4 days was allowed between subsequent uses of an individual animal.

Mass Absorption Effects.—In the initial experimentation it was necessary to determine the effects of the variability of whole body mass absorption, caused by variations in geometry and body mass surrounding the gastrointestinal tract of the animal on the reproducibility of whole body count rates as measured in the Sinco-P. An insoluble sealed source of ^{131}-iodine was prepared by imbedding an ^{131}I Radiocap[7] in an epoxy resin polymer.[8] Each sealed source was tested *in vitro* in simulated gastric and intestinal juices for absence of leach-out prior to animal dosing. Periodic determinations of whole body radioactivity were made over a 24 hr. period in the whole body counter for the animals administered the sealed sources. In all cases the sealed ^{131}I source was recovered intact from the fecal material, and the urine and feces were monitored and found to be free of radioactivity.

Dosage Regimen.—The animals used were fasted, restricted, and catheterized as described earlier. After bladder drainage and rinsing, the following dosage regimen was followed. (*a*) A dose of 1.0 ml. of a sterile aqueous solution of sodium ^{131}I-*o*-iodohippurate containing 0.14 μc./ml. was injected into each of four animals *via* the cephalic vein. (*b*) A solution containing 10 mg. of nonlabeled sodium-*o*-iodohippurate[9] and approximately 0.1 μc. of sodium ^{131}I-*o*-iodohippurate was administered orally to each of four animals. In regimens 1 and 2 whole body radioactivity was determined at zero time and at scheduled intervals thereafter. Values for whole body retention and cumulative per cent excretion were plotted as a function of time. (*c*) A solution containing 10 mg. of nonlabeled sodium-*o*-iodohippurate, and from 15–22 μc. sodium ^{131}I-*o*-iodohippurate was administered orally to four animals. At scheduled intervals following this oral administration, 1 ml. of blood was removed from the cephalic vein and analyzed for per cent of administered dose per milliliter in the Harshaw NaI(Tl) well crystal described earlier. (*d*) Ten milligrams of nonlabeled sodium *o*-iodohippurate

and approximately 0.1 μc. sodium ^{131}I-*o*-iodohippurate were administered to four animals in each of two sustained-release dosage forms which exhibited zero-order release kinetics *in vitro*. (*e*) Ten milligrams of nonlabeled sodium *o*-iodohippurate and approximately 0.1 μc. of sodium ^{131}I-*o*-iodohippurate was administered to four animals in an enteric coated delayed-release dosage form.

Preparation of the Solid Dosage Form.—Sustained-release oral dosage forms of sodium ^{131}I-*o*-iodohippurate containing 0.1 μc. of ^{131}I per tablet were prepared. Three groups in all, each weighing 400 mg., were prepared containing 10, 30, and 50%, respectively, of carboxypolymethylene polymer.[10]

Care was taken to compress the tablets to the same thickness and hardness.

The *in vitro* release characteristics of these three formulas are shown in Fig. 1, with the release half times ($R_{1/2}$) and zero-order rate constants (k_0) for the 30 and the 50% formulas.

Four-hundred-milligram tablets, each containing 10 mg. of nonlabeled sodium *o*-iodohippurate and approximately 0.1 μc. of sodium ^{131}I-*o*-iodohippurate were prepared and coated with a mixture of cellulose acetate phthalate,[11] diethylphthalate,[11] and acetone. These tablets were designed to release their active principle in a delayed manner in the weakly acid or alkaline reaction of the proximal small intestine, but not in the strongly acid stomach.

When tested *in vitro* on the rotating bottle apparatus at 36–38°, the tablets prepared in this manner were seen to release less than 5% of the radioactive principle after 2.5-hr. exposure to simulated gastric juice U.S.P. without pepsin, and 100% of the radioactive principle within 15 min. after exposure to simulated intestinal fluid U.S.P. without pancreatin.

RESULTS AND ANALYSIS

Statistical evaluation of the data accumulated on corrected whole body activity determined intermittently during 24 hr. following administration of a sealed source of iodine-^{131}I showed the individual determinations to be within two standard deviations of the mean. These limits represent an average of plus or minus 5.45% of the mean, indicating minimal influence of mass absorption.

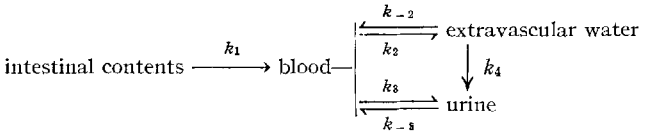
The average results of whole body retention, and cumulative excretion, of ^{131}I-*o*-iodohippurate after intravenous and oral administration in aqueous solution, are compared in Fig. 2 and plots of log per cent whole body retention as a function of time are presented and resolved into apparent first-order processes by the method of Sapirstein *et al.* (22) and Tauxe *et al.* (26) as shown in Figs. 3 and 4.

A simplified compartmental analysis of sodium ^{131}I-*o*-iodohippurate after oral administration is shown in Scheme I.

In Fig. 3, the plot for intravenous administration, the fast component A (Table I), is considered to be k_3, and the slow component B, k', a combination of k^{-2} and k_4 (the constant of tubular secretion). Figure 4 for oral administration is analyzed in the same way, designating the fast component A, k_3, and the slow component B, K' a combination of k'_{-2} and k_4.

Table I compares the apparent first-order rate constants and biological half-lives (T_B) derived from the linear components in Figs. 3 and 4.

Figure 5 shows the correlation of observed and theoretical whole body retention of sodium ^{131}I-*o*-



Scheme I

iodohippurate administered intravenously and orally in aqueous solution. The theoretical whole body retention is derived by subtracting the cumulative per cent excreted from 100%. If the theoretical per cent whole body retention perfectly matched the observed per cent whole body retention, the straight line shown in Fig. 5 would connect such points in complete agreement. The extent of departure of the points in Fig. 5 is a reflection of the departure of the observed data from the theoretical data. The data for intravenous administration can be seen to depart somewhat from complete agreement, while the data of oral administration exhibit excellent correlation.

Figure 6 illustrates the cumulative excretion, theoretical whole body retention, and whole blood disappearance following oral administration of sodium ^{131}I-*o*-iodohippurate in aqueous solution. The data can be seen to be extrapolated to the 12-hr. value for use in Fig. 7. Figure 7 is a plot of the log per cent whole body retention, and log of the per cent of the dose in the blood as a function of time. The rate constants derived from the linear components of this figure are shown in Table II. The fast component of the theoretical whole body retention curve is represented by k_3 and the slow

DISCUSSION

Sodium ^{131}I-*o*-iodohippurate was found to satisfactorily meet most of the requirements for a γ-emitting test substance outlined earlier. It does not concentrate in the thyroid gland or liver. It is at least 90% excreted by the kidneys.

Mathematical treatments of the excretion of substances excreted both by glomerular filtration and tubular secretion are given by Sapirstein *et al.* (22) for creatinine and by Conn *et al.* for sodium-*o*-iodohippurate.

Benzoic acid is detoxified in man by conjugation with glycine to form hippuric acid and by conjugation with glucuronic acid to form benzoyl glucuronide. Analogously, ^{131}I-orthoiodobenzoic acid forms the similar corresponding metabolites, one of which is ^{131}I-*o*-iodohippuric acid (23). Thus, it was felt that if a test substance were supplied to the body as a metabolite, degradation of the test substance would be reduced and interpretation of accumulated data would be simplified.

TABLE III.—COMPARISON OF THE *In Vivo* AND *In Vitro* ZERO-ORDER RATE CONSTANTS, RELEASE HALF TIME, AND BIOLOGICAL HALF-LIVES OF SODIUM ^{131}I-*o*-IODOHIPPURATE IN SUSTAINED-RELEASE DOSAGE FORMS

	30% Carboxypolymethylene Polymer	50% Carboxypolymethylene Polymer
In vitro k_0	0.168%/min.	0.082%/min.
In vivo k_0	0.227%/min.	0.147%/min.
Apparent $T_{1/2}$[a]	4.65 hr.	6.0 hr.
T_B[b]	3.60 hr.	5.7 hr.
$R_{1/2}$[c]	4.20 hr.	7.3 hr.

[a] Determined from 50% whole body retention values in Fig. 9. [b] Calculated from the expression for the half life of a zero-order process. $T_{1/2} = 1/2\ Co/k_0$. [c] Determined from 50% released values in Fig. 1.

It is possible that when administered intravenously, a certain amount of sodium ^{131}I-*o*-iodobenzoylglycine may be converted to the glucuronide, and further it is possible that on oral administration the iodobenzoic acid moiety may be liberated from its glycine conjugate by the effect of intestinal enzymes, then absorbed and detoxified by conjugation with glucuronic acid or glycine.

Regardless of the metabolic pathway followed by sodium ^{131}I-*o*-iodohippurate on oral administration, it has been observed that reproducible values for the fast and slow components of a plot of log per cent whole body retention as a function of time are readily obtainable.

It will be noted from Table II that the rate constant (k_3) for the fast component upon intravenous administration of sodium ^{131}I-*o*-iodohippurate was 0.048 min.$^{-1}$, while the k_3 value for sodium ^{131}I-*o*-iodohippurate administered orally in aqueous solution was 0.0143 min.$^{-1}$. If the k_3 obtained after intravenous administration is considered to be the renal excretion rate constant, then the k_3 obtained after oral administration, which is approximately one-third of the value of the intravenous k_3, must be the rate constant for some rate-limiting process in the passage of sodium ^{131}I-*o*-iodohippurate from the gastrointestinal tract to the urine. This rate-limiting step is hypothesized to be the intestinal absorption rate of sodium ^{131}I-orthoiodohippurate. This hypothesis is supported, but not confirmed, by the fact that the whole body clearance becomes a zero-order process when sodium ^{131}I-*o*-iodohippurate is administered orally in a sustained-release dosage form which exhibits zero-order release kinetics on *in vitro* testing.

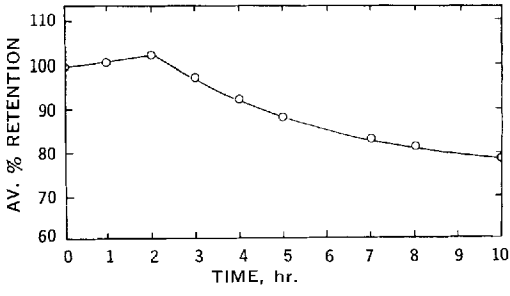

Fig. 10.—*In vivo* whole body retention of sodium ^{131}I-*o*-iodohippurate administered orally in a delayed-release dosage form.

It will be noted from Fig. 9 that contrary to the characteristics observed for the sustained-action dosage forms *in vitro* in Fig. 1, the zero-order elimination begins to deviate from linearity at 4–5 hr. after dosage. This deviation may be due to decreased biological availability of sodium ^{131}I-*o*-iodohippurate. This may occur due to enzymatic degradation of the compound to form one which is not readily absorbed, due to liberation of free ^{131}-iodine which would concentrate in the thyroid gland, or more likely may occur due to the pH of the environment being such that the compound is ionized and thus not readily absorbable. This phenomenon may also be observed from Fig. 10 where only about 22% of the administered dose was excreted over a 10-hr. period.

It has been demonstrated that the property of biological availability of a test substance, a parameter most important in dosage design and formulation, can be readily evaluated by the whole body monitoring of the γ-emissions of the test substance. An insight into *in vivo* release rates from sustained and delayed-release oral dosage forms is gained along with the effect of these dosage forms on the biological availability of the test substance in the body. Furthermore, specific information can be gained on the effect of the dosage form on absorption, excretion, and distribution of the test substance in the body. In addition, in the test substance under study, whole body retention of the radionuclide could be correlated very well to the excretion rate of the drug orally administered and fairly well to drug intravenously administered. The whole blood disappearance rate of the radionuclide could also be correlated to whole body retention as determined by the whole body scintillometry method described.

The added advantage of simplicity of animal and sample handling is also evident. Since urine samples in the larger animals must be accumulated on the short term basis by catheterization, the excretion of the test substance can be evaluated after urine drainage in as little as 3 min. without the necessity for further urinalysis. This is accomplished by determining the per cent whole body retention in a large volume liquid scintillation detector. Sinco-P, the whole body scintillation counter at Purdue University, was used in this study, but smaller and less expensive units are available which will readily accommodate a dog the size of a 20-lb. beagle (24, 25).

SUMMARY AND CONCLUSIONS

The use of the large volume liquid scintillation counter at Purdue University was investigated for its applicability to the evaluation of the pharmacodynamic properties of selected drugs and oral dosage forms. Use of data accumulated on the whole body retention of ^{131}I-orthoiodohippurate sodium was illustrated. Semilog plots of per cent whole body retention as a function of time were constructed and analyzed on the basis of first-order kinetics. Data obtained from *in vivo* analysis were compared with *in vitro* data for sodium ^{131}I-*o*-iodohippurate in sustained and delayed-release oral dosage forms. These studies indicated the following.

1. A large volume liquid scintillation counter is useful in obtaining information on the pharmacodynamic properties of a test substance in oral dosage form.

2. Whole body retention data may be readily correlated to cumulative excretion rates and blood disappearance rates.

3. Meaningful rate constants are obtainable from semilogarithmic plots of whole body retention as a function of time.

4. The biological availability of a test substance may be readily determined from whole body retention data.

5. Rates of release of a test substance in sustained or delayed-release dosage forms may be obtained *in vivo* without the necessity of blood and urine analysis.

6. Sodium ^{131}I-*o*-iodohippurate was found to be a suitable γ-emitting radioactive test substance.

Hemolysis of Erythrocytes by Antibacterial Preservatives III

Influence of Dimethyl Sulfoxide on the Hemolytic Activity of Phenol

By HOWARD C. ANSEL and WILLIAM F. LEAKE*

The influence of dimethyl sulfoxide (DMSO) on the hemolytic activity of phenol has been investigated *in vitro*. Although DMSO freely penetrates the erythrocytic membrane and, in high concentrations, is destructive to red cells, it did not enhance but greatly reduced phenol-induced hemolysis of both washed and unwashed erythrocytes. This interference may be manifest through chemical interaction with phenol or through a direct cellular effect.

DIMETHYL sulfoxide (DMSO) is currently the subject of numerous reports and investigations directed toward determining its efficacy as a pharmaceutical adjunct and therapeutic agent. In a review of the medicinal and pharmaceutical aspects of DMSO, Block (1) has collated preliminary reports that indicate the varied potential of DMSO as a primary pharmacologic agent in producing analgesia, tranquility, diuresis, and reduced inflammation.

DMSO has been the subject of conflicting reports concerning its ability to act as a penetrant carrier of drugs through biologic membranes. Some investigators (2–4) attribute greatly increased drug penetration to the presence of DMSO whereas others (5, 6) report effects much the same as those produced by more common vehicles and experimental controls.

DMSO has been employed as a solvent in certain biochemical procedures (3, 7) and as an endocellular cryophylactic agent for the protection of cells, including erythrocytes, and tissues against freeze damage during low-temperature preservation (3, 7, 8–14).

The present investigation represents a continuation of studies (15–17) to determine the hemolytic activity of antibacterial preservatives alone and in the presence of pharmaceutical adjuncts. The controversial reputation of DMSO as a penetrant carrier of drugs prompted the question of whether its presence would affect the hemolytic activity of an antibacterial preservative. The hemolytic activity of certain antibacterial preservatives including phenol has been shown to be indicative of their antimicrobial activity (15). An alteration in the hemolytic response of erythrocytes to phenol in the presence of DMSO would be suggestive of a like alteration in antimicrobial activity. This information would be useful should future pharmaceuticals containing DMSO as a solvent, penetrant carrier, or primary pharmacologic agent require the presence of an antibacterial preservative. Phenol was selected for the present study since its hemolytic activity has recently been characterized in this laboratory (15, 16).

EXPERIMENTAL

Materials.—Dimethyl sulfoxide was experimental drug grade (Crown Zellerbach Corp., Camas, Wash.). Phenol and sodium chloride were reagent grade.

Blood Samples.—Rabbit blood, obtained by heart puncture in the manner described by Grosicki and Husa (18), was used throughout this study. Each blood sample was collected just prior to its use and was verified for osmotic normalcy during the course of each experiment (15).

Quantitative Determination of Per Cent Hemolysis.—The colorimetric method employed for the determination of the degree of hemolysis occurring in each test solution has recently been described (15). In brief, it involved the addition of 0.05 ml. of defibrinated blood to duplicate pairs of colorimeter tubes each containing 5 ml. of test solution. The test mixtures were incubated in a water bath for 45 min. at 37° after which the unhemolyzed cells were settled by centrifugation and the absorbance readings of the hemolysate determined with a Klett-Summerson photoelectric colorimeter. Each absorbance reading was compared with a total hemolysis reading obtained by laking red cells in distilled water. The degree of hemolysis occurring in each test solution was calculated as a per cent of total hemolysis. The data reported represent the average of a minimum of two like experiments.

During and after the 45-min. incubation period, each test mixture was macroscopically observed for color changes, precipitation, and other signs

of denaturation. Throughout the investigation signs of blood denaturation were observed in solutions of high DMSO concentration. The following experiment was conducted to determine which test solutions affected hemoglobin such that colorimetric determinations no longer remained an accurate measure of degree of hemolysis. Washed blood cells were laked in distilled water, and like amounts of the resulting hemoglobin solution added to 5-ml. volumes of water, to individual solutions of phenol, sodium chloride, and DMSO, and to combinations of these ingredients as employed in the hemolysis experiments. The absorbance of each test solution was determined prior to and after the addition of hemoglobin solution and the final readings adjusted by subtracting the blank readings. Variations in the final readings were indicative of alterations in the hemoglobin. Each solution was also macroscopically examined for discoloration and precipitation.

Experimental Solutions.—Aqueous solutions were employed throughout the investigation. Concentrations of DMSO are expressed as per cent v/v and phenol and sodium chloride as per cent w/v.

Solutions of DMSO ranging in concentration from 0.5 to 99.5% were prepared and their absorbance readings determined. These readings served as blank readings that were subtracted from the colorimetric readings of subsequent hemolysis experiments.

Solutions containing 0.5 to 90% DMSO in 0.6% sodium chloride were similarly handled. The sodium chloride was added to provide protection to the erythrocytes against osmotic hemolysis. Hemolysis which occurred could be attributed to the presence of DMSO.

The primary objective of this investigation was to determine the influence of DMSO on the hemolytic activity of phenol. Previous studies (16) showed that phenol in the presence of 0.6% sodium chloride induced trace hemolysis of unwashed rabbit erythrocytes at approximately 0.41% phenol concentration and caused total hemolysis when present at 0.47% concentration. In the present study 0.44% phenol was employed. At this concentration 50 to 90% hemolysis usually occurs and the effect of added DMSO, whether it be increased or decreased hemolysis, could be readily detected. Hemolysis studies were conducted on test solutions containing 0.6% sodium chloride, 0.44% phenol, and concentrations of DMSO varying from 0.5 to 80%. Solutions containing sodium chloride and phenol but not DMSO served as the controls.

Similar experiments utilizing washed red blood cells were conducted to reveal the influence of serum on the DMSO–phenol activity. Erythrocytes separated from defibrinated blood by centrifugation were washed approximately 5 times with 0.6% sodium chloride until the washings tested free of protein to 0.5 *N* mercuric chloride T.S. After the final washing, the cells were resuspended in 0.6% sodium chloride to the approximate volume of the original blood sample. The cell suspension was employed in the same manner as the unwashed blood samples.

Kinetic Studies.—The experimental design of this investigation was such that the hemolytic effect of the various test solutions was determined after a constant 45-min. incubation period. Test solutions that were fundamental to the experiments or in which the erythrocytes responded diversely were selected for a time study. The hemolytic activity of these solutions was determined at intervals of from 5 to 15 min. during a period of 60 min.

RESULTS AND DISCUSSION

DMSO Solutions.—Erythrocytes incubated in aqueous DMSO solution ranging in concentration from 0.5 to 25% completely hemolyzed (Fig. 1). The color of the hemolysate appeared normal and there were no macroscopic signs of blood denaturation. Thirty and 40% DMSO solutions also induced total hemolysis; however, the resulting hemoglobin solutions were slightly turbid. At 50 and 60% DMSO concentrations, the hemolysate was no longer red but amber. At 80% DMSO concentration the test mixtures contained bulky brown-colored sediments with no sign of intact red cells or hemoglobin.

DMSO is not capable of maintaining the integrity of erythrocytes, for it permeates the red cell membrane (19) and allows the influx of water and the hemolytic consequence. To prevent the osmotic hemolysis of erythrocytes, the presence of an extracellular ingredient to which the red-cell membrane is impermeable is required. It should be noted that in the successful preservation of blood against freeze damage, the optimal concentration of DMSO is 15 to 20% (20) and an agent that contributes to the tonicity of the solution is added (10, 19).

The deleterious effect of high concentrations of DMSO on blood was noticed throughout this investigation. The discoloration of blood, the flocculation of its components, and the precipitation of hemoglobin were observed consistently in test solutions containing more than 40% DMSO.

In a toxicologic study of DMSO, conducted to determine the feasibility of employing the material as the vehicle during the intravenous administration of water-insoluble antitumor agents, Willson *et al.* (21) attributed perivascular inflammatory reactions and intravascular thrombi in dogs to the use of undiluted DMSO injections. They found hemolytic anemia to occur in both rats and dogs subjected to repeated intravenous injections of DMSO. Both hematuria and hemoglobinuria were also noted. The latter claimed to be the result of intravascular hemolysis.

Similar observations were reported by DiStefano and Klahn (22) who studied the hematologic effects of DMSO on cat blood *in vivo* and *in vitro*. Their work indicated that DMSO is a potent hemolytic agent through direct action on the blood cells and that the degree of dilution of DMSO is an important determinant of its hemolytic activity.

