Application of Statistical Methodology in Quality Control Functions of the Pharmaceutical Industry

A Survey

By T. N. T. OLSON and I. LEE

CONTENTS

INTRODUCTION

"OF WHAT Significance Statistics" was the title of an editorial by Edward G. Feldmann in the November 1963 issue of the *Journal of Pharmaceutical Sciences* (1). Feldmann recognized the increased use of statistics and commented on the merit of the uses to which statistics were then being applied. This paper, which is limited to the application of statistical methods to pharmaceutical quality control, is intended to amplify that editorial.

There has been a steady increase in the use of statistics in the quality control functions of most of the companies in the pharmaceutical industry over the past 10 years. This is not too well evidenced when examining the literature of the pharmaceutical sciences, but is readily apparent if one examines the technical statistical literature.

The past few years have shown that the analytical controls, and those after-the-fact subjective or inspection-type controls employed during the manufacture of a pharmaceutical product may be about only 10% of the effort used to control a product adequately. The other 90% would consist of the people, material, facilities, building, equipment, product design, procedures and specifications, and documentation under which and by which the product is manufactured.

Statistical methods applied to outgoing material, and control charts on analytical assays are after the fact, that is, after the material or product has been manufactured. Statistical methods applied to filling operations or on-line inspection of products are of much more value since they are controlling the material at the time of manufacture. The 1962 drug amendments to the Food and Drug Act of 1938 acknowledge that it is the in-process controls applied to a product which in effect make a quality product.

Five years ago statistical sampling plans with a sensitivity in the range of 1 to 5% defective

Received from the Quality Control Division, Parke, Davis and Co., Detroit, Mich.

were considered adequate for inspection of packaging supplies. Now engineers would like 0.1% sensitivity for certain types of defects which interrupt high-speed packaging lines. When problems such as these arise, statistical methods must be modified for a different approach to the problem because the cost of sampling 3000 to 5000 units would be prohibitive, let alone the cost to manufacture certain materials with a value of defectiveness so low.

Mainland (2) poses 2 interesting questions that could be applied to our desire for increased knowledge and perfection: "If the verdict of a test is 'significant' at our predetermined level, what will we do in consequence thereof?" And the second question: "If the verdict of a test is 'not significant' at our predetermined level, what will we do in consequence thereof?" These two questions applied to a series of alternative quality control situations will soon show that the way to produce a product is to design it right and do it right the first time. It is obvious that sampling plans which examine 10 out of a million tablets do not adequately control a product. A sampling plan which weighs 1 out of each 100 tablets as they are produced is controlling the product.

The statistical methods which are discussed in this paper are not discussed from an "after-the-fact" or "during-processing" concept, but it is obvious that the value of statistical methods will be the greatest if directed at the during-processing concept. Statisticians working in the quality control field all find quite a change from dealing with the research aspects of pharmaceuticals. The scientist who is inherently an optimist may accept odds of 5 to 1, the statistician being analytically a pessimist prefers odds of 20 to 1, but the quality control man wants zero defects, unrealistic as this may be.

STATISTICS OF ANALYTICAL PROCEDURES

The accuracy of an analytical procedure can be established by applying it to a product or material containing known amounts of the material to be assayed or by using unknowns and running both the new procedure and another whose accuracy has been established.

Accuracy refers to the closeness of the result to the true chemical content. Precision refers to the agreement of repetitive results with each other (3). The accuracy of an analytical test would be the mean of any repeated results as compared to the amount of material predicted to be in the product. The standard deviation may be estimated from the repetitive assays performed on the product and is a measure of the precision.

Youden (3) describes a simple method of analyzing analytical data by plotting the amount found against the amount taken for analysis. The plot should be a straight line. Figure 1 indicates the types of problems encountered with assays. A constant per cent bias of the slope is an inability to obtain in the amount found the same per cent increase that was in the amount taken. A constant intercept bias is the inability to recover the amount found in proportion to the amount taken.

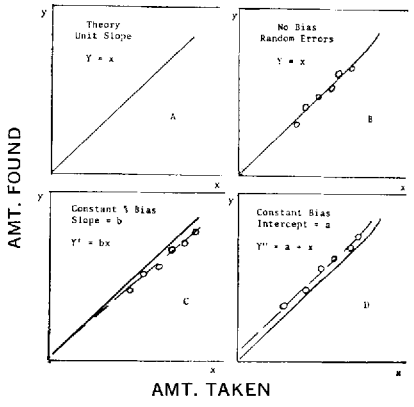

Fig. 1.—Diagram to show the effect of random errors, constant per cent errors, and constant error of analytical results. [Figure 1 of Youden (3).]

Youden describes the many types of problems encountered with the evaluation of new analytical methods including comments on Round Robins. He suggests a half-dozen different materials might be sent to a minimum of 5 different laboratories with requests for only single analytical determinations. He asserts that it is not necessary to ascertain the laboratory's precision because of the large number of results necessary to estimate the precision, the usual faithfulness of deviations from a procedure, and the possibility of censoring the duplicated data.

In a series of papers (4–8), Garrett *et al.* discuss the selection, evaluation, and control of the assay of several pharmaceutical products. Garrett makes use of many statistical techniques in these papers, including control charts, analysis of variance, design of experiments, and degradation rate statistics in addition to the usual statistical tests of significance. Statistical treatment of the data permitted Garrett to determine optimum solvent quantities for separation of the active ingredient, the number of dosage units to assay within a desired confidence limit, the reproducibility of fill weights, the homogeneity of the fill mix, and other relationships between assay economy and product variability. This series of articles provides a good summary of the statistical

methods available to an analytical laboratory in evaluating assay and dosage form variation.

Davies (9) outlines an economical testing program whereby the costs of routine analytical tests are compared to the costs of accepting material which is either above or below stated specifications. His cost for the rejection of acceptable batches (the α-error) is on the basis of reprocessing cost; the cost for accepting unacceptable batches (the β-error) is not quite as easy to quantify.

In the pharmaceutical industry, the probability of wrongly classifying good material is rather low because of the tendency to attempt to test quality into the product. It would be expected that any material to be rejected would be tested sufficiently to prove that point; and so the cost would only be for additional testing. These points are explored further in the paper.

Calder (10) suggests a revised method of calibrating instrumentation relating to spectrochemical analysis where the calibration procedure involves plotting the instrumental response for an element against the concentration of that element. By calculating regression lines using the method of least squares for the response *versus* concentration, only 24 instead of 84 spectra and only 18 hr. instead of 60 hr. were required as compared to the original method.

Wernimont (11) used a computer to compare 16 Beckman spectrophotometers as to (*a*) the variation of the absorbance curve of each spectrophotometer about its own absorbance curve, (*b*) a comparison of the variation of a selected group of spectrophotometers about their average absorbance curve, and (*c*) a comparison of the remaining unselected group of spectrophotometers to the standards and tolerances of the selected group. Spectral analysis was used to analyze the data. The data were explained by the computation of 2 characteristic vectors. The first vector related to the vertical displacement of the absorbance curves and the second vector to the horizontal shift of the curves. Wernimont described a tentative absorbance standard of 60 mg. potassium chromate per liter, together with a procedure to check the Beckman spectrophotometers and a high-speed computer program which will make the necessary transformation to scale multiples of the 2 vectors.

The current growth in the use of statistics as applied to analytical chemistry can be attributed to an increased awareness of the colleges to mathematics in general. The use of automated analyses and computers will ultimately require extensive use of statistical methodology in the modern analytical laboratories.

SAMPLING PLANS

Description of Sampling Plans.—Acceptance sampling, which received its start during World War II, when it was used to pass on the quality of armaments, has been accepted for a large number of uses by the pharmaceutical industry.

An acceptance sampling plan may be described as follows. A company produces a lot of compressed tablets. It obtains a representative sample of tablets from the lot, examines the sample and, based on information obtained from the sample, either accepts the lot as conforming to standards or rejects it. The sampling plan is defined by (*a*) the size of the sample taken and (*b*) the number of defectives or degree of defectiveness allowed in the tablets. Graphically, a sampling plan can be explained by an operating characteristic curve.

Four points are defined on the operating characteristic curve selected for an example by Breunig and King (Fig. 2, *A*). First, a lot of tablets is said, for the sake of illustration, to be satisfactory if it contains only 10% defective tablets (the acceptable quality level, AQL). Second, a lot of tablets is said to be unacceptable if it

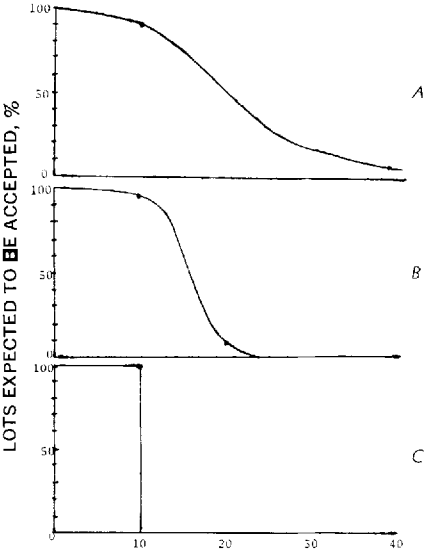

Fig. 2.—Key: *A*, operating characteristic (OC) curve for tablet example from *Reference 15*, p. 11, illustrating AQL = 10%, UQL = 40%, R_p = 10%; R_c = 8%, n = 10 [figure 5 of Breunig and King (12)]; *B*, typical operating characteristic curve from *Reference 15*, p. 27, illustrating AQL = 10%, UQL = 20%, R_p = 5%, R_c = 10%, n = 85 [figure 4 of Breunig and King (12)]; *C*, ideal operating characteristic curve illustrating perfect discrimination but unrealistic stringency [figure 3 of Breunig and King (12)].

contains more than 40% defective tablets (the unacceptable quality level, UQL). Third, there is a certain probability that a lot which in reality is 10% or less defective is observed on test to be more than that with the result that the lot is wrongly rejected. This is the producer's risk or α error. Fourth, there is the probability that a lot which is truly 40% defective is observed on test to be less than that with the result that the lot is accepted. This is the consumer's risk or β error. Once the above four values are selected the sample size is automatically determined.

Figure 2, *B*, shows an operating characteristic curve where the UQL has been decreased to 20% with a sample size of 85 tablets, and Fig. 2, *C*, shows a curve where the AQL and UQL are identical. To obtain the curve shown in Fig. 2, *C*, the entire lot of tablets would have to be examined.

The ability of a sampling plan to discriminate is dependent upon the size of the sample. Sampling plans requiring 10 to 30 samples have relatively low powers of discrimination.

There are two types of sampling plans: attribute and variables. Attribute sampling refers to a zero-one situation where a tablet is either good or bad; variables sampling is based on a continuous distribution of degrees of defectiveness and covers the gray zone between good and bad situations.

Attribute sampling plans require only the counting of the number of defectives found in the sample, or a mean or percentage of defectiveness [100 × (number of defects/sample size)]. The acceptance or rejectance of the lot depends on whether this value is smaller or larger than the one stated by the sampling plan.

Variables sampling plans require the calculation of a mean and standard deviation or range. For example, a sample of 10 tablets is taken which should have a theoretical mean weight of 100 mg. The mean weight of the sample is 94 mg./tablet, with a calculated standard deviation of 2 mg. Using the formula (100 mg. − 94 mg.)/2 mg. = 3.0, and entering a set of tables similar to the normal tables, it is found that the value of 3.0 indicates the material is 1.2% defective, which is acceptable or unacceptable depending on the values of acceptance.

Double sampling refers to the following example situation. A sample of 50 tablets is taken. If it contains 2 or less defectives, the lot is accepted. If it contains more than 4 defectives, it is rejected. If it contains more than 2 defectives but less than 4 defectives, a second sample of size 50 is taken. If in the 2 samples, there are less than 4 defectives, the lot is accepted. Triple and multiple sampling are merely extensions of the above premise.

Sequential analysis of sequential sampling is an extension of multiple sampling developed by Wald during World War II (13). Successive samples are taken based on a varying set of criteria until either a decision to accept or reject is made. There is, of course, the possibility that no decision could ever be made and the samples would stay in the indifference zone indefinitely. The problem is easily resolved, however, by deciding to stop at a given sample size.

For practical purposes the need to design a sampling plan has been eliminated by a series of government-sponsored sampling plans, 2 of which are MIL-STD-105D for attribute single, double, and multiple sampling plans (14); and MIL-STD-414 for variables sampling plans (15). These books have gained acceptance throughout most of United States industry in a manner much like the U.S.P. and N.F. Government contracts for the purchase of pharmaceuticals usually refer to one or both of these books. The obvious advantage of selecting plans from either of these books is communicability and acceptance throughout industry. Hence, there is little or no advantage to specially designed sampling plans

Application of Sampling Plans.—Pharmaceutical products which are solutions are sampled ordinarily with a sample size of 1. This is based on the premise that a solution is a homogeneous mixture in which every milliliter is like every other milliliter. Suspensions are frequently sampled the same way, but this is predicated on a thorough or continuous mixing. It is frequently necessary to take more than 1 sample from a suspension to verify that it is truly homogeneous. If a lack of homogeneity is known to be present, then a suspension could be thought of statistically as resembling a lot of compressed tablets with an infinite population size.

If a drum of a powdered chemical is known to be homogeneous, then for statistical purposes it can be thought of as a solution. Single or duplicate samples then are considered sufficient to obtain a reliable response by an analytical test. If a drum of chemical is known to come from a process where the entire lot of chemical is not blended prior to being filled into drums, there can be no assumption of homogeneity for certain properties of the chemical. For practical purposes an infinite population size could be assumed such as for a lot of tablets. The reliability of 1 or 2 samples from such a drum would be of serious doubt no matter how good the

answers appeared. According to MIL-STD-105D, sample sizes in the range of 2500 may be necessary for attributes, and for MIL-STD-414, sample sizes of 200 may be necessary to obtain adequate representation of an entire production lot. It is obvious that if sample sizes of this size were used, they would be economically impossible to test. The military plans, however, allow the dividing of the production lot under certain conditions into inspection lots (subsets of the production lot) which substantially reduce the astronomic sample sizes mentioned above.

A situation analogous to the sampling of pharmaceuticals in the powder state was studied extensively by Duncan (16–18) under the auspices of the National Plant Food Institute. Four different fertilizers, 3 different sampling instruments, and 3 different laboratories were used in the experiments. It was noted that under certain conditions, 1 of the instruments showed a tendency to take in a higher percentage of larger particles and a lower percentage of smaller particles, which in turn gave a higher assay value. Little or no evidence was found to indicate that instrument sampling differed more on the average than samples obtained by riffling. Relative differences between laboratories were noted along with differences between days from the same laboratory. The official method of the Association of Official Agricultural Chemists for sampling bulk material requires a sample from 10 bags for lot sizes greater than 10 bags. One tube core is removed from each bag. For lot sizes less than 10 bags, at least 10 cores are to be taken, but at least 1 core from each bag. From a blended sample of the 10 cores, a sufficient quantity is taken for analysis. Duncan assumes the running of 2 tests on the samples, no more, no less, in his mathematical model of the sampling and assay procedure.

The work done by Duncan in the fertilizer experiment would lend itself to the formation of an official method of sampling bulk pharmaceutical powders where the mean of the replicate assays is the standard for acceptance.

Duncan (19) devised the operating characteristic curves for fertilizer inspection plans which utilized sample sizes of 20 and 10. Ten samples were suggested for use because of the lower cost of sampling which is comparable to the pharmaceutical problem.

All of the above discussion is useful as long as it can be assumed that the characteristics being sampled are randomly distributed between bags or packages. However, the writer has investigated the problem of powder in barrels from a lot containing varying particle size distributions, although the material was accepted on the basis of its chemical purity. In this case, particle size distribution in certain ranges caused undesirable physical properties in the final product.

For adequate sampling in a situation such as this, reversion to knowledge of how the powder was manufactured is a necessity if homogeneity of a property is known to be a problem. Statistical sampling of the product is no substitute for manufacturing the product by a process known to produce satisfactory characteristics. All that should be necessary is to run an identity test of the material.

Literature on appearance of pharmaceutical dosage forms is rather conspicuous by its absence in the case of sterile types of products. As a result, most manufacturers inspect 100% of all sterile products for appearance-type defects such as particulate matter within the vial. It apparently is not desirable to say that a given lot of ampuls contains particulate matter in 1% of the vials. Still, at the present state of the art, particle-free sterile products are virtually impossible to manufacture and also exceedingly difficult to inspect on an economic basis. Each company, however, must have a set of standards and a method for verifying that the standards are being followed. This represents its level of excellence. Attribute sampling techniques can do this verifying with ease.

Tablets and capsules are frequently 100% inspected. Tablets, however, frequently are produced with a very high degree of excellence and also do not carry with them the problem of sterility and injectable elegance. Sampling plans therefore, work well with tablets, except for the large lot sizes which, depending on how the lot is sampled or divided, may require that large sample sizes be taken.

If tablets are inspected as they come off the compressor and little or no capping is noticed, it is not uncommon to find an unacceptable level of capping a few days later when they are packaged. This, in reality, is saying that a measurement for the potential to cap has not been employed in the inspection process; but in addition it says that the tablets were not manufactured correctly the first time.

What is the proper way to handle a tablet containing a metal chip traced to the feed frame of the compressor? Is the whole lot to be 100% inspected, a portion of the lot 100% inspected, or more samples taken? This is not really a problem in statistics, but in quality control.

The statistics of weight variation have been undergoing a gradual but continuous refinement in the pharmaceutical industry. The following

discussion outlines the various approaches that have been investigated over the past two decades along with the problems associated with the various plans.

The U.S.P. XIV and N.F. IX had the following weight variation test for compressed tablets (20):

"Weigh 20 whole and uncoated tablets and calculate the average weight. When weighed singly, not more than two of the tablets deviate from the average weight by a greater percentage than that shown in the following table, and no tablet deviates by more than double that percentage."

Average Weight	Percentage of Deviation
13 mg. or less	15
More than 13 mg. and including 130 mg.	10
More than 130 mg. and including 324 mg.	7.5
More than 324 mg	5

(The above table has been modified in U.S.P. XVII by eliminating the first weight class.)

Dunnett and Crisafio (21) derived the operating characteristic curves for the above official tablet weight variation method using sample sizes of 10, 20, 50, and 100. It was found that by simulating a batch containing 5% defective tablets (too heavy or too light) the lot would be accepted 93, 95, 98, or 99%, depending on whether a sample size of 10, 20, 50, or 100 was used. A batch containing 20% defective would be accepted, 40, 23, 4, or 0% using the same sample sizes. It was concluded that a sample size of 10 tablets had only meager ability of protection against inferior products. The use of a standard deviation test for 10 and 20 tablets was discussed and also a 2-sample attribute plan requiring a total of 50 tablets. If the first sample of 20 was satisfactory, the remaining were not examined. The operating curve for this was better than the operating characteristic curve for the 10- and 20-tablet standard deviation plans.

Non-normality of tablet weight variation was studied. The higher proportion of non-normal lots found, than was expected, was attributed to (*a*) the incapability of machines to turn out uniform tablets, (*b*) the differences between punches, (*c*) the sampling at various times from the machine. Dunnett concluded that no reasons could be found for the substitution of another mathematical distribution in place of the normal distribution.

Smith (22) suggested as an alternative to the B.P. and U.S.P. methods of weight variation the use of sequential analysis using formulas given by Wald (13). The use of half-defective (tablets deviating by half the specified amount) and double-defective (tablets deviating by double the specified amount) were discussed, and a table for acceptance or rejectance using sequential analysis for half-defective tablets was presented. The advantage of using sequential analysis was in the fewer weighings (about half the number requested by the B.P.) required for a decision on acceptability. Disadvantages cited were the very small sample size which is to represent the lot and the ease of giving exactly 20 tablets to an analyst for weighing.

Green and Knudsen (23) discuss three types of sampling which were applied to samples of 20 dry-filled ampuls. These could be stated as (*a*) the average of the sample shall not be greater than or less than ___, and no individual ampul from the sample shall be greater than or less than ___; (*b*) the average of the sample shall not be greater than or less than ___, (*c*) and no individual ampul from the sample shall be greater than or less than ___. A comparison of the operating characteristic curves for the 3 plans indicates that the average plan, and the combined average and individuals plan are comparable and that both of these are better than the plan dealing with individuals. By analyzing collected data, it was asserted that a plan then suggested by the manufacturers in 1950 and a Canadian tolerance were too tight in the lower weight ranges and too loose in the upper weight ranges.

Breunig and King (12) described the advantages of variables sampling plans as having a greater ability to detect excessive tablet weight variation than the plan employed by the U.S.P. When Breunig and King compared their variables plan to a 2-step attribute sampling plan such as is now in the U.S.P. XVII and N.F. XII for assay variation, they found the variables plan superior for (*a*) cases of excessive variation and (*b*) for excessive variation combined with a shift in the mean and about equal for cases of mean shift alone. Two nonstatistical points were stated by Breunig and King which illustrate how inadequate the use of a statistical sampling plan is without simultaneous human thought. (*a*) A lot is accepted or rejected on the basis of an exceedingly small number of units (10 or 30 out of 1,000,000). As a result, it is not practical to expect a sampling plan to guarantee that all accepted lots will be of acceptable quality, although such a plan may be quite effective in detecting an occasional bad lot when all others are of good quality. (*b*) If many highly defective lots are submitted to such a plan, it is possible that half of them will end up being used by the consumer.

The solution to the above is an adequate quality control system throughout all the various stages of the processing of the product, which assures that the product is made right the first

time. The U.S.P. and N.F. sampling plans then become merely guide rules as to what level of quality is expected of the manufacturer of a pharmaceutical. From an enforcement viewpoint, however, the sampling plan's quality standards must be enforced on a lot-to-lot basis.

Haynes (24) demonstrated by the use of actual data from sterile solid weight variation and by computer simulation that certain suggested attribute plans were more robust than equivalent variables plans. Robustness refers to the problem which causes variables plans to be more susceptible to the effects of non-normal distributions commonly found in small samples (10 to 30 items). Figure 3, *A*, shows a normal distribution of weights as generated by simulation on an IBM 7070 with approximately 5% of the values outside the vertical dotted lines; Fig. 3, *B*, shows a platykurtotic distribution of weights; and Fig. 3, *C*, shows a leptokurtotic distribution of weights.

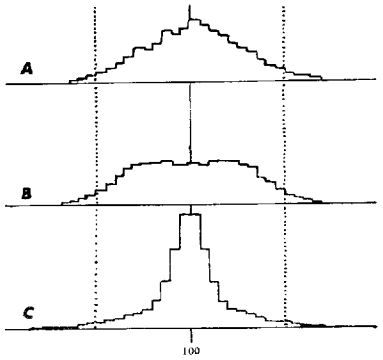

Fig. 3.—Key: *A*, normal weight distribution, quality index 94.5%; *B*, platykurtotic weight distribution, quality index 95.1%; *C*, leptokurtotic weight distribution, quality index 95.0%. [Figures 3, 4, and 5 of Haynes (24).]

Both platykurtosis and leptokurtosis are types of non-normality found in pharmaceutical dosage form weight and assay variation. Paul (25), by using data accumulated for individually assayed compressed tablets, reinforced the work of Haynes that pharmaceuticals were indeed manufactured in non-normal distributions as evidenced by samples of 10, 20, and 30.

In response to a request from the Food and Drug Administration, the Pharmaceutical Manufacturers Association, Quality Control Section, in 1961 set about to collect data for dosage form variation for sterile solids without diluents and for compressed tablets.

By October 1962, two differing plans were advanced by industry statisticians. These were the variables type sampling plan advanced by Breunig and King for compressed tablets and the attribute plan advanced by Haynes.

Although one type of plan was advanced for tablets and another for sterile solids, this was the result of two different committees working on the problem separately. Both tablets and sterile solids were, however, later considered using a single type of sampling plan.

Based on the work of Haynes and other industry statisticians, the P.M.A. Quality Control Section through its subcommittees recommended to the U.S.P. that an attribute type of plan be adopted in the U.S.P. for a selected group of tablets as a test for composition variation.

As a result, the U.S.P. XVII and N.F. XII have adopted the following statement regarding "content uniformity" for certain compressed tablet monographs: "Select a sample of 30 tablets. Assay ten of these individually as directed. The requirements of the test are met if all ten results fall within the limits of 85% and 115% of the average of the tolerances specified in the monograph. If one result falls outside these limits, assay the remaining 20 tablets individually. The requirements are met if not more than one of the 30 results is outside of the limits of 85% and 115%."

An interesting question arises when one asks, "What type of distribution of doses does the consumer have a right to expect when in fact he cannot be given on a repetitive basis exactly 5 gr. of aspirin?" Clearly, a leptokurtotic distribution gives the consumer on the average some of what he expects; likewise, a platykurtotic distribution of values shows a lack of control in a manufacturing process. If a normal distribution or leptokurtotic distribution is suitable for a customer, then is it not consistent to set the bias of the sampling plan against the platykurtotic distribution generated by a poorly controlled process?

Moskalyk *et al.* (26) expressed the observation that dosage variation was greatest in the lightest weight tablets within a batch. Then the question arose concerning whether this could be proved true for all tablets; if it was, a sample of lightweight tablets could be adopted as a control over uniformity of drug dosage.

Haynes (27) also was interested in control of weight variation as a means of controlling drug dosage.

It is clear that what is needed is a non-analytical test which statistically predicts the degree of potency variation between dosage forms. With the advent of the Mettler and Cahn automatic weighing balances, it is not impossible to weigh thousands of tablets, either as they are being processed or as a sample obtained from the finished lot. From the distribution of values obtained from them, a statistical test of normality

could be made. If a statistical technique can then be derived that would allow us to draw conclusions from 3 singly assayed tablets, the 3 lightest, or the heaviest, middle, and lightweight from a random sample of specified size, is it then not possible to predict with an acceptable degree of reliability that the lot conforms to U.S.P. or N.F. standards? Here is an area for some statistical research with great economic rewards.

Although attribute sampling plans are the simplest to use and simplest to enforce legally, variables sampling plans are still the most useful for the internal operations of a pharmaceutical manufacturer. Especially will this be true with the automation of the quality control function of pharmaceutical product manufacture.

The sampling of product container fills by a regulatory agency is properly a sampling technique, although it is routinely controlled by control charts and might logically be discussed under *Control Charts.*

The Department of Agriculture, State of California (28), has now put into effect Article 5 which will attempt to control from a legal viewpoint the concept of filling variation. The size of the sample of consumer size packages required for sampling follows closely the approach used by the Association of Official Agricultural Chemists for sampling bulk material in lot sizes of 10 containers or less. For lot sizes greater than 10 packages, the sample size approximates the square root of the number of packages in the lot. The plan, although not similar to either an attribute sampling plan or a variables plan, contains features of both type plans. The basic feature of Article 5 is that tables are presented for all possible situations which the investigator might meet. Article 5 does not say, however, for example, that a 5-lb. package must contain at least 95% of label claim. It merely says that for a given sample of package weights or fills, the average range and the average error are to be determined. Based on these values, unreasonable weight errors are to be determined, the values of which will determine whether the lot is acceptable or unacceptable.

True statistical sampling has very limited if any application at all in detecting a single foreign label or carton in a lot of labels or cartons. Only 100% nonhuman inspection of the entire lot will give any degree of reliability in detecting a foreign label or carton. Human inspection is second in preference to machine inspection. At the present time, it is better to consider machine inspection as a means of determining the presence of foreign labels, but not as a means of removing them from a lot of labels. It would be preferable to have the inspection machine stop rather than try to remove the offending label. Statistical sampling does, however, work very well in controlling the quality of printed material for poor printing, coloring, centering, etc.

Sampling and inspection of bottles, containers, and cartons has had wide application in the pharmaceutical industry. MIL-STD-105D works very well on this type of application since the vendor should understand the use of this plan.

It is not the statistical aspects of sampling plans which are of major concern in the above applications, but rather the definition of what is a defect. It is possible to have 20 or more types of defects for glass bottles. Are they all to have the same weight as to being called a defect? At what point is a defect called a minor defect, and when does it become a major or critical defect? If the inspection process is human, there is an ever-present tendency to tighter standards. Likewise, if a lot does not quite meet sampling plan standards, there is a tendency to go outside the sampling plan for information as to whether to accept or reject. If this item is needed for production due to low inventories or if the defects all run to 1 type which is not too serious there is a desire to accept the lot. Hence, the most important aspect of designing a sampling plan is a definition of what a defect is or what is to be sampled for. The most important aspect of using a sampling plan is drawing a truly random sample and following and maintaining the definition of a defect.

CONTROL CHARTS

Description of Control Charts.—Control charts are a method of graphing or plotting data in such a manner that a time series of events is summarized. Figure 4 shows a control chart described by Breunig.

Control charts are characterized by a vertical axis which has a scale of a varying measurement such as a mean, range, standard deviation, or fraction defective, and a horizontal axis which is time-oriented. There are frequently 3 horizontal lines on a control chart. The center line is the target value or the historical process average. The upper line is the upper control limit (UCL) which is normally 3 standard deviations above the center line. Likewise, the lower line is the lower control limit (LCL), again 3 standard deviations below the center line. The 6 standard deviation spread between the upper and lower control limits will encompass 99.97% of the values in a distribution with its mean at the

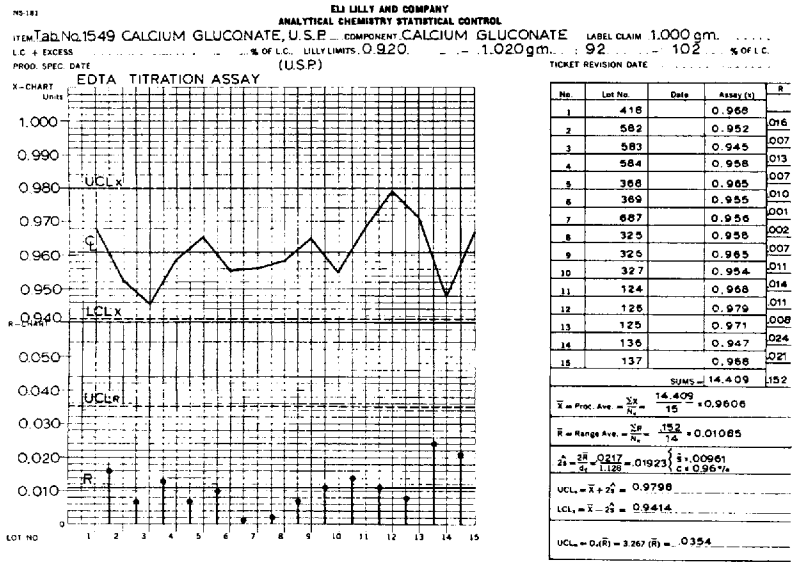

Fig. 4.—A typical analytical laboratory control chart. (Breunig.)

center line or process average. Control charts which are used for plotting sample averages are frequently used in conjunction with a range or standard deviation chart. One chart is used to plot the process average and the other the process variability. If a given value falls outside of the upper or lower control limit, the process is usually adjusted to bring it close to the center line.

It is frequently desirable in pharmaceutical processes to add another set of limits which could be called tolerance limits. If a given value falls outside the tolerance limits, the operation must be halted. If a tablet compressor normally operates under control limits well within the U.S.P. and N.F. specifications, the tolerance limit might well be the equivalent of the U.S.P. and N.F. specifications. This ensures the manufacturer that few, if any, products are manufactured outside of acceptable limits.

There have been many modifications to the structure of control charts, notably the cumulative sum type. However, the use of control limits for decision making is common to all types of them.

Application of Control Charts.—Control charts are primarily used for plotting routine (*a*) analytical or biological assay results or parameters, (*b*) fills of fluid or injectable products, (*c*) weights of tablets or capsules, and (*d*) the percentage or number of defects in a sample of packages emanating from a packaging operation. They are also useful for plotting data gathered at the beginning of a research problem.

Yehle (30) in an investigation of laboratory precision and specification limits used a type of control chart to plot the results of laboratory analyses.

Noel (31) discussed the use of control charts as applied to collecting data about particulate matter in ampuls in order to check the difference between machines and of fill weights. Noel's discussion on control charts was the second of a 5 part series of articles dealing with the use of statistics in the pharmaceutical industry (32–35).

Recently, Breunig (29) discussed the application of statistical control charts to analyses which were run in duplicate on vitamin A palmitate where the problem was *cis–trans* isomerization. Product and analytical control was obtained by purchasing an equilibrium mixture of *cis–trans* vitamin A palmitate. He also discussed the use of control charts for studying tablet weight variation and assay variation prior to introducing single tablet assays.

Brochmann-Hanssen and Medina (36) described the uses of control charts for determining weight variation and composition variation for phenobarbital tablets. Their inspection of the charts indicated that some disruption of uniformity occurred during the compression of the tablets.

One of the problems with control charts for routine applications is the objection of the analyst or operator to writing the results of a test on a control chart since the result is usually first written on another document. Wherever a control chart is a secondary document, resistance to its use is apt to appear. If the control chart can be the primary document, acceptance is made easier.

Breunig suggests as a solution to this problem

an instruction manual, a training course, consultation, and management support. Breunig also suggested that the reason analytical laboratories have not adopted statistical quality control programs is because the U.S.P. and N.F. have their sampling and control procedures "couched" in terms which can be considered obsolete in the light of the knowledge available today (29).

The above statement was in reference to the U.S.P. and N.F. attribute sampling plans for tablet and capsule weight and assay variation, the single assays performed on composite samples, and the associated unrealistic limits specified by the monograph.

EVOP AND ADAPTIVE QUALITY CONTROL: STATISTICS FOR CHEMICAL PROCESS EVALUATION

Quality control whose main forte is controlling new and existing operations, must at times be concerned with improving existing manufacturing operations. After publishing extensively (37–40) in the field of response surface statistics, Box (41) published a paper dealing with a very simple technique called "EVOP" (evolutionary operation) which was useful in finding the optimum operating conditions for a chemical batch process or similar process. His first paper dealt with 2 variables (*e.g.*, concentration and temperature) and 3 variables (*e.g.*, concentration, temperature, and pH) models. Without developing the theory of EVOP, a 2-variable EVOP cycle would consist of 5 experiments performed under the conditions shown in Fig. 5. By some very simple calculations (42), it can be established whether the process is at its optimum or whether the increase of one or both variables in a given direction tends to give a significant increase in response. Usually 3 cycles or 15 experimental units are required to show which variables are significantly influencing the process and in which direction they should be adjusted to maximize the response (yield, impurities, or cost of the process).

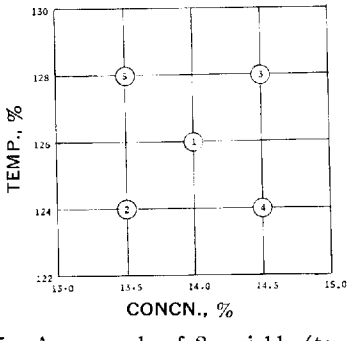

Fig. 5.—An example of 2-variable (temperature and concentration) EVOP cycle. [Figure 4 of Box (41).]

There have been other statistical models, such as adaptive quality control (42), developed for maximizing yield, but these are beyond the scope of this paper.

The point to be made about response surface statistics, as applied to making fine pharmaceutical chemicals or other material, is not with the statistical aspects of the technique, but with the control aspects.

EVOP and similar response surface techniques are difficult for the quality control function of a company to evaluate because they are opposed to the basic control precept of making the product by the same method under the same conditions for every batch. In conclusion, EVOP and related techniques are very useful and powerful statistical tools which definitely should be used on applicable production processes. Nonstatistical problems, however, may play a predominant or controlling part in the extent of the usefulness of these statistical production process optimizing techniques in the pharmaceutical industry.

BIOLOGICAL ASSAYS

Description of Biological Assay.—There are two types of indirect bioassay: one is based on quantitative responses, the other on quantal responses.

An example of a quantitative assay is the guinea pig skin test in which the activity of tuberculin P.P.D. is estimated from the varying size of wheals resulting from the injection of tuberculin-sensitized pigs with graded doses of the antigen.

An example of a quantal response bioassay is a mouse potency test in which antigenicity of a vaccine is measured from the proportion of mice still living after first being injected with the vaccine under test and then being challenged with the live organism against which the vaccine is to protect.

Biological assays can be further divided into two types: analytical dilution assays and comparative assays. In an analytical dilution assay (either quantitative or quantal), both a standard (or reference) and test preparation are considered to consist of an "effective constituent" suspended in an inert diluent (43). Relative potency in such an assay is defined as the ratio of the concentration in an effective dose in a unit amount of the test preparation to that of the standard. It then follows that the postulated relative potency characterizes the two preparations and

not the biological systems which are used to assay them (44).

Assays in which the postulated relative potency is not a constant are often referred to as "comparative" (43). A variable potency may occur in the comparison of a test and standard preparation which are qualitatively different. There are cases where the requirements of an analytical dilution assay are considered to be met and yet the outcome of the assay is far from being analytic because of the unknown extraneous factors which have caused qualitative differences in either preparation. (Analytical dilution assays are usually characterized by the reference and unknown having different slopes.)

In most biological assays, primary concern is directed at estimating the (*a*) effective dose of a test material in terms of the known effect of its constituents and (*b*) precision of that estimate.

Quantal Response Assay.—Finney (45) has pointed out that the ED_{50} (effective dose required to produce a 50% response) may have 1 standard error between determinations by 1 worker, another standard error between different workers using the same apparatus and the same stock of animals in a given laboratory, and still another between determinations in different laboratories. However extensive the experimentation on one population, no statistical analysis can demonstrate the applicability of the conclusion to a different population.

Finney further states that from the basic concept of plot technique, it can be deduced that the magnitude of an assay error is inversely proportional to the degree of correlation among the test subjects. An estimated internal assay error is necessarily an indication of what would be found in repeated tests of the same stock of subjects under the same conditions of testing. This limited interpretation must always be attached to statements about the ED_{50} of unknown material.

Nevertheless, much of the present difficulty seems to be removed by an adoption of comparative experiments (46). The numerous bioassay data which have been available to the writer appear to confirm Finney's statement that a theoretical reason exists for believing a numerical result to be applicable more widely than in the circumstances of the particular experiment that produced it.

The considerations that influence the interpretation of assay validity are of two types: statistical and other. Under statistical considerations, criteria such as linearity and parallelism of the dose–response relationships are included. The nonstatistical considerations include such matters as environmental factors which may have affected the quality of the effective constituent of either preparation. Obviously, both considerations are necessarily integral and eventually lead to a determination of whether the irregular occurrence is merely due to chance.

Such an extraneous factor as a physical disturbance apparently has an effect on the antigenicity of a certain type of vaccine to the extent that the effective constituent in the test material is no longer comparable to the standard. However, this type of deviation from parallelism does not necessarily imply that the assay is invalid (44).

From the realistic point of view, an assay may be considered to be invalid if and only if statistically significant nonlinearity and nonparallelism are accompanied with such factors as inconsistent testing conditions and heterogeneous test subjects which are not randomly allocated to each preparation.

In numerous cases of quantal response assays (6 points with approximately 16 subjects at each point), the test of linearity and parallelism often turns out to be so insensitive that the slope of the dose–response curve for 1 preparation must be at least 2.5 times steeper than that for the other preparation in order for the departure from parallelism to be statistically significant.

In such cases, neither the choice of the form of the transformation of the biological responses nor the arbitrary increase in the number of test subjects would overcome this difficulty. This type of insensitivity evidently stems from the inefficient allocation of dose levels which would be reflected by the insensitive responses.

It has been well-established that the relative potency, slope of the dose–response curve, and assay error represent characteristics of the test material (47, 48). In order for the subjects to be able to produce the true characteristics of the test material, it is a prerequisite for the experimenter to allocate an optimal amount of effective constituent in such a way that the minimum effective dose can be detected with a minimum of error.

Cramer (49) compared methods of fitting the dose–response curve for small samples (3-dose test with 10 subjects at each dose and 5-dose test with 4 subjects at each dose) and found that the probit analysis is superior to the minimum normit χ^2 method with respect to the assay error. This superiority is found to be substantial if the dose levels are poorly placed with respect to the true assay parameters.

The relative merits of the various methods for fitting the dose–response curve would be more meaningful if the existing antigenicity tests (mouse potency tests for influenza vaccine and

pertussis vaccine) are biologically unbiased. For instance, the following question may be asked: Is the antibody level at the time of challenge directly proportional (by an approximately constant factor) to the amount of a vaccine injected at the time of immunization?

It should be pointed out that many statistical analyses of quantal response bioassay are being utilized under the assumption that the reply to the above question is positive. This type of question further complicates the situations in which the valid evaluation of potencies of polyvalent vaccines are required.

Quantitative Bioassay.—The fundamental concepts involved in quantitative bioassay are essentially the same as those discussed under *Quantal Response Assay*. The quantitative assay in general, however, is subject to greater control and in turn requires more elaborate assay plans than the quantal response case.

Some of the antibiotic assays and vitamin assays consist of a number of plates, each plate being regarded as block. The different positions within a plate may have different effects on the response which should be solely attributed to a given concentration of the test material. Each sample should be rotated or allocated at random within a plate, depending on whether the position-to-position difference is systematic across the plates or unique to the individual plates. Both the test and the standard preparations should be represented in each plate, even in the cases where the position difference can be neglected.

It is well known that, when the dose and response are suitably transformed, the mode of the action of organisms can be represented by the monotonic dose–response relationship (either approximately sigmoidal or straight). Whenever a prior knowledge suggests that the dose-response relation for a given test material is approximately sigmoidal or linear, it is advisable to select two reference (standard) concentrations which cover the linear portion of the dose–response curve. The difference in response which is due to the difference in concentration is best detected along the linear portion of the dose–response curve.

The only remaining problem then is to choose target dilutions for the unknown preparation in such a way that at least 1 dilution for the unknown produces the response which stays within the responses produced by the 2 reference concentrations (50).

Another type of quantitative bioassay is that in which the response is measured by an instrument with a response in units of per cent transmission. Because of the possible instrumental drift which may be linear or nonlinear, the time required to process a set of standard and unknown dilutions may be regarded as a block.

There is still another type of quantitative assay in which the potency is measured from time. The activity of prothrombin samples, for example, is estimated from the clotting times for the standard and unknown samples.

Loomis (50) developed an assay method for fibrinolysin which uses a simple formula for estimating activity. His method is based on the assumption that the concentration–time relation for the unknown samples and standard is not only linear but also parallel to each other within the dilution range.

Stone and Bruce (51) reported (based on 250 humans injected intradermally with tuberculin) that there exists a linear relation between the induration–area and the log–dose in constant volume. However, they pointed out that the following questions deserve further clarification. (*a*) Can the form of the dose–response relation of intradermal tests (tuberculin) be extended to other diseases such as diphtheria toxin? (*b*) Is the form of the dose–response relation of intradermal test dependent on experimental technique?

They also presented a method by which the antibody level may be estimated from a knowledge of the dose and concentration of tuberculin used and the resultant area of induration.

The discussion under *Biological Assays* was included in this paper merely to show that it is a part of quality control. The subject alone is so large that a journal, *Biometrics*, is published to keep up with the changes in this one specialized field of statistics.

U.S.P. XVII (54) now recognizes the subject of biologics and biological assay and gives them prominent attention, as can be traced historically from 1950 to 1965.

U.S.P. XIV (20) had a single paragraph dealing with the significance of the standard error in a biological assay. There was no mention of the method of assay for antibiotics; antibiotic products were said to comply with the requirements of the Food and Drug Administration.

U.S.P. XV (52) included a section on the "Design and Analysis of Biological Assays," by C. I. Bliss. In addition, a section was added detailing the methodology for performing assays on the antibiotics included in the U.S.P.

U.S.P. XVI (53) expanded the section on antibiotic assays to show the formula necessary to calculate the slope and potency of the material being assayed. The section on the "Design and Analysis of Biological Assays" was continued.

U.S.P. XVII (54) again expanded the section on antibiotic assays to include some of the tech-

niques of designing antibiotic-type assays. Some revision was made to the section on "Design and Analysis of Biological Assays," including a glossary of symbols used within the section.

In a period of 15 years, the U.S.P. has gone from a book which included no statistical methodology dealing with biological products, to a book which from a legal point of view is an authority on how statistics are to be applied. Included in the section on "Design and Analysis of Biological Assays" is an official method for rejection of outlying or aberrant observations and the replacement of missing values. Likewise, the sections on the combination of independent assays and joint assay of several preparations are of great value to the industry. For the first time, a glossary of statistical symbols with official status is printed for all to use. The writer has a personal preference for a different set of symbols, but the benefits to be gained within the industry from a uniform set of symbols and formulas more than offset any personal feeling.

Beginning in U.S.P. XVI (53), a small section was added called "Biologics," which simply stated that for vaccines, antitoxins, etc., the National Institutes of Health, Division of Biological Standards, controlled the testing requirements and that the actual assay procedure was beyond the scope of the book.

Many methods are commonly used for computing the potency of biological products, some of which are defined adequately by the National Institutes of Health. However, there is a definite need for a specification of the statistical method of choice, regardless of the length of calculation, and very definite rules for the determination of assay validity, combination of independent assays, and joint assay of several preparations.

Bliss' section on the combination of independent assays states that: "additional animals can be added to an insufficiently precise assay until the combined results reduce the confidence interval within the lines specified in the monograph."

Since many biologics are assayed on the basis that the unknown is equal to or greater than the reference standard in potency, it is logical for a manufacturer to make the potency of the vaccine just potent enough to exceed the reference a certain percentage of the time. If the manufacturer performs 4 assays on the unknown and combines their results, which in reality doubles the precision of the assay, this then allows the manufacturer to produce a product whose potency tests greater than the reference about the same percentage of the time, but on a comparison basis does not have to be so excessively potent as material which is only controlled by a single assay.

If the Division of Biological Standards performs a single assay on material which has had multiple assays performed on it by a manufacturer, there is a high probability that the material will fail; hence, the lot is not suitable for distribution. If the Division of Biological Standards reference standard is to be a standard of potency to which a vaccine is to be equated, then the manufacturer should be allowed to use all available statistical methodology to warrant that the product is equal to or greater than the standard.

SUMMARY

Mathematical statistical methods have been found to be useful through all areas of quality control. Statistical sampling plans applied to dosage form variation, by their very controversial nature, have exposed large segments of the pharmaceutical industry to statistics. Analysis of variance, design of experiments, and hypothesis testing have not in themselves found extensive usage in quality control functions because of their research orientedness. Applications using these methods apply and are very effective when dealing with materials which are not routinely meeting their specifications or where specifications are in the process of being developed. Biological assays are now having increased attention paid to their problems, as witnessed by the U.S.P. sections dealing with biologicals.

Most statistical techniques are based on a measure of accuracy (the mean of a set of data) and a measure of variation (the standard deviation). With the advent of the food and drug law amendments of 1962, the increased emphasis on good manufacturing practice, the introduction of high-speed packaging lines, dosage form variation, glass bottle defects, missing bottle labels, and granulation characteristic variation, etc., the concept of statistical variation is no longer welcome to the quality control function. Statistical methodology says there will always be defects. Quality control says there must be zero defects.

The next 15 years will be interesting to see how well the statisticians can adapt themselves to problems implying sample sizes in the 500 to 10,000 range rather than 1 to 1,500.

The statistician and the quality control man must bear in mind the truism, "To attain quality, one must first measure it, and to measure quality, one must establish a standard of rejection." As Youden has pointed out, statistics are the laws of measurement. The new era for quality control statistics may well be in product design, control system design, or quality control simulation—all things to be done before the product is ever manufactured.

Effects of Potential Inhibitors on Metabolism of Griseofulvin *In Vitro*

By S. A. KAPLAN, S. RIEGELMAN, and K. H. LEE

The inhibitory effects of *p*-ethoxyacetanilide, *p*-methoxybenzylamine, codeine, and SK&F 525-A on the metabolism of griseofulvin were studied in a Krebs-Ringer bicarbonate liver-slice system. This investigation sought to determine the possibility of prolonging the biological activity of griseofulvin.

GRISEOFULVIN, the first available oral antifungal antibiotic, was originally isolated from the mycelium of *Penicillium griseofulvum* by Oxford in 1939 (1). However, it was not until 1958 that Gentles (2) reported that he was able to eradicate experimental ringworm of guinea pigs as a result of oral treatment with griseofulvin. This was followed by the works of Riehl (3, 4), Blank *et al.* (5), and Williams (6), who obtained favorable results in the treatment of superficial fungi infections of man.

Received August 13, 1965, from the School of Pharmacy, University of California, San Francisco Medical Center, San Francisco.
Accepted for publication September 15, 1965.
Abstracted in part from a thesis submitted by Stanley A. Kaplan to the Graduate Division, University of California, San Francisco Medical Center, in partial fulfillment of Doctor of Philosophy degree requirements.
This investigation was supported in part by grants AI 05241 and 5 TI GM 728 from the U. S. Public Health Service, Bethesda, Md.
The authors are grateful to Miss Darlene Tanneberg for technical assistance.

Effects of Potential Inhibitors on Metabolism of Griseofulvin *In Vitro*

By S. A. KAPLAN, S. RIEGELMAN, and K. H. LEE

The inhibitory effects of *p*-ethoxyacetanilide, *p*-methoxybenzylamine, codeine, and SK&F 525-A on the metabolism of griseofulvin were studied in a Krebs-Ringer bicarbonate liver-slice system. This investigation sought to determine the possibility of prolonging the biological activity of griseofulvin.

GRISEOFULVIN, the first available oral antifungal antibiotic, was originally isolated from the mycelium of *Penicillium griseofulvum* by Oxford in 1939 (1). However, it was not until 1958 that Gentles (2) reported that he was able to eradicate experimental ringworm of guinea pigs as a result of oral treatment with griseofulvin. This was followed by the works of Riehl (3, 4), Blank *et al.* (5), and Williams (6), who obtained favorable results in the treatment of superficial fungi infections of man.

Received August 13, 1965, from the School of Pharmacy, University of California, San Francisco Medical Center, San Francisco.
Accepted for publication September 15, 1965.
Abstracted in part from a thesis submitted by Stanley A. Kaplan to the Graduate Division, University of California, San Francisco Medical Center, in partial fulfillment of Doctor of Philosophy degree requirements.
This investigation was supported in part by grants AI 05241 and 5 TI GM 728 from the U. S. Public Health Service, Bethesda, Md.
The authors are grateful to Miss Darlene Tanneberg for technical assistance.

It has been shown that griseofulvin localizes in the prekeratin cells (7–9), and that the amount of griseofulvin deposited in the prekeratin cells depends upon the blood levels achieved. Therefore, in treatment it is important that the drug be deposited in the keratin of the hair shaft, skin, or matrix of the nails in fungistatic concentration to keep the organism in check pending removal of the infected tissue and replacement by healthy tissue. Since the turnover rate of these tissues is slow, oral therapy can involve periods of treatment up to 6 months or longer.

The high-dosage regimen required for griseofulvin to exert its therapeutic effect can be attributed to its low water solubility of approximately 1 mg. %, its slow rate solubility, and its relatively rapid rate of metabolism. It is difficult, therefore, to maintain a prolonged high concentration of drug in the blood.

Generally, the duration of drug action after absorption depends upon the rate of metabolism and excretion. Griseofulvin is unique in that it is not excreted intact but apparently only after being metabolized. Barnes *et al.* (10) reported that the major metabolite of griseofulvin in man and rabbits is 6-demethylgriseofulvin. *In vitro* studies by Bedford *et al.* (11) also confirm that griseofulvin is metabolized by the liver and results in the formation of 6-demethylgriseofulvin. Aromatic ethers are known to be metabolized by *O*-dealkylation (12). The authors have chosen several potential inhibitors of griseofulvin. These include *p*-ethoxyacetanilide, *p*-methoxybenzylamine, codeine, and SK&F 525-A. The first three mentioned compounds are aromatic ethers metabolized by oxidative *O*-dealkylation as is griseofulvin, and could therefore act in a competitive manner to inhibit the metabolism of griseofulvin and thereby prolong its biological activity. SK&F 525-A is a well-known nonspecific metabolic inhibitor in animals and affects many *O*-dealkylation reactions.

EXPERIMENTAL

Tissue Preparations.—Livers were obtained from young adult New Zealand white male rabbits of 2.0 to 2.5 Kg. The rabbits were stunned and exsanguinated, and the slices were prepared on a McIlwain mechanical tissue chopper (13) at a thickness of approximately 0.5 mm. at 3° in the cold room. Thirty-milliliter samples containing 10 mcg./ml. griseofulvin in Krebs-Ringer bicarbonate buffer (14) were incubated with 1.5 Gm. of liver slices, with and without the addition of the potential inhibitors at 37°, with shaking under an atmosphere of 5% carbon dioxide in oxygen saturated with water vapor. These samples were incubated for varying time intervals, after which the flasks were removed from the incubator, and supernatants were separated from the tissue slices by decanting. An aliquot of the supernatant was then immediately extracted twice with ethyl ether, evaporated, and reconstituted in ethanol. The griseofulvin was determined by both the spectrophotometric and spectrophotofluorometric methods of analysis. In the ultraviolet the samples were determined in ethanol at 292 mμ, while in the spectrophotofluorometric analysis the samples were activated at 315 mμ, and the maximum fluorescence determined at 450 mμ. SK&F 525-A did not interfere with the ultraviolet analysis of griseofulvin and the samples could be determined directly. However, codeine, *p*-ethoxyacetanilide, and *p*-methoxybenzylamine interfered with the ultraviolet analysis of griseofulvin as they were partially extracted by the ethyl ether along with the griseofulvin. Codeine and *p*-methoxybenzylamine were completely removed by washing the ether extracts with two 25-ml. portions of 1 *N* hydrochloric acid, allowing for the direct ultraviolet analysis of griseofulvin. *p*-Ethoxyacetanilide could not be separated from griseofulvin by extraction and was therefore analyzed by the spectrophotofluorometric method.

Microsomal Preparations.—Twenty-five per cent homogenates of liver were prepared in 1.15% potassium chloride solution by use of a Dounce homogenizer (15) in the cold room at 3°. The tissues were homogenized first with the loose-, then the tight-fitting pestle, and centrifuged at 9000 × *g* for 20 min. The supernatants were decanted and used in the subsequent experiments where each 5.1-ml. sample contained glucose-6-phosphate, 20 μm.; NADP, 0.4 μm.; nicotinamide, 50 μm.; magnesium chloride, 75 μm.; potassium chloride, 1 *M*, 0.1 ml.; griseofulvin in 0.1 *M* phosphate buffer or buffer alone, 1.5 ml.; and enzyme preparation, 1.5 ml. The above samples were incubated at 37° with shaking (110 oscillations per minute) in a Dubnoff metabolic shaker for varying time intervals at which time 2.0-ml. aliquots were removed from the flasks and added to 7.0 ml. of freshly distilled anhydrous ether and analyzed by means of the spectrophotofluorometric assay. The co-factors did not interfere with the analysis of griseofulvin on the Aminco Bowman spectrophotofluorometer.

Standardization of the Microsomal Activity.—*p*-Ethoxyacetanilide has been shown to be metabolized by the microsomal enzyme fraction (12). Therefore, with each determination samples containing *p*-ethoxyacetanilide without the addition of griseofulvin were run to determine the relative activity of the enzyme preparation.

Analysis of 6-Demethylgriseofulvin.—This compound is characterized by its ultraviolet spectrum which has a maximum peak at 293 mμ in acidic ethanolic solution, which shifts to 328 mμ in neutral to alkaline solution. 6-Demethylgriseofulvin is recoverable by extracting the acidified supernatant (pH 1) after removal of the griseofulvin, with two 25-ml. portions of ethyl ether. Other supernatant samples after removal of the griseofulvin were divided into two equal portions. One portion was analyzed for 6-demethylgriseofulvin as described above. The other portion was acidified to pH 4.5 with acetic acid, and incubated with β-glucuronidase at 37°. This system was then extracted as described to determine the amount of free 6-demethylgriseofulvin present in solution.

RESULTS AND DISCUSSION

The per cent of griseofulvin remaining unmetabolized in solution as a result of being incubated with

the Krebs-Ringer bicarbonate rabbit liver slice system has been calculated from 17 individual experiments. The metabolism of griseofulvin appears to follow pseudo first-order kinetics as is determined from the linearity of the semilogarithmic plot seen in Fig. 1. The half-life for the disappearance of griseofulvin has been calculated by the method of least squares to be 53.5 ± 3.8 min. (p = 0.025). Since the metabolism of griseofulvin in this system occurs within defined limits, a control was established to which the inhibitory studies with the potential inhibitors could be compared.

In each of the following experiments rabbit liver slices were incubated with and without the addition of a 100 to 1 molar ratio of inhibitor to griseofulvin. The experiments were repeated at three different levels of griseofulvin concentration, but the system is limited by the low solubility of griseofulvin in water. Figure 2 includes three curves, each of which is from the mean data of a minimum of four experiments and illustrates the pseudo first-order metabolism of griseofulvin and p-methoxybenzylamine with griseofulvin. Figure 3 shows similar experiments utilizing codeine as the potential inhibitor. The compound, SK&F 525-A, is not added to the *in vitro* system but is administered prior to sacrifice and preparation of liver slices. Figure 4 shows the results obtained from animals pretreated 2 hr. prior to sacrifice with 75 mg./Kg. of SK&F 525-A as compared to control animals.

The results indicate that at a molar ratio of 100 to 1, p-ethoxyacetanilide to griseofulvin, the rate of metabolism of griseofulvin is decreased approximately fourfold to give a half-life of 200.6 ± 9.2 min., indicating the rate of metabolism is significantly different in the presence of p-ethoxyacetanilide ($p < 0.01$). p-Methoxybenzylamine decreased the rate of metabolism approximately twofold to 116.5 ± 8.8 min., again indicating a significant difference in the rate of metabolism ($p < 0.001$), codeine with a half-life of 57.4 min. ($p > 0.60$), and SK & F 525-A with a mean half-life of 49.6 min. ($p > 0.80$) showed no inhibitory effects on the metabolism of griseofulvin.

In studying the metabolism of griseofulvin it has been inferred that the metabolism of the drug probably occurs in the microsomal enzyme fraction of the liver. The results in Table I clearly indicate that the microsomal enzymes in the presence of the co-factors of the soluble fraction are responsible for the metabolism of griseofulvin.

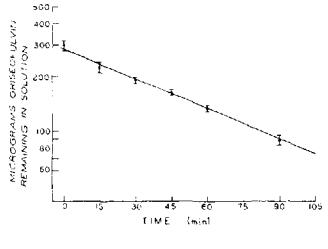

Fig. 1.—Disappearance of griseofulvin from the Krebs-Ringer bicarbonate liver-slice system reported with the 95% confidence intervals.

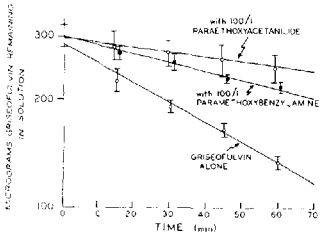

Fig. 2.—Disappearance of griseofulvin in the presence of a 100 M ratio of p-ethoxyacetanilide or p-methoxybenzylamine to griseofulvin with its 95% confidence interval.

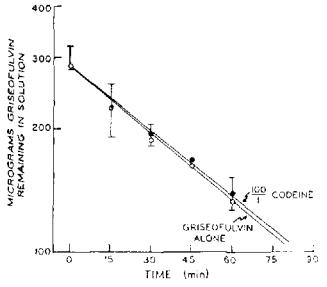

Fig. 3.—Disappearance of griseofulvin in the presence of a 100 M ratio of codeine phosphate to griseofulvin with its 95% confidence interval.

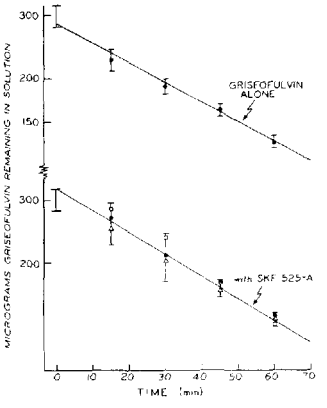

Fig. 4.—Disappearance of griseofulvin as a result of incubating the drug with liver slices pretreated with 75 mg./Kg. of SKF 525-A, reported with its 95% confidence intervals, as compared to that of griseofulvin alone.

TABLE I.—METABOLISM OF GRISEOFULVIN IN THE MICROSOMAL ENZYME SYSTEM

Expt.	Half-Life of Metabolism, min.
1	57.5
2	50.3
3	101.4
4	40.35
5	40.25
6[a]	44.0
7[a]	30.9

[a] Animals starved prior to experimentation.

The results indicate the mean half-lives of experiments *1* through *5* to be 57.9 ± 39.7 min. (p = 0.025).

Starvation is known to lower glycogen levels markedly. Therefore, rabbits were starved for 24 and 38 hr. prior to sacrifice and preparation of the microsomal and soluble fractions of the liver. When the metabolism of griseofulvin was followed as a result of incubation with these glycogen-depleted microsomal enzymes, the results in Table I indicate that starvation did not interfere with or affect the ability of the microsomal enzymes to metabolize griseofulvin. A comparison of the results of the metabolism studies of griseofulvin, to those previously reported by Axelrod for p-ethoxyacetanilide (12) are recorded in Table II.

TABLE II.—COMPARISON OF RESULTS OF METABOLISM STUDIES OF GRISEOFULVIN

	Griseofulvin	*p*-Ethoxyacetanilide
Metabolized by the microsomal system	+	+
Inhibited by SK&F 525–A	−	−
Inhibited by *p*-methoxybenzylamine	+	+
Inhibited by codeine	−	−
Inhibited by *p*-ethoxyacetanilide	+	

Based on the criteria established by Axelrod for differentiating between the two possible *O*-dealkylating enzyme systems, it would appear that griseofulvin is metabolized by the same enzymes that metabolize *p*-ethoxyacetanilide and *p*-methoxybenzylamine rather than by the *O*-dealkylating enzyme system shown to metabolize codeine.

In both the liver slice and the microsomal studies the disappearance of griseofulvin was compared to the appearance of 6-demethylgriseofulvin. Table III presents an analysis of the total recovery of griseofulvin and 6-demethylgriseofulvin.

TABLE III.—PER CENT RECOVERY OF THE TOTAL DOSE OF GRISEOFULVIN AS GRISEOFULVIN AND 6-DEMETHYLGRISEOFULVIN

Time of Incubation, min.[a]	% Recovered as Griseofulvin	% Recovered as 6-Demethylgriseofulvin	Total % Recovery
0	100	0	80.0
15	75.0	2.16	77.16
30	62.7	15.1	77.8
45	54.6	17.4	72.0
60	44.4	31.9	76.3
75	40.0	33.0	73.0

[a] Extrapolated zero-time value.

In no instance was there a material balance since only 75.3 ± 3.8% of the original dose of griseofulvin could be accounted for. The remainder of the dose was sought as a possible glucuronide conjugate of 6-demethylgriseofulvin which would not be extracted prior to hydrolysis. Supernatants were incubated with β-glucuronidase to determine the possibility of glucuronide conjugation.

No real increase in free 6-demethylgriseofulvin was noted as compared to samples which had not been incubated with β-glucuronidase. These results would tend to indicate that 6-demethylgriseofulvin does not form a glucuronide in the rabbit.

It is possible that the glucuronide conjugate does not form due to properties inherent in the 6-demethylgriseofulvin molecule since the 6 pKa has been found to be 4.3. The accepted mechanism for glucuronide conjugation has been postulated as follows (16, 17):

uridine diphosphoglucuronic acid + R − OH

$$\xrightarrow{\text{Walden inversion}} \text{glucuronosyl} - \text{OR} + \text{uridine diphosphate}$$

If this were to occur with 6-demethylgriseofulvin in the body at a pH of 7.3, the metabolite would be in the form of a phenolate anion.

The Walden inversion is a S_N2 displacement reaction. The nucleophile in a S_N2 reaction attacks by using a pair of its own electrons. Therefore, the most effective nucleophile would be one whose attacking atom has the valence electrons most available for coordination. Since this is the criterion for basic strength, it would be reasonable to assume that the strongest base might make the most effective nucleophilic reagent. The phenolate anion is known to be a nucleophilic reagent with reasonable activity. However, basic strength, resonance characteristics, and steric effects may interfere with the relative nucleophilicity of an agent. Perhaps, owing to some adverse nucleophilic properties of 6-demethylgriseofulvin, it might be possible for the metabolite to form a glucuronide conjugate on a purely mechanistic basis.

Dodgson and co-workers (18) have suggested that the ability of a hydroxyl compound to form an ethereal sulfate may depend on its ionization constant. A survey of phenols which are known to conjugate with sulfate has shown that the pKa's of the hydroxyl groups varied from 7 to 10. Anderton *et al.* (19) compared the amount of ethereal sulfate produced with the pKa of the hydroxyl group for a number of compounds. They concluded that the hydroxyl group must have a pKa between 7 and 10 in order to be able to form an ethereal sulfate. Since the pKa of 6-demethylgriseofulvin is 4.3, this factor alone might disqualify possible sulfate conjugation.

It is clear from the above that an explanation for the lack of a material balance cannot be accounted for by presuming conversion of the metabolite to conjugates such as glucuronide or sulfate, and the possibility of the formation of a second metabolite is being investigated.

Further reports will follow on studies of the effect of varying concentration of *p*-ethoxyacetanilide and *p*-methoxybenzylamine to that of griseofulvin and of *in vivo* effects of these inhibitors.

SUMMARY

1. The metabolism of griseofulvin has been demonstrated *in vitro*, using rabbit liver slices respiring in a Krebs-Ringer bicarbonate buffer medium. The metabolism appears to follow pseudo first-order kinetics with a half-life of 53 min.

2. Griseofulvin has been shown to be metabolized also by the microsomal enzymes of the liver in the presence of the co-factors of the soluble reaction, and the metabolism is independent of the glycogen content of the liver.

3. The *in vitro* inhibition of griseofulvin metabolism by *p*-ethoxyacetanilide and *p*-methoxybenzylamine is reported. Evidence is presented for the microsomal enzyme fraction responsible for the *O*-demethylation of griseofulvin.

4. The metabolite, 6-demethylgriseofulvin, as the free phenol has been isolated and quantitated. A glucuronide conjugate has not been found, and reasons for this lack of conjugation are presented.

Interaction of 8-Hydroxyquinoline Sulfate with Components Present in a Tuberculin PPD Solution I

Binding of 8-Hydroxyquinoline by Polysorbate 80

By S. LANDI and H. R. HELD

This article deals with the interaction between the preservative 8-hydroxyquinoline sulfate (8-HQS) and the surface-active agent polysorbate 80. In buffered solution (pH 7.38) 8-HQS is dissociated to 8-hydroxyquinoline (8-HQ) and H_2SO_4, and it is the base 8-HQ that forms a reversible association with polysorbate 80. The degree of binding of 8-HQ to polysorbate 80 was shown to be a function of the concentration of the nonionic surface-active agent. Polysorbate 80 at low concentration (about 0.005 per cent) has practically no effect on the concentration of 8-HQ in a buffered solution (pH 7.38) as used for preparing dilutions of tuberculin PPD for the intracutaneous method (Mantoux test). 8-HQS, in a buffered solution of pH 3, does not interact with polysorbate 80.

8-HYDROXYQUINOLINE sulfate (8-HQS)[1] is added to tuberculin PPD solutions as an antimicrobial agent. In a previous report (1) the authors described how 8-HQS disappears from these solutions when dispensed in glass vials stoppered with rubber closures and showed that most of the loss of 8-HQS from the solution was caused by sorption of 8-HQ by the rubber closures.

Numerous investigators have shown, by using solubility studies and equilibrium dialysis, that binding of preservatives (3–9) or pharmaceuticals (10–14) with polysorbate 80[2] or other macromolecules takes place.

Tuberculin PPD solutions are used intracutaneously for diagnostic purposes in tuberculosis-prevention programs. Such solutions contain 0.01% 8-HQS added as a preservative and 0.005% polysorbate 80 as a stabilizing agent (2). It was, therefore, of interest to find out if some binding between 8-HQS and polysorbate 80 takes place in the buffer used to prepare these solutions.

The solubility method (3) and the equilibrium dialysis method (3) were used by the authors to determine the compatibility of polysorbate 80 and 8-HQS.

Received September 8, 1965, from the Connaught Medical Research Laboratories, University of Toronto, Toronto, Ontario, Canada.
Accepted for publication October 19, 1965.

MATERIALS AND METHODS

Reagents.—8-Hydroxyquinoline sulfate (8-HQS)[1] (Eastman Organic Chemicals, 1776), 8-hydroxyquinoline (8-HQ) (Fisher Scientific Co., 0-261), polysorbate 80 (polyoxyethylene 20 sorbitan monooleate).[2]

Buffer Solution (pH 7.38).—Isotonic phosphate buffered solution (2), pH 7.38 (1.45 Gm. of KH_2PO_4, 7.60 Gm. of Na_2HPO_4, and 4.8 Gm. of NaCl in 1050 ml.). This buffer is also used as diluent for the preparation of tuberculin PPD solutions (Mantoux).

Buffer Solution (pH 3.0).—McIlvaine's buffered solution (15) was prepared by mixing 79.5 ml. of 0.1 *M* citric acid solution and 20.5 ml. of 0.2 *M* Na_2HPO_4 solution.

Dialysis Membranes.—Thin nylon membrane,[3] as recommended by Patel and Kostenbauder (3), was used for dialysis of 8-HQ. A seamless regenerated cellulose tubing, size identity 36/32 (obtained from the Visking Division of Union Carbide, Canada, Ltd.) was used for the dialysis of 8-HQS and of 8-HQ.

Determination of 8-HQ and 8-HQS.—8-HQS, dissolved in buffered solution (pH 7.38), is dissociated in 8-HQ and H_2SO_4. The distinct absorption maximum of 8-HQ in the ultraviolet region at 240 mμ lends itself well to the quantitative deter-

Interaction of 8-Hydroxyquinoline Sulfate with Components Present in a Tuberculin PPD Solution I

Binding of 8-Hydroxyquinoline by Polysorbate 80

By S. LANDI and H. R. HELD

This article deals with the interaction between the preservative 8-hydroxyquinoline sulfate (8-HQS) and the surface-active agent polysorbate 80. In buffered solution (pH 7.38) 8-HQS is dissociated to 8-hydroxyquinoline (8-HQ) and H_2SO_4, and it is the base 8-HQ that forms a reversible association with polysorbate 80. The degree of binding of 8-HQ to polysorbate 80 was shown to be a function of the concentration of the nonionic surface-active agent. Polysorbate 80 at low concentration (about 0.005 per cent) has practically no effect on the concentration of 8-HQ in a buffered solution (pH 7.38) as used for preparing dilutions of tuberculin PPD for the intracutaneous method (Mantoux test). 8-HQS, in a buffered solution of pH 3, does not interact with polysorbate 80.

8-HYDROXYQUINOLINE sulfate (8-HQS)[1] is added to tuberculin PPD solutions as an antimicrobial agent. In a previous report (1) the authors described how 8-HQS disappears from these solutions when dispensed in glass vials stoppered with rubber closures and showed that most of the loss of 8-HQS from the solution was caused by sorption of 8-HQ by the rubber closures.

Numerous investigators have shown, by using solubility studies and equilibrium dialysis, that binding of preservatives (3–9) or pharmaceuticals (10–14) with polysorbate 80[2] or other macromolecules takes place.

Tuberculin PPD solutions are used intracutaneously for diagnostic purposes in tuberculosis-prevention programs. Such solutions contain 0.01% 8-HQS added as a preservative and 0.005% polysorbate 80 as a stabilizing agent (2). It was, therefore, of interest to find out if some binding between 8-HQS and polysorbate 80 takes place in the buffer used to prepare these solutions.

The solubility method (3) and the equilibrium dialysis method (3) were used by the authors to determine the compatibility of polysorbate 80 and 8-HQS.

Received September 8, 1965, from the Connaught Medical Research Laboratories, University of Toronto, Toronto, Ontario, Canada.
Accepted for publication October 19, 1965.

MATERIALS AND METHODS

Reagents.—8-Hydroxyquinoline sulfate (8-HQS)[1] (Eastman Organic Chemicals, 1776), 8-hydroxyquinoline (8-HQ) (Fisher Scientific Co., 0-261), polysorbate 80 (polyoxyethylene 20 sorbitan monooleate).[2]

Buffer Solution (pH 7.38).—Isotonic phosphate buffered solution (2), pH 7.38 (1.45 Gm. of KH_2PO_4, 7.60 Gm. of Na_2HPO_4, and 4.8 Gm. of NaCl in 1050 ml.). This buffer is also used as diluent for the preparation of tuberculin PPD solutions (Mantoux).

Buffer Solution (pH 3.0).—McIlvaine's buffered solution (15) was prepared by mixing 79.5 ml. of 0.1 *M* citric acid solution and 20.5 ml. of 0.2 *M* Na_2HPO_4 solution.

Dialysis Membranes.—Thin nylon membrane,[3] as recommended by Patel and Kostenbauder (3), was used for dialysis of 8-HQ. A seamless regenerated cellulose tubing, size identity 36/32 (obtained from the Visking Division of Union Carbide, Canada, Ltd.) was used for the dialysis of 8-HQS and of 8-HQ.

Determination of 8-HQ and 8-HQS.—8-HQS, dissolved in buffered solution (pH 7.38), is dissociated in 8-HQ and H_2SO_4. The distinct absorption maximum of 8-HQ in the ultraviolet region at 240 mμ lends itself well to the quantitative deter-

[3] Supplied through the courtesy of Youngs Rubber Corp., New York, N. Y.

mination of 8-HQ and herewith to the determination of 8-HQS. The 8-HQS concentration of a solution was determined by measuring its absorbance at 240 mμ after dilution with buffer of pH 7.38, containing 0.005% polysorbate 80 and comparing it with the absorbance at the same wavelength of a standard solution. This method was described previously (1).

The H_2SO_4 liberated from 8-HQS was determined by precipitation and weighing as $BaSO_4$.

Determination of Polysorbate 80.—Polysorbate 80 shows an absorption maximum in the ultraviolet region at 230 mμ. The degree of absorption is too weak to be used for very low concentrations of polysorbate 80 or for higher concentrations of polysorbate 80 in the presence of strong U.V. absorbers like phenolic preservatives, etc. However, for pure aqueous solutions of polysorbate 80, this absorption at 230 mμ can be conveniently used for its determination. The authors determined the polysorbate 80 content by diluting 1 ml. of a pure aqueous solution of polysorbate 80 with 19 ml. of a buffered solution (pH 7.38), and comparing its absorbance at 230 mμ with the absorbance at the same wavelength of a standard solution of polysorbate 80.

Solubility Method.—The solubility of 8-HQS or 8-HQ in polysorbate 80 solutions was evaluated by placing into glass-stoppered weighing bottles 10 ml. of buffered solution containing various amounts of polysorbate 80 and an excess of either 8-HQS (200 mg. of a mixture, consisting of equivalent amounts of 8-HQS and $NaHCO_3$) or of 8-HQ (140 mg.). The bottles were agitated for 3 hr. at 28° then the contents were filtered through Whatman No. 1 filter paper and the 8-HQS or 8-HQ in solution determined spectrophotometrically.

Dialysis Method at pH 7.38.—The dialysis membrane was used in the form of small nylon bags. Into each bag was placed 10 ml. of a buffered solution containing different concentrations of polysorbate 80. Each nylon bag was then placed in a glass-stoppered weighing bottle, containing 10 ml. of buffered solution and 200 mg. of a mixture consisting of equivalent amounts of 8-HQS and $NaHCO_3$. In another experiment the weighing bottles contained 10 ml. of a 0.02% solution of 8-HQS in the same buffer. Each bottle was then stoppered tightly while the end of the nylon bag was protruding to the outside of the bottle, thus providing also a tight closure for the nylon bag. The bottles were then agitated for 4 days at 28°. After this period of time, an equilibrium between the inner and outer solution was reached for each concentration of polysorbate 80 employed, and samples were taken from the inside and outside of the nylon bags to determine the concentration of 8-HQ.

The same type of dialysis as described above was carried out for 2 days using a seamless cellulose tubing instead of the nylon bags.

Dialysis Method at pH 3.—Similar experiments as described were carried out in a solution of approximately pH 3 using as dialysis membrane a seamless cellulose tubing. Into each tubing was placed 10 ml. of an aqueous solution of different concentrations of polysorbate 80. The glass-stoppered weighing bottles contained in one experiment 10 ml. of a 0.2% solution of 8-HQS in H_2O (final pH 3.2), and in another experiment the weighing bottles contained 10 ml. of a 0.02% solution of 8-HQS in buffer (pH 3.0). The bottles were agitated for 2 days at 28°.

RESULTS AND DISCUSSION

Interaction between Polysorbate 80 and 8-HQ at pH 7.38.—When 8-HQS is dissolved in buffered solution (pH 7.38), it is dissociated in 8-HQ and H_2SO_4. This is evidenced from the fact that 8-HQ can be completely extracted with diethylether from this buffered solution into which 8-HQS was added. Further evidence that 8-HQ is present in a buffered solution (pH 7.38) was obtained in a previous article (1), where it was shown that rubber absorbed 8-HQ only while the H_2SO_4 remains entirely in the aqueous solution. Dialysis experiments to be described will show that it is 8-HQ that interacts with polysorbate 80 and not 8-HQS. Nevertheless, since in the literature dealing with tuberculin the concentration of this preservative is given as percentage of 8-HQS, the authors have in the present investigation expressed all measurements in 8-HQS equivalents.

Figure 1 shows that the solubility of 8-HQS or 8-HQ increases linearly with increasing polysorbate 80

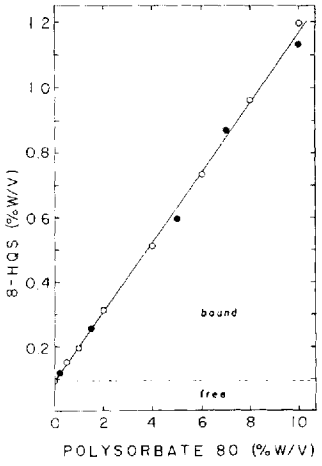

Fig. 1.—Solubility of 8-HQS and of 8-HQ in a buffered solution (pH 7.38, temperature 28°) containing various amounts of polysorbate 80. Key: ○, solubility of 8-HQS; ●, solubility of 8-HQ, plotted in 8-HQS-equivalents.

concentration, and when the solubility of 8-HQ is expressed in 8-HQS equivalents the same slope is obtained for both substances. Because the solubility of free preservative in a buffered solution is constant, as represented by a dashed line in Fig. 1, the increase in solubility of the preservative with increasing polysorbate 80 concentration can be considered to be due to bound preservative. This binding represents a relatively high degree of interaction. Such interaction between polysorbate 80 and other preservatives had been reported previously by several investigators (3–9).

To obtain further evidence of binding between polysorbate 80 and 8-HQ and to obtain data of binding between polysorbate 80 and low concentrations of 8-HQ, the equilibrium dialysis method (3) was used. Figures 2 and 3 show that when the concentration of polysorbate 80 in a buffered solution con-

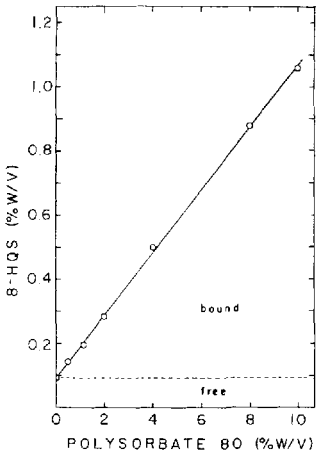

Fig. 2.—Equilibrium dialysis through a nylon bag. Outside the bag was placed a buffered solution (pH 7.38) to which an excess of solid 8-HQS and $NaHCO_3$ was added. Inside the bag was placed a buffered solution (pH 7.38), containing various amounts of polysorbate 80. The total 8-HQ concentration in the dialysis bag is plotted in 8-HQS equivalents *vs.* the polysorbate 80 concentration.

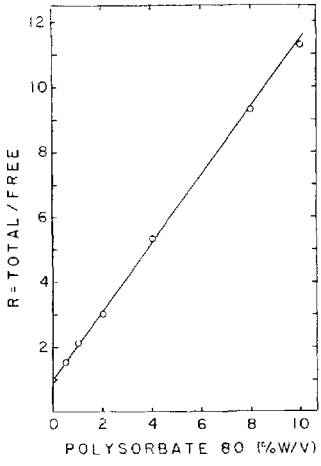

Fig. 3.—Equilibrium dialysis through a nylon bag as in Fig. 2. The binding of 8-HQ (expressed as the ratio R = total/free) is plotted *vs.* the polysorbate 80 concentration.

tained in the nylon bag is increased from 0 to 10% the total concentration of 8-HQ in this solution increases linearly from 0.094 to 1.06%. In this experiment an excess of solid 8-HQS and $NaHCO_3$ was added to the solution outside the dialysis bag. Since at equilibrium the concentration of free preservative is assumed to be approximately the same inside and outside the dialysis bag (12), the increase of 8-HQ with increasing polysorbate 80 concentration (represented by the area above the dashed line in Fig. 2) must correspond very closely to the degree of interaction between polysorbate 80 and 8-HQ. The authors designated this increase in 8-HQ "*bound 8-HQ.*" To test the reversibility of this interaction the contents of the bags were dialyzed against running tap water, and it was found that all 8-HQ (free plus bound) dialyzed out of the bags in approximately 10 days. This shows that the "bound 8-HQ" was reversibly associated to the polysorbate 80.

Figure 2 confirms the results of solubility studies (Fig. 1) and also shows that the concentration of free 8-HQ is independent of the polysorbate 80 concentration when enough preservative is present to form a 8-HQ saturated solution. The free 8-HQ is represented by a dashed line in Figs. 1 and 2. It follows that the ratio between total 8-HQ (bound plus free) and free 8-HQ also increases linearly with increasing polysorbate 80 concentration (Fig. 3). This linearity facilitates the calculation of this ratio for any other concentration of polysorbate 80. Therefore, the results in Table I reveal that, when a concentration of 0.005% polysorbate 80 is present in a buffered solution containing an added amount of 0.094 to 1.06% total 8-HQS, there should be approximately 99.5% of free 8-HQ present. Thus, the loss of free 8-HQS caused by the interaction of 8-HQ with polysorbate 80 should be approximately 0.5%. In order to verify these results for lower concentrations of total 8-HQS (0.0096 to 0.0181%), the dialysis method (3) was also employed by using a concentration of 0.02% 8-HQS in the solution outside the nylon bag. Table II shows that the ratios between total and free 8-HQS are of the same order as those measured for more concentrated solutions of 8-HQS (0.094 to 1.06%, Table I), and that the loss of free 8-HQS caused by the presence of 0.005% polysorbate 80 should also be approximately 0.5%. Therefore, it is obvious that the reversible interaction between 0.005% polysorbate 80 and the 8-HQ liberated from 0.01% 8-HQS, in the buffer solution, as used for the preparation of tuberculin PPD solutions (2, 16), will have practically no effect on the concentration of free 8-HQ and presumably on its antimicrobial activity. That tuberculin PPD solutions containing these concentrations of polysorbate 80 and 8-HQS exhibit antimicrobial activity has been recently demonstrated by Pivnick *et al.* (17).

Further evidence that 8-HQ, and not 8-HQS, interacts with polysorbate 80 was obtained by using a cellulose instead of a nylon membrane. While 8-HQ dialyzed readily through the nylon membrane and reached equilibrium after 4 days, only traces of H_2SO_4 liberated from 8-HQS had passed through the nylon membrane (0.002% w/v inside as compared to 0.35% w/v outside the bag, Table I). It was further ascertained that sulfates like 8-HQS or Na_2SO_4 in buffered solution (pH 7.38) dialyze very slowly, if at all, through a nylon membrane. However, the seamless cellulose tubing was found to be readily permeable to 8-HQ as well as to 8-HQS and Na_2SO_4. Although the cellulose tubing was found to be to some extent permeable to polysorbate 80 (3), as in the case of the nylon membrane, most of the polysorbate 80 was kept inside the bag after 2 days, dialysis. However, considerable water was drawn inside the cellulose tubing from the outside solution changing the concentration of polysorbate 80. For this reason all the concentrations inside (C_i) and outside (C_0) the cellulose tubing were determined after equilibrium was reached. In fact, Table III shows that the binding of 8-HQ by polysorbate 80 is of the same order as previously determined using a

nylon membrane. Example: 10% w/v polysorbate 80, binding of 8-HQ 11.28 (Table I) and 11.30 (Table III); 0.005% w/v polysorbate 80, binding of 8-HQ 1.0052 (Table I) and 1.005 (Table III). Furthermore, when the cellulose tubing was used the final concentration of H_2SO_4 (liberated from 8-HQS) becomes equal on both sides of the dialysis membrane for all the concentrations of polysorbate 80 employed (Table III). This indicates that only 8-HQ and not 8-HQS interacts with polysorbate 80 because, if an appreciable amount of 8-HQS was present at pH 7.38 and did interact with polysorbate 80, the ratio $C_i/C_0 = 1$ of H_2SO_4 (Table III) would become numerically higher than 1.

Interaction between Polysorbate 80 and 8-HQS at pH 3.—Although a diluent at this pH is not used for the preparation of tuberculin PPD solutions, it is, nevertheless, useful to describe briefly the results of a study of a possible interaction between polysorbate 80 and 8-HQS at pH 3. It might con-

tribute to the understanding of the basic mechanism between these two substances in the buffer (pH 7.38) previously employed.

8-HQS, dissolved in buffered solution (pH 3), shows no noticeable dissociation. This was evidenced from the fact that 8-HQ cannot be extracted with diethylether from 8-HQS in solution at pH 3 and that, in contrast to what was found previously using a buffered solution (pH 7.38), pure rubber does not absorb 8-HQ from 8-HQS in a buffered solution (pH 3).

Figure 4 shows the result of an equilibrium dialysis experiment in which seamless cellulose tubing

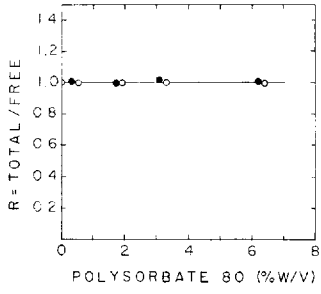

Fig. 4.—Equilibrium dialysis of 8-HQS through seamless cellulose tubing at pH 3. No interaction was detected. Key: O, 0.2% 8-HQS dissolved in H_2O was placed outside the dialysis tubing; ●, 0.02% 8-HQS dissolved in buffered solution (pH 3.0) was placed outside the dialysis tubing.

was used as a dialysis membrane. The ratios of the 8-HQS concentrations inside (C_i) and outside (C_0) of the tubing were plotted *versus* the polysorbate 80 concentration at equilibrium. The final polysorbate 80 concentrations were determined separately by ultraviolet spectrophotometry. The horizontal line (Fig. 4) indicates that there is no interaction between polysorbate 80 and 8-HQS at pH 3.

Interaction of 8-HQ with Other Macromolecules.—The interaction of 8-HQ liberated from 8-HQS with other macromolecules (tuberculoprotein, nucleic acid, and polysaccharide) present in tuberculin PPD solutions is now under investigation and will be reported subsequently.

SUMMARY

1. The interaction of 8-HQS with polysorbate 80 in buffered solutions of pH 7.38 and of pH 3.0 have been studied by means of the solubility method and the equilibrium dialysis method.

2. 8-HQS dissolved in buffered solution (pH 7.38) is dissociated in 8-HQ and H_2SO_4, and it is the base 8-HQ which interacts with polysorbate 80.

3. The degree of binding of 8-HQ by polysorbate 80, expressed as the ratio of total to free 8-HQ, increases linearly with increasing concentration of polysorbate 80.

4. The degree of binding of 8-HQ by polysorbate 80 is the same, regardless of whether 8-HQS or 8-HQ is added to a buffered solution (pH 7.38) containing polysorbate 80.

5. A relatively high degree of interaction has been observed for polysorbate 80 concentrations of 1 to 10%. However, when polysorbate 80 is added at the concentration of 0.005%, as used in tuberculin PPD dilutions for the Mantoux test, practically all 8-HQ (approximately 99.5%) is still present in the free state.

6. The association between 8-HQ and polysorbate 80 is reversible.

7. 8-HQS in a buffered solution of pH 3 does not interact with polysorbate 80.

Surfactant–Base–Barbiturate Suppositories I

Rectal Absorption in Rabbits

By J. H. FINCHER, D. N. ENTREKIN, and C. W. HARTMAN

A series of petrolatum–paraffin–surfactant suppository bases were tested in rabbits under carefully controlled conditions with a series of barbiturates included. Each surfactant had a different HLB value and each barbiturate had a different distribution coefficient. The depression of the respiratory rate was measured for a period of 2.5 hr. to determine absorption rates. A comparative analysis of the data is presented. The effects of the chemical type of the drug and the surfactant are shown in the comparative studies. Surfactants enhanced the release and absorption of the barbiturate in some bases; however, binding of the drug is suspected in some bases. The relationships of the HLB of the surfactant and the distribution coefficient of the drug to release and absorption are presented. Further work, using different approaches to this problem, is indicated.

THE PRIMARY purpose of this work was to investigate the relationship of some of the physicochemical properties of the drug and the base on the efficacy of base–drug suppository formulations *in vivo*.

The hydrophile–lipophile balance (HLB), as a system of classifying and evaluating surfactants, was proposed and expanded by Griffin (1, 2). The effect of this property has been studied *in vitro* by Spittle and Hartman (3) and Rhyne *et al.* (4). Base composition has been long recognized as having an influence on the therapeutic activity of base–drug combinations (5–9). Emulsification of the base has been shown to effect drug release by many researchers (10–19). Others have shown that the chemical type of the ingredients in a formulation influences the desired clinical response (1, 2, 20). Other factors that have been considered are the distribution coefficient of the drug between the base and body fluids and the pKa of the drug (21–25). While some of the research cited above was conducted *in vivo*, the greater portion was conducted *in vitro*. The need for studies on animals is apparent. For this reason a series of 8 barbiturates were evaluated in a series of petrolatum–paraffin–surfactant suppository bases differing with respect to the emulsifiers which had different HLB values. Since each barbiturate was evaluated under the same conditions, a comparison could be made. A suppository formulation containing an emulsifier and medicament when placed in the rectum produces a complex system indeed. However, it is felt that such a comparative study as described above will reveal some of the major factors to consider when conducting further research intended to place drug diffusion, release, and absorption on a predictable basis.

Received April 1, 1965, from the School of Pharmacy, University of Mississippi, University.

Accepted for publication October 19, 1965.

Presented to the Scientific Section, A.PH.A., Detroit meeting, March 1965.

Abstracted from a thesis submitted by Julian H. Fincher to the Graduate School, University of Georgia, Athens, in partial fulfillment of Master of Science degree requirements.

EXPERIMENTAL

Preparation of Bases.—Bases were prepared utilizing white petrolatum, white paraffin, polyethylene glycol (PEG), and surfactants. Surfactants with established HLB values (1, 2) were added to obtain a concentration of 10% by weight in each base. To produce anhydrous bases all materials except the emulsifiers were dried to constant weight. The consistency of all bases was standardized by varying the proportion of petrolatum and paraffin, or in the case of the PEG, by varying the proportion of PEGs of different molecular weights. The standard consistency selected was a penetration depth of 60 mm. (±6 mm.), when tested by the U.S.P. method at 25°.

Ten per cent by weight of surfactant was incorporated by fusion methods into lots of petrolatum and paraffin. Portions of these two emulsifier–base mixtures were then combined by trial and error to obtain the desired consistency. An HLB value of 0 was represented by using only petrolatum and paraffin as a base, and a water-soluble base was represented by use of a mixture of PEGs. Base composition and properties are shown in Table I. Table II gives a list of the barbiturates and their chemical properties. Several days before the time of the *in vivo* experiments the barbiturate was incorporated into the various bases using a glass mortar and pestle. The bases were stored in a temperature controlled room (21–23°) until the time of the experiments.

In Vivo Experimental Procedure.—The experimental animals were New Zealand white male rabbits weighing 1.5 to 2.3 Kg.

Seven to ten rabbits were used for each suppository base–barbiturate combination. One rabbit receiving the PEG base plus the drug and one rabbit receiving the petrolatum–paraffin base plus the drug were used as controls. All bases contained 0.0008 mole of the barbiturate per Gm. of suppository, thus regulating the concentration so that 1 Gm. of base would provide a dose of (0.0004 mole/Kg. body weight) for a rabbit weighing 2 Kg. This dose would be lethal to the rabbit if it were available for complete absorption in a short period of time.

A plastic injector having a tube length of 6.35 cm.

TABLE I.—COMPOSITION AND PROPERTIES OF SUPPOSITORY BASES[a]

Base No.	Ingredients	% by Wt.	Consistency in mm. Penetration	HLB Value of the Surfactant

and a diameter of 0.63 cm. was used to inject the suppository into the rectum.

All the rabbits used in a given experiment were fasted for 12 to 13 hr. before the time of the studies to render the rectum free of excess fecal matter and bladder free of excess urine. Fasting was begun at 7:30 p.m. (±30 min.) and each experiment was begun at 9:30 a.m. (±30 min.), thus keeping the time of day reasonably uniform. The rabbits were weighed, marked, and tied to a rabbit board (47.0 × 73.7 cm.) at least 45 min. before the injection of the suppository.

After weighing each injector an excess of the base–barbiturate mixture was molded directly into the injector and the exact calculated dose was adjusted by trial and error weighings.

The injector containing the base was then inserted into the rectum 1.3 cm. (indicated by a mark on the plastic tube) using no lubricant except the base itself. The plunger was then used to eject the suppository from the injector into the rectum. Polishing the sharp edge of the injector closed the end just enough to prevent the insertion of the plunger beyond this point, thus geometrically placing the suppository 1.3 cm. into the rectum as measured from the caudal end of the suppository. To prevent expulsion of the suppository a rubber hose clamp was used to hold the anus closed. Each animal was used only one time.

The barbiturates were released from the bases in sufficient quantity to cause marked changes in the respiratory rate. Administration of varying amounts of sodium pentobarbital by intravenous injection showed the change of respiration rate with a change of the dose (Fig. 1).

After administration of the suppository, the respiratory rate per minute was measured at time intervals ranging from 2 to 30 min., depending on the rate of change. Measurement of the respiratory rate was accomplished using a stopwatch and visually counting chest expansions. The respiratory counts were continued through a minimum period of 2.5 hr.

A constant time interval between 50 and 60 min. after rectal administration was arbitrarily selected as the end point for the comparative studies. The lowest respiratory rate within this interval for each

of the animals tested with a given base–drug formulation was used to evaluate the base. The mean respiratory rate was calculated, and from this the individual standard errors of the mean (σm) were determined. Appropriate t tests were performed for the data where quantitative comparisons of data are presented (26).

RESULTS AND DISCUSSION

The comparative results of the surfactant–base–barbiturate studies are summarized in Table III. The availability of pentobarbital is much less than that of calcium and sodium pentobarbital in all bases used with the exception of the petrolatum–paraffin base containing calcium pentobarbital (Fig. 2). This is in partial agreement with Riegelman and Crowell (17), who found the absorption of anions to be enhanced by the presence of surfactants while the absorption of an undissociated molecule was markedly retarded. The solubility of the sodium and calcium salts of pentobarbital in normal rectal fluids is probably much greater than the solubility of pentobarbital. The drug molecule having the

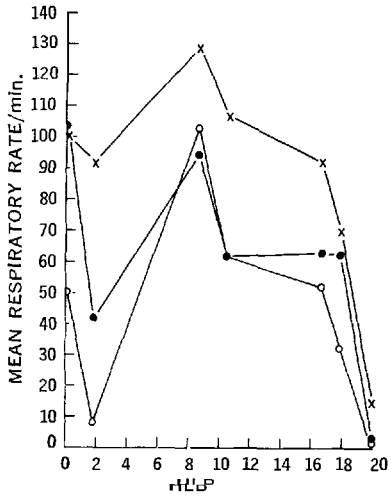

Fig. 2.—Mean respiratory rate as a function of the surfactant HLB value in the base. Comparison of a relatively undissociated barbituric acid to its partial or completely dissociated salts. Key: ×, pentobarbital; ●, calcium pentobarbital; ○, sodium pentobarbital. Statistical analysis: test of significance of difference of means nearest each other (t test) at the respective HLB values. Data are obtained from Table III. The probability of error (p) in the statement that the two means are different is tabulated as follows: × and ●, p <0.4> 0.35, 0 (HLB value); ● and ○, p <0.01> 0.005, 0 (HLB value); × and ●, p <0.005, 1.8 (HLB value); ● and ○, p <0.025> 0.01, 1.8 (HLB value); × and ○, p <0.15> 0.1, 8.6 (HLB value); ○ and ●, p <0.35> 0.20, 8.6 (HLB value); × and ●, p <0.01> 0.005, 10.5 (HLB value); ○ and ●, p ≃100, 10.5 (HLB value); × and ●, p <0.025> 0.01, 16.7 (HLB value); ● and ○, p <0.35> 0.2, 16.7 (HLB value); × and ●, p <0.35> 0.2, 17.9 (HLB value); ○ and ●, p <0.005, 17.9 (HLB value); × and ●, p <0.005, 20 (HLB value); ● and ○, p ≃100, 20 (HLB value). (The symbols consist of drugs compared.)

greater solubility would then be more available for absorption through the rectal membrane, if the drug were released from the base. Binding or complexing is suspected in all forms of pentobarbital, as well as of other barbiturates, used in the sorbitan monolaurate base (Table III).

In an effort to determine the effect of the distribution coefficient (DC) of the drug on release and absorption of barbiturates from suppositories after rectal administration, barbituric acids having varying DCs were chosen (Table II) and studied in bases containing different surfactants. Graphical presentation of the mean respiratory rate as a function of DC (chloroform/water) shows that those surfactants with a close chemical similarity (polyoxyethylene sorbitan tristearate and polyoxyethylene monostearate) yielded curves with approximately the same shape (Fig. 3). Sorbitan trioleate and sorbitan monolaurate yielded similar shaped curves (Fig. 4). When comparing Fig. 3 (polyoxyethylene sorbitan tristearate and polyoxyethylene monostearate) with Fig. 4 (sorbitan monolaurate and sorbitan trioleate), representing a more varied chemical structure, this similarity in the shape of the curves does not exist.

To study the effect of the HLB of the surfactants on release and absorption of barbiturates from the suppositories, surfactants with HLB values covering a large part of the HLB scale were utilized (Table II). A plot of the mean respiratory rate as a function of HLB of the surfactant shows that the two barbituric acids, aprobarbital and secobarbital, which have almost identical chemical structures, exhibited curves very similar in shape, and the degree of respiratory depression at the various HLB values was also similar (Fig. 5). Aprobarbital (5-allyl-5-isopropylbarbituric acid) and secobarbital (5-allyl-5[1-methyl butyl]barbituric acid) differ by 2 carbon atoms in the side chain. When comparing the results obtained with pentobarbital with

those obtained with secobarbital and aprobarbital (Figs. 2 and 5), this closeness in structure does not seem significant. The influence of the HLB of the surfactant, however, is not conclusive.

Since the HLB of a surfactant largely determines the type of emulsion formed and the degree of emulsification (27), and since some emulsification probably takes place in the rectum, when using suppository bases which contain surfactants, the effect on drug release at different HLB values may be quite significant. The predicted points of inflection are: (*a*) the point at which the most stable water-in-oil emulsion is formed, (*b*) the inversion point (point of changing from water-in-oil to an oil-in-water emulsion or vice-versa), and (*c*) the point at which the most stable oil-in-water emulsion is formed. The relative solubilities of the drug in the oil and water phases (distribution coefficient) would determine if these inflection points occur at a maximum or minimum biological response.

The change of the median respiratory rate in rabbits as a function of time and the type surfactant used in the bases is exemplified in Fig. 6. It is interesting to note that the laurates[1] exhibited linear relationships, whereas the oleate, stearate, and lauryl ether exhibited similarly shaped curves. The effect of similar chemical types of the surfactant on absorption is obvious here.

The change of the median respiratory rate of rabbits with time using various barbiturates in a base containing a polyoxyethylene lauryl ether[2] are exemplified in Fig. 7.

A complete analysis of the kinetic data will be presented for publication in the near future.

SUMMARY AND CONCLUSIONS

1. The absorption of barbiturates from eight suppository bases, which differed only by including surfactants with different HLB values, has been determined. Seven different barbiturates were used in

the suppositories which were administered to rabbits.

2. The salts of pentobarbital are more available for absorption from most bases containing surfactants based on the results of this study.

3. The relationship between the distribution coefficient of the drug and the HLB value of the surfactants used in the bases and their combined effects on absorption are inconclusive.

4. The chemical type of the surfactant and drug greatly influences the degree of release or absorption of barbiturates from suppositories in rabbits.

5. The addition of a surfactant to a base in most cases affects the availability of the drug from the base to the tissues. Complexation or binding may be one major factor causing these marked changes.

Condensation of Aldoses and Their Aldehydo Derivatives with Compounds of the Type 1,3-Cyclohexanedione

Synthesis of 2,2-Aldosylidene-bis-[5-(*p*-hydroxyphenyl)-4,6-dicarbethoxy-1,3-cyclohexanedione] and 2,2-Aldosylidene-bis-[5,5-dimethyl-1,3-cyclohexanedione] and Derivatives

By PHILIPPOS E. PAPADAKIS

Glycoaldehyde, glyoxal, *dl*-glyceraldehyde, D-arabinose, D-glucose, and D-mannose react with compounds of the 1,3-cyclohexanedione type to form 2,2-aldosylidene-bis-1,3-cyclohexanedione derivatives.

THE PREPARATION of various 2,2-alkylidene or arylidene bis[5-(*p*-hydroxyphenyl)-1,3-cyclohexanedione] by the condensation of an aliphatic or an aromatic aldehyde with 5-(*p*-hydroxyphenyl)-1,3-cyclohexanedione or its derivatives was reported in a previous publication (1). It was also shown in that report that 5-(*p*-hydroxyphenyl)-1,3-cyclohexanedione could condense with 1,2-acetone-D-xylotrihydroxyglutaric dialdehyde to give [5,5-bis-<2′,2′-{5′,5′-(*p*-hydroxyphenyl)-cyclohexanedione-1′, 3′}>-1,2-isopropylidene-5-desoxy-D-xylofuranose]$_2$ monohydrate. This suggests that the aldehydo form of aldoses and of metabolic products of carbohydrates having a carbonyl group may condense with cyclic 1,3-diketones to form bis-derivatives. Such reactions should be of scientific and pharmacological interest (9).

In the present work 5-(*p*-hydroxyphenyl)-4,6-dicarbethoxycylohexane-1,3-dione was condensed with each of the following carbohydrates (or derivatives) to give bis-derivatives which may be represented by the general formula (I): glycolaldehyde, glyoxal, *dl*-glyceraldehyde, L-

This research began at Creighton University in 1954.

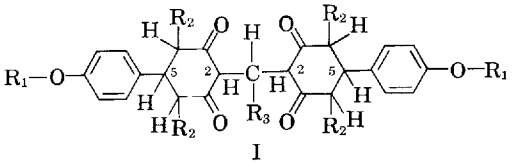
arabinose, 4,6-*O*-benzylidene-D-glucose, D-mannose, and D-galactaric dialdehyde.



I

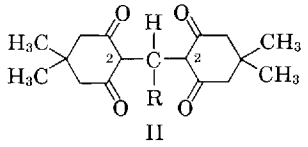
R_1 = H in experiments *1,2,3,5,7;* $-CH_3$ in *4* and $-COCH_3$ in *6* and *8*. R_2 = $-COOC_2H_5$ in *1, 2,3,5,6,7,8* and H in *4*. The value of R_3 is shown in Table I.

The method of preparation described under *Experimental* is similar to that used by Horning and Horning (2) with some modifications (1).

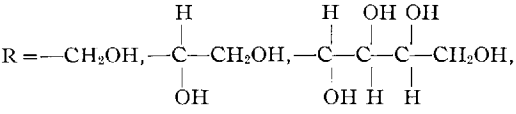
Other β-diketones are known to condense with aldehydes to give bis-derivatives (3–6).

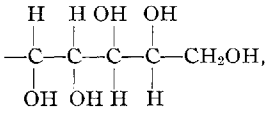
Vorlander (7) treated dimethone (5,5-dimethylcyclohexane-1,3-dione) with each of the following: glycolaldehyde, glyoxal, and *dl*-glyceraldehyde and obtained (bis-derivatives) anhydrides. His method consisted in dissolving the diketone with each of the respective substances and allowing it to stand at room temperature several hours whereby a precipitate was formed which was purified and analyzed. He failed to obtain precipitates with tetroses and higher aldoses. Bourne *et al.* (8) have reported that, under the conditions which they used, D-xylose does not react with dimedone.

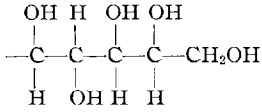
Fletcher (9) and co-workers found that: "D-xylose and dimedone containing a trace of quinoline mutarotates slowly over an extended period and yields a crystalline product which has the analysis of xylose-dimethone anhydride. A crystalline benzoate has also been obtained." In the present work aldosylidene-bis-dimedone derivatives were obtained, general formula (II), by condensing dimedone with each of the following carbohydrates in 75% methanol containing 2 drops of piperidine: glycolaldehyde, *dl*-glyceraldehyde, D-arabinose, D-mannose, and D-glucose. (*Experiments A–E.*)



II







The results of the experiments *A* and *B* indicate that glycolaldehyde and glyceraldehyde react with dimedone to form (bis-derivatives)

anhydrides. This is in agreement with Vorlander's work. Experiments *C*, *D*, and *E* indicate that contrary to Vorlander's findings the dimedone can condense with pentoses and hexoses. Analogous reactions have already been shown in Table I of this report where 5-(*p*-hydroxyphenyl)-4,6-dicarbethoxy-1,3-cyclohexanedione reacted with pentoses and hexoses to form bis-derivatives. (Experiments *6–8*.)

EXPERIMENTAL

5 - (*p* - Acetoxyphenyl) - 4,6 - dicarbethoxy - 1,3-cyclohexanedione, 1, 3, and 5-(*p*-hydroxyphenyl)-1,3-cyclohexanedione and related materials were prepared according to methods previously described (10).

METHOD

The method used for the condensation of the aldehydoform of the sugars to form aldosylidene-bis-derivatives with the above cyclic 1,3-diketones and with dimedone (type formula I and II) is similar to that used previously by the present author (1). In a general way, the molar proportions of the diketone to the aldose were 2:1. The materials were dissolved in hot 75% methyl alcohol, 1 or 2 drops of piperidine were added, and the mixture refluxed 2 hr. and then allowed to stand 3 days at room temperature, and in some cases, in the refrigerator.

Besides this method of procedure, experiments *5* and *7* were repeated and modified. After the reagents and solvents were mixed, they were allowed to stand at room temperature; compound *5* for 6 months and compound 7 for 13.5 months.

After evaporation of the solvents under reduced pressure using a water bath, the residue was purified by recrystallization from 50% methanol and in some cases from boiling distilled water. Details of purification varied, depending on the solubilities of the reagents and products in the different solvents.

1.—**2,2 - (2′ - Hydroxyethylidene) - bis - [5 - (p-hydroxyphenyl) - 4,6 - dicarbethoxy - 1,3 - cyclohexanedione].**—Glycolaldehyde, 60 Gm., 5-(*p*-hydroxyphenyl) - 4,6 - dicarbethoxy - 1,3-cyclohexanedione, 6.96 Gm., and 1 drop of piperidine were dissolved and refluxed in 75% methanol for 1 to 2 hr. The mixture was allowed to stay at room temperature 3 days. The solution was concentrated by evaporation on a water bath to an oily liquid which solidified upon addition of water. It was recrystallized from 75% methanol. It softens at 120° to a waxy consistency; it melts and decomposes at 143°. The bubbles formed are opalescent but clear at 156°.

Anal.—Calcd. for $C_{35}H_{42}O_{15} \cdot 1/2\ H_2O$: C, 61.03; H, 5.61. Found: C, 60.81; H, 5.74.

2.—**2,2 - Formalformylidene - bis - [5 - (p - hydroxyphenyl) - 4,6 - dicarbethoxy - 1,3 - cyclohexanedione].**—To 6.96 Gm. of 5-(*p*-hydroxyphenyl)-4,6-dicarbethoxy-1,3-cyclohexanedione dissolved in hot 75% methanol, 2 ml. of 30% glyoxal and 1 drop of piperidine were added. The mixture was refluxed 0.5 hr., then cooled and allowed to stand in the refrigerator 3 days. A precipitate was formed which was processed. It was recrystallized from 75% methanol, m.p. 145°, dec. 156°. This compound is analogous to the bis-derivative of glyoxal with dimedone (5,5-dimethyl-1,3-cyclohexanedione) obtained by Vorlander.

Anal.—Calcd. for $C_{38}H_{40}O_{15} \cdot H_2O$: C, 60.41; H, 5.60. Found: C, 60.07; H, 5.45.

3.—**2,2 - (2′,3′ - Dihydroxypropylidene) - bis-[5 - (p - hydroxyphenyl) - 4,6 - dicarbethoxy - 1,3-cyclohexanedione].**—To 2.32 Gm. of 5-(*p*-hydroxyphenyl)-4,6-dicarbethoxycyclohexane-1,3-dione dissolved in 75% hot methanol, 0.30 Gm. of *dl*-glyceraldehyde and 1 drop of piperidine were added with stirring. The mixture was refluxed 2 hr., then the solvents were evaporated and the residue recrystallized from hot distilled water. It melted at 90° and decomposed at 110°.

Anal.—Calcd. for $C_{39}H_{44}O_{16}$: C, 60.93; H, 5.76. Found: C, 61.17; H, 5.70.

The above product treated with phenylhydrazine gave an orange-red precipitate, a small part of which dissolved in ether. The residue was dissolved in alcohol and reprecipitated with distilled water, m.p. 161–163°.

Anal.—Calcd. for $C_{51}H_{56}N_4O_{14}$: N, 5.90. Found: N, 6.27.

From the ether solution after evaporation of the solvent, the small amount of material obtained was dissolved in alcohol and reprecipitated with distilled water, m.p. 129°.

Anal.—Calcd. for $C_{57}H_{60}N_6 \cdot 3H_2O$: N, 7.68. Found: N, 7.66.

4.—**2,2 - (L - Arabosylidene) - bis - [5 - (p-methoxyphenyl) - 1,3 - cyclohexanedione].**—5-(*p*-Methoxyphenyl)-1,3-cyclohexanedione, 4.36 Gm., L-arabinose, 1.5 Gm., and 2 drops of piperidine were dissolved in 75% methanol. The mixture was refluxed for 1 hr., then allowed to stand 3 days at room temperature. After evaporation of the solvents, the residue was recrystallized from boiling distilled water. At 138° it changed to a waxy consistency and melted and decomposed at 140°.

Anal.—Calcd. for $C_{31}H_{35}O_{10} \cdot 1/2\ H_2O$: C, 64.75; H, 6.29. Found: C, 64.76; H, 6.30.

5.—**2,2 - (D - Glucosylidene) - bis - [5 - (p-hydroxyphenyl) - 4,6 - dicarbethoxy - 1,3 - cyclohexanedione].**—5 - (*p* - Hydroxyphenyl) - 4,6 - dicarbethoxy-1,3-cyclohexanedione, 6.96 Gm. (0.02 mole), and dextrose, 1.80 Gm. (0.01 mole), were placed in a ground-stoppered bottle with 200 ml. of 75% methanol and 3 drops of piperidine, and the mixture was allowed to stand 7 months in a cupboard at room temperature. Then the solvents were evaporated in a rotating evaporator under reduced pressure using a water bath. The solid residue was recrystallized from boiling water, m.p. 187–188°. The product was dried under reduced pressure at 100°. Yield, 67%. $[\alpha]_D^{20°} = +11.65$ (c 3.0896; acetone).

Anal.—Calcd. for $C_{42}H_{50}O_{19} - 2H_2O$: C, 61.30; H, 5.63. Found: C, 61.49; H, 5.70.

6.—**2,2 - (4′,6′ - O - Benzylidene - glucosylidene)-bis - [5 - (p - acetoxyphenyl) - 4,6 - dicarbethoxy-1,3 - cyclohexanedione].**—5 - (*p* - Acetoxyphenyl)-4,6-dicarbethoxy-1,3-cyclohexanedione, 7.8 Gm., and 2.68 Gm. of 4,6-*O*-benzylideneglucose (11) and 2 drops of piperidine were dissolved in 75% methanol and refluxed for 2 hr. The solvents were distilled off under reduced pressure and the product recrystallized from methyl alcohol, m.p. 168°.

Anal.—Calcd. for $C_{53}H_{58}O_{21}$: C, 61.73; H, 5.67. Found: C, 61.45; H, 5.74.

A phenylhydrazine derivative of the product above was formed in the usual way. It was dissolved in alcohol and reprecipitated with distilled water, m.p. 121°.

Anal.—Calcd. for $C_{74}H_{82}N_8O_{17}\cdot 2H_2O$: C, 64.79; H, 6.03; N, 7.85. Found: C, 64.40; H, 6.19; N, 7.59.

7.—**2,2 - (D - Mannosylidene) - bis - [5 - (p-hydroxyphenyl) - 4,6 - dicarbethoxy - 1,3 - cyclohexanedione] - $2H_2O$.**—5 - (*p* - Hydroxphenyl)-4,6-dicarbethoxy-1,3-cyclohexanedione, 6.96 Gm. (0.02 mole), and mannose, 1.80 Gm. (0.01 mole), were placed in a ground-stoppered bottle with 200 ml. of 75% methanol and 3 drops of piperidine. The mixture was allowed to stand 13.5 months at room temperature in a closed cupboard. After the solvents were evaporated under reduced pressure using a water bath, the solid residue was recrystallized from boiling water. The product was dried at 100° under reduced pressure, m.p. 180°. $[\alpha]_D^{18°} = 0$ (c 1.328; acetone).

Anal.—Calcd. for $C_{42}H_{50}O_{19} - 2H_2O$: C, 61.30; H, 5.63. Found: C, 61.37; H, 5.97. C, 61.13; H, 5.98. C, 61.04; H, 5.82.

8.—**2,2 and 2,2-(Galactar-di-ylidenetetraacetate)-tetrakis - [5 - (p - hydroxyphenyl) - 4,6 - dicarbethoxy-1,3-cyclohexanedione].**—Tetraacetyl galactaricdialdehyde, 0.346 Gm., and 1.392 Gm. of 5-(*p* - acetoxyphenyl) - 4,6 - dicarbethoxy - 1,3 - cyclohexanedione and 1 drop of piperidine were dissolved in 75% hot methanol and allowed to stand at room temperature. After 2 days the solvents were evaporated under reduced pressure and the product recrystallized from methanol, m.p. 184°.

Anal.—Calcd. for $C_{94}H_{102}O_{40}$: C, 60.31; H, 5.49. Found: C, 60.41; H, 5.94.

Aldosylidene-bis-dimedone Derivatives

2,2 - (2′ - Hydroxyethylidene) - bis - [5,5 - dimethyl - 1,3 - cyclohexanedione] - H_2O.—*Experiment A.*—Dimedone, 2.33 Gm. (0.0166 mole), glycolaldehyde, 0.50 Gm. (0.0083 mole), 15 ml. of methanol, and 5 ml. of water and 1 drop of piperidine were refluxed for 2 hr. and allowed to stand at room temperature 3 days. The solution was concentrated and cooled. The crystals formed were separated and recrystallized from 50% methanol, m.p. 233°. (Vorlander found m.p. 227°.)

Anal.—Calcd. for $C_{18}H_{26}O_5 - H_2O$: C, 71.02; H, 7.97. Found: C, 70.73; H, 7.92.

2,2 - (2′,3′ - Dihydroxypropylidene) - bis - [5,5-dimethyl - 1,3 - cyclohexanedione] - H_2O.—*Experiment B.*—Dimedone, 1.4 Gm. (0.01 mole), *dl*-glyceraldehyde, 0.45 Gm. (0.005 mole), 15 ml. of CH_3OH, 5 ml. of water, and 1 drop of piperidine were heated at refluxing temperature for 1 hr. and allowed to stand at room temperature for 3 days. The solution was concentrated to 7 ml. and cooled. The crystals formed were recrystallized from 50% methanol, m.p. 209°. (Vorlander found m.p. 197°.)

Anal.—Calcd. for $C_{19}H_{28}O_6 - H_2O$: C, 68.26; H, 7.83. Found: C, 68.17; H, 7.50.

2,2 - (D - Arabosylidene) - bis - [5,5 - dimethyl-1,3-cyclohexanedione].—*Experiment C.*—Dimedone, 2.80 Gm. (0.02 mole), D-arabinose, 1.5 Gm. (0.01 mole), 15 ml. of methanol, 5 ml. of water, and 1 drop of piperidine were placed in a ground-stoppered flask and allowed to stand for 1 week. Then the solution was refluxed 1 hr. and concentrated almost to dryness. The residue, after cooling, was stirred with ether. The ether was decanted and the residue stirred with ethanol and filtered. The white residue was recrystallized from boiling distilled water, m.p. 146°. $[\alpha]_D^{21°} = -274.9°$ (c 1.98; water).

Anal.—Calcd. for $C_{21}H_{32}O_8$: C, 61.14; H, 7.82. Found: C, 61.05; H, 7.81.

2,2 - (D - Mannosylidene) - bis - [5,5 - dimethyl-1,3-cyclohexanedione] · $2H_2O$.—*Experiment D.*—Dimedone, 5.60 Gm. (0.04 mole), and D-mannose, 3.60 Gm. (0.02 mole), were dissolved in 50 ml. of 70% methanol containing 2 drops of piperidine. The solution was refluxed 2 hr. and allowed to stand at room temperature 3 days. The solvents were evaporated under reduced pressure to a thick jelly-looking material which was soluble in alcohol but insoluble in ether. On stirring, it became like taffy. The material was dried on a porous plate and recrystallized from boiling water. It sinters at 87°, froths at 90°, and becomes clear at 112°.

Anal.—Calcd. for $C_{22}H_{34}O_9\cdot 2H_2O$: C, 55.21; H, 8.00. Found: C, 54.76; H, 8.18.

2,2 - (D - Glucosylidene) - bis - [5,5 - dimethyl-1,3 - cyclohexanedione] - H_2O.—*Experiment E.*—Dimedone, 5.60 Gm. (0.04 mole), and D-glucose, 3.60 Gm. (0.02 mole), were dissolved in 50 ml. of 75% methanol containing 2 drops of piperidine. The solution was refluxed 2 hr., then it was allowed to stand at room temperature for 2 weeks. The solution was concentrated under reduced pressure on a water bath. Alcohol and benzene were added for azeotropic distillation. After partial distillation, the solution was cooled, ether was added, and the precipitate formed was filtered, washed with ether, and dried, m.p. 189°, dec. 190°. Yield, 62%. $[\alpha]_D^{21°} = 173.58°$ (c, 4.01536; water).