DMSO–NaCl Solutions.—The presence of 0.6% sodium chloride protected erythrocytes against osmotic hemolysis in solutions containing less than 20% DMSO (Fig. 1). Trace hemolysis was detected in saline solutions containing 25% DMSO, and 25% hemolysis occurred when 40% DMSO was present. In sodium chloride solutions containing 50% DMSO and greater there was no evidence of intact cells but rather a brown flocculant sediment and a green amber-colored supernatant liquid. The results show that although sodium chloride is

capable of preventing osmotic hemolysis in solutions of less than 20% DMSO strength, it is incapable of preventing the cytotoxic effects of higher concentrations of DMSO.

DMSO-NaCl-Phenol Solutions.—Figure 1 shows the influence of varying concentrations of DMSO on the hemolytic activity of 0.44% phenol in 0.6% sodium chloride. It should be noted that in the absence of DMSO, the phenol–salt solution induced 70% hemolysis of the erythrocytes. With the phenol and sodium chloride concentrations held constant, the addition of DMSO altered the hemolytic response. As the DMSO concentration was increased to 7%, phenol-induced hemolysis was virtually eliminated. With greater concentrations of DMSO, hemolysis increased steadily until denaturation ensued at 40% DMSO concentration and prevented further quantitation. At that concentration a red flocculant sediment was observed, indicating that a portion of the hemolysate was no longer in solution. At concentrations of DMSO exceeding 50%, the sediment was the often-seen brown flocculant material underlying a green-amber supernatant liquid.

Hemoglobin solution, prepared by lysing washed erythrocytes in distilled water, was increasingly discolored and precipitated by all test solutions containing DMSO in concentrations of 40% and greater; therefore, in experiments employing DMSO in high concentrations the colorimetric readings were no longer an accurate indication of the degree of hemolysis, for the hemoglobin released by laked cells was at least partially precipitated and colorimetrically undetectable.

Washed Erythrocytes.—Under the conditions of this study, erythrocytes were found to be more easily hemolyzed by phenol in the absence of blood serum. A standard test solution of 0.44% phenol in 0.6% sodium chloride consistently induced complete hemolysis of washed erythrocytes after 45 min., whereas an average of 70% of the unwashed cells lysed in one series of experiments (Fig. 1) and 90% in another (Fig. 2). The greater degree of lysis with washed cells could be attributed to the absence of the protective action of the serum proteins and to the increased fragility of the erythrocytes caused by the repeated washings. The influence of DMSO on phenol-induced hemolysis, however, followed a similar pattern for both the washed and unwashed red blood cells (Fig. 1). As the DMSO concentration in the phenol–salt test solution was increased to 7%, hemolysis decreased from complete hemolysis to about 5% hemolysis. As the DMSO concentration was further increased, hemolysis increased until denaturation occurred at 40% DMSO concentration.

Interpretation of Results.—The data seem to suggest the biologic inactivation of phenol as part of a chemical complex with DMSO or by virtue of increased cellular resistance to its hemolytic capabilities.

The observation that antimicrobial agents are inactivated by various chemical agents resulting in a loss of antimicrobial and hemolytic activities is not new (16, 23–28). Although phenol and DMSO have been shown (14) to react under certain laboratory conditions (dissimilar to those of the present study) the addition of small amounts of DMSO to solutions of a number of other organic chemicals has produced evidence of complex formation (3).

In a separate investigation (29) involving the hemolytic activity of the antimicrobial agent chlorhexidine diacetate, DMSO had an influence on hemolysis similar to that shown with phenol. Chlorhexidine diacetate was employed in hemolytic concentrations, as phenol had been, in the presence of 0.6% sodium chloride and varying amounts of DMSO. Curiously, the hemolytic activity of chlorhexidine diacetate was decreased with increasing amounts of DMSO with minimal hemolysis occurring in the presence of 9% DMSO; greater concentrations of DMSO resulted in increased hemolysis.

The possibility of a direct influence of DMSO on the erythrocyte rendering the phenol ineffective in its hemolytic activities was explored. In pursuing the premise that DMSO was directly affecting the red cell membrane, experiments were designed in which washed erythrocytes were incubated in saline and varying amounts of DMSO with the intention of later removing the DMSO and subjecting the cells

to phenol to determine whether the cells were permanently altered by the DMSO pretreatment. Erythrocytes were incubated with 1, 7, 20, and 30% concentrations of DMSO. Attempts to remove the DMSO by washing the cells with 0.6% sodium chloride were unsuccessful. The red cells pretreated with 20 and 30% DMSO solutions completely hemolyzed on the first attempted washing. Appreciable hemolysis occurred in the 7% DMSO pretreated cell sample and trace hemolysis in the 1% DMSO pretreated cells as washing was attempted. The same washing fluid was efficient in the concurrent washing of the control cells subjected to the same conditions except for the exposure to DMSO. In blood preservation work, the use of DMSO as an endocellular cryophylactic agent has stimulated investigators to seek an effective method of removing DMSO from within the cells prior to transfusion (20). As in the present work, efforts to wash the cells free of DMSO have resulted in hemolysis (20). It has been found possible to dialyze erythrocytes free of DMSO, but the required dialysis time has been found prohibitive to practical application (20).

Kinetic Studies.—As can be seen in Fig. 2, both distilled water and 30% DMSO induced total hemolysis within the first 5 min. of the experiment. Hemolysis occurring in the 30% DMSO test solutions can be largely attributed to osmotic hemolysis resulting from the penetration of this hygroscopic material (3, 14) through the erythrocytic membrane (19). It is not unlikely, however, that the high concentration of DMSO also exerted damaging changes to the cell structure.

The addition of 0.6% sodium chloride to 30% DMSO reduced the hemolytic effect of the latter such that at the conclusion of the experiment, only 12% hemolysis had occurred. Since 0.6% sodium chloride is sufficient to prevent osmotic hemolysis, the hemolysis that did occur can be attributed to the cytotoxic activity of DMSO.

Phenol at a concentration of 0.44% in the presence of 0.6% sodium chloride induced trace hemolysis after 25 min. of incubation and total hemolysis after 55 min. The inclusion of 0.5% DMSO to the phenol–sodium chloride solution slightly decreased the rate of hemolysis. The inclusion of 30% DMSO to the phenol–sodium chloride solution prompted an initial hemolytic response that progressed steadily throughout the duration of the experiment. At the conclusion of the study, however, only about half of the erythrocytes were lysed in contrast to total hemolysis which occurred in the other solutions containing phenol.

In summary, DMSO has been shown to interfere with the hemolytic activity of phenol *in vitro*. This interference may be manifest through chemical interaction or through a direct cellular effect. It would be interesting to investigate the antimicrobial activity of phenol and other preservatives in the presence of DMSO. Such a study would further elucidate the analytical value of erythrocytes in predicting microbial responses to preservatives. It would also provide useful information relative to the preservation of pharmaceuticals containing DMSO.

Use of a Precision Coagulation Timer in the Biological Assay of Thrombin

By H. PATRICK FLETCHER, RICHARD J. BURNHAM, ROBERT J. COLE, and NORRIS W. DUNHAM

A new *in vitro* assay for the determination of thrombin potency has been studied using a precision coagulation timer. This instrument showed a more objective and quantitative clot-time determination of the human and bovine plasmas. The 2 × 2 and 3 × 3 assay designs were employed utilizing the dose-response relationship established between thrombin and the plasma. The differences between the present and proposed methods and between plasma of the two species are discussed.

THE PRESENT method used for the assay of thrombin is essentially the same as that published by the Federal Security Agency, National Institutes of Health, Bethesda, Md., 1946. In this method, two dilutions of unknown bovine thrombin are chosen so that one has a slightly higher and the other a slightly lower clotting time than a dilution of N.I.H. standard thrombin. The potencies (units/ml.) of the unknown thrombin dilutions, which are based on their assumed potencies, are plotted with the clotting times and these points are connected by a straight line. A point on this line which corresponds to clotting time of the standard thrombin is determined. A ratio is set up by comparing the potency corresponding to this point with the assigned potency of the standard. The potency of the unknown thrombin is obtained by multiplying the assumed potency by the ratio, as follows:

$$\frac{\text{assigned potency (of standard) units/ml.}}{\text{obtained potency (of standard) units/ml.}} \times \text{assumed potency (of unknown)} = \text{potency of unknown}$$

The clotting times in this method are visually determined by observing the clot in a small test tube after the plasma has been added to the thrombin and the clotting time is recorded by using a stop watch. During the observation time, the test tube is tilted once every second until coagulation occurs.

Due to its simplicity, this assay can be done rapidly. However, the dependence on subjective judgment for the end point determination and a complete lack of any statistical validity tests appear as serious disadvantages of this method. Thus, it was the purpose of this study to attempt the automation of the end point determination and to design a new assay in which the procedure will have to pass at least one validity test.

In this study we used a precision coagulation timer.[1] This instrument is being used by many clinical laboratories for the determination of prothrombin times.

For the determination of the clotting times, a plastic cup[2] containing 0.2 ml. of plasma is placed in the reaction well and the timer is automatically started when 0.1 ml. of thrombin is delivered from a pipet. After 1.5 sec. delay, the probe arm inserts the two electrodes into the plasma–thrombin mixture. The electrodes consist of a stationary electrode and a moving electrode which moves in and out of the plasma–thrombin mixture. When the moving electrode has risen above the reaction mixture, it reaches a contact point which would complete the circuit except for the gap between the two electrodes. Thus, when thrombin has converted the fibrinogen to fibrin, the latter is partially pulled out of the reaction mixture by the moving electrode and completes the electrical circuit between the electrodes. This electrical short stops the timer and the clotting time is recorded. The clotting times are obtained at 37° since the instrument is equipped with heating blocks which maintain this constant temperature.

The moving electrode completes a cycle (in and out of the reaction mixture) every 0.5 sec. Since the circuit can only be completed when the moving electrode has moved out of the reaction mixture, the clotting time end point can occur in an interval which is one-half of a cycle. Thus, in 1 sec. there are two intervals of approximately 0.25 sec. duration in which the end point can be detected. This means that the exact clotting time is not always given to the tenth of a second as the timer indicates. However, since this is a constant error, and it is the relative clotting times which are important in the biological assay, the clotting times to the tenth of a second as shown on the timer are used for the assay calculations.

Although there is some chance for error in the end point determination, this instrument has the advantage of a more objectively determined clot

time than the method now being used. It is anticipated that this increased objectivity will reduce the variation in obtained potencies between operators.

EXPERIMENTAL

Assay.—For the 2 × 2 assay, thrombin dilutions of 5.64 and 8.46 units/ml. (a log 1.5 interval) were prepared for both standard and production material. The dilutions were made up in 10-ml. volumetric flasks with normal saline. The individual dilutions were numbered so that a random order could be used for the collecton of data. For the 3 × 3 assay design, 5.64, 7.05, and 8.81 units/ml. dilutions of thrombin were used (a log 1.25 interval). The dilutions for unknown thrombin were based on their assumed potencies. The 50% plasma solutions were prepared by adding 5 ml. of distilled water and 5 ml. of normal saline to a vial containing 5 ml. of lyophilized human plasma.[3]

Two tenths of a milliliter of plasma solution was delivered to the plastic cup by using the autopipet. One rack of cups containing plasma was placed in the heating block. At the same time, the appropriately numbered cups containing the thrombin dilutions were also placed in the heating block. At the end of the 3-min. warm-up period, one of the cups containing plasma was placed in the well directly beneath the electrodes. One-tenth milliliter (0.1) of the thrombin solution was delivered to the plasma *via* the autopipet. The autopipet activates the timer when the plunger is depressed and the switch is in the "on" position. When coagulation occurs, the timer automatically stops, and the time of the end point is recorded.

The data for this assay were gathered as quickly as possible due to the effect of the 37° temperature on the thrombin and plasma. According to the manufacturer, plasma begins to decompose after 15 min. at this temperature. In this study it was found that effects on the plasma are insignificant if the plasma was used within 6 to 7 min. when at 37°.

The data were arranged under the appropriate dilutions (six determinations per dilution) and the clotting times in seconds were converted to logs. The logs are treated as numbers rather than as exponents in the computations of the statistics of the assay. In this laboratory the computations were carried out by an IBM 1620 computer. The computations for this 2 × 2 assay were described by Bliss (1).

Dose-Response Curve.—In order to design a new assay, the dose-response relationship was determined. Since there are many unknown variables in plasma coagulation, several dose-response curves were determined using both human and bovine plasmas and also for N.I.H. standard and production thrombins.

Although the curves shifted slightly from day to day, the shapes of the curves were the same even for the plasmas of the two different species. The dose-response relationship is a curved line. Examination of these lines led to the selection of the middle part of the curve for the assay work. The dose-response relationships in this area were somewhat linear and the sensitivity of the response in this area was more suitable for assay work. The linearity of this part of the dose-response curve was confirmed when orthogonal analysis of curvature was not significant in this area. However, the variance due to curvature was significant for the entire dose-response curve, and curvature still remained a problem in many of the assays. However, this problem was partly solved by plotting log dose *versus* log response as will be discussed later.

From the dose-response curve study it was determined that the dilutions of thrombin which resulted in clotting times between 10–22 sec. were useful dilutions for assay purposes. This useful area of the curve was determined for the different types of plasma used, *e.g.*, bovine, human plasma[3] half-strength, human plasma full-strength.

Statistical Design of Assay.—At the outset of this study it was felt that a statistical design was needed which would allow the operator to establish limits for the assay. At the beginning of this study the statistical design used for the three-dose balanced assay of corticotropin injection U.S.P. XVII (referred to as the 3 × 3 assay) was chosen since it contained four different validity tests. The present assay method contains no validity tests. Although the validity tests in the 3 × 3 assay design are far from perfect, they do serve as a source of confidence for the operator. The passing of these validity tests depends upon the "F" values obtained by dividing the mean squares resulting from deviation from parallelism, curvature, differences in curvature, and the combination of these three by the error variance. The weakness in these validity tests is that a high error variance can increase the probability that the validity test will be passed. Thus, it is up to the operator and the laboratory to limit the error variance which will be accepted. This may also be accomplished by placing limits on the "L" value. All of the computations for the statistical designs used in the study were programmed for the IBM 1620 computor.

RESULTS AND DISCUSSION

It became apparent in the early part of this study that temperature had an effect on the clotting times when the thrombin solutions remained at 37°. Thus, it was important that each dilution of thrombin be kept standing at 37° for the same length of time prior to clotting time determination. In order to insure this, tubes containing the dilutions of thrombin should be placed in the heating block at the same time. After the 3-min. warm-up period, the clotting times for the different thrombin solutions are determined using a random order design. In this design for the collection of data, the effect of standing at 37° will be distributed over the different dilutions.

For the 3 × 3 assay, the responses (clot times) are statistically compared to the log dose for the standard and unknown thrombin dilutions. In this assay, we were using a statistical design which was intended for a linear dose-response relationship for data which possessed a curved dose-response relationship. Therefore, several of the assays failed the curvature validity test. A log × log transformation of the data was attempted in order to obtain a straight line.

The portion of the dose-response curve in which we were working became more linear when log dose was plotted against log response (Fig. 1.) Another

[3] Normal Plasma Control (5-ml. size), Baltimore Biological Laboratory, Division of B-D Laboratories, Inc., Baltimore, Md.

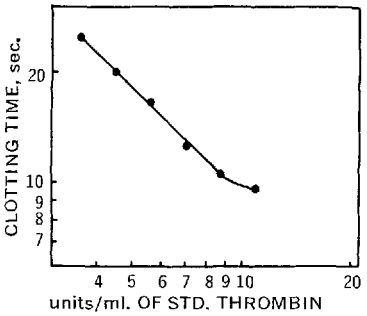

Fig. 1.—Log × log dose-response curve for N.I.H. standard thrombin and human plasma. Each point represents mean of six clotting times.

advantage of using the log × log transformation is that it tends to decrease the differences in the response variation which were often noted between the long and short clotting times.

A study to determine whether the log × log transformation reduced the sensitivity of the validity tests was conducted by intentionally making increased "errors" in one of the test dilutions in consecutive assays. The effect of these increased "errors" on the mean squares resulting from deviation from parallelism, curvature, and difference in curvature was observed and a comparison was made between semilog and log × log designs.

The results of this comparison indicated that the log × log transformation did not make the assay less sensitive than the semilog assay. The assays failed and passed in the same instances. The mean squares resulting from deviation from parallelism were increased in the assays where intentional errors were made in dilutions.

A 2 × 2 (log × log) assay (two standard and two unknown dilutions) was also used in this study and is now being used in place of the 3 × 3 design. This 2 × 2 design is thought to be more practical for routine work since it requires less time and reduces the amount of time the thrombin is kept standing at 37°.

The 2 × 2 assay has only one validity test to pass and this is deviation from parallelism. This is one of the more important validity tests since the log × log transformation reduced the problem of curvature. It was also observed that the potencies of 2 × 2 assays differed very little (0.5 to 1%) from the potencies obtained with the 3 × 3 design.

Results of many assays have shown that bovine plasma at 37° gave a high error variance. Analysis of the row effect, which represented the effect of time at 37°, revealed that the variance resulting from time was significant. It is probable that after a short time, the bovine plasma was breaking down at 37°. This temperature effect was not present when human plasma was used in the same time interval and at the same temperature. It was also revealed that in assays using human plasma, the thrombin was more efficient when the 0.2 ml. of plasma solution consisted of 50% plasma rather than 100% plasma. More thrombin was required by the 100% plasma to obtain the same clotting time as the 50% plasma. Apparently the optimal substrate concentration is closer to the 50% plasma solution than to the 100% solution.

The statistical data indicated that there was no

advantage in using 100% plasma solution rather than 50% solutions. The error variance remained about the same in both instances.

Samples from five production lots of thrombin, three 1000-units/vial and two 5000-units/vial, were assayed with bovine and human plasma solutions. These results were compared with the results obtained using the present N.I.H. method. The result of this study appears in Table I. Examination of these data reveals that the thrombin was more potent when assayed with bovine plasma than with human plasma. It was observed that the precision coagulation timer method employing human plasma at 37° results in a higher potency for thrombin than does the present method employing bovine plasma at 28°. This increase in assayed potency was about 50–150 units for the 1000 units/vial material and about 250–400 units/vial for the 5000 units/vial material. Part of this increase is probably due to the increased temperature from 28° to 37°. However, the results in Table II indicate that part of this difference in potency between the present and proposed precision coagulation timer methods is due to the method employed to calculate the potency. When the single point assay which is used to calculate the potency in the present method was applied to the new method, the potency values are closer together.

SUMMARY AND CONCLUSIONS

It is felt that this new assay offers advantages over the assay presently being used. Human plasma which is used at 37° is closer to the conditions which exist when thrombin is used clinically.

The automated end point eliminates the reliance on subjective observation on the part of the analyst. The statistical design which contains a validity test can be a source of increased confidence in the results.

Blood Level Distribution Patterns of Diazepam and Its Major Metabolite in Man

By J. ARTHUR F. DE SILVA, B. A. KOECHLIN, and G. BADER

The effect of different diazepam dosage regimens on the blood level patterns of diazepam (I) and of its metabolite *N*-desmethyl diazepam (II) in man was studied, using specific GLC and TLC techniques, and an ultraviolet assay measuring both components. Single oral doses of diazepam (10 mg.) produced low (0.18–0.21 mcg./ml.) and rapidly declining diazepam (I) blood levels. Repeated daily doses (30 mg.) caused a progressive increase of diazepam (I) levels. The metabolite (II) appeared 24–36 hr. after the first dose, and, thereafter, the levels increased rapidly, approaching those of I. Upon discontinuing the drug after repeated dosing, components I and II disappeared from blood very slowly, II persisting longer than I. The patterns indicated a redistribution into blood of I and II previously stored by tissues. Following chronic massive doses (150–200 mg./day), levels of I averaged 1.60 mcg./ml. (after 1 week of continuous dosage), while II continued to increase until an apparent equilibrium was reached at a ratio of I–II of 1:2.5. Only traces of the urinary metabolites, oxazepam and 3 OH-diazepam, were identified in blood.

DIAZEPAM,[1] 7-chloro-1,3-dihydro-1-methyl-5-phenyl-2H-1,4-benzodiazepine-2-one (Ro-S-2807) is a psychotherapeutic agent, synthesized by Sternbach and Reeder (1), which among the other members of the benzodiazepine class of compounds is distinguished by tranquilizing and antitension activity combined with marked muscle tone regulating properties (2). The correlations between pharmacological activity and chemical structure of the 1,4-benzodiazepine derivatives have been reviewed by Childress and Gluckmann (3).

Distribution and fate of diazepam labeled with tritium in the C_5-phenyl ring have been studied by Schwartz *et al.* (4). Following the oral administration of 10 mg. of diazepam, blood level maxima of about 0.10 mcg./ml. were found after 1–2 hr. Blood level fall-off patterns indicated a rapid and extensive uptake by tissues. Although the radioactivity in the blood appeared to represent mainly the intact drug, diazepam was shown to be excreted exclusively in the form of its metabolites. The major metabolic pathways were shown to consist of demethylation at the nitrogen in position 1, addition of a hydroxyl group at carbon 3, and conjugation of the respective derivatives (Scheme II). Oxazepam glucuronide was the predominant metabolite in urine. *N*-Demethylated diazepam was also found in urine, and in addition could be detected in the blood several hours after a 10-mg. single diazepam dose. The excretion rates of the radioactivity indicated an over-all drug half-life of 2–3 days.

Blood level studies on larger groups of patients under different diazepam dosage conditions employing a U.V. spectrophotometric analytical procedure yielded inconclusive results on account of the limited sensitivity and specificity of that method. Subsequently, a gas liquid chromatographic (GLC) assay was developed capable of measuring nanogram quantities (10^{-9} Gm.) of diazepam with a high degree of precision and selectivity (5). This procedure established its usefulness in investigations of the placental transfer of diazepam (6), and also permitted the determination of the major metabolite in blood from diazepam treated patients in a single assay.

The objective of the present study was to establish blood level distribution patterns of diazepam and its metabolite produced under a variety of diazepam dosage conditions, by means of carefully designed and controlled clinical studies, and by very sensitive and specific analytical methodology. Blood level curves are reported for single therapeutic doses, administered by oral, intravenous, and intramuscular routes, for repeated oral therapeutic doses and for chronic treatment with massive doses. Three independent analytical procedures and improved modifications thereof are described and their scopes are compared, including (*a*) a quantitative spectrophotometric assay of more limited sensitivity and specificity but of usefulness in toxicology; (*b*) a modified quantitative gas liquid chromatographic procedure differentiating between the intact drug and its *N*-demethylated metabolite; and (*c*) a qualitative thin-layer chromatographic (TLC) technique capable of definite identification of the individual benzodia-

zepin derivatives in extracts of biological materials.

ANALYTICAL PROCEDURE

U.V. Assay.—The U.V. method measures both intact diazepam and its major metabolite, *N*-demethylated diazepam (Ro 5-2180). Both of these compounds are extractable into diethyl ether from blood at pH 7.0 and exhibit similar U.V. absorption spectra with maxima at 240 and 285 mμ, respectively (Fig. 1), the absorbance at 240 mμ being twice that at 285 mμ.

Two-milliliter aliquots of oxalated specimens of control blood taken from the patient prior to medication and a 2-ml. specimen of control blood containing 5.0 mcg. of standard diazepam from a stock solution were run along with the unknowns. The samples were extracted twice with ether by a procedure described previously (5), and the extracts were combined. The combined ether extracts were washed twice with 5 ml. of 0.1 *N* NaOH, centrifuged, and the NaOH layer removed with a capillary pipet. The ether was extracted with 2 ml. of 2 *N* HCl which was then washed twice with 10-ml. portions of ether, centrifuged, the ether removed by aspiration. The ether washed HCl extract was transferred into a micro quartz cell (0.6-ml. capacity) with a clean glass capillary pipet. Using a 1-mm. pinhole slit in a Beckman DU spectrophotometer in conjunction with the micro quartz cell, the U.V. absorption spectrum of control, internal standard, and sample blood extracts were scanned by measuring their respective absorbances at 230, 240, 250, 265, 275, 285, 295, and 320 mμ to establish the presence of the characteristic diazepam spectrum with maxima at 240 and 285 mμ.

The absorbances (A) of the internal standards and the unknowns at 240 and 285 mμ were corrected for the corresponding control absorbance. The concentration of the unknowns was calculated from the corrected absorbance values at 240 mμ of the internal standard. The recovery of 5.0-mcg. amounts of diazepam and Ro 5-2180 added to blood was 90 ± 5.0% and was determined from the absorbance at 240 mμ in a 1-cm. cell of standard solutions of diazepam and Ro 5-2180, respectively. The A_{240} for 1 mcg./ml. solutions was 0.091 and 0.101, respectively. The method has a sensitivity limit of 0.3–0.5 mcg./ml. of blood, and a range of linearity up to 10 mcg./ml. of final solution (Fig. 2) and is sufficiently sensitive to measure blood levels resulting from doses greater than 50 mg.

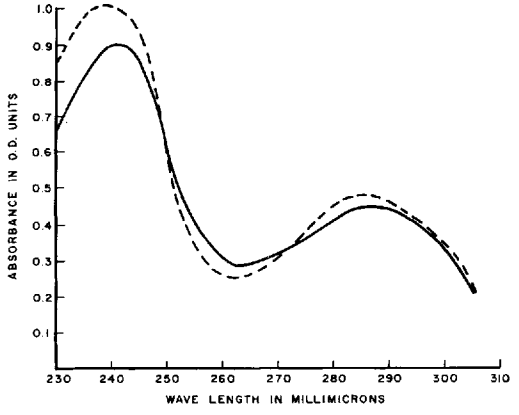

Fig. 1.—U. V. absorption spectra of diazepam and its metabolite (Ro 5-2180) in 2 *N* HCl (10 mcg./ml.). Key: ———, diazepam A_{240} = 0.091/mcg.; ·····, metabolite A_{240} = 0.101/mcg.

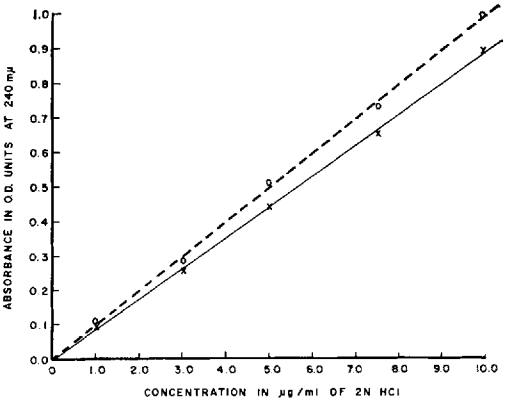

Fig. 2.—Standard curves of diazepam and its metabolite (Ro 5-2180) at 240 mμ. Key: ×, diazepam; O, Ro 5-2180.

Separation of Diazepam and Its Metabolites by Thin-Layer Chromatography.—Thin-layer chromatography was employed for the qualitative identification of the presence of diazepam and its metabolites extracted from blood and assayed cumulatively in the 2 *N* HCl acid extract by the U.V. method. Following spectrophotometric measurement, the acid extract was neutralized with 2 *N* NaOH to a blue end point, using bromothymol blue indicator, and extracted into diethyl ether which quantitatively removes diazepam and the metabolites. The residue of this extract was dissolved in 0.2 ml. of *n*-hexane (Fisher spectrograde) and quantitatively transferred onto a thin-layer plate of Silica Gel G (Stahl) containing a fluorescent indicator. Pure standards of diazepam and other possible metabolites were run alongside the sample extracts for identification of the compounds.

The plates were developed for about 2 hr. in chloroform–acetone, 90:10, and then viewed under ultraviolet shortwave light to identify the compounds on the plate. A typical chromatogram is shown in Fig. 3. The results were further verified by two-dimensional thin-layer chromatography using either chloroform–heptane–ethanol (10:10:1) followed by chloroform–heptane–acetic acid–ethanol (5:5:1:0.3) or chloroform–acetone (90:10) followed by chloroform–heptane–ethanol (10:10:1) as the developing solvents. A typical chromatogram is shown in Fig. 4.

Determination of Diazepam and Its Metabolites by Gas-Liquid Chromatography.—The more sensitive and specific gas chromatographic method is capable of quantitatively resolving diazepam and its major metabolite (Ro 5-2180) in blood, after they are hydrolyzed to their respective benzophenones (5) (Scheme I). By this method the amount of diazepam and Ro 5-2180 can be determined in the same sample of blood in a single assay.

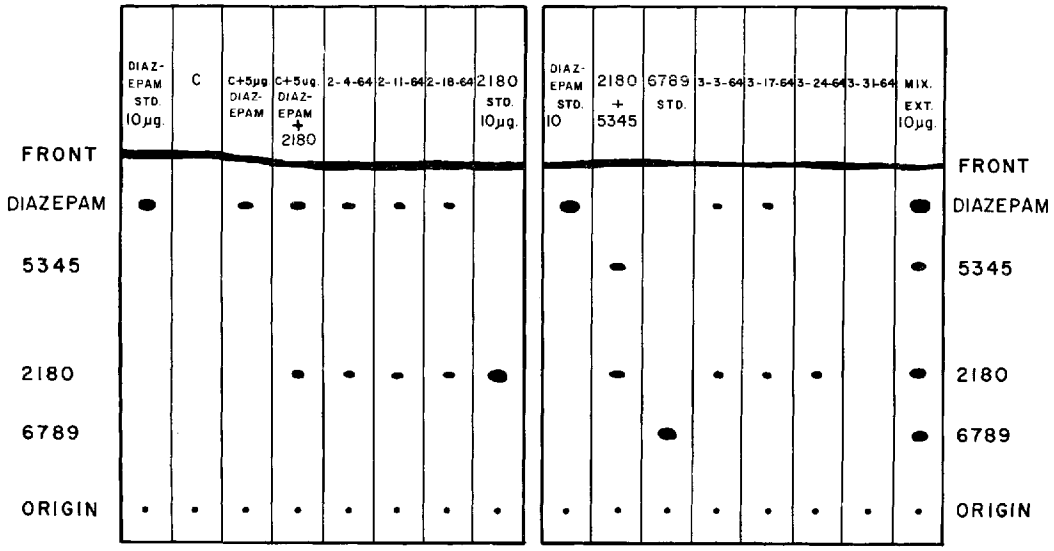

Fig. 3.—Thin-layer chromatograms of blood extracts showing the presence of intact diazepam and its *N*-demethylated metabolite, Ro 5-2180, in a patient maintained on high doses of diazepam for an extended period of time. Silica Gel G (Stahl) with fluorescent indicator. Solvent: chloroform–acetone, 90:10 v/v, 2 hr.

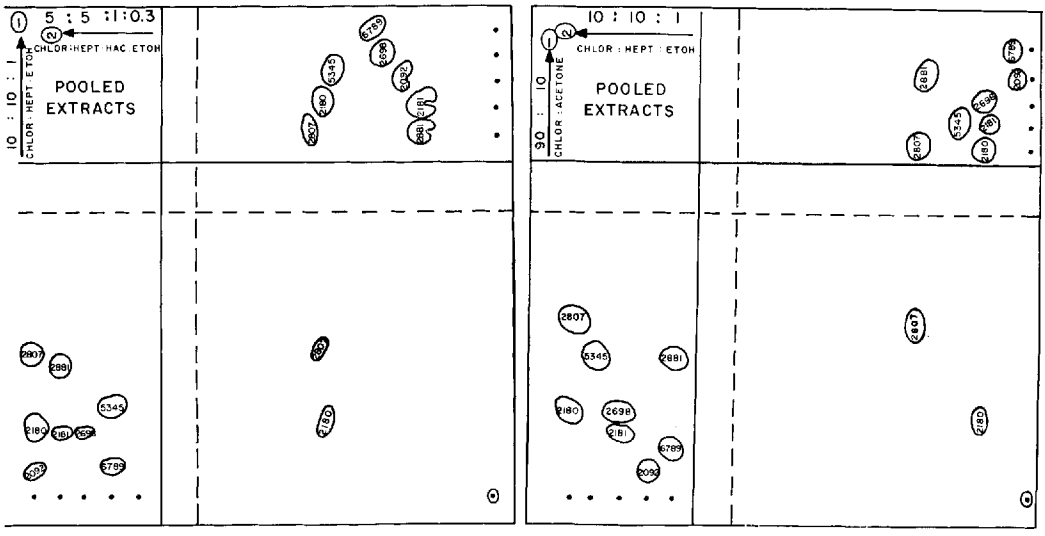

Fig. 4.—Two-dimensional thin-layer chromatograms of pooled blood extracts showing the presence of intact diazepam (Ro 5-2807) and its major metabolite (Ro 5-2180).

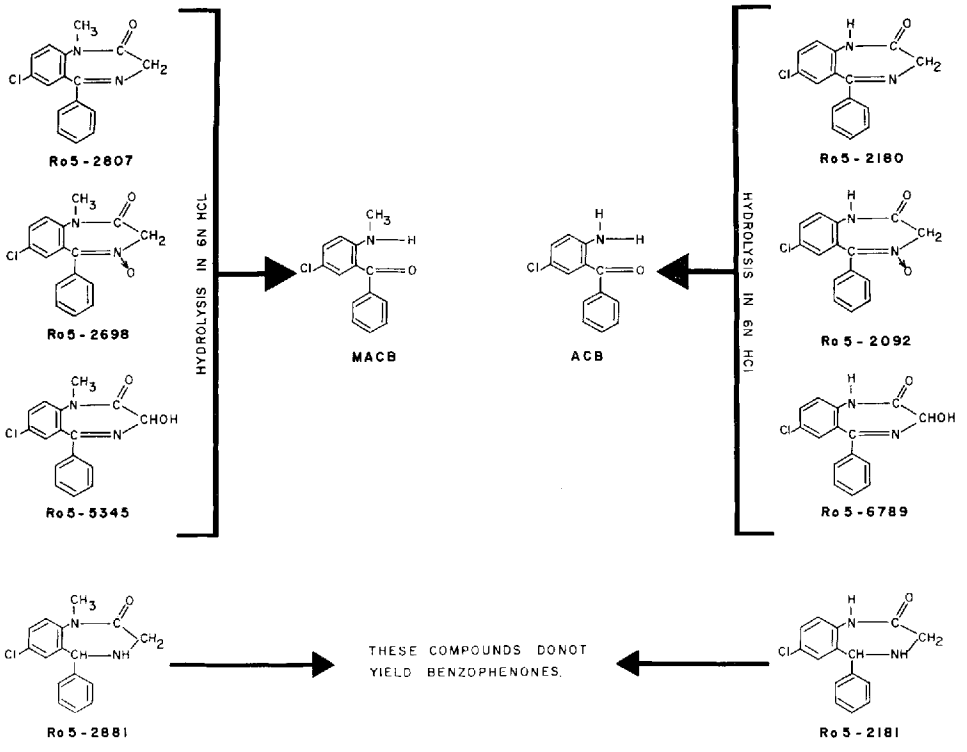
An improved procedure is described employing a liquid phase of 2% Carbowax 20M–terephthalic acid (CBW-20M-TPA), a synthetic polyester (7), which was found to be superior to Carbowax 20M used in the original method. It is a more polar phase with greater temperature stability, bleed resistance, column life, uniform coating characteristics, and produces very sharp well-resolved symmetrical (Gaussian shaped) peaks (Fig. 5). Its physical characteristics make it very selective for a number of benzophenones. The sample preparation for gas chromatography was carried out exactly as published (5).

Gas chromatographic parameters were obtained on a Jarrell-Ash instrument model Universal 26-700 equipped with an electron capture detector (No. 26-755) containing a 100 mc. titanium tritide β ionization source. Column: a 2-ft. column of 2% Carbowax 20M–terephthalic acid polyester phase on silanized Gas-Chrom P 100/120 mesh contained in $\frac{1}{4}$ in. stainless steel tubing was used. Carrier gas: nitrogen (oil pumped and dry) passed through a molecular sieve before entering the column was adjusted to a flow rate of 150–170 ml./min. measured at room temperature. The column head pressure was 17–20 psig on the second stage of the gas regulator. Condition of column head pressure and flow rate may be varied to obtain a retention time



Chemical structures and reactions of diazepam (Ro 5-2807) and some of its analogs. MACB = 2-methylamino-5-chloro-benzophenone. ACB = 2-amino-5-chloro-benzophenone.

Scheme I

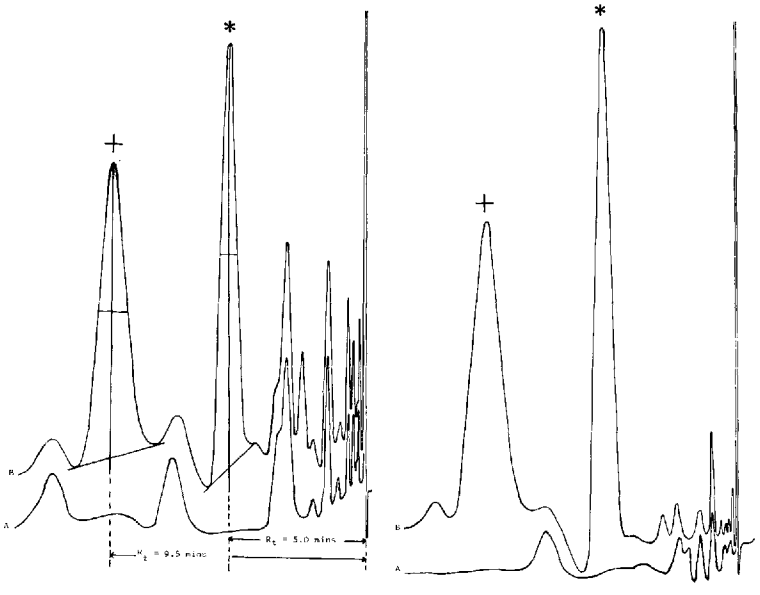


Fig. 5.—Chromatogram of diazepam and its *N*-demethylated metabolite determined by GLC as the MACB and ACB derivatives from blood extracts of patient L. R.; 30 mg. of diazepam per day for 10 days. Key: *, MACB; +, ACB; A, control blood from patient; B, patient blood after medication. Left, GLC assay of blood ether extract (10/100 μl.). Right, two-dimensional TLC of pooled blood ether extract and GLC assay of the two components (2/300 μl.).

(R_t) of 5–6 min. for MACB (diazepam) and 9–10 min. for ACB (Ro 5-2180) for effective resolution from adjacent peaks.

Temperatures: injection port, 250° ± 2.0; detector, 210° ± 2.0; oven, 215° ± 2.0 (isothermal); amplifier range, 10×10^{-9} amp. full-scale deflection (fsd); recorder, Bristol, output, 10 mv.; time constant, 1 sec. (fsd); chart speed, 1.25 cm./min. = 30 in./hr.; detector voltage, 20–30 v. d.c. Optimal detector voltage has to be determined for each compound assayed and should be checked frequently to compensate for any changes in detector response due to variation in standing current. Minimum detectable amounts of MACB = 5.0×10^{-9} Gm. (5 nanograms) and ACB = 10×10^{-9} Gm. (10 nanograms).

Preparation of Column Substrate.—The inert support Gas-Chrom P 100/120 mesh (Applied Sci-

ence Laboratories, State College, Pa.) was silanized according to the method described by Horning *et al.* (1959) to inactivate any adsorbent sites present. Two grams of Carbowax 20M–terephthalic acid (TPA) polyester phase (Wilkens Instrument and Research, Inc., Walnut Creek, Calif.) dissolved in 500-ml. of hot methylene chloride and 98 Gm. of silanized Gas-Chrom P 100/120 mesh were shaken for 30 min. on a reciprocating shaker with intermittent release of pressure. The material was transferred into a flat dish and the solvent evaporated off on a hot plate with continuous stirring. The coated substrate was then dried overnight in an oven at 200°, cooled to room temperature, and stored in an airtight container. A 2-ft. piece of stainless steel or aluminum tubing was packed with the prepared substrate and conditioned for 48–72 hr. at 230–240°. The column was then ready for use, and had a useful life span of at least 6 months of continuous use.

Preparation of Standard Curves of MACB and ACB.—2 - Methylamino - 5 - chlorobenzophenone (MACB) and 2-amino-5-chlorobenzophenone (ACB) synthesized by Sternbach *et al.* (8), of at least 99% purity, were dissolved in *n*-hexane (Fisher spectrograde) to yield separate stock solutions of 1 mg./ml. From this solution suitable dilutions were made in *n*-hexane to yield final solutions covering the range of 5 ng./10 µl. to 30 ng./10 µl. Three 10-µl. aliquots of each of the final solutions were injected into the gas chromatograph and from their average peak area a standard curve of peak area (cm.^{2}) *versus* nanograms of MACB or ACB was drawn. A standard curve should be determined for each day of analysis because column performance and detector response to these compounds changes with time.

Preparation of Standard Solutions of Diazepam and Ro 5-2180.—Diazepam and Ro 5-2180, synthesized by Sternbach and Reeder (1), of pharmaceutical grade purity (>99%), was used in the preparation of pure standard solutions.

Ten milligrams of each pure compound was weighed into separate 100-ml. volumetric flasks, and dissolved in 10–15 ml. absolute ethanol, warming the flask if necessary to effect solution. The solutions were made to volume with absolute ethanol, and should be water white in color.

The stock solution (A) contains 100 mcg./ml. One milliliter of solution A was transferred into another 100-ml. volumetric and diluted to volume with distilled water. The standard solution (B) contains 1 mcg./ml.

Suitable aliquots of solution B were used for obtaining recovery data from blood. Solutions A and B should be made fresh daily.

RESULTS AND DISCUSSION

The blood level distribution patterns of diazepam and its *N*-demethylated analog (Ro 5-2180) in man were determined by a gas-chromatographic procedure (5), which has an over-all recovery of 90% ± 6.0 and a sensitivity limit of 0.02–0.03 mcg. of diazepam/ml. of blood. The recovery of Ro 5-2180 is of the order of 70% ±7.0 with a sensitivity limit of 0.05–0.10 mcg./ml. (Table I.)

Diazepam Blood Levels Following Single Doses.—Blood level fall-off curves following single 10-mg. oral doses (Fig. 6), indicated that peak blood diazepam levels ranging from 0.18–0.22 mcg. were obtained 1 hr. after dosing, after which these levels declined rapidly within 6 hr. (half-life = 2–3 hr.) to a plateau level of 0.04–0.05 mcg./ml. This level was maintained for 12–24 hr. after which a gradual decline was seen (half-life = 27–28 hr.). These data appear to confirm the fall-off pattern using ^{3}H-labeled diazepam where the ether extractable radioactivity was measured by liquid scintillation counting.

In another study using a parenteral formulation (F-126) a group of three patients received a single 10-mg. intravenous dose of diazepam, while another group of three patients received the same formulation as a single 10-mg. intramuscular dose. The blood level curves (Fig. 7) indicate that the blood level maxima obtained with the parenteral formulation were of the same order of magnitude as those obtained with the oral doses. As before, the maxima were followed by a decline in the blood level

within 4 hr. (half-life = 2–3 hr., indicating removal into tissue storage depots. No measurable amounts of the *N*-demethylated metabolite of diazepam were seen after these 10-mg. single doses.

Blood Level Distribution Pattern of Diazepam and Its Metabolite During Administration of Repeated Doses.—In this series of experiments the blood level patterns of diazepam and its *N*-demethylated metabolite were studied in two patients during periods of repeated daily dosage and immediately following the discontinuation of drug treatment.

Total daily oral doses of 30 mg. of diazepam (lying within the normal therapeutic range) were administered in divided doses either in the form of regular 10-mg. tablets (t.i.d.) or in the form of 15-mg. (7.5 + 7.5 mg.) repeat action tablets (b.i.d.). Blood specimens were drawn for analysis every 12 hr. (8 a.m. and 8 p.m.) during the entire experimental period; and, in addition at 1, 4, and 6 hr. after the first dose.

One patient (L. R.) received the drug for 10 consecutive days which represented a cumulative dose of 300 mg. He was taken off medication for 7 days, after which diazepam treatment was resumed for 10 more days, giving a second cumulative dose of 300 mg. The other subject (H. W.) was treated for 5 days with a cumulative dose of 150 mg. After a drug free period of 7 days, he received diazepam treatment for another 5 days or a second 150-mg. cumulative dose. The two dosage forms were alternated and their sequence was reversed in a crossover fashion in the two subjects. This was of no consequence to the particular purpose of this study.