Anal.—Calcd. for $C_{22}H_{34}O_9 - H_2O$: C, 62.07; H, 7.59. Found: C, 61.90; H, 7.67. C, 62.11; H, 7.78.

Interaction of Pharmaceuticals with Schardinger Dextrins VI

Interactions of β-Cyclodextrin, Sodium Deoxycholate, and Deoxycholic Acid with Amines and Pharmaceutical Agents

By JOHN L. LACH and WAYNE A. PAULI*

Data are presented for the interactions of β-cyclodextrin and sodium deoxycholate with 11 pharmaceutical agents in aqueous solution. Three of the compounds were also studied as to possible reactivity with deoxycholic acid. Interactions were observed with all of the systems studied. Similar solubility isotherms were obtained for the three pharmaceuticals when interacted with both deoxycholic acid and its sodium salt indicating possible similarities in the reaction mechanisms for these two complexing agents. The larger molecules showed a lower degree of interaction with both β-cyclodextrin and sodium deoxycholate, indicating the importance of molecular size and structure for optimum reactivity. Stoichiometries could be determined for several of the interactions due to the presence of plateau regions in their solubility isotherms. Formation constants and free energies of formation are also reported for a number of the insoluble complexes.

THE IMPORTANCE of molecular complex formation in pharmaceutical formulation is certainly evident. Applications of this type of interaction can be made in the area of drug solubilization, stabilization, etc. The problem of stabilization is of particular interest in that numerous attempts have been made to retard degradation of pharmaceutical compounds. These include pH considerations, changes in solvent systems, antioxidants, and complex salt formation. The use of molecular complex formation in this area represents a relatively new approach to this problem of stability (1–5). Complexation by means of inclusion formation has been used successfully in the stabilization of labile drugs such as benzocaine, vitamin A, and various fatty acids (6, 7). This mode of protection for an unstable molecule offers definite advantages in that the entire molecule can be shielded from its surroundings. It has also been recognized that complexes not only influence the stability and appearance of pharmaceutical preparations, but may also exert some influence on the pharmacological and even biochemical mechanisms by which they operate.

The previous paper of this series dealt with a study of the interactions of β-cyclodextrin with a series of phenyl-substituted carboxylic acids in an effort to explain more clearly the nature of cyclodextrin interaction in aqueous solution. It was the objective of this study to investigate and compare the interaction tendencies of various medicinal agents with both β-cyclodextrin and deoxycholic acid, as only a limited number of these interactions have been reported in the literature. The solubilizing effect of sodium deoxycholate on these drugs was also studied with the hope of understanding more fully the mechanism responsible for this phenomenon.

EXPERIMENTAL

Reagents.—β-Cyclodextrin $[\alpha]_D^{25°}$ in water = + 162.5 ±0.5; lidocaine,[1] m.p. 68–69°; adiphenine hydrochloride,[2] m.p. 113–114°; antazoline hydrochloride,[3] m.p. 234–236°; methapyrilene hydrochloride,[4] m.p. 161–163°; tripelennamine hydrochloride,[5] m.p. 189–192°; testosterone, m.p. 155–156°; morphine, m.p. 250°; procaine hydrochloride, m.p. 154–156°; meperidine hydrochloride, m.p. 187–189°; cortisone acetate, m.p. 235–238°; reserpine, m.p. 257–260°; sodium deoxycholate, analytical grade; deoxycholic acid, m.p. 171–172°; 1 *N* standard sodium hydroxide solution.

Apparatus.—The same apparatus described in the previous paper of this series was used in this study with the following addition: radiometer pH meter, type PHM4C.

Procedures.—The β-cyclodextrin was prepared by the procedure used previously in these laboratories (8). Complex formation was studied by means of the solubility method of Higuchi and Lach (9). The experimental procedures were similar to those outlined in the previous paper of this series, except for the following modifications.

With a few of the drugs, the free bases were formed in the reaction vials from the corresponding hydrochloride salts by the addition of a sufficient amount

of standard sodium hydroxide solution. A 10% excess of the standard solution was added to insure complete neutralization of the salts. In these particular systems, the amount of distilled water was reduced to compensate for the volume of standard base solution. When deoxycholic acid was used as the complexing agent, it was necessary to employ hydroalcoholic systems because of the acids limited solubility in water. The drugs were analyzed spectrophotometrically at the following wavelengths: lidocaine, 262.5 mμ; adiphenine, 258 mμ; antazoline 242 mμ; methapyrilene, 239 mμ; tripelennamine, 245 mμ; testosterone, 238 mμ; morphine, 285 mμ; procaine, 289 mμ; meperidine, 257 mμ; cortisone acetate, 238 mμ; reserpine, 268 mμ. Because of the concentrations used and corresponding dilutions prior to spectrophotometric analysis, no interference in the absorption characteristics of the compounds tested was observed due to the presence of the various complexing agents. The pH of each reaction vial was determined following its analysis, and no appreciable pH changes were observed in any of the systems investigated.

RESULTS AND DISCUSSION

Solubility isotherms representing the interactions of various drugs with β-cyclodextrin, deoxycholic acid, and sodium deoxycholate are shown in Figs. 1–12. Although several of the amines studied with these complexing agents are known to be relatively unstable at high pH, no appreciable degradation was observed for any of the compounds during the course of this investigation. Definite interactions were observed with all of the systems studied. Linear plots, indicating a first-order dependence of the interactions on the complexing agent concentration, were obtained in most cases. Smaller slopes were generally observed for interactions of both β-cyclodextrin and sodium deoxycholate with larger and thus more sterically hindered molecules. This finding is in agreement with results reported in an earlier article in this series (10). It should be pointed out here that definite relationships between interaction slopes and relative reactivities exist only if the stoichiometries of the various systems are the same. Since stoichiometries could not be evaluated for a number of these interactions due to the nature of the solubility isotherms, the comparison of slopes must be viewed with some reservation.

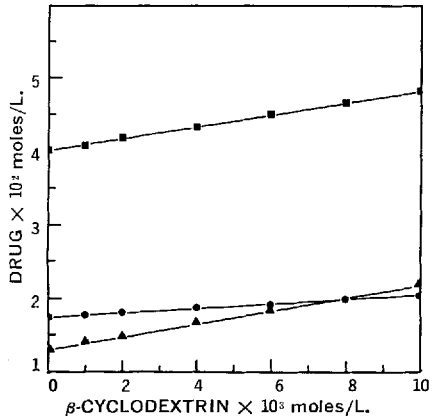

Fig. 1.—Interactions of procaine (■), lidocaine (●), and meperidine (▲) with β-cyclodextrin at 30°.

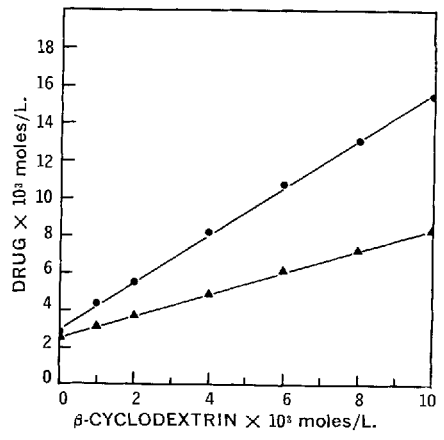

Fig. 2.—Interactions of antazoline (●) and methapyrilene (▲) with β-cyclodextrin at 30°.

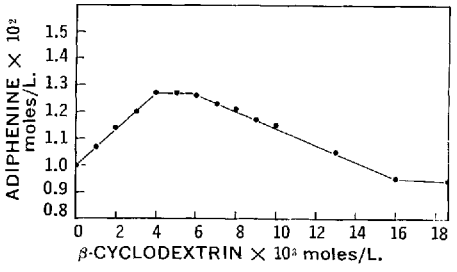

Fig. 3.—Interaction of adiphenine with β-cyclodextrin at 30°.

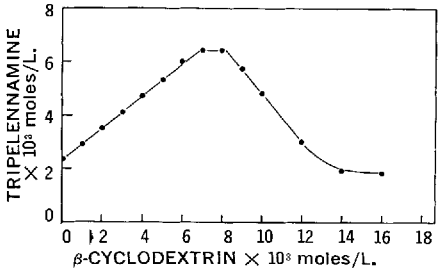

Fig. 4.—Interaction of tripelennamine with β-cyclodextrin at 30°.

Because of the hydroalcoholic systems employed for the deoxycholic acid studies, necessitated by the limited solubility of this acid in water, it is rather difficult to compare the interaction tendencies of this complexing agent with those of sodium deoxycholate and β-cyclodextrin. However, certain similarities were observed in the shapes of the solubility isotherms for both deoxycholic acid and its sodium salt.

β-Cyclodextrin Interactions.—A structural comparison of the compounds interacted with β-cyclodextrin reveals some interesting relationships. Referring to Table I, it can be observed that larger slopes are found for systems composed of β-cyclo-

dextrin and small or medium-sized guest molecules containing one or more branched ring systems.

This increased reactivity resulting from the presence of a branched ring system might be attributed to the availability of a ring for either total or partial inclusion by the cyclodextrin. Therefore, inclusion, in combination with other attractive forces, would be expected to enhance the reactive tendency of a particular guest compound with β-cyclodextrin. If ring availability were assumed to be the primary factor for interaction with β-cyclodextrin, similar reactivities would be expected with both antazoline and adiphenine, since both molecules contain several branched phenyl groups. On comparison of the slopes for these compounds, listed in Table I, it can be seen that the slope representing the antazoline interaction is almost double that for the adiphenine system, again pointing toward a complex mechanism for these interactions. A smaller slope than would be expected for the interaction between lidocaine and β-cyclodextrin might be attributed to steric hindrance resulting from the multiple methyl group substitution on the phenyl ring. The bulky multi-ringed molecules including morphine, cortisone acetate, and reserpine show extremely small interaction slopes with β-cyclodextrin indicating only limited interactions for these systems. This would be expected due to the extreme size of the molecules and the resulting steric interference that would oppose their proper combination or fit with the cyclodextrin structure. It becomes obvious for molecules of this size, that interactions with β-cyclodextrin could not possibly occur by means of complete or true inclusion formation. The presence of reactive functional groups in these large molecules, capable of bonding with or of being partially included by the cyclodextrin, could be responsible for the observed interactions. Cortisone acetate and testosterone, because of structural similarity, would be expected to interact similarly with β-cyclodextrin. But on a comparison of the slopes for these interactions in Table I, a marked difference is observed with testosterone possessing the greater slope. As indicated previously, molecules of this size would obviously be too large to allow complete inclusion within the cyclodextrin cavity and therefore the mechanism might involve either interaction of or the enclosure of a functional group of the steroid by the cyclodextrin. The hydroxyl group in the C-17 position is relatively open and free in the testosterone structure, while the same group in the cortisone acetate molecule is in close proximity to a rather bulky side chain also at the C-17 position. Interference introduced by this group in the cortisone acetate structure could partially explain the decreased reactivity of this compound with β-cyclodextrin. Again, as emphasized previously, these interactions are, as expected, quite complex due to the size and complexity of the interacting species, and therefore it is quite conceivable that a number of factors are responsible for the net interactions observed.

Stoichiometries were calculated for those systems characterized by the presence of plateau regions in their solubility isotherms. These values, along with stoichiometries determined from an analysis of the isolated complexes, are found in Table II.

The formation constants, calculated in a manner

Table II.—Stoichiometries of the Drug–β-Cyclodextrin Complexes

Compd.	From Phase Diagram Drug–BCD	Analysis of Isolated Complex Drug–BCD
Cortisone acetate	1.98:1.00	2.05:1.00

Tripelennamine	6.5×10^2	6.5×10^2	−3900
Adiphenine	2.1×10^2	2.1×10^2	−3220

[a] Values determined by the method of Thoma and Stewart for 1:1 complexes only.

analogous to those employed in previous studies (9), and the corresponding free energies of formation for these insoluble complexes are listed in Table III. A method proposed by Thoma and Stewart (11), involving a mathematically derived expression for the calculation of formation constants of 1:1 complexes, was applied to some of our interactions in an effort to check our calculations. These results were in good agreement with the formation constants determined from the solubility isotherms.

The magnitude of the apparent formation constants and free energies of formation observed for these insoluble complexes is indicative of the relative high degree of interaction. Formation constants for other systems involving β-cyclodextrin have been reported in the range of 10^2 to 10^4 (12, 13), again indicating the existence of very stable systems. These formation constants are quite high compared to the values of 1 to 100 reported in pharmaceutical interaction studies with complexing agents such as caffeine (9, 14). Thus interactions involving more than hydrogen bonding or dipole-dipole attractions are suspected, and a combination of these plus inclusion formation is a definite possibility.

Deoxycholic Acid and Sodium Deoxycholate Interactions.—The same compounds studied with β-cyclodextrin were also interacted with sodium deoxycholate in an attempt to clarify further the mechanism by which this agent exerts its solubilizing effects. Interactions were observed with all of the compounds and are represented by Figs. 7–10. No

[a] The second slope was used when multislope isotherms were present.

plateau regions were found in the solubility isotherms for these interactions which prevented the determination of the exact stoichiometric relationships and the corresponding thermodynamic values. Slopes for interactions of these compounds with sodium deoxycholate are found in Table IV.

In general, as was true for the β-cyclodextrin interactions, the smallest compounds are seen to exhibit the greatest interaction slopes with sodium deoxycholate. This could either be due to the small size of the molecules or to their greater solubility, as one property is a corollary of the other. In most cases the interactions with β-cyclodextrin yielded larger slopes than the corresponding interactions with sodium deoxycholate, indicating a greater degree of complex formation with the cyclodextrin and possibly a different mechanism. Although there are certain similarities in the reaction isotherms observed, it should be pointed out that β-cyclodextrin is known to form monomolecular inclusion compounds, while a polymolecular mechanism, necessary in the build-up of the channel-like host structure, is essential for choleic acid inclusion formation.

Systems containing the amine bases and either of the complexing agents were quite alkaline (pH 9–12) due to the nature of the guest compounds themselves and to the excess sodium hydroxide added to insure complete liberation of the bases from their corresponding salts. While varying concentrations of sodium deoxycholate would be expected to have a measurable effect on the pH of neutral or acidic systems, no effect was observed in these investigations because of the elevated pH conditions employed. The pH changes observed in less basic systems ranged from 0.1–0.2 pH units. Even though this basic environment would not be expected to have any appreciable effect on β-cyclodextrin, it would markedly suppress hydrolysis of sodium deoxycholate resulting in a predominance of the deoxycholate anion in solution. Also in this pH range, the amine bases would exist as the nonprotonated form, and, therefore, the observed interactions would presumably be between the deoxycholate anion and the free bases. An acid–base reaction between a few of the strongly basic amines and deoxycholic acid in solution might be expected, but at this pH, the probability of an interaction of this type between the nonprotonated amine and the deoxycholate anion is small.

Multislope interaction isotherms obtained for a number of the sodium deoxycholate systems indicate the complexity of these molecular associations. At the present time, the popular theory is that sodium deoxycholate, acting as an anionic surfactant, exerts its solubilizing effects through micelle formation. There has been considerable evidence that lends support to this proposed mechanism (15–17). However, owing to the inability of isolating the reaction products for structural examination, the possibility of a mechanism similar to that for deoxycholic acid, involving channel-like inclusion formation, cannot be ruled out. Deoxycholic acid is believed to bond intermolecularly through the hydroxyl groups in the 3 and 12 positions forming a channel-like host structure. It is quite conceivable that the anion of this acid could assume a similar structure resulting in inclusion formation of the guest amines. Assuming that the carboxyl group of deoxycholic acid is also an active site for the intermolecular bonding necessary in the build-up of the host structure, one might expect a lesser degree of inclusion formation with the anion than with the undissociated acid. The complexity of these interactions could certainly point toward a mechanism composed of both inclusion formation and micellar solubilization. This combination might well account for the different slopes observed in the interaction isotherms for a number of the interactions that could also represent the formation of higher order complexes.

In an attempt to elucidate further the complex nature of sodium deoxycholate's mechanism of interaction, three of the compounds previously studied with this complexing agent were also interacted with deoxycholic acid. The interactions observed between each of the three compounds and deoxycholic acid are represented in Figs. 11 and 12. Hydroalcoholic systems were used for these interactions because of the acid's limited solubility in water. It is interesting to note that in these alcoholic systems, deoxycholic acid would exist almost entirely as the free acid, and, therefore, the concept of micellar solubilization would appear to be minimized as a possible mechanism since it has been

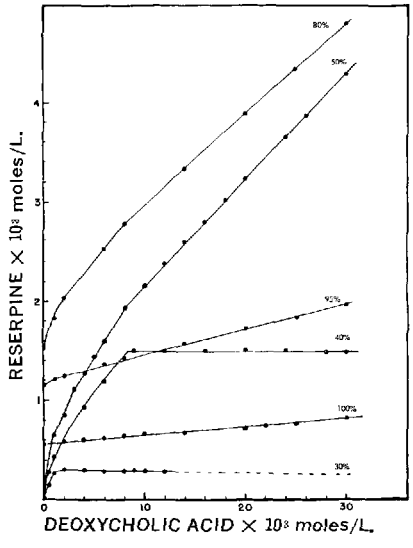

Fig. 11.—Interaction of reserpine with deoxycholic acid at 30° in hydroalcoholic systems.

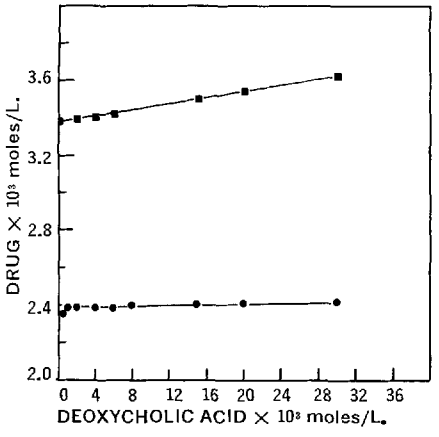

Fig. 12.—Interactions of cortisone acetate (■) (50% EtOH system) and testosterone (●) (30% EtOH system) with deoxycholic acid at 30°.

known for some time that micelles do not readily form in alcoholic solvents. A comparison of the slopes for these systems with the corresponding slopes for the sodium deoxycholate interactions is difficult because of the different solvent systems employed. However, the shapes of the solubility isotherms representing interactions of both the acid and its sodium salt do show certain similarities which might indicate a common mechanism for these complexing agents. Because of the unique multislope isotherm representing the reserpine–deoxycholic acid interaction in a 50% hydroalcoholic solvent, it was felt that a study of this system in solvents of varying alcoholic strength would be interesting, and might possibly yield a plateau region permitting the determination of the stoichiometry for this system. Therefore, this particular interaction was examined in alcoholic systems ranging from 0–100% ethanol. The corresponding isotherms representing the different alcoholic strengths are found in Fig. 11. As would be expected, the solubility pattern of the resulting complexes parallels the alcoholic concentration up to 80% ethanol, but a marked decrease in the interaction slopes is observed at higher alcoholic levels. The presence of deoxycholic acid is seen to exert a pronounced effect on the solubility of reserpine at the lower alcoholic concentrations employed over that of its solubility in the same alcoholic solutions without the deoxycholic acid. In the 50% alcoholic system, formation of the complex is seen to result in almost a fourfold increase in the solubility of reserpine. At lower alcoholic concentrations, the solubility of the complex appears to lie midway between the individual solubilities of reserpine and deoxycholic acid as would be expected. However, the marked decrease in solubility of the reserpine complex and interaction in 95% and absolute ethanol appears to parallel the unexpected decrease in solubility of the uncomplexed reserpine at these solvent concentrations. The solubility profiles of reserpine and deoxycholic acid in various hydroalcoholic systems are shown in Fig. 13. While deoxycholic acid is shown to be infinitely soluble at higher alcoholic concentrations, the solubility profile of reserpine is seen to possess a maximum in approximately 80% ethanol. Solubility studies involving a number of medicinal agents have pointed out the presence of such a maximum solubility in various cosolvent mixtures (18, 19), suggesting that a definite correlation exists between the solubility of the solute and the dielectric constant of the solvent system employed. The solubility of reserpine in these cosolvent systems involves solute-solvent and solvent-solvent associations, and since complexation of reserpine with deoxycholic acid would be in competition with these various associations, it becomes obvious that the mechanism involved in reserpine–deoxycholic acid interaction in these systems is complex. Since it is known that stable deoxycholic acid–alcohol complexes exist (20), the association between the deoxycholic acid and alcohol at these high alcoholic concentrations must be much greater than that for the reserpine–deoxycholic acid interaction. This and the decreased solubility of reserpine in high alcoholic concentrations could account in part for the marked decrease in the observed interaction between reserpine and deoxycholic acid.

The plateau region obtained in the 40% plot found in Fig. 11, representing the solubility limit of deoxycholic acid at this alcoholic strength, made possible the calculation of the apparent stoichiometry that was found to be 1:1. The multislope isotherms observed for the interaction in these alcohol–water systems (*e.g.*, 50%) could represent the successive formation of a series of higher order complexes in solution and certainly illustrate the complexity of this interaction. This was also mentioned as a possible explanation for similar multislope systems observed in many of the sodium deoxycholate interactions, although in these systems, micelle formation is also a definite possibility. It is interesting to note that the stoichiometries determined from the isolation and subsequent analysis of deoxycholic acid complexes prepared from saturated alcoholic solutions are usually of higher order (6:1, 8:1, etc.), while stoichiometries obtained from the solubility isotherms (1:1 for the reserpine–deoxycholic acid complex) are much lower. Such differences in the reported stoichiometries of deoxycholic acid interactions indicate that the complexes formed can be

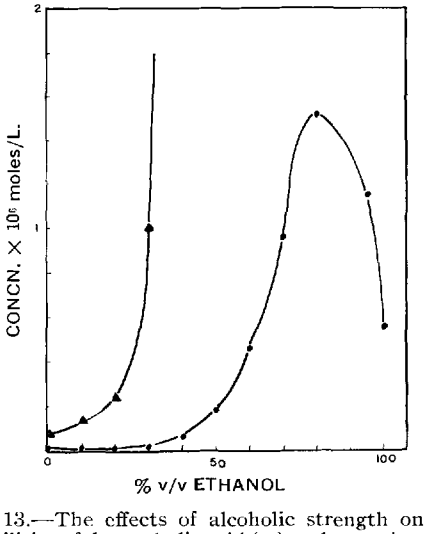

Fig. 13.—The effects of alcoholic strength on the solubilities of deoxycholic acid (▲) and reserpine (●).

greatly influenced by the type of solvent system employed (20).

CONCLUSION

Both β-cyclodextrin and sodium deoxycholate are shown to interact with a variety of pharmaceutical compounds. While varying concentrations of sodium deoxycholate would be expected to have a measurable effect on the pH of systems at lower pH levels, no effect was observed in these investigations because of the elevated pH conditions employed. In general, greater complexing activity is observed between the smaller guest molecules and both complexing agents, illustrating the importance of molecular size and structure in these interactions. Compounds known to be too large for complete inclusion, such as morphine and reserpine, are seen to interact with β-cyclodextrin. The presence of certain functional groups in these large molecules, capable of interacting with or of being partially included by the cyclodextrin, could be responsible for the observed interactions. The high-formation constants determined for some of the β-cyclodextrin interactions indicate the formation of extremely stable complexes. Pure inclusion is described as an association taking place without intermolecular bonding between the guest and host components. Although in aqueous solution, the net interactions could result from both inclusion and intermolecular forces, particularly hydrogen bonding.

Similarities in the shapes of solubility isotherms obtained for interactions of both deoxycholic acid and its sodium salt with several pharmaceutical compounds could indicate similar mechanisms for these two complexing agents. Even though sodium deoxycholate, an anionic surfactant, is currently thought to exert its solubility effects through micelle formation, the possibility of total or even partial inclusion formation by this agent cannot be ignored. Multislopes obtained in the solubility isotherms for many of the sodium deoxycholate interactions could indicate a complex mechanism consisting of both micellar solubilization and inclusion formation, or they might represent the presence of higher order complexes. The complexity of these interactions is clearly shown in the studies dealing with the reserpine–deoxycholic acid interaction in various alcoholic solutions.

Synthesis of *N*-Substituted Phenethylamines and Corresponding Cyclohexyl Analogs

Preliminary Evaluation as Bronchodilators

By JOHN B. DATA, MARTIN O. SKIBBE, T. LAMAR KERLEY, and LAWRENCE C. WEAVER

A series of *N*-substituted phenethylamines and their corresponding cyclohexyl analogs were prepared and tested pharmacologically for their effects on the duration of hexobarbital anesthesia in mice, and systemic blood pressure and bronchodilatory activity in dogs. Methods for the preparation of these compounds are described, and procedures used in pharmacological testing are indicated and the biological results tabulated. There were no consistent or appreciable bronchodilatory effects observed.

EPINEPHRINE (I) and isoproterenol (II) represent two potent and useful bronchodilators containing the catechol nucleus. Other structurally related substances which have been rated (1–3) as relatively potent bronchodilators are levarterenol (III), 3,4-dihydroxyephedrine (IV), and equine (V). A recently introduced adrenergic substance used in the management of bronchial asthma is the potent inhibitor, protokylol (VI).

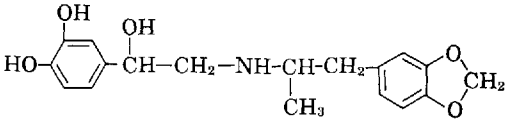
V

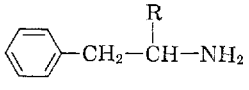


VI

These examples support the conclusion of Tainter and his co-workers (1, 2) and of Biel *et al.* (4) that the catechol nucleus appears to be essential for a high degree of bronchodilation efficiency.

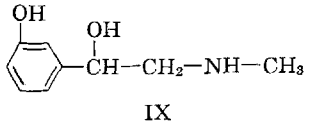
DISCUSSION

Mono-hydroxy and mono-methoxy derivatives of phenethylamine (VII) and 2-phenylisopropylamine (VIII) exhibit this same type of activity, although quantitatively not as great.

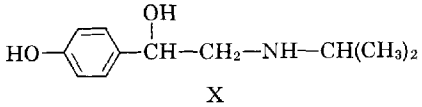


VII, R is H
VIII, R is CH_3

While phenylephrine (IX) has been reported as a fair (3) and a poor (2) bronchodilator, Konzett (5) reported that *p*-hydroxy-*α*-(isopropylaminomethyl)-benzyl alcohol (X) possesses marked activity; the corresponding *N*-methyl derivative is less active. Corrigan *et al.* reported (6) on the activity of additional hydroxy compounds in which the *N*-isopropyl group of X is replaced by other alkyl substituents. These in general were found to be active.

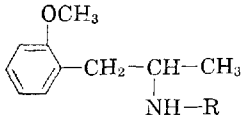


IX



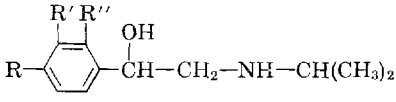
X

All possible mono-hydroxy derivatives of 2-phenyl-isopropylamine have been evaluated (7) for bronchial activity, but these isomers have shown no appreciable response; the corresponding mono-methoxy derivatives were tested by the same investigators, who concluded that the more active compounds were the methoxy derivatives. 2-(*o*-Methoxyphenyl)-isopropylamine (XI), the *N*-methyl, *N,N*-dimethyl, and *N*-benzyl derivatives have been shown (8) to possess a very high degree of specific bronchodilatory activity with little or no pressor effect. These latter studies may have been responsible for the introduction of the orally active and useful medicament, methoxyphenamine (XII).



XI, R is H
XII, R is CH_3

The quantitative difference in the ability of the hydroxyl and the methoxyl group to supply electrons to the conjugated ring system (9) suggests a means for correlating bronchial activity to chemical structure. The finding that isoprophenamine (XIII) is a potent bronchodilator (10) and, in addition has other physiological properties (11) qualitatively similar to methoxyphenamine, suggests that the chloro group, too, can be considered along with the hydroxyl and the methoxyl; while the chloro group is an electron withdrawing group, it can also release electrons to the conjugated ring system. This idea can be extended to include compounds which have two such groups as in the case of isoproterenol and dichloroisoproterenol (XIV), even though the latter is known to block the action of the former (12). While the exact role each group plays in broncho-



XIII, R is H; R′ is H; R″ is Cl
XIV, R is Cl; R′ is Cl; R″ is H

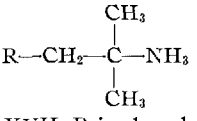
dilatory effect is unknown, the strength of the bond between the drug and receptor due to the magnitude of electron density in the phenyl ring because of the presence of these groups may be very important to explain and/or correlate the effect of a drug. Although from the standpoint of satisfying structural requirements for the same receptor site the chloro, the hydroxyl, or the methoxyl group may or may not be required, differences in pharmacological response may be due basically to difference in electron density created by these substituents. For example, isoproterenol and dichloroisoproterenol very likely possess the same structural requirements for the same *β*-receptor, even though the nature of the ring substituents are different. The difference in the ability of the chloro and the hydroxyl group to supply electrons to the phenyl ring would be evident in rates of release of the drug–receptor complex in a reversible reaction. Thus, the bond strength attributed to the difference in electron density can account, at least in part, for difference in pharmacological behavior of isoproterenol and dichloroisoproterenol. The reported pharmacology for these compounds bear out some of these points. For instance, Moran and Perkins (13) indicate that dichloroisoproterenol may be involved in an equilibrium type of blockade since the block can be reversed by excess of certain amines. Powell and Slater (14) report data which strongly support the

suggestion that the same β-receptors are involved, and they explain that the brief effects of isoproterenol are due to a rapid bio-transformation and/or weak bonding between drug and receptor; for dichloroisoproterenol they suggest the drug–receptor complex to be fairly stable.

Various types of substituents attached to the amino nitrogen have received considerable attention in the search for effective bronchodilators. Simple aliphatic groups from one to five carbons (4–6, 15–21), cycloalkyls (4, 15–17, 19), aralkyls (4, 18–20, 22), and cycloalkylalkyls (4) have been evaluated. The *N*-isopropyl derivative has been suggested for optimal activity in one series of compounds (16), and the *N*-butyl was found to be the most active in a second series (17). There does not appear to be any structural specificity for activity. These examples and the studies cited suffice to suggest that the kind of substitutions on the amino group is not crucial.

Effects of other substituents on the ethyl or isopropyl moiety of VII and VIII other than the amino group is not well documented. Studies designed to evaluate the importance of the hydroxyl group β to the amino are lacking. Seemingly, the literature records only three like pairs of compounds evaluated for their bronchial activity in which the β-OH group is the only variable. The first pair is epinephrine and equine; Pedden *et al.* (2) have rated these as excellent bronchodilators. The second pair is 2-phenylisopropylamine and α-(1-aminoethyl)benzyl alcohol (XV), which are reported (1) to act predominately as bronchoconstrictors, although Alles and Prinzmetal (23) reported slight bronchodilation for 2-phenylisopropylamine. The third pair is isoproterenol and *N*-isopropyl-3,4-dihydroxyphenethylamine (XVI); Siegmund *et al.* (21) indicate that the absence of a β-OH group in XVI causes very marked reduction in activity between this last pair of compounds. While these three pairs do not clearly indicate the effect of the β-OH group, Siegmund and his co-workers (21) concluded from their studies that the β-OH group is essential for bronchial activity.

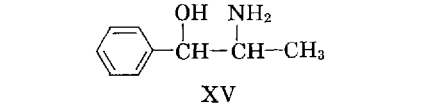
The lack of information on the effect of other substituents on the propyl moiety of 2-phenylisopropylamine prompted the authors to prepare and biologically evaluate as a matter of interest a series of *N*-substituted derivatives of α,α-dimethylphenethylamine (XVII) and their corresponding cyclohexyl derivatives (XVIII).



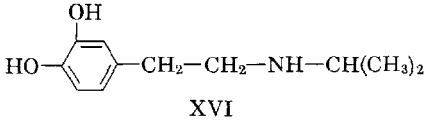
XVII, R is phenyl
XVIII, R is cyclohexyl

Except for α,α-dimethylphenethylamine (18) no one seems to have reported on the broncho-spastic relieving properties of these compounds. The only closely related study among the cyclohexylethylamines is the work of Lands *et al.* (24), who evaluated the spasmolytic activity of such compounds on isolated guinea pig ileum.

The α,α-dimethylphenethylamines and their corresponding cyclohexyl analogs were prepared by reducing with lithium aluminum hydride the formamides obtained by the Ritter reaction from 1,1-dimethyl-2-phenylethanol or its cyclohexyl analog and a nitrile as described under *Experimental.* (Scheme I.)



XV



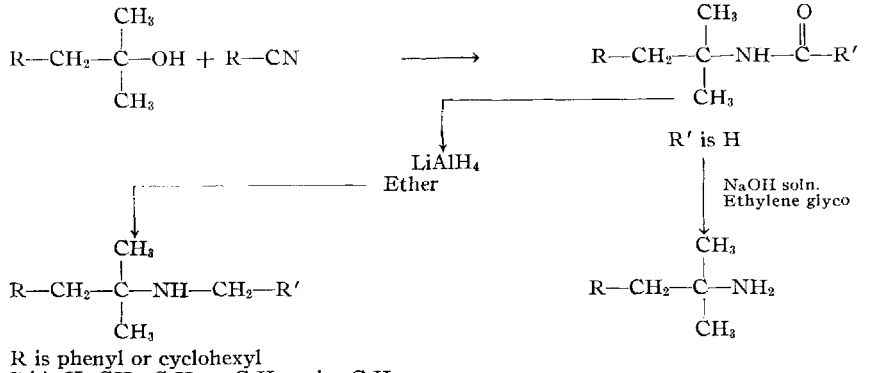
XVI

EXPERIMENTAL

All melting points are uncorrected. Chlorine was determined by the method of Blicke and Zienty (25), and the carbon and hydrogen analysis was performed by Galbraith Laboratories, Inc., Knoxville, Tenn. No attempt was made to improve yields obtained from the first trial.

Preparation of 1,1-Dimethyl-2-phenylethanol.—This product was prepared by the Grignard reaction for the synthesis of tertiary alcohols from esters.

Ethyl phenylacetate, 75.0 Gm. (0.455 mole), was added during 0.5 hr. to 600 ml. of an ethereal solution of methylmagnesium iodide prepared in the usual way from 24.3 Gm. (1.0 Gm. atom) of mag-



R is phenyl or cyclohexyl

Scheme I

nesium turnings and 150.0 Gm. (1.06 moles) of methyl iodide. The mixture was then refluxed for 3 hr., cooled, and poured onto about 300 Gm. of cracked ice, and then decomposed by the slow addition of 300 ml. of hydrochloric acid (10%). The organic layer was separated from the aqueous portion, which was then extracted 3 times with 100-ml. portions of ether. The combined ethereal extracts were washed successively with 100 ml. of sodium carbonate (5%) and 100 ml. of water. The ethereal solution was then dried over anhydrous potassium carbonate, filtered, the solvent removed under reduced pressure and the residue fractionated to give 59.2 Gm. (86.5%) of product distilling at 100–104° (14 mm.). [Reported (26) b.p. 103–105° (10 mm.).]

Preparation of 1,1-Dimethyl-2-cyclohexylethanol.—This product was prepared by the Grignard reaction for the preparation of tertiary alcohols from ketones.

The Grignard reagent was prepared in the usual fashion from 4.86 Gm. (0.2 Gm. atom) of magnesium and 35.4 Gm. (0.2 mole) of cyclohexylmethyl bromide dissolved in about 150 ml. of ether. To the reagent there was added during a period of about 0.5 hr. while stirring 11.6 Gm. (0.2 mole) of dry acetone in 50 ml. of ether. After 2 additional hr. of stirring and refluxing, the reaction mixture was hydrolyzed by the addition of about 100 Gm. of cracked ice and 75 ml. of hydrochloric acid (10%). The organic layer was separated from the aqueous portion, and the aqueous layer extracted 3 times with 30-ml. portions of ether. The ether extracts were then combined and washed successively with several 25-ml. portions of sodium carbonate (10%) and 25 ml. of water. The organic layer was dried with fused sodium sulfate, filtered, and fractionated. There was obtained 14.5 Gm. (46.5%) of a colorless oil distilling at 97–100° (16 mm.).

A second run twice as large gave 32.0 Gm. (51.2%) of product which distilled at 67–70° (2.2 mm.). The analytical sample distilled at 69° (2.2 mm.) and had a refractive index of 1.4650 at 20°.

Anal.—Calcd. for $C_{10}H_{20}O$: C, 76.92; H, 12.82. Found: C, 76.58; H, 12.60.

The alcohol gave a white, crystalline phenylurethan derivative which, when recrystallized 3 times from hexane, melted at 117–118°.

Anal.—Calcd. for $C_{17}H_{25}NO_2$: C, 74.18; H, 9.09. Found: C, 73.80; H, 9.09.

Preparation of 1,1-Dimethyl-2-cyclohexylethylamine (D-3-1)

N - (1,1 - Dimethyl - 2 - cyclohexylethyl)formamide.—This compound was prepared according to the method described by Ritter and Kalish (27) for the synthesis of *N-tert*-butylformamide.

Sodium cyanide, 19.6 Gm. (0.4 mole), and 50 ml. of glacial acetic acid was mixed with cooling and stirring. A solution of 100 Gm. of concentrated sulfuric acid in 50 ml. of glacial acetic acid was then added while continuing to stir the reaction mixture and maintaining the temperature at 20°. 1,1-Dimethyl-2-cyclohexylethanol, 62.4 Gm. (0.4 mole), was then added and the temperature permitted to rise spontaneously to 40–50°. The mixture was heated to 70° for 1 hr., stoppered, allowed to stand for 2 hr., diluted with 600 ml. of water, and neutralized with sodium carbonate. The formamide which separated as a viscous oil was extracted 3 times with 100-ml. portions of ether, dried over fused sodium sulfate, filtered, and the solvent removed under reduced pressure. The residue was fractionated to give 69.7 Gm. (95.5%) of product which distilled at 170–171° (15 mm.).

1,1 - Dimethyl - 2 - cyclohexylethylamine.—A mixture of 40.0 Gm. (1.0 mole) of sodium hydroxide in 60 ml. of water, 300 ml. of ethylene glycol, and

[a] −13/44 = biphasic systemic blood pressure response; 13% decrease for 1 min., followed by a 44% increase for 60-min. duration. [b] LD_{50} in mice is 95 mg./Kg. [c] Ratios for 5 mg./Kg. were 1.0 and 0.93, while 10 mg./Kg. gave 1.21 and 0.61.

70.0 Gm. (0.382 mole) of *N*-(1,1-dimethyl-2-cyclohexylethyl)formamide was refluxed for 36 hr. It was then cooled and extracted 3 times with 100-ml. portions of ether. The combined ether extracts were washed with 50 ml. of water, dried over potassium carbonate, and distilled. The yield of product which boiled at 92–93° (17 mm.) was 48.2 Gm. (81.2%).

The base was dissolved in anhydrous ether and converted into the hydrochloride salt with gaseous hydrogen chloride in the usual way. The salt which was soluble in the ether–hydrogen chloride solution was obtained by evaporating off the ether. The crude product was recrystallized several times from ethyl acetate to give a pure product melting at 152–153°. [Reported (28) m.p. 147–148°.]

Preparation of *N*-Substituted 1,1-Dimethylphenethylamines and *N*-Substituted 1,1-Dimethyl-2-cyclohexylethylamines

N - (1,1 - Dimethyl - 2 - phenylethyl)amides and N-(1,1-Dimethyl-2-cyclohexylethyl)amides.—These amides were prepared by a slight modification of the method described by Ritter and Kalish (27). All amides listed in Table I were synthesized by the following procedure.

To a solution of 10.0 Gm. (0.1 mole) of concentrated sulfuric acid in 50 ml. of glacial acetic acid maintained at about 20° there was added portionwise 0.11 mole of the appropriate nitrile. One-tenth mole of 1,1-dimethyl-2-phenylethanol or 1,1-dimethyl-2-cyclohexylethanol, depending upon which of the amides was to be prepared, was added slowly. The mixture was stirred mechanically while raising the temperature to 50°, then stirred without heat for 0.5 hr. longer, during which time the temperature rose spontaneously to 60–80° leading to complete solution of the alcohol. The mixture was allowed to stand for 8 hr. and then diluted with 300 ml. of water to precipitate an oil which after several hours solidified to a crystalline mass. The solid was broken up, filtered, washed with water, and then air dried.

The yield and melting points for each *N*-substituted amide are listed in Table I. All products were recrystallized from dilute ethyl alcohol (50%).

N-Substituted 1,1-Dimethylphenethylamines and N - Substituted 1,1 - Dimethyl - 2 - cyclohexylethylamines.—For the preparation of these compounds a modified procedure of the method used by Moffett (29) for synthesizing 2,2-dimethylpyrrolidine was employed. All amines listed in Table II were prepared by the following procedure.

To a mixture of 3.8 Gm. (0.1 mole) of pulverized lithium aluminum hydride and 75 ml. of anhydrous ether, which had been refluxed gently for 1/4 hr. was added a solution of 0.05 mole of the amide in 150 ml. of anhydrous ether at such a rate that the solution refluxed gently without any further external heating. When the addition was complete and the initial reaction subsided, the mixture was stirred and refluxed for 15 hr. The reaction mixture was allowed to cool, and then 5 ml. of ethyl acetate was added slowly with vigorous stirring and, finally 50 ml. of 6 *N* hydrochloric acid was added in the same manner. The mixture was then steam distilled several minutes after the boiling point reached 100° and the

distillate discarded. The mixture in the flask was cooled and to it was added carefully with stirring 35 ml. of 12 *N* sodium hydroxide solution. The alkaline mixture was then steam distilled until the distillate was no longer basic (about 600 ml.). The amine was extracted from the distillate with three 100-ml. portions of ether, the combined ethereal extracts dried over potassium carbonate, filtered, and the solvent removed *in vacuo*. The residue was then fractionated under reduced pressure.

The base was dissolved in anhydrous ether and then precipitated as the hydrochloride salt by passing anhydrous hydrogen chloride into the solution in the usual way.

The yield and boiling points of each *N*-substituted amide are listed in Table II. The melting point for each *N*-substituted amine hydrochloride is listed in the same table. All amine salts were recrystallized from ethyl acetate–ethanol as solvent.

PHARMACOLOGY

Comparative pharmacological studies were conducted on all of the amine hydrochlorides prepared. Their effects were observed on the duration of hexobarbital anesthesia in mice and systemic blood pressure and bronchodilatory activity in dogs.

Groups of 10 male, albino Swiss-Webster mice were pretreated subcutaneously with the test compound 2 hr. before the intraperitoneal administration of a dose of 100 mg./Kg. of sodium hexobarbital. The end point was taken as that time when the mouse moved from a supine position. Similar groups of control mice were tested simultaneously, and the results presented as a ratio of the average duration of anesthesia of test mice to control mice. A ratio of 1.0 indicates the results were the same for both groups: a value less than 1.0 suggests antagonism of hexobarbital anesthesia. In addition, these compounds were administered orally in increasing doses to determine the degree and type of toxicity produced. The results are recorded in Table III. All test compounds were orally active as indicated by the fact that they were all lethal when administered orally to mice. Only compound D-3-5 and D-3-7 produced appreciable alteration in the hexobarbital anesthesia of mice. In both cases it was a decrease probably indicating central nervous system stimulation.

Adult mongrel dogs, unselected as to sex, were employed in the cardiovascular and bronchodilator experiments. Anesthesia was maintained by the judicious use of sodium pentobarbital. Solutions of test compounds were freshly prepared and injected intravenously. The ability of these compounds to alter systemic blood pressure at a constant dose of 4 mg./Kg. was investigated in 2 or 3 dogs for each compound and the results averaged. Furthermore, the same dose was repeated at various intervals to determine whether tolerance developed to the blood pressure effects. These results are also presented in Table III. For the phenyl derivatives the first dose of *N*-methyl (D-3-2) and *N*-ethyl (D-3-4) produced a pressor effect that became negligible after subsequent doses; with progressively longer chain length, including *N*-propyl (D-3-6), *N*-butyl (D-3-8), and *N*-isobutyl (D-3-10), no pressor activity was found. Similarly, for the cyclohexyl derivatives the magnitude of the pressor effect decreased with an increase in chain length of the *N*-substituent and completely disappeared with *N*-butyl (D-3-9). For some unexplained reason it was again present at *N*-isobutyl (D-3-11). As was expected tachyphylaxis developed readily to the pressor effect. The vasopressor effect following tachyphylaxis was not influenced by atropinization of the dog or by a combination of atropinization and bilateral midcervical vagotomy.

Changes in bronchiolar resistance of dogs were recorded by a modification of the method of Konzett and Rossler (30). In brief, under constant volume respiration variations in bronchiolar resistance were indicated by changes in the volume of air in excess of that required for adequate ventilation. Histamine, 10 mcg./Kg., or carbachol, 1 to 4 mcg./Kg., administered intravenously, were used as the bronchoconstricting agents. The ability of the test compound to block this bronchoconstriction was determined following intravenous administration of 2 and 4 mg./Kg. doses of the test compound. No consistent or appreciable bronchodilatory effect was observed.

Stability and Flocculation of Oil Droplets in Dilute Emulsions

By HIROYUKI MIMA and NOBUYUKI KITAMORI

By using a Coulter counter, it was found that flocculation of oil droplets stabilized with acacia occurred even in dilute emulsions (8×10^{-3} to 10^{-4} vol. per cent oil). This phenomenon was reversible and the equilibrium in floc size distribution was attained rapidly, and the flocculation depended upon the concentration of oil droplets, the size distribution of primary droplets, and the amount of salts added. Since the rate of creaming depends upon the size of particles, the stability of emulsions is affected by the flocculation of emulsion droplets. The stability of emulsions in the presence of 0.1 per cent sodium chloride was measured quantitatively by measuring the fluorescence of anthracene dissolved in oil phase, and it is concluded from the experimental results that there is a distinct relationship between the floc-size and the stability of emulsions.

MANY STUDIES have been made on the stability of o/w emulsions. However, the previous methods to determine the stability, especially the rate of creaming, including measurement of the time elapsed to the beginning of creaming or the volume of the cream separated after a definite time, were not quantitative (1–5).

According to Stokes' law, it is known that the rate of creaming is affected by the size of particles, the difference between the gravities of oil phase and water phase, and the viscosity of water phase. The size of particles in emulsion depends

$$u = \frac{(P_1 - P_2)\, gd^2}{18\eta}$$

not only upon the size of primary droplets, but also upon the degree of flocculation of the primary droplets. As for suspensions, a study of the effect of suspensoid concentration on the degree of flocculation has been reported (6). However, no papers have yet dealt with the relationship between flocculation and concentration of oil in emulsions.

During the authors' studies on the applications of emulsions in the fields of pharmacy and foodstuff, it was observed that the creaming occurred rapidly in the original emulsions, which contained a high concentration of oil phase, while in the diluted emulsion, the rate of creaming was not so rapid. To clarify these phenomena, a Coulter counter was used to measure particle-size distribution of flocculated droplets (7, 8). From these experimental results, it was found that the more the emulsion was diluted, the more the modal diameter of the dispersed particles became smaller, and the ratio of the number of droplets per concentration of oil phase increased. These facts indicate that the deflocculation depends upon the concentration of oil in the emulsion, but all the emulsion droplets were deflocculated to primary ones in very diluted concentration, where there was no relation between flocculation degree and oil concentration.

In order to elucidate the relationship between flocculation of oil droplets and emulsion stability, the rate of change in concentration of oil at a fixed depth was also determined quantitatively as a function of time by measuring the fluorescence of anthracene which had been dissolved in the oil phase of emulsion.

From these results, it was shown that there was a distinct relationship between the floc-size measured with the Coulter counter and the stability of emulsions.

Received September 13, 1965, from the Technological Research Laboratories, Research and Development Division, Takeda Chemical Industries Ltd., Osaka, Japan.

Accepted for publication October 27, 1965.

The authors thank Dr. S. Tatsuoka, General Manager, Research and Development Division of Takeda Chemical Industries for permission to publish this work.

EXPERIMENTAL

Material.—Liquid paraffin, olive oil, and orange oil were all reagent grade materials. Ethyl dihydroabietate was synthesized from abietic acid by esterification and hydrogenation; b.p. 160–195°/0.2 mm. Hg, d_{20}^{20} 1.0269, n_D^{20} 1.5230, acid value 3.0.

Gum arabic was used as an emulsion stabilizer. Sodium chloride and anthracene were of special grade. Ether used for extraction of anthracene was freed from fluorescent impurities by passage through an alumina column.

Preparation of Emulsions.—Anthracene was dissolved in oils to give 0.2% (w/v) solutions. Ten grams of gum arabic was dissolved in 1 L. of distilled water under stirring with a homo-mixer (Type Tokusyu Kikai Kogyo Co.). Twenty milliliters of oil (containing anthracene) was then added and pre-emulsified for 2 min. This relatively coarse emulsification was then followed by passing through a Monton Gaulin homogenizer under about 4500 p.s.i. Size distribution of primary droplets of emulsions depended upon the pressure under which the emulsion was forced through the valve of homogenizer. In addition, viscosity of oils and number of times of homogenization had effects on the droplet size distribution of the resultant emulsions. The emulsions containing 2.0% oil phase by volume were used as the original emulsions.

Measurement of Size Distributions.—The method for measurement of droplet-size distribution of emulsions with the Coulter counter has been reported previously in detail (9). Our experiment followed this method. The aperture of 30 or 50 μ was used in accordance with the size of droplets. The threshold scale of the instrument was calibrated with polystyrene latex,[1] 0.769 and 1.305 μ in diameters. One-tenth per cent of saline was used as suspending medium. Since the floc-size distribution varied slightly with stirring, the measurement was carried out without stirring in this experiment. As the reproducible results were obtained with the same sample in the repeated measurements, it was thought that creaming did not occur during the measurement. The size distribution of emulsion was measured at various concentrations by diluting with 0.1% saline solution. Deflocculation was facilitated by dilution of emulsion, and at last the further dilution of emulsion resulted no longer in any change of the characteristic shape of the distribution curve. The size distribution of primary droplets was obtained at a diluted concentration under which the modal diameter of the distribution curve did not become smaller. The droplet size was also determined photomicroscopically. The floc-size distributions of emulsions were corrected according to the table of coincident passages supplied by Coulter Electronics, Inc. The modal diameters obtained from the floc-size distribution curves were used as the criterion of the degree of flocculation of droplets in emulsions.

With olive oil emulsion, the size distribution was measured at constant emulsion concentration (2×10^{-3}% oil) by diluting with varying salt concentration. The threshold scale of instrument was calibrated on every occasion of measurement.

Stability Measurement of Dilute Emulsions.—In these experiments, the concentration of oil phase of emulsion was 1×10^{-3} to 4×10^{-3}% and for this low concentration, a special method was necessary to determine the concentration of the oil in a small amount of samples collected from these emulsions. For example, when 1 ml. of a sample was collected, the amount of oil in the sample was only about 10^{-5} ml., which was too small to determine quantitatively with gas chromatography. For this reason, fluorescent analysis was used in order to determine the small amount of oil. The method is as follows:

The previously prepared stock emulsion containing anthracene was diluted to 1×10^{-3} to 8×10^{-3}% oil phase by volume with 0.1% saline solution. The diluted emulsions were allowed to stand in large glass cylinders (A) equipped with a small side orifice (B) closed by a rubber stopper (C) at the lower part of the cylinder. The vessel was about 9 cm. in diameter and about 60 cm. in height. The small orifice was fitted at the height of about 2 cm. from the bottom of the vessel. A long needle (D) was put into the vessel through a rubber stopper, and the tip of the needle was located at the center of the cylinder and just 2 cm. in height from the bottom (Fig. 1). Samples were easily collected through the needle at certain time intervals at the constant depth. Two milliliters of a sample emulsion was taken for one test, and the oil composition and the anthracene, of course, were extracted from the sample with 5 ml. of refined ether, and the fluorescent strength of this ethereal solution was measured with Aminco's spectrophotofluorometer at 404 mμ by activating at 252 mμ. The volume of the emulsion in the cylinder was 2.1 L., and the total volume of the collected samples was 20–25 ml., which is only about 1% of the whole volume of emulsion, and is negligibly small. It was found that the fluorescence of the extract remained constant within an error with the same sample, in which the concentration of oil remained constant at a certain depth, and also there was a linear relationship between anthracene concentration (parallel to oil concentration) and strength of fluorescence. However, the strength of fluorescence of anthracene in orange oil decreased with time. Therefore, in the case of orange oil, it was necessary to use controls that were equal in concentration to that of test emulsion and were shaken at certain intervals in order to prevent creaming. The difference in fluorescence between the test emulsion and the control was considered as the decrease of anthracene due to creaming.

RESULTS AND DISCUSSION

Floc-Size Distribution.—The floc-size distribution of olive oil, liquid paraffin, and orange oil emulsions at various concentrations measured with a Coulter counter are given in Figs. 2 and 3 and Table I. The droplet-size distributions are included in these figures. These figures clearly show that the peak of the floc-size distribution curve migrates to larger droplet size with increase in emulsion concentration, and to the contrary, with decrease in emulsion concentration, they shift to smaller size. Table I shows the total number particles counted by the Coulter counter at various oil concentrations. According to these data, particle number is not only parallel to oil concentration, but less than the number calculated from the numbers of primary droplets. The measured number

TABLE I.—TOTAL NUMBERS OF PARTICLES IN ORANGE OIL EMULSION AT VARIOUS CONCENTRATIONS MEASURED WITH A COULTER COUNTER (IN 0.1% SODIUM CHLORIDE SOLUTION)

Emulsion Concn. ($\times 10^{-3}$%)	No. of Particles in 0.05 ml.	Relative No.	Relative No./ Emulsion Concn.
8.0	61,500	1.000	1.00
4.0	58,000	0.943	1.89
2.0	48,500	0.789	3.16
1.0	49,000	0.797	6.38

of particles approached to the calculated number with dilution. At a very dilute concentration, for example, in 1×10^{-3}% orange oil emulsion, the characteristic shape of the distribution curve did not change, and only the peak height of curve decreased according to the concentration after dilution. At this concentration, the size distribution curve was regarded as that of primary droplets in emulsions. These size distributions were in good agreement with the photomicroscopic observation. It may be reasonable to explain these phenomena as the deflocculation of flocculated emulsion by dilution. The scheme of these phenomena is illustrated in Fig. 4.; *i.e.*, in concentrated emulsion, which represents 4×10^{-3} to 8×10^{-3}% of orange oil emulsion in Fig. 2, the flocculation occurred highly; in medium concentrated emulsion, which represents 2×10^{-3}% in Fig. 2, the flocculation is not so high, and in diluted emulsion which has 1×10^{-3}% of orange oil, the particles were separated to primary ones. Thus, determination of size distribution with a Coulter counter confirmed the presence of flocs in emulsion. In the previous studies of flocculation and deflocculation of oil droplets in soap-stabilized emulsions (2, 7), the rate of creaming of emulsion or cream volume after a definite time period has been taken as the criterion of flocculation. In addition, microscopic observation and turbidity measurement have been made for studies of flocculation. In comparison with these methods, a Coulter counter method is excellent for the determination of floc-size, as it makes it possible to measure more exact floc-size distribution than that obtained by the previous methods. However, this method is not suitable for the investigation of the effect of surfactant only on flocculation, as an electrolyte solution must be employed as a medium in the measurement.

In the present work, the flocculation of emulsion droplets stabilized with acacia (which was one of the strong anticoalescent agents) in 0.1% saline was investigated. Here only the effect of oil phase concentration on flocculation of droplets in the same kind of emulsion and the same salt concentration was studied.

Because the rate of flocculation seems to be rapid and 20–30 min. were necessary for a determination of the distribution curve, the rate of flocculation could not be determined with this method. Therefore, the determination of the distribution curve was carried out after 5–10 min. of dilution of emulsion.

According to Smoluckowski's theory of coagulation kinetics (10, 11), the time required for the droplets to collide by Brownian motion is a function of the Boltzman constant, the temperature, the viscosity of the continuous phase, and the number of primary droplets. The time required for the flocculation of these emulsion droplets (about 0.6–0.7 μ, 8×10^{-3} to 10^{-4}%) was not more than 10 min. The numbers measured at various concentrations with the Coulter counter (N) were regarded as the total numbers of flocs in emulsion and the numbers

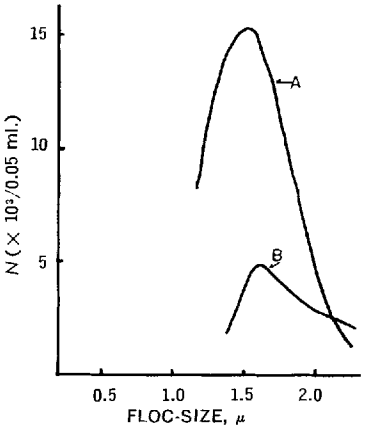

Fig. 6.—Floc-size distribution curves of 2×10^{-3}% olive oil emulsion in different salt concentrations. Key: A, in 1% NaCl solution; B, in 0.1% NaCl solution.

of primary droplets (N_0) which constituted the flocs were calculated from the total numbers of droplets measured in very diluted concentration, where the droplets did not form any flocs. The relation between N/N_0 and N_0 obtained with ethyl dihydroabietate emulsion in 1% saline is given in Fig. 5. The curve in Fig. 5 shows the relation similar to that of Smoluckowski's theory of coagulation. From these results, it is concluded that the flocculation is attributed to the collision of droplets, and the flocculation is reversible so that the equilibrium is attained rapidly after dilution.

In these cases, the flocculation of emulsion droplets was demonstrated in 0.1% saline solution. As pointed out earlier (12), it can be considered that the flocculation was affected by the concentration of salt. Actually, as shown in Fig. 6, the numbers of smaller particles in 1% NaCl solution were more than those in 0.1% NaCl solution at constant emulsion concentration.

Emulsion Stability.—Figures 7–10 illustrate the emulsion stabilities at various concentrations of olive oil, liquid paraffin, orange oil, and ethyl dihydroabietate emulsions. The changes in oil concentration of emulsion at fixed position upon standing indicate the floating or settling of oil droplets in emulsion at a certain rate.

The floating or settling rate depends mainly upon the size and the density difference between oils and media, and upon Brownian motion in small droplet size range. Actually, with ethyl dihydroabietate emulsions, oil concentration at the lower position of the test cylinder inclined to increase, because its density is slightly larger than that of water (Fig. 10), while with other emulsions oil concentration inclined to decrease. As shown in

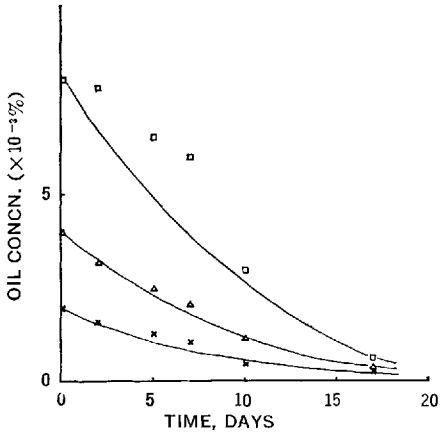

Fig. 7.—Stability of olive oil emulsion as reflected in changes with time of the concentration of the oil phase near the bottom of the test vessel. The 3 plots correspond to 3 different initial concentrations.

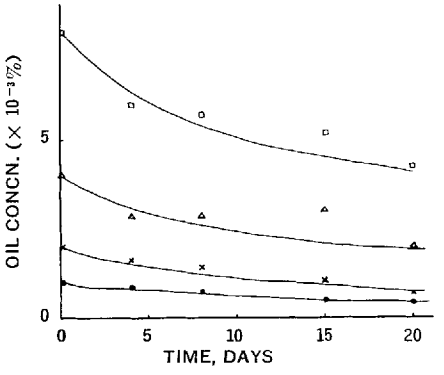

Fig. 8.—Stability of liquid paraffin emulsion.