All the specimens were assayed for intact diazepam and its *N*-demethylated metabolite by GLC. The blood levels of diazepam and of Ro 5-2180 are plotted against time in Figs. 8 and 9, respectively. In both patients the curves for diazepam and the metabolite are seen to follow basically very similar patterns. Diazepam blood levels after the expected initial drop from the maxima after the first dose, increased with each day of continued medication. In the first subject (L. R.) the diazepam levels rose from a 24 hr. value of 0.18 mcg./ml. to a final value of 0.8–1.0 mcg./ml. during the 10-day period of medication. In the second subject (H. W.) there was a corresponding rise from an initial 24 hr. level of 0.12 mcg./ml. to a maximum of 0.50 mcg., within 4 days. The metabolite Ro 5-2180 could not be detected initially in either subject up to 36 hr. after the first dose, but from then on its blood levels showed a steady increase, gradually approaching the concentrations of the parent compound. This pattern was more systematic in patient L. R., especially during the first 10-day period of medication.

In both experiments discontinuation of the drug did not show an immediate change in the blood level

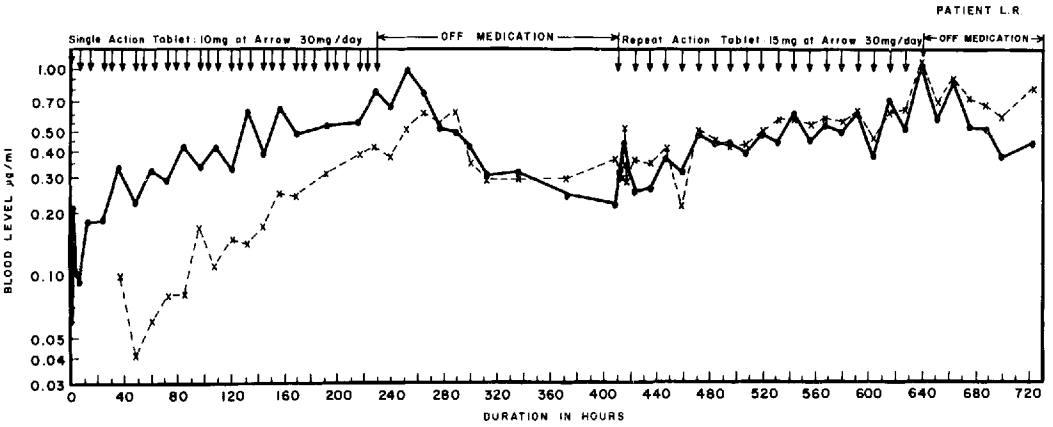

Fig. 8.—Blood level distribution pattern of diazepam and Ro 5-2180 in man following administration of single action tablets *vs.* repeat action tablets. Key: ●, diazepam Ro 5-2807; ×, metabolite Ro 5-2180.

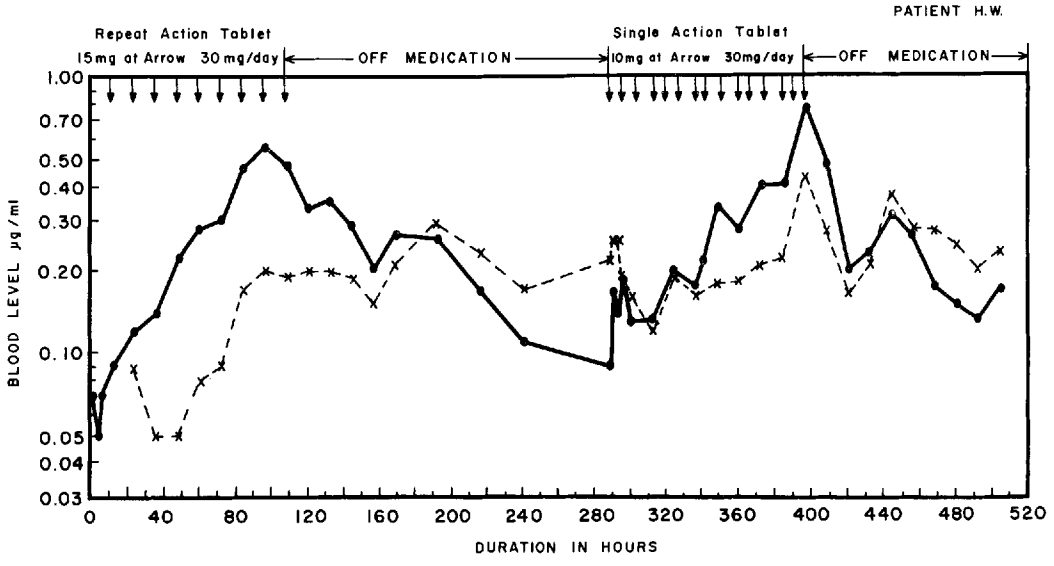

Fig. 9.—Blood level distribution pattern of diazepam and Ro 5-2180 in man following administration of repeat action tablets *vs.* single action tablets. Key: ●, diazepam Ro 5-2807; ×, metabolite Ro 5-2180.

of either component. The diazepam levels showed an erratic but definite decline with time but were still measurable at the end of the 7-day fall-off period. The metabolite levels fluctuated without a distinct downward trend. As a result, the ratio of the two components changed gradually in favor of the metabolite. By the end of the drug-free period the metabolite levels consistently exceeded those of intact diazepam.

Uptake of the drug during the second period of medication produced an increase in the cumulative blood levels over and above the residual threshold levels after the first fall-off period. Owing to the high residual metabolite levels, the ratio of the metabolite to diazepam was maintained close to unity, especially in patient L. R. where the earlier cumulative dose had been higher.

These blood level curves bring out the important fact that the concentration of diazepam, the ratio of diazepam to its metabolite, and also the rate of elimination of these components from blood depend not merely on the dose administered at the time of sampling but also depend greatly on the preceding dosing history and its ultimate duration. These levels are governed specifically by the cumulative amount of drug administered continuously and by the duration of time of continuous medication. The blood level distribution pattern is influenced by all these parameters, and it is also indicative of drug accumulation in some tissue storage depots.[2] Release from such depots back into the blood stream is manifested by the slow and erratic saw-toothed fall-

[2] Tissue storage depots implies those compartments of the body which are associated in drug accumulation, metabolism, and excretion. Such depots are defined in the terminology of biopharmaceutics and pharmacokinetics as "shallow" compartments of soft extra vascular tissues, *e.g.*, liver, kidney, intestinal tract, and other associated organs and "deep" compartments of tissues such as bone, marrow, muscle, fat, all of which are accessible and interconnected through the blood circulatory system. Consequently, chemical compounds carried in the blood can be stored and/or metabolized in these depots, and later released back into circulation prior to excretion. [See Wagner, J. G., *J. Pharm. Sci.*, **50**, 359(1961); Doluisio, J. T., and Swintosky, J. V., *Am. J. Pharm.*, **137**, 144(1965); **137**, 175(1965).]

off pattern seen after the discontinuation of dosing. The faster buildup and the much slower disappearance of the metabolite levels indicate a relatively slower metabolism and excretion of this product.

Blood Level Distribution Pattern of Diazepam and Its Metabolite During Chronic Administration of Massive Doses.—An opportunity to study the blood level distribution pattern of diazepam and its metabolites under more extreme conditions of chronic dosing was offered by a unique therapeutic experiment. It involved a male patient (L), age 53, with a history of chronic alcoholism and related psychic disorders who was able to tolerate daily doses of diazepam as high as 200 mg. without major side effects (9).

Blood specimens were taken at weekly intervals. They were originally analyzed by the U.V. spectrophotometric assay for "total" diazepam, and then reexamined by the differential GLC procedure (Table II).

[a] The patient was under the care of Dr. K. S. Ditman, Alcoholism Research Clinic, Department of Psychiatry, Center for Health Sciences, University of California at Los Angeles. [b] N.M. = not measurable.

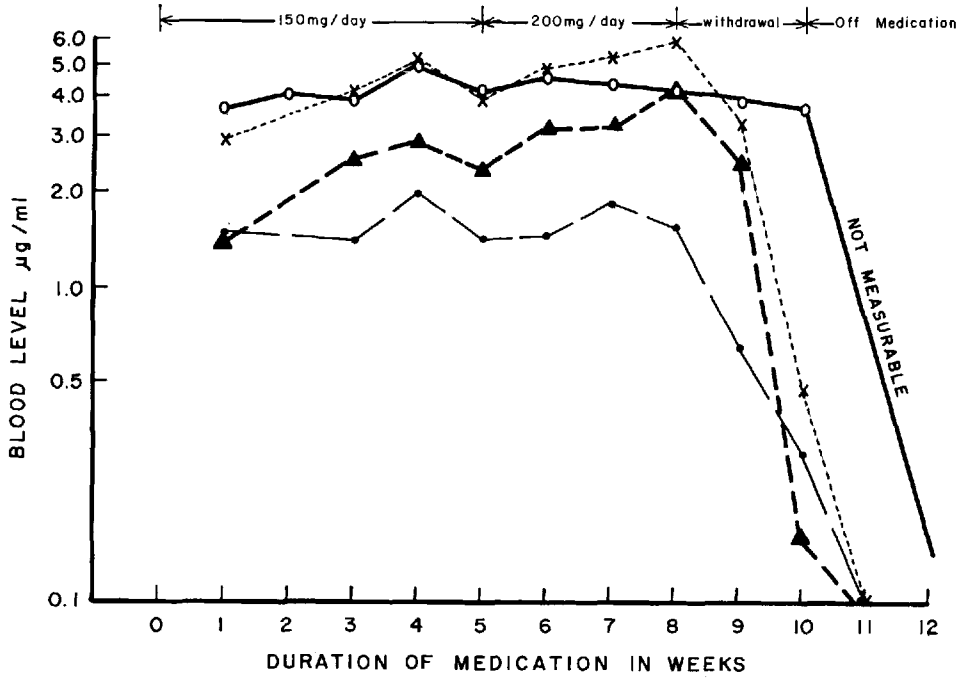

Fig. 10.—Blood levels of diazepam and its metabolite (Ro 5-2180) from a human given 150–200 mg./day orally for 8 weeks followed by gradual withdrawal of medication. Key: ●, diazepam (GLC); ▲, metabolite (2180) (GLC); ×, total diazepam equivalent GLC (calcd.); ○, total diazepam + metabolite (U. V.).

The blood level distribution pattern of the two individual components, of the calculated sum of the two, and of the total spectrophotometrically measured material are shown in Fig. 10. After a cumulative dose of 750 mg. within the first week the blood level of intact diazepam was 1.51 mcg./ml. but then tended to stabilize itself rapidly with continued medication at 1.60–1.64 mcg./ml. After 4 weeks of continuous medication at a dosage of 150 mg./day, followed by 3 weeks at an increased dosage of 200 mg./day, the blood level of intact diazepam did not show a significant increase over the first week level of this component in blood. This seemed to indicate than an equilibrium was established between drug uptake and its disposition by metabolism, excretion, and/or tissue distribution. The levels of Ro 5-2180 equaled those of the parent component by the end of the first week, but continued to rise to about twice this value during 2 more weeks of treatment. Thereafter, with fluctuation of the absolute blood levels of the two components, the ratio of the metabolite to intact diazepam maintained a fairly constant value of about 1.8, with the exception of the last week of treatment at the highest daily dose when a further increase of this ratio was noted. A more pronounced rise of this ratio during the final phase of gradual drug withdrawal was the result of a relatively faster decline of the intact diazepam blood level over that of the metabolite.

The curves for the total drug levels as measured by the two procedures indicated reasonable agreement, except for the discrepancies during the withdrawal period, which remain unexplained.

The clinical observation of an abnormally high drug tolerance suggested the possibility of either a congenital or of a drug-induced increased metabolic rate in this subject. An increased rate of diazepam metabolism due to congenital factors would manifest itself by a slower buildup of the blood levels, by a lower stabilization level, and by a more rapid fall-off after withdrawal. A drug-induced stimulation of a metabolizing enzyme system, *e.g.*, the liver microsomal enzyme system, would be reflected in a gradual lowering of the stabilization level during continued dosing at a constant rate. The blood level curves obtained provided no conclusive evidence of such factors in operation in this patient. The diazepam blood level of 1.51 mcg./ml. produced by a cumulative dose of about 750 mg. during the initial phase appears to be in keeping with a corresponding value of 0.8–1.0 mcg./ml. produced by a 300-mg. total dose, and of a value of 0.50 mcg./ml. following a 150-mg. total dose in the earlier low dose experiments. This, therefore, indicated similar rates of drug accumulation in all three patients. The stabilization levels of both diazepam and Ro 5-2180 maintained a fairly constant value throughout the entire period of dosing at the high level. The blood level fall-off rates during the withdrawal period were difficult to evaluate in terms of possible changes in metabolic rates due to the stepwise reduction of drug discontinuation and to the insufficient number of samples measured during this period.

Since the GLC method is capable of resolving diazepam from its metabolite Ro 5-2180, the specificity of the method depends on the absence of other analogs of diazepam, which if present in blood, and/or are ether extractable, would be hydrolyzed to MACB and ACB, respectively, and give erroneous values for diazepam and Ro 5-2180 (Scheme I). Blood specimens from the high dose patient were pooled and analyzed first by one-dimensional and then by two-dimensional thin-layer chromatography to observe the presence, if any, of other possible metabolic analogs which might interfere with the GLC assay.

The chromatoplates (Figs. 3 and 4) showed only the presence of intact diazepam and its major metabolite Ro 5-2180. This was further verified in

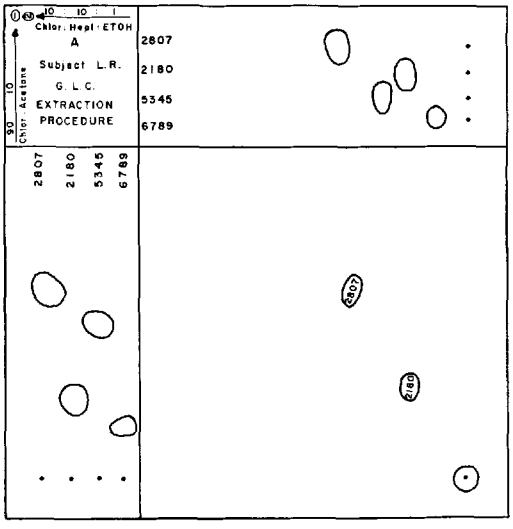

Fig. 11.—Two-dimensional thin-layer chromatogram of pooled blood extracts of a patient (L. R.) who had received 30 mg. of diazepam per day for 10 days, using the extraction procedure for GLC assay, showing the presence of only diazepam and its *N*-demethylated metabolite, Ro 5-2180.

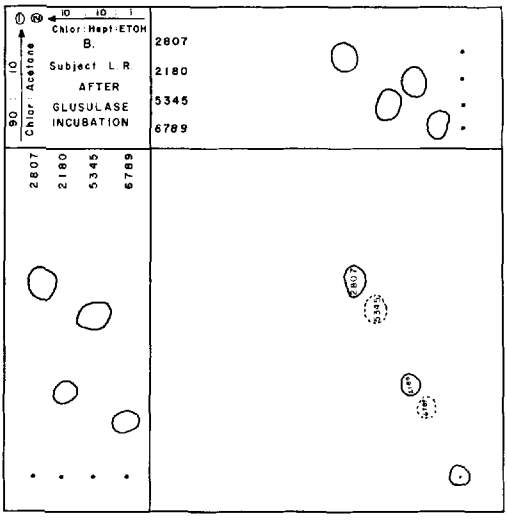

Fig. 12.—Two-dimensional thin-layer chromatogram of pooled blood extracts of a patient (L. R.) who had received 30 mg. of diazepam per day for 10 days. Using the same extraction procedure as in Fig. 11, but after incubating the blood with Glusulase enzyme, shows the presence of diazepam, Ro 5-2180, Ro 5-6789, and Ro 5-5345.

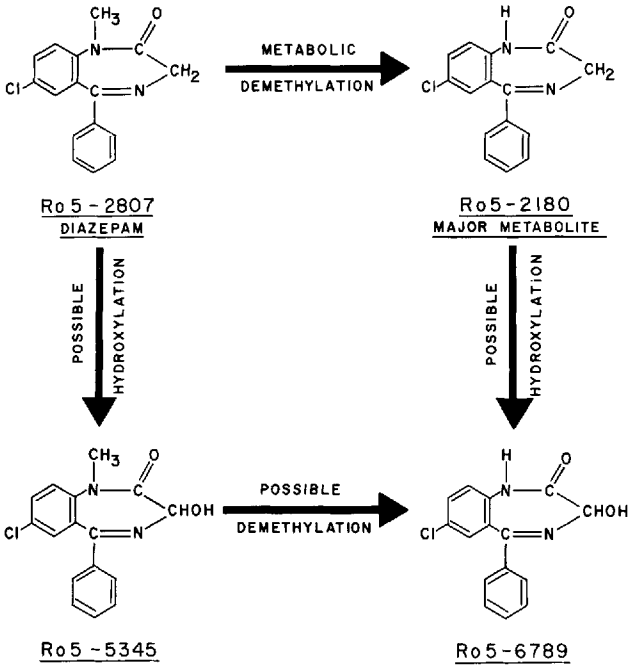

Possible metabolic pathways of diazepam in humans.

Scheme II

pooled blood ether extracts from the patients (L. R. and H. W.) of the low dose experiments (Fig. 11). The areas on the plate corresponding to diazepam and the metabolite were scraped off, extracted with ether, and then taken through the GLC procedure. The chromatograms (Fig. 5) establish the formation of MACB and ACB (benzophenones) from the hydrolysis of their respective parent compounds found in the blood, thus establishing the specificity of the GLC method for diazepam and Ro 5-2180. By two analytical procedures (TLC and GLC) diazepam and its *N*-demethylated analog Ro 5-2180 have been shown to be the major ether extractable components present in the blood of patients treated with the pharmaceutical formulations of diazepam.

Since the 3-hydroxy compounds, Ro 5-5345 and Ro 5-6789 (oxazepam) (10), have been shown to be significant metabolites of diazepam in human urine in the form of conjugated glucuronides (4), their presence in the blood as such was also investigated. Aliquots of blood were pooled (32 ml.), acidified with diluted HCl to pH 5.5, and incubated in a 37° water bath with 0.5 ml. of Glusulase enzyme (Endo Labs, Inc., Richmond Hill, N. Y.; activity = 100,000 units of glucuronidase, 50,000 units of sulfatase/ml.) for 2 hr., swirling every 15 min. The samples were then buffered to pH 7.0, extracted with ether, and analyzed by two-dimensional TLC using the same solvent systems as before.

The chromatoplates (Fig. 12) showed the presence of significant amounts of diazepam and Ro 5-2180 and also trace amounts of Ro 5-5345 and Ro 5-6789. After acid hydrolysis and GLC analysis, the identity of diazepam and Ro 5-2180 recovered from the chromatoplates was again established with significant amounts of their respective benzophenones, whereas Ro 5-5345 and Ro 5-6789 present in trace amounts gave much less significant but measurable amounts of MACB and ACB, respectively. It was estimated that the pooled blood contained approximately 0.19 mcg./ml. of diazepam and 0.13 mcg./ml. of Ro 5-2180, whereas Ro 5-5345 (0.008 mcg./ml.) and Ro 5-6789 (0.004 mcg./ml.) were present and/or extractable in trace amounts as the free hydroxy compounds only after incubation with Glusulase. Of these four compounds only diazepam and Ro 5-2180 were directly extracted and quantized by the GLC procedure, the other two being present as nonextractable conjugated glucuronides in the blood, which were only released as the free hydroxy compounds after incubation with Glusulase enzyme.

Studies on the metabolism of diazepam in the dog (11) have indicated a metabolic pathway in this species which is similar to man. However, when rabbits were fed chronic doses of diazepam (600–800 mg./Kg.), Jommi *et al.* (12) detected the presence of two other possible metabolites in addition to those found in man and in the dog. These were identified after strong acid hydrolysis as 2 methyl amino-5-chloro-4′-hydroxybenzophenone and 2 amino-5-chloro-4′-hydroxybenzophenone, being derived from their respective 1,4-benzodiazepines. Metabolites corresponding to these two compounds have not yet been reported in man or dog.

The findings of Schwartz *et al.* (4), on the metabolism of diazepam in man using tritiated diazepam labeled in the C_5 phenyl ring, were verified in man using TLC and GLC as analytical techniques with diazepam in pharmaceutical formulations used as the vehicle of administration. The metabolic pathways of diazepam in man are summarized in Scheme II and the data obtained indicate that the principal pathway is through the *N*-demethylation of diazepam to Ro 5 2180, which is then hydroxylated at position C-3 to Ro 5-6789. There is also evidence for a hydroxylation at C-3 of diazepam to yield Ro 5-5345 which could then be *N*-demethylated to give Ro 5-6789. The 3-hydroxy compounds are excreted as conjugated glucuronides, whereas the *N*-demethylated

metabolite Ro 5-2180 is excreted as the intact compound. No measurable amounts of intact diazepam have yet been found to be excreted in human urine, and the 3-hydroxy compound Ro 5-6789 (oxazepam) (13, 14) is a major urinary metabolite of diazepam in man.