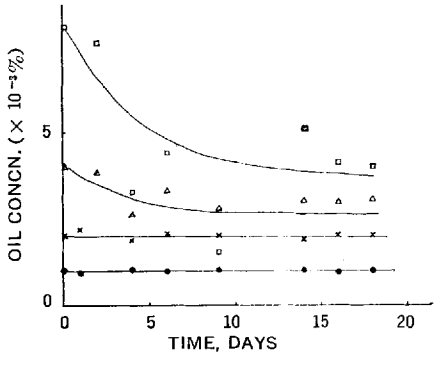

Fig. 9.—Stability of orange oil emulsion.

Figs. 8 and 9, the rates of decrease in oil concentration were initially rapid, gradually became slower, and attained to equilibria. The rate of decrease of concentrated emulsion is much more than that of diluted one, but the stability curve of the olive oil emulsion illustrated in Fig. 7 is slightly different from that of Figs. 8 and 9. In the very diluted emulsion of any oil, floating or settling of droplets does not occur, and therefore oil concentration remains constant. Even if droplets in emulsion float equally at any concentration, it follows that the rates of decrease in oil concentration of more concentrated emulsion are larger than those of more dilute emulsions. Therefore, the rate of creaming must be compared by using the specific rate of decrease in oil concentration, $1/c\ (dc/dt)$, where c is oil concentration at time t at a constant depth.

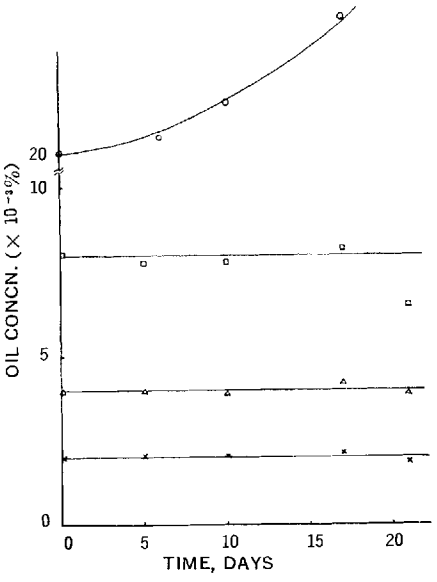

Fig. 10.—Stability of ethyl dihydroabietate emulsion.

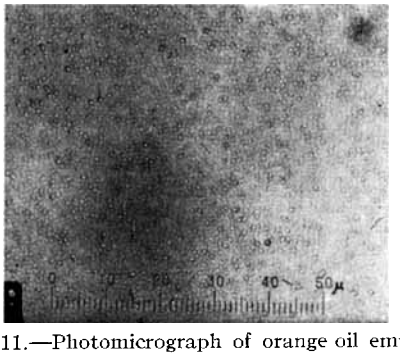

Fig. 11.—Photomicrograph of orange oil emulsion.

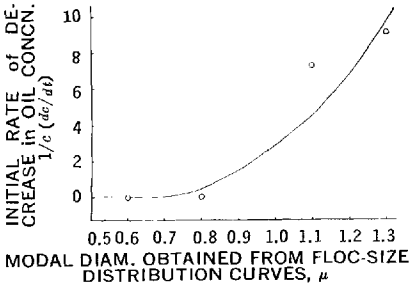

Fig. 12.—Relation between stability and floc-size in orange oil emulsion.

Relation between Flocculation and Stability of Emulsions.—Creaming of emulsions is the phenomenon that occurs in consequence of separation of oil droplets due to the density difference between the dispersed and continuous phases. Hence, the rate of creaming depends upon the density difference, the size of particles, and others according to Stokes' law. If the flocculation occurs in emulsion, a flocculated particle behaves as a larger droplet, although primary droplets were small. As shown in Figs. 2 and 3, the droplet size of the primary particles of emulsions prepared in this laboratory was about 0.6–0.7 μ and this was confirmed with photomicrograph (Fig. 11), in which none of the larger droplets were contained. From the data of the emulsion stability and the floc-size distribution measured with the Coulter counter, the relation between them may be concluded as follows.

For smaller droplets, a continuous random zig-zag motion called Brownian motion was expected to account for the stability against creaming; while, in the concentrated emulsion, Brownian motion of droplets affects the growth of flocs, and the larger flocs float according to Stokes' law. The relation between flocculation and emulsion stability of orange oil emulsion is given in Fig. 12. The modal diameter of floc-size measured with the Coulter counter was used as the size of flocs, and the specific rate of decrease in oil concentration was used as the measure of emulsion stability. The stability decreased rapidly with the increase of floc-size above a certain size. Below this size, creaming did not occur to any extent and emulsion was stable.

Specific Activity of Trypsin

By ROBERT C. PETERSON

Trypsin has been fractionated electrophoretically on cellulose acetate into four zones. The lead zone, which contains the tryptic activity, was treated with specific substrate for enzyme activity and with the Lowry test for protein content. Specific activity of pure trypsin appears to be slightly greater than 8000 N.F. u./mg. Unexpected interference from commercial cellulose acetate was found with the protein test; this was reduced to a practical level. The phenomenon of tailing of protein in electrophoresis was studied.

THE ELECTROPHORETIC heterogeneity of commonly available trypsin is well established (1–13). Investigations in this laboratory on the purity of trypsin suggested the desirability of a simplified method for determining specific activity which could be applied to micro amounts of this enzyme and with slight modification to other enzymes. Electrophoresis on cellulose acetate combined with colorimetry offers such a method.

Earlier work included attempts at quantitative elution from cellulose acetate. It was found that the tryptic activity remaining on the cellulose acetate could be followed with the assay of Schwert and Takenaka (14) using the specific substrate benzoyl arginine ethyl ester (BAEE). From this it was decided that a method for specific activity might be derived from a combined direct determination of protein and tryptic activity in the electrophoretically fractionated zones while on the cellulose acetate. This article reports (*a*) the fractionation of trypsin by cellulose acetate electrophoresis, (*b*) determination of the amount of protein and tryptic activity in the isolated enzyme zone, and (*c*) a calculation of specific activity for the enzyme isolated under these conditions.

Previous similar work includes the extraction or elution of chromatographically or electrophoretically produced zones followed by reaction and measurement (9, 13, 15, 16), the production of color on the strip followed by extraction and measurement (15, 17–21), and direct reaction of the substance in the separated zone without a preceding or following elution (22–27).

Considering the difficulty of total elution, the time needed, and the viability of enzymes, direct test-tube reactions of the excised zones seemed more practical. While fluorigenic substrates (25) or the ninhydrin reaction for amino acids (22–24, 26, 27) have been used in this fashion, the author is not aware of a combination of similar tests being used to determine the specific activity of an enzyme.

Received August 30, 1965, from the Analytical Research Department, Eli Lilly and Co., Indianapolis, Ind.
Accepted for publication October 25, 1965.
The author expresses his gratitude to Mr. Max M. Marsh for guidance and encouragement, to Mr. Robert Beck and Mrs. Ruby Smith of these laboratories for technical assistance, and to Dr. Edward Grinnan, Glandular Products Development Laboratories, Eli Lilly and Co., for the sample of trypsin.

METHODS AND MATERIALS

The standard for all determinations was N.F. trypsin, lot 6040, 3226 N.F. u./mg. (28).

Electrophoresis was carried out in a greatly modified, horizontal cell.[1] Rigidity of components was provided, and evaporation was controlled by supplying inner and outer seals, a slotted inner plate, and by filling air spaces with Lucite blocks and sponges.

Cellulose acetate[2] was selected as the supporting medium. Several brands were tried, and in no case was sufficient precision of mobility found among several strips on a single run for quantitative purposes. Excellent precision was acquired on a single strip, however, by spotting 2 zones at the origin, 0.5 in. from either edge on a 5-cm. wide strip and using one half (a longitudinal cut) as a guide. (See Fig. 1.) The guide strip was dyed for 1 min. when tryptic activity was to be determined; a longer time was permissible when protein was determined. The dye solution was 0.1% Ponceau S in 5% trichloroacetic acid.

Some investigators found that the electrophoretic heterogeneity of trypsin depended to some extent upon the presence of calcium or other ions (2, 4–7, 9) while others did not (11, 13). The greater stability of trypsin in the presence of calcium ions and at an acid pH is well known (29–32). With this in mind, it was decided to use calcium ions in the assay but not during electrophoresis. The buffer was formic acid–pyridine–water/15 of 90%: 2.5: 982.5 by vol., pH 2.65. The strips were prerun 15 min. with reversed polarity before application of sample. The runs were for 3 hr. at room temperature and about 7.8 v./cm. For determination of tryptic activity, the wet strips were used within 1 min. after removal from the chamber; for protein determination, the strips were air dried.

Protein was determined with the Lowry (33) modification of the Folin-Ciocalteu (34) reagent using phenol reagent prepared in this laboratory according to Folin-Ciocalteu (34). The phenol reagent was tested for optimal dilution according to Oyama and Eagle (35), and their Lowry reagent modifications were used. In practice, the protein zone on the cellulose acetate was cut out and placed in a test tube. To this was added 0.5 ml. of water and 2.5 ml. of Lowry's reagent C, and the preparation was allowed to stand exactly 10 min. with frequent agita-

tion. Folin reagent at the proper dilution, 0.25 ml., was jetted in by syringe and immediately mixed. The tubes were agitated frequently, and the absorption was determined at 1 hr. at 750 mμ with a spectrophotometer.[3] The reference solution was prepared similarly from a blank piece of cellulose acetate cut from the same strip immediately next to the test zone. Early inability to gain precision of results with the Lowry test when trypsin was spotted or electrophoresed on cellulose acetate was found to be due, in great part, to the presence of material in the cellulose acetate, as received, which gave a Lowry-positive test. From experience, it was found that an overnight soak in 0.01 *N* HCl followed by 2 rinses in fresh 0.01 *N* HCl and 2 rinses in deionized water would reduce this Lowry-positive material to usable values.

The Lowry test as described in this report was applied to 5 different lots (strips received at different times were considered different lots) of the cellulose acetate. One strip from each lot was used. Each strip was divided in half; equal sections from each half, with and without the special wash, were submitted to the Lowry test. The results are in Table I. All strips used for the Lowry test in this report were washed as above before being placed in the proper buffer. The contaminant has not been identified.

With each series of protein determinations, freshly dissolved trypsin in water and L-tyrosine[4] [stored in 0.2 *N* HCl, 0.5% by vol. in 37% formaldehyde (36)] were run as standards to assure stability of the Folin reagent.

Benzoyl-DL-arginine-*p*-nitroanilide (BAPA)[4] was

used as the chromogenic substrate for tryptic activity (37–39). The substrate solution consisted of 100 mg. of BAPA dissolved in 20 ml. of redistilled dimethylsulfoxide and diluted to 100 ml. with pH 8, 0.1 *M* Tris buffer, 0.005 *M* in $CaCl_2 \cdot 2H_2O$. Five milliliters was used for each test; the reaction was carried out for 15 min. at 37° and stopped with 1 ml. of 30% acetic acid. Absorption was measured at 410 mμ *versus* a reference solution containing acetic acid as inhibitor.

RESULTS AND DISCUSSION

Determination of Protein.—The Lowry test was applied to the determination of protein (trypsin) which had been spotted on cellulose acetate under conditions appropriate for, but without, electrophoresis. The linear relationship between absorption values and amounts of protein is shown in Fig. 2. The span of values indicated at each point on the curve is ±1 standard error. Trypsin (30 mcg.) and L-tyrosine (15 mcg.), in solution, were brought through the Lowry test as standards simultaneously with the above series. The daily integrity of the Folin reagent and the test is indicated by the 7 absorbance averages and their standard deviations (trypsin, $\bar{x} = 0.361$, % coefficient of variation = ±1.4; L-tyrosine, $\bar{x} = 0.467$, % coefficient of variation = ±0.8). The plot in Fig. 2 provides a standard for determination of protein in

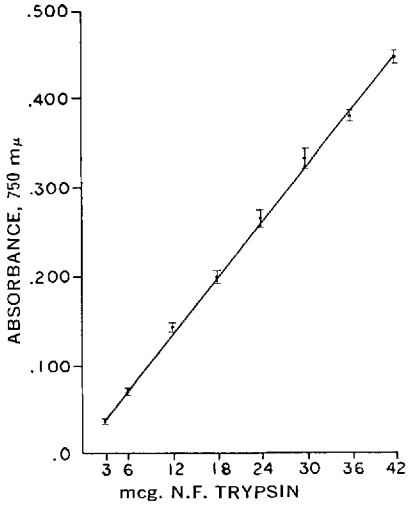

Fig. 2.—Lowry test for protein (trypsin) spotted on cellulose acetate.

the trypsin zone resolved by electrophoresis. Since the Lowry test varies with different proteins, such a curve would have to be constructed for each protein for which such a quantitative procedure would be established.

By incubating the various electrophoresed zones with gelatin, the main part of the tryptic activity was found in the leading zone. Very small amounts of tryptic activity were found all along the strip from the leading zone to the origin; this tailing will be clarified later in this report.

The Lowry test was applied to the lead zone after electrophoresis of varying amounts of N.F. trypsin. For determination of specific activity, only one level is needed, but it was of interest to determine its applicability over the range generally used in cellulose acetate electrophoresis. With the electrophoresis procedure as described, three 5 × 25.4-cm. strips were electrophoresed at one time and used for a single assay. The same amount of enzyme was spotted in duplicate on each strip. A longitudinally cut half served as guide—either after brief dyeing or after partial drying during which the protein zones became opaque and visible. By the latter method a fourth zone can be seen which Ponceau S is too insensitive to stain. Three electrophoretic runs (3 assays) were averaged to give the value at one level of application. Table II gives these values. At the 3-mcg. level there is insufficient protein in the lead zone for application of the test, and, in addition, it can be seen that not until about 18 mcg. is applied is a constant percentage of the applied protein found in the lead zone. This results from the tailing of trypsin activity with a certain saturation of the attracting sites on the cellulose acetate. A plot of applied trypsin against Lowry test absorption from the lead zone is given in Fig. 3. Linearity is found in the range of 18–42 mcg. applied trypsin.

TABLE II.—LOWRY PROTEIN DETERMINATION OF LEAD ZONE AFTER ELECTROPHORESIS OF N.F. TRYPSIN

[a] From standard curve of N.F. trypsin spotted on cellulose acetate.

As with the Lowry tests on trypsin spotted on cellulose acetate, the tests on each level of electrophoresed trypsin were accompanied by standards of trypsin and L-tyrosine. The average absorption values were 0.360 for trypsin (compared to 0.361 before) and 0.465 for L-tyrosine (compared to 0.467 before). The Folin reagent and method have been stable during the course of this work.

Determination of Tryptic Activity.—The chromogenic (BAPA) assay was applied to the determination of enzyme or tryptic activity in zones when various amounts were spotted on cellulose acetate.[2]

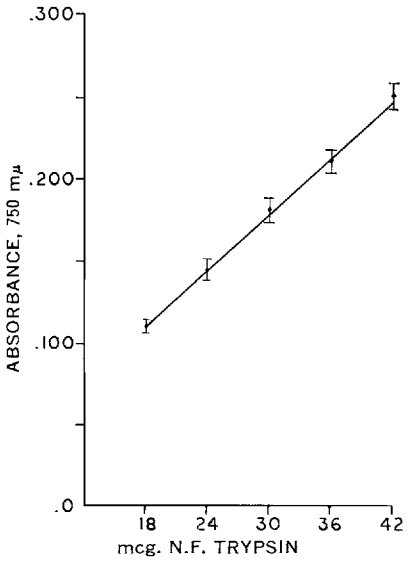

Fig. 3.—Lowry test for protein (trypsin) applied to lead zone (tryptic activity) after electrophoresis. Data are from Table II.

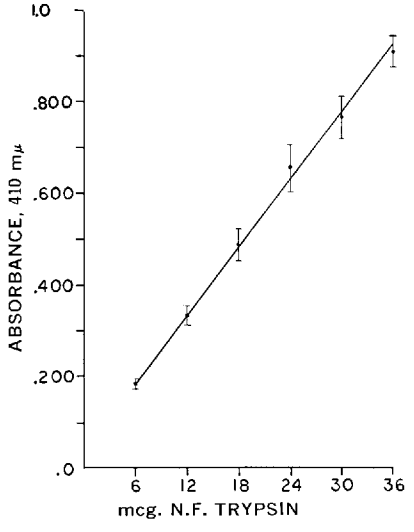

Fig. 4.—BAPA assay of tryptic activity in zones when N.F. trypsin is spotted in various amounts on cellulose acetate.

The cellulose acetate was prepared as for electrophoresis before application. As soon as the applied zone had soaked in, it was cut out and dropped into the reaction solution. Equal-size zones were cut according to a pattern (1 in. wide and 1.5 in. long with length of strip; these corresponded to the enzyme-zone size for the Lowry test), and the time of cutting was staggered every 1 min. A straight line can be drawn to relate the amount of enzyme applied and the average absorption value (Fig. 4).

The BAPA assay was applied to a quantitative study of tailing after electrophoresis of 30 mcg. of N.F. trypsin. The entire pattern of the wet strip was sectioned into 10 equal parts using a dyed guide strip and cardboard template to insure uniformity of zone size. Three electrophoretic runs gave the

average values listed in Table III. The range of absorption values for the lead zone was 0.707–0.720. The average total absorption of all sections was 0.812 with a range of 0.809–0.817. Reasonable agreement of results from application of the BAPA assay to spotted enzyme and to electrophoresed enzyme is indicated by the total absorption values at the 30 mcg. level, 0.763 and 0.812, respectively. N.F. trypsin was used as an indicator of the integrity of BAPA substrate. Ten micrograms in 1 μl. of buffer solution was treated simultaneously with the trypsin zones on cellulose acetate. Indicator values ranged from 0.448 to 0.510 with an average of 0.477; the substrate was satisfactory during the tests. The use of an indicator is necessary since BAPA is not stable indefinitely, even under refrigeration.

TABLE III.—STUDY OF TAILING OF N.F. TRYPSIN DURING ELECTROPHORESIS ON CELLULOSE ACETATE BY MEANS OF BAPA ASSAY

Acetate Section	A, 410 mμ (Tryptic Activity)							
	1,2[a]	3	4	5	6	7	8	9	10
	.712	.031	.018	.012	.009	.009	.008	.007	.006

[a] The absorption values for two equal sections were combined to give the lead zone value.

Since the enzyme activity does not coincide with the dyed protein zones (other than the lead zone), but decreases gradually toward the origin, this is tailing, and zones other than the lead zone do not have trypsin activity. This type of study could be applied to many supporting media in chromatography and electrophoresis in order to determine the influence of the medium on pattern formation.

Determination of Specific Activity.—Following electrophoresis of 30 mcg. of enzyme, the protein in the lead zone was determined with the Lowry test, and the percentage of applied enzyme found in this zone was determined with BAPA. From an assay of N.F. u./mg. of enzyme before electrophoresis the total amount of applied enzyme in N.F. units was determined. The assay values in N.F. u./mg. for these samples before electrophoresis are: *A*, 3226; *B*, 3615; *C*, 3095; *D*, 3565. (See Table IV for coding.) An assumption is made at this point, that since linear plots of concentration *versus* absorbance are obtained with both enzyme assays, a constant ratio exists between the two assays. It is realized that some variation might exist because of a difference in reaction of the N.F. trypsin and the more pure trypsin in the electrophoretic zone, but this is considered to be insignificant. Since in all cases the BAPA assay showed that 87–88% of the applied activity was found in the lead zone, a multiplication of the initial assay in N.F. u./mcg. by the 30 mcg. applied and the per cent recovered, gives the total amount of enzyme found in the lead zone as N.F. units. These totals are found in the second column of Table IV. The specific activity in the lead zone was calculated from these totals and from the totals of protein found in this zone. It appears from these data that the absolute specific activity of pure trypsin is above 8000 N.F. u./mg. The variation in specific activity may be due to the presence of varying amounts of denatured trypsin. All samples were stored as solids under refrigeration, but it has been our experience that occasional degradation is found even under these conditions. It should be pointed out that these samples had been refrigerated for varied amounts of time.

Substrate Specificity with Palladium-on-Silica Gel Catalysts

By ROBERT L. BEAMER and W. WENDELL LAWSON

Hydrogenation studies using palladium deposited upon silica gels prepared in the presence of various alkaloids indicate substrate selectivity. The selectivity appears analogous to that observed with enzymes (biocatalysts).

PADGETT and Beamer (1) have demonstrated the stereospecific hydrogenations of α-methylcinnamic acid catalyzed by palladium deposited upon silica gels precipitated in the presence of various cinchona alkaloids. That similarly prepared silica gels possess adsorption specificity has been demonstrated by Dickey (2) and Haldeman and Emmett (3). Beckett and co-workers (4) have shown stereoselective absorption on gels prepared in the presence of various alkaloids.

The present work is concerned with extending the hydrogenation studies of Padgett and Beamer (1) to include substrates in addition to α-methylcinnamic acid and silica gel carriers prepared in the presence, not only of cinchona alkaloids, but a modification of the cinchona alkaloidal structure (quinene). Studies using gels prepared in the presence of strychnine and brucine also were made.

EXPERIMENTAL

Reagents.—α-Methylcinnamic acid (K and K Laboratories), quinine sulfate N.F., quinidine sulfate U.S.P., cinchonine sulfate U.S.P. IX, cinchonidine sulfate U.S.P. X, strychnine sulfate N.F., brucine (Nutritional Biochemicals Corp.), propiophenone (Eastman Organic Chemicals), and ethylphenyl carbinol C.P. (Columbia Organic Chemicals).

Quinene.—Confusion exists in the literature concerning the melting point of quinene which reportedly melts indefinitely between 67 and 90° (5).

Comstock and Koenigs (6) first prepared quinene in 1884 and reported a melting point of 81–82° for the dihydrate. Giemsa and Halberkann (7) also prepared quinene but reported a melting point of 67°. The compound then resolidified and remelted from 90–91°. Both papers describe the preparation of quinene by dehydrohalogenations of 9-chloro-9-deoxyquinene using alcoholic potassium hydroxide, but differ in their methods of isolation.

The isolation described by Comstock and Koenigs proceeded through the zinc chloride–hydrochloric acid double salt (6). Giemsa and Halberkann crystallized quinene from a 50% acetone–water solution without prior conversion to the zinc chloride–hydrochloric acid double salt (7).

The discrepancy in melting points possibly could arise from the different isolation procedures. Therefore, we chose to isolate quinene by both procedures and to compare the products as to melting point, infrared spectra, and optical rotation.

Quinene was prepared by dehydrohalogenation of 9-chloro-9-deoxyquinine as described by both Koenigs and Giemsa. The product was isolated by use of each of the described procedures (6, 7) and compared as to yield, melting point, infrared spectra, and optical rotation. The infrared spectra were obtained in chloroform solution using a Perkin-Elmer Infracord model 137 spectrophotometer and were identical for the products of each separation. The specific rotation values were obtained using a Rhudolph spectropolarimeter model 200. The data for the yields, melting points, and specific rotations are summarized in Table I. A mixed melting point of the two products produced no depression.

The authors also prepared quinene by starting with 9-chloro-9-deoxyquinidine. The product of this reaction was identical with that prepared from 9-chloro-9-deoxyquinine. These results are in accord with those reported by Koenigs (8).

9-Chloro-9-deoxyquinine.—Preparation of this compound followed the procedure of Pouwels and Veldstra (9) which involves the replacement of the hydroxy group of quinine by chlorine through thionyl chloride.

9-Chloro-9-deoxyquinidine.—This compound was prepared according to the thionyl chloride procedure of Pouwels and Veldstra (9).

Propiophenone Oxime.—Thirty grams of hydroxylamine hydrochloride were added to 33.5 Gm. of propiophenone in 150 ml. of pyridine and 150 ml. of absolute alcohol. The mixture was refluxed 24 hr. Following the reaction period, the mixture was concentrated *in vacuo* with a rotary evaporator and left stoppered in the hood for 3 days, during which time white crystals formed.

The crystals were collected by filtration and

TABLE I.—COMPARISON OF QUINENE BY DIFFERENT ISOLATION METHODS

Method	Yield, Gm.	% Yield[a]	M.p.[b]	Specific Rotation[c]
Comstock-Koenigs	3.67[d]	39.7	76–80°	+48.93[e]
Giemsa-Halberkann	3.40[d]	36.8	75–78°	+45.98[e]

[a] Based on 9-chloro-9-deoxyquinine and on quinene dihydrate (5). [b] Uncorrected. [c] In 95% alcohol using the dihydrate (C = 1.776 Gm./ml.), temperature = 20°, wavelength = 589 mμ, length of tube was 200 mm. [d] Starting with 9.4 Gm. of 9-chloro-9-deoxyquinine. [e] The literature value for the dihydrate was unavailable.

Received July 26, 1965, from the School of Pharmacy, University of South Carolina, Columbia.
Accepted for publication October 25, 1965.
Presented to the Scientific Section, A.PH.A., Detroit meeting, March 1965.
This work was supported in part by grant GM-12109-01 from the U. S. Public Health Service, Bethesda, Md.

washed with a small amount of water. The filtrate was concentrated further on the rotary evaporator and cooled in a refrigerator. The additional crystals were collected by filtration, washed with water, and recrystallized from ethanol and water. The weight of the product after recrystallization was 23.0 Gm., representing a yield of 62% of theory. The crystals melted from 52–55°. [Reported (10) m.p. 53°.]

Preparation of Carriers.—The silica gel carriers were prepared by the procedure of Padgett and Beamer (1). The silica gels were precipitated from an aqueous sodium silicate solution using a solution of the alkaloid in 5.7 *N* hydrochloric acid. The gel was dried under a current of air in a fume hood, and the alkaloid was removed by washing with methanol in a Soxhlet extractor.

Hydrogenation Studies.—The catalysts were prepared by the method of Hartung (11) using 100 mg. of palladous chloride per gram of gel and sodium acetate as a buffer. Hydrogenations were performed using 0.05-mole substrate in absolute ethanol on a low-pressure Parr hydrogenation apparatus at an initial pressure of 4.2 Kg./sq. cm. and using initially 1.0 Gm. of catalyst. Heating was accomplished with an infrared heat lamp. After 24 hr., an additional 1.0 Gm. of catalyst was introduced, and the hydrogenation continued for another 8 hr. for a total reduction time of 32 hr. The reaction period of 32 hr. was used in all experiments and was based on the time required for reduction of 0.05 mole of α-methylcinnamic acid (1). No kinetic studies were attempted because of the abnormally long reduction period and the lack of an adequate temperature control.

Following hydrogenation, the catalyst was removed by filtration, and the alcohol evaporated at room temperature.

Infrared Studies.—Infrared spectra of α-methylcinnamic acid, propiophenone, and quinene were determined in chloroform using a Perkin-Elmer model 137 Infracord spectrophotometer. The concentrations of the solutions were 10%. The spectra of α-methylcinnamic acid and dihydro-α-methylcinnamic acid were also determined as 5% solutions.

Infrared spectra of mixtures of varying proportions of α-methylcinnamic acid and dihydro-α-methylcinnamic acid were determined and their absorptions *versus* concentrations were plotted at 910 and 1625 cm.$^{-1}$.

The same degree of absorption at 1710 cm.$^{-1}$ (carboxyl group) was obtained with the spectra of each of the mixtures. Following evaporation of solvent, the infrared absorptions of the hydrogenation mixtures were determined at 910, 1625, and 1710 cm.$^{-1}$, and estimations of composition were made.

Gas Chromatographic Studies.—These determinations were made using a Beckman G.C.-2A gas chromatograph. The column was composed of silicone 550, 50% on C-22 firebrick (42/60 mesh). The column length was 6 ft. The instrument was equipped with a Bausch & Lomb Vom 7 recorder and a thermal conductivity detector.

The studies were made at a column temperature of 160° and with a flow rate of 60 ml./min. Helium was used as the carrier gas. The sample size was 0.005 ml. and was introduced using a Beckman 22400 liquid sampler.

RESULTS

When substrates other than α-methylcinnamic acid are employed with palladium-on-quinine silica gel catalysts, a lowered reactivity or a lack of reactivity was noted. These results are summarized in Table II.

TABLE II.—HYDROGENATIONS WITH PALLADIUM-ON-QUININE SILICA GEL

Group	Compd. Employed	% Yield
		81.1
		0.0 (With alc. HCl) 15.6 (No. alc. HCl)
		0.0

It should be noted that of the substrates employed, only α-methylcinnamic acid and propiophenone oxime in the absence of alcoholic hydrogen chloride gave a detectable yield. A lack of reaction was determined by no significant fall in hydrogen pressure and isolation within experimental error of all the starting material.

The absence of hydrogen chloride from the propiophenone oxime reduction introduced the possibility of secondary amine formation. So far, no secondary amine has been detected by infrared spectroscopy.

Vapor phase chromatography produced only two peaks having retention times of 52 sec. and 18 min., respectively. The peak at 52 sec. was identified as the solvent, ethanol. The peak at 18 min. was identified as 1-phenyl-1-propyl amine. Treatment with benzenesulfonyl chloride followed by sodium hydroxide indicated only primary amine.

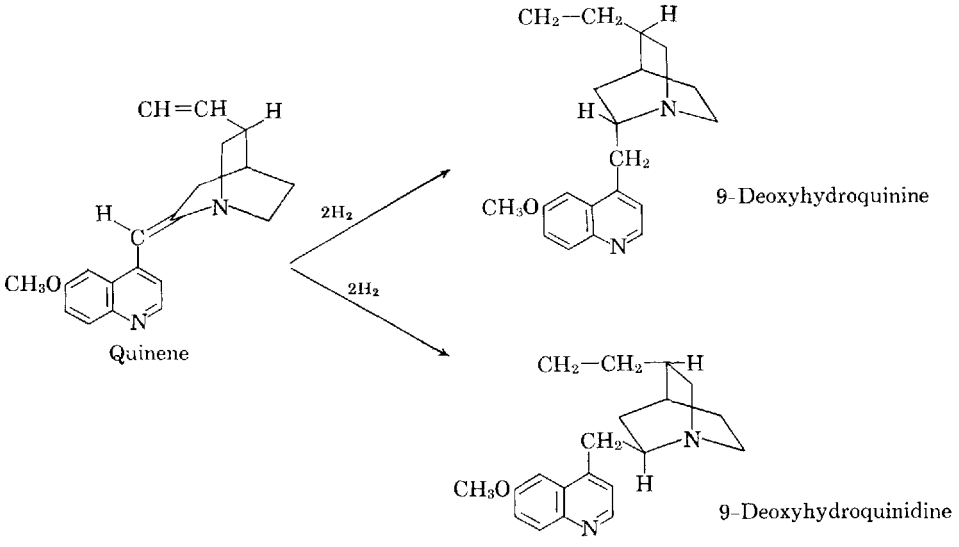
That only starting material was isolated from the attempted reduction of propiophenone was shown by infrared spectroscopy and gas chromatography and a comparison with known propiophenone. The possible hydrogenation products, ethylphenyl carbinol or *n*-propylbenzene (12), could not be detected by infrared spectroscopy or vapor phase chromatography.

The choice of quinene as a substrate for hydrogenation with palladized quinine silica gel as the catalyst was made because of its structural similarities to quinine.

The complete reduction of quinene is shown in Scheme I and leads to either dihydro-9-deoxyquinine or dihydro-9-deoxyquinidine. It was hoped that a stereoselective carrier would direct the reduction to one of the possible diastereoisomers.

Thus far, only quinene has been isolated from the reaction mixture. However, partial reduction could also lead to 9-deoxyquinine, 9-deoxyquinidine, or dihydroquinene. The authors are currently using other isolation techniques to attempt isolation of any of the possible products.

In view of the substrate selectivity with the



Hydrogenation of Quinene

Scheme I

palladium-on-quinine silica gel catalyst, varying the catalysts while employing the same substrate should give further information concerning the substrate selectivity of these catalysts. The results of these experiments are summarized in Table III.

TABLE III.—HYDROGENATIONS OF α-METHYLCINNAMIC ACID USING PALLADIUM-ON-SILICA GELS

Carriers	% Yield (After 32 hr.)
QN 0.5 SG[a]	81.1
QDN 0.5 SG	68.0
CN 0.5 SG	77.1
CDN 0.5 SG	87.9
Strych. SG	00.0
Brucine SG	00.0
Quinene SG	00.0
Plain SG	44.3

[a] Quinine silica gel which was prepared using 0.5 Gm. of quinine sulfate in the gel preparation. QDN = quinidine sulfate; CN = cinchonine sulfate; CDN = cinchonidine sulfate.

Only the catalysts prepared with the plain gel and the cinchona gels, with the exception of quinene, afforded reduction with α-methylcinnamic acid. Attempted hydrogenations employing catalysts prepared in the presence of strychnine, brucine, or quinene showed no indication of reduction after 32 hr. of hydrogenation and all of the unreacted α-methylcinnamic acid could be accounted for following the hydrogenation period.

However, the presence of large amounts of the starting material, α-methylcinnamic acid, can interfere with the isolation of dihydro-α-methylcinnamic acid by vacuum distillation (1). Therefore, we were never certain that where we have indicated no reduction that such was entirely the case. In other words, reduction too slight to be noted by a fall in the hydrogen gauge pressure might have occurred. Infrared spectra were determined with both α-methylcinnamic acid and D,L-dihydro-α-methylcinnamic acid. These spectra are shown in Figs. 1 and 2, respectively. The following absorption peaks are applicable to this work.

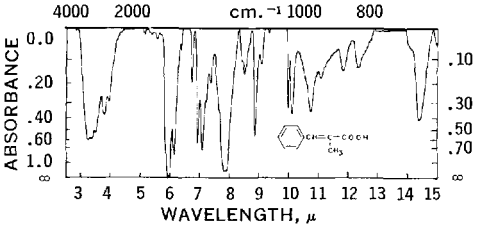


Fig. 1.—Infrared spectrum of α-methylcinnamic acid.

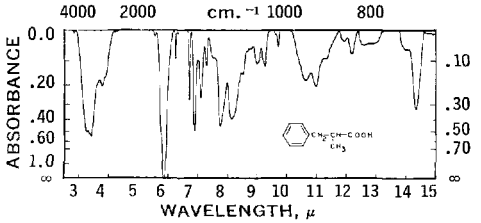

Fig. 2.—Infrared spectrum of D,L-dihydro-α-methylcinnamic acid.

α-methylcinnamic acid (Fig. 1):

(a) —COOH absorption at 1710 cm.$^{-1}$

(b) $>C=C<$ absorption at 1625 cm.$^{-1}$

(c) $>C=C<$ absorption at 930 cm.$^{-1}$

D,L-dihydro-α-methylcinnamic acid (Fig. 2):

(a) COOH absorption at 1710 cm.$^{-1}$

(b) disappearance of  absorption at 1625 cm.$^{-1}$

(c) disappearance of  absorption at 930 cm.$^{-1}$

(d) appearance of  absorption at 910 cm.$^{-1}$

The absorption of mixtures of varying proportions of α-methylcinnamic acid and D,L-dihydro-α-methylcinnamic acid were plotted at 1625, 930, and 910 cm.$^{-1}$, as described earlier in this report. In each case a straight line was obtained. However, the plots at 910 and 1625 cm.$^{-1}$ were best applied to the determination of α-methylcinnamic acid and D,L-dihydro-α-methylcinnamic acid, and these are shown in Fig. 3. Use of these plots and the absorption at 1710 cm.$^{-1}$ (COOH) indicates the reaction mixture from the strychnine gel catalyst was 93% α-methylcinnamic acid and 7% dihydro-α-methylcinnamic acid.

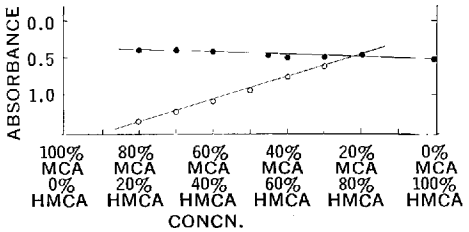

Fig. 3.—Plots of mixtures containing varying proportions of α-methylcinnamic acid and D,L-dihydro-α-methylcinnamic acid (HMCA). Key: ●, plot at 910 cm.$^{-1}$; ○, plot at 1625 cm.$^{-1}$.

DISCUSSION

The data indicate that the substrate selectivity observed with palladium-on-silica gel catalysts is similar to that observed with enzymes.

Beckett and co-workers have attributed the stereospecific adsorption of alkaloids by cinchona and other alkaloidal silica gels to imprints left on the gel surface by the alkaloid present during the precipitation of the gel (4). Likewise, the substrate selectivity of palladium-on-silica gel catalysts must arise from imprints left on the catalytic surface. The nature of these imprints is not known but may arise from some charge distribution on the surface of the adsorbent.

Such an explanation necessitates the presence of catalytic centers or sites similar to those proposed to explain enzyme specificity (1, 13–15).

According to Beckett's hypothesis, quinene should have been hydrogenated to a greater extent than α-methylcinnamic acid. That such is not the case could arise from steric hindrance (16, 17).

Another explanation for the substrate selectivity of α-methylcinnamic acid over quinene involves the nature of the silica gel surface as influenced by the cinchona alkaloids. This hypothesis supposes the gel surface to be of basic character, thus attracting the carboxylic acid. The incorrectness of this explanation is indicated by the results with the brucine and strychnine, the reduction of propiophenone oxime in the absence of alcoholic hydrogen chloride, and by Beckett's observations (4).

Therefore, the most probable explanation appears to involve active sites of proper size, shape, and charge distribution to accommodate the substrate molecules. These sites are imprinted on the carrier surface by the alkaloid. That α-methylcinnamic acid is not hydrogenated by the catalysts prepared from the brucine and strychnine gels can be explained by sites of improper size, shape, and charge distribution to accommodate the substrate molecules. This does not preclude the possibility of other substrates being hydrogenated by palladized strychnine or brucine gels.

Before definite answers concerning the nature and extent of the substrate selectivity of these catalysts can be obtained, studies must be made employing other substrates and carriers.

SUMMARY

Hydrogenations using palladium-on-quinine silica gel and various substrates indicate a degree of substrate selectivity by this catalyst. Substrate specificity also was shown in studies using α-methylcinnamic acid as a substrate and palladium deposited on various alkaloidal gels as catalysts. The selectivity may be explained by imprints left on the carrier surface by the alkaloid.

Biological-Chemical Indicator for Ethylene Oxide Sterilization

By JOHN H. BREWER and RUSSELL J. ARNSBERGER

The use of a biological-chemical indicator for ethylene oxide sterilization of disposable medical and pharmaceutical materials is reported. The indicator system affords an immediate visible indication of gas penetration into the materials during the sterilization cycle and also serves as a biological (spore) control. Preparation of the indicator is discussed in some detail, including the organisms and chemicals employed and the basic chemical reactions. The usefulness of the indicator for determination of gas penetration is discussed in terms of diffusion of the gas and permeability of the materials, including latex and plastic films.

A NUMBER of indicators have been suggested for use with ethylene oxide. For the most part these depend on a pH change or other type of chemical reaction, and some attempt has been made to have these indicate time as well as the presence of ethylene oxide. Since moisture content and other factors have a great deal to do with the efficiency of gas sterilization, the most satisfactory indicator of sterilization is the use of positive spore controls. These have the disadvantage that one must wait for the required incubation before reading the results.

In the sterilization of many of the disposable medical and pharmaceutical materials such as gloves, syringes, transfusion, and infusion sets, it is of the utmost importance to determine whether the gas is reaching the intricate spaces within these items and sterilizing them. As pointed out by Rubbo and Gardner (1), this is particularly true of such items as syringes with rubber plungers which might have two or more ribs in contact with the glass or plastic barrel.

If one depended on pressure alone to get the gas into these spaces, then this pressure would be too great to be reached by most gas-sterilization processes. One must also take into consideration the diffusion characteristics of the materials employed, and this makes a visual indicator quite valuable. Most of the chemical indicators are so sensitive that a very small amount of gas might cause a color change and yet not be sufficient to kill any bacterial spores present. For this reason the authors have sought an indicator system that combined both a chemical indicator, which did not depend on a pH change alone, and bacterial spores.

CHEMICAL INDICATOR

The compound 4-(4-nitrobenzyl) pyridine[1] has been described as a sensitive reagent for the determination of alkylating agents (2, 3). This reagent reacts with ethylene oxide to form a methine dye which is blue in an alkaline medium. (Scheme I.) The mechanism in the reaction of the reagent with an alkylating agent has been reported (4).

4-(4-Nitrobenzyl) pyridine has been used in this laboratory as an ethylene oxide indicator in solution, dried on filter paper, and adsorbed on silica gel. It has been found useful to indicate ethylene oxide permeability of latex and plastic films, ethylene oxide retention of plastics and elastomers, and as an exposure indicator for ethylene oxide sterilization.

The indicator paper is prepared by first dipping Whatman No. 1 filter paper in a 2% aqueous solution of sodium carbonate. After drying, the paper is dipped in a 2% solution of the indicator reagent in acetone. The indicator paper thus formed can then be cut into convenient-sized strips and inoculated with bacterial spores.

Indicator strips prepared as described will turn blue within a few seconds when exposed to the vapors of pure ethylene oxide. The same strips have been exposed to sterilization gas mixtures of ethylene oxide and carbon dioxide in ratios of 10:90 and 20:80, and it was observed that as long as the strip remained in the mixed-gas atmosphere the color did not change. Furthermore, if the strip was sealed in a permeable plastic container which would retain some residual gas mixture after removal from the sterilizer, no color change would occur. However, when the paper was removed to the air after exposure, the blue color would develop. This effect was explained by the fact that carbon dioxide prevented the reaction product from assuming the alkaline form until the CO_2 was diffused from the paper.

EXPERIMENTAL

In order to determine ethylene oxide penetration to the area between the plunger-stopper rings of both glass and plastic syringes, indicator strips were cut to size and inserted in this area. (Fig. 1.) The assembled syringes were placed in a glass desiccator; the desiccator was evacuated to approximately 25 in. of mercury and ethylene oxide admitted to a concentration of approximately 1000 mg./L. No color change of the strips in the syringes was noted until after about 1.5 hr. of exposure. After this time, a faint blue color was noted, which continued to darken. After 3 hr. of exposure, the syringes were removed from the desiccator. For the next 24 hr. the indicator strips continued to darken to a deep blue.

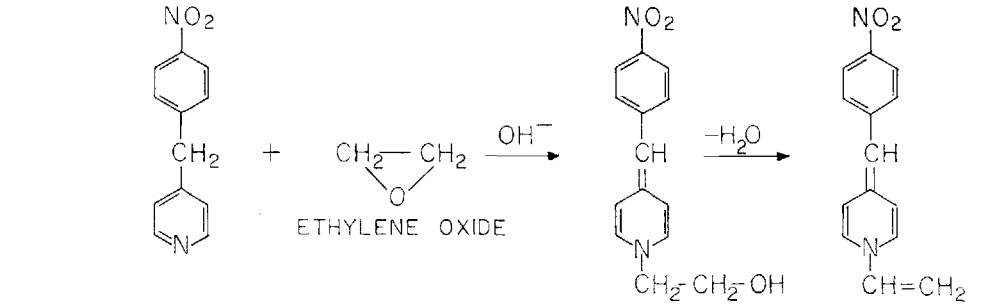
It appeared from the above experiment that dif-

Received September 3, 1965, from the Department of Biological Safety and Control, Becton, Dickinson and Co., Rutherford, N. J., and the Baltimore Biological Laboratory, Baltimore, Md.

Accepted for publication October 14, 1965.

[1] The authors acknowledge the suggestion of Dr. David N. Kramer, Army Chemical Center, Md., that we investigate this compound as an indicator.

The cost of the preparation of the color picture which appears in this article has been borne by the authors.



Scheme I

fusion of ethylene oxide gas through to the area between the syringe stopper rings is slow; however, the gas will eventually penetrate to this area and in sufficient concentration to kill the control organisms. There was also an indication that ethylene oxide continues to diffuse from the stopper for a period of time after the syringes are removed from a sterilizer. To investigate these observations further, syringes were assembled with 5 stoppers and indicator strips in each barrel and exposed as in the previous experiment. When the syringes were removed from the desiccator after 3 hr. of exposure, the strips in the 2 outer stoppers were blue and the 3 inner stoppers were white. Twenty-four hours after the syringes were removed, the strips in the stoppers next to the outer stoppers had turned blue and the center strip remained white; 36 hr. after exposure, the center strip had turned blue. These are exaggerated laboratory tests, since no syringe has over 1 rubber plunger.

This might indicate that the gas remains in the rubber or within the syringe, tubing sets, or other items, and might possibly contaminate drugs being administered to the patient. To prove this is not the case, gas chromatographs are run to show that all the gas has diffused out within the 10-day quarantine period and is further demonstrated by the toxicity tests which are run on each lot.

BIOLOGICAL INDICATOR

As spore controls we have employed both *Bacillus stearothermophilus* and *Bacillus globigii*. For our

Fig. 1.—Sterilized and unsterilized ethylene oxide indicators and controls.

purposes we have found the thermophilic organism much more satisfactory. One is not likely to encounter this type of organism as a laboratory contaminant in the sterility test, thereby causing a false positive reaction. This would necessitate the retesting of the load and delay production.

A very important consideration in the selection of the chemical indicator was to make sure that it did not inhibit the growth of the control organisms. Bacteriostatic-type tests were made using diluted spore suspensions with the paper strips, both before and after exposure to the sterilizing gas. No inhibition was noted and controls from small inocula grew quite luxuriantly in the test media.

The spores used to inoculate the indicator strips were prepared by suspending washed spores of *B. stearothermophilus* in distilled water containing 1% sorbitol. The suspension was standardized to approximately 5 million spores per ml. Spore counts were determined by appropriate dilution of the suspension and plating on trypticase soy agar. Plates were incubated at 60° for 24 hr. Paper strips were inoculated with 0.02 ml. of the suspension or approximately 100,000 spores. After sterilization, strips were transferred to fluid thioglycollate medium and incubated at 60° for 7 days to determine survival of spores. Control tubes containing indicator strips, both before and after exposure to ethylene oxide and inoculated with diluted spore suspension, showed no inhibition of the control organism.

APPLICATION

In commercial lots, dye-spore strips with 100,000 spores are prepared in a size to fit the item being sterilized. They have been prepared in sizes similar to the commercially available spore strips[2] for use in the index finger and in the cuff of rubber gloves, since it is felt that these are the most difficult places for the gas to reach in this item. These controls in the index finger change color, and the organisms are killed even if a knot is tied in the wrist part of the glove, indicating adequate penetration. In the sterilization of commercial lots of gloves,[3] the use of these indicators throughout the sterilizer load give assurance that the entire lot has been sterilized.

Pharmacokinetic Model for Nalidixic Acid in Man I

Kinetic Pathways for Hydroxynalidixic Acid

By G. A. PORTMANN, E. W. MCCHESNEY, H. STANDER, and W. E. MOORE

A model which includes the parameters of absorption, metabolism, and excretion of hydroxynalidixic acid (HNA) is presented. Individual rate constants for the absorption and disappearance of HNA in 5 subjects were determined. Theoretical plasma-level curves based upon these constants were calculated, and good agreement with the experimental data was obtained. Rate constants for glucuronide formation, oxidation, and excretion of HNA were calculated.

HYDROXYNALIDIXIC acid (1-ethyl-1, 4-dihydro-7-hydroxymethyl-4-oxo-1, 8-naphthyridine-3-carboxylic acid) is 1 of 4 metabolites of nalidixic acid[1] formed in man. It has been isolated and shown to have an *in vitro* antibacterial spectrum similar to that of nalidixic acid (1). The other 3 metabolites, all of which have not shown biological activity, are nalidixic acid glucuronide, hydroxynalidixic acid glucuronide, and the 3,7-dicarboxylic acid.

A previous article by the authors (2) described a simplified working model which permitted calculation of the apparent kinetics of the biologically active and inactive forms of nalidixic acid as separate groups.

Because nalidixic acid has been found to be clinically effective in the treatment of Gram-negative infections (3, 4), more definitive studies of its pharmacokinetics have been continued. These experiments would also illustrate the mechanisms which enabled the simplified model to describe absorption and elimination parameters.

In order to describe the complete pharmacokinetic profile of nalidixic acid, it is necessary to quantitate all the rate processes, including those occurring after its oxidation to the 7-hydroxy derivative. This article deals with a study of the absorption, metabolism, and excretion of hy-

purposes we have found the thermophilic organism much more satisfactory. One is not likely to encounter this type of organism as a laboratory contaminant in the sterility test, thereby causing a false positive reaction. This would necessitate the retesting of the load and delay production.

A very important consideration in the selection of the chemical indicator was to make sure that it did not inhibit the growth of the control organisms. Bacteriostatic-type tests were made using diluted spore suspensions with the paper strips, both before and after exposure to the sterilizing gas. No inhibition was noted and controls from small inocula grew quite luxuriantly in the test media.

The spores used to inoculate the indicator strips were prepared by suspending washed spores of *B. stearothermophilus* in distilled water containing 1% sorbitol. The suspension was standardized to approximately 5 million spores per ml. Spore counts were determined by appropriate dilution of the suspension and plating on trypticase soy agar. Plates were incubated at 60° for 24 hr. Paper strips were inoculated with 0.02 ml. of the suspension or approximately 100,000 spores. After sterilization, strips were transferred to fluid thioglycollate medium and incubated at 60° for 7 days to determine survival of spores. Control tubes containing indicator strips, both before and after exposure to ethylene oxide and inoculated with diluted spore suspension, showed no inhibition of the control organism.

APPLICATION

In commercial lots, dye-spore strips with 100,000 spores are prepared in a size to fit the item being sterilized. They have been prepared in sizes similar to the commercially available spore strips[2] for use in the index finger and in the cuff of rubber gloves, since it is felt that these are the most difficult places for the gas to reach in this item. These controls in the index finger change color, and the organisms are killed even if a knot is tied in the wrist part of the glove, indicating adequate penetration. In the sterilization of commercial lots of gloves,[3] the use of these indicators throughout the sterilizer load give assurance that the entire lot has been sterilized.

Kinetic pathways of hydroxynalidixic acid in man; k_A = availability rate constant; k_{M_i} = metabolic rate constants; k_{E_2} and k_{U_i} = excretion rate constants. Designations for the rate constants subnumber are those used in the larger model for nalidixic acid (7).

Scheme I

droxynalidixic acid, gives basic information about the compound, and [as will be illustrated (7)] permits a detailed description of the pharmacokinetics of nalidixic acid.

THEORETICAL

The work of McChesney and co-workers (1) leads to the model depicted in Scheme I. This represents the present knowledge of the kinetic pathways for hydroxynalidixic acid in man.

Equations describing the change of each component in Scheme I with respect to time were derived assuming total absorption and first-order rate processes. The total urine recovery was found to be 98.3 ± 2.9% (±S.E.), indicating complete absorption of the drug in every case. Those equations that were used in the present study are listed below. Lag time is defined as the time interval between ingestion of the dosage form and the appearance of hydroxynalidixic acid in the plasma. A_0 is equal to the administered dose since complete absorption occurs. Time (t) is measured after the lag time interval. The disappearance rate constant (k_{d_2}) for hydroxynalidixic acid is taken as the sum of $k_{E_2} + k_{M_3} + k_{M_4}$. The availability rate constant (k_A) from the gastrointestinal tract encompasses many factors, including motility, dissolution rate, and the intrinsic absorption rate.

$$[\text{HNA-B}] = \frac{k_A A_0}{(k_A - k_{d_2})}\left(e^{-k_{d_2}t} - e^{-k_A t}\right) \quad \text{(Eq. 1)}$$

$$k_{E_2} = \frac{k_{d_2}\,[\text{HNA-U}]_\infty}{A_0} \quad \text{(Eq. 2)}$$

$$k_{M_4} = \frac{k_{d_2}\,[\text{HNAG-U}]_\infty}{A_0} \quad \text{(Eq. 3)}$$

$$k_{M_4} = \frac{k_{d_2}\,[\text{DA-U}]_\infty}{A_0} \quad \text{(Eq. 4)}$$

EXPERIMENTAL

Medication and Sampling Protocol.—The sodium salt of HNA was given in hard gelatin capsules

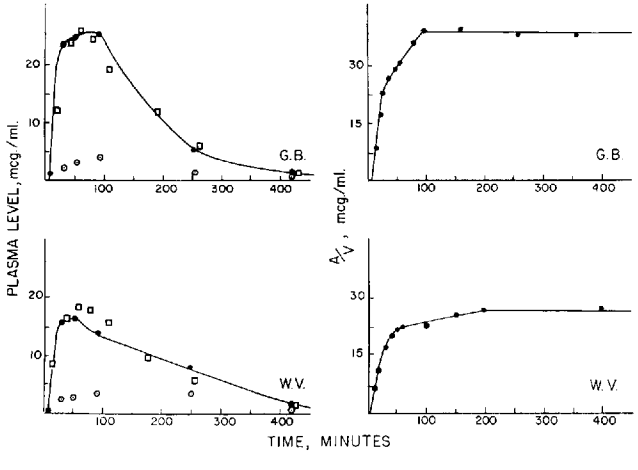

Fig. 1.—Plasma levels and A/V as a function of time. Key: ●, hydroxynalidixic acid; ⊙, hydroxynalidixic acid glucuronide; □, calculated values for hydroxynalidixic acid. Initials identify subjects.

(equivalent to 500 mg. of the acid per capsule) to 5 healthy subjects in a 1-Gm. dose (2 capsules) after overnight fasting. Food, but not water, was withheld until 3 hr. postmedication. Blood samples were taken after 0, 10, 30, 50, 90, 250, and 420 min. after drug administration. Urine collections were made at 0, 8, 24, and 48 hr. after administration of the drug. Plasma and urine concentrations of HNA and HNAG were determined in each sample using a previously published method (1). DA also was determined in the urine samples as previously described (1).

METHODS OF CALCULATION

The rates of availability of HNA to the plasma were determined by the method of Wagner and Nelson (5). Typical plots of A/V values are shown in Fig. 1 and represent the cumulative amount absorbed/apparent volume of distribution as a function of time. Individual disappearance rate constant values (k_{d_2}) were obtained from semilogarithmic plots of plasma hydroxynalidixic acid *versus* time. These rate constants multiplied by the cumulative area under experimental plasma level curves (Fig. 1) at different times, plus the plasma level at each time, gives A/V as defined by

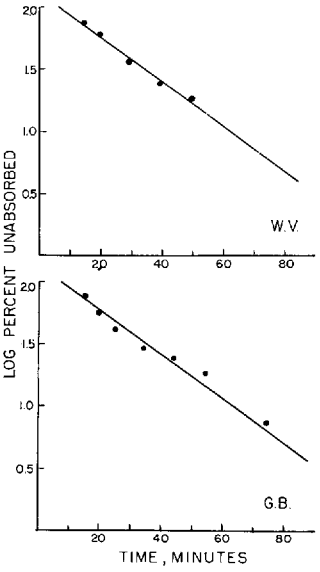

Fig. 2.—Log per cent hydroxynalidixic acid unabsorbed as a function of time. Initials identify subjects.

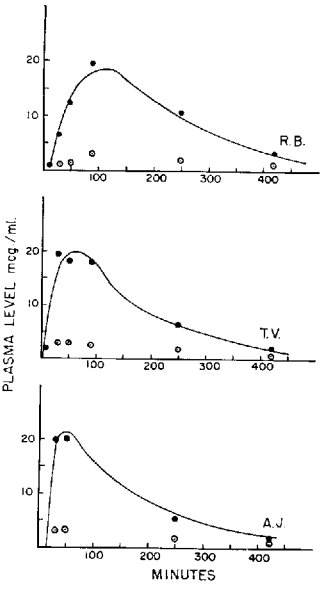

Fig. 3.—Plasma levels as a function of time. Key: ●, experimental hydroxynalidixic acid; ⊙, experimental hydroxynalidixic acid glucuronide; —, calculated curves for hydroxynalidixic acid. Initials identify subjects.

Wagner and Nelson. With these values, the per cent of the drug unabsorbed at different times was calculated. Availability rate and lag time were determined from graphs of log per cent unabsorbed as a function of time as shown in Fig. 2 and as listed in Table I.

Individual values for the excretion rate constant (k_{E_2}) and metabolic rate constants (k_{M_3} and k_{M_4}) were calculated using Eqs. 2, 3, and 4. It was found, as expected, that the 0–48 hr. urinary excretion amounts would represent infinity values for HNA-U, HNAG-U, and DA-U.

From $[A/V]_\infty$ values, the apparent volumes of distribution were calculated and are expressed in Table I as a percentage of body weight.

RESULTS AND DISCUSSION

Theoretical curves of HNA plasma levels *versus* time were calculated using Eq. 1 and the individual parameters. In order to obtain concentration values, HNA-B was divided by the individual's apparent volume of distribution. Excellent agreement was obtained between the theoretical plasma level values based on the model and the experimental values as shown in Figs. 1 and 3. This indicates that small deviations from the first-order rate process (*e.g.*, Fig. 2, G.B.) as measured from the experimental curve are not of great significance.

TABLE I.—KINETIC PARAMETERS FOR SODIUM HYDROXYNALIDIXATE

Subject	% Urinary Recovery	Lag Time, min.	k_A (min.$^{-1}$) × 10^3	k_{d_2} (min.$^{-1}$) × 10^3	k_{E_2} (min.$^{-1}$) × 10^3	k_{M_3} (min.$^{-1}$) × 10^3	k_{M_4} (min.$^{-1}$) × 10^3	Apparent Vol. of Distribution as % of Body Wt.
A.J.	105	13	70	7.37	1.44	4.30	1.99	45.9

[a] Incomplete urine collections.

The short lag time of 8 ± 1.5 min. (±S.E.) shows the rapid appearance of the drug in the plasma. That the drug is also rapidly absorbed is apparent from the high values for k_A. Sodium salts of acidic drugs usually have fast dissolution rates (6), and in the case of nalidixic acid (NA), the sodium salt had a shorter lag time and greater availability rate than the acid in capsule form (2). The mean lag time of 8 min. for the sodium salt of HNA (Table I) is very similar to the previously reported mean lag time of 3 min. for the sodium salt of NA (2). Also, the mean availability rate constant for HNA (sodium salt) of 0.042 $min.^{-1}$ is identical to this rate constant for NA (sodium salt) (2). This similarity in lag time and availability rate constant between the sodium salts of NA and HNA is related to their similar pKa, dissolution rate, and chemical structure.

All 5 subjects showed remarkably similar disappearance rate constants (k_{d_2}, range from 7.00–7.88) with a threefold difference in excretion rate constants (k_{E_2}, range from 0.96–2.94). A high excretion rate constant was compensated by a low metabolic rate constant (k_{M_3} and k_{M_4}) and vice versa. This fact could be predicted from the model because of the small variation in disappearance rates.

Glucuronide formation (k_{M_3}) is 2 to 5 times faster than the oxidative formation of the dicarboxylic acid (k_{M_4}). Hydroxynalidixic acid excretion (k_{E_2}) is slower in all cases than the formation of glucuronide (k_{M_3}), and in 2 cases (subjects A. J. and W. V.) slower than the formation of the dicarboxylic acid (k_{M_4}). This high rate of glucuronide formation plus the observed low glucuronide plasma levels (Figs. 1 and 3) indicates that HNAG has a large volume of distribution and/or a rapid excretion rate.

A relatively high apparent volume of distribution is evident for HNA [49.0 ± 3.0% (±S.E.)], indicating that it is distributed in extravascular compartments. The data of McChesney and coworkers (1) of tissue levels in dogs and monkeys showed that NA and HNA have a relatively uniform tissue distribution. This is particularly significant since nalidixic acid is used to treat infections which are localized in tissues.

CONCLUSION

A pharmacokinetic model for hydroxynalidixic acid has been presented and has been shown to be applicable in 5 subjects after oral administration of the sodium salt in capsule form. The good fits of theoretical plasma level curves with the actual data support the definitions of such parameters as lag time, k_A, k_{d_2}, and V_D. Calculated rate constants for excretion and metabolism will be used in a subsequent article in which an extensive model for nalidixic acid will be assumed.

APPENDIX

Expressions relating the amounts of DA-U, HNAG-U, and HNA-U as a function of time are presented. By letting time (t) approach infinity, equations are obtained which enable the calculation of metabolic constants (k_{M_3} and k_{M_4}) and the excretion constant (k_{E_2}) without making any assumptions about the relative values of consecutive rate constants.

These equations were derived from Scheme I where the rate constants are assumed to be first order and the compartments are defined as the (a) GI tract, (b) body or apparent volume of distribution, and (c) urine. Definitions of terms are stated under *Theoretical*.

$$[\text{HNA-U}] = \frac{k_{E_2}k_A A_0}{(k_A - k_{d_2})}\left(\frac{e^{-k_A t}}{k_A} - \frac{e^{-k_{d_2}t}}{k_{d_2}}\right) + \frac{k_{E_2}A_0}{k_{d_2}} \quad \text{(Eq. 1}a\text{)}$$

$$[\text{HNAG-U}] = \frac{k_{U_1}k_{M_3}k_A A_0}{(k_A - k_{d_2})(k_{d_2} - k_{U_1})}\left(\frac{e^{-k_{d_2}t}}{k_{d_2}} - \frac{e^{-k_{U_1}t}}{k_{U_1}}\right) - \frac{k_{U_1}k_{M_3}k_A A_0}{(k_A - k_{d_2})(k_A - k_{U_1})}\left(\frac{e^{-k_A t}}{k_A} - \frac{e^{-k_{U_1}t}}{k_{U_1}}\right) + \frac{k_{M_3}A_0}{k_{d_2}} \quad \text{(Eq. 2}a\text{)}$$

$$[\text{DA-U}] = \frac{k_{U_3}k_{M_4}k_A A_0}{(k_A - k_{d_2})(k_{d_2} - k_{U_3})}\left(\frac{e^{-k_{d_2}t}}{k_{d_2}} - \frac{e^{-k_{U_3}t}}{k_{U_3}}\right) - \frac{k_{U_3}k_{M_4}k_A A_0}{(k_A - k_{d_2})(k_A - k_{U_3})}\left(\frac{e^{-k_A t}}{k_A} - \frac{e^{-k_{U_3}t}}{k_{U_3}}\right) + \frac{k_{M_4}A_0}{k_{d_2}} \quad \text{(Eq. 3}a\text{)}$$

It is apparent that when time (t) is permitted to approach infinity, the above equations reduce to their last terms and give on rearrangement Eqs. 2, 3, and 4 of the text.

Effect of Inert Tablet Ingredients on Drug Absorption I

Effect of Polyethylene Glycol 4000 on the Intestinal Absorption of Four Barbiturates

By PARVINDER SINGH*, J. KEITH GUILLORY†, THEODORE D. SOKOLOSKI‡, LESLIE Z. BENET, and V. N. BHATIA

The effect of polyethylene glycol 4000 on dissolution and absorption rates of 4 barbiturates has been studied. It has been shown that in the case of phenobarbital, which formed a complex of reduced solubility with polyethylene glycol 4000, the dissolution and intestinal absorption rates of the drug were reduced. The other 3 barbiturates did not interact with the polyethylene glycol 4000, and its presence did not affect their dissolution and absorption rates. The reduction in the absorption rate of the phenobarbital was closely related to the reduced dissolution rate of the complex, although only the phenobarbital was shown to be absorbed through the gut. It was also shown that the absorption rate of the phenobarbital from the complex was independent of the degree of dissociation of the latter in the mucosal fluid. An hypothesis is proposed to explain that phenomenon.

IN THE PREPARATION of medicinal tablets, a number of so-called inert ingredients are used as adjuvants. These adjuvants are used as binding agents, disintegrators, lubricants, diluents, or coating materials. Since the adjuvants often constitute a considerable portion of a tablet (in some cases as much as 30% or more), there is good reason to believe that they might influence drug availability and absorption in those instances where drug–adjuvant interactions occur. This point of view has been expressed in numerous reports (1, 2). More recently, studies have been concerned specifically with quantifying the effects of selected complexations on drug absorption rates (3, 4).

The objectives of this study are to determine the influence of 8 selected adjuvants on a group of selected drugs with respect to (*a*) the occurrence of interactions between the adjuvants and the drugs, (*b*) the effect of interactions on the dissolution rates of the drugs, and (*c*) the effect of the interactions on the absorption rate of the drugs.

The adjuvants selected for this study have been picked because they are among the ones frequently used in the manufacture of tablets. They are: polyethylene glycols, sodium carboxymethylcellulose, sodium alginate, cation-exchange resins, starch, acacia, cellulose acetate phthalate, and polyvinylpyrrolidone.

Twelve drugs have been chosen for this study. These drugs have been selected because either they or closely related chemicals are frequently used in tablet form, and because, as a group, they provide a wide range of physical properties including solubility, partition coefficient, and pK useful for this study. The 12 drugs are: barbital, phenobarbital, pentobarbital, barbituric acid, salicylamide, salicylic acid, benzyl penicillin, caffeine, acetanilide, phenacetin, sulfadiazine, and sulfathiazole.

This first report deals with the descriptions of the methods and procedures as well as the study of the effect of the adjuvant, polyethylene glycol 4000 (hereafter referred to as PEG 4000), on the dissolution and absorption of 4 barbiturates: barbital, phenobarbital, pentobarbital, and barbituric acid. In general, the procedure consisted of the following steps. (*a*) Determination of any complex formation between the drugs and the adjuvant by the phase solubility method. (*b*) Determination of the dissolution rates of pure drug tablets in pH 5.3 buffer, both in the presence and in the absence of the adjuvant. (With phenobarbital where an insoluble complex could be isolated, the dissolution rate of the pure complex tablets was studied.) (*c*) Determination of the absorption rate of the drug by the "everted intestinal sac" technique, both in the presence and in the absence of the adjuvant. (In the case of phenobarbital where an insoluble complex could be isolated, the absorption rate of the complex was studied.)

EXPERIMENTAL

Reagents.—Recrystallized phenobarbital U.S.P., m.p. 175–176°; recrystallized pentobarbital U.S.P. m.p., 128–129°, (prepared from sodium pentobarbital); recrystallized barbital N.F., m.p. 188–190°; recrystallized barbituric acid (Eastman Kodak); PEG 4000 (Union Carbide Chemicals Co.); isotonic phosphate buffer,[1] pH 5.3; isotonic phosphate buffer (5), pH 7.4; sodium borate buffer (0.05 *M*), pH 9.1.

Complexation.—All interaction studies between PEG 4000 and the barbiturates under consideration were carried out in a manner similar to that used by Higuchi and Lach (6). An excess of the barbiturate was placed in each of a series of 125-ml. glass-stoppered flasks and varying amounts of PEG 4000 added. Specifically, 250 mg. each of phenobarbital and pentobarbital, 500 mg. of barbital, and 1.9 Gm. of barbituric acid were used in each flask in these studies. Fifty milliliters of isotonic phosphate buffer solution (pH 5.3) was added to each flask, and the contents were equilibrated in a mechanical shaker bath at 37° for 24 hr.

Measured aliquot portions were removed and analyzed for their barbiturate content in a Beckman DB recording spectrophotometer. (The absorption maxima for phenobarbital, barbital, and pentobarbital were taken to be 240 mμ and for barbituric acid 258 mμ.) All spectrophotometric analyses were conducted in a sodium borate buffer having a pH of 9.1.

Manufacture of Tablets.—Cylindrical tablets of the pure drug were compressed in a single punch Colton machine using $^{9}/_{32}$ in. flatfaced punches. Tablet hardness ranged between 5 and 7 on the Strong-Cobb scale.

Phenobarbital tablets weighed 190 mg., pentobarbital 155 mg., barbital 180 mg., and barbituric acid 200 mg.

Dissolution.—The barbiturate tablets were firmly fixed into cylindrical Plexiglas containers with the aid of paraffin wax in such a way that only one surface of the tablet was exposed to the solution. [This is a variation of the technique first introduced by Nelson (7).] The Plexiglas disks were weighted down with a metal plate which prevented them from overturning or sliding during an experimental run (Fig. 1). The tablets were so fixed that their upper surfaces were level with those of the disks. Two such affixed tablets were placed in each of a set of 250-ml. glass-stoppered flasks. One hundred milliliters of isotonic phosphate buffer (pH 5.3) was added to each flask, and the flasks were placed in a constant-temperature (37°) shaker bath and mechanically stirred at 120 strokes/min.

Aliquot portions of the solution were removed at fixed time intervals and analyzed spectrophotometrically for their barbiturate content.

Dissolution in the Presence of PEG 4000.—The experimental procedure was similar to that used for pentobarbital, barbital, and barbituric acid (the 3 barbiturates that did not complex with PEG 4000) as described above, except that a known amount of PEG 4000 was added to the solution (0.880 Gm./100 ml. of PEG 4000 in each flask).

[1] One liter contains 0.568 Gm. of anhydrous disodium hydrogen phosphate, 13.248 Gm. of sodium phosphate, monobasic, and 3.40 Gm. of sodium chloride.

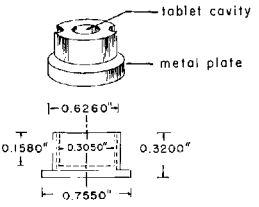

Fig. 1.—A Plexiglas disk with tablet cavity used to hold tablets for dissolution study.

With phenobarbital, which formed an insoluble complex in the presence of PEG 4000, a different procedure was adopted. To a saturated solution of phenobarbital in pH 5.3 buffer, sufficient PEG 4000 was added so that the ratio of adjuvant to drug was identical to the ratio found in the complexation studies (*vide infra*). Specifically, 77.38 mg. of PEG 4000 was added to each 100 ml. of a pH 5.3 buffered solution of phenobarbital having a concentration of 170 mg. %. The phenobarbital–*polyethylene glycol 4000 complex* (hereafter referred to as PB–PEG complex) was allowed to form over a period of 24 hr., filtered, and dried, m.p. 145–147°. The dry powder was then compressed into cylindrical tablets having the same specifications as the drug tablets and weighing 175 mg. The tablets were fixed into the Plexiglas disks, and the dissolution study was conducted. Spectrophotometric determinations were carried out by measuring the phenobarbital equivalent of the complex in solution. It should be noted that the presence of PEG 4000 had no effect on the absorption maxima of the barbitals, and that the pH of all solutions, containing either pure drug or the drug in the presence of PEG 4000, remained constant at pH 5.3.

Absorption.—The "everted intestinal sac" technique of Wilson and Wiseman (8) was adopted in all absorption studies conducted in the present series. Female Sprague-Dawley rats weighing about 250 Gm. were starved for 24 hr. prior to the experiments. The small intestine was freed of all adhering tissue, removed, and cut into 6-cm. segments. No more than 5–6 segments were used from any rat, and these segments were continually bathed in pH 5.3 buffered medium which was aerated with oxygen. Preliminary experiments showed that under our experimental conditions, there was no difference in absorption rates obtained from segments taken from different parts of the small intestine. This is corroborated by Schanker *et al.* (9) in the case of perfused rat intestines. Once cut, the segments were everted and sacs containing 0.4 ml. of isotonic 7.4 buffer were prepared by established techniques. The sacs were kept in a aerated pH 5.3 buffered medium.

One segment was introduced into each of a series of 250-ml. glass-stoppered flasks containing 100 ml. of a solution of known strength of a barbiturate drug. The flasks were placed in a shaker bath at 37°. Before starting the experiment, the air in the flasks was replaced by oxygen.

Corresponding to each sample flask containing the barbiturate solution, a control flask was also run simultaneously. The contents of the control flask were similar to the sample flask except that it did not contain the drug.

The flasks were mechanically stirred at 120 strokes/min., and 2 flasks (a sample and a control)

were removed at regular time intervals. The 2 intestinal sacs were removed from solution, wiped dry with tissue paper, punctured, and 0.16 ml. of the solution contained in each was removed and diluted to an appropriate extent with pH 9.1 buffer, so that the barbiturate content of each sample could be analyzed spectrophotometrically.

Absorption in the Presence of PEG 4000.—With pentobarbital, barbital, and barbituric acid the experiments described above were repeated except that a known weight of PEG 4000 was added to both the sample and control flasks (0.880 Gm./100 ml. of PEG 4000 in each flask).

With phenobarbital, however, the solution in the flask was prepared by placing a weighed quantity of the powdered complex described above into 100 ml. of phosphate buffer (pH 5.3). Initially an attempt was made to have the amount of phenobarbital available (170 mg. %) correspond to the amount used in the absorption studies run without PEG; therefore, 247.38 mg. of the complex (each 247.38 mg. of complex contained 170 mg. of phenobarbital and 77.38 mg. of PEG 4000) was added to 100 ml. of the 5.3 buffer. Since the complex only has a limited solubility (61.7 mg. % measured as the phenobarbital content[2]) an excess of the complex was always present as a solid in all of the sample flasks. Absorption studies were also run at lower complex concentrations (48.0 mg. % and 25.8 mg. % measured as the phenobarbital content), where, in these cases, all of the complex present was in solution.

RESULTS

Complexation.—Phenobarbital was the only one of the 4 barbiturates which complexes with PEG 4000. The complex formed in this case was an insoluble one, the ratio being 1:2.4 (*i.e.*, 1 Gm. molecular weight of phenobarbital and 2.4 Gm. equivalents of the ether linkages of PEG 4000). The data for the complexation are illustrated in Fig. 2. It should be noted that Higuchi and Lach (6) obtained a ratio of 1:2 for this complexation; however, this value was obtained at a different temperature (30°) and in a nonbuffered system at a different pH.

Dissolution.—Figure 3 shows that the dissolution rate of the PB–PEG complex differs from that of phenobarbital by a factor of about 3. (Rate for phenobarbital was 0.208 mg. %/min., and rate for PB–PEG complex was 0.07 ± 0.002 mg. %/min.) The dissolution rates of pentobarbital, barbital, and barbituric acid were not affected by the presence of PEG 4000. An example of this (barbital) is shown in Fig. 4. The dissolution rate values for all 4 drugs, as determined under the authors' experimental conditions, are given in Table I. (In each case, the method of least squares was used to calculate the rates. Each rate listed is a statistically treated average of 4–6 experiments.)

Absorption.—Figure 5 shows the absorption rates of the free phenobarbital and the PB–PEG complex (when excess complex was present). The absorption rate of the complex is about one-third that of pure phenobarbital, but these values must be

[2] All spectrophotometric measurements were made with reference to phenobarbital in solution. Therefore, the abscissas of Figs. 2 and 5 and the ordinate of Fig. 7 should be read as concentration of phenobarbital.

[a] Measured as phenobarbital equivalents.

related to the concentration of phenobarbital equivalents in the outside solution. For free phenobarbital the outside concentration was 170 mg. %, while the concentration of phenobarbital equivalents was only 61.7 mg. % when 247.38 mg. of the PB–PEG complex was added to 100 ml. of buffer. The absorption rates of the 3 other barbiturates were not affected by the presence of PEG 4000. An example of this (barbital) is shown in Fig. 6. The absorption rates of all 4 barbiturates, in addition to the absorption rates of the complex at 3 different outside concentrations, are given in Table II. In each case, the method of least squares was used to calculate the rates.

DISCUSSION

Schanker *et al.* (9) have stated that most drugs are absorbed by passive diffusion. This hypothesis applied to the drugs in this study. Figure 7 shows that in absorption studies carried out by using phenobarbital solutions of different concentrations (closed circles), the absorption rate bears a linear relationship to the initial concentration of the solutions. The open circles on this plot correspond to average absorption rates found for the 3 different concentrations of PB–PEG complex listed in Table II.

A modification of Fick's first law of diffusion has been employed by Higuchi (10) to explain the phenomenon of percutaneous absorption. The equation can also be applied to absorption through the small intestine. The rate of absorption is then given by

$$\frac{dq}{dt} = \frac{DA}{L}(\text{P.C.})\,C \qquad \text{(Eq. 1)}$$

where dq/dt is the absorption rate, D is the diffusion coefficient, A is the cross-sectional area of the gut wall exposed to the drug, L is the thickness of the gut wall, C is the concentration of the drug solution outside the everted sac, and P.C. is the partition coefficient of the barbiturate between the wall and the drug solution.

Similar equations can be written to describe both the phenobarbital absorption rate and the PB–PEG complex. The ratio of the absorption rates is given by

$$\frac{\text{absorption rate of phenobarbital}}{\text{absorption rate of the PB–PEG complex}} = \frac{D_{PB}\,A/L\,(\text{P.C.}_{PB})C_{PB}}{D_{PB-PEG}A/L\,(\text{P.C.}_{PB-PEG})\,C_{PB-PEG}} \qquad \text{(Eq. 2)}$$

Equation 2 is only applicable if the PB–PEG complex can be shown to diffuse through the gut membrane as an intact complex. This seems unlikely in light of recent work which shows that PEG 4000 does not pass through the biological membrane (11). In addition, experiments were run with uneverted whole (40 cm.) rat guts. These guts were first flushed with distilled water, and then filled with a solution of the PB–PEG complex in distilled water (60 mg. % measured as phenobarbital equivalents). The guts were continually aerated as previously described and were placed in flasks containing 25 ml. of distilled water. The flasks were shaken at 37° for 1 hr., after which the gut was discarded, and the outside solution was centrifuged and filtered so as to remove insoluble gut particles. The solution was concentrated by evaporation, and the precipitate was dried overnight at 60°. The melting point of the solid was then observed on a microscope equipped with a hot stage. Although the concentrate was not purified,

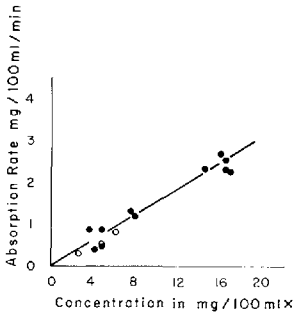

Fig. 7.—Plot showing the linear dependence of the absorption rate on the initial concentration of phenobarbital in the solution surrounding the everted sac. Key: ●, absorption runs with pure phenobarbital; O, average values obtained for absorption runs with excess complex (61.7 mg. % phenobarbital equivalent) and for a series of runs with all complex in solution (48.0 mg. % and 25.8 mg. %).

particles were seen to melt beginning at 173°.[3] Similar results were obtained when pure phenobarbital was placed in the large uneverted gut segments. Although the above experiments were not run under the same conditions as the absorption studies, it seems reasonable to conclude that only phenobarbital passes through the gut wall.

Under this assumption Eq. 2 will reduce to Eq. 3, since D, A, L, and (P.C.) are the same for both the solutions of pure phenobarbital and PB–PEG complex.

$$\frac{\text{absorption rate of phenobarbital}}{\text{absorption rate of phenobarbital from complex}} = \frac{C_{PB}}{C_{PB-PEG}\ \text{(measured as PB equiv.)}} \quad \text{(Eq. 3)}$$

If Eq. 3 is valid, the rate of absorption of phenobarbital from the complex will be a function of the concentration of phenobarbital in solution as the complex, and, therefore, the rate of absorption of the complex should follow the same linear relation with concentration as does the rate of absorption of pure phenobarbital. This relation is shown in Fig. 7, and seems to be true within the experimental error expected from biological work.

It should be pointed out that Fig. 7 implies that the rate of absorption of phenobarbital from the complex is a function of the *total* phenobarbital in solution, not just the concentration of the free phenobarbital resulting from dissociation of the complex. This was checked by running everted gut absorption studies with solutions containing PB–PEG complex (at the 3 concentrations studied) and various concentrations of excess PEG 4000 (up to 1:1 weight–weight, complex to PEG). If absorption was a function of the concentration of free phenobarbital resulting from complex dissociation, the rate of absorption should decrease as excess PEG 4000 is added. In all cases the rates of absorption of phenobarbital from the complex were similar to the rates reported in Table II when no excess PEG was present, indicating that the rate of absorption of phenobarbital from the complex is, indeed, a function of the total phenobarbital in solution, and is not dissociation related.

In light of the evidence presented it would seem that the gut is acting as a "dissociating membrane," causing the complex to dissociate and allowing the diffusible phenobarbital to be absorbed. This hypothesis has previously been proposed by Levy and Matsuzawa (4) to explain the fact that eosin-B was absorbed through the cannulated everted intestine at the same rate from solutions containing the free dye as from solutions containing the dye (at an identical concentration) complexed with atropine and pheniramine. In the previous work (4) the complexes dissociated into 2 components, both of which passively diffused through the intestine, while in the present study the complex dissociates to give 1 passively diffusible component, and 1 component which cannot pass through the intestinal membrane.

Although the above reasoning is hypothetical, it appears that complex dissociation does take place either at the gut surface or in an outer layer of the gut, since the absorption rates are related to total phenobarbital concentration. Additional tests of the above hypothesis are being carried out in this laboratory on a PEG-sulfathiazole complex which increases the total solubility of the drug.

CONCLUSIONS

This portion of the study has demonstrated that the absorption of phenobarbital in the presence of PEG is markedly decreased and that the decrease is probably a function of the decreased solubility of the PB–PEG complex. It has also been demonstrated that the dissolution rate of the complex is only about one-third the rate for pure phenobarbital. As has been pointed out in the literature (12, 13), dissolution is usually the rate-limiting step in attaining therapeutic blood levels. Thus, a PB-PEG complex would markedly decrease the therapeutic efficacy of phenobarbital at both the level of availability rate (dissolution) and at the level of maximum availability attainable (solubility). It was also observed that the dissolution and absorption rates of 3 other closely related drugs were not affected when the same adjuvant showed no interaction with them. Thus, the work so far supports the validity of the hypothesis that tablet adjuvants may not be as inert in their effect as has been traditionally assumed.

SUMMARY

1. The effect of a tablet adjuvant (polyethylene glycol 4000) on the dissolution and absorption rates of 4 barbiturates has been studied.

2. It has been shown that in the case of pentobarbital, barbital, and barbituric acid, all of which did not interact with polyethylene glycol 4000, the dissolution and absorption rates were not affected.

3. Phenobarbital formed a complex of reduced solubility with polyethylene glycol 4000. The effect of this interaction was to reduce the dissolution and absorption rates of the drug.

4. The reduction in the absorption rate of phenobarbital was found to be closely related to the reduced solubility of the complex, and although it was

[3] Phenobarbital, m.p. 174–178°; PEG 4000 congeals at 53–56°; PB–PEG complex, m.p. 145–147°.

demonstrated that only phenobarbital was absorbed through the gut, it was also shown that the rate of absorption was independent of the degree of dissociation of the complex in the mucosal fluid. It has been proposed [after Levy and Matsuzawa (4)] that the intestinal membrane has a dissociating effect on the complex, allowing the phenobarbital to be absorbed, but preventing absorption of PEG.

Chemistry and Biochemistry of Polyvalent Iodine Compounds V

Ionization of Heterocyclic Polyvalent Iodine Compounds

By WALTER WOLF, JAMES C. J. CHEN, and LAUREEN L. J. HSU

The ionization constants of several polyvalent compounds were determined and found to be consistent with the ionization of an hydroxyl group of polyvalent iodine. The pKa of 1,3-dihydro-1-hydroxy-3-oxo-1,2-benziodoxole is 7.35 ± 0.13, and those of its two immediate higher homologs are 7.54 ± 0.29 and 7.37 ± 0.17, respectively. The behavior of 1,3-dihydro-1-hydroxy-3-oxo-1,2-benziodoxole was studied in varying concentrations of sulfuric acid. Two protonation steps seem to occur, with apparent pKa values of −0.58 and −5.75, on the H_0 scale. The structural implications of these findings on the heterocyclic nature of the benziodoxole ring are discussed.

RECENT WORK on the structure of certain polyvalent iodine compounds (1, 2) confirms their heterocyclic nature. The structure of 1,3-dihydro-1-hydroxy-3-oxo-1,2-benziodoxole (I) has been unequivocally determined by X-ray crystallography (3). This study revealed a significant difference between the two I—O bonds; the intra-annular bond between iodine and oxygen is 2.30 Å. long, while the bond between iodine and the hydroxylic oxygen is 2.00 Å. This difference can be ascribed either to the steric strain of a 5-membered ring or to a strong ionic contribution to the iodine-oxygen (ring) bond. An alternative possibility, that a betaine type of ring (iodonium-carboxylate, I*a*) makes a significant contribution to the structure of 1,3-dihydro-1-hydroxy-3-oxo-1,2-benziodoxole had to be evaluated. The behavior of 2-carboxy-diphenyl iodonium (III), containing such a ring system, had been studied recently (4). The ionization constants of I and its homologs (II, $n = 1$ or 2) were investigated in order to provide further information on the structure of these iodine-containing heterocyclic rings, and to evaluate the possible contribution of betainic structures such as (I*a*). This study was conducted both in dilute aqueous

solutions and in media of very high acidity (H_0 to -10).

EXPERIMENTAL

Products.—1,3 - Dihydro - 1 - hydroxy - 3 - oxo-1,2-benziodoxole was prepared by the method of Meyer and Askenasy (5) as modified by Wolf and Hsu (1). 3,4-Dihydro-1-hydroxy-3-oxo-1*H*-1,2-benziodoxin and 1,3,4,5-tetra-hydro-1-hydroxy-3-oxo-1,2-benziodoxepin were prepared as described previously (1, 2). Baker and Adams reagent grade sulfuric acid (95%) was used.

Methods.—The method used for the determination of the pKa in dilute aqueous solutions was that of Albert and Sarjeant (6), using a Cary 14 recording spectrophotometer, a Beckman DB recording spectrophotometer, and a Beckman-Gilford direct-reading spectrophotometer. The pH measurements were performed on a Photovolt 115 pH meter, which was standardized against Beckman buffers before each measurement. All measurements were conducted at 23 ± 3°.

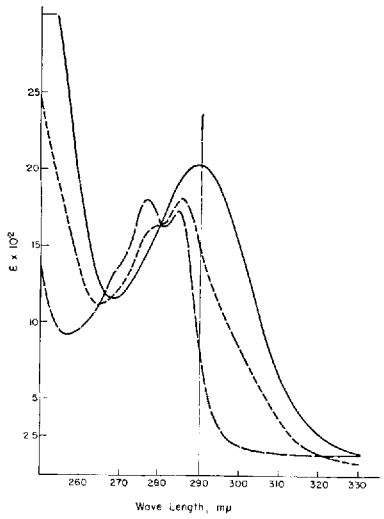

Fig. 1.—Absorption spectra of 1,3-dihydro-1-hydroxy-3-oxo-1,2-benziodoxole in $^1/_{15}$ *M* phosphate buffer. Key: ——, pH 11.19; - - -, pH 7.5; – – –, pH 1.85.

TABLE I.—MOLAR ABSORPTIVITIES OF POLYVALENT IODINE COMPOUNDS AND THEIR ANIONS[a]

Compd.		Anion[b]	Un-ionized Molecule[c]
1,3-Dihydro-1-hydroxy-3-oxo-1,2-benziodoxole	2900	2044	849
	2845	1915	1739
	2765	1267	1811

	2900	496	809
	2500	1547	2619

[a] In phosphate buffers, 1/15 *M*. [b] pH 10–12. [c] pH 1–2.

The spectrophotometric method as modified by Davis and Geissman (7) was used to determine the ionization constants in the concentrated sulfuric acid solutions. Stock solutions of 1,3-dihydro-1-hydroxy-3-oxo-1,2-benziodoxole in 96% H_2SO_4 were prepared and their stability checked periodically. No apparent decomposition could be observed during the course of this work. The stock solutions were diluted, under refrigeration, to the desired final concentrations in 1,3-dihydro-1-hydroxy-3-oxo-1,2-benziodoxole and sulfuric acid. The H_0 scale used was that of Paul and Long (8) for the 40–95% sulfuric acid region and that of Bascombe and Bell (9) for the 0–40% sulfuric acid concentration.

RESULTS AND DISCUSSION

The changes in the absorption spectra of a solution of 1,3-dihydro-1-hydroxy-3-oxo-1,2-benziodoxole in $^1/_{15}$ *M* phosphate buffers at pH 1.85, 7.5, and 11.19 are illustrated in Fig. 1. By using 290 mμ ($\lambda_{max.}$ for the anion, Table I) as the analytical wavelength, the pKa values listed in Table II were obtained.

Similar determinations for 3,4-dihydro-1-hydroxy-3-oxo-1*H*-1,2-benziodoxin and 1,3,4,5-tetrahydro-1-hydroxy-3-oxo-1,2-benziodoxepin are illustrated in Tables III and IV.

The pKa and ionization constants of the 3 heterocyclic polyvalent iodine compounds are listed in Table V.

For comparison, the pKa values, as reported in the literature for some related iodo compounds, are listed in Table VI.

The influence of the iodo group on the ionization of the benzoic and phenylacetic acids is seen to be strongest when the halogen is in the *ortho* position. The decrease in pKa has been ascribed to both inductive and resonance effects (10, 13), which could be enhanced in *o*-iodobenzoic acid by the participation of a betaine type of structure.

The introduction of a methylene group shields the carboxylate function from such effects. Thus, for *o*-iodophenylacetic acid, the ΔpKa is 0.27, compared with a ΔpKa of 1.34 for *o*-iodobenzoic acid. The ΔpKa values are 0.15 and 0.34 for the *m*-analogs, respectively. While no data are available for the corresponding iodophenylpropionic acids, it can be assumed that the introduction of the second methylene group would further shield the carboxylic acid group. [*Cf.* pKa of propionic acid, 4.88 (6).]

In contrast, the authors' results on the ionization constants of the related polyvalent iodine deriva-

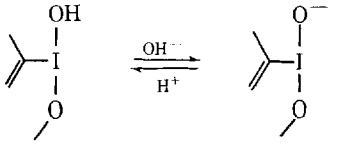
TABLE V.—pKa AND IONIZATION CONSTANTS OF THREE HETEROCYCLIC POLYVALENT IODINE COMPOUNDS

	pKa	Ionization Constant
1,3-Dihydro-1-hydroxy-3-oxo-1,2-benziodoxole	7.35 ± 0.13	$(2.2 \pm 0.5) \times 10^{-7}$
3,4-Dihydro-1-hydroxy-3-oxo-1*H*-1,2-benziodoxin	7.54 ± 0.29	$(3.4 \pm 1.6) \times 10^{-7}$
1,3,4,5-Tetrahydro-1-hydroxy-3-oxo-1,2-benziodoxepin	7.37 ± 0.17	$(2.3 \pm 0.8) \times 10^{-7}$

TABLE VI.—pKa VALUES OF SOME *o*-IODOPHENYL CARBOXYLIC ACIDS

Compd.	H	*o*-Iodo	*m*-Iodo	*p*-Iodo	Ref.
Benzoic acid	4.20	2.86	3.86	3.93	(10, 11)
Phenylacetic acid	4.31	4.04	4.16	...	(10, 12)
β-Phenyl propionic acid	4.66	...	...	...	(10)

tives fail to detect any such variations in their pKa values, and this suggests that the ionizable function is not located on a carboxylic acid. Instead, the authors suggest that a common ionizable function is present in the three heterocyclic polyvalent iodine systems, namely, the iodine-bonded hydroxyl group.



This function is independent, except for steric factors, of the number of methylene groups between the carbonyl group and the benzene ring.

Further arguments supporting this assignment can be made if we consider the pKa values of the proven betaine structures reported by Beringer (4), who studied the acidities of carboxydiphenyliodonium compounds in acetonitrile–water solutions at 24°. Under their conditions the apparent pKa values are 6.92 for benzoic acid, and 6.24, 6.45, and 6.64, respectively, for the *o*-, *m*-, and *p*-iodobenzoic acids, and 3.5 ± 1, 5.55, and 4.6 for the *o*-, *m*-, and *p*-phenyliodoniumbenzoic acids (2,3 and 4-carboxydiphenyliodonium). The iodonium substituted benzoic acids appear to be stronger acids than the corresponding iodo-benzoic acids under the conditions studied. Thus, while in all the above examples, the *o*-iodo or the *o*-iodonium derivatives were stronger acids than unsubstituted benzoic acid, the contrary is the case for 1,3-dihydro-1-hydroxy-3-oxo-1,2-benziodoxole, which is a weaker acid than either benzoic or *o*-io-

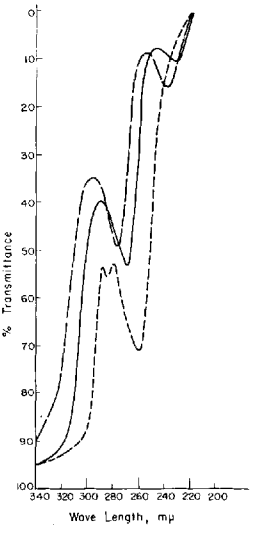


Fig. 2.—Absorption spectra of 1, 3-dihydro - 1 - hydroxy- 3-oxo - 1,2 - benziodoxole in sulfuric acid solution. Key: - - -, in 9.6% H_2SO_4; ——, in 48% H_2SO_4; – – –, in 86.3% H_2SO_4.

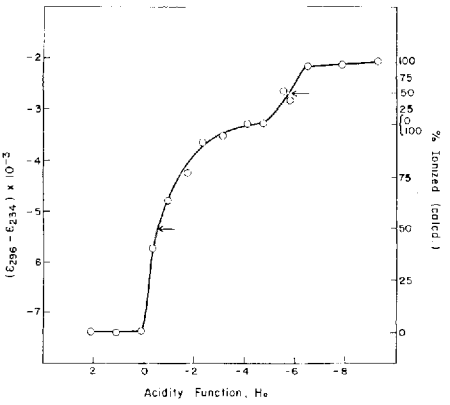

Fig. 3.—1,3-Dihydro-1-hydroxy-3-oxo-1,2-benziodoxole: acidity function *vs.* (ϵ 296–ϵ 234); points from spectral data, pKa's calculated from curve, −0.58 and −5.75.

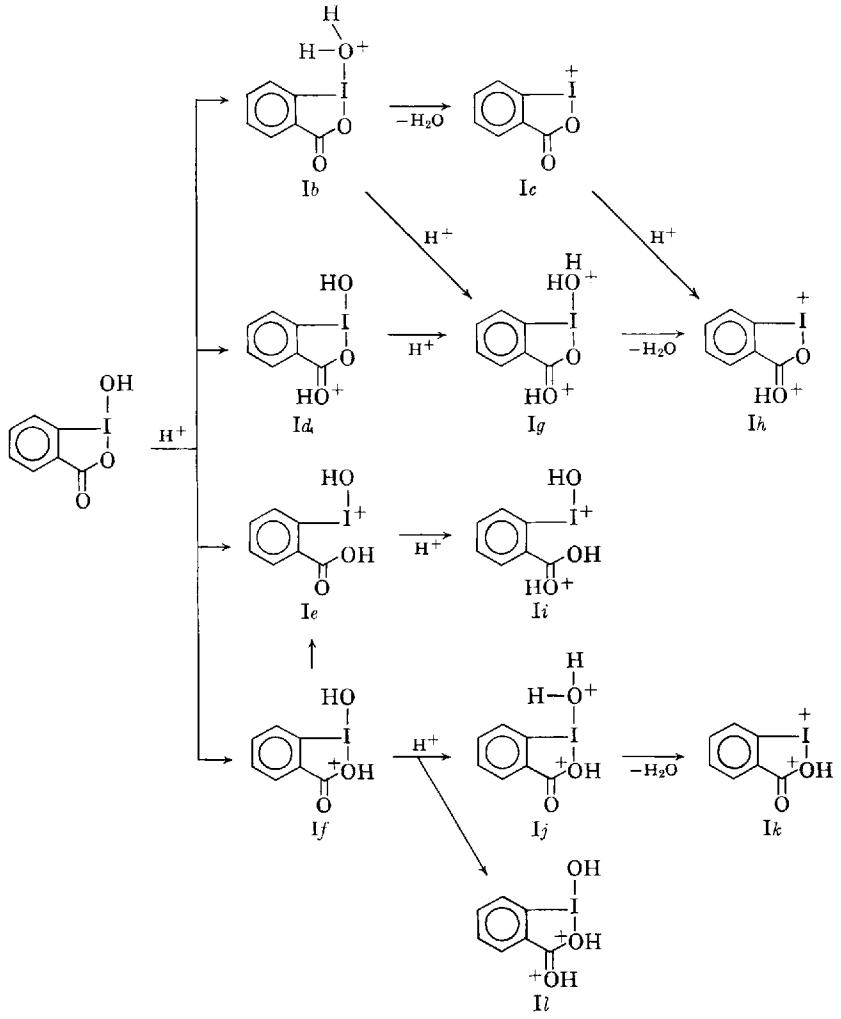
dobenzoic acid. We can, therefore, safely assume that structures such as I*a* make only an extremely small, if any, contribution to 1,3-dihydro-1-hydroxy-3-oxo-1,2-benziodoxole.

Carboxylic acids exhibit a second protonation in strongly acidic media (14), and the pKa's determined in the acidity function (H_0) region are −7.38, −7.78, −7.64, and −7.50 for benzoic acid, and its *o*-, *m*-, and *p*-iodo analogs, respectively. A single protonation step is observed, and the suggestion has been made that protonation occurs on the carboxylic oxygen atom rather than on the hydroxyl group (15).

The behavior of the benziodoxole ring in strongly acidic media is of interest, since this system provides a number of potential protonation sites. Particularly, it might be possible to observe if ring opening occurs or if a protonation of the carbonyl function, similar to that of other benzoic acids, is detectable.

The change in absorption of a solution of 1,3-dihydro-1-hydroxy-3-oxo-1,2-benziodoxole in various concentrations of sulfuric acid is illustrated in Fig. 2. A plot of $\Delta\epsilon$ (ϵ 296 − ϵ 234) *versus* H_0 is given in Fig. 3, and it shows a complex curve, which appears to have two inflection points at H_0 = −0.58 and at H_0 = −5.75. These results indicate



Scheme I

a two-step protonation. As a check of the method, the pKa of *o*-iodobenzoic acid was determined concurrently, yielding the value of −7.4 which is in good agreement with previously published data (12).

A first protonation of compound I could lead to structures I*b*, I*d*, I*c*, or I*f*; loss of water from I*b* will yield I*c*. (Scheme I.)

Of these structures for a single protonation, I*b* and I*f* are considered least likely. Protonation of a conjugated carbonyl function, such as that of benzophenone, occurs at pKa = −6.41 (16), and protonation of a lactone occurs at the carbonyl rather than the ether oxygen; an electronic shift would convert "structure" I*f* into I*e*. Examination of Fig. 2 reveals that protonation of compound I gives rise to a new peak at 256 mμ, while the doublet at 276–284 coalesces to a single peak at 288 mμ. By comparison, *o*-iodobenzoic acid shows a peak at 285 mμ which, in strong acid, shifts to 328 mμ. Thus, the 288 mμ peak of mono-protonated 1,3-dihydro-1-hydroxy-3-oxo-1,2-benziodoxole could be indicative of the presence of a carboxylic acid function (I*e*). However, not enough is known about the spectral characteristics of iodonium compounds to rule out the possible contribution of structure I*d*.

The possibility of a sulfonation reaction appears unlikely, as dilution of the above concentrated sulfuric acid solutions resulted in an absorption spectra identical to that obtained by mild acidification of an aqueous solution.

The second protonation (H_0 = −5.75) may be associated with that of a carbonyl group, leading to structures such as I*g*, I*h*, I*i*, I*j*, or I*l*; loss of water could lead to I*k*, or I*h*. The shift of the absorption band from 288 mμ to 296 mμ is quite small. Structures I*j* and I*l* would contain a protonated lactone oxygen, and are therefore considered far less likely than structure I*i*, which represents a classically protonated carboxylic acid and is resonance stabilized. Although the pKa observed is significantly less than those recorded for other *o*-substituted benzoic acids (−6.78 to −7.78), the effect of an *o*-iodonium function must be taken into consideration. Thus, no conclusion can be made at present on the possible significance of these data on deciding between structures I*i* and I*h* for the doubly protonated species, or between I*e* and I*d* for the singly protonated molecule.

The ionization properties of 1,3-dihydro-1-hydroxy-3-oxo-1,2-benziodoxole and homologs thus support the heterocyclic nature of these compounds.

Pharmacokinetic Model for Nalidixic Acid in Man II

Parameters for Absorption, Metabolism, and Elimination

By G. A. PORTMANN, E. W. McCHESNEY, H. STANDER, and W. E. MOORE

The absorption, metabolism, and excretion of nalidixic acid in man is illustrated by a model, and appropriate equations are derived. A total of 7 rate constants are calculated: 4 metabolic constants, 2 excretory constants, and 1 availability constant. All 5 components of the urine compartment and 2 components of the plasma compartment are measured. Comparisons between experimental and calculated values are good.

THE CONSTRUCTION of pharmacokinetic models, their utility in dosage form design, and the mathematical description of the fate of a drug in the body has been adequately treated by Wagner (1, 2), Nelson (3), Levy (4), and others (5).

A complex model illustrating the pharmacokinetic parameters relating to the absorption, metabolism, and elimination of nalidixic acid[1] in man has been presented previously (6). A practical model was developed which enabled calculation of the biologically active and inactive forms as separate groups. Another article by the authors describes a pharmacokinetic

model for hydroxynalidixic acid (9) which is an active metabolite.

The present article gives further experimental results which permit the complete pharmacokinetic description of nalidixic acid in man. This model has been applied to blood levels and urinary excretion data obtained from two different tablet formulations.

THEORETICAL

Equations describing the change of each component in Scheme I with respect to time were derived, assuming total absorption and all rate processes to be first order. The recovery of the drug from the urine in terms of all forms detected analytically was found to be 95 ± 2% (± S. E.) indicating essentially total absorption in every case.

The equations used in the present study are listed below. Lag time is defined as the time interval between ingestion of the dosage form and the appearance of nalidixic acid in the plasma. A_0 is equal to the administered dose since complete absorption occurs. Time (t) is measured after the lag time interval. The nalidixic acid (NA) disappearance rate constant (k_d) is equal to the sum of $k_{E_1} + k_{M_1} + k_{M_2}$. The disappearance rate constant (k_{d_2}) for hydroxynalidixic acid (HNA) is the sum of $k_{E_2} + k_{M_3} + k_{M_4}$. The availability rate from the intestinal tract (k_A) is a resultant of such factors as gastrointestinal motility, dissolution rate, etc., and the absorption rate itself.

$$A = A_0 e^{-k_A t} \qquad \text{(Eq. 1)}$$

$$\text{NA-B} = \frac{k_A A_0}{(k_A - k_d)} (e^{-k_d t} - e^{-k_A t}) \qquad \text{(Eq. 2)}$$

$$\text{HNA-B} = \frac{k_{M_1} k_A A_0}{(k_A - k_d)(k_A - k_{d_2})} (e^{-k_{d_2} t} - e^{-k_d t}) - \frac{k_{M_1} k_A A_0}{(k_A - k_d)(k_A - k_{d_2})} (e^{-k_{d_2} t} - e^{-k_A t}) \qquad \text{(Eq. 3)}$$

$$\text{NA-U} = \frac{k_{E_1} A_0}{(k_d - k_A)} (1 - e^{-k_A t}) + \frac{k_{E_1} k_A A_0}{(k_d - k_A) k_d} (e^{-k_d t} - 1) \qquad \text{(Eq. 4)}$$

$$k_{E_1} = \frac{k_d [\text{NA-U}]_\infty}{A_0} \qquad \text{(Eq. 5)}$$

$$\text{HNA-U} = \frac{k_{E_2} k_{M_1} k_A A_0}{(k_A - k_d)(k_d - k_{d_2})} \left(\frac{e^{-k_d t}}{k_d} - \frac{e^{-k_{d_2} t}}{k_{d_2}} \right) - \frac{k_{E_2} k_{M_1} k_A A_0}{(k_A - k_d)(k_A - k_{d_2})} \left(\frac{e^{-k_A t}}{k_A} - \frac{e^{-k_{d_2} t}}{k_{d_2}} \right) + \frac{k_{E_2} k_{M_1} A_0}{k_{d_2} k_d} \qquad \text{(Eq. 6)}$$

$$[\text{HNA-U}]_\infty = \frac{k_{E_2} k_{M_1} A_0}{k_d k_{d_2}} \qquad \text{(Eq. 7)}$$

$$k_{M_2} = \frac{k_d [\text{NAG-U}]_\infty}{A_0} \qquad \text{(Eq. 8)}$$

$$[\text{HNAG-U}]_\infty = \frac{k_{M_3} k_{M_1} A_0}{k_d k_{d_2}} \qquad \text{(Eq. 9)}$$

$$[\text{DA-U}]_\infty = \frac{k_{M_4} k_{M_1} A_0}{k_d k_{d_2}} \qquad \text{(Eq. 10)}$$

$$k_{M_1} = \frac{k_d [\text{HNA} - \text{U} + \text{HNAG} - \text{U} + \text{DA} - \text{U}]^\infty}{A_0} \qquad \text{(Eq. 11)}$$

EXPERIMENTAL

Protocol.—Two tablet formulations,[1] both containing micropulverized nalidixic acid crystals, but with different tablet excipients, were given orally as a 1-Gm. dose (2 Caplets) to 8 subjects according to a crossover design, with 1 week between experiments. The drug was administered with water after overnight fasting. To maintain uniformity of absorption, food, but not water, was withheld until 3 hr. postmedication.

Blood samples were taken at 0, 20, 50, 80, 120, 270, and 420 min. postmedication. A 0- and 24-hr. urine sample was also collected. Previous experiments have shown essentially complete recovery in 24 hr.

Analytical Methods.—Nalidixic and hydroxynalidixic acids may be extracted from biological materials by means of toluene at pH 1–2, as previously described (7). Prior hydrolysis for 1 hr. at this pH releases both compounds from their glucuronide conjugates. It is possible to distinguish between NA and HNA on the basis of their differing extractabilities as a function of pH, as described below.

(*a*) Free (or total) naphthyridine is determined by extracting with toluene at pH 1.2 (0.1 *N* HCl), transfer from toluene to 0.5 *M* borate pH 9, and reading the fluorescence at 325/375 mμ after acidification as described previously (7). The results are calculated on the basis of NA standards carried through the same procedures; the recovery of NA, therefore, is 100%, while that of HNA is 134%. The latter figure is a result of 2 factors: the extractability of HNA under the conditions used in 77%, but, since its fluorescence on a weight basis is 172% of that of NA, a net value of 134% will be obtained for HNA read against NA standards.

(*b*) A second aliquot of the material to be analyzed (1–2 ml.) is diluted as necessary with an aqueous buffer of pH 5.63. (Composition of buffer per liter: *sodium chloride*, 10 Gm.; *potassium acid phosphate*, 12.25 Gm.; basic potassium phosphate, 1.75 Gm.) The solution is extracted with 30 ml. of toluene, of which 25 ml. is extracted with the 0.5 *M* borate, which is assayed in the usual way. Under these conditions the extractability of NA is 5.8 times that of HNA, but the relative fluorescence factor of 1.72 reduces the advantage in favor of NA to 3.4. When read against NA standards carried through the same steps, this method will recover 100% of the NA present, and 33% of the HNA. The following relationship, therefore, exists:

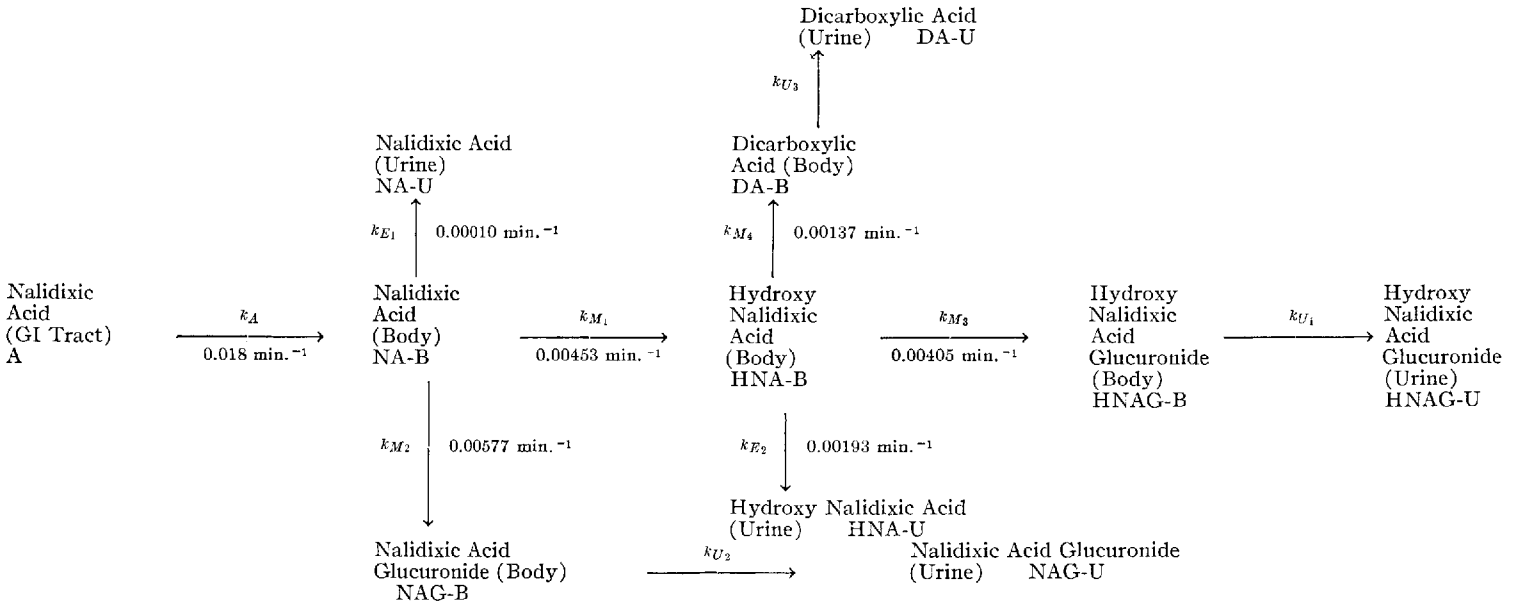
step *1* = 100% NA + 134% HNA

step *2* = 100% NA + 33% HNA

step *1* − step *2* = 101% HNA

For practical purposes, then, step *1* − step *2* is taken simply as equal to the amount of HNA present, and the amount of NA is readily calculated from either *1* or *2*. When applied to the analysis of mixtures of the 2 compounds ranging from 5–40 mcg. of NA and 60–5 mcg. of HNA, the recovery

[1] Negram Caplets, 500 mg./Caplet.



Kinetic pathways of nalidixic acid in man; k_A = availability rate constant; k_{M1} = metabolic rate constants; k_{E1} and k_{U1} = excretion rate constants.

of HNA was 96.5 ± 5% of the amount added, and the recovery of NA was 103 ± 9%. If total NA + HNA is determined following acid hydrolysis in the same way, and the values for free NA and HNA are subtracted, the amounts present as conjugated NA and conjugated HNA may be estimated, NA and HNA being stable to this hydrolysis.

In addition, urine levels of NAG, HNAG, and DA were determined with previously described methods (7).

RESULTS AND DISCUSSION

The Wagner and Nelson method (8) of calculating availability rates of drug to plasma was used, and results (k_A) are shown in Table I. Typical plasma level curves and A/V values are shown in Figs. 1 and 2 for 2 individuals and 2 dosage forms. For these same subjects, the logarithm of the per cent unabsorbed at various times was calculated and is shown in Fig. 3. Lag time is read as the time when 100% is unabsorbed by extrapolating the line to log 2.

Three of 13 observations for availability rates are apparently of the zero-order type. The mean of the 10 first-order availability rates is 0.018 min.$^{-1}$ which is very similar to the mean rate of 0.020 min.$^{-1}$ reported for nalidixic acid in caplet form for 8 subjects (6). The use of total plasma naphthyridine for determining absorption rates (6) results in a small error because practically all of the naphthyridine is in the form of nalidixic acid.

With the exception of W. H., subjects showed little variation in disappearance rates, either among themselves or between dosage forms. Using Eq. 2, with division by V_D to obtain concentration, the theoretical values of NA were calculated for the 2 subjects shown in Figs. 1 and 2. Excellent agreement was obtained between the calculated values and those from the actual plasma level curve.

Because of low HNA plasma levels (Figs. 1 and 2), it is apparent that very little difference would be seen between the disappearance rates of NA and NA + HNA. In fact, in our previous study (6), where active naphthyridine (NA + HNA) was measured in 8 subjects, their apparent average disappearance rate was 0.011 min.$^{-1}$, which is identical to the average rate for NA (Table I).

Individual values for excretion (k_{E_1}) and metabolic (k_{M_1}, k_{M_2}) rate constants were calculated using Eqs. 5, 8, and 11 with the 0–24-hr. urinary data as the infinity values (Table I). Data previously obtained (6) indicated that a 24-hr. urine analysis would represent complete excretion. Rate constants for the formation of NAG (k_{M_2}) are the

highest of the various constants for disappearance in 4 of 6 subjects. The variation in metabolic rates with each individual between forms A and B is slight compared to the variation among individuals.

Because of the low excretion rate of nalidixic acid and its high metabolic rates, the over-all effect is an extremely small quantity of NA appearing in the urine. In fact, if the active drug is measured in the urine (NA + HNA), the observed apparent excretion rate constant should be essentially that of HNA. The apparent mean excretion rate constant of the active drug (NA + HNA) in the urine has been reported as 0.0015 min.$^{-1}$ ± 0.0003 (18 observations) (6) compared to an average excretion rate constant for HNA of 0.0019 min.$^{-1}$ ± 0.0004 (4 observations) (9).

The excretion of acidic and basic organic compound is sometimes modified greatly as a result of changes in urinary pH usually induced by large doses of sodium bicarbonate or ammonium chloride. McChesney and co-workers (7) have shown that the urinary excretion of active naphthyridine (NA + HNA) is increased with $NaHCO_3$ and decreased with NH_4Cl given simultaneously with nalidixic acid. No attempt was made to control urinary pH in the present study since normal variations in excretion rates were sought.

The apparent volumes of distribution for NA and HNA are inversely proportional to the per cent of plasma protein binding at pH 7.4 in therapeutic concentration ranges. These are 93% for NA and 63% for HNA using equilibrium dialysis techniques.

In order to evaluate the processes beyond the formation of HNA, the results of an experiment in which HNA is given orally (9) are needed. For 2 subjects (A. J. and G. B.) common to both these experiments, their individual disappearance rate constants (k_{d_2}) and apparent volumes of distribution for HNA (9) plus their k_A, k_{M_1}, k_d, and V_D values for NA (Table I) were used in Eqs. 2 and 3 to calculate plasma levels. These results which are shown in Fig. 4 indicate a reasonable agreement with the experimental data for NA.

For HNA, the agreement with experimental data for A. J. (form A) is reasonable, however, for G. B. and A. J. (form B) the general shape of the theoretical curve is good indicating that the rate constants are sufficiently good estimates, but the heights of the curves are too low or too high. The complexity of the HNA system is of such a magnitude that good fits should not be expected with the use of apparent distributive volumes and disappearance rate constants from separate experiments. Good fits can be obtained by only changing the volume of distribution. By increasing the V_D for G. B. from 40.8 to 50.0% of body weight, the height of the plasma level curve is lowered (dashed curve, Fig. 4), producing a good correlation with experimental values. For A. J. (form B), decreasing the V_D from 45.9 to 31% of body weight also gives a good fit with experimental values (dashed curve, Fig. 4).

Assuming average rate constants and using Eqs. 5, 7, 8, 9, and 10, the average urinary excretion values at infinity were calculated. A comparison between these values and the average experimental values is given in Table II. Again a reasonable agreement is apparent.

The plasma level comparison (NA and HNA) plus the good agreement with urinary excretion data indicate that these average rate constants (Table II) will give a good picture of the metabolism and excretion of nalidixic acid and its metabolite (HNA). Such a picture is presented in Figs. 5 and 6 where the changes occurring in plasma and urine

with respect to time for the active components of the model are presented. Average rate constants and V_D's were used in Eqs. 2, 3, 4, and 6 to generate these curves for a 1-Gm. dose of nalidixic acid.

SUMMARY

A differential extraction procedure has been developed which enabled the separate determination of NA and HNA in plasma and urine.

The solution of a pharmacokinetic model for nalidixic acid which involves 5 components in the body and urine compartments has been mathematically described in terms of rate equations. A total of 7 rate constants have been determined: 2 for glucuronide formation, 2 for oxidation, 2 for excretion of NA and HNA, and 1 for the availability of NA. The reasonable agreement between calculated and experimental curves has been illustrated.

APPENDIX

Equations relating the quantities of NAG-U, HNAG-U, and DA-U as a function of time are presented. By letting time (t) approach infinity, equations are obtained which enable the calculation of metabolic and excretion constants without making any assumptions about the relative values of consecutive rate constants.

These equations were derived from the model (Fig. 1) where the rate constants are assumed to be first order and the compartments are defined as the: (a) GI tract, (b) body or apparent volume of distribution, and (c) urine. Definitions of terms are stated under *Theoretical*.

NAG-U =

$$\frac{k_{U_2}k_{M_2}k_A A_0}{(k_A - k_d)(k_d - k_{U_2})}\left(\frac{e^{-k_d t}}{k_d} - \frac{e^{-k_{U_2}t}}{k_{U_2}}\right) - \frac{k_{U_2}k_{M_2}k_A A_0}{(k_A - k_d)(k_A - k_{U_2})}\left(\frac{e^{-k_A t}}{k_A} - \frac{e^{-k_{U_2}t}}{k_{U_2}}\right) + \frac{k_{M_2}A_0}{k_d} \quad \text{(Eq. 4a)}$$

HNAG-U =

$$\frac{k_{M_3}k_{M_1}k_A k_{U_1}A_0}{(k_A - k_d)(k_d - k_{d_2})(k_{U_1} - k_{d_2})}\left(\frac{e^{-k_{U_1}t}}{k_{U_1}} - \frac{e^{-k_{d_2}t}}{k_{d_2}}\right) - \frac{k_{M_3}k_{M_1}k_A k_{U_1}A_0}{(k_A - k_d)(k_d - k_{d_2})(k_{U_1} - k_d)}\left(\frac{e^{-k_{U_1}t}}{k_{U_1}} - \frac{e^{-k_d t}}{k_d}\right) - \frac{k_{M_3}k_{M_1}k_A k_{U_1}A_0}{(k_A - k_d)(k_A - k_{d_2})(k_{U_1} - k_{d_2})}\left(\frac{e^{-k_{U_1}t}}{k_{U_1}} - \frac{e^{-k_{d_2}t}}{k_{d_2}}\right) + \frac{k_{M_3}k_{M_1}k_A k_{U_1}A_0}{(k_A - k_d)(k_A - k_{d_2})(k_{U_1} - k_A)}\left(\frac{e^{-k_{U_1}t}}{k_{U_1}} - \frac{e^{-k_A t}}{k_A}\right) + \frac{k_{M_3}k_{M_1}A_0}{k_d k_{d_2}} \quad \text{(Eq. 5a)}$$

DA-U =

$$\frac{k_{M_4}k_{M_1}k_A k_{U_3}A_0}{(k_A - k_d)(k_d - k_{d_2})(k_{U_3} - k_{d_2})}\left(\frac{e^{-k_{U_3}t}}{k_{U_3}} - \frac{e^{-k_{d_2}t}}{k_{d_2}}\right) - \frac{k_{M_4}k_{M_1}k_A k_{U_3}A_0}{(k_A - k_d)(k_d - k_{d_2})(k_{U_3} - k_d)}\left(\frac{e^{-k_{U_3}t}}{k_{U_3}} - \frac{e^{-k_d t}}{k_d}\right) - \frac{k_{M_4}k_{M_1}k_A k_{U_3}A_0}{(k_A - k_d)(k_A - k_{d_2})(k_{U_3} - k_{d_2})}\left(\frac{e^{-k_{U_3}t}}{k_{U_3}} - \frac{e^{-k_{d_2}t}}{k_{d_2}}\right) + \frac{k_{M_4}k_{M_1}k_A k_{U_3}A_0}{(k_A - k_d)(k_A - k_{d_2})(k_{U_3} - k_A)}\left(\frac{e^{-k_{U_3}t}}{k_{U_3}} - \frac{e^{-k_A t}}{k_A}\right) + \frac{k_{M_4}k_{M_1}A_0}{k_d k_{d_2}} \quad \text{(Eq. 6a)}$$

It is apparent that when time (t) is permitted to approach infinity, the above equations reduce to their last term and give Eqs. 8, 9, and 10 of the text.