Polarography of Various *N*-Alkyl-*N*-nitrosoureas

By EDWARD R. GARRETT and ANTHONY G. CUSIMANO

The irreversible polarographic reductions of various *N*-alkyl-*N*-nitrosoureas were studied from a pH of 1.1–6.7. Below pH 3.2, the limiting current, $i_{lim.}$, of *N*-methyl-*N*-nitrosourea (NNMU) is controlled by diffusion. Above this pH, adsorption or chemical reaction is the electrode-controlling process and buffer effects are observed. Similar results were obtained for *N*-ethyl-*N*-nitrosourea (NNEU) and 1,3-dimethyl-1-nitrosourea (SRI-1384), except that the buffer effects were greatly diminished for the latter compound. The acetate buffer effects on $i_{lim.}$ have been quantified and have been attributed either to adsorption of the nitrosourea (NNMU) and the buffer components onto the microelectrode, or to a reaction between these species. The polarographic method offers a sensitive (1×10^{-6} *M*) and reliable (0.91 per cent standard error among days) assay procedure for the nitrosoureas. All of the compounds studied in this series were more easily reduced than the parent methyl compound. A correlation between the change in the half-wave potentials and the Taft substituent constants (σ^*) was noted for simple alkyl groups such as methyl, ethyl, butyl, etc. A correlation between the half-wave potentials and the apparent first-order rate constants (k, sec.$^{-1}$) for hydroxyl ion catalyzed solvolysis was noted for several of the compounds studied.

THE ANTILEUKEMIC and antiviral activities of various *N*-nitrosoureas have been reported (1–4). They have a high degree of lipoid solubility, are essentially nonionized, and are not bound to any extent by plasma proteins.

Degradation studies (5) of the broad spectrum antibiotic streptozotocin indicated that it is a substituted *N*-methyl-*N*-nitrosourea, and the maintenance of the biological activity could be related to the stability of the *N*-nitroso group.

A physicochemical parameter which could be correlated with biological activity, chemical structure, or reactivity would be useful in molecular modification to obtain a better drug. Although the mechanism of action of the *N*-alkyl-*N*-nitrosoureas is not known for certain, it is plausible that they may act as alkylating agents since a diazoalkane may be a solvolytic intermediate (6) or that they may act *via* a redox mechanism. The polarographic half-wave potential ($E^1/_2$) is a good electrochemical measure of the ease of reduction of such compounds.

Polarographic studies of *N*-nitrosoureas have been limited (5, 7) and have primarily been used to study the degradation of streptozotocin (5) and *N*-methyl-*N*-nitrosourea (7). This is in contrast to the detailed work on the polarographic reductions of various *N*-nitrosamines which have been studied by many investigators (8–14).

The purposes of this investigation were to characterize polarographically the reduction of a series of *N*-alkyl-*N*-nitrosoureas, to develop analytical methods, and to test for correlations of half-wave potentials with solvolytic rate constants and with substituent constants.

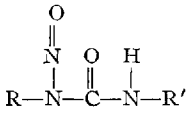
TABLE I.—NAMES AND STRUCTURES OF VARIOUS *N*-ALKYL-*N*-NITROSOUREAS



Compd.	Symbol	R	R′	Mol. Wt.
N-Methyl-*N*-nitrosourea	NNMU[a]	CH_3	H	103.1
N-Ethyl-*N*-nitrosourea	NNEU[a]	CH_3CH_2	H	117.1
N-Butyl-*N*-nitrosourea	NNBU[a]	$CH_3(CH_2)_3$	H	145.1
N-Isobutyl-*N*-nitrosourea	NNisoBU[a]	$CH_3CH(CH_3)CH_2$	H	146.1
N-Allyl-*N*-nitrosourea	NNAU[a]	CH_2=$CHCH_2$	H	129.1
N-Cyclohexyl-*N*-nitrosourea	NNCyU[a]	C_6H_{11}	H	171.2
N-Benzyl-*N*-nitrosourea	NNBcU[a]	$C_6H_5CH_2$	H	179.2
1,3-Dimethyl-1-nitrosourea	SRI-1384[b]	CH_3	CH_3	117.1
1,1′-Trimethylene bis(3-methyl-3-nitrosourea)	SRI-1631[b]	CH_3	$(CH_2)_3NHCON(NO)CH_3$	246.2
1,3-Bis (2-chloroethyl)-1-nitrosourea	SRI-1720[b]	$ClCH_2CH_2$	CH_2CH_2Cl	214.1
3-(*p*-Fluorophenyl)-1-methyl-1-nitrosourea	SRI-1746[b]	CH_3	*p*-F-C_6H_4	197.2
1-Methyl-1-nitroso-3-phenethylurea	SRI-1833[b]	CH_3	$CH_2CH_2C_6H_5$	207.2
1-Nitroso-1-phenethylurea	SRI-1834[b]	$C_6H_5CH_2CH_2$	H	193.2
1-(2-Chloroethyl)-nitroso-3-phenylurea	SRI-1879[b]	$ClCH_2CH_2$	C_6H_5	227.7

[a] Compounds synthesized in these laboratories (6). [b] Code number of the Southern Research Institute, Birmingham, Ala. (3).

EXPERIMENTAL

Materials and Equipment.—The *N*-alkyl-*N*-nitrosoureas (Table I) were synthesized either in these laboratories (6) or by the Southern Research Institute, Birmingham, Ala. (3). All other chemicals used were of analytical reagent grade. The buffer compositions were similar to those used by Malspeis and Hung (14). The pH values of all buffers except hydrochloric acid solutions were measured, before and after each run, with a Beckman expanded scale pH meter, model 76. The pH meter was standardized at 25.0° with Beckman standard buffers of pH 4 and 7. The pH values of hydrochloric acid buffers were calculated using the activity coefficients (15) at 25.0°. The ionic strength (μ) of each solution was adjusted to 0.200 with KCl.

A Sargent model XV polarograph was used. The electrolysis cell was a Sargent H-type which was immersed in a constant-temperature bath at 25.0° ± 0.1°.

Polarographic Procedure.—A master solution of the *N*-nitrosourea in distilled water was prepared at least every other day and was refrigerated when not in use. Degradation under these conditions was negligible. In those experiments where all of the compounds were studied, 8% alcohol by volume was used in preparing the master solution since some of the nitrosoureas, in particular the disubstituted derivatives, were difficultly soluble in water alone. An aliquot of the master solution was diluted with the appropriate buffer which was previously purged with nitrogen. No more than 1% alcohol by volume was present in the polarographed solutions. Alcohol did not have an effect on the polarograms.

The sample solutions were purged with nitrogen for 10 min., and their polarograms run over that of the appropriate blank solutions. Due to the instability of the nitrosoureas in phosphate buffers, this purging was limited to 3 min. The buffers were purged for 15–30 min. prior to the dilution of aliquots of the master solution.

Each polarogram was recorded at a constant mercury head and at a constant temperature of 25.0° ± 0.1°. The indicator electrode used was the dropping mercury electrode (DME), whereas a saturated calomel electrode (SCE) was the reference electrode. The DME had values of $m^{2/3}t^{1/6}$ of 2.780 mg.$^{2/3}$ sec.$^{-1/2}$ open circuit and 2.766 mg.$^{2/3}$ sec.$^{-1/2}$ at −1.0 v. *versus* SCE in HCl–KCl buffers, 2.799 mg.$^{2/3}$ sec.$^{-1/2}$ open circuit and 2.786 mg.$^{2/3}$ sec.$^{-1/2}$ at −1.0 v. *versus* SCE in tartrate buffers, 2.753 mg.$^{2/3}$ sec.$^{-1/2}$ open circuit and 2.741 mg.$^{2/3}$ sec.$^{-1/2}$ at −1.1 v. *versus* SCE in acetate buffers, and 2.741 mg.$^{2/3}$ sec.$^{-1/2}$ open circuit and 2.695 mg.$^{2/3}$ sec.$^{-1/2}$ at −1.4 v. *versus* SCE in phosphate buffers. These values were obtained at a column height of 62.2 cm.

Measurement of Half-Wave Potential and Limiting Current.—An arbitrary procedure was chosen to measure the half-wave potentials. The limiting currents of the polarographed solutions of the *N*-nitrosoureas were not exactly parallel to the currents of the blank solutions at the same applied potentials.

A line was drawn through the polarogram of the blank at the midpoints of the oscillations (curve A in Fig. 1). Another line was drawn through the midpoints of the oscillations for the sample polarogram in the region where the wave height halted its precipitous rise and before the hydrogen discharge wave (curve B in Fig. 1). The distances between these two lines were halved (curve C in Fig. 1). This third line intersected the polarogram at a potential which was designated the half-wave potential ($E_{1/2}$). No correction for resistance across the cell was necessary since the resistance was always less than 500 ohms.

The limiting currents, $i_{lim.}$ (Fig. 1), were estimated

from the differences between the currents for the sample solutions and the blank solutions at potentials 0.35 v. more negative than the half-wave potential. This was a reasonable estimate of the midpoint of the linear portion of the polarogram between the wave for the reduction of the *N*-nitrosourea and the hydrogen discharge wave.

PROCEDURES

Calibration Curve for NNMU.—A 10.3-mg. sample of NNMU is accurately weighed into a 25-ml. volumetric flask. It is dissolved and brought to volume with distilled water to give a 4×10^{-3} *M* master solution. This solution is refrigerated when not in use and is prepared freshly each day. Into several 25-ml. volumetric flasks are placed aliquots of the master solution ranging from 0.025–2.00 ml. Enough nitrogen purged distilled water is added to each flask to make 2.00 ml. and acetate buffer is added to volume. The acetate buffer is prepared so that the final solution is: $[HC_2H_3O_2]$ = 0.005 *M*, $[NaC_2H_3O_2]$ = 0.003 *M*, and [KCl] = 0.197 *M*. The polarogram of each standard solution is then run.

Assay Method.—The polarographic procedure is the same as that previously described. Each sample is purged with nitrogen for 10 min. and the polarogram is run over that of a blank solution. Samples of unknown concentrations of NNMU are prepared and run in a similar manner. The limiting currents are measured at −1.3 v. *versus* SCE.

The method may be modified somewhat to study the fast solvolysis of these compounds in alkaline or strong acid media at higher temperatures. In this case the degrading solution is kept in the electrolysis cell during the entire run, and the polarogram is obtained at specified time intervals.

RESULTS AND DISCUSSION

Wave Characteristics.—The *N*-alkyl-*N*-nitrosoureas (Table I) exhibited well-defined polarographic waves throughout the entire pH range. The polarographic parameters, $E_{1/2}$ and $i_{lim.}$, were easily measured and no maxima were observed. Typical polarograms of NNMU at various pH values and in various buffers are shown in Fig. 1. The curves are drawn through the midpoints of the oscillations. The half-wave potential shifted to more negative values with increased pH of the solution. Since the reduction of most organic compounds involves hydrogen ions, this shift is in accordance with the Nernst equation (16).

The irreversible nature of the reduction was evident from the results of the logarithmic analyses (16) of representative polarograms of NNMU.

Reversibility is characterized by a single straight line for the plot of the applied potential, *E versus* $\log[i/(i_{lim.} - i)]$, where *i* is the current at a specified potential, *E*, and $i_{lim.}$ is the limiting current. For a reversible electrode process the number of electrons (*n*) involved in the reduction can be directly obtained from the slopes of such plots (16). Reversible polarographic waves are symmetrically S-shaped.

Such logarithmic analyses yielded two straight line segments for pH 1.10 solutions. Single straight lines were obtained for solutions in the pH range

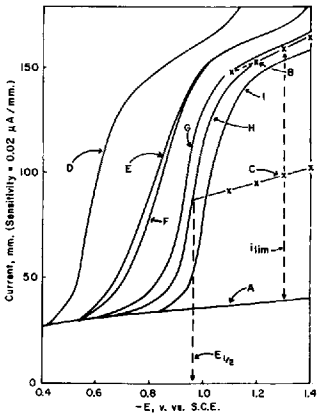


Fig. 1.—Typical polarograms of NNMU (1.1×10^{-4} *M*) in various buffers at 25.0° and at column height of 62.2 cm. Key: A, polarogram of blank solution; B, polarogram of sample solution; C, line through half-values of limiting current intersecting wave at half-wave potential ($E_{1/2}$); D, HCl–KCl buffer, pH 1.10; E, HCl–KCl buffer, pH 2.33; F, tartrate buffer, pH 2.52; G, acetate buffer, pH 3.70; H, acetate buffer, pH 4.81; I, phosphate buffer, pH 6.28.

2.0–4.8. However, the calculated values of *n* were less than unity. Typical values of *n* were 0.35–0.37 in HCl–KCl buffer (pH 2.33) and tartrate buffer (pH 2.78), and 0.54–0.59 in acetate buffers from pH 3.5–4.8.

The skew S-shaped curves (Fig. 1) are also representative of irreversibility where the electron transfer process is either slower or of the same order of magnitude as the electrode controlling process, *e.g.*, diffusion or adsorption.

Effect of pH on Half-Wave Potential and Limiting Current.—Typical data for the half-wave potentials and the limiting currents for NNMU at various pH values are presented in Table II. The half-wave potential-pH profile is shown in Fig. 2. The latter has two straight line segments. The intersection of these segments at a pH of 3.2 indicates a change in either the mechanism of the reduction reaction or in the electrode controlling process. The equations which describe the dependence of the half-wave potential on pH for NNMU are

$$-E_{1/2} = 0.165\ \text{pH} + 0.384 \quad \text{(pH 1.0 to 3.2)} \quad \text{(Eq. 1)}$$

$$-E_{1/2} = 0.030\ \text{pH} + 0.824 \quad \text{(pH 3.2 to 6.8)} \quad \text{(Eq. 2)}$$

Large changes in pH produced only small changes in the limiting current throughout the entire pH range (Table II). Malspeis and Hung (14) have reported that the wave height produced by the reduction of *N*-nitrosoephedrine decreased with pH. This was attributed to reduction controlled by both reaction rate and diffusion to the microelectrode. An electrode process in which the limiting current is essentially independent of pH is said to be controlled either by diffusion of the compound to the microelectrode or by adsorption onto the electrode surface (17). Malspeis and Hung (14) ascribed their results to a polarographic pKa with

[a] Limiting currents were measured at a potential 0.35 v. more negative than the half-wave potential. Each result is the average of three determinations. The deviations from the means were ±0.03. [NNMU] was 1×10^{-4} *M*. Height of mercury column was 58.0 cm. [b] Each result is the average of three determinations. The deviations from the means were ±0.003. [NNMU] was 1.1×10^{-4} *M*. Height of mercury column was 62.2 cm.

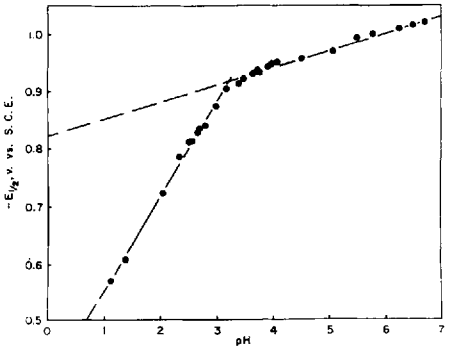

Fig. 2.—Effect of pH on half-wave potential ($E_{1/2}$) for reduction of NNMU (1.1×10^{-4} *M*) at 25.0° and at column height of 62.2 cm.

nitrosamine protonated at the microelectrode. Zahradnik (12) reported that the pKa values of *N*-nitroso derivatives of secondary aliphatic and heterocyclic amines ranged from −1.28 to −1.99 in 18.4% sulfuric acid at 22°. The absence of a spectrophotometric pKa was shown by no significant change in the absorbance and wavelength of maximum absorption of NNMU with pH at values above 1.10. There was no titratable pKa above pH 2.00 (6). There is no indication of a polarographic pKa for NNMU from a pH of 1.10–6.50.

Similar results were obtained for the reduction of *N*-ethyl-*N*-nitrosourea (NNEU) and 1,3-dimethyl-1-nitrosourea (SRI-1384). The equations describing the effect of pH on the half-wave potential for these compounds are for NNEU

$$-E_{1/2} = 0.153\ \text{pH} + 0.367 \quad \text{(pH 1.0 to 3.7)} \quad \text{(Eq. 3)}$$

$$-E_{1/2} = 0.027\ \text{pH} + 0.827 \quad \text{(pH 3.7 to 5.0)} \quad \text{(Eq. 4)}$$

and for SRI-1384

$$-E_{1/2} = 0.158\ \text{pH} + 0.330 \quad \text{(pH 1.0 to 4.3)} \quad \text{(Eq. 5)}$$

$$-E_{1/2} = 0.034\ \text{pH} + 0.808 \quad \text{(pH 4.3 to 7.0)} \quad \text{(Eq. 6)}$$

The similarities in the coefficients of the pH terms indicate that the mechanism of the reduction reaction or the electrode controlling process is the same for the three compounds and probably for all simple alkyl substituted nitrosoureas.

Effect of Height of Mercury Column on Limiting Current.—The dependence of the limiting current on the height of the mercury column is shown in

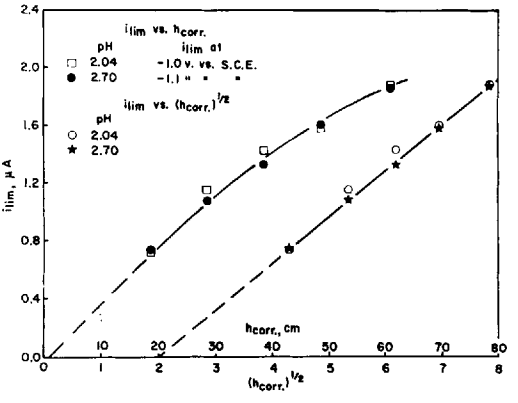

Fig. 3.—Effect of height of mercury column on limiting current for reduction of NNMU (9×10^{-5} *M*) in HCl–KCl (pH 2.04) and tartrate buffers (pH 2.70) at 25.0°.

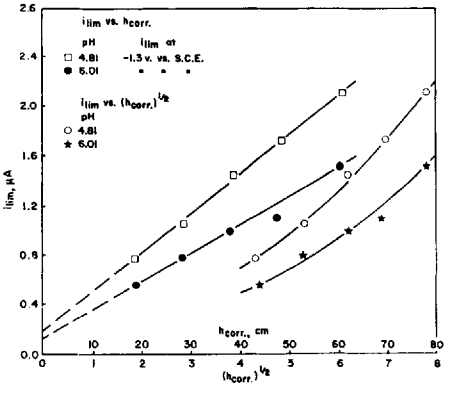

Fig. 4.—Effect of height of mercury column on limiting current for reduction of NNMU in acetate (pH 4.81, [NNMU] 9×10^{-5} *M*) and phosphate (pH 6.01, [NNMU] 8×10^{-5} *M*) buffers at 25.0°.

Figs. 3 and 4 for NNMU. In hydrochloric acid and tartrate buffers the limiting current was directly proportional to the square root of the corrected height of the mercury column (Fig. 3). Therefore, the control of the electrode process is consistent with diffusion of the nitrosourea to the microelectrode (17) in these buffers and at these pH values.

In acetate and phosphate buffers (Fig. 4) the limiting current was proportional to the corrected height of the mercury column and not to its square root. Thus, the control of the electrode process is consistent with adsorption of the nitrosourea onto the dropping mercury electrode surface (17) in these buffers and at these pH values.

These relations are consistent with the change in linearity in the half-wave potential-pH profile of NNMU (Fig. 2). Below a pH of 3.2, the electrode process is diffusion controlled, and above this pH adsorption may be the controlling process.

Effect of Buffer Concentration on Polarographic Parameters.—In tartrate buffers (0.001–0.01 *M* in each component) there was no significant change in the limiting current and half-wave potential of NNMU with buffer concentration at a particular pH. In acetate and phosphate buffers (0.001–0.01 *M* in each component) some decreases were observed in the limiting current and some positive shifts in the half-wave potential. A similar effect had been observed previously (5).

The parameters derived from polarograms in acetate buffers (0.010–0.200 *M* in each component) at several pH values are given in Table III. A typical plot of the limiting current against the concentration of acetic acid for various pH values is given in Fig. 5. Similar plots of varying slopes were obtained for the limiting current *versus* concentration of sodium acetate. It is apparent that the limiting current is dependent upon the concentrations of acetic acid, sodium acetate, and hydrogen ion in the acetate buffer region.

This functional dependence of the limiting current may be quantified in a manner similar to the procedure established for general acid-base catalysis (18). Therefore, we have

$$i_{lim.} = i_0 + a_{H^+}[H^+] + b_{HA}[HA] + c_{Ac^-}[Ac^-] \quad \text{(Eq. 7)}$$

where a_{H^+}, b_{HA}, and c_{Ac^-} are coefficients for the effect of a particular buffer species, i_0 is the limiting current in the absence of buffer species, and $[H^+]$, $[HA]$, and $[Ac^-]$ are the molar concentrations of hydrogen ion, acetic acid, and sodium acetate, respectively.

At constant pH, Eq. 7 reduces to

$$i_{lim.} = i_0 + a_{H^+}[H^+] + \{b_{HA} + c_{Ac^-}([Ac^-]/[HA])\}[HA] \quad \text{(Eq. 8)}$$

A plot of the limiting current *versus* the concentration of acetic acid is a straight line (Fig. 5) at each pH with

	0.150	0.015	1.94	0.825

[a] Each result is the average of three determinations. Limiting currents were measured at a potential 0.35 v. more negative than the half-wave potential.

$$\text{slope} = b_{HA} + c_{Ac^-}([Ac^-]/[HA]) \quad \text{(Eq. 9)}$$

and

$$\text{intercept} = i_0 + a_{H^+}[H^+] \quad \text{(Eq. 10)}$$

The values of the slopes of Eq. 8, when plotted against the buffer ratio in accordance with Eq. 9, gave a straight line with an intercept, b_{HA}, and a slope, c_{Ac^-}. Similarly, the values of the intercepts of Eq. 8, when plotted against the hydrogen ion concentration, gave a straight line with an intercept, i_0 and a slope, a_{H^+}. The same constants were evaluated similarly from a plot of the limiting current against the concentration of sodium acetate in accordance with an expression analogous to Eq. 8.

The resultant quantifiable expression for the limiting current in acetate buffers, [NNMU] = 9×10^{-5} M, is

$$i_{lim.}, \mu A = 2.02 + 210\,[H^+] - 0.740\,[HA] - 1.13\,[Ac^-] \quad \text{(Eq. 11)}$$

This expression is valid for acetate buffers up to 0.300 M in total buffer and where the concentration of NNMU is less than 0.16 mM. The expression is not valid below pH 3.2 for NNMU since buffer effects were not observed and would not be expected for a diffusion controlled process (17). Similar effects were found in phosphate buffers. It must be realized that the i_0 values will depend on the concentration.