Equation 11 of the text is derived from the sum of the expressions for DA-U, HNAG-U, and HNA-U at $t = \infty$.

$$[\text{DA-U}]_\infty + [\text{HNAG-U}]_\infty + [\text{HNA-U}]_\infty = \frac{k_{M_4}k_{M_1}A_0}{k_d k_{d_2}} + \frac{k_{M_3}k_{M_1}A_0}{k_d k_{d_2}} + \frac{k_{E_2}k_{M_1}A_0}{k_d k_{d_2}} \quad \text{(Eq. 7a)}$$

which reduces to

$$[\text{DA-U}]_\infty + [\text{HNAG-U}]_\infty + [\text{HNA-U}]_\infty = \frac{k_{M_1}A_0}{k_d k_{d_2}}(k_{M_4} + k_{M_3} + k_{E_2}) \quad \text{(Eq. 8a)}$$

By definition $k_{d_2} = k_{M_4} + k_{M_3} + k_{E_2}$.

Therefore, Eq. 8a, upon substituting for k_{d_2}

and solving for k_{M_1} reduces to Eq. 11 of the text. This equation permits the calculation of the metabolic rate constant (k_{M_1}) for the oxidation of nalidixic acid to hydroxynalidixic acid.

Drug Standards

Determination of Free Salicylic Acid in Aspirin and Aspirin Products

By JOHN D. WEBER and JOSEPH LEVINE

In a previously described method for the determination of free salicylic acid in aspirin, the salicylic acid is isolated on a partition chromatographic column as its purple ferric–phenol complex, using ferric chloride solution as immobile phase. With the addition of a high concentration of urea to the ferric chloride, the method is significantly improved. The separation is more sharply defined, making feasible the analysis of larger samples of aspirin and permitting the use of a more easily prepared chromatographic column.

A PROCEDURE has been described (1) for the isolation and determination of small amounts of salicylic acid which occur in aspirin and aspirin products. The salicylic acid is retained on a Celite:2% ferric chloride partition chromatographic column as its ferric complex while the nonphenolic aspirin is eluted with chloroform. The ferric complex is then dissociated with acetic acid and the free salicylic acid eluted with chloroform.

Several investigators have encountered difficulty with the published method (2). During the elution of the aspirin, the salicylic acid migrates slowly down the column (as evidenced by the position of the purple complex) and spreads out into a diffuse band, which sometimes becomes difficult to discern. Unless the chromatographic column is packed with great uniformity, channeling may occur during both the elution of aspirin and the recovery of salicylic acid.

A radical improvement in the chromatographic separation is achieved with a modified ferric chloride reagent, which contains a high concentration of urea. The band of the ferric–salicylate complex obtained with this reagent is much more deeply colored than that obtained with the simple ferric chloride reagent. The dense, sharply delineated band migrates only very slightly during the elution of aspirin. The use of shorter columns, which do not require extraordinary care in packing, is therefore feasible. Columns prepared with the modified reagent will also accommodate much larger samples of aspirin than those prepared with ferric chloride alone.

Addition of urea to the ferric chloride reagent was suggested from the report of a urea–salicylic acid complex by Bolton (3). It is apparent that the formation of this binary complex does not account for the trapping of salicylic acid by the ferric chloride–urea reagent, however, since urea solutions alone, at any concentration, are completely ineffective in removing salicylic acid from chloroform solution.

Optimum results are obtained with an immobile phase containing 5% ferric chloride and which is 10 *M* with respect to urea. It must be maintained at a pH between 3.1 and 3.3. At lower pH levels the salicylic acid band becomes diffuse and more loosely retained, while at higher levels recovery of salicylic acid from the column may be incomplete using the specified volume of eluant.

The concentration of urea in the reagent must

Determination of Free Salicylic Acid in Aspirin and Aspirin Products

By JOHN D. WEBER and JOSEPH LEVINE

In a previously described method for the determination of free salicylic acid in aspirin, the salicylic acid is isolated on a partition chromatographic column as its purple ferric–phenol complex, using ferric chloride solution as immobile phase. With the addition of a high concentration of urea to the ferric chloride, the method is significantly improved. The separation is more sharply defined, making feasible the analysis of larger samples of aspirin and permitting the use of a more easily prepared chromatographic column.

A PROCEDURE has been described (1) for the isolation and determination of small amounts of salicylic acid which occur in aspirin and aspirin products. The salicylic acid is retained on a Celite:2% ferric chloride partition chromatographic column as its ferric complex while the nonphenolic aspirin is eluted with chloroform. The ferric complex is then dissociated with acetic acid and the free salicylic acid eluted with chloroform.

Several investigators have encountered difficulty with the published method (2). During the elution of the aspirin, the salicylic acid migrates slowly down the column (as evidenced by the position of the purple complex) and spreads out into a diffuse band, which sometimes becomes difficult to discern. Unless the chromatographic column is packed with great uniformity, channeling may occur during both the elution of aspirin and the recovery of salicylic acid.

A radical improvement in the chromatographic separation is achieved with a modified ferric chloride reagent, which contains a high concentration of urea. The band of the ferric–salicylate complex obtained with this reagent is much more deeply colored than that obtained with the simple ferric chloride reagent. The dense, sharply delineated band migrates only very slightly during the elution of aspirin. The use of shorter columns, which do not require extraordinary care in packing, is therefore feasible. Columns prepared with the modified reagent will also accommodate much larger samples of aspirin than those prepared with ferric chloride alone.

Addition of urea to the ferric chloride reagent was suggested from the report of a urea–salicylic acid complex by Bolton (3). It is apparent that the formation of this binary complex does not account for the trapping of salicylic acid by the ferric chloride–urea reagent, however, since urea solutions alone, at any concentration, are completely ineffective in removing salicylic acid from chloroform solution.

Optimum results are obtained with an immobile phase containing 5% ferric chloride and which is 10 *M* with respect to urea. It must be maintained at a pH between 3.1 and 3.3. At lower pH levels the salicylic acid band becomes diffuse and more loosely retained, while at higher levels recovery of salicylic acid from the column may be incomplete using the specified volume of eluant.

The concentration of urea in the reagent must

Received May 19, 1965, from the General Methods Branch, Division of Pharmaceutical Chemistry, Bureau of Scientific Research, Food and Drug Administration, U. S. Department of Health, Education, and Welfare, Washington, D. C.
Accepted for publication November 4, 1965.

be 10 *M* to maintain dense salicylic acid bands during the elution of the aspirin. A quantity of salicylic acid which forms a zone 5 mm. deep with this reagent, for example, forms a zone spread throughout the column when the concentration of urea in the immobile phase is reduced to 7.5 *M*. In the absence of aspirin, the effect of the urea concentration is minor. Dense bands are obtained with urea concentrations over a range of 2.5 to 10 *M*.

It has been shown (1) that only dilute solutions of ferric chloride remove salicylic acid from chloroform solution; the U.S.P. ferric chloride test solution (9%) is virtually ineffective. In contrast, the effectiveness of the urea–ferric chloride reagent in maintaining a dense salicylic acid band increases with increase of ferric chloride concentration over a range of 1 to 15%. The color of the reagent at the higher concentrations deepens, however, lessening the visual contrast between its color and that of the salicylic acid complex. A concentration of 5% ferric chloride was selected as optimum for providing suitable color contrast while maintaining the compactness of the salicylic acid band on the column.

PROCEDURE

Reagent.—To 60 Gm. of reagent grade urea, add 8 ml. of 60% ferric chloride solution[1] and 42 ml. of 0.05 *N* HCl. Shake, without heating, to dissolve the urea. The pH of freshly prepared solution is about 3.2. It should be checked on a pH meter daily, and, as necessary, adjusted to between pH 3.1 and 3.3 by dropwise addition of 6 *N* HCl.

Salicylic Acid Standard.—Accurately weigh about 25 mg. of salicylic acid and dissolve in 100.0 ml. of chloroform. Transfer 5.0 ml. to a 100-ml. volumetric flask; add 2 ml. of glacial acetic acid, 20 ml. of ether, 20 ml. of methanol, and 4 drops of hydrochloric acid. Dilute to volume with chloroform.

Chromatographic Tube.—A 25- × 250-mm. test tube to which is attached a 50-mm. length of 6- or 8-mm. tubing. The tamping rod consists of a disk of stainless steel, aluminum, or glass, of a diameter 1 mm. less than that of the column, attached to a rod 12 to 18 in. long. Pack fine glass wool[2] in the base of the column as support.

Preparation of Trap Column.—To 3 Gm. of Celite 545[3] add 2 ml. of *Reagent*. Mix thoroughly, transfer to the column, and tamp, using gentle pressure, to a uniform mass. Cover with a pad of cotton about 20 mm. thick. (This insures uniform distribution of the solvent over the column cross section.)

Procedure.—Use water - saturated solvents throughout.

Aspirin and Aspirin Tablets.—Weigh a quantity of sample, equivalent to about 200 mg. of aspirin, into a beaker. Add 10 ml. of chloroform and stir for 3 min. to dissolve the sample. Transfer the solution to the column, rinsing the beaker with 10 ml. of chloroform in small portions. Wash the column successively with 10- and 50-ml. portions of chloroform to remove the aspirin. Rinse the tip of the column with a jet of chloroform. (If the purple zone reaches the bottom of the column, repeat with a smaller sample of aspirin.)

Place as receiver under the column a 50-ml. volumetric flask containing 10 ml. of methanol and 2 drops of hydrochloric acid. Elute the column with 10 ml. of ether containing 1 ml. of glacial acetic acid, followed by 30 ml. of chloroform, and dilute to volume with chloroform. Concomitantly determine the absorbance of this solution and of the standard solution at the maximum at about 306 mμ.

APC Tablets and Flavored Tablets.—Mount in series directly above the trap column a second column containing a pad of cotton about 20 mm. deep. Dissolve the sample as described above and transfer it to the upper column with the aid of 10 ml. of chloroform. Pass 20 ml. of chloroform over the columns; discard the upper column, and continue as described under *Aspirin and Aspirin Tablets*, beginning with "Wash the column successively with 10- and 50-ml. portions of chloroform."

DISCUSSION AND RESULTS

A moderate amount of urea is eluted together with the salicylic acid during the recovery of the latter from the column. Hydrochloric acid is added to insure acidity of the eluate, and methanol to achieve miscibility of the acid with the eluting solvent. The absorbance maximum of the resulting solution is at 306 mμ, as compared with the wavelength of 310 mμ in the absence of methanol. The standard reference solution is therefore prepared to have the same solvent composition as the eluate.

No measurable degree of hydrolysis of aspirin occurs during the analysis. The salicylic acid fraction obtained from 500-mg. samples of purified aspirin had an absorbance of 0.003, equivalent to about 0.001% of salicylic acid.

Measured amounts of salicylic acid were added to powdered aspirin U.S.P. and to powdered commercial tablets. Recoveries are presented in Tables I and II, respectively. The latter values show that the excipient materials present in these commercial formulations do not interfere with the procedure.

A number of samples of buffered aspirin tablets were assayed, employing the preliminary boric acid treatment described in the earlier procedure (1). Because of the precision of the analyses, it was thought that these represented the true content of free salicylic acid of the tablets. However, following a suggestion (4) that boric acid might not be fully effective in liberating salicylic acid from the buffering agents, it was indeed found that recovery of salicylic acid added to aluminum hydroxide gel, calcium carbonate, and magnesium trisilicate, which are commonly used in these formulations, was incomplete. A methanolic solution of oxalic acid effected complete recovery of salicylic acid from its calcium salt while producing only a negligible degree of hydrolysis of aspirin. However, neither this nor any other reagent thus

far tested quantitatively releases salicylic acid from aluminum hydroxide gel without causing extensive hydrolysis of aspirin.

Analyses of buffered tablets using the oxalic acid reagent had a precision equal to that obtained with boric acid, and uniformly indicated a higher free salicylic acid content. Examination of the insoluble residue showed, however, that these analyses did not represent the entire nonaspirin salicylate content of the tablets. Despite this incomplete recovery, 4 of 7 samples analyzed gave values in excess of 1% salicylic acid.

TABLE III.—ANALYSIS OF COMMERCIAL SAMPLES

Sample	Salicylic Acid Found, %
Aspirin powder, U.S.P.	0.018, 0.019, 0.020
Aspirin tablets, 5 gr. U.S.P.	
Brand 1	0.045, 0.043
Brand 2	0.019, 0.020, 0.020
Brand 3	0.076, 0.078, 0.070
Brand 4	0.125, 0.122, 0.124
Brand 5	0.285, 0.280, 0.280
Aspirin tablets, flavored 1¼ gr.	
Brand 1*a*	0.199, 0.209, 0.196

Brand 4	1.04, 1.06, 1.07
Brand 5	0.262, 0.264, 0.259

Aspirin products of various brands, both local and nationally advertised, were obtained from local retail pharmacies and food markets. The samples were purchased directly from the stock on the shelves; no information is available on their age. The analyses of these samples are presented in Table III.

Three of 5 samples of 5-gr. aspirin tablets were well within the U.S.P. XVII limits of 0.15% salicylic acid; 1 approached this value, and 1 exceeded it. Three of 5 samples of 1¼ gr. of children's flavored aspirin tablets exceeded this limit.

Four of the 5 samples of aspirin, phenacetin, and caffeine tablets were well within the N.F. XII limits of 0.75%, while a fifth, which had a loose bottle cap at the time of purchase, exceeded the limits.

Film Coating Theory and Practice

By GILBERT S. BANKER

Recent theory and developments relating to the formation and modification of synthetic polymeric films are discussed in relation to the pharmaceutical uses of such films in dosage form development. Fundamental mechanical and physicochemical properties of films as affected by plasticization, solvent effects, polymer chemistry, film additives, and other factors are considered in relation to film dissolution, permeability, and diffusion properties.

POLYMERIC FILMS are finding an ever-increasing range of application in pharmaceutical research, development, and dosage form design. In the coating of tablets and other solid dosage forms there is presently no coating methodology that can match film coating in production capability or economy. Polymeric film coatings have been increasingly employed to coat drug particles and drug-containing pilules to produce products with a delayed or prolonged pharmaceutical action. Approximately 1000 pharmaceutical patents pertaining to polymeric materials as adjuvants, including polymeric coatings, have been issued in the last 15 to 20 years. In addition to application to all types of solid oral dosage forms, polymeric films are being employed for such diverse uses as the coating of suppositories, the encapsulation of liquids, and aerosol spray bandages. As film theory and technology continue to advance, both fundamentally and in selected pharmaceutical applications, increasing and more effective utility of polymeric films will be made by the pharmaceutical industry. The purpose of this paper is to relate some of the more recent theory and developments in film technology to pharmaceutical applications and practice.

THEORY OF FILM FORMATION

Forces in the Film.—In any pharmaceutical film coating operation in which a polymer film is being applied to a matrix, sets of forces operate between the film forming polymer molecules on the one hand (cohesion), and between the film and the substrate on the other hand (adhesion). Cohesion, also known as autohesion or self-adhesion, refers to the ability of contiguous surfaces of the same material, at a molecular or at a supermolecular level, to form a strong bond which prevents or resists separation at the point of contact. To obtain high levels of cohesion 2 phenomena are necessary: the cohesive (autoadhesive) strength of the material, molecule to molecule, must be relatively high, and the contiguous surfaces of the film material must coalesce on contact (1). Coalescence or the disappearance of boundary layers between adjacent polymer molecular layers or surfaces is explained by diffusion theory. According to theory, movement (diffusion) of individual macromolecules or segments of macromolecules between and within film layers may occur under a variety of conditions, including during gelation, when polymers are deposited in solution over a previous polymer layer, or at elevated temperatures corresponding to a semisolid state (2). The result, if there is adequate cohesive attraction between the molecules and sufficient diffusion and coalescence, will be a restoration of the polymer structure to a uniform nonlaminated matrix at the contact zone (Fig. 1) affected by the displacement (diffusion) of whole molecules or of individual segments of the macromolecular chains. Only high polymers, owing to their molecular structure, combine sufficient cohesive strength and capacity for coalescence to produce fiber and film structures, drawn or deposited from appropriate solvents.

The significance of the degree of cohesion in film structures is fundamental to film properties. An increase in cohesion in the structure of 1 polymer to another, or of 1 analog of a homologous series to another will increase film density and compactness, may decrease porosity and permeability, decrease flexibility, probably increase brittleness, as well as affecting other film properties either directly or indirectly (3).

Controllable Processing Factors Affecting Cohesion in Pharmaceutical Film Coatings.—The factors which may increase film cohesion, polymer surface to polymer surface, not all of which are readily controllable in the typical pharmaceutical film coating operation include: increased surface contact time (4), increased contact temperature (5), increased contact pressure (4), coat thickness, and control of coat solution or coat dispersion concentration, degree of polymer solvation, and viscosity. Increased coat-contact temperature,

Received April 30, 1965, from the School of Pharmacy and Pharmacal Sciences, Purdue University, Lafayette, Ind.
Accepted for publication November 1, 1965.
Presented to the Pharmaceutical Technology Section, A.PH.A., Detroit meeting, April 1965.
The author expresses his appreciation to Mr. Tom Dinndorf, Rowell Laboratories, Baudette, Minn., for his helpful comments on this paper.

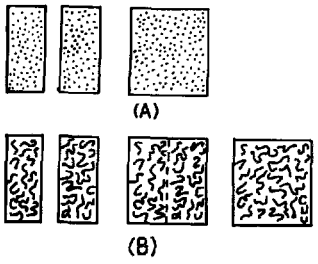

Fig. 1.—Schematic representation of the coalescence of (A) low molecular weight liquids, and (B) high polymers in a polymeric film structure.

time, or pressure all promote cohesion by promoting molecular diffusion at the contact boundaries.

Temperature.—Temperature is directly related to autohesion; indeed, the temperature dependence of cohesion is a proof of the diffusional basis of the process. As the contact temperature increases, the cohesive strength of the contiguous polymer surfaces increases over a definite temperature interval along an exponential curve, not unlike the exponential dependence of diffusion rate on temperature observed for low molecular weight materials (7). This exponential increase in diffusion rate with temperature is due to the increased thermal motion of complete polymer chain molecules or fractions of such molecules, and is probably secondarily related to decreased polymer, polymer gel, or polymer film density. That a more cohesive film generally results from the application of a warm coating solution to a warm substrate is well known to those skilled in coating technology. There are, of course, limits to the amount of heat which may be advantageously used, as excessive heat may cause premature spray drying of the coat, slipping and peeling of the coating as it approaches its melting or glass point, or the development of pinholes in the coat caused by solvent evaporation under high localized vapor pressure through a case-hardened film surface. It is also well known that an increased temperature generally greatly facilitates adhesion between polymer film and substrate, with the temperature effect probably eliciting the same phenomena as in cohesion (promoted diffusion).

Contact Pressure and Contact Time.—Contact pressure is not a readily controllable factor in the typical pharmaceutical film coating application. Contact time refers to the duration during which a newly deposited polymer film layer is "setting-up" and the polymer molecules, wholly or in part, are capable of diffusion and orientation. Reasonably rapid solvent evaporation rates are sought in most film coating applications to facilitate rapid coating. However, solvents which flash off prematurely not only may lead to spray drying of the atomized coat solution, but may produce noncohesive films due to a premature immobilization of the polymer molecules in the film structure prior to molecular orientation, as well as to poor diffusion of the polymer molecules between molecular layers in the film.

Film Coat Thickness.—Cohesive strength of films is commonly expressed as the peeling strength, represented as the work of ergs/cm.^{2}, required to separate bonded layers of film (5). The cohesive film strength (peeling strength) has been found to increase as a zero-order function of film thickness up to some fixed value, dependent on polymer film chemical class, after which the cohesive strength is constant with further increases in thickness.

Coat Solution Concentration, Solvation, and Viscosity.—Viscosity, hence polymer solvation and solution concentration, are of great importance to the self-adhesion of high polymers. At low viscosity or at high polymer solvation levels self-diffusion should be promoted. On the other hand, at low viscosities most coating solutions will be very dilute, coating times will be unduly long, and it will be comparatively easy for a selected deposited film component forming the bond to separate from the bulk of the previously homogeneous film substrate. Consequently, an intermediate viscosity will usually result in the highest cohesive strength (6). The viscosity at which the deposited coating solution gels will also affect cohesive strength, and this will be a function of the solvent or mixed solvent system used and the rate of desolvation and stereochemical displacement of the polymer from the solvent during evaporation.

Formulation Factors Affecting Cohesion in Pharmaceutical Film Coatings.—The formulation factors primarily affecting cohesion in pharmaceutical films include polymer chemistry (stereochemistry and functionality) and polymer structural properties (molecular order and crystallinity in the film), solvent effects, the presence of added dispersed solids, and plasticization.

Polymer Chemistry.—The shape of polymeric molecules exerts a strong influence on cohesion in films, since molecular shape largely determines both the diffusibility of a macromolecule or its individual branches or segments, and the strength of its interlacing areas. Macromolecules with a regular structure, provided they are not in a strongly crystalline state, should be more diffusible than molecules with a highly irregular stereochemical structure (8, 9). Branched molecules in which the branching does not greatly hinder diffusion may have a greater cohesive strength than nonbranched equally noncrystalline polymers, based on a firmer anchoring of such macromolecules in the diffusion layer. In a homologous series, lower molecular weight fractions exhibit a greater cohesion, and show a greater change in cohesion strength with temperature changes (5). In strongly polar polymers, self-adhesion by diffusion is insignificant, due to the minimal flexibility and fixed order of the macromolecules caused by the intermolecular forces holding the polymer chains in a fixed form. Proteins and cellulosics are examples of such polymers exhibiting minimal molecular diffusion, proteins tending toward a helix, and cellulosics having a rigid ring structure chain backbone. In crystalline polymer structures, the cohesion between ordered polymer molecules may greatly exceed that possible by the diffusion process in amorphous polymers (10).

The theory of cohesion in polymer films is complex and may involve the concepts both of diffusion and ordered structure. The cohesive strength of the crystalline–amorphous polymers used pharmaceutically is related to the presence, concentration, location, and relative polarity of polar groups along the polymer chain, regularity of chain structure, branching, molecular weight, and molecular weight distribution.

Polymer Structural Properties (Molecular Order and Crystallinity).—A highly ordered, crystalline polymer represents a polymer system of maximum

cohesive structure (compactness) and cohesive strength (represented by crystal strength). The intermolecular forces which promote cohesion, particularly hydrogen bonding, also promote crystallinity (11). While polar groups diminish molecular self-diffusion, strongly polar groups or hydrogen bonding groups (such as —OH and —COOH groups of substituted cellulosics, —COOH groups of pendant carboxyl containing linear polymers such as acrylics, or —CO—NH— groups of polyamides or polypeptides), if they are regularly distributed along the chain, will produce a distinct tendency for the formation of laterally ordered chains (structure I). The closer the polar groups

are to one another along the chain and the better their lateral fit, the more pronounced will be their effect to promote crystallinity (12, 13). Regardless of the factors promoting molecular order, it is extremely doubtful that any polymer is 100% crystalline, due to the molecular weight distribution found in polymer systems and imperfect chemical and stereochemical repeating molecular structures (14).

Typical noncrystalline polymers include those in which an irregularity of structure occurs, as in copolymers of two or more dissimilar monomer constituents, and in polymers having atactic configurations (a random sequence in the branching of substituents about the polymer chain). There are a few exceptions of atactic polymers such as poly(vinyl alcohol) which do crystallize. This is because certain groups such as CH_2, CHOH, CF_2, and C=O, are small enough to fit into the crystal lattice of the polymer structure. However, most atactic polymers, such as poly(vinyl acetate), due to their stereoirregularity, are noncrystalline and have never been crystallized (15).

The nearly limitless gradations between substantially completely crystalline polymers and truly amorphous polymers are typical of the great majority of pharmaceutically significant polymers which are composed both of distinct crystalline and amorphous phases. Such polymers commonly possess some features leading to disorder, such as atactic configuration, irregular substitution, or bulky side groups which space the individual linear macromolecules apart from each other, plus features leading to an ordered structure, such as a rigid chain or polar substituents. Thus, in addition to having a given chemical molecular structure or range of structures, polymeric fibers and films also have what is termed a fine structure (16) or a supermolecular structure (14). This structure describes the relative co-existing ordered-disordered lateral position or placement of the linear polymer chains or groups of chains in the particular polymer structure, and relates to the general over-all crystallinity of that structure (Fig. 2). The relative degree of molecular chain order to disorder in a film varies with such factors as the method of film application, the solvent system from which the film was cast, and the stresses in the film; and affects such physical properties as film strength, solubility, and miscellaneous mechanical properties (14). The toughness and rigidity of films are favored by a high chain order (14). Crystallinity, independent of molecular weight, is the single effective determinate which is directly related to film stiffness and yield point, and also affects film permeability, flexibility, and brittleness (17–19). In general it is more difficult to correlate the physical properties of a polymer film to a lateral order parameter (crystallinity) for derivatives of a parent polymer, such as cellulose derivatives, than for the parent polymer itself, *i.e.*, cellulose (14).

Solvent Effects (Solvation).—Pharmaceutical polymeric film coatings, almost without exception, are applied to the substrate from colloidal solution in an organic solvent system. During the dissolution of a macromolecular substance, the cohesive forces between the solute macromolecules are neutralized by unions with the solvent molecules (solvation). The more crystalline a polymer, the greater the intermolecular cohesive forces, and the more difficult it will usually be to dissolve such a polymer.

The polymers used in pharmaceutical film coating and other operations, so as not to be inert in the human gastrointestinal tract, are generally polyfunctional polyelectrolytes, containing an aliphatic polymeric nonpolar carbon chain with polar substituents along the chain. Depending on the aqueous pH at which the functional groups ionize and on the rate of ionization, the coating polymer may produce a fast, an enteric, or a prolonged disintegrating or dissolving coating. Polymers which are completely aliphatic (polyethylene), substantially crystalline (pure cellulose), or which contain only nonionizable functional groups or a very high proportion of such groups to ionizable groups (highly esterified carboxyl containing polymers) will be insoluble in water regardless of pH.

The functionality of the polymer also relates to solution properties and to film characteristics. As the functional groups on a linear polymer become ionized during dissolution, the charged groups will repel each other, producing a stretching of the poly-

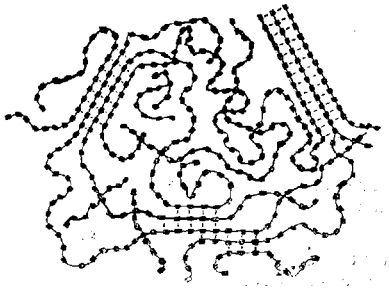

Fig. 2.—The fine structure or supermolecular structure illustrating the laterally ordered (crystalline)–disordered (amorphous) placement of linear polymer chains in a film matrix.

mer chain. The greater the degree of dissociation and the more extensively the chain is charged, the more the chain will uncoil. Simultaneously, the solvation effect, or the interaction between the charged polymer molecules and the molecules of the polar solvent, will increase with the increasing charge on the chain. With increased solvation there will usually be a viscosity increase due to the envelop of solvent surrounding each chain more effectively, keeping the chains from coming into contact and aggregating, and due to the extended configuration and greater spatial requirements of the more completely solvated system.

Polar solvents (Table I) tend to be solvents for polar substances including macromolecular polyelectrolytes (Table II), and nonpolar solvents are generally poor solvents for such polymers. A given polymer is most soluble in solvents that best match the polymer or its solvated derivative in cohesive energy density (Tables I and II) (20). Solubility properties of colloidal macromolecules in organic solvents are complex and depend on chemical, electrical, structural, and steric effects, which lead to mutual interactions between solute and solvent.

Copolymers present a special solubility problem,

[a] The cohesive energy densities were calculated from latent heats of vaporization and molecular volumes at 20°. C.E.D. is a measure of the intermolecular attraction and molecular cohesion of a substance and is particularly useful in predicting solvent power for polymers. (See *Reference 72*). [b] Dielectric constants determined at 25°. [c] Dielectric constants determined at 20°. As the dielectric constant decreases, the relative polarity, solvent to solvent, decreases. With a decrease in temperature the dielectric constant increases, and a polar organic solvent may become a better solvent for a polar polymer.

TABLE II.—RELATIVE POLARITY AND SOLUBILITY PARAMETERS (COHESIVE ENERGY DENSITY) OF POLYMERIC MATERIALS

since virtually all pharmaceutically employed copolymers contain a substantially nonpolar comonomer plus a polar comonomer. Examples of such copolymers, with the nonpolar component given first are: styrene, vinyl alcohol or acrylic acid copolymers; ethylene, maleic anhydride or acid copolymers; acrylate, acrylic acid copolymers.

The solubility of copolymers is generally low in solvents for either homopolymer, but may be high in mixtures of these solvents wherein maximum solvation and extension of the polar and nonpolar comonomer units occur in a polar–nonpolar mixed solvent system. A single solvent of intermediate polarity will not usually be as effective for such copolymers or for a mixture of 2 or more homopolymers which differ widely in polarity as the mixed polarity compound solvent system.

Not only the degree of substitution (D.S.) and the polarity of substituents, but also the space requirements of substituents, may affect the solubility properties of some polymers. The water solubility of cellulosics has been related to the wedging apart of the cellulose ring structure chains by the substituent groups to bare the remaining hydroxyls for hydration (21). Bulky substituent groups, being more effective in wedging the chains apart, enable water solubility to occur at lower degrees of substitution. Methylcellulose is soluble at D.S. 1.3 (22, 23), ethylcellulose at D.S. 0.7, and sodium carboxymethylcellulose at D.S. 0.3 (24). Solubility of cellulosics in organic solvents stems from a predominance of alkyl ether substituent groups over the remaining hydroxyl groups.

As a rule, maximum coating solution solvation and polymer chain extension will produce the most superior films showing the greatest combined strength and cohesiveness. Since solvation and polymer chain extension is reflected in the viscosity of the sol, viscosity provides a useful control measure to (*a*) compare the relative effectiveness of various solvents for a particular polymer or polymer system, and (*b*) appraise the adequacy of solvation and chain extension of a polymer system in a given solvent according to formulation and method of preparation prior to film application. Other physical methods have been used to measure solvation making use of birefringence measurements, vapor pressure data, heats of solution, and infrared absorption spectra (25–27), but the usefulness of such measurements varies with the polymer structure, and the results are often difficult to interpret. As a control procedure of the polymeric sols used in film coating operations, viscosity remains the most simple and direct, although empirical, method of comparing solvation.

Plasticization.—A plasticizer is defined as a substantially nonvolatile, high boiling, nonseparating substance, which when added to another material changes certain physical and mechanical properties of that material. Plasticizers (28–31) are added to polymeric substances for a variety of reasons, but they are especially necessary adjuncts to most polymeric films in order to reduce brittleness, improve flow, impart flexibility, and increase toughness, strength, tear resistance, and the impact resistance of the film coating. The mechanism by which the plasticizer achieves these changes is theorized to be a decrease in the cumulative intermolecular forces along the polymer chains (reduction in cohesion), which generally produces a decreased tensile strength, a lower softening temperature, and a decrease in the glass transition temperature. The plasticizer and polymer are generally thought to be held together by intermolecular secondary valence forces forming a complex or molecular aggregate (31). The lowering of the glass transition temperature below room temperature by plasticization changes a hard, brittle, glass-like material at room temperature to a soft, flexible, and tough material.

Two types of plasticization are recognized (3). External plasticization is the process, thus far described, by which a substance is added to the polymer structure and may be physicochemically associated to it, reducing cohesion in the structure to effectively extend, dilute, and soften the structure. Similar changes can be accomplished by altering the internal chemical structure of the polymer, as by copolymerization, which is known as internal plasticization. The method of plasticization employed with cellulosic and other comonomer polymeric pharmaceutical films is external plasticization. Acrylic, vinyl, styrene, and other polymers which may be readily copolymerized will require little, if any, external plasticization after copolymerization.

The basic requirements of any plasticizer in a polymer system are compatibility and permanence. To be compatible the plasticizer must be miscible with the polymer, indicating similar intermolecular forces in the 2 components. The most effective plasticizers will generally resemble most closely in structure the polymers they plasticize. Thus, water-soluble cellulose ethers (retaining a high ratio of hydroxyls to such ethers) are best plasticized by hydroxyl containing compounds such as glycerin, glycols, and other hydroxy containing compounds. Substantially aliphatic nonpolar polymers are best plasticized by chemically similar materials such as nonsolvent oils. However, since the intermolecular forces in nonpolar polymers, such as polyethylene, are low, it is difficult to find a plasticizer for such materials. Likewise, since the intermolecular forces of strongly crystalline polymers are so high, plasticizers cannot be found with adequately high intermolecular forces to satisfy such polymers and be compatible with them. Effective plasticization is, thus, usually limited to amorphous polymers or to amorphous-crystalline polymers in which the crystalline phase is not predominant.

It cannot be emphasized too strongly that the total film coating formulation of polymer-plasticizer-solvent, plus other components, such as insoluble additives or surfactants to promote spreading, must be considered as primarily affecting, in consort, the nature and properties of the film that is formed. Thus, in considering the 3 fundamental elements of polymer-plasticizer-solvent, not only must the polymer and plasticizer be compatible and the polymer be effectively solvated in the solvent, but the plasticizer must approximately match the solubility properties of the polymer in the solvent system used. In simple systems, since the polymer and plasticizer probably possess common functional groups, solvents can usually be readily selected in which the components are equally readily soluble, thereby preventing premature plasticizer or polymer separation during film dep-

osition and drying. In compound systems in which two or more polymers differing in polarity and chemical type are used with one or more plasticizers in a mixed solvent system, the problem of compatibility becomes complex. If a satisfactory mixed solvent system may be formed which is an azeotrope, the problems of changes in solvent composition during evaporation and premature separation of film components during drying will have been overcome. In nonazeotropic mixed solvent systems, drastic changes in solvent composition during drying with accompanying heterogeneous film component separation may be avoided if solvents can be selected which have somewhat similar vapor pressures at the film-drying temperature.

The permanence requirement of plasticizers in pharmaceutical operations is very important, since it relates to the physical and mechanical stability of the film with time and under stress environmental conditions. External plasticizers, which are physicochemically associated with the polymer by miscibility and by primary or secondary forces, may not readily be leached out of the film matrix and may resist losses by evaporation. The use of the higher molecular weight plasticizers of an effective plasticizer series, which have a lower vapor pressure and lower diffusion rate in the film matrix, will produce a plasticized film of greater permanence. The plasticity of an unmodified as well as of a plasticized polymer film is related to the chemical composition of the polymer (and plasticizer) and to the arrangement, stereochemistry, and forces acting between the chain macromolecules, including intermolecular and internuclear distances, and to the effect of the regularly interposing plasticizer molecules within the molecular polymeric network. These relationships and effects will dictate the proportion in which the plasticizer must be used to produce the desired film properties. Cellulosic polymeric films commonly require 30 to 60% plasticizer, relative to polymer weight for adequate plasticization. Less rigid polymers and copolymers will rarely require the addition of more than 10–20% of an external plasticizer.

Plasticizer efficiency, stability, compatibility, and permanence may be evaluated by a number of semiempirical tests, including measurement of the amount of nonsolvent required to cause phase separation of each component from the polymer-plasticizer solution, viscosity studies, polymer-solvent interaction constants of the solutions, depression of the glass transition temperature, and other physical and mechanical properties of plasticized free film samples. (See under *Mechanical Properties of Films.*) Since these tests are semiempirical they will not all rate a series of plasticizers in the same order. The ultimate selection of a particular plasticizer may also depend on selected physical properties of the plasticizer, *e.g.*, hygroscopicity (which may affect moisture uptake by the film and its effectiveness as a moisture barrier) and water solubility. Plasticizer water solubility is often important in pharmaceutical applications especially when higher plasticizer concentrations are required. A soluble plasticizer may be needed for a soluble coating, and an insoluble plasticizer may be required to produce an enteric or slow release coating.

Plasticizers having pharmaceutical applications include (15, 32): (*a*) phthalate esters, which account for over half of all the plasticizers used industrially; (*b*) phosphate esters, chiefly tricresyl phosphate, which may be restricted to topical film use; (*c*) adipates, azelates, oleates, and sebacates, especially useful for vinyls; (*d*) epoxy plasticizers produced by reacting hydrogen peroxide with unsaturated vegetable oils and fatty acids; (*e*) fatty acid esters from natural sources, which are also useful as extenders to reduce cost or to produce a slowly soluble coating; and (*f*) glycol derivatives which are particularly useful for cellulosics and poly(vinyl alcohol).

Addition of Dispersed Solids.—Frequently the most expensive aspect of film coating is the cost of the organic solvent carrier of the coating polymer. Recovery systems for these solvents in the exhaust air outlets of coating equipment have been prohibitively costly to date. Depending on the molecular weight of the polymeric materials and on the viscosity produced in the organosols, 2–10% w/v of polymer is the usual range of polymer which can be applied as a coating solution. When coating powders, beads, or pilules containing drug, the increased surface of the smaller particles may require that 25–100% of uncoated particle weight be added as film coating material on a dry weight basis. This means that for 1 Gm. of product to be coated from 2.5–50 ml. of coating solution may be required. In such cases solvent costs become extremely high and coating times are unduly long. To combat this problem pharmaceutical scientists have borrowed an approach of the paint industry by adding insoluble particulate fillers or extenders to the film compositions, either dispersed in the film coating polymer solution or dusted on the drug containing particles during coating. Alternate deposition of film coating polymer and dusting powder leads to the deposition of alternate polymer-powder monolayers with relatively low adhesional energies and a consequent loss of film durability (33, 34). The effects of dispersed added solids on polymer film structures, with the dispersed solids having been added from a coat solution containing suspended filler, are generally predictable according to the effect on properties wrought by a decrease in molecular order in the film. The decrease in order may result in plasticization-like effects, while the increased density and solids content in the film may actually increase film strength. Properly formulated fillers and extenders may greatly enhance film dimensional stability, impact resistance, tensile and compressive strength, abrasion resistance, and thermal stability (35, 36).

Desolvation (Gelation).—As the solvent of the applied polymer solution evaporates, an organogel commonly forms at some critical solids concentration during film formation. The most important property, which gives information about the onset of such gelation during drying, is the increase in viscosity with time at constant temperature and during increasing concentration of the colloid. Gelation involves structuration of the organosol system. In the less concentrated organosols prior to solvent evaporation, Brownian movement will be adequately intense and unhindered to keep the aggregates in a continually dispersed condition by the molecular impacts. Upon cooling or with an increasing concentration of polymer in the solution

via solvent evaporation, the power of the impacts diminishes, and the particles can stick together or form a network type of structure. If the chains are asymmetric, as are most of the pharmaceutical polymeric polyelectrolyte materials, they will be joined into a substantially random three-dimensional mesh on gelation, which will immobilize the organic solvent liquid. Another way of visualizing the gel as it forms is by desolvation of the colloidal polymeric material by evaporation of the organic solvent. Since the number of molecules of solvent per molecule of polymer decreases as evaporation proceeds, desolvation of the polymer is continuously affected, and at some point gel growth will occur, and the system will go through an organogel or semigel phase. The dry film will, therefore, represent the final stage of a gel-like aggregate resulting from the progressive evaporation of the volatile solvent.

The rate of desolvation and gelation is a primary function of the evaporation rate of the solvent or compound solvent system (37). A rather rapid rate of desolvation and gelation is usually indicated in pharmaceutical film coating operations to permit more rapid application of the coat, to reduce the duration of the tacky state of the coat during drying on continuous or intermittent application, and to promote simultaneous desolvation of the various coat components. If the coating is being applied from a spray system, the solvent must not evaporate prematurely so as to deposit a spray dried or gelatinized coating on the matrix. The major advantage of the airless spray technique is in circumventing this last problem.

MECHANICAL PROPERTIES OF FILMS

Polymeric films possess mechanical and stress-strain (rheological) properties which are comparable to the viscosity properties of liquids. These film properties relate to such characteristics of film coatings as impact strength, flexural strength, coat stability to temperature change, peel strength, flexibility, and coat resistance to many types of environmental and physical stresses. The stress-strain properties are determined by measuring the linear expansion of standard free test film strips under increasing load forces (38). From the stress-strain curve (40) (Fig. 3) the following physical characteristics of the film samples may be determined: tensile strength, yield point, breaking strength, modulus of elasticity, plastic deformation, and other properties.

The modulus of elasticity, also known as Young's modulus, is the constant of proportionality of stress to strain, and is equal to the slope of the straight-line portion of the stress-strain curve. This parameter is a measure of the "stiffness" of the film, or the ability of the film to withstand a high stress while undergoing little elastic deformation. The greater the slope of the curve and the higher the modulus of elasticity, the stiffer and stronger the film, and the more stress will be required to produce a given amount of deformation.

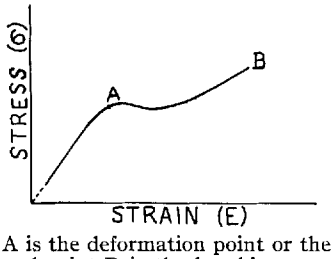

Fig. 3.—Stress (Gm. load/cm.^{2} of surface)—strain (cm. or per cent elongation). Curve of a typical pharmaceutical thermoplastic polymer film structure. Point A is the deformation point or the lower yield point, and point B is the breaking stress, breaking point, or the upper yield point.

Tensile stress is the load per unit area of the original cross section at any instant, usually expressed as force/unit area (39). The maximum tensile stress during a test (A of Fig. 3) is termed the tensile strength. Point A of the stress-strain curve also represents a stress at which the film first undergoes a marked increase in strain without a corresponding increase in stress, representing permanent deformation. This stress value for a standard film sample is termed the "yield point." Sometimes the stress at the deformation point, A, is called the "lower yield point," and the stress at point B, the film break point, is called the "upper yield point." Some materials have no lower yield point since they fail or break before they deform materially. A yield strength may then be determined, which can either be the maximum stress above which the material is damaged or, in comparing a series of films, is the stress of some fixed strain.

The distance between A and B along the stress-strain curve (Fig. 3) indicates the degree of plastic deformation the sample undergoes before breaking. If the film sample has a low yield point and undergoes little deformation before breaking (the distance A to B is short), the film is weak and brittle. Lever and Rhys (40) classify polymeric materials into 4 categories according to the relative height of the yield point on the stress axis and according to the difference between the yield point and the breaking point along the strain axis.

Ordinary substances are little affected by changes in the external environment such as pressure, temperature, humidity, or physical stress, relative to their ordering or crystallinity. Polymers behave quite differently. Environmental factors may appreciably affect the mechanical properties and the stress-strain relationships of certain polymer films, especially polar polymers such as the cellulosics, due to the moisture sorption and swelling of the film structure (41, 42). The effect of such moisture sorption is similar to plasticization; elongation (strain) begins at a lower stress (load), elongation is much greater for given load forces, and the presence of a yield point may not be detectable. The amount of strain (elongation) under stress (load) is also generally significantly increased with a temperature increase (43, 44). Polymer structures also tend to increase greatly in crystallinity with stress. The reasons for this difference lie in the filiform shape and the high internal flexibility of the individual molecules in the macromolecular compounds.

Stress-strain data may be used in comparing film samples as a function of formulation factors, *e.g.*, polymer combinations used, plasticizer, solvent system or surfactant employed, the effect of dispersed solids; or the data after correlation to coat mechanical stability properties on a given substrate may provide a direct indication of coat friability resistance, impact strength, abrasion resistance, and other properties. Munden *et al.* (45)

and Utsumi (46) have recently reported the modulus of elasticity, tensile strength, and per cent elongation of plasticized and unplasticized free films. Kabre (47) reports that the plasticizer is the most important formulation factor affecting mechanical properties of films, and he compared a series of plasticizers for their effect on the mechanical properties of a cellulosic polymer system.

An important mechanical effect of polymeric films, from a pharmaceutical coating standpoint, relates to their surface friction. Hardy (48) has reported on the property of polar organic compounds lowering the coefficient of friction of rubbing solids. Langmuir reported early on the effectiveness of fatty acid films in reducing frictional coefficients (49) and also found that multimolecular layers of film did not significantly reduce the coefficient of friction beyond the reduction produced by a monomolecular film (50). The mechanism of the lowered surface friction is related to the polar film forming groups adhering to the substrate, leaving the more aliphatic and less polar polymer structure exposed to comprise a surface of lower free surface energy, with the film coating initially deposited therefore acting like a boundary lubricant (51). The problems encountered in tablet and particle film coating in conventional equipment due to the lowered coefficient of friction of the coated material, the sliding of the polymer coated contents in the coating pan, and the common necessity for baffling the coating pans is well known. As polymer coat buildup proceeds beyond the monolayer, the problem involved with slipping and sliding of the coating pan contents often diminishes. The reason for this is that as the substrate is covered and the coat builds, there is less polymer orientation to the substrate, polymer deposition in the film is more random, and there is a consequent increase in the coefficient of friction of the coating.

PERMEABILITY PROPERTIES OF FILMS

The permeability of polymeric film coatings involves 3 processes of interest to the pharmaceutical scientist: (*a*) gas diffusion processes, notably oxygen permeation, through the film; (*b*) water and water vapor sorption and permeation (liquid permeation processes); and (*c*) dialysis processes concerned with the dialysis and permeation of soluble components across the intact or modified film.

Munden (45) found an oxygen permeability range of 10^{-4}–10^{-3} Gm. cm./cm.^{2} 24 hr. for the oxygen permeability through free unplasticized films. With a few exceptions, he found an inverse relationship between water vapor transmission and oxygen permeability. Water vapor permeability has been shown to be dependent on the relative polarity of the polymer (52). The more polar films tend to be more ordered and less porous, hence less oxygen permeable; while the less polar films are more porous, permitting the permeation of oxygen but not necessarily of the larger water molecules; and, being more lipophilic, the less polar films have less affinity for moisture and water sorption. Gas permeation through a completely crystalline polymer is known to be negligible. Bent (53) reports that gas permeation is proportional to the volume fraction of the amorphous phase of a film structure,

$$P = P_a X_a$$

where P_a is the premeability for the amorphous phase, and X_a is the volume fraction of the amorphous phase in the film structure.

Lamonde (54), in studying a series of substantially insoluble films, found that the addition of phthalate plasticizers increased water permeability rates with an increasing concentration of plasticizer, and with a decrease in molecular weight of the plasticizers of a homologous series at a constant concentration level. Figure 4 shows the latter relationship for Lucite 46, a 50/50 *n*-butyl/isobutyl methyl acrylate copolymer. The water permeability decrease is related to a water solubility decrease in the plasticizer as one goes up in molecular weight in a homologous series of plasticizers. Even though the difference in water solubility in the plasticizers within the series is small, the slight water sorption by the plasticizer as described by solution theory (55) promotes further sorption, frequently nonideal (56) by the film, related to a clustering tendency of the penetrant molecules in the film (57–59). The addition of other additives, such as surfactants, to a film of ethylcellulose has been reported to produce clustering centers for water sorption (60).

The relationship between the assorted formulation factors and oxygen, and water vapor or water permeability and actual stability parameters of coated products remains to be established.

Dialysis and liquid permeability properties may be important to both fast and slow releasing film coating formulations. Some present commercial pharmaceutical tablet film coatings, presumably composed of cellulose acid phthalate and polyethylene glycol, release medicament substantially completely within 1 hr. through an intact film. An obvious application with marked advantages of

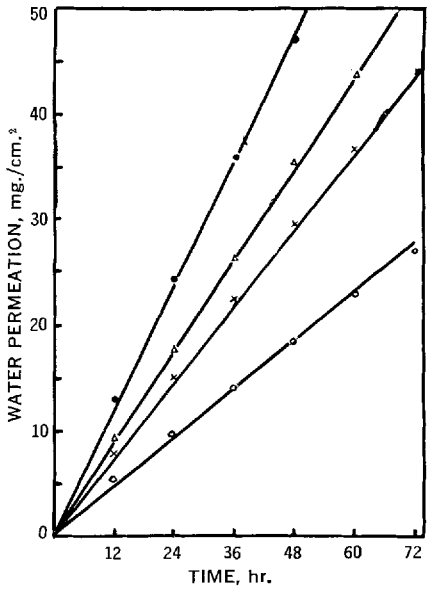

Fig. 4.—The effect of plasticizer composition (molecular weight and substitution) on the water permeability of *n*-butyl/isobutyl methacrylate (Lucite 46) copolymer films containing 15% plasticizer. Key: ○, unplasticized; ×, dioctyl phthalate; △, dibutyl phthalate; ●, diethyl phthalate.

liquid permeable and dialyzing film coatings of controlled release rates is in the sustained-release field.

Glass powder beads are reported to increase the glass transition temperature (Tg) of polyisobutylene, polyurethane (61), polystyrene, and poly (methyl methacrylate) (62), and titanium dioxide is reported to have the same effect on the Tg of other polymers (63). The increase in glass transition temperature appears to depend on the volume fraction of the filler in the system with the effect being attributed to the immobilization by adsorption of the polymer segments close to the surface of the filler particles. Carbon black did not affect the Tg of several polymers studied (64). Polar titanium dioxide as well as nonpolar fillers substantially reduce the sorption of organic vapors by poly (vinyl acetate), even at very low vapor pressures (65). The absorption isotherms of filled polymer films closely resembled that of the pure polymers below their glass transition temperatures, which also was attributed to immobilization of polymer segments at the solid surface.

As more is learned about methods of controlling the film membrane diffusion coefficients of pharmaceutical films as functions of added dispersed solids, film structure and orientation, salt concentration, ion ratios, film membrane–solution interactions (65–67), acid and base concentrations (68), and liquid boundary layer thickness (69), and according to formulation and methods of application, this physicochemical approach to controlled drug release will certainly advance, and the utility of polymeric films as more effective protective coatings may be exploited more completely.

Some Spray-Dried Formulations of Sulfaethylthiadiazole for Prolonged-Release Medication

By AHMED F. ASKER* and CHARLES H. BECKER

Aqueous and organic solvent solutions containing sulfaethylthiadiazole and dissolution-retarding materials were spray dried with the purpose of preparing sulfaethylthiadiazole in prolonged-release form. Shellac, cellulose acetate phthalate, Glycowax S-932, Castorwax MP 80, aluminum monostearate, and glyceryl monostearate were used as the dissolution-retarding materials. Microscopic examination and infrared spectral analysis were carried out on some of the spray-dried products. An *in vitro* evaluation of the antibacterial activity of spray-dried sulfaethylthiadiazole was compared with an original sample. Dissolution characteristics of the products were studied *in vitro,* and one product was evaluated *in vivo* by urinary excretion data.

THE PHARMACEUTICAL industry has in the last decade become increasingly active in the manufacture of oral dosage forms intended to impart prolonged, sustained, or long-acting therapeutic effects. Spray drying as a method of processing such products has received little attention. Although the process is mentioned in the patent literature, detailed information is not given.

Spray drying usually results in the production of free-flowing monodispersible particles which could be directly compressed into tablets, filled into capsules, or made into suspensions.

The technique of spray drying suspensions, as shown by literature reports, necessitates the use of micronized drug, the maintenance of stirring the feed throughout the operation, and the use of suspending agents to maintain a uniform suspension. There also appears to be a limitation concerning the amount of solids which can be suspended to give a satisfactory spray. Therefore, solutions rather than suspensions were used in this study. The use of solutions also adds simplicity to the process of manufacture, thus insuring better reproducibility of product.

Aqueous ammonia has been widely used as a solvent for shellac. Ammonia was reported to volatilize when an ammoniacal solution of shellac was used in coating tablets (1). For some sulfonamides, such as sulfadiazine and sulfathiazole, Higuchi *et al.* (2) demonstrated that, when their ammonium salt solutions were spray dried, ammonia volatilized, and the drug reverted to its original form. Use was made, therefore, of the solvent action of aqueous ammonia on shellac and sulfaethylthiadiazole to prepare clear solutions, which were then spray dried.

Malm *et al.* (3) reported the formation of soluble sodium and triethanolamine salts of cellulose acetate phthalate. Its ability to form an ammonium salt was utilized in this study for the same reasons mentioned for shellac.

In the case of Glycowax S-932,[1] Castorwax MP 80,[2] and glyceryl and aluminum monostearate, a solvent mixture of 1 part by volume of absolute alcohol and 3 parts of chloroform was used to dissolve both the drug and the dissolution-retarding material with the aid of gentle heat.

EXPERIMENTAL

Materials.—Sulfacthylthiadiazole (SETD) was obtained from the American Cyanamid Co. The dissolution-retarding materials used included white dewaxed shellac,[3] cellulose acetate phthalate,[4] Glycowax S-932, Castorwax MP 80, aluminum monostearate U.S.P., and glyceryl monostearate N.F.

Preparation of Solutions.—In the case of shellac and cellulose acetate phthalate, their ammonium salt solutions were mixed with solutions of the ammonium salt of SETD prepared by essentially the same method described by Higuchi *et al.* (2). Glycowax S-932 and Castorwax MP 80 were dissolved in warm solutions of a mixture of 1 part by volume of absolute alcohol and 3 parts of chloroform in which the SETD was previously dissolved.

Preparation of Spray-Dried Materials.—The solutions were spray dried in a Bowen table model spray dryer. The solutions were fed by gravity and the feed rate controlled by means of a glass stopcock. The resulting products were screened through a 100-mesh sieve, transferred to tight containers, and stored at room temperature. Table I

Received April 29, 1965, from the College of Pharmacy, University of Florida, Gainesville.
Accepted for publication October 4, 1965.
Abstracted in part from a dissertation submitted by Ahmed F. Asker to the Graduate School, University of Florida, Gainesville, in partial fulfillment of Doctor of Philosophy degree requirements.
* Fellow, Faculty of Pharmacy, University of Alexandria, Alexandria, Egypt, United Arab Republic.

[1] Glycowax S-932 is a product of Glyco Chemicals, Williamsport, Pa.
[2] Castorwax MP 80 is a product of the Baker Castor Oil Co., Bayonne, N. J.
[3] Bradshaw-Praeger and Co., Chicago, Ill.
[4] Marketed as C-A-P by Eastman Kodak Co., Rochester, N. Y.

TABLE I.—OPERATING CONDITIONS FOR SPRAY DRYING THE SOLUTIONS OF SETD AND DISSOLUTION-RETARDING MATERIALS

Soln.	SETD-Dissolution-Retarding Material Ratio	Feed Solids, % w/v	Feed Rate, ml./min.	Temp. Ranges, °C. Inlet	Outlet	Cooling Ports
SETD–shellac	1:1	3.8	12	210–216	38–40	Partially open
	1:2	4.3	18	210–216	38–40	Partially open
	1:3	4.0	13	210–216	37–39	Partially open
SETD–cellulose acetate phthalate	1:1	5.7	30	220–223	36–38	Partially open
	1:2	5.0	30	216–221	37–38	Partially open
	1:3	4.7	42	216–221	38–40	Partially open
SETD–Castorwax MP 80	1:1	8.0	16	138–149	36–38	Open
	2:3	8.0	18	143–149	37–38	Open
	1:2	6.8	20	143–149	37–38	Open
SETD–Glycowax S-932	1:1	6.7	12	171–174	38–40	Open
	2:3	7.5	20	171–173	37–39	Open
	1:2	4.7	18	171–175	36–39	Open

shows feed concentrations and operating conditions for spray drying the solutions made.

Microscopic Examination of the Spray-Dried Materials.—Microphotographs were taken of the spray-dried formulations which consisted of 1 part of the drug and 2 parts of the dissolution-retarding material. The characteristic particle shape and size are seen in Figs. 1–4.

In Vitro Evaluation of the Antibacterial Activity of SETD.—The agar cup-plate method of assay (4) on samples of original SETD and spray-dried ammonium salt of SETD was carried out against *E. coli* and *S. aureus*. A microstatistic advocated by Dixon and Massey (5) was utilized in the evaluation of the results at $\alpha = 0.05$. The results obtained are shown in Table II.

Infrared Spectral Analysis.—Infrared spectral analysis of original SETD, shellac, cellulose acetate phthalate, and their spray-dried ammonium salts was performed by the potassium bromide pelleting technique on a Perkin-Elmer Infracord model 137.

In Vitro Dissolution Studies.—The *in vitro* release patterns of the spray-dried products were determined in 0.1 *N* HCl (pH 1.1) and alkaline pancreatin solution (pH 8.3). The method used is essentially the same as that given by Robinson and Swintosky (6). The rotating-bottle apparatus described by Souder and Ellenbogen (7) operating at 40 r.p.m. in a 30 ± 0.5° water bath was employed. The amount of SETD released at various time intervals was determined in the filtrate by the Bratton and Marshall (8) colorimetric assay.

The *in vitro* release curves of products consisting of 1 part of SETD by weight and 2 parts of the dissolution-retarding materials are shown in Figs. 5 and 6.

In Vivo Evaluation.—The method is basically the same as that described by Nicholson *et al.* (9) for the clinical evaluation of sustained-release tablets of SETD using urinary excretion studies. Four healthy adult male subjects were utilized in the evaluation of the spray-dried formulation of SETD–Glycowax S-932 which gave a satisfactory *in vitro* release pattern as compared with a sustained-release powder of SETD.[5] Urine samples were collected at various time intervals, and the amounts of free SETD excreted were determined by the Bratton and Marshall method (8).

RESULTS AND DISCUSSION

Preparation of Spray-Dried Materials.—Solutions of the dissolution-retarding materials were spray dried in order to study their behavior during the operation. The spray-dried material also served as blanks for the *in vitro* dissolution studies.

Shellac, cellulose acetate phthalate, Glycowax S-932, and Castorwax MP 80 presented no difficulties in spray drying. This behavior was reflected in spray drying their formulations containing the drug (Table I).

Difficulty was encountered in spray drying an aluminum monostearate solution due to its gelatinization in the feed line. Spray drying of a glyceryl monostearate solution resulted in the production of sticky particles. These difficulties were not overcome by operating the dryer over a wide range of feed rates and inlet gas temperatures.

The ammonium salt solution of sulfaethylthiadiazole was spray dried to serve as a control. The spray-dried material was found to have a melting point of 185–186.5° which is in agreement with the literature value for sulfaethylthiadiazole.

Microscopic Examination.—Examination of Figs. 1–4 shows the spherical or nearly spherical shape associated with spray-dried materials. The porous nature of the particle is quite evident in the case of the SETD–cellulose acetate phthalate combination. This is possibly due to the good film-forming properties of cellulose acetate phthalate with the result that a case-hardening effect was produced.

In the case of formulations of cellulose acetate phthalate and shellac, more isolated particles were obtained than with formulations of Glycowax S-932 and Castorwax MP 80, of which a greater portion was in the form of aggregates. This may be expected from wax or wax-like materials because of the tendency of wax particles to adhere to each other.

In Vitro Evaluation of the Antibacterial Activity of Spray-Dried SETD.—Although it is accepted that heat degradation does not occur during spray drying, Smith (10) pointed out that the spray of the smallest particles is dried faster than the main portion of the spray; therefore, the smallest par-

ticles approach the inlet gas temperature and could be damaged by heat. In order to study the effect spray drying might have on the antibacterial activity of SETD, the agar cup-plate method was carried out. The results obtained appeared to show no significant difference between original SETD and spray-dried ammonium salt of SETD when tested against *E. coli* and *S. aureus* (Table II).

Infrared Spectral Analysis.—The infrared spectrum of the spray-dried ammonium salt of SETD compared well with that of the original sample of SETD, suggesting no apparent changes in the chemical constitution of the drug during spray drying. This was also confirmed by the melting point determination. Spectra of the spray-dried ammonium salts of shellac and cellulose acetate phthalate, however, were not comparable with the original materials. The complex constitution of shellac, the possibility of its polymerization during spray drying, and the polymeric nature of cellulose acetate phthalate may account for these differences.

The spectral analysis provided by this study was not sufficient to support a conclusion of more significance, but it gives some insight of the apparent changes produced by spray drying.

In Vitro Dissolution Studies.—The *in vitro* screening test was carried out in order to identify products worthy of *in vivo* evaluation (Figs. 5 and 6).

SETD–shellac formulations gave substantial retardation of release when tested in 0.1 *N* HCl. The higher the proportion of shellac to the drug, the more retardation was obtained. However, no significant retardation was demonstrated by formulations of SETD–shellac in alkaline pancreatin solution, regardless of the amount of shellac to drug used in this study. This may be attributed to the formation of highly soluble salts of shellac in alkaline pancreatin solution. This insignificant retardation was amplified by the use of dewaxed shellac and the small porous particles obtained in spray drying.

SETD–cellulose acetate phthalate formulation demonstrated more release of the drug in 0.1 *N* HCl as compared to those of SETD–shellac combinations. However, less dissolution of drug was obtained in alkaline pancreatin solution.

No appreciable retardation of drug release was demonstrated by SETD–Castorwax MP 80 in either 0.1 *N* HCl or alkaline pancreatin solution. This may be attributed to the slightly hydrophilic nature of Castorwax MP 80 as compared to other waxes due to hydroxy acid esters present.

SETD-Glycowax S-932 formulations showed a significant retardation of release of the drug in 0.1 *N* HCl and in alkaline pancreatin solution especially at a concentration of 1 part of the drug and 2 parts of the wax. The *in vitro* release pattern of this combination compared within a reasonable range with that of a sustained-release control sample (supplied by Smith Kline & French Laboratories) consisting of 2 parts of SETD and 3 parts of Castorwax MP 80. This formulation was therefore utilized in the *in vivo* evaluation.

In Vivo Evaluation.—Evaluation of SETD–Glycowax S-932 (1:2) by urinary excretion data showed that an insignificant amount of drug appeared to be released in the first 3 hr. after drug administration (Table III and Fig. 7).

Results also showed that less drug appeared to be released *in vivo*, contrary to what was expected from the *in vitro* screening results. This emphasizes the fact that *in vitro* testing does not necessarily reflect *in vivo* response. This was also reported by Blythe (11), who found that although sulfaethylthiadiazole in sustained liquid or tablet form

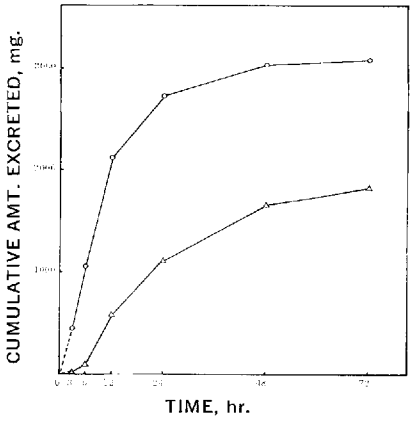

Fig. 7.—Average cumulative urinary excretion of free SETD for 4 humans receiving a 3.9-Gm. oral dose of SETD in plain form (○) and SETD–Glycowax S-932 combination (△).

gave substantially different release rates *in vitro*, yet both gave practically identical blood levels when tested in humans.

The fact that little or no drug was released in the first 3 hr. after drug administration, suggests that plain SETD can be added to the initial dose of the SETD–Glycowax S-932 combination without complications as far as product design is concerned.

Since less drug was released from the SETD–Glycowax S-932 (1:2) combination, a lower proportion of the wax appears necessary to obtain a medication that would meet the requirements for a more desired prolonged-release product.

The average physiologic availability of the drug from SETD–Glycowax S-932 combination tested *in vivo* was 59% after 72 hr. This low physiologic availability would reflect the incomplete release of the drug as indicated by urinary excretion data.

Automated Differential Amperometric Analyzer

Application to Penicillin Determination

By JOSEPH BOMSTEIN, J. M. SHEPP, S. T. DAWSON, and W. J. BLAEDEL*

An automated, differential amperometric analyzer has been constructed, based on the tubular platinum electrode and a differential signal detection system. Its chief advantages are sensitivity to species which are oxidizable or reducible at the platinum electrode, and a linear relationship between concentration and signal. As applied to the iodimetric determination of several penicillins, precision is 0.7–2.6 per cent and accuracy ranges from 1.0 to −3.0 per cent.

CONSIDERABLE progress has been made in recent years in automating analytical laboratory processes. A number of reports deal with automation of 1 or more steps of analytical procedures, and outstanding success has been achieved industrially with the AutoAnalyzer (Technicon Instruments Corp., Chauncey, N. Y.), generally applying spectrometric techniques. A greater range of applications might be handled by combining the instrument's continuous-flow and chemical-physical processing capabilities with an electrometric detector. Redox analyses could then be performed. Such a system has been designed, constructed, and evaluated for the iodimetric determination of penicillins.

The method involves degradation of the penicillin with alkali or penicillinase, followed by iodimetric determination of the resulting penicilloic acid (1). A published procedure, in which a penicillin stream after hydrolysis and dialysis reacts with iodine to cause an absorbance decrease (2), has been modified and used to prove the practicality of an amperometric technique.

Automated Differential Amperometric Analyzer

Application to Penicillin Determination

By JOSEPH BOMSTEIN, J. M. SHEPP, S. T. DAWSON, and W. J. BLAEDEL*

An automated, differential amperometric analyzer has been constructed, based on the tubular platinum electrode and a differential signal detection system. Its chief advantages are sensitivity to species which are oxidizable or reducible at the platinum electrode, and a linear relationship between concentration and signal. As applied to the iodimetric determination of several penicillins, precision is 0.7–2.6 per cent and accuracy ranges from 1.0 to −3.0 per cent.

CONSIDERABLE progress has been made in recent years in automating analytical laboratory processes. A number of reports deal with automation of 1 or more steps of analytical procedures, and outstanding success has been achieved industrially with the AutoAnalyzer (Technicon Instruments Corp., Chauncey, N. Y.), generally applying spectrometric techniques. A greater range of applications might be handled by combining the instrument's continuous-flow and chemical-physical processing capabilities with an electrometric detector. Redox analyses could then be performed. Such a system has been designed, constructed, and evaluated for the iodimetric determination of penicillins.

The method involves degradation of the penicillin with alkali or penicillinase, followed by iodimetric determination of the resulting penicilloic acid (1). A published procedure, in which a penicillin stream after hydrolysis and dialysis reacts with iodine to cause an absorbance decrease (2), has been modified and used to prove the practicality of an amperometric technique.

EXPERIMENTAL

Differential Electrode Detection System.—The detector is a differential electrode system based on the tubular platinum electrode (TPE) (3, 4). Figure 1 shows the pair of platinum electrodes and the saturated calomel reference electrode. The sample stream enters one side of the Y-tube, flowing past a pulse suppression overflow tube, then through 0.5 in. length of platinum tubing (i.d. 0.06 in., o.d. 0.07 in.) which serves as 1 arm of a Wheatstone bridge. (See TPE_1 in Fig. 2.) The reference stream, which serves the purpose of blank compensation, flows past a second overflow tube, then through a second TPE identical to the first. This is the arm of the bridge TPE_2, in Fig. 2. The two streams combine to give a conducting path for current flow through the saturated-calomel reference electrode (SCE), physically separated from the flowing stream by a porous glass wall (code 7730 Vycor, Corning). Impurities introduced by diffusion into the SCE are displaced by a flow of saturated KCl/Hg_2Cl_2. The ground connections are added to improve electrical stability.

Bridge Circuit.—Figure 2 shows the schematic diagram of the bridge to which the signal from the electrodes is applied. Except for the replacement of the microvoltammeter and recorder by the VOM-6 recorder (Bausch & Lomb, Rochester, N. Y.) alone, it is identical to the bridge discussed by Blaedel and Olson (3). Initial balance is obtained

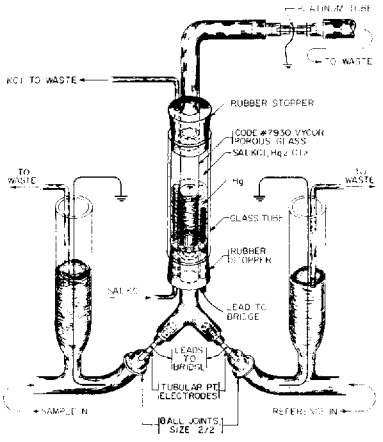

Fig. 1.—Electrode system.

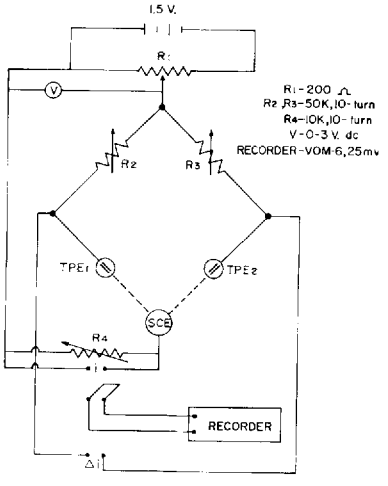

Fig. 2.—Bridge circuit. Key: —, wiring; – – –, solution (conducting) path.

by adjusting R_2 and R_3 while the blank solution is flowing through both TPE's. R_1 is set to a potential suitable for the amperometric measurement of iodine, as determined by the nature of the chemical system. When the sample replaces the blank in TPE_1, the balance between the 2 diffusion currents is disturbed, resulting in a displacement of the recorder pen when the switch is closed in the Δi-position. Closing the switch in the i position provides a convenient way to measure total current flow in order to select the proper recorder range. Impedance matching with the VOM-6 recorder requires the use of a millivolt range.

Pulse Suppression.—The reagent pump in this automated analyzer is peristaltic, and capable of long-term operation with excellent reproducibility over a wide range of speeds. The peristalsis, however, causes a pulsing flow of the reactive species through the electrodes, inducing a corresponding pulsing electrical signal at the recorder. Even careful matching of blank and sample channels is not adequate to remove the pulse effect when high recorder sensitivity is used. In order to provide a smooth base-line and sample record, a pulse suppression system is introduced. A flow-control pump (model PA-56, New Brunswick Scientific Co., New Brunswick, N. J.) is installed at the exit end of the system, pumping out at a rate less than the combined rate of the reagent, blank, and sample influent streams. The resulting difference in pressure causes an overflow from each channel into a chamber (10-ml. syringe body) which is open to the atmosphere at the other end. The liquid head is held at a predetermined level by pumping off the excess liquid to waste through the same pump used to supply electrolyte to the reference electrode. (See Figs. 1, 3, 4.)

Application to Penicillins.—The flow system for determining penicillins is shown in Fig. 3, and the relationship among the basic units is shown in Fig. 4. For test purposes, samples were fed manually, omitting any programming device. The reagent pump is the Harvard model 600-1200 (Harvard Apparatus Co., Dover, Mass.) having dual peristaltic channels pumping 180° out of phase. To accommodate the 8 (standard instrument) pump tubes required, an adjustable slotted rack is mounted on top and is positioned to hold 4 tubes tautly in each channel. (See Fig. 5.) Penicillin solution is continuously aspirated in a single tube and is split at a tee before passing through sample and blank lines in the Harvard pump. Successive samples are separated by allowing air to enter the pick-up tubing. In order to insure equal pump rates in blank and sample streams, the reagents are paired in each channel, *e.g.*, both KIO_3 streams are pumped in the same channel, etc. Despite this precaution, a small time difference may arise in the arrival of the streams at the TPE's. This difference

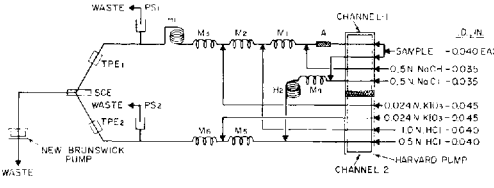

Fig. 3.—Iodimetric determination of penicillins.

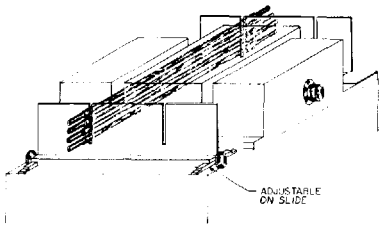

Fig. 5.—Pump modification.

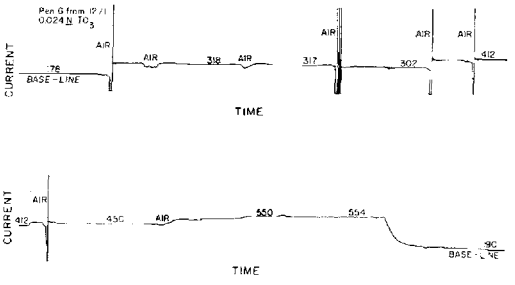

Fig. 6.—Typical amperometric recording.

can be minimized by extending or shortening 1 path as required, by means of a glass-in-Teflon telescoping sleeve arrangement at A (Fig. 3).

On the sample side, NaOH is added, and 3 large mixing coils at M_1 permit hydrolysis to proceed for 15 min. HCl is added to neutralize the alkali and to provide enough of an excess to liberate all available iodine from the KIO_3 which is added next. M_2 and M_3 are small mixing coils. The stream passes through a 12-min. holding coil H_1 to permit iodination, and is finally pumped through TPE_1, and SCE to waste. On the blank side, the sample is first mixed (mixer M_4, holding coil H_2) with NaCl equivalent to that produced on the sample side by the reaction of alkali with acid. Excess acid is added next, mixed at M_5, and KIO_3 is added finally to produce the same concentration of iodine at TPE_2 that would exist at TPE_1 in the absence of hydrolyzed penicillin. M_4, M_5, and M_6 are single mixing coils, and H_2 is made long enough to equalize the total path length of both streams. All mixers and holding coils are standard instrument parts. Tubing up to M_3 on the sample side and M_6 on the blank side is standard instrument transmission tubing; beyond these points the system is built of glass and Teflon to minimize absorption of iodine, except for the portions carrying the streams to waste.

The TPE potential is set at −50 mv. with respect to the SCE, recorder range at 25 mv. full-scale, and resistors R_2, R_3 at about mid-range. Reagents are those indicated in Fig. 3, except that the iodate contains 13.3 Gm. of KI per liter, required for the reaction $IO_3^- + 5\ I^- + 6\ H^+ = 3\ I_2 + 3H_2O$. Standards are prepared to cover the range 200–500 mcg. penicillin/ml. (Other operating conditions could have been chosen to accommodate lower or higher concentrations.) Adjustment of the pumps is important, and is accomplished as follows. The Harvard pump is set for 24 r.p.m., and the platen is moved toward the pumping fingers until flow through the tubing is just perceptible. The platen control knob is tightened 2 divisions more and is then locked in place. The New Brunswick pump is operated at 56 r.p.m., and the backing plate is tightened until the liquid levels in the pulse-suppressors are barely rising. The plate is then locked in position. The sampling pattern for penicillin determinations was chosen to provide maximum stability at the electrode and to minimize mixing between successive samples. Data reported here were obtained with the following manual program: sample aspiration, 2 min.; air, 15 sec.; sample, 5 min.; air, 15 sec. These 4 steps are repeated for each succeeding sample.

RESULTS

Penicillin G, oxacillin, phenethicillin, and ampicillin were determined successfully by the amperometric technique. Data were obtained by measuring the differences between diffusion current differentials recorded for samples and base-line, the latter recorded when samples were replaced by water in both channels. A typical trace is shown in Fig. 6.

Table I shows good precision and accuracy for several determinations on penicillin G, oxacillin, phenethicillin, and ampicillin, compared to Auto-Analyzer values determined colorimetrically (2). Instrumental response is linear (Fig. 7), plots of diffusion current against sample concentration giving straight lines within experimental error. Under these conditions, sensitivity is about 10–15 mcg./ml., and a range of 1–2 mcg./ml. appears attainable.

Data for the other penicillins show respective precision and accuracy of 1.0 and −0.2% for oxacillin, 0.7 and 1.0% for phenethicillin, and 2.6 and −3.0% for ampicillin. Methicillin could not be analyzed, probably because of its instability in acid solutions (5).

DISCUSSION

Advantages and Disadvantages.—Two major advantages accrue to the amperometric system: (*a*) linearity, the signal arises from the diffusion current, which is linear with concentration, and this eliminates the spectrometric problem of working with a logarithmic function; (*b*) measurement of spectroscopically inactive species which are reducible or oxidizable at the platinum electrode. Specificity may be obtained by proper choice of applied potential, electrode material, masking reactions, and solvent systems.

The measurement of a difference signal also permits simultaneous handling of the sample and its blank. In principle, the same advantage may be utilized in spectrophotometric analysis, although in practice this technique has not yet been widely applied in routine determinations.

Several difficulties have also been encountered with the amperometric system. Some are due to the choice of iodimetry for the application, but some are inherent in the electromechanical system. Chief among the latter are: (*a*) peristaltic pulsing. As discussed earlier, suppression of pulsing results in some experimental complexity. Considerable improvement in sensitivity was available for the

penicillins, but it is likely that the ratio of pulse-height/signal imposes a limitation. (*b*) Sample diffusion. In extended systems, such as is required in the determination of penicillins, diffusion occurs between adjacent samples unless some form of mechanical separation is introduced. When no separation is used, a steady state cannot be achieved, even with 10 to 15-min. sampling times. When air is introduced, a steady state is reached in about 4 min. This period, added to the 2-min. scrub, limits the throughput for the penicillin determinations to not more than about 8 samples/hr. This compares with the effective rate of 20/hr. for the colorimetric method (2). (*c*) Timing. Careful control is required to insure that sample and appropriate blank reach the electrodes simultaneously. The extent to which they are out-of-phase has a strong influence on the time required to reach a plateau in the diffusion current.

Effects of Iodate Concentration.—Although 0.004 *N* iodate is sufficient to react stoichiometrically with the highest penicillin concentration used (500

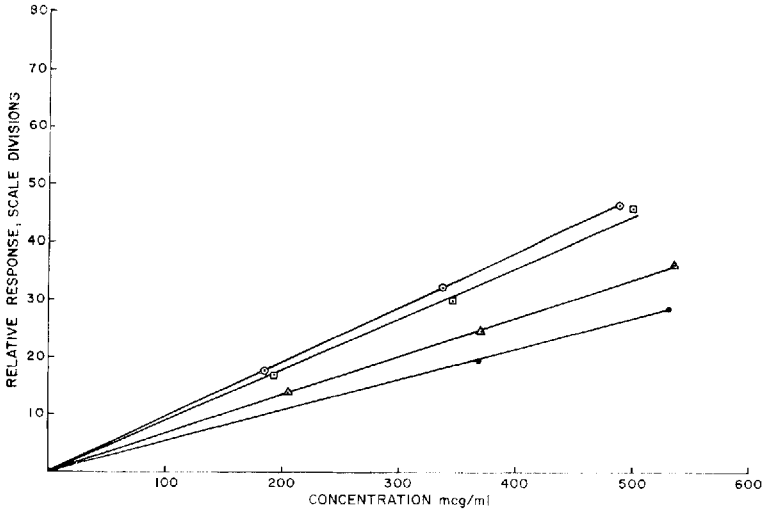

Fig. 7.—Instrument response for penicillins. Key: ⊙, phenethicillin; ⊡, ampicillin; ⧋, penicillin G; ●, oxacillin.

mcg./ml.), a deviation from linearity between response and concentration is observed at this concentration. All published iodimetric methods for penicillin require a greater-than-stoichiometric iodine-to-penicillin ratio; the reason has not been reported in the literature.

For the 4 penicillins studied, best linearity is obtained with 0.016 *N* iodate for penicillin G and oxacillin, and 0.024 *N* iodate for phenethicillin and ampicillin. At much higher iodate concentrations, deviations from linearity become apparent, possibly due to the increased influence of substitution reactions.

Iodine absorption on the tubing walls is minimized by using an all-glass-Teflon system beyond the point of acidification of iodate. Nevertheless, without air-scrubbing, visible deposits of iodine accumulate on the glass. Deposits also build up in the porous glass wall isolating the calomel electrode, but these can be washed out at the end of each working day. When more extensive washing appears desirable, 3 *N* HNO_3 is pumped through the entire system for 3 hr.

The influence of iodide ion on the penicillin method is minimized by holding a high concentration of excess iodide in all streams. In view of the current belief that the platinum electrode has an adsorbed I^- layer (6), the iodide is considered important to avoid electrical drift.

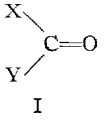
Molecular Orbital Localization Energies and Carbonyl Nucleophilic Reactivity

By LEMONT B. KIER

Molecular orbital anion localization energies have been calculated for a number of carbonyl group-containing compounds using the LCAO–MO Hückel procedure and the ω-technique. These energies have been found to reflect very adequately the summation of electronic effects from neighboring atoms to the carbonyl group as evidenced by the excellent correlation of the energies calculated with the rate constants of base catalyzed hydrolysis.

THE RELATIVE rate of nucleophilic reactivity of a carbonyl group-containing system such as I can be of great importance from the standpoint of



I

drug activity and drug stability, as well as contributing to structural and mechanistic theory. Classical resonance theory has dictated that a balance of mesomeric and inductive effects derived from atoms X and Y in I should facilitate or retard the ease of hydroxyl ion attack on the carbonyl carbon, this becoming the rate-determining step in the reaction sequences. The contributions of X and Y manifest themselves in the form of an energy barrier referred to as the free energy of activation, $\Delta F^{\ddagger}$. It has been assumed that, as a good approximation, $\Delta F^{\ddagger}$ is composed chiefly of $\Delta E^{\ddagger}_{\pi}$, the change in π electronic energy between the unreacted molecule and the transition state (1). In comparing the relative rates of reaction in a closely related set then the relationship holds

$$-RT \log \frac{k_2}{k_1} = [(\Delta E^{\ddagger}_{\pi})_1 - (\Delta E^{\ddagger}_{\pi})_2] \quad \text{(Eq. 1)}$$

The evaluation of $\Delta E^{\ddagger}_{\pi}$ demands a consideration of the nature of the transition state, or a reasonable model of it, in order to base the calculations on physical reality. Among several models proposed for the transition state, the σ complex or the Wheland intermediate has appeared to be the most satisfactory simple approach in the quantum mechanical study of chemical reactivity (2). In the case of the carbonyl carbon subjected to nucleophilic attack, the Wheland intermediate is a carbon surrounded by 4 bonds, each containing 2 electrons, III.

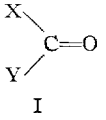
Molecular Orbital Localization Energies and Carbonyl Nucleophilic Reactivity

By LEMONT B. KIER

Molecular orbital anion localization energies have been calculated for a number of carbonyl group-containing compounds using the LCAO–MO Hückel procedure and the ω-technique. These energies have been found to reflect very adequately the summation of electronic effects from neighboring atoms to the carbonyl group as evidenced by the excellent correlation of the energies calculated with the rate constants of base catalyzed hydrolysis.

THE RELATIVE rate of nucleophilic reactivity of a carbonyl group-containing system such as I can be of great importance from the standpoint of



I

drug activity and drug stability, as well as contributing to structural and mechanistic theory. Classical resonance theory has dictated that a balance of mesomeric and inductive effects derived from atoms X and Y in I should facilitate or retard the ease of hydroxyl ion attack on the carbonyl carbon, this becoming the rate-determining step in the reaction sequences. The contributions of X and Y manifest themselves in the form of an energy barrier referred to as the free energy of activation, $\Delta F^{\ddagger}$. It has been assumed that, as a good approximation, $\Delta F^{\ddagger}$ is composed chiefly of $\Delta E^{\ddagger}_{\pi}$, the change in π electronic energy between the unreacted molecule and the transition state (1). In comparing the relative rates of reaction in a closely related set then the relationship holds

$$-RT \log \frac{k_2}{k_1} = [(\Delta E^{\ddagger}_{\pi})_1 - (\Delta E^{\ddagger}_{\pi})_2] \quad \text{(Eq. 1)}$$

The evaluation of $\Delta E^{\ddagger}_{\pi}$ demands a consideration of the nature of the transition state, or a reasonable model of it, in order to base the calculations on physical reality. Among several models proposed for the transition state, the σ complex or the Wheland intermediate has appeared to be the most satisfactory simple approach in the quantum mechanical study of chemical reactivity (2). In the case of the carbonyl carbon subjected to nucleophilic attack, the Wheland intermediate is a carbon surrounded by 4 bonds, each containing 2 electrons, III.

II III

Justification for this model is found in the tests of Hammond's postulate; if the σ complex is an unstable intermediate in the reaction, the transition state should closely resemble it in energy (3).

A means of estimating the energy difference between II and III, known as the localization procedure (2), has been proposed by Wheland. It is based on the concept that the essential difference in π electronic energy between the 2 states is the energy required to perturb the delocalized π electrons to permit the nucleophile to attack the carbon atom. The electron contributed by the carbon atom in the ground state must now be delocalized over the remaining π system or specifically in the case of the carbonyl group system II, it must be localized on the oxygen atom, with the accompanying disruption of the π system due to loss of participation of the central carbon atom. The problem then reduces to one of calculating the energies of the ground state, E_π, and the transition state $E_\pi^\ominus$, and calculating the anion localization energy

$$L_c^\ominus = E_\pi - E_\pi^\ominus \qquad \text{(Eq. 2)}$$

The means of calculating these energies is available through the method of molecular orbitals.

The simple LCAO–MO procedures are well suited for calculations involving heteroatoms because of the relative simplicity of these calculations, and because the present crude nature of heteroatom treatments emphasizes only compatibility with as many observed properties as possible, rather than correct numerical values. In the course of quantum mechanical studies on drug molecules, the author and co-workers have arrived at a set of parameters for heteroatoms which give calculated quantities mirroring physical experience (4). These values, listed in Table I, have been derived from ionization potentials, hence, they bear a consistent relationship to each other as well as the ionization phenomena (5). In other studies in this laboratory these values have been used to calculate successfully π dipole moments and carbonyl oxygen charge densities (4).

TABLE I.—VALUES OF h_x AND k_{cx} FOR HETEROATOMS FOR $\alpha_x = \alpha_c + h_x\beta_{cc}$

$\beta_{cx} = k_{cx}\beta_{cc}$

Atom X[a]	h_x	k_{cx}
Ȯ	1.3	0.8
Ö	2.7	0.6
N̈	1.7	0.7
C̈l	2.8	0.5
C̈H$_3$	3.0	0.7

[a] The designation Ȯ refers to oxygen with a core charge of 1, *i.e.*, an oxygen donating 1 electron to the π system. In this study this would be used for the carbonyl oxygen. Similarly, Ö and N̈ refer to heteroatoms donating 2 electrons to the π system, hence, having core charges of 2. This is used for ester- and amide type atoms in the C—X—C linkage. The values for Cl and CH$_3$ reflect the concept of 2 electron donation to the π system as discussed and used by Streitwieser (7).

The values listed in Table I are modifying parameters used in the expressions for the Coulomb and resonance integrals, α and β, for the heteroatom, X. The methyl group is treated as a heteroatom.

$$\alpha_x = \alpha_c + h_x\beta \qquad \text{(Eq. 3)}$$

$$\beta_{cx} = k_{cx}\beta_c \qquad \text{(Eq. 4)}$$

The integrals for the heteroatoms are commonly expressed in terms of a standard aromatic carbon atom.

There has been a further attempt to treat the failure of the simple Hückel method to account for electron correlation by using the ω technique, first suggested by Wheland and Mann (6) and later studied by Streitwieser (7). The technique employs a disposable parameter, ω, to modify the Coulomb integral based on the calculated charge density, q_i, so that

$$\alpha_i = \alpha_0 + q_i\omega\beta_0$$

The process is reiterated to a self-consistent value of the Coulomb integral. The use of this parameter effectively increases the Coulomb attraction between a π electron and a donating atom. The example of Streitwieser (7) and others (8) has been followed in using a value of 1.4 for ω.

The carbonyl-containing compounds calculated in this study (Table II) were selected to represent a wide diversity of heteroatoms for X and Y in I. They were also selected so as to minimize as far as possible any steric interaction with the carbonyl group. Finally, the set selected is known or thought to undergo base-catalyzed hydrolysis by a second-order nucleophilic attack of hydroxyl ion on the carbon atom (9–14). It was further thought that success in this correlation would constitute further proof of the value of the parameters in Table I and justify their use in other studies.

TABLE II.—SECOND-ORDER BASE HYDROLYSIS RATE CONSTANTS AND ANION LOCALIZATION ENERGIES FOR SEVERAL CARBONYL COMPOUNDS

Compd.	log k + 5 (moles^{-1}, min.$^{-1}$, 25°)[a]	$L_c^\ominus$ (in β)
Urea	0.250	1.144
Acetamide	1.352	1.002
Urethan	2.079	0.966
Methyl acetate	3.945	0.804
Ethyl carbonate	5.447	0.766
Ethyl chloroformate	6.380	0.643

[a] See *References 9–14* for the respective kinetic data.

Calculation of Ground State π Energies.—The value of the π energy of the ground state of each compound is obtained by the solution of a secular determinant of the Coulomb and resonance integrals of participants in the π network. The eigenvalues so derived are expressed in terms of the Coulomb and resonance integrals and each represents an energy level. Filling each level according to aufbau principles, and summing the occupied levels, the total energy of the ground state in terms of α and β is obtained.

Calculation of $L_c^\ominus$ and Correlation with Base Hydrolysis Rate Constants.—From Eq. 2 the value of $L_c^\ominus$ is computed in terms of β (Table II). As a test of the relative value of these energies, the

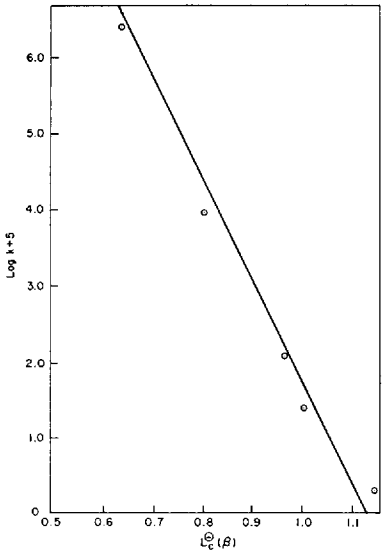

Fig. 1.—Correlation line for log $k + 5$ *vs.* $L_c^{\ominus}$. Correlation coefficient = 0.986. Equation for line: log $k + 5 = 15.25 - 13.57\ L_c^{\ominus}$.

values calculated have been plotted in Fig. 1 along with the least squares equation. The correlation is excellent (correlation coefficient of 0.986) fully justifying the use of parameters to reflect the participation of the atoms X and Y, adequately, in the reaction studied. Also corroborated by the correlation is the use of the transition state model and accompanying mechanism for each compound studied. The parameters used and the techniques employed may further permit a prediction of relative base hydrolysis rates within the framework of the approximations made and limitations imposed.

Numerical Computations.—The numerical computations were performed on an IBM computer. The program used for the ω-Hückel calculations was translated from Fortran to Scatran.[1] The program determines the eigenvalues and eigenvectors of a real symmetric matrix, using an HDIAG subroutine, according to the method of Jacobi. The program has been further modified with the help of Douglas Fleckner of this computation laboratory, to accept core charges other than 1, for use with some heteroatoms. This is necessary in the use of the ω technique. For example, the oxygen of a carbonyl group would have a core charge of 1 while the oxygen of an ester C—O—C would have a core charge of 2.

The calculation of correlation coefficients, least squares regression line, and other statistical data were computed using standard subroutines from this numerical computation laboratory.

Summary.—The anion localization energies have been calculated for a number of simple substituted carbonyl systems undergoing hydroxyl ion-catalyzed hydrolysis. The localization energies calculated have been assumed to be, as a first approximation, a relative measure of the free energy of activation of the reactions, using the Wheland intermediate as a model for the transition state. An excellent correlation is exhibited between these calculated values and the log of the rate constants for the compounds studied.

It has thus been shown that the LCAO–MO Coulomb and resonance integral modifying parameters for the heteroatoms were well chosen and truly mirror their relative electronic interaction within the delocalized electron framework. It is also apparent that the model for transition state and the proposed mechanism of action were correctly reflected by the reaction model chosen. The correlation of the calculated localization energies with the rate constants attests to the utility of quantum chemical methods in studying and predicting drug molecule reactions, stability, and possibly even pharmacological activity.

[1] The Ohio State Computer Center language, by Evan L. Brill of the Numerical Computation Laboratory staff. The program was originally written by G. Pettit, the University of Minnesota, and modified for use with the ω technique by D. Lazdins, the University of Minnesota.

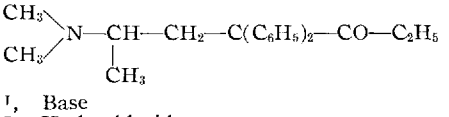
Molecular Asymmetry of Methadon

By LELAND L. SMITH

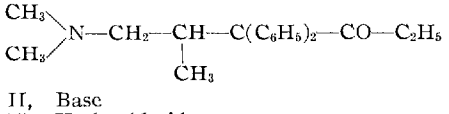
Proton nuclear magnetic resonance spectra of methadon hydrochloride, isomethadon hydrochloride, and related derivatives are recorded and interpreted in terms of a molecular asymmetry and a preferred conformation concept.

SUGGESTIONS relating the potent analgesic activity of methadon (6-dimethylamino-4, 4-diphenylheptan-3-one) (I) and isomethadon (6-dimethylamino-5-methyl-4, 4-diphenylhexan-3-one) (II) with stereochemical considerations of restricted rotation and subsequent molecular asymmetry have been made (1–6) based on indirect evidence of chemical unreactivity of the hindered carbonyl group (7), ultraviolet light absorption and dipole moment measurements (8), dissociation constants (3), and differential analgesic activity of the optical antipodes (9). Proton nuclear magnetic resonance spectra in Table I for several methadon and isomethadon derivatives provide independent evidence for molecular rigidity and for a preferred conformation of the molecule.

These proton spectra have certain features in common, including an acetyl methyl proton triplet, an acetyl methylene quartet, a secondary C-methyl doublet, a 10-proton aromatic signal, and 3 unanalyzed 1-proton multiplets. Whereas the dimethylamino protons of I base appeared as sharp 6-proton singlets at 2.14 p.p.m., the dimethylamino proton signals of salts of I were shifted characteristically downfield (0.6–0.7 p.p.m. except for I*c*) and involved greater multiplicity dependent on salt form, solvent composition, concentration, and temperature.



I, Base
I*a*, Hydrochloride
I*b*, Deuterochloride
I*c*, Sulfur trioxide compound
I*d*, Hydrogen sulfate



II, Base
II*a*, Hydrochloride

Spectra of I*a* were dominated by an unexpected 6-proton 1:2:1 triplet pattern centered about 2.77 p.p.m. The same pattern was observed in 40-Mc. spectra (center at 2.75 p.p.m.). From the slightly different spacings of the 60-Mc. triplet an overlapping doublet of doublets pattern was suspected, and indeed, spectra of solutions cooled in dry ice–acetone exhibited the clearly resolved doublet of doublets pattern. The center of the low-field doublet (J = 5.5 c.p.s.) was separated from the center of the highfield doublet (J = 5.0 c.p.s.) by 10 c.p.s., and as the cooled solution warmed to room temperature the downfield doublet shifted upfield toward the stationary doublet, so that at room temperature a triplet signal was obtained. The triplet was not collapsed by recording the spectra at 60°.

The dimethylamino proton doublet of doublets pattern in I*a* spectra collapsed to a sharp singlet on equilibration of the deuterochloroform solutions with deuterium oxide or by dilution with pyridine. Deuterium oxide solutions of I*a* likewise showed a 6-proton singlet. In contrast, the deuterochloride I*b* exhibited a doublet pattern in suitably dilute deuterochloroform solution. These solvent dependent effects on the dimethylamino proton signal form were not accompanied by other significant changes in spectra, and integration of spectra established that no carbon-bound proton in I*a* exchanged with deuterium oxide in deuterium oxide–deuterochloroform media, or had any exchange of carbon-bound proton for deuterium occurred in the preparation of the deuterochloride I*b*.

The dimethylamino protons of the sulfur trioxide compound I*c* appeared as two well-separated 3-proton singlets at 2.44 and 2.85 p.p.m., but the dimethylamino protons of the hydrogen sulfate I*d* appeared as a 6-proton broad signal.[1]

Proton spectra of II*a* were also characterized by a well-resolved doublet of doublets pattern centered at 2.79 and 3.12 p.p.m. (also reproduced at 40 Mc. at 2.73 and 3.10 p.p.m.). Equilibration of deuterochloroform solutions of II*a* with deuterium oxide again collapsed the dimethylamino proton doublet of doublets pattern to a sharp singlet, and integration of the spectra established that no carbon-bound proton in II*a* had exchanged with deuterium.

Concentration effects were observed in spectra of I*b* and II*a* in deuterochloroform, initial 15% solutions of both salts exhibiting singlet signals for the dimethylamino protons, which were split into doublet of doublets patterns, respectively, on 1:1 dilution with deuterochloroform.

The observed complexities of the N-methyl proton signals in I*a*, I*b*, I*c*, and II*a* must arise through magnetic nonequivalence on the 2 N-methyl groups in each case.[2] Thus, in I*a* and II*a* the 2 nonequivalent N-methyl groups appear as two 3-proton signals further split into a doublet of doublets pattern by coupling between the N-methyl protons and the ammonium proton.[3] The absence of an

Accepted for publication October 27, 1965.

The author is indebted to Dr. C. Hetzel and Mrs. J. Watson, Wyeth Laboratories, Radnor, Pa., and Dr. J. Lancaster, American Cyanamid Co., Stamford, Conn., for determination of proton spectra; to Merck and Co., Rahway, N. J., for a gift of isomethadon hydrochloride monohydrate, α-methadol, 4-dimethylamino-2,2-diphenylvaleronitrile hydrochloride, and 4-dimethylamino-3-methyl-2,2-diphenylbutyronitrile hydrochloride; and to Winthrop-Stearns, Inc., New York, N. Y., for a gift of methadon hydrochloride.

[1] Similar in appearance to the broad N-methyl signal of dimethyl-3-chloropropylammonium chloride (11).

[2] Temperature dependence and dilution effects in spectra of I*a*, I*b*, and II*a* deny spin–spin interactions as a reasonable basis for the observed multiplicities; also long-range coupling constants are generally smaller than the 5–6 c.p.s. (10 c.p.s. at dry ice temperatures) separations found.

[3] The field independence of the 5 c.p.s. spacings in the doublet of doublets pattern in I*a* and II*a* spectra as well as their magnitude support this assignment. Spin–spin interactions between N-methyl protons and an ammonium proton giving rise to coupling constants of 4.5–6.17 c.p.s. in various solvents have been observed (12–14).

[a] Spectra were obtained on 15% (w/v) deuterochloroform solutions using a Varian Associates A-60 spectrometer. Chemical shifts (δ) are measured in p.p.m. downfield from an internal reference of tetramethylsilane. Data are recorded in order: chemical shift in p.p.m., multiplicity (in parenthesis), coupling constant in c.p.s. Signals are singlets except as noted. Abbreviations used are: b, broad; d, doublet; m, multiplet; t, triplet; q, quartet. [b] Fine splitting of about 1.5 c.p.s. was also observed. [c] Observed on 1:1 dilution of the initial 15% solution. [d] Two water protons are also observed in this range on 15% solutions. On 1:1 dilutions the water protons are consolidated as a 2 proton singlet at 2.42 p.p.m. The sample of II*a* used was a hydrochloride monohydrate (10). [e] Five unassigned protons appear: 1H, 1.88; 2H, 1.0–1.7 (m); 2H, 2.15–3.0 (m). A single proton geminal to hydroxyl is at 3.90 p.p.m. (q), J = 9.5 and 3.0 c.p.s. by first-order analysis.

ammonium proton in the deuterochloride I*b* simplified the *N*-methyl proton signals so that only a doublet is present. In the sulfur trioxide compound (I*c*) there likewise is no ammonium proton; however, in this instance the 2 *N*-methyl singlets are separated by 0.4 p.p.m.

The magnetic nonequivalence of the 2 *N*-methyl groups of these derivatives is not a consequence of restricted rotation about the N—C_6 bond. Such restricted rotation and consequent *N*-methyl nonequivalence occurs in *N*-methylamides (15), *N*-methylamidinium compounds (16), and in certain heterocyclic *N*-methyl compounds (17–19) where partial planar character of the nitrogen–carbon bond is involved. A very slow rate of amine inversion might be a basis for nonequivalence of the *N*-methyl protons, and some similarities exist between the present instance and spectra of dibenzylmethylammonium chloride (20) in aqueous acid. However, persistence of the nonequivalence of 60° does not support this explanation. Were slow inversion the case, however, some of the solvent effects could be readily understood as resulting from increased nitrogen inversion rates.

Of the conditions under which unexpected nonequivalence of protons obtain, as summarized by Bible (21), more favored explanation of the instant nonequivalence derives from inherent molecular asymmetry attributed to the nearby asymmetric carbon atom in the methadon and isomethadon molecules (C_6- and C_5-, respectively). This inherent asymmetry could manifest itself in nonequivalence of the *N*-methyl protons, of the C_5- or C_6-methylene protons, or of both sets of protons. The concept has been used to explain similar spectral complexity for other dimethylamino compounds (22, 23).

However, presence of dilution effects in the spectra of I*b* and II*a*, equivalence of the *N*-methyl protons of the related nitriles *dl*-4-dimethylamino-2,2-diphenylvaleronitrile hydrochloride (IV) and *dl* - 4 - dimethylamino - 3 - methyl - 2,2 - diphenylbutyronitrile hydrochloride (V), and identity of effect in both methadon (where the asymmetric C_6-carbon is 3 bonds separated from the *N*-methyl protons) and isomethadon (where the asymmetric C_5-carbon is 4 bonds separated), as measured by the coupling constants J = 5–6 c.p.s., suggest other factors may be involved. These several observations are consistent with a molecular asymmetry associated with a preferred conformation of the molecules I and II, the preferred conformation being formed through hydrogen bonding between cationic nitrogen and the carbonyl group as postulated by Beckett (2–4).

The dilution effects of the spectra of I*b* and II*a*, together with the simplification of spectra on equilibration with deuterium oxide suggest that the preferred conformations of the I and II molecules in solution giving rise to the magnetically nonequivalent *N*-methyl groups are not assumed in every instance of concentration and solvent choice, but that such asymmetric conformations may exist in special situations. Extension of these considerations to the complex media of living animals must therefore be done with caution.

The increased shielding (0.50 p.p.m.) of the C_6-methyl protons of I*a* in comparison with that of the C_5-methyl protons of II*a* may also be considered in terms of a preferred conformation of the molecules involving close approach of the carbonyl oxygen and the ammonium proton. In such conformation the C_5-methyl group of II*a* is very nearly in the plane of the C_4-benzene ring (using Dreiding models), whereas the C_6-methyl group of I*a* is more nearly above the plane of the C_4 benzene ring and thereby is subject to increased long-range diamagnetic shielding of the benzene ring.

The three C_5- and C_6-methylene and methine protons of I and II derivatives are magnetically nonequivalent. One proton appeared as a singlet overlapping the acetyl methylene quartet, and 2 protons appeared as a series of lines overlapping one another and/or the *N*-methyl signals. One of these latter

multiplets must be the C_6-proton (in I*a*), since it would be spin-spin coupled to the C-methyl protons, the ammonium proton, and probably one or both C_5-protons, and being adjacent to nitrogen, must be at low field. The other low field proton is then one of the C_5-methylene protons, the other being at higher field and overlapping the acetyl methylene quartet.

The nonequivalence of these methylene protons in I and II derivatives is most readily explained in terms of the nearby amsymmetric carbon atom C_6- and C_5,-, respectively (21), and in this matter, the precursor nitrile salts IV and V exhibit methylene proton nonequivalence also.

Attempts at further analysis of the methylene/methine proton signals on spectra of α-methadol (*dl* - α - 6 - dimethylamino - 4,4 - diphenylheptan-3-ol) (III) or of the nitrile precursors of I and II, IV and V, respectively, were thwarted by overlapping of these signals with one another and with those of the dimethylamino protons. It is to be noted that the dimethylamino proton signals in both nitriles IV and V fall in a high field relative to their ketone analogs I*a* and II*a*.

EXPERIMENTAL[4]

6 - Dimethylamino - 4,4 - diphenylheptan - 3-one Deuterochloride (Ib).—Ten grams of commercial methadon hydrochloride was recrystallized 3 times from 99.8% deuterium oxide (Stuart Oxygen Co., San Francisco, Calif.) to constant melting point, m.p. 232–234°.

6 - Dimethylamino - 4,4 - diphenylheptan - 3 - one Sulfur Trioxide Compound (Ic).[5]—A mixture of 1.5 Gm. of I*a*, 1.8 ml. of isopropenyl acetate, and 2 drops of concentrated sulfuric acid was distilled slowly over a 7-hr. period. The mixture was filtered from insoluble material (0.32 Gm. of recovered I*a*, m.p. 230–234°), and the filtrate was concentrated. A red resinous precipitate formed and crystallized over several weeks, yielding 0.37 Gm. of product I*c*. Recrystallization from benzene gave crystals, m.p. 139.0–141.0°, and from ethanol–ether gave the analytical sample, m.p. 140.0–142.5°. $\lambda_{max.}$ 255 mμ (ϵ 579, inflection), 260 mμ (ϵ 646), 266 mμ (ϵ 629), 292 mμ (ϵ 624); $\lambda_{min.}$ 250 mμ (ϵ 526), 264 mμ (ϵ 624), 277.5 mμ (ϵ 502).

Anal.—Calcd. for $C_{21}H_{27}NO_4S$: C, 64.75; H, 6.99; N, 3.59; S, 8.23. Found: C, 64.89; H, 6.98; N, 3.57; S, 8.54.

6 - Dimethylamino - 4,4 - diphenylheptan - 3 - one Hydrogen Sulfate (Id).—A solution of 1.0 Gm. of methadon in absolute ethanol was treated with an ethanolic sulfuric acid solution. The solution was evaporated under vacuum and the oily residue was crystallized from chloroform–ether, yielding 0.30 Gm. of salt, m.p. 147.0–149.0°. An additional 0.21 Gm., m.p. 144.0–146.5°, was recovered from the filtrate. After further recrystallizations from methanol–ether and from ethanol–ether, the salt melted at 146.0–148.0°.

Anal.—Calcd. for $C_{21}H_{27}NO.H_2SO_4$: N, 3.44; S, 7.87. Found: N, 3.39; S, 8.13.

[4] Melting points were determined using a calibrated thermometer and a heated oil bath. Ultraviolet light absorption spectra were recorded on methanol solutions using a Beckman model DU spectrophotometer.

[5] The minor by-product I*c* was obtained in otherwise unsuccessful attempts at enolacetylation of I*a*. The structure of I*c* as a sulfur trioxide derivative of I is supported by elemental analysis, ultraviolet light absorption essentially identical with spectra of I*a* (8), water solubility (from which water solutions barium chloride precipitated barium sulfate), and nonidentity with the hydrogen sulfate salt I*d* prepared with sulfuric acid in the usual way.

Identification of Pyrethrol with Taraxasterol

By WERNER HERZ and R. N. MIRRINGTON

The insecticidally inactive substance pyrethrol from pyrethrum flowers has been identified as taraxasterol.

THE OLEORESIN obtained by extraction of pyrethrum flowers (*Chrysanthemum cinerariaefolium* Vis.) contains not only the active insecticidal principles pyrethrin I and II,[1] but also comparatively large quantities of inactive material, including such compounds as the monocarbocyclic sesquiterpene lactone pyrethrosin (2) and an unidentified substance called "pyrethrol." The latter, first isolated by Fujitani (3) and referred to briefly by Staudinger and Ruzicka (4) had m.p. 199°, $[\alpha]_D$ + 73°, and was assigned (3) the molecular formula $C_{21}H_{34}O$. More recently (5), pyrethrol was stated to be a triterpene alcohol isomeric with lupeol.

The authors received a sample of crude pyrethrol[2] isolated a number of years ago (6) during the purification of pyrethrosin and have investigated its properties. Purification and conversion to a number of derivatives established its identity as taraxasterol.

In this laboratory, pyrethrol had m.p. 217–219° after several recrystallizations from chloroform–ethanol and $[\alpha]_D$ +92°.

The presence of 1 secondary hydroxyl group was indicated by the infrared and NMR spectra (complex signal at 3.2 p.p.m., H_3) and confirmed by the formation of a monoacetate, m.p. 246–248°, $[\alpha]_D$ +105°, NMR signal at 4.6 c (H_3), a monobenzoate, m.p. 244–247°, and by mild oxidation to a ketone, m.p. 179–182°, infrared band at 1710 cm.$^{-1}$, positive Zimmermann test, which contained no other hydroxyl groups. Furthermore, an exocyclic methylene group was clearly indicated in all four of the above compounds by infrared bands at 1650 and 890 cm.$^{-1}$ and, in the NMR spectra, by a broad singlet, $W_{1/2}$ 4 c/s, intensity 2 protons, at 4.65 p.p.m. The NMR spectra also indicated the presence of 7 methyl groups.

The melting points and rotations of pyrethrol and its derivatives bore a reasonable resemblance to those most widely accepted (7) for taraxasterol, m.p. 226–227°, $[\alpha]_D$ +97°; acetate, m.p. 256–257°, $[\alpha]_D$ +100°; benzoate, m.p. 242–244°; taraxastenone, m.p. 184–185°. The spectral data were also in harmony with the supposition that the 2 substances might be identical.

This supposition was verified by direct comparison (mixed melting point and infrared spectra) of pyrethrol with an authentic sample of taraxasterol.[3] The 2 samples were undistinguishable. Pyrethrol is therefore identical with taraxasterol and the former name should be stricken from the literature.

EXPERIMENTAL[4]

Pyrethrol.—Crude pyrethrol crystallized from chloroform–ethanol as colorless needles, m.p. 217–219°, $[\alpha]_D$ +92°, infrared bands at 3400, 1050 (hydroxyl), 1650, 890 cm.$^{-1}$ (exocyclic methylene), NMR signals at 4.65 (broad singlet, $W_{1/2}$ 4 c/s, 2 protons, exocyclic methylene), 3.2 p.p.m. (multiplet, 1 proton, H_3). The infrared spectrum was superimposable on that of an authentic sample of taraxasterol, m.p. 219–221°, mixed m.p. 219–221°.

Derivatives of Pyrethrol.—*Acetate.*—Acetylation of pyrethrol with acetic anhydride and pyridine at 80° for 2 hr. gave a monoacetate which crystallized from chloroform–ethanol as lustrous plates, m.p. 246–248°, $[\alpha]_D$ +105°, infrared bands at 1735, 1250 (acetate), 1650, 890 cm.$^{-1}$ (exocyclic methylene), no hydroxyl absorption, NMR signals at 4.65 (as in pyrethrol above), 4.5 (multiplet, 1 proton, H_3), 2.02 p.p.m. (singlet, 3 protons, acetate).

Benzoate.—Benzoylation of pyrethrol with benzoyl chloride and pyridine at 50° for 2 hr. gave a monobenzoate which crystallized from ethanol as colorless needles, m.p. 244–247°, infrared bands at 1730, 1280 (benzoate), 1650, 890 (exocyclic methylene), 1605, 1595, 715, 690 cm.$^{-1}$ (monosubstituted benzene ring).

Dehydropyrethrol.—A suspension of 0.5 Gm. of pyrethrol in 50 ml. of acetone was treated with Jones reagent at 25° until a brown color persisted. Dilution with water gave a flocculent precipitate which was collected and crystallized from ethanol to furnish 0.41 Gm. of dehydropyrethrol, m.p. 179–182°, infrared bands at 1710 (cyclohexanone), 1650, 890 cm.$^{-1}$ (exocyclic methylene), no hydroxyl absorption, NMR signal at 4.65 (broad singlet, 2 protons, exocyclic methylene).

Blood Nitrite and Nitrate Concentration After Oral and Intravenous Administration of Glyceryl Trinitrate in Rabbits

By O. J. LORENZETTI*, ARTHUR TYE, and JOHN W. NELSON

Blood nitrite and nitrate concentrations were measured after oral and intravenous administration of glyceryl trinitrate at 1.0 mg./Kg. in rabbits. Nitrate and nitrite blood concentrations attained peak concentrations in 90–120 min. after oral administration and slowly returned to control levels. Nitrate and nitrite blood concentrations decreased slowly after intravenous administration of glyceryl trinitrate, then fell rapidly after 60 min. Blood nitrate concentrations were twice the blood nitrite concentrations 60 min. after either oral or intravenous administration of glyceryl trinitrate.

THE ABSORPTION of glyceryl trinitrate from the gastrointestinal tract has been questioned for over a half century. Most investigators believe the absorption to be poor on the basis of resulting physiological effects observed. Sollman states that when glyceryl trinitrate is ingested it is absorbed into the portal circulation and destroyed by the liver (1). Oral and intravenous administration of organic nitrates to dog and man have provided evidence that there is no correlation between blood nitrite and nitrate concentration and the observed physiological activity (2, 3). Recent investigations utilizing the observation of the vascular bed of the rabbit ear have shown that glyceryl trinitrate is absorbed in the gastrointestinal tract after oral administration (4).

The following study was undertaken to determine the blood nitrite and nitrate levels after oral and intravenous administration of glyceryl trinitrate in the rabbit.

METHODS

White New Zealand male rabbits weighing 3.5–4.5 Kg. were used in this study. The rabbits were lightly anesthetized with pentobarbital (25 mg./Kg., i.p.). One group of rabbits received glyceryl trinitrate orally (1.0 mg./Kg. from a stomach tube) in 1.5 ml. of water. A second group received glyceryl trinitrate intravenously (1.0 mg./Kg.) from a needle cannula in the marginal ear vein. The intravenous injection was made in 0.5 ml. of solution over a 60-sec. period. Blood samples were taken over a 2–3-hr. time period.

Each group of rabbits was used for only 3 successive blood samples, because of the large blood sample required (4 ml.) for the complete assay. A total of 30 rabbits was used for the assay. Blood samples were taken from an indwelling catheter (PE50) in the femoral artery.

Each 4-ml. blood sample was laked with 4 ml. of deionized water in a 125-ml. conical flask, and the following were added: 10 ml. of 0.2% solution of sulfanilamide, 2 ml. of 50% concentrated hydrochloric acid solution, and 2 ml. of 5% aqueous solution, prepared from mercuric chloride that had been sublimed 3 times. The resulting brownish mixture was thoroughly mixed by swirling and then centrifuged for 15 min. at 6000 r.p.m. in a horizontal centrifuge. The clear, deproteinated, decanted filtrate was quantitatively divided into two 10-ml. portions. One portion was used for the nitrite assay and the other for the nitrate assay (5).

Nitrite Assay.—To the 10-ml. portion of the deproteinated filtrate was added 1.0 ml. of 0.1% aqueous solution of *N*-(1-naphthyl)-ethylene diamine dihydrochloride to act as a coupling agent. Then the solution was allowed to stand for 10 min. and the color read on a Beckman DU spectrophotometer at the 540-mμ wavelength. The nitrite concentration was read from a previously determined standard curve prepared by plotting absorbance *versus* known concentrations of nitrite.

Nitrate Assay.—The remaining 10 ml. of the deproteinated filtrate was transferred to a 25-ml. test tube and hydrogen sulfide was bubbled through to precipitate unreacted mercury ions as mercuric sulfide. The excess hydrogen sulfide was removed by boiling the solution carefully to avoid bumping and subsequent loss of the solution. When all trace odor of hydrogen sulfide was removed, the murky solution was transferred to a 75-ml. conical flask, and 5.0 Gm. of Amberlite IR 120 AA (Mallinckrodt No. 3323), a strongly acidic, sulfonic cation exchange resin, was added.

The mixture was swirled for several minutes and centrifuged at 4000 r.p.m. for 10 min., or until all nitrite was absorbed, which was confirmed by placing 1 drop of coupler upon 1 drop of the decanted filtrate on a spot plate and by noting the absence of a color change. To the nitrite-free filtrate contained in a 125-ml. conical flask was added 5.0 ml. of 12% concentrated ammonium hydroxide solution and 1.0 ml. of 1% manganous chloride tetrahydrate to catalyze the reduction of nitrate ions. The solution was immediately placed in a water–ice bath maintained at 14 to 15° for 10 min. A 0.2 Gm. portion of zinc dust was added and the mixture stirred on a magnetic stirrer for 10 min. The slurry was filtered through a 3-in. funnel. To 5 ml. of the collected filtrate was added 1.0 ml. of *N*-(1-naphthyl)-ethylenediamine dihydrochloride, and the resulting solution was allowed to stand for 10 min., after which the absorbance was read at the 540-mμ wavelength. The nitrate concentration was read from a previously determined standard curve prepared by plotting absorbance *versus* known concentration of nitrate.

RESULTS

The results are presented in Fig. 1. By plotting the blood nitrate concentration and the blood nitrite concentration after intravenous injection, *versus* time, 2 curves running similarly were obtained. On the other hand, after oral administration the

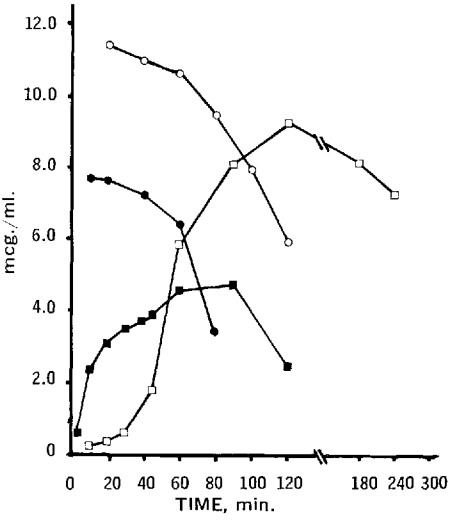

Fig. 1.—Micrograms of nitrate and nitrite per milliliter of blood in rabbits after oral and intravenous administration of glyceryl trinitrate, 1.0 mg./Kg. Key: O—O, nitrate, intravenous; ●—●, nitrite, intravenous; □—□, nitrate, oral; ■—■, nitrite, oral. Control blood nitrate level, 1.05 mcg./ml. ±0.54, as determined in 8 rabbits; control blood nitrite level, less than 0.50 mcg./ml., as determined in 6 rabbits.

initial nitrite concentration was higher than the nitrate concentration but was followed by a higher nitrate-to-nitrite concentration ratio of approximately 2:1 at 90 min.