The effect of concentration of sodium acetate on the half-wave potential of NNMU is shown in Fig. 6. The half-wave potential at a specific pH shifted nonlinearly in a positive direction as the buffer concentration increased. Similar buffer effects were observed for the antibiotic streptozotocin (5). It had been suggested that this effect might be due to complexation of the antibiotic with the buffer components in the region of the microelectrode since the half-wave potential of a complexed species depends upon the concentration of the complexing agent (16).

Mechanisms for Effects of Buffers on Polarographic Parameters.—Adsorption may be the electrode-controlling process (17, 19) for reduction in acetate and phosphate buffers. The shift in the half-wave potential to more positive values with increased buffer concentration (Table III) implies that such adsorption could be enhanced by the components of acetate buffers. Competition for adsorption sites may exist between the nonreducible buffer components and the nitrosourea. This would limit the numbers of molecules available for reduction and result in the observed decrease in limiting current with increased buffer concentration. Consistent with the hypothesis is the negative deviation from linearity of the plot of limiting current *versus* NNMU concentration at high acetate buffer concentrations (Fig. 7). The Ilkovic equation holds at low buffer concentrations for the same NNMU concentration range and the calibration curve is linear to 0.320 mM in NNMU for acetate buffers less than 0.020 M in total buffer.

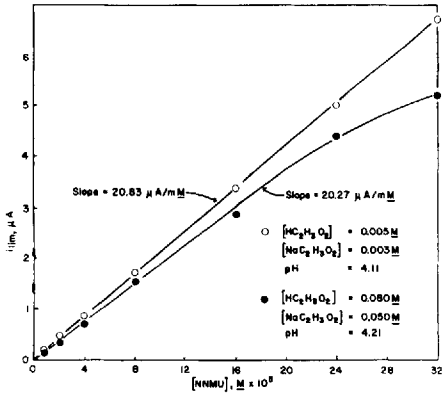

Fig. 7.—Effect of concentration of NNMU on limiting current at low and high acetate buffer concentrations at 25.0° and at column height of 60.0 cm.

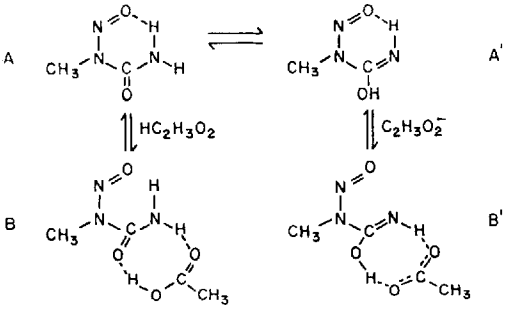
In hydrochloric acid and tartrate buffers the limiting current was proportional to the concentration of NNMU to 0.320 mM.

Additional evidence for this competition with buffer, or other substance present in solution, for adsorption sites can be found in the literature. The reduction of nitromethane and nitroethane is easier in citric acid–disodium phosphate and acetate buffers than in either benzoate or phthalate buffers at the same pH (20). This is thought to be due to adsorption phenomena at the microelectrode. In the reduction of cystine (19) the wave was shifted to more negative potentials by the addition of thymol or camphor which prevents or counteracts the stereospecific adsorption of cystine necessary for its reduction.

An alternative explanation may be offered to account for these buffer effects. A catalytic current can range from an independent to a linear function of the height of the mercury column (17). Acetic acid or acetate ion may react with the nitrosourea to form a hydrogen bonded species, B or B′, respectively, in Scheme I. The possibility of



Scheme I

an equilibrium between NNMU and an intramolecularly hydrogen bonded species, A or A′, in Scheme I is also present.

On the basis of this hypothesis of complexation through hydrogen bonding of the buffer species with the nitrosourea (NNMU), it was predicted that the limiting current for the reduction of 1,3-dimethyl-1-nitrosourea (SRI-1384) would show greatly lessened dependence on concentration of the acetate buffer components. The reasoning was that this compound would have half the probability of forming B from A with acetic acid since a nonbonding methyl is substituted for one of the hydrogens on the urea. Also, the possibility of forming an analogous B′ from A′ with acetate ion would not exist since an

[a] All compounds were initially dissolved in 8% alcohol since some were difficultly soluble in water alone. Each result is the average of three determinations. Limiting currents were measured at a potential 0.35 v. more negative than the half-wave potential. [b] Polarogram was a single, well-defined wave. [c] Polarogram was a single wave, not well-defined. [d] Polarogram was a double, well-defined wave. Master solution became darkened after about 1 hr. at room temperature. [e] Concentration of *N*-nitrosourea was $8 \times 10^{-5}\ M$. [f] Concentration of *N*-nitrosourea was $9 \times 10^{-5}\ M$. [g] From *Reference 24*. At 35.0° and pH = 5.95 (6).

unsubstituted urea is demanded in the formation of B′.

The limiting currents for 1,3-dimethyl-1-nitrosourea ($8 \times 10^{-5}\ M$) in acetate buffers (0.010 M − 0.200 M in each component) were in order of increasing buffer concentration: 1.59, 1.60, 1.58, 1.51 μA at pH 4.27; 1.55, 1.52, 1.58, 1.57, 1.51 μA at pH 4.85; and 1.54, 1.52, 1.53, 1.52 μA at pH 5.50. This represents less than a 5% decrease in the limiting current with the same increasing concentrations of acetate buffer components that caused large (more than 10%) and systematic decreases in the limiting current of NNMU (Fig. 5, Table III).

In the same concentration ranges of acetate buffers as used for NNMU, the $-E_{1/2}$ values of 1,3-dimethyl-1-nitrosourea were 0.855, 0.826, 0.806, 0.800 v. *versus* SCE at pH 4.27; 0.902, 0.860, 0.837, 0.830, 0.823 v. *versus* SCE at pH 4.85; and 0.960, 0.946, 0.940, 0.938 v. *versus* SCE at pH 5.50. The shift in $E_{1/2}$ to more positive values with increased buffer concentration is similar but to a lesser extent than for NNMU (Table III).

The compound 1,3-dimethyl-1-nitrosourea was found to be more easily reduced than NNMU in acetate buffers at a particular pH. This is also consistent with the mechanism proposed in Scheme I. The presence of a 3-methyl group may inhibit the intramolecular hydrogen bonding of A by a statistical factor of 0.5 and permit more readily the reduction of the *N*-nitroso group.

A plausible mechanism for the reduction of the *N*-nitroso group in NNMU is through the hydroxylamino to an amino group. This route has been well-established for the reduction of *N*-nitrosamines (8–14).

Reliability of Polarographic Assay Method.—The effect of concentration of NNMU on the limiting current in acetate buffer ($[HC_2H_3O_2] = 0.005\ M$; $[NaC_2H_3O_2] = 0.003\ M$; $[KCl] = 0.197\ M$) was evaluated on 3 days at eight concentrations ranging from 0.004 mM in NNMU to 0.320 mM. Three replications were run at each concentration on each day. An analysis of variance (21) of these data was performed in the following manner. The regression coefficients were determined for each of the nine sets of data. From each regression equation a theoretical value of y ($i_{lim.}$, μA) was calculated for each fixed value of x (concentration, mM). The effect of concentration on the values of the limiting current was removed by taking the ratio $y_{exptl.}/y_{theoret.}$. The analysis of variance was then performed on the values obtained for this ratio for each concentration on each day. The results of the analysis of variance are shown in Table IV. The determinations of the limiting current did not vary significantly from day to day. The standard error

[a] All compounds were initially dissolved in 8% alcohol since some were difficultly soluble in water alone. Each result is the average of three determinations. Limiting currents were measured at a potential 0.35 v. more negative than the half-wave potential. [b] Polarogram was a single, well-defined wave. [c] Polarogram was a double, well-defined wave. [d] Master solution became darkened after about 1 hr. at room temperature. [e] Reported as per cent increase in life span of mice treated with leukemia L1210 over that of controls (2).

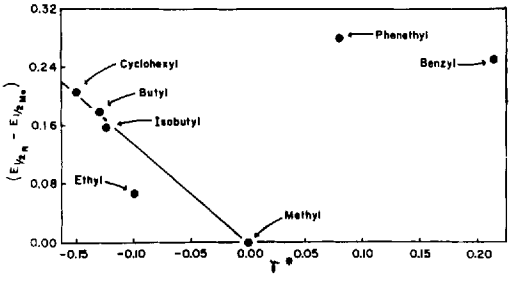

Fig. 8.—Effect of substituents on ease of reduction of various *N*-alkyl-*N*-nitrosoureas (8×10^{-5} *M*) in tartrate buffer (pH 2.51) at 25.0° and at column height of 60.0 cm.

for the difference between two-day means was 0.91%. The standard error for the difference between two concentration means was 1.31%. The regression equation obtained from the average values of the regression coefficients is

$$i_{lim.}, \mu A = 20.85\ [\text{NNMU}],\ M \times 10^3 + 0.062 \quad \text{(Eq. 12)}$$

The intercept is not significantly greater than zero.

The reproducibility of the assay method from day to day is good and the procedure is quite sensitive. A concentration of NNMU of 1×10^{-6} *M* could be detected. The polarographic method of assay is equally or more sensitive than other procedures for the assay of nitrosoureas (5, 6, 22, 23). Unlike the colorimetric method (5, 22, 23), it may be used in a pH region where the compounds are most stable, *i.e.*, between pH 3.0 and 5.0 (5, 22), and no corrections for drug instability are required. The polarographic method is less time consuming than the colorimetric method which requires a 45-min. incubation period at 50° (23). Although definite buffer effects due to adsorption or chemical reaction have been shown to occur in acetate buffers, a linear calibration curve is obtained up to concentrations of 0.320 m*M* in NNMU as long as the concentration of one of the buffer components does not exceed 0.010 *M*. Therefore, it is suggested that routine assays of these compounds be run in appropriate acetate buffers at 25.0°.

Effect of Substituents on Ease of Reduction of Various N-Nitrosoureas.—The effect of substituents on the ease of reduction of various alkyl substituted nitrosoureas is shown in Tables V and VI for several buffer systems. The data indicate that all of the compounds are more easily reduced than the parent methyl compound with more positive half-wave potentials. A reasonable correlation (Fig. 8) between the change in the half-wave potentials and the Taft (24) substituent constants (σ^*) is noted for the simple alkyl groups, *i.e.*, methyl, ethyl, butyl, etc., in tartrate buffer. Substituents containing an aromatic ring, *i.e.*, benzyl and phenethyl, did not follow this relationship. Thus, the ease of reduction of the nitrosourea due to substitution of another simple alkyl group for methyl seems to depend primarily on an inductive effect. However, it should be noted that the reduction reaction is facilitated by both electron donating groups (ethyl, butyl, etc.) and by electron withdrawing groups (benzyl and phenethyl). It is possible that steric factors may also be involved in the case of the last two compounds.

The most active compound from a biological standpoint is 1,3-bis-(2-chloroethyl)-1-nitrosourea (SRI-1720), which is one of the easiest to reduce.

In the diffusion controlled region (tartrate buffer) the limiting current decreased in approximate order of increasing molecular weights for the simple

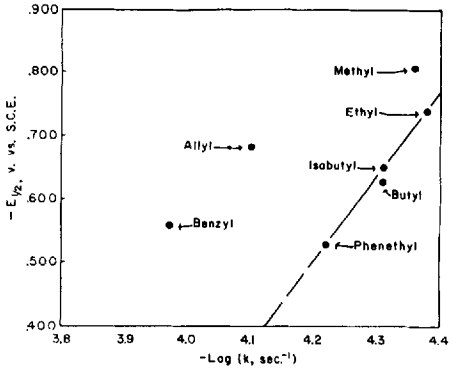

Fig. 9.—Relationship between half-wave potentials (pH 2.51) of various *N*-alkyl-*N*-nitrosoureas (8×10^{-5} *M*) at 25.0° and rate constants (k, sec.$^{-1}$ at 35.0° and pH 5.95) for hydroxyl ion catalyzed solvolysis.

alkyl substituted nitrosoureas, *i.e.*, NNMU, NNEU, NNBU, etc. Compounds with large groups in the R and R′ positions (Table V), *i.e.*, the disubstituted nitrosoureas, show deviations in this respect and imply that steric factors may affect the reduction reaction. Apparently both nitroso groups in SRI-1631 are equivalent and are reduced simultaneously, producing a current about twice that expected for a molecule of this size.

In the adsorption controlled region (phosphate buffer) the changes in the half-wave potentials and the limiting currents due to different substituents are not so pronounced as in the diffusion controlled region. However, many of the nitrosoureas, *i.e.*, NNBeU, SRI-1834, and those disubstituted derivatives with large groups in the R or R′ positions, exhibit a double wave in phosphate buffer (Table VI), indicating that the adsorbed species may be reduced more easily than the free form. Again steric factors may assume a role in the reduction of these particular compounds.

The relationship between the half-wave potentials and the apparent first-order rate constants (k, sec.$^{-1}$) for the solvolysis of various *N*-alkyl-*N*-nitrosoureas (6) in the neutral pH region is shown in Table V and in Fig. 9. In this case large discrepancies are noted when the substituents contain a double bond close to the electroactive site, *i.e.*, allyl and benzyl.

No correlation (Table VI) could be demonstrated between the half-wave potentials of the *N*-nitrosoureas and the available biological activity data (2). However, the biological data are limited and those which are available may not be entirely reliable due to the instability of these compounds in the neutral pH region.

Rheological Study of Selected Pharmaceutical Semisolids

By JAMES C. BOYLAN

Rheograms were obtained with a Ferranti-Shirley cone and plate viscometer at 20, 25, 30, and 35° for 13 pharmaceutical semisolids. As the temperature was raised, all the products studied showed a decrease in viscosity, thixotropy, and yield value. For many of the semisolids there appears to be a straight line relationship between thixotropic area and temperature. For ointments whose base is predominately white ointment, the viscosity is reduced by a factor of 0.5 for every 5° rise in temperature. At 35° many of the products studied showed similar values for thixotropy and viscosity.

A GREAT VARIETY of test procedures have been utilized over the years for the evaluation of the spreading and flow characteristics of pharmaceutical semisolids. Today, even widely used test equipment, such as the cone penetrometer, leave much to be desired as to the amount and type of data obtained. At the present time no single instrument can provide all the information required for complete product evaluation. However, this situation can be improved by the use of a viscometer capable of obtaining the complete hysteresis profile of non-Newtonian pharmaceutical semisolids.

Schulte and Kassem (1–6) have recently published an excellent series of papers dealing with the flow properties of several semisolid systems including silicone gels, triglyceride gels, polyethylene gels, polyethylene glycol gels, various vaselines, and carbohydrate gels. In addition,

[a] All figures are expressed as per cent w/w. Preservative materials are also present in some of the semisolids.

Van Ooteghem (7) has written a helpful review of the methods currently used to measure rheological properties of ointments.

The purpose of this paper is to report the rheological characteristics of several pharmaceutical semisolid products in the temperature range 20–35° and to show how these results can be valuable to the formulator and manufacturer of these products.

EXPERIMENTAL

Materials.—Except for white petrolatum, petrolatum, and white ointment, the semisolid products studied were in commercial 1-oz. tubes.[1] Table I lists the products studied and their component ingredients. The age of the semisolids varied from 4 to 21 months, with most of the samples being from 7 to 14 months in age. Storage was, in all cases, at room temperature.

Rheological Evaluation.—The viscometer used in this study was a Ferranti-Shirley cone and plate viscometer[2] equipped with a 1200-Gm. cm. spring, an automatic gap-setting device, an *x–y* recorder,[3] and a constant-temperature water bath.[4] The use of this viscometer has been described elsewhere (8). Calibration of the instrument was carried out using N.B.S. standard viscosity oils. The temperature region 20–35° was studied because this range includes the normal range of temperatures encountered during storage or application to the skin (see *Results and Discussion*). The water bath maintained the sample temperature at ±0.1° of the reported temperatures.

The sample to be evaluated (about 1 ml.) was gently squeezed from a tube onto the plate of the viscometer. The plate was immediately raised into position with the cone. The sample then remained undisturbed for 5 min. in this position (to allow temperature equilibration) before obtaining the rheogram. All rheograms were obtained using a truncated cone having an angle of 33 min., 26 sec., and a radius of 2 cm. The instrument was set at an upsweep time of 120 sec., a downsweep time of 120 sec., a maximum r.p.m. of 100, and a scale expansion of 4×. In the case of a few 20 and 25° determinations it was necessary to use a scale expansion of 5×.

The method of reporting a meaningful value for viscosity presented a problem. The products studied were plastic and pseudoplastic materials, all exhibiting thixotropy. It is normally necessary to use different equations when reporting viscosity values for plastic and pseudoplastic materials. Debate continues on whether a satisfactory equation exists for pseudoplastic materials, although the equation of Farrow *et al.* (9) seems to serve adequately for most purposes. Cross (10) has recently discussed the mathematical representation of pseudoplastic flow in some detail.

For the purposes of this study, the viscosity values reported were calculated as follows (11).

[1] Eli Lilly and Co., Indianapolis, Ind.
[2] Ferranti Electric Co., Plainview, Long Island, N. Y.
[3] Houston Instrument Co., Bellaire, Tex. (model HR-92).
[4] Brinkmann Instrument Co., Westbury, N. Y. (Haake model F).

TABLE II.—RHEOGRAMS: SCALE DEFLECTION IN dynes/cm.^{2} (UPCURVE)

	At 1074 sec.$^{-1}$ (100 r.p.m.)				At 120 sec.$^{-1}$ (11 r.p.m.)

Bacitracin ointment U.S.P.	10,265	6,875	4,665	2,400	5,535	3,625	1465	665
Ichthammol ointment N.F.	21,470	14,750	7,935	5,200	11,735	8,150	3730	1865
Cyclomethycaine ointment	12,200	8,000	4,300	2,800	10,000	6,250	3200	2000
Cyclomethycaine cream	1,335	1,500	1,465	1,335	1,000	1,125	935	935
Cyclomethycaine jelly	11,865	12,500	10,800	10,000	8,000	8,000	5700	5265

The potentiometer scale reading was recorded for the maximum sample shear rate (100 r.p.m. in all cases). The viscosity (in poises) was then calculated from Eqs. 1 and 2.

$$R = \text{scale reading} \times \text{scale expansion} \quad \text{(Eq. 1)}$$

$$\eta = \frac{R}{100} \times C \quad \text{(Eq. 2)}$$

where η is the viscosity in poises, and C is a cone constant. The value of C is determined by Eq. 3

$$C = \left(\frac{3}{2\pi V}\right)\left(\frac{aT}{r^3}\right) \quad \text{(Eq. 3)}$$

where a is the cone angle in radians, T is the torque spring constant in dyne-cm./division (×5 scale), V is the angular velocity in radians/sec., and r is the radius of the cone in cm. The value of C for the truncated cone used in this study was 13.36.

The thixotropic area was measured directly in square inches with a compensating planimeter.[5]

Effect of Aging.—Rheological changes with time have been observed in several pharmaceutical systems (12–15). Consequently, it was necessary to ascertain whether any significant changes were occurring in the semisolids reported here. This was accomplished for a given material by obtaining rheograms of a second production lot of a different age and also by rerunning the original lot at a later date.

RESULTS AND DISCUSSION

Effect of Temperature.—The results obtained are shown in Table II and Figs. 1–14. As the temperature was raised from 20 to 35°, all products studied demonstrated a decrease in viscosity, thixotropy, and yield value. This was expected and agrees with the data of Schulte and Kassem (1–6) for other pharmaceutical semisolids.

Effect of Aging.—There was no evidence that the semisolids studied were undergoing any significant rheological changes during the course of this study. When stored properly, it was felt that if significant changes in the rheograms were going to occur, they would likely occur in the first few weeks after manufacturing. As was noted previously, the most recently prepared material was 4 months old.

Petrolatum.—Although the particular petrolatums studied differ slightly in both viscosity and thixotropy, the rheogram of each has a characteristic initial "spur" at low rates of shear (Table II, Figs. 1 and 2).

In their comprehensive paper on petrolatum from various sources, Schulte and Kassem (4) pointed out that petrolatum is a mixture of *n*, iso, and isocyclic paraffins. They show that the ratio of these constituents to each other determines the rheological properties of the particular petrolatum studied. *n*-Paraffins form the characteristic structure network and petrolatums with a low content of *n*-paraffins are considered good for ointments. The change of structure involution is greatly dependent upon the isoparaffin content. A gel network built up of large crystallites is more susceptible to mechanical strain than a gel whose network is built up of very small crystallites. In the presence of isoparaffins a finer gel structure forms. With a decrease in crystallite size, the viscosity of the petrolatum increases also.

White Ointment Series.—The addition of 5% white wax to white petrolatum when preparing white ointment increases the thixotropy somewhat and modifies the shape of the "spur," but has only a slight effect on the viscosity (Table II, Figs. 2 and 3).

Ammoniated mercury, sulfur, and boric acid ointments are composed of white ointment, mineral

[5] Keuffel and Esser Co. (model 3636).

oil, and medicament (Table I). Neomycin ointment and ammoniated mercury ointment basically differ only in the lack of white wax in the neomycin product (Table I). This lack, combined with the slight increase in mineral oil and white petrolatum in the neomycin ointment, results in a less viscous and less thixotropic product with a smaller yield value (Table II, Figs. 4 and 5). The base for sulfur ointment and boric acid ointment differ in that the sulfur ointment contains 5% more mineral oil (and, consequently, 5% less white petrolatum). As a result, the viscosity of sulfur ointment is less than that of boric acid ointment, although the thixotropy and the shape of the rheograms of the two products vary only slightly (Figs. 4 and 5).

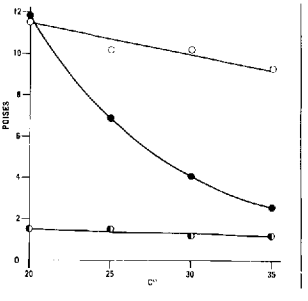

Fig. 6.—The effect of temperature on viscosity. Key: ○, cyclomethycaine jelly; ●, ointment; ◐, cream.

Figure 5 and cyclomethycaine[6] ointment in Fig. 6 illustrate a trend of importance to the pharmaceutical formulator—namely, that for every 5° rise in temperature the viscosity is reduced by a factor of 0.5. The viscosity of these ointments, containing predominately white ointment, demonstrate a definite first-order relationship between (loss of) viscosity and temperature (increase).

It may be seen from Figs. 2, 4, and 7 that there appears to be a linear relationship between thixotropic area and temperature (in the region 20–35°) for neomycin, bacitracin, ammoniated mercury,

sulfur, ichthammol, and white ointments, zinc oxide paste, and petrolatum.

Cyclomethycaine Series.—The cyclomethycaine series shows interesting and unique differences (Figs. 6, 8–11). Cyclomethycaine cream exhibits the least viscosity and thixotropy of any of the semisolids studied in this report. The rheograms for cyclomethycaine jelly retain their unique shape (Fig. 9) over the entire temperature range studied. In addition, it can be seen from Figs. 6 and 8 that there is relatively little change in thixotropy and only moderate change in viscosity for this product. This jelly is predominately a polypropylene glycol–water base (Table I) which would suggest a potential use as an all climate vehicle. Cyclomethycaine ointment follows the general pattern established by the other predominately white ointment base products.

Zinc Oxide Paste.—Zinc oxide paste, because it is designed as a protective and adsorptive material, is a deliberately stiff product with poor spreading and melting qualities. These characteristics are borne out by Figs. 7, 12, and 13. Using the Ferranti-Shirley cone and plate viscometer under the test conditions described, it was not possible to obtain data for zinc oxide paste at 20°.

Spreading.—The ease of application of a pharmaceutical semisolid to the surface of the skin is an

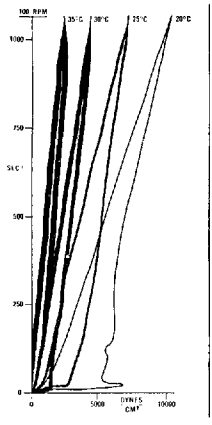

Fig. 14.—The effect of temperature on the rheogram of bacitracin ointment U.S.P.

important factor in consumer acceptance. Each individual applies ointment-like materials to the skin with a slightly different motion, stroke, and rate. Any rheological estimate of this process would, therefore, be limited accordingly. Henderson *et al.* (16) have approximated the rate of shear encountered when spreading an ointment on a surface by assuming a stroke averaging 6 cm., a rate of 4 strokes/sec., and an ointment layer thickness of 1 to 3 mm. Under these conditions they calculated a shear rate of 120 sec.$^{-1}$. If this value is used as a guide, recognizing its shortcomings, an estimate of the spreading resistance can be graphically shown by extending a dashed line through the rheograms at 120 sec.$^{-1}$. On the upcurve of nearly every rheogram 120 sec.$^{-1}$ occurs in a region of great resistance to flow. For example, in the instances of white petrolatum and white ointment (Figs. 1 and 3), 120 sec.$^{-1}$ represents the point of greatest resistance at low rates of shear. In nearly all the rheograms the area between 0 and 250 sec.$^{-1}$ appears to be an extremely important one when characterizing the spreading properties of pharmaceutical semisolids. A rheological investigation of this region has been undertaken and will be the subject of a forthcoming communication.

Relation to Body Temperature.—In his authoritative text, Rothman (17) discusses the temperature of the various regions of human skin under a wide variety of conditions. He clearly shows that there is a great variation in the temperature of human skin depending, *e.g.*, on the region of the body, the quantity and type of clothing worn, the degree of activity and state of health of the subject, environmental conditions, and whether the individual has eaten recently. Under these varying conditions a normal, healthy person's skin temperature will vary from 25 to 35°. If the extremities, especially the toes, are disregarded, the body surface temperature will probably fall between 30 and 35°.

At 35° many of the products studied had nearly the same thixotropy and nearly the same viscosity. This is as expected, since these products are designed to melt at or near the temperature of the human skin surface. An example of a product designed to melt at body temperature is bacitracin ointment U.S.P. (Lilly). As the temperature progresses from 20 to 35° the viscosity, thixotropy, and yield value of this product substantially decrease (Fig. 14). This figure, with minor modifications, is typical of the rheological changes the other semisolids in this study undergo in this temperature range. The curves shown in Fig. 14 also agree with the data of Schulte and Kassem (1–6) for other pharmaceutical semisolids.

Statistical Procedures for Bioassays When the Condition of Similarity Does Not Obtain

By C. PHILIP COX and PAUL E. LEAVERTON*

Well-established statistical procedures are available for the analysis of dilution parallel line or slope ratio assays for which the condition of similarity obtains. Research scientists have long been aware that this condition is commonly violated, in log-dose response assays, for example, divergent rather than parallel lines may be obtained. The deviation cannot always be traced to deficient experimental techniques. In fact, as indications of differences in the response processes of the standard and test preparations, or as indications of impure test preparations, such findings may provide the most important inference from an assay experiment and immediately suggest further investigation into the causes of the differences. Statistical procedures have been developed to describe the phenomena in quantitative terms and, especially, to permit potency comparisons. The procedures may also have merit even in dilution assay situations where the condition of similarity may apparently be violated if appreciable differences between the responses of the standard and test preparations result from poorly matched doses.

THE TERM "analytical dilution assay" refers to an assay of a preparation of unknown potency which can be regarded as nothing but a dilution of the standard preparation in a diluent which does not contribute to the response by either chemical or physical properties. In such cases it follows that when response is plotted against log-dose the curves for the two preparations are the same apart from a constant relative displacement parallel to the log-dose axis. Furthermore, as was pointed out by Gaddum (1), the relative potency estimate obtained from an analytical dilution assay should not be dependent on the particular assay circumstances. The estimate should agree with one obtained by, for example, chemical determinations since both procedures should give estimates of the reciprocal of the dilution factor.

When the log-dose response curves are straight parallel lines well-established statistical procedures, such as those described by Bliss (2) and Finney (3), are available for obtaining the relative potency estimate. Estimation procedures for quadratic parallel curves have been described by Bliss (4) and Elston (5). Relatedly, Leaverton (6) has discussed methods, based on techniques described by Lewish (7), for fitting quadratic curves constrained to be strictly monotonic for use in bioassay contexts.

Similar statistical procedures are used if parallel log-dose response curves are obtained—for a particular response—even though the inert diluent assumption is not generally true. Such assays have been termed "comparative assays." Since both types of assay involve comparative experiments, however, there are grounds for using the general term "assay" for either type when distinction is not essential, the qualification "analytical dilution" or just "dilution" being used to distinguish the subclass of assays defined above.

As a prerequisite for estimation of relative potency in the above cases, statistical analyses incorporate tests for the relevance of the assumed mathematical model to the observed phenomena. In particular, an index sensitive to divergence, *i.e.*, to departure from parallelism, can be obtained from the sum of squares for interaction between preparations and log-doses in the analysis of variance. In research, as distinct from routine, bioassay situations it is usually not possible to assert that an unknown preparation is a dilution of the standard preparation; assays may, in fact, be initiated to examine just this question. As isolated from an animal or plant organism, for example, the unknown preparation may consist of a mixture of substances which may affect the response in different degrees. Accordingly, assay research workers, in pharmacology and endocrinology, for examples, have long been aware that assays where divergent rather than parallel lines are obtained are common, although the statistical significance of the divergence term may occasionally be masked because the assay is of low precision.

It should also be remembered that except in the somewhat unusual case that the log-dose response relationship is exactly rectilinear over a wide response range—as distinct from being approximately straight locally—it is an event with probability zero that doses will be so chosen to

give exactly parallel lines even for an analytical dilution assay.

One early idea on statistical procedures appropriate for divergent line assays was put forward by Ing *et al.* (8), who suggested the computation of an average relative potency determined over a wide range of doses. Later, in Gibbs *et al.* (9), an estimate of the logarithm of the relative potency was computed at the 50% response level as a not strictly valid but nevertheless useful comparison. Neither of these suggested procedures, however, properly incorporate the basic fact that the relative potency is different for different doses or responses. And it was pointed out by Grimshaw and D'Arcy (10) that there was then no adequate method for quantitative assessment in such situations.

Discussions of the above introductory points and related statistical aspects may be found in Thompson (11), Leaverton (6), Cornfield (12), and Finney (13). In Cornfield (12), a procedure is presented for estimating the logarithm of the relative potency as a function of the log-dose in cases when linear log-dose response curves for both preparations can be estimated for each of a number of experimental subjects. Procedures are given here for divergent line assays obtained using the common experimental plan in which only one preparation-dose combination is observed on each of a number of experimental subjects.

SPECIFICATION

Let X_S and X_T denote log-doses of the standard and test preparations, respectively, and let Y denote the response.

Then linear log-dose response lines can be written as,

$$Y = \alpha_S + \beta_S X_S \qquad \text{(Eq. 1)}$$

$$Y = \alpha_T + \beta_T X_T \qquad \text{(Eq. 2)}$$

for the standard and test preparations, respectively.

The fact that, if $\beta_S \neq \beta_T$, the logarithm of the relative potency is a function of the log-dose or the response can now be expressed in any of the three ways *A*, *B*, and *C* described below.

A. Linear Relation Between Equipotent Log-Doses.—If log-doses X_S and X_T give the same response, Y, Eqs. 1 and 2 show that X_S and X_T are related by

$$\alpha_S + \beta_S X_S = \alpha_T + \beta_T X_T$$

that is,

$$X_S = -\frac{(\alpha_S - \alpha_T)}{\beta_S} + \frac{\beta_T}{\beta_S} X_T \qquad \text{(Eq. 3)}$$

B. Log (Relative Potency) as a Linear Function of Log-Dose.—If $\mu(X_T)$ denotes the logarithm of the relative potency at dose X_T, that is, $\mu(X_T)$ is the difference between equipotent log-doses, we have, at log-dose X_T,

$$\mu(X_T) = X_S - X_T$$

so that, from Eq. 3,

$$\mu(X_T) = \frac{(\alpha_S - \alpha_T)}{\beta_S} + \left(\frac{\beta_T}{\beta_S} - 1\right) X_T \qquad \text{(Eq. 4)}$$

C. Log (Relative Potency) as a Linear Function of Response.—If $\mu(Y)$ denotes the logarithm of the relative potency at response Y, $\mu(Y)$ is the difference between equally effective log-doses so that,

$$\mu(Y) = \frac{Y - \alpha_S}{\beta_S} - \frac{Y - \alpha_T}{\beta_T} \qquad \text{(Eq. 5)}$$

$$= -\left(\frac{\alpha_S}{\beta_S} - \frac{\alpha_T}{\beta_T}\right) + \left(\frac{1}{\beta_S} - \frac{1}{\beta_T}\right) Y \qquad \text{(Eq. 6)}$$

Presentation of the relations has been made in the above form to give expressions which are consistent with those obtaining in the usual parallel line assay case when $\beta_S = \beta_T$. In some applications, however, predictions in terms of the test rather than the standard preparation may be of interest. For example, it may commonly be required to estimate the log-dose, X_T, of the test preparation which will give a response equivalent to that obtained with a specified log-dose, X_S, of the standard. The expressions above and their developments below can readily be applied in such cases by simply interchanging the suffixes S and T so that Eq. 3, for example, would give,

$$X_T = -\frac{(\alpha_T - \alpha_S)}{\beta_T} + \frac{\beta_S}{\beta_T} X_S$$

Choice between the various alternative expressions may, therefore, be made according to the practical requirements of particular situations. Care, however, is required in any application because, apart from the simple indication that the test preparation is not a dilution of the standard preparation, the equations in themselves cannot readily be interpreted to give information about modes of action in a context more general than that of the particular assay. Thus, although Eq. 3 represents a calibration relationship between equipotent log-doses, it cannot be assumed that the parameters in such a relation determined from one laboratory species will remain constant for application to another species. In the absence of information about modes of action, therefore, the relationships should preferably be regarded as concise local descriptions of the observed phenomena. The relations are, of course, applicable in repetitions of the original assay circumstances of which accurate and detailed specifications are accordingly desirable. This latter aspect is particularly important for interlaboratory studies, as was recently emphasized by Youden (14).

ESTIMATION

Estimation procedures for the above relationships will first be considered for an assay in a completely randomized design in which one observation is obtained from each of N experimental subjects and r responses are observed at each of n_S log-dose levels of the standard preparation and n_T log-dose levels of the test preparation, so that,

$$N = r(n_S + n_T) \qquad \text{(Eq. 7)}$$

The assumptions will be made that (a) the log-dose response lines for each preparation are straight lines over the range of doses tested; (b) residual errors are normally and independently distributed with population mean zero and variance σ^2, this variance being the same for both preparations.
The following notation will be used:

S refers to the standard and T to the test preparation,
x_{iS} is the ith log-dose value for S, $i = 1, 2, \ldots, n_S$,
x_{jT} is the jth log-dose value for T, $j = 1, 2, \ldots, n_T$,
y_{ikS} and y_{jkT} are the kth response observations at the ith log-dose of S and the jth log-dose of T, $k = 1,2,\ldots,r$, and correspondingly
$\bar{y}_{iS}$ and $\bar{y}_{jT}$ are the mean responses at these log-doses.

By regression analyses described in standard texts estimates, a_S, b_S, a_T, and b_T, of the regression parameters, α_S, β_S, α_T, and β_T, in Eqs. 1 and 2 are first calculated. Thus, for S, with

$$\bar{x}_S = \frac{1}{n_S} \sum_{i=1}^{n_S} x_{iS} \qquad \text{(Eq. 8)}$$

$$\bar{y}_S = \frac{1}{n_S} \sum_{i=1}^{n_S} \bar{y}_{iS} = \frac{1}{rn_S} \sum_{i=1}^{n_S} \sum_{k=1}^{r} y_{ikS} \qquad \text{(Eq. 9)}$$

so that $\bar{y}_S$ and $\bar{y}_T$ are the means of the mean responses at the individual log-dose values, the estimates are

$$a_S = \bar{y}_S - b_S\bar{x}_S \qquad \text{(Eq. 10)}$$

$$b_S = \frac{\sum_{i=1}^{n_S} (x_{iS} - \bar{x}_S)(\bar{y}_{iS} - \bar{y}_S)}{\sum_{i=1}^{n_S} (x_{iS} - \bar{x}_S)^2} \qquad \text{(Eq. 11)}$$

In practice, of course, b will be calculated using the well-known identity that for any number, n, of pairs (x_i, y_i) with means $\bar{x}$ *and* $\bar{y}$,

$$\Sigma(x_i - \bar{x})(\bar{y}_i - \bar{y}) = \Sigma xy - \frac{1}{n}(\Sigma x)(\Sigma y) \qquad \text{(Eq. 12)}$$

The estimate s^2 of the residual variance σ^2 is calculated by pooling the mean squares for deviations from regression obtained from the two regression analyses. This estimate will have $N - 4$ degrees of freedom and is compounded from the deviations of the mean responses at individual log-dose levels and the deviations between individual responses at each of the log-dose levels, a procedure which is valid under the assumptions (a) and (b) above.

Estimates of the quantities defined in the Eqs. 3, 4, and 6 above can now be calculated as follows.

From Eq. 3, the estimate of the true value of X_S is $\hat{X}_S$ where,

$$\hat{X}_S = -\frac{1}{b_S}(a_S - a_T - b_T X_T) \qquad \text{(Eq. 13)}$$

or equivalently in terms of means as defined in Eqs. 8 and 9,

$$\hat{X}_S - \bar{x}_S = -\frac{1}{b_S} \times \{\bar{y}_S - \bar{y}_T - b_T(X_T - \bar{x}_T)\} \qquad \text{(Eq. 14)}$$

$$= -\frac{1}{b_S}(\bar{y}_S - \hat{Y}_T) \qquad \text{(Eq. 15)}$$

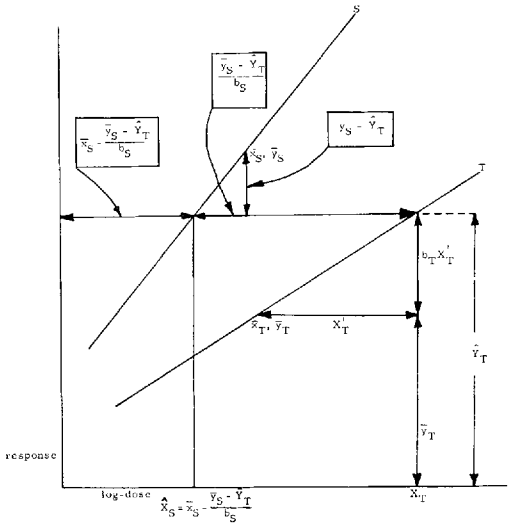

Fig. 1.—The relation between equipotent log-doses.

where

$$\hat{Y}_T = \bar{y}_T + b_T(X_T - \bar{x}_T) \qquad \text{(Eq. 16)}$$

is the response predicted from the line for the test preparation at log-dose X_T. A geometrical construction which illustrates how the above quantities are used to obtain the log-dose estimate $OA = \hat{X}_S$ from the specified value $OB = X_T$ is given in Fig. 1.

Next from Eq. 4 $M(X_T)$, the estimate of $\mu(X_T)$ is given by

$$M(X_T) = -\frac{1}{b_S}\{a_S - a_T - (b_T - b_S)X_T\} \qquad \text{(Eq. 17)}$$

which may alternatively be written as

$$M(X_T) = \bar{x}_S - X_T - \frac{1}{b_S} \times \{\bar{y}_S - \bar{y}_T - b_T(X_T - \bar{x}_T)\} \qquad \text{(Eq. 18)}$$

$$= \bar{x}_S - \bar{x}_T - \frac{\bar{y}_S - \bar{y}_T}{b_S} + \left(\frac{b_T}{b_S} - 1\right)(X_T - \bar{x}_T) \qquad \text{(Eq. 19)}$$

Third, from Eq. 6 $M(Y)$, the estimate of $\mu(Y)$ is given by

$$M(Y) = -\frac{1}{b_S b_T} \times \{a_S b_T - a_T b_S - (b_T - b_S)Y\} \qquad \text{(Eq. 20)}$$

or

$$M(Y) = \bar{x}_S - \bar{x}_T - \frac{1}{b_S b_T} \times \{\bar{y}_S b_T - \bar{y}_T b_S - (b_T - b_S)Y\} \qquad \text{(Eq. 21)}$$

INTERVAL ESTIMATION OF THE EQUIPOTENT DOSE

By an adaptation of the procedure Fieller (15, 16) for interval estimation from a ratio, a fiducial interval will now be derived for the true value of $\hat{X}_S$ calculated from Eqs. 13 or 14 for a single specified

X_T value. For this, Fieller's argument can be applied to a variate constructed as

$$u = a_S + b_S X_S - a_T - b_T X_T \quad \text{(Eq. 22)}$$

where X_S is the true or population value for the log-dose of the standard preparation corresponding to a log-dose X_T of the test preparation.

Under the stated assumptions, u is a linear combination of the normally distributed variates a_S, b_S, a_T, and b_T and so is itself normally distributed. In virtue of Eq. 3 it is also true that the population or expected value of u is zero. It follows that, if the estimated variance of u is $d_u s^2$, where d_u is a known constant coefficient determined by the construction of u from the original observations, the quantity $u^2/d_u s^2$ is distributed according to the F distribution with 1 and $N - 4$ degrees of freedom.

Hence, if F_c is the tabulated value from this distribution such that

$$P[F \leq F_c] = 1 - \alpha$$

we have

$$P\left[\frac{u^2}{d_u s^2} \leq F_c\right] = 1 - \alpha$$

By Fieller's theorem it now follows that solutions of

$$u^2 - F_c d_u s^2 = 0 \quad \text{(Eq. 23)}$$

which from Eq. 22 is a quadratic equation in the X_S corresponding to a given value of X_T, will give values defining a $100(1 - \alpha)\%$ fiducial interval for the required X_S value.

To obtain d_u, it is first convenient to write u from Eq. 22 in the equivalent form,

$$u = \bar{y}_S + b_S(X_S - \bar{x}_S) - \bar{y}_T - b_T(X_T - \bar{x}_T) \quad \text{(Eq. 24)}$$

in which all the estimates are statistically independent. Hence,

$$V(u) = V[\bar{y}_S + b_S(X_S - \bar{x}_S)] + V[\bar{y}_T + b_T(X_T - \bar{x}_T)]$$

which can be estimated as $d_u s^2$ where

$$d_u s^2 = \left[\frac{1}{n_S} + \frac{(X_S - \bar{x}_S)^2}{r\Sigma(x_S - \bar{x}_S)^2} + \frac{1}{n_T} + \frac{(X_T - \bar{x}_T)^2}{r\Sigma(x_T - \bar{x}_T)^2}\right] s^2 \quad \text{(Eq. 25)}$$

It is now convenient to introduce a more concise notation, wherein a prime is used to denote values "corrected for their means." Thus, we write

$$X_S' = X_S - \bar{x}_S, \quad X_T' = X_T - \bar{x}_T \quad \text{(Eq. 26)}$$

and

$$\Sigma_S' = r\sum_1^{n_S}(x_{iS} - \bar{x}_S)^2, \quad \Sigma_T' = r\sum_1^{n_T} \times (x_{jT} - \bar{x}_T)^2 \quad \text{(Eq. 27)}$$

Then, from Eqs. 24 and 25

$$u = \bar{y}_S - \bar{y}_T + b_S X_S' - b_T X_T' \quad \text{(Eq. 28)}$$

and

$$d_u = \frac{1}{n_S} + \frac{1}{n_T} + \frac{X_S'^2}{\Sigma_S'} + \frac{X_T'^2}{\Sigma_T'} \quad \text{(Eq. 29)}$$

Inserting these values into Eq. 23 and collecting terms then gives the quadratic equation for the unknown X_S' as,

$$AX_S'^2 + 2BX_S' + C = 0 \quad \text{(Eq. 30)}$$

where

$$A = b_S^2 - \frac{F_c s^2}{\Sigma_S'} \quad \text{(Eq. 31)}$$

$$B = b_S\{\bar{y}_S - \bar{y}_T - b_T X_T'\} \quad \text{(Eq. 32)}$$

$$= b_S(\bar{y}_S - \hat{Y}_T) \quad \text{(Eq. 33)}$$

from Eq. 16, and

$$C = (\bar{y}_S - \bar{y}_T - b_T X_T')^2 - F_c s^2\left(\frac{1}{n_S} + \frac{1}{n_T} + \frac{X_T'^2}{\Sigma_T'}\right) \quad \text{(Eq. 34)}$$

By the usual formula for the roots of a quadratic equation the lower and higher limits, X_{SL} and X_{SH}, of the fiducial interval are then given by

$$X_{SL}', X_{SH}' = \frac{-B \mp \sqrt{B^2 - AC}}{A} \quad \text{(Eq. 35)}$$

that is,

$$X_{SL} = \bar{x}_S - \frac{1}{A}\{B + \sqrt{B^2 - AC}\},$$

$$X_{SH} = \bar{x}_S - \frac{1}{A}\{B - \sqrt{B^2 - AC}\} \quad \text{(Eq. 36)}$$

In practice, the computations can be simplified by first calculating the quantity $\hat{X}_S' = \hat{X}_S - \bar{x}_S$ from the point estimate $\hat{X}_S$ of the equipotent dose. Then, substituting $-b_S\hat{X}_S'$ for $\bar{y}_S - \bar{y}_T - b_T X_T'$ in Eqs. 32 and 34 leads to an expression for the interval as,

$$X_{SL}', X_{SH}' = \frac{1}{A}\left[b_S^2 X_S' \mp \sqrt{F_c s^2\left\{A\left(\frac{1}{n_S} + \frac{1}{n_T} + \frac{X_T'^2}{\Sigma_T'}\right) + \frac{b_S^2\hat{X}_S'^2}{\Sigma_S'}\right\}}\right] \quad \text{(Eq. 37)}$$

By analogy with the usual calculations for parallel line assays [Finney (3)], an approximate formula, which is often sufficiently accurate, can now be easily obtained. For this we note that the quantity s^2/Σ_S' in Eq. 31 is the variance of b_S, and, if b_S^2 is very much larger than its variance, *i.e.*, if the square of the coefficient of variation of b_S is very small, we have, from Eq. 31

$$A = b_S^2\left(1 - \frac{F_c s^2}{b_S^2\Sigma_S'}\right) \simeq b_S^2$$

As an empirical working rule, following Finney (3), it may be suggested that the approximation will give sufficiently accurate results if $A/b_S^2 > 0.95$, or, equivalently, if $20\,F_c < b_S^2\Sigma_S'/s^2$. In such cases it can easily be checked that the fiducial interval defined above becomes,

$$X_{SL}, X_{SH} = \hat{X}_S \mp \sqrt{\frac{F_c s^2}{b_S^2}\left(\frac{1}{n_S} + \frac{1}{n_T} + \frac{X_T'^2}{\Sigma_T'}\right)} \quad \text{(Eq. 38)}$$

TABLE I.—FOUR-POINT ASSAY OF LUTEINIZING HORMONE IN SWINE PITUITARY TISSUE BY ASCORBIC ACID DEPLETION METHOD

	Standard (N.I.H.)		Test	
	0.4 mg.	1.6 mg.	0.0625 mg.	0.2500 mg.
	77	55	64	60
	81	45	71	54
	80	47	70	54
	78	52	80	61
	80	48	72	54
Total	396	247	357	283
Mean	79.2	49.4	71.4	56.6

The fiducial intervals calculated as above apply when the $\hat{X}_S$ value corresponding to only one X_T value is required. Commonly, however, the procedure may be required for an unspecified number of X_T values. The theoretical treatment by Scheffé (17) then indicates that the interval should be calculated by substituting for F_c, as defined above, the value $4F_c'$ where F_c' is the tabulated value from the F-distribution with 4 and $N - 4$ degrees of freedom such that,

$$P[F \leq F_c'] = 1 - \alpha$$

EXAMPLE

The data in Table I were obtained from a four-point assay of luteinizing hormone (LH) in swine pituitary tissue [Melampy and Hendricks (18)] by the ascorbic acid depletion (AAD) method. The responses are in units of mcg. AAD/100 mg. rat ovary tissue.

When the doses are, as here, conveniently chosen so that the ratio of the higher to the lower dose is the same for both preparations, the log-dose transformations can be chosen to give a log-dose metameter which takes simple integral values. Thus, in Table I, where the dose-ratio is 4, the transformations from doses z_S and z_T to metameters x_S and x_T such that,

$$x_S = \frac{1}{\log 4}\{\log z_S - \log 0.4\} \qquad \text{(Eq. 39)}$$

$$x_T = \frac{1}{\log 4}\{\log z_T - \log 0.0625\} \qquad \text{(Eq. 40)}$$

give $x_S = x_T = 0$ at the two lower doses and $x_S = x_T = 1$ at the two upper doses.

The usual assay analysis of variance then gives:

	d.f.	Mean Squares
Between preparations	1	0.45
Common regression	1	2486.45
Divergence	1	281.25
Residual	16	16.15

Since the $\alpha = 0.05$ critical F-value for 1 and 16 degrees of freedom is 4.49 it can be seen (*a*) from the between preparations term that closely similar response levels were achieved and (*b*) from the divergence term that the slopes of the regression lines for the standard and test preparations were significantly different.

We are therefore in a situation for which the preceding procedures are appropriate with $n_S = n_T = 2$ doses for each preparation and $r = 5$ responses at each preparation-dose combination. Conventional regression calculations, as indicated by Eqs. 8, 9, and 11 and similar equations for the test preparation, then give

$$\bar{x}_S = \bar{x}_T = {}^1/_2$$

and

$$\bar{y}_S = (396 + 247)/10 = 64.3$$

$$\bar{y}_T = (357 + 283)/10 = 64.0$$

Again, from Eq. 27

$$\Sigma_S' = \Sigma_T' = 5\left(\frac{1}{4} + \frac{1}{4}\right) = \frac{5}{2}$$

and it follows from Eqs. 11 and 12, or because the interval between the two values of x_S is unity, that

$$b_S = -(79.2 - 49.4) = -29.8$$

and similarly,

$$b_T = -(71.4 - 56.6) = -14.8$$

The equation for the prediction of an X_S value corresponding to a specified X_T value can now be written down from Eq. 14 as

$$\hat{X}_S - \frac{1}{2} = \frac{1}{29.8}\left\{64.3 - 64.0 + 14.8\left(X_T - \frac{1}{2}\right)\right\}$$

$$= \frac{1}{29.8}(-7.1 + 14.8\,X_T)$$

that is,

$$\hat{X}_S = 0.26 + 0.50\,X_T \qquad \text{(Eq. 41)}$$

With $F_c = 4.49$, for $\alpha = 0.05$, and $s^2 = 16.15$

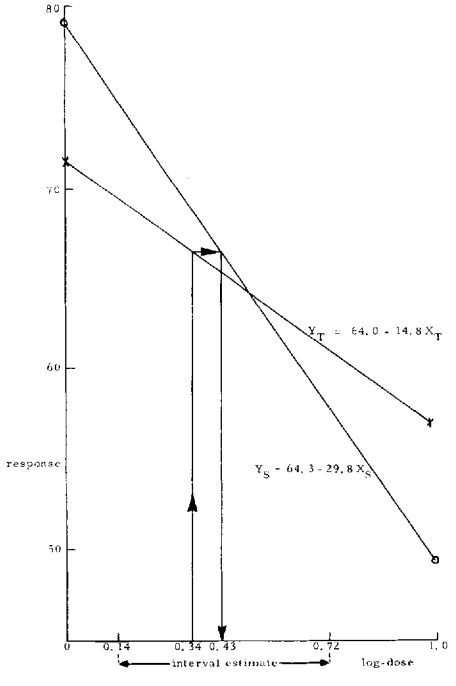

Fig. 2.—Assay of LH in swine pituitary tissue (18).

(16 d.f.) the fiducial interval can now be calculated. For this, from Eq. 31,

$$A = 29.8^2 - \frac{2}{5}(4.49)(16.15)$$
$$= 888.04 - 29.01$$
$$= 859.03$$

Hence, from Eq. 37

$$X_{SL}', X_{SH}' = \frac{1}{859.03}\left[29.8^2\hat{X}_S' \mp \sqrt{(4.49)(16.15)\left\{859.03\left(\frac{1}{2}+\frac{1}{2}+\frac{2X_T'^2}{5}\right)+\frac{2(29.8^2)}{5}\hat{X}_S'^2\right\}}\right] \quad \text{(Eq. 42)}$$

$$= 1.03\hat{X}_S' + \sqrt{0.0844\,(1 + 0.40\,X_T'^2 + 0.42\,\hat{X}_S'^2)} \quad \text{(Eq. 43)}$$

Now, in particular, suppose it is desired to estimate the dose of the standard preparation equivalent to 0.1 mg. of the test preparation. First, from Eq. 40, the specified value of X_T is

$$X_T = \frac{1}{\log 4}\{\log 0.1/0.0625\} = 0.3390$$

Hence, from Eq. 41,

$$\hat{X}_S = 0.26 + (0.50)(0.3390) = 0.4295$$

and, from Eq. 39,

$$\log(z_S/0.4) = 0.4295 \log 4$$

from which the estimated equipotent dose is

$$\hat{Z}_S = 0.73 \text{ mg.}$$

Noting that $X_T' = 0.3390 - 0.50 = -0.1610$ and $X_S' = -0.0705$, the corresponding 95% fiducial interval is obtained from Eq. 43 as,

$$X_{SL}', X_{SH}' = -(1.03)(0.0705) \mp \sqrt{0.0844\,\{1 + (0.40)(0.1610^2) + 0.42(0.0705)^2\}}$$
$$= -0.365, +0.220$$

From Eqs. 26 and 39 the interval for the equipotent dose can then be calculated as

$$Z_{SL}, Z_{SH} = 0.48, 1.09 \text{ mg.}$$

Alternatively, since for these data $A/b_S^2 = 0.97$, the approximate formula in Eq. 38 may be used to give,

$$X_{SL}, X_{SH} = 0.4295 \mp \sqrt{\frac{(4.49)(16.15)}{29.8^2}(1 + 0.4X_T'^2)}$$
$$= 0.14, 0.72$$

and on subtraction of $\bar{x}_S = 0.5$, values are obtained which closely agree with those obtained above for X_{SL}' and X_{SH}'.

The results are illustrated in Fig. 2. In this the width of the interval estimate serves to emphasize the fact that an experiment designed to give sufficient precision for a parallel line assay will give poor precision for an estimate of an equipotent dose if divergence has to be admitted as the more realistic situation.

For simplicity of exposition, the above development and the example have been carried through for a constant number r of response observations at each preparation-dose level combination. The extension to the unequal numbers case readily follows, *mutatis mutandis*, using the standard statistical procedures for dealing with unequal numbers in single classification experiments. Additionally, assays based on designs other than the completely randomized design can be treated by the basic techniques described above.

QUADRATIC RESPONSE CURVES

The principles described above are also applicable when one or both of the log-dose response relationships can be described by quadratic curves about which the responses of individual experimental units are normally distributed. As expected, however, more computation is required.

If the two quadratic relationships are

$$\bar{y}_S = a_S + b_S X_S + c_S X_S^2 \quad \text{(Eq. 44)}$$

and

$$\bar{y}_T = a_T + b_T X_T + c_T X_T^2 \quad \text{(Eq. 45)}$$

the log-dose of the standard preparation equivalent to a specified log-dose X_T of the test preparation can be estimated as one solution of the quadratic equation,

$$c_S\hat{X}_S^2 + b_S\hat{X}_S + a_S - a_T - b_T X_T - c_T X_T^2 = 0 \quad \text{(Eq. 46)}$$

Identification of the appropriate root can be made without difficulty because the two dose-response curves must be monotonic (though not necessarily in the same sense) in the region of interest and because the specified X_T and its correspondent $\hat{X}_S$ should be within the dose ranges over which the curves themselves were estimated.

In many practical cases extreme accuracy will not be required of such estimation procedures and, particularly if numerous equipotent doses are required, it may be more convenient to read them from graphs of the two curves.

Fiducial intervals for the estimate defined in Eq. 46 can also be obtained on the above principles as the appropriate solutions of Eq. 23 with u equal to the expression on the left of Eq. 46. Solution of a fourth degree equation is required in this case. The interpretation of solutions of quartic equations in a similar inverse estimation problem has been discussed by Williams (19).

RELATIVE POTENCY AS A FUNCTION OF DOSE

Divergent line assays may occur in some contexts where it may be of interest to estimate the relative potency itself, although this quantity is now of more restricted use than in the simple case when it is constant. For example, if we now find that 1 mg. of the test preparation is equipotent to ρ(1 mg.) of the standard preparation it is no longer true that 1 Gm. of the test and 1000ρ(1 mg.) of the standard preparations are equipotent.

When, however, the relative potency itself is required it can be estimated as a function of log-dose from Eq. 19. Since $\mu(X_T) = X_S - X_T$, where X_S is the equipotent log-dose of the standard preparation, an interval estimate for $\mu(X_T)$ can be obtained by subtracting X_T from the interval estimate previously determined for X_S. Alternatively, we may proceed directly by applying Fieller's procedure, *via* Eq. 23 with

$$u = b_S\{\mu(X_T) - \bar{x}_S + \bar{x}_T\} + (\bar{y}_S - \bar{y}_T) - (b_T - b_S)X_T' \quad \text{(Eq. 47)}$$

As a result if, for convenience, we write $\lambda = \mu(X_T) - \bar{x}_S + \bar{x}_T$ the interval can be determined by adding $(\bar{x}_S - \bar{x}_T)$ to each root of the quadratic equation

$$A\lambda^2 + 2B\lambda + C = 0 \quad \text{(Eq. 48)}$$

where

$$A = b_S^2 - \frac{F_c s^2}{\Sigma_S'} \quad \text{(Eq. 49)}$$

$$B = -b_S^2\{M(X_T) - \bar{x}_S + \bar{x}_T\} + \frac{F_c s^2}{\Sigma_S'} \quad \text{(Eq. 50)}$$

$$C = b_S^2\{M(X_T) - \bar{x}_S + \bar{x}_T\}^2 - F_c s^2\left\{\frac{1}{n_S} + \frac{1}{n_T} + X_T'^2\left(\frac{1}{\Sigma_S'} + \frac{1}{\Sigma_T'}\right)\right\} \quad \text{(Eq. 51)}$$

RELATIVE POTENCY AS A FUNCTION OF RESPONSE

The point estimate $M(Y)$ of $\mu(Y)$, the log relative potency at response Y can be calculated from Eq. 21, but exact interval estimation is not so straightforward as in the previous cases. In many practical cases, however, it will be sufficient to use approximate fiducial intervals which can be obtained as follows.

It is a well-known result that, if

$$r = \frac{u}{v}$$

is a ratio of two variates, u and v, which are statistically independent, and if the coefficient of variation of the denominator, v, is small, then

(coefficient of variation of r)^2 = (coefficient of variation of u)^2 + (coefficient of variation of v)^2 (Eq. 53)

That is, if $d_u s^2$ and $d_v s^2$ are the estimated variances of u and v, respectively, $V(r)$, the estimated variance of the ratio is given by,

$$V(r) = r^2 s^2\left(\frac{d_u}{u^2} + \frac{d_v}{v^2}\right) \quad \text{(Eq. 54)}$$

To apply this in the present context we have, from Eq. 21

$$M(Y) - \bar{x}_S + \bar{x}_T = \left\{\frac{(Y - \bar{y}_S)}{b_S} - \frac{(Y - \bar{y}_T)}{b_T}\right\} \quad \text{(Eq. 55)}$$

The difference between two independent ratios appears on the righthand side and hence

$$V\{M(Y) - \bar{x}_S + \bar{x}_T\} = V\left(\frac{Y - \bar{y}_S}{b_S}\right) + V\left(\frac{Y - \bar{y}_T}{b_T}\right) \quad \text{(Eq. 56)}$$

and now, applying Eq. 54

$$V\left(\frac{Y - \bar{y}_S}{b_S}\right) = \left(\frac{Y - \bar{y}_S}{b_S}\right)^2 s^2\left\{\frac{\frac{1}{n_S}}{(Y - \bar{y}_S)^2} + \frac{\frac{1}{\Sigma_S'}}{b_S^2}\right\} = \frac{s^2}{b_S^2}\left\{\frac{1}{n_S} + \frac{(Y - \bar{y}_S)^2}{b_S^2\Sigma_S'}\right\} \quad \text{(Eq. 57)}$$

The variance of $(Y - \bar{y}_T)/b_T$ can be similarly calculated and, on the assumption that the quantity $M(Y) - \bar{x}_S + \bar{x}_T$ in Eq. 55 is normally distributed, the approximate fiducial limits of $\mu(Y)$ are then,

$$\mu_L(Y),\ \mu_H(Y) = \bar{x}_S - \bar{x}_T \mp \sqrt{F_c s^2\left\{\frac{1}{n_S} + \frac{1}{n_T} + \frac{(Y - \bar{y}_S)^2}{b_S^2\Sigma_S'} + \frac{(Y - \bar{y}_T)^2}{b_T^2\Sigma_T'}\right\}} \quad \text{(Eq. 58)}$$

SLOPE RATIO ASSAYS

Suppose that the two dose-response lines in a slope ratio assay are

$$Y_S = a_S + b_S z_S \quad \text{(Eq. 59)}$$

$$Y_T = a_T + b_T z_T$$

where z_S and z_T represent doses, and the intercepts a_S and a_T are estimates of the parameters α_S and α_T and, instead of α_S being equal to α_T as in the regular slope ratio assay case, we now have $\alpha_S \neq \alpha_T$. The dose Z_S which is equipotent with a specified dose Z_T of the test preparation is then estimated as

$$\hat{Z}_S = -\frac{1}{b_S}(a_S - a_T - b_T Z_T) \quad \text{(Eq. 61)}$$

It can now be seen that this is directly analogous to Eq. 13 for the previous case, except that we now have doses Z_S and Z_T instead of log-doses X_S and X_T, so that *mutatis mutandis*, the above procedures can readily be applied in slope-ratio assay situations.

DISCUSSION

Finney (1965) has recently given an interesting general discussion of the role of the concept of constant relative potency, or equivalently of the condition of similarity, in bioassay. It should be noted that the estimation procedures in the present paper are referred to situations when the condition of similarity does not obtain. Such situations are common in research situations for which the condition would often be an unrealistically ideal assumption.

Relatedly, although techniques have been presented for estimating relative potency as a function of dose (concentration) or response, it is considered that these are of less importance and value than those described for the estimation of equipotent doses. It is suggested that this latter is the more basic concept for bioassay in general because, even when relative potency is constant, applications of its estimation are often, in effect, made toward determinations of equipotent doses.

Drug Standards

Standardization of Papain Activity

Report of a Collaborative Study

By EDGAR A. LAZO-WASEM

Methods of assay for the enzyme papain were evaluated, and those endorsed are presented. A procedure which measures the hydrolysis of casein under standardized conditions was found to be the method of choice.

PAPAIN, a crude or purified proteolytic enzyme derived from the tropical plant *Carica papaya*, has been used in the pharmaceutical and food industries for over half a century. Twenty years ago, a monograph for papain was included in the eighth edition of the "National Formulary" (1). The then official assay procedure consisted of a limit test based on digestion of beef muscle.

After deletion of papain from the "National Formulary," many procedures came into use for the standardization of commercial papain. For pharmaceutical and food grade papain, the most widely used procedures have been milk-clotting (2), casein digestion (3), and digestion of hemoglobin (4, 5). For crystalline papain, most laboratories have, at least recently, relied on the initial rate of hydrolysis of synthetic peptide substrates such as *N*-benzoyl-L-arginine ethyl ester hydrochloride.

In an attempt to bring about unification in methods of assay throughout United States laboratories, a committee was established within the Quality Control Section of the Pharmaceutical Manufacturers Association in the fall of 1962. This group was to study current prevailing methods and recommend a generally acceptable method for use throughout the industry. This report describes the findings and recommendations of that committee.

PLAN OF STUDY AND RESULTS

Member firms of the Pharmaceutical Manufacturers Association, representing manufacturing suppliers and pharmaceutical firms marketing papain in dosage forms, were invited to supply their procedures. The methods received involved either milk-clotting, casein digestion, or hemoglobin digestion. From the procedures received, three assays based on the above principles were prepared and forwarded to eight laboratories for collaborative study. "Standard" and "unknown" papain preparations were also forwarded, and thus an effort was initiated whereby

Received March 15, 1966, from Strong Cobb Arner, Inc., Cleveland, Ohio.
Accepted for publication May 4, 1966.
A study by the Committee on Papain, Quality Control Section, Pharmaceutical Manufacturers Association. Committee Membership: J. E. Giesemann, Brayten Pharmaceutical Co.; N. Kartinos, Baxter Laboratories, Inc.; G. F. McCutcheon, S. B. Penick & Co.; C. F. Peterman, Kremers-Urban Co.; J. V. Saenger, Warner-Chilcott Laboratories; I. S. Shupe, Winthrop Laboratories; L. A. Underkoffler, Miles Chemical Co.; and E. A. Lazo-Wasem, Strong Cobb Arner, Inc. (Chairman).
After the study reported here was underway, it was learned that efforts toward uniformity of enzyme assays, including papain, were being made by the International Commission for the Standardization of Pharmaceutical Enzymes, Fédération Internationale Pharmaceutique. Since then this writer has been kept informed of the efforts of this predominantly European group, the initial studies of which have been excellently summarized in the commission's First Report (6). For papain, the commission has endorsed a method based on the initial rate of hydrolysis of a synthetic substrate, *N*-benzoyl-L-arginine ethyl ester hydrochloride, for both crystalline papain and less purified preparations. A comparison of the unit of activity reported here with that adopted by the commission will be the subject of a future report.