DISCUSSION

The fact that blood nitrate and nitrite concentrations do not correlate with the time of peak effect of vasodilative action is well documented for glyceryl trinitrate and other organic esters of nitric acid (6). It is interesting to observe the prolonged high blood concentration of inorganic nitrate following either the intravenous or oral route of administration. Although the observed dilatation reported in the literature is said to last 60 min., these investigations show the blood concentration to remain significantly elevated 2–3 hr. after ingestion of glyceryl trinitrate at the dose reported. The possibility of buccal absorption is eliminated since the glyceryl trinitrate was placed directly in the stomach by intubation. Recently, DiCarlo, Hartigan, and Phillips have shown quantitative absorption of pentaerythritol tetranitrate by the gastrointestinal route (7). Crandall reported the enzymatic degradation of glyceryl trinitrate and related organic esters by erythrocytes in dogs (8). This enzymatic degradation was further correlated to the action of glyceryl trinitrate reductase in hog liver and heart (9). A similar enzyme system has been reported for pentaerythritol tetranitrate in human erythrocytes (10).

SUMMARY

Data for the blood nitrate and nitrite concentration after oral and intravenous administration of glyceryl trinitrate have been presented. After oral glyceryl trinitrate, the peak blood concentrations of nitrate were approximately twice that of nitrite. The blood nitrate and nitrite concentrations decreased similarly after intravenous administration of glyceryl trinitrate.

Chlorpromazine: Effect on Food Intake and Glucose Distribution in Obese and Nonobese Mice

By P. D. CULLEN*, D. C. ARNEY†, and H. A. SWARTZ

Chlorpromazine, in doses of 1 mg./Kg., caused a significant reduction of food intake, weight loss, and oxygen consumption in both gold thioglucose-obese and normal nonobese mice as compared to saline-treated controls. Tissue activities after glucose-1-C-14 administration were reduced, but the blood levels were increased.

Gold thioglucose-obese mice have been employed in numerous studies involved with the etiology of obesity and hyperphagia. A summary of these studies, presented in a previous report (1), included evidence of the role and relationship of the lateral and ventro medial hypothalamic nuclei in food-intake regulation and satiety. The ventro medial nuclei, in response to blood glucose, have been shown to inhibit a lateral hypothalamic feeding center (2, 3) which results in an inhibition of food intake (4, 5). Stimulation of the feeding center results in hyperphagia and its destruction in a temporary cessation of food intake or aphagia. It is probable that any agent that could increase or block glucose uptake by the ventro medial nuclei could influence food intake. The role of centers in the frontal lobes cannot be overlooked, and is discussed in a review by Andersson and Larsson (6).

Selected anorectic agents were observed to reduce food intake in both normal nonobese and gold thioglucose-obese mice, with *d*-amphetamine and phenmetrazine the most effective of the agents employed (7). Reduction was much higher in the normal nonobese mice. These agents also caused a significant increase in residual hypothalamic activity following the administration of labeled glucose in the nonobese mice (1).

Interest arose over the effects of central depressants, and chlorpromazine was selected on the basis of its reported actions on hypothalamic centers, such as depression of emotional centers, sedative action, and tissue distribution (8–10).

EXPERIMENTAL

Food Intake and Weight Loss.—Gold thioglucose-obese mice were prepared as previously described (1, 7), and the treated and nontreated mice were maintained in separate groups for 3 to 4 months until a weight plateau was observed. At this time the mice were placed into individual cages with free access to food and water. Food was placed in hoppers suspended from the cage lid. After a period of 2 weeks to allow for adjustment to environment and isolation, the normal body-weight change and average daily food intake for a 7-day period was determined for both groups of mice. Food intake was determined by accurately weighing the food on the first and final day, and weight changes were determined from the initial and final body weights. The control values for both groups of mice were obtained from animals administered saline i.p. daily in volumes equivalent to those employed for the administration of chlorpromazine. Chlorpromazine,[1] as the hydrochloride, was administered in saline i.p. daily in a dose of 1 mg./Kg. (2.83 μ moles/Kg.). The observed values for both groups of mice are tabulated in Table I.

Oxygen Consumption.—Oxygen consumption for both groups of mice was determined by means of a spirometer (Minute Oxygen Uptake Spirometer, V68808 Aloe Scientific). Saline and chlorpromazine were administered as previously described 10 min. prior to placing the animals in the spirometer chamber. Following a 20-min. equilibration period, the oxygen consumption was determined for a 60-min. period, the values corrected to S.T.P. and the ml./hr./Gm. determined. From these values the Gm.-cal./hr./cm.^{2} were calculated. The values for both groups of mice are tabulated in Table II.

Glucose-1-C-14 Distribution.—The effect of chlorpromazine on residual tissue activity after the administration of glucose-1-C-14 was determined in both groups of mice. Saline was employed for the controls. The glucose-1-C-14 dose was 0.05 μc./Gm. and was administered i.p. in an aqueous solution of glucose 20 mg./ml., which gave a dose of 100 mg./Kg. Chlorpromazine and saline were administered as previously described 30 min. prior to the administration of the labeled glucose. The animals were sacrificed by decapitation 30 min. after the administration of the labeled glucose. Blood was collected in a porcelain container which was previously smeared with a saturated solution of sodium citrate to prevent coagulation, and a sample was obtained by means of micropipets. Tissue samples of adrenal, kidney, liver, and muscle were obtained, wiped free of external blood, and accurately weighed. The intact brain was removed, chilled in a deep freeze, and dissected so as to separate the cerebrum, diencephalon (thalamus and hypothalamus), and the hind brain. Weighed samples of each area were obtained and placed, along with the blood and other tissue samples, into individual counting vials containing 1 ml. of 1 *M* benzethonium chloride[2] base in methanol (11). The vials were sealed with screw caps and incubated at 55° for 24 hr. to facilitate solution, then cooled to room temperature, and 10 ml. of a liquid scintillation solvent system added (2,5-diphenyloxazole 0.4%, naphthalene 5.0%, cellosolve 300 ml., 1,4-dioxane 300 ml., and toluene to 1000 ml.) (12). The vials and contents were dark-adapted and temperature adjusted to −20° for 48 hr. A standard of the labeled glucose solution employed for the administration of the glucose-1-C-

[a] Each value is the arithmetical mean of 5 individual animals. [b] Administered 30 min. prior to administration of glucose-1-C-14.

14 was prepared by adding an aliquot of the solution to 10 ml. of the liquid scintillation solvent system. The activity of each blood and tissue sample and the glucose-1-C-14 standard was determined by means of a liquid scintillation detector and associated β spectrometer (Ekco Detector model N664 and Scaler model N610A). Quenching of the true count rate of each sample was corrected by use of an internal standard of hexadecane-1-C-14 (13). Blank samples were prepared to determine the background count. The per cent of the administered radioactive dose per Gm. of dry tissue and per ml. of blood was calculated for each animal. The mean values are tabulated in Table III. The dry tissue weights were calculated from the known moisture contents, determined as previously described (1).

RESULTS AND DISCUSSION

The administration of chlorpromazine caused a significant ($p > 95$) loss of body weight, reduction of food intake, oxygen consumption in ml./Gm./hr., and lowered Gm.-cal./hr./cm.^{2} in both the gold thioglucose-obese and the normal nonobese mice, as compared to their respective controls.

The actual weight loss was greater in the obese mice than with the nonobese mice (1.5–0.72 Gm.), but when calculated as Gm./Gm. of the initial body weight or per cent, the values were 0.028 Gm./Gm. or 2.8 % of the obese and 0.022 Gm./Gm. or 2.2 % for the nonobese mice. Food intake was reduced 1.85 Gm. (29.8%) or 0.028 Gm./Gm. initial body weight for the obese mice and 0.45 Gm. (10.3%) or 0.02 Gm./Gm. initial body weight for the nonobese mice.

Oxygen consumption in ml./Gm./hr. was similar in both groups of mice, but when calculated on the basis of body surface and expressed as Gm.-cal./hr./cm.^{2}, the obese mice had higher values than the non-

obese and in both groups the administration of chlorpromazine caused a significant ($p > 95$) reduction in the observed values. This effect is not expected with weight loss and is indicative of a reduced metabolic rate and/or depression of the C.N.S. The latter was not observed, and in fact, there was no visual difference in activity between the saline controls and the chlorpromazine-treated animals in either groups of mice. It is known, however, that the release of TSH to affect the secretion of the thyroid hormone is influenced by hypothalamic centers (14), and the action of chlorpromazine to lower the metabolic rate could be due to an action on this sequence, and in particular on the hypothalamic nuclei involved.

The mechanism by which chlorpromazine affected food-intake reduction was of sufficient magnitude to result in significant weight losses in both groups of mice even with the reduction of caloric output. As both the weight losses and food intake reduction values were similar in the obese and nonobese mice when compared on the Gm./Gm. initial body weight basis, it is probable that the mechanism was similar in both groups of mice. The effect of chlorpromazine on the residual tissue activity following administration of labeled glucose was studied as a possible clue to the mechanism of food-intake reduction and in general, a slight reduction in residual tissue activity was observed in all tissues as compared to the controls, with the exception of kidney tissue from the gold thioglucose-obese mice. Blood levels were significantly higher ($p > 95$) in both groups of mice. The lowered tissue levels, coupled with the increased blood levels are in agreement with the observed reduced oxygen consumption and energy output; and the increased blood levels, undoubtedly associated with elevated blood sugar, would be expected to have activated the ventro medial nuclei to inhibit the lateral hypothalamic feeding center (4, 5). This action is not supported, however, by the brain residual tissue activities, as chlorpromazine was observed to cause lower levels in all the brain tissues examined, and if activation of the ventro medial nuclei had occurred, the hypothalamic levels should have been higher than in the controls. Furthermore, the gold thioglucose-obese mice with destroyed or partially destroyed ventro medial nuclei had a similar food-intake reduction as the nonobese on the Gm./Gm. basis. The lower tissue activities in all brain tissue indicate a general mild depression, and this could include the lateral hypothalamic feeding center or centers in the forebrain. Sedation would not be expected to cause sufficient reduction in food intake to cause weight loss as observed, particularly with the reduction in the metabolic rate. Thus, it would appear that the action of chlorpromazine to reduce food intake involves a specific central action. The data presented do not permit a conclusion as to centers involved, but do exclude action through activation of the ventro medial nuclei and increased glucose uptake by these cells. Hypothalamic activity can be postulated, however, for both food intake reduction and lowering of the metabolic rate, on the basis of previous reports as to the tissue distribution of chlorpromazine and action on other hypothalamic centers (8–10).

Nuclear Magnetic Resonance Spectra of Amines I. Identification of *N*-Methyl Tertiary Amines

By W. E. THOMPSON, R. J. WARREN, J. E. ZAREMBO, and I. B. EISDORFER

The effects of strongly acidic solvents on the chemical shift and spin-spin splitting of the methyl protons in *N*-methyl tertiary amines are found to be unique for this particular functional group. These effects provide the basis for the simultaneous identification of the *N*-methyl group and the tertiary amine structure in compounds of unknown structure.

AN ANALYTICAL method using NMR has been developed for the qualitative analysis of the tertiary *N*-methyl amine function. The method is specific for aliphatic tertiary *N*-methyl amines and also distinguishes aliphatic from aromatic compounds. The method is based upon the effects of strongly acidic solvents on the NMR spectra of tertiary *N*-methyl amines.

The dependence of the NMR spectrum of *N*-methyl groups on hydrogen-ion concentration and the proton exchange rate in aqueous solutions is well known. Loewenstein and Meiboom (1) have made an extensive study of methylamine, dimethylamine, and trimethylamine in this regard. The splitting of the NMR absorption band of the methyl group in methylamine into a quartet by the 3 protons in the adjacent primary amine ion has likewise been studied and reported by Jackman (2) and Pople, Schneider, and Bernstein (3).

In this investigation the effects of protonation of the nitrogen atom and subsequent splitting of the *N*-methyl protons in aliphatic tertiary amines are illustrated. The NMR spectral changes are recommended for rapid identification of this class of amine.

EXPERIMENTAL

All spectra were recorded on a Varian A-60 spectrometer using Varian sample tubes. Deuterated chloroform and trifluoroacetic acid were used as solvents. Concentrated reagent sulfuric acid was used for diamine and aromatic amines. The spectra were obtained on samples at room temperature at a concentration of 50 mg./ml.

The simple tertiary amines were Eastman Organic Chemicals as purchased from Distillation Products Industries, Rochester, N. Y. The chlorpromazine base was analytical standard grade.

RESULTS AND DISCUSSION

Tertiary aliphatic amines containing 1 or more *N*-methyl groups show nuclear magnetic resonance (NMR) absorption of the methyl protons as a single peak in the vicinity of 2.2 p.p.m. downfield from tetramethylsilane as reported by Jackman (2). This single peak is characteristic of *N*-methyl tertiary amines as free base. The 2.2-p.p.m. chemical shift occurs in solvents of low dielectric constant, *e.g.*, carbon tetrachloride and chloroform. In a strongly acidic solvent such as trifluoroacetic acid the amine is transformed into the tertiary amine ion. The positive electrostatic charge on the ion increases the *N*-methyl chemical shift approximately 1 p.p.m. and the single peak is split into a doublet with a coupling constant of 5 to 6 c.p.s.

Figure 1 illustrates the NMR spectrum of an *N*-methyl tertiary amine as free amine in deuterated chloroform (spectrum A), and as the tertiary amine ion in trifluoroacetic acid (spectrum B). This phenomenon is seldom observed for an amine salt in chloroform solution due to the poor NMR spectrum resolution of ion dipoles and other ion aggregates in solvents of low dielectric constants. Solvents of medium to high dielectric constant such as water, methanol, or trifluoroacetic acid are preferred for high resolution spectra of amine salts.

The splitting of the methyl absorption band observed in trifluoroacetic acid solution is due to coupling of the methyl protons with the proton bound to the nitrogen in the tetrahedral tertiary amine ion. As mentioned previously in this paper, a similar effect has been observed in the case of primary amines. The protons adjacent to the NH_3^+ ion are split into a quartet (2, 3).

The observations from spectra A and B are general for *N*-methyl aliphatic tertiary amines. Table I lists the *N*-methyl chemical shift data for the NMR spectra of 8 *N*-methyl aliphatic amines and

TABLE II.—NMR CHEMICAL SHIFTS FOR TERTIARY *N*-METHYL GROUPS IN AROMATIC AMINES AND ALIPHATIC DIAMINES

Compd.	δ in $CDCl_3$	δ in CF_3COOH	J in CF_3COOH	δ in H_2SO_4	J in H_2SO_4
N,N-Dimethylaniline	2.83	3.42	0	3.41	5.0
N-Methyldiphenylamine	3.27	3.90	0	3.80	5.0
N-Methylpiperazine	2.22	3.21	0	3.09	5.5
N,N-Dimethylpiperazine	2.28	3.22	0	3.07	5.0

corresponding amine ions. Aromatic amines and aliphatic diamines generally require a stronger acid (*e.g.*, sulfuric) to split the methyl absorption (Table II). In sulfuric acid the ion is stable. These weaker amines exchange protons in CF_3COOH at a high enough rate to effectively decouple the ion proton (NH^+) resulting in a J constant of zero. The larger chemical shift due to ring currents in aromatic amines can be used to differentiate an aliphatic *N*-methyl amine from an aromatic amine.

The splitting has been observed for every *N*-methyl aliphatic tertiary amine examined to date at room temperature in trifluoroacetic acid. The amine must be added to the trifluoroacetic acid as the free base. If an amine salt of a strong inorganic acid such as amine hydrochloride is dissolved in trifluoroacetic acid, the amine ion-strong acid dipole remains unionized in the acid. The NMR spectrum in this case is usually too poorly resolved to allow one to observe the 5 to 6 c.p.s. splitting.

Chloroform and trifluoroacetic acid are much more widely useful as solvents for NMR than are either acidic or basic water, since many large tertiary amines and their salts are poorly soluble in either aqueous acid or base.

CONCLUSION

The differences between tertiary amine free base NMR spectra and tertiary amine ion spectra are an extremely useful diagnostic tool. The increased chemical shift and splitting of the *N*-methyl peak in the case of the ion makes it possible to establish the presence of the *N*-methyl group and aliphatic tertiary amine structure in compounds of unknown structure.

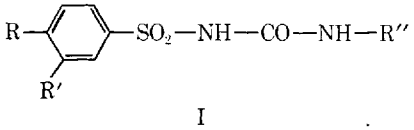
Preparation of Tritium-Labeled Compounds I. Series of Sulfonylurea Hypoglycemic Agents by Exchange with Tritium Gas

By RICHARD C. THOMAS and GEORGE J. IKEDA

A series of tritium-labeled sulfonylurea hypoglycemic agents was prepared by the tritium-gas exposure method. Sodium salts of the sulfonylureas were found to incorporate stably bound tritium more effectively than did the corresponding free compounds. Exposure to tritium gas in the presence of an electrical discharge was also found to be an effective method for preparing tritium-labeled sulfonylureas.

As part of a program to develop improved hypoglycemic agents of the sulfonylurea class (I), it became necessary to label a number of these com-



I

pounds with tritium for use in studying their absorption, distribution, metabolism, and excretion in humans. The tritium-gas exchange method of Wilzbach (1) was chosen because of the relatively low cost of tritium gas and the need for labeling a large number of sulfonylureas, not all of which would necessarily prove of sufficient clinical interest for continued study. An advantage of the Wilzbach method is that a large number of compounds can be exposed to tritium with minimal cost and little investment in time. If a particular compound proves of sufficient interest, the more difficult task of purification can then be undertaken without delay. Thus, in the present case, only 7 of a series of 10 sulfonylureas that had been exposed to tritium were actually purified.

Preparing this series of tritium-labeled sulfonylureas offered an opportunity to study not only the feasibility of labeling this type of compound by tritium-gas exposure but the effects of several variables on their incorporation of tritium. Thus, 15 sulfonylurea samples, representing 7 structure types within the series, were tritiated and purified. Five compounds were exposed to tritium, both as the free sulfonylurea and as the corresponding sodium salt. Two additional sulfonylureas were tritiated, both by conventional tritium-gas exposure and by exposure in the presence of an electrical discharge.

Although exposure of a compound to tritium is relatively inexpensive and easy, subsequent purification of the compound to a state of radiochemical purity can be extremely time consuming and difficult. Trace impurities of very high specific activity are often formed by reduction of an unsaturated bond or by radiation-induced reactions, such as fragmentation, isomerization, and polymerization (1–4). Such impurities, although present in only trace amounts by weight, may contain the bulk of the tritium in the crude sample. These impurities are often difficult to remove, and great care must be taken to establish the radiochemical purity of the final product. Attainment of constant specific activity following recrystallization from several solvent systems is not a sufficient criterion of radiochemical purity for a compound labeled by exposure to tritium gas. After establishing constant specific activity, it is necessary to confirm the radiochemical purity by 1, or preferably several, multistage tests such as thin-layer, paper, or gas chromatography or countercurrent distribution (1–4).

Establishing chemical purity of the final product by elemental and spectral analysis, although of little value in determining the radiochemical purity of a compound labeled by exposure to tritium, is necessary to be certain that the compound will exert its normal biological activity when used in metabolism studies. This is particularly important when the labeled compound is to be administered to humans.

EXPERIMENTAL AND RESULTS

Preparation of Samples for Exposure to Tritium Gas.—The sodium salts of the sulfonylureas were prepared by adding a molar equivalent of 1 *N* aqueous sodium hydroxide solution to a rapidly stirred suspension of the finely ground compound in water. The resulting solution was lyophilized to obtain the desired sulfonylurea salt as a finely divided solid suitable for exposure to tritium gas. The free sulfonylureas were prepared for exposure by grinding them to a very finely pulverized state in a mortar. Particle-size determinations were not made in either case.

Exposure to Tritium Gas.—The samples were exposed to carrier-free tritium gas under the conditions noted in Table I.[1] When exposures were made in this laboratory, tritium gas was transferred by means of a Toepler pump into an ampul containing the material at a pressure of 10^{-5} to 10^{-6} mm. of mercury. The ampul and its contents under approximately 0.2 Atm. of tritium were stored in the dark at room temperature for an appropriate period of time, usually 2 to 4 weeks. At the end of the exposure period, the waste tritium gas was removed by means of the Toepler pump to leave the crude tritiated material at a pressure of 10^{-5} to 10^{-6} mm. of mercury.

Exposure to Tritium Gas with Electrical Discharge.—The discharge was carried out in a cell similar to the ones described by Dorfman and Wilzbach (6) and Jackson *et al.* (7) at a tritium pressure of approximately 15 mm. using a Tesla coil leak detector as a source of voltage. The sample was suspended in a glass cylinder between the 2 electrodes. Conditions used in the exposures are noted in Table II.

Purification.—Following exposure to tritium gas, each crude sample was precipitated from alkaline solution by addition of a slight excess of acid and then filtered and washed with water. This procedure was carried out 3 times to remove labile tritium from the sample completely. During one of the precipitations, the alkaline solution was treated with activated charcoal (Darco G-60). Some removal of high specific activity impurities was effected by this treatment. Samples were then recrystallized to constant specific activity using 2–4 solvent systems and 3–10 recrystallizations. The state of radiochemical purity was followed by paper chromatography and by scanning for radioactivity as described below. The number of recrystallizations required, solvent systems used, weight yield, specific activity, and stably bound tritium incorporated for each sample are presented in Tables III and IV.

Determination of Chemical Purity.—Ultraviolet and infrared spectra of each purified sample corresponded to authentic standards. Elemental analyses—carbon, hydrogen, nitrogen, and sulfur (chlorine for those containing this element)—were satisfactory (within ±0.3% absolute of theory) in each case.

Determination of Radiochemical Purity.—Each sample was subjected to paper chromatography in the 1-butanol–piperidine–water (81:2:17 by volume) system on Whatman No. 1 paper and to thin-layer chromatography in the chloroform–formic acid (95:5 by volume) system on silica gel GF. The compound was located in each case by fluorescence quenching under short-wave ultraviolet light. The developed paper chromatograms were scanned for radioactivity by means of a 4-π windowless, paper-strip scanner[2] having a counting efficiency of approximately 1–2% for tritium. The developed thin-layer chromatograms were first sprayed with a plastic dispersion[3] and allowed to dry at room temperature to give the silica gel a paper-like consistency

[1] Certain of the exposures, as indicated in Table I, were carried out by New England Nuclear Corp. or Tracerlab, Inc.

TABLE IV.—RESULTS OF EXPOSURE OF SULFONYLUREAS TO TRITIUM WITH ELECTRICAL DISCHARGE

Exposure No.	Compd.[a]	Recrystallizations, No.	Yield,[b] Gm.	Specific Activity,[b] μc./mg.
14	I	5[c,d]	0.514	3.67
15	II	5[c,d]	0.479	3.57

[a] See Table I for structures. [b] Based on free sulfonylurea. [c] Methanol–water. [d] Ethyl acetate–heptane.

and thus facilitate its handling. The silica gel film was then cut into sequential 0.5-cm. sections (usually 30) which were transferred to individual counting vials. One-half milliliter of dimethylformamide was added to each vial to dissolve the plastic dispersion,[3] releasing the silica gel, and the series of vials was counted as described below. Each purified sample showed a single radioactive zone in each chromatographic system corresponding to the zone of fluorescence quenching which in turn corresponded to the migration of the authentic sulfonylurea.

Radioactivity Measurements.—All counting was performed with a Tri-carb[4] model 314X or 314EX-2A liquid scintillation spectrometer at −8° under conditions suitable for measuring tritium. Suitable aliquots of samples were dissolved in 15 ml. of diotol scintillator{toluene–dioxane–methanol [350:350:210 by volume] containing 73 Gm. of naphthalene, 4.6 Gm. of 2,5-diphenyloxazole, and 0.080 Gm. of 1,4-bis-2-(5-phenyloxazolyl)-benzene per liter}. The absolute counting efficiency (usually 12 to 16%) for each sample was determined by addition of an internal standard of tritium-labeled toluene and results then expressed as microcuries.

DISCUSSION

As shown in Table III, the sulfonylureas were more satisfactorily labeled with tritium by exposure of their sodium salts, rather than the free compounds, to tritium gas. The sodium salts incorporated 5 times as much stably bound tritium on the average as did the free sulfonylureas. It is possible that in the case of the free sulfonylureas the tritium tends to localize at the labile —NH— position, diluting the tritium gas with hydrogen and thereby decreasing the rate of exchange of tritium with the more stable hydrogens. Blocking the labile position by formation of the sodium salt may thus allow tritium to exchange with stable hydrogens at a more favorable rate. Other explanations, such as more self-destruction of the desired labeled species when a large quantity of tritium is present in a labile position or a larger particle size or less porous surface in the cases of the free sulfonylureas, although speculative, are also possible.

Incorporation of tritium into stable positions of the sulfonylurea sodium salts was remarkably uniform for the series of 7 compounds, ranging from 67 to 165 μc. per curie-day exposure. In the single case where 2 samples of the same sulfonylurea sodium salt (compound V, Table III) were tritiated, the incorporations were in good agreement, 67 and 74 μc. per curie-day exposure, even though substantially different exposures were made in different laboratories.

Incorporation of stably bound tritium into the free sulfonylureas did not appear to be nearly so uniform, ranging from 12.5 to 111 μc. per curie-day exposure. However, except for the high value of 111 μc. per curie-day exposure (compound IV, Table III), the range of incorporations (12.5 to 32.8 μc. per curie-day exposure) was no greater than that of the sodium salts.

Compounds I and III (structures in Table I) were also tritiated by exposure to tritium gas in the presence of an electrical discharge as summarized in Tables II and IV. These tritiations were successful although the specific activities attained were not as high as those obtained by the conventional exposure method. Increasing the discharge time might have increased incorporation of stably bound tritium, but it probably would also have increased degradation (6). Even with a 20-min. discharge, more degradation appeared to take place than was the case where conventional exposure conditions were used. It is interesting to note that the specific activities of the 2 sulfonylureas prepared by the discharge method were essentially the same, whereas the specific activity of I was twice that of III when the conventional exposure method was used. These results may be due to a difference in mechanisms or a relative difference in the contributions of several mechanisms leading to incorporation of tritium by the 2 methods as discussed by Ache *et al.* (8).

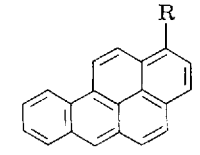
Unusual Grignard Reaction of 1-Acetylbenzo[*a*]pyrene

By O. LEROY SALERNI, JAMES F. ENGEL, and JAMES J. DOWNS

A unique dimeric alcohol, 2,4-bis(1-benzo[*a*]pyrenyl)-4-methyl-2-pentanol (IV*a*), was formed in excellent yield by the Grignard reaction of 1-acetylbenzo[*a*]pyrene (I) and methyl magnesium iodide. This unusual product was isolated when a hydrochloric acid solution was used in the work-up. Use of an ammonium chloride work-up did not give the dimeric alcohol. The preparation and some properties of other 1-substituted benzo[*a*]pyrenes are described.

In the course of the authors' program dealing with the carcinogenesis of polynuclear aromatic hydrocarbons, it became of paramount importance to prepare some 1-substituted benzo[*a*]pyrene derivatives.

Whereas methyl aryl ketones (1, 2) undergo Grignard reactions with methylmagnesium iodide to give excellent yields of carbinol or olefin, we find that 1-acetylbenzo[*a*]pyrene (3) (I) reacts with methylmagnesium iodide in an unexpected manner. The reaction of 1-acetylbenzo[*a*]pyrene (I) with methylmagnesium iodide, on subsequent acidification with hydrochloric acid, did not yield the expected product, either dimethyl-1-benzo[*a*]pyrenylcarbinol (II*a*) or 1-isopropenylbenzo(*a*)pyrene (III).



I, R = —C(=O)—CH$_3$

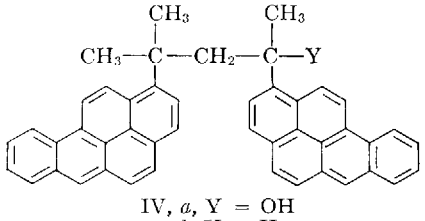
II, R = CH$_3$—C(CH$_3$)—X

a, X = OH

b, X = H

III, R = CH$_2$=C(CH$_3$)—

Rather, the reaction gave a dimeric alcohol, 2,4-bis-(1-benzo[*a*]pyrenyl)-4-methyl-2-pentanol (IV*a*), in 84% yield.



IV, *a*, Y = OH

b, Y = H

The nuclear magnetic resonance spectrum of the product is in complete agreement with the proposed structure. Integration of the NMR spectrum in aromatic and aliphatic regions showed a ratio of 22:11 of aromatic to aliphatic hydrogens. An ebulliometric molecular weight measurement in benzene gave a value of 590, in excellent agreement with the calculated value of 602. The infrared spectrum showed a small, rather broad band, centered around 3400 cm.$^{-1}$, characteristic of a hydroxyl group (4). Finally, elemental analyses supported the structure.

The structure of 2,4-bis(1-benzo[*a*]pyrenyl)-4-methyl-2-pentanol (IV*a*) was further supported by chemical evidence. Reaction of 2,4-bis(1-benzo[*a*]pyrenyl)-4-methyl-2-pentanol (IV*a*) with red phosphorus and iodine in refluxing acetic acid (5) gave the corresponding hydrocarbon, 2,4-bis(1-benzo[*a*]pyrenyl)-2-methylpentane (IV*b*), in 77% yield. The structure of IV*b* was supported by elemental analyses and infrared spectrum. The infrared spectrum of the compound did not show a peak for hydroxyl.

Mechanistically speaking, the formation of the dimeric compound can be rationalized by assuming that dimethyl-1-benzo[*a*]pyrenylcarbinol (II*a*) in acid medium forms an oxonium ion which undergoes facile cleavage to the corresponding carbonium ion and 1-isopropenylbenzo[*a*]pyrene (III). The 1-isopropenylbenzo[*a*]pyrene (III), in turn, combines with the carbonium ion in such a way as to give rise to a new stable tertiary carbonium ion (V) which is attacked in the aqueous medium by a nucleophilic water molecule with subsequent loss of a proton to afford 2,4-bis(1-benzo[*a*]pyrenyl)-4-methyl-2-pentanol (Scheme I).

A study of molecular models clearly shows the dimeric carbonium ion (V) to be sterically crowded so that reaction with another isopropenyl moiety appears all but impossible, thus explaining why further polymerization does not occur.

When the Grignard reaction of 1-acetylbenzo[*a*]pyrene (I) with methylmagnesium iodide was carried out with subsequent acidification with ammonium chloride solution, the dimeric alcohol (IV*a*) did not form. The substance isolated, on the basis of the nuclear magnetic resonance spectrum, was a 60:40 mixture of dimethyl-(1-benzo[*a*]pyrenyl)carbinol (II*a*) and 1-isopropenylbenzo[*a*]pyrene (III). The mixture was dissolved in glacial acetic acid and heated in a water bath to 50°. Almost instantly, bright-yellow needles of 1-isopropenylbenzo[*a*]-pyrene (III) began to precipitate. The infrared spectrum of the collected crystalline material was different from that of the mixture. Furthermore, the nuclear magnetic resonance spectrum indicated an 11:5 ratio of aromatic to aliphatic hydrogens and displayed peaks at δ = 5.2 and 5.6 p.p.m., indicative of an α-methylstyrene moiety (6). Elemental analyses supported the structure, and the

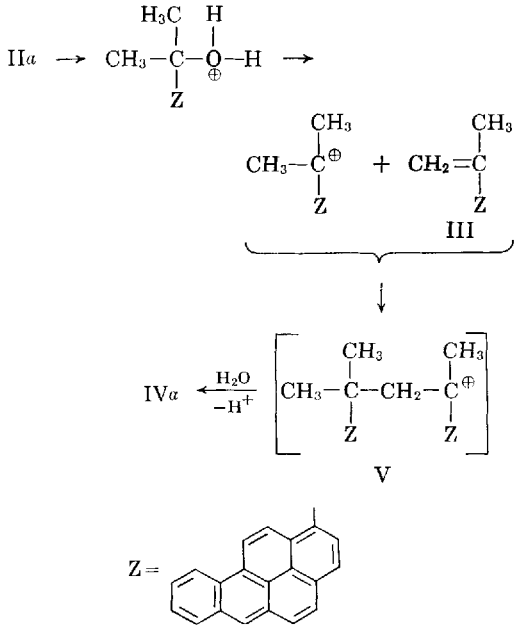

Scheme I

compound gave a m. p. 110–112° in agreement with the literature.[1]

The isopropenyl compound (III) was converted to 1-isopropylbenzo[*a*]pyrene (II*b*) in 75% yield by room temperature hydrogenation for 2 hr. using a 2:1 ratio of substrate to palladium black catalyst at 52 p.s.i. The nuclear magnetic resonance spectrum of the compound showed a characteristic 7-line pattern for the methine proton, and was void of peaks at δ = 5.2 and 5.6 p.p.m., indicating that the double bond of the α-methylstryrene moiety had been reduced to give the isopropyl derivative (II*b*).

EXPERIMENTAL[2]

2,4 - Bis(1 - benzo[a]pyrenyl) - 4 - methyl - 2 - pentanol (IV).—A Grignard reagent was prepared from 2.3 Gm. (83 mmoles) of magnesium, 6.4 ml. (100 mmoles) of methyl iodide, and 44 ml. of dry ether. When the reaction was complete, a slurry of 4.4 Gm. (15 mmoles) of 1-acetylbenzo[*a*]pyrene (I) in 420 ml. of dry benzene was added. The mixture was stirred and heated under reflux for 4 hr., cooled, and decomposed with 300 ml. of ice-cold 10% hydrochloric acid solution and worked up in the usual way. The product crystallized when triturated with cold ethanol and was purified by passing its benzene solution through an alumina column. In this way was obtained 3.6 Gm. (84%), m.p. 200–205° (gradual decomposition).

Anal.—Calcd. for $C_{46}H_{34}O$: C, 91.66; H, 5.69; mol. wt., 602. Found: C, 91.68; H, 5.64; mol. wt., 592.

1-Isopropenylbenzo[a]pyrene (III).—A Grignard reaction was carried out using the same procedure and quantities of magnesium, methyl iodide, and 1-acetylbenzo[*a*]pyrene, as above, except that the reaction was decomposed with 300 ml. of ice-cold saturated ammonium chloride solution. The oily product obtained was dissolved in 25 ml. of glacial acetic acid and heated to 50°, at which time bright-yellow needles precipitated. After chilling, the solid was collected by suction filtration and recrystallized from absolute ethanol, yielding 2.2 Gm. (50%) of bright yellow needles, m.p. 110–112.° [Lit. (3) m.p. 114.°]

Anal.—Calcd. for $C_{23}H_{16}$: C, 94.48; H, 5.52. Found: C, 94.37; H, 5.46.

1-Isopropylbenzo[a]pyrene (IIb).—A solution of 2.0 Gm. (4.3 mmoles) of III in 100 ml. of benzene was hydrogenated at a pressure of 52 p.s.i. and at room temperature using 1.0 Gm. of palladium black as the catalyst. After 2 hr., the catalyst and solvent were removed. The crude yield was quantitative. Recrystallization from absolute alcohol yielded 1.5 Gm. (75%), m.p. 128–130°.

Anal.—Calcd. for $C_{23}H_{18}$: C, 93.84; H, 6.16. Found: C, 93.76; H, 6.21.

2,4 - Bis - (1 - benzo[a]pyrenyl) - 2 - methylpentane (IVb).—In 125 ml. of glacial acetic acid and 10 ml. of water was suspended 1.0 Gm. (1.6 mmoles) of IV*a*, 200 mg. of iodine, and 200 mg. of red phosphorus. The mixture was stirred and heated under reflux for 29 hr., cooled, then extracted with three 80-ml. portions of benzene. The combined organic layers were washed with water and then dried over anhydrous sodium sulfate. Filtration and concentration yielded a crystalline solid which after recrystallization from benzene–ligroin afforded 603 mg. (77%), m.p. 210–215° dec.

Anal.—Calcd. for $C_{46}H_{34}$: C, 94.16; H, 5.86. Found: C, 93.87; H, 6.01.

[1] See *Reference 3*, p. 162. Windaus reported the synthesis of 1-isopropenylbenzo[*a*]pyrene by heating the product from the reaction of methylmagnesium iodide with 1-acetylbenzo[*a*]pyrene after an ammonium chloride workup at 230–280° under high vacuum in the presence of powdered zinc.

[2] All melting points were taken on a Thomas-Hoover capillary melting point apparatus and are uncorrected. All analyses and molecular weight determinations were carried out by Galbraith Laboratories, Inc., Knoxville, Tenn. Infrared absorption spectra were taken as Nujol mulls and determined on a Perkin-Elmer model 137 spectrophotometer. The NMR spectra were determined on a Varian A-60 spectrometer with tetramethylsilane as the internal reference. Deuterochloroform solutions were used for all spectra.

Small Tube Method for the Evaluation of Antifungal and Antibacterial Activity

By PHILIP CATALFOMO and H. WAYNE SCHULTZ

Small tubes containing a thin layer of agar medium have been used in a method for screening pure chemicals for antifungal and antibacterial activity. Employing known agents, this method provided results comparable to those obtained by other methods. In addition, the method affords the following advantages which make it suitable as a screening procedure: a no-growth end point which may be readily determined, it is effective for nonaqueous as well as aqueous solutions, it utilizes inexpensive apparatus, a minimum quantity of media and test agents are required, and a relatively small amount of working area is needed for conducting the tests.

ALTHOUGH there are numerous techniques available to test for antimicrobial activity, none of them appear suitable for the simultaneous screening of a large number of agents. The various modifications of these methods have been reviewed and evaluated by Reddish *et al.* (1), Skinner (2), and Heatley (3). Vanbreuseghem (4) recently considered the merits of those methods which determine antifungal activity.

The *in vitro* methods generally are classified as either dilution or diffusion methods. The former are best suited for assay procedures, but the methods are time-consuming for screening purposes, and many of them are not satisfactory to determine antifungal activity when filamentous fungi are used as test organisms. This is particularly so if partial inhibition is studied because it is difficult to determine the amount of growth of these fungi. Diffusion methods, such as represented by the use of filter paper disks on an agar plate, find limited value with water-insoluble agents and with organic solvents having antimicrobial activity. Also, the determination of the end point, usually the measuring of clear zones of inhibition, is tedious and somewhat arbitrary, especially with filamentous fungi.

The above factors, plus certain other innate disadvantages of existing methods, prompted this study. A technique has been developed which appears to be suitable for screening, qualitatively and semiquantitatively, large numbers of agents for antifungal and/or antibacterial properties.

EXPERIMENTAL AND RESULTS

Materials and Methods.—The fungal species used were *Candida albicans*, ATCC 10231, and *Trichophyton mentagrophytes*, ATCC 9972. The bacterial species employed were *Escherichia coli* and *Staphylococcus aureus* from the collections maintained at the Department of Microbiology, Oregon State University.[1]

The fungal organisms were maintained on Sabouraud dextrose medium Difco (liquid and agar), and the bacteria were maintained on nutrient medium Difco (broth and agar). The liquid cultures also served as a source of inocula. The experimental studies were conducted in flatbottom, screw-capped vials (17 × 60 mm.) containing 0.5 ml. of the desired medium. This volume provided a layer of medium approximately 2 mm. in depth. Antifungal activity was determined on Sabouraud dextrose agar medium and antibacterial activity on nutrient agar medium.

Actively growing 2- to 4-day-old liquid cultures (10 ml./culture tube) of bacteria and *C. albicans* were used as inocula. The small experimental tubes were inoculated by adding 1 drop of a suspension of the respective organisms utilizing a sterile standard medicine dropper (about 20 drops/ml. of water). To facilitate obtaining inocula with a medicine dropper, all organisms were transferred to sterile 15-ml. wide-mouth containers.

For studies using *T. mentagrophytes*, transfers were made from agar slants to 125-ml. conical flasks containing 30 ml. of Sabouraud medium. The mycelial growth from 5- to 7-day-old stationary cultures was homogenized in a sterile semimicro Waring blender for 30 sec. and added as inocula to the experimental tubes as described previously. All incubations were conducted at 37°.

Solutions of the agents to be tested were prepared in acetone, water, or 95% ethanol, depending on their solubility, and placed in dropper bottles. Unless otherwise indicated, dilutions of 1:100, 1:500, 1:1,000, 1:5,000, and 1:10,000 were tested for all compounds. Prior to inoculation with microorganism, 2 drops (approximately 0.04 ml.) of the various freshly prepared solutions were added to the tubes, and the solvent was allowed to evaporate or be absorbed into the agar medium.

The tubes were examined for growth after 24–48 hr. of incubation for bacteria and *C. albicans* and 48–72 hr. for *T. mentagrophytes*. In certain instances incubation was allowed to continue for 5–7 days in order to determine if the method might be suitable to indicate fungistatic *versus* fungicidal activity.

Antimicrobial Studies.—The agents used to test antifungal activity included salicylic acid, salicylanilide, griseofulvin, nystatin, tolnaftate,[2] and penicillin V. Antibacterial determinations were made with penicillin V, streptomycin sulfate, sulfadiazine, sulfathiazole, and sodium sulfathiazole. The series of dilutions previously described were prepared as follows: acetone–salicylic acid, salicylanilide, griseofulvin, penicillin V, and sulfadiazine; water–streptomycin sulfate and sodium sulfathiazole; 95% ethanol–nystatin and tolnaftate. Replicates of 3 tubes per dilution for each organism

were prepared. Controls consisted of tubes inoculated with the organism only, and blanks consisted of solvent and the respective microorganism. The results are summarized in Tables I and II. Unless stated otherwise, the final results are based on 48-hr. readings. The data reported here are consistent with those well documented for the agents listed (5, 6).

At the higher concentrations (1:100 and 1:500) the compounds which were relatively water-insoluble and tested as nonaqueous solutions tended to crystallize on the surface of the medium after the solvent evaporated. To determine if the presence of surface crystals affected the growth of the organism, or the activity of the agent, a modified procedure was tested. The compounds were suspended in the modified agar media (diluted 50%) in dilutions of 1:100, 1:500, and 1:1,000. Two drops of the suspension was added to the small tubes providing them with a thin film of medium containing the uniformly dispersed compound. The compounds tested in this manner were salicylanilide, griseofulvin, and penicillin V, with fungi; and penicillin V and streptomycin sulfate against bacteria. All except the last one are not soluble in water. Since the results did not vary from those obtained in the original study, they were not recorded here.

The study utilizing nystatin (Table I), comparing the effects of this agent on both fungi, was allowed to continue for 7 days. During this period, and commencing at 72 hr., growth of *C. albicans* developed in those tubes containing the 2 lower concentrations. Growth of *T. mentagrophytes* was noted at dilutions of 1:500 and higher at 72 hr., and which appeared completely uninhibited at the seventh day. Thus, it was shown that nystatin most likely acts as a fungicide against *C. albicans* in all but the extremely diluted concentrations and as a fungistat against *T. mentagrophytes* in all but the highest concentration, while having a low order of effectiveness. These data are in general agreement with previously recorded findings (7).

Growth of the microorganisms in those tubes designated as controls and blanks was luxuriant in all but 1 instance. Alcohol appears to have a slight fungistatic action against *T. mentagrophytes*. In those cases where alcohol was used as the solvent (nystatin and tolnaftate) readings were taken only after 72 hr.

DISCUSSION

A simplified method for the simultaneous screening of a relatively large number of pure chemicals for antimicrobial activity has been devised. Using established antifungal and antibacterial agents, it was demonstrated that the method provided results consistent with those obtained by other techniques. Thus, it would appear that other pure chemicals may be screened in a similar manner. Extended studies have indicated that this method is further applicable to the screening of crude plant extracts (8).

Since a no-growth end point is used and determined by mere visual inspection of the small tubes, the tedious task of measuring clear zones of inhibi-

tion is avoided. This factor bears particular significance with microorganisms that produce irregular defined zones, *i.e.*, many filamentous fungi. According to Cavillito (9), complete absence of visual growth is the most reproducible and satisfactory end point in an inhibition test.

The effectiveness of most diffusion methods is dependent on those factors which govern the ability of the agent to diffuse both horizontally and vertically throughout the medium. Cooper (10) indicates the importance of these factors in critical assay procedures. They are less important when applied to general screening procedures which are primarily designed to merely distinguish between active and nonactive agents. Through the use of small tubes and thin layers of media, the extent of horizontal and vertical diffusion has been limited, thus rendering diffusion factors negligible.

Those compounds which were highly water insoluble and tested as nonaqueous solutions tended to crystallize on the surface of the medium after evaporation of the solvent. The occurrence of these crystals had no apparent effect on the growth of the microorganisms or on the suspected activity of the antimicrobial agents. For example, penicillin V, having the properties of low water solubility, antibacterial but not antifungal activity, demonstrated in this experiment no effect on the growth of the fungi while it did inhibit growth of the bacteria. Furthermore, when griseofulvin was tested it was shown that the surface crystals had no effect on the growth of *C. albicans*, against which this agent is ineffective, but it did exhibit its usual inhibitory effect on *T. mentagrophytes* (11). These findings were also substantiated in the experiment where the compounds were uniformly dispersed and added to the tubes in a thin film of the respective medium. In this instance the results did not vary from those observed in the original study.

A slight antifungal effect was noted when alcohol was used as a solvent for those agents tested against *T. mentagrophytes*, but this was easily overcome by merely extending the incubation period slightly and providing adequate control tubes for comparison.

The method appears to distinguish between fungistatic and fungicidal activity. This may be accomplished by extending the incubation period to 7 days or longer but not beyond 10 days, since the medium begins to show signs of drying. It would also be a simple matter to attempt to reculture the microorganism to determine the nature of the activity of the agent being studied.

Additional advantages afforded by this method are a minimum of expenditure for materials or apparatus, and that a relatively small amount of working area is required to test a series of compounds when compared to the space needed if Petri dishes are employed.

Inhibition of Replication of Lee Influenza Virus in Tissue Culture by Puromycin

By K. S. PILCHER and J. N. HOBBS

Puromycin, an inhibitor of protein synthesis with general growth inhibitory properties, was found to inhibit replication of influenza virus in tissue culture in low concentrations without destroying all metabolic activity of the tissue. The aminonucleoside of puromycin, reported to be as effective as the complete compound against trypanosomes, was inactive as an inhibitor of the virus. Evidence suggests the mechanism of the virus inhibition is probably interference with protein synthesis, and that the antitrypanosomal activity has a different mechanism.

PUROMYCIN (I) is an antibiotic whose structure, proved by total synthesis by Baker *et al.* (1), is that of a nucleoside bound to an unusual amino acid.

Puromycin has been found to inhibit the growth of a variety of cells, including bacteria (2), protozoa (3, 4), and animal tumors (5). This compound has been shown to inhibit protein synthesis in several biological systems, including a cell free rat liver extract (6), Ehrlich ascites tumor cells, and rabbit reticulocytes (7). It was effective in curing experimental infections of mice and rabbits with several species of trypanosomes (3, 8), and also in the therapy of human trypanosomiasis (9).

Puromycin's mechanism of action seemed to offer a possible new approach to the inhibition of virus protein formation. During the course of this study, the inhibition of poliovirus replication in tissue culture by puromycin was reported (10).

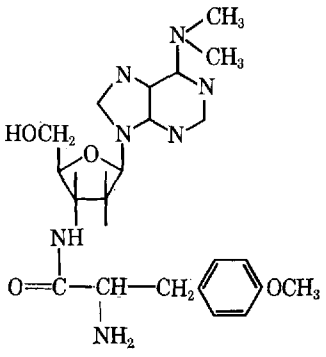
Effect of puromycin on outgrowth of chorio-allantoic cells in vitro	No growth	No growth	Definite cell growth	Definite cell growth

[a] HA indicates hemagglutinating units. [b] Virus hemagglutinin and infectivity measured after 44–48 hr. incubation on shaker at 35°. Initial virus concentration from inoculum about 5×10^5 EID_{50}/ml. [c] Each value is a geometric mean of 30–32 cultures from 5 experiments. [d] Values from a single representative experiment. [e] NT indicates not tested.



Puromycin (I)

MATERIALS AND METHODS

The Lee strain of influenza virus was employed in these experiments and was maintained as frozen chick embryo allantoic fluid stored at −60°. Puromycin and its aminonucleoside were obtained from the Nutritional Biochemicals Corp., Cleveland, Ohio.

The tissue culture system has been previously described (13). Each culture consisted of about 4 cm.² of chorio-allantoic tissue from 10-day chick embryos. The tissue was suspended in 2.0 ml. of Hanks' balanced saline (BSS) in 25 × 150 mm. Pyrex culture tubes.

The method of measuring virus concentration in culture fluids by hemagglutinin titration, and the method of determining toxicity for tissue cells have also been described (13). For the measurement of infectious virus, a series of decimal dilutions of the culture fluid was made and each dilution inoculated into a group of five 10-day chick embryos. After 48-hr. incubation, the number of infected embryos in each group was determined, and the number of 50% infectious doses (EID_{50}) per milliliter of the undiluted virus calculated.

RESULTS AND DISCUSSION

The combined results of 5 experiments designed to determine the effects of puromycin on virus replication are presented in the first row of data in Table I. Puromycin was incorporated in the fluids of the tissue cultures which had been inoculated with the Lee strain of influenza virus, and the concentration of the latter after incubation was determined by hemagglutination. It is evident that a concentration of 4 mcg./ml. reduced the virus yield markedly, and even 2 mcg./ml. produced a slight reduction, which was significant in view of the relatively large number of replicate cultures. In some experiments virus concentration was measured by infectivity titrations in 10-day chick embryos. Results of a representative experiment of this type are shown in the second row of Table I. In the presence of 4 mcg. of puromycin per milliliter the titer of infectious virus was 2 log units lower than in control cultures. Relatively few virus inhibitors are active at such low concentrations.

In vitro experiments in which the virus was exposed to a puromycin concentration of 4 mcg./ml. in a phosphate–glycine buffer[1] of pH 8.0 for 24 hr. at 35° yielded results which indicated that the titer of infectious virus was essentially the same as in control preparations similarly treated, but without puromycin. Data from such an experiment are shown in the third row of Table I. Thus, the compound seemed to have no direct effect on the virus itself. It was also found to cause no interference with the hemagglutination reaction, or with adsorption of the virus to the chick chorio-allantoic tissue. These observations pointed to an effect of the compound on the infected cell as the basis for inhibition of virus replication.

It was noted that fragments of chorio-allantoic tissues exposed to a puromycin concentration of 4 mcg./ml. for 44–48 hr. appeared very similar to those in control cultures, and some metabolic processes were still active, as indicated by continuing acid production in such cultures. Thus, gross or destructive tissue toxicity was not apparent. However, employing a more sensitive criterion, it was found that outgrowth of new cells from tissue fragments in roller tube cultures containing BSS, did not occur in the above concentration of the antibiotic. Cell growth did occur, however, in a concentration of 2 mcg./ml. It is of interest to note that the concentration of 4 mcg./ml. is close to that which Yarmolinsky and de la Haba (6) found necessary for marked inhibition of leucine-^{14}C incorporation into protein in a rat liver extract.

The biological activity of the aminonucleoside of puromycin or that portion of the molecule remaining after splitting off the amino acid, has been studied by several workers. In the experimental infection of mice with *Trypanosoma equiperdum*, both puromycin and its aminonucleoside were found

[1] Concentrations of buffer components in final mixture with virus were: glycine, 0.025 *M*; NaCl, 0.025 *M*; and Na_2HPO_4, 0.0167 *M*.

TABLE II.—REPLICATION OF LEE INFLUENZA VIRUS IN TISSUE CULTURES CONTAINING PUROMYCIN AMINONUCLEOSIDE

	Concn. of Aminonucleoside in Tissue Culture Fluid, mcg./ml.			
	400	200	100	0
HA units of virus/ml.[a,b] of tissue culture fluid	136	164	137	91

[a] Virus concentration measured as hemagglutinating (HA) units after 44–48 hr. incubation on shaker at 35.° Each value is a geometric mean of 15 cultures from 3 experiments. [b] Initial virus concentration from inoculum about 5×10^5 EID_{50}/ml.

about equally effective on a molar basis in curing the disease (11), and the *in vivo* activity of each was reversed by administration of adenine.

The aminonucleoside was compared with puromycin for its ability to inhibit virus replication in tissue culture. It was found that the former compound had no inhibitory activity in concentrations comparable on a molar basis to the effective levels of puromycin shown in Table I. Much higher concentrations resulted consistently in somewhat higher yields of virus in the culture fluid than those in control cultures. The results obtained are presented in Table II. In the experiments represented, tissue culture fluids containing 200 mcg. of the aminonucleoside per milliter were found to yield virus titers nearly twice that of controls. These experiments showed conclusively that the amino acid moiety of the puromycin molecule was essential for inhibition of influenza virus formation. They also indicated that the mechanism of action of puromycin against trypanosomes is apparently different from that responsible for the virus inhibition. A further difference was revealed by experiments in which attempts were made to block or reverse the virus inhibition by means of adenine, guanine, cytosine, uracil, and the corresponding nucleosides and nucleotides added to the tissue culture medium. In no case could any significant or reproducible reversal be demonstrated.

Preliminary experiments were performed to determine the activity of puromycin in mice infected with minimal doses of Lee influenza virus. These animals were given intraperitoneal injections of 1 mg. at 12–14-hr. intervals for 3 days. This treatment had no effect on the virus concentration in the lungs at the end of that period. Larger doses and more frequent injections should be tried, as well as administration by aerosol inhalation.

Yarmolinsky and de la Haba found that while puromycin inhibited protein synthesis in their rat liver extract system, the aminonucleoside showed only slight activity in equivalent molar concentrations (6). Rabinovitz and Fisher found the complete antibiotic molecule a potent inhibitor of protein synthesis in Ehrlich ascites tumor cells and in rabbit reticulocytes, while the aminonucleoside was inactive (7).

Several characteristics of the influenza virus inhibition by puromycin suggest that the mechanism probably depends on inhibition of protein synthesis. The concentrations required for the virus inhibition are very similar to those found necessary by the above investigators to inhibit incorporation of amino acids into protein. The aminonucleoside has been found to have little or no inhibitory activity for either virus replication or protein synthesis. In the virus tissue culture system described, when puromycin was present in inhibitory concentrations, multiplication of the host cells was also inhibited, without destruction of metabolic activity as measured by acid production. The amino acid moiety of puromycin, which was essential for virus inhibition, is *p*-methyoxyphenylalanine. *p*-Fluorophenylalanine is an antimetabolite which has also been found to interfere with protein metabolism (12). When combinations of puromycin and the latter compound were studied in the influenza virus system as previously reported for other inhibitor combinations (13), it was found that the degree of virus inhibition was no greater than that produced by either agent alone. This suggested a similar site of action for the 2 inhibitors.

Fractionation of the Black Snake Venom (*Walterinnesia aegyptea*) by Sephadex Gel Filtration

By O. A. ZAKI*

By the use of a column of Sephadex G-200, it was possible to separate from venom 7 protein components which showed different patterns in electrophoretic mobility. Only 2 of the separated fractions have toxic effects on albino rats.

SNAKE VENOMS are known to contain a number of enzymes. Attempts have been made to correlate the toxicity of snake venoms with their enzymatic activity (1). Most of these studies have been carried out on whole venoms (2) or after elimination of some components by heat treatment (3). A number of methods, such as electrophoresis, use of ion exchange resins such as Amberlite, and cellulose ion exchangers have been used for fractionation. All the methods used were not quite efficient for the complete separation of the different factors in the venom. Yang *et al.* (4) used electrophoresis on potato starch for the separation of the components of Hyopoda venom, and they found that the proteases and phosphatases occurred in the same fractions as the toxic components. Master *et al.* (5) stated that the use of paper and agar gel electrophoresis did not give a sufficiently good separation of the components of Indian cobra and Russel's viper venom.

Mohammed and Zaki (6) studied the properties of the black snake venom, and their chemical studies proved that the venom is a protein mixture. Sephadex gels act as molecular sieves allowing separation of protein mixtures (7). These gels are composed of small granules prepared by the crosslinking of dextran. Sephadex G-200 retains materials of molecular weight up to 200,000. Molecules larger than the pore size pass directly through the gel-packed column, whereas those small enough to enter the grains are retained until replaced by the eluant.

The present study was undertaken to see if any useful separation of the various protein factors in the black snake venom could be obtained by gel filtration.

METHODS

For protein, Sephadex G-200 is the most suitable type since the available capacity is high even for relatively large molecules. Gel filtration was performed by the method of Porath and Flodin (8). A column 7.5 × 41 cm. (volume of 1800 ml.) with Sephadex G-200 was used. Before being packed into the column, Sephadex G-200 was allowed to swell until equilibrium was attained. Forty-eight hours was allowed for swelling. The swelling of Sephadex was in an excess of water containing the buffer. The column was filled to about one-third of its height with the buffer. This consisted of 0.163 *M* NaCl in 0.0004 *M* trihydroxyaminoethane (Tris) previously adjusted to pH 7.4 with HCl. A ball of glass wool was placed at the bottom of the column, and a layer of small glass beads, sufficient to cover the glass wool to a depth of about 1 cm., was added. The suspension of Sephadex G-200 was poured into the column, filling an extension tube of about 20 cm. joined to the top of the column. The gel particles were allowed to sediment until a layer a few centimeters thick had formed. The outlet of the column was then gradually opened, and if the effluent was clear, packing was continued. When packing was finished, the extension tube was removed and the buffer reservoir connected.

The bed, stabilized by washing overnight, was ready for use. In each experiment the column was washed by NaCl–buffer solution (100:20). The venom (10 mg. in 2 ml. of buffered solution) was added to the column by a tip pipet. Before introduction of the sample, all the liquid above the surface of the bed was removed with care. After the sample had been layered on the bed, the bottom outlet was opened. A small volume of the buffer was added in the same manner and was allowed to enter the bed. The column was then filled with the buffer and the buffer reservoir was connected. In each experiment 32 fractions of 2 ml. each were collected. The rate was that each fraction was collected in 15 min. Then 0.4 ml. of each fraction was diluted by 3.6 ml. of buffered solution. The proportion concentration of each fraction was estimated from measure-

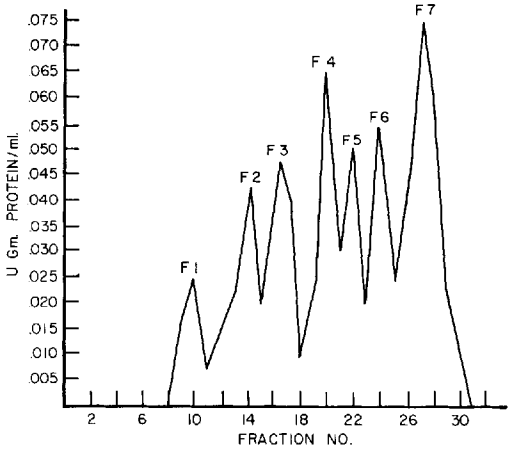

Fig. 1.—The position of the different factors in the black snake venom according to their protein extinction when the venom is fractionated with Sephadex G-200. The extinction of each fraction, of 32 fractions, is plotted on the curve. The summit of each fluctuation in the curve is taken as a definite fraction and these fractions are represented on the curve as F_1, F_2, F_3, F_4, F_5, F_6, and F_7. Eluant, 0.163 *M* NaCl in 0.004 *M* Tris buffer. Fraction size, 2 ml.

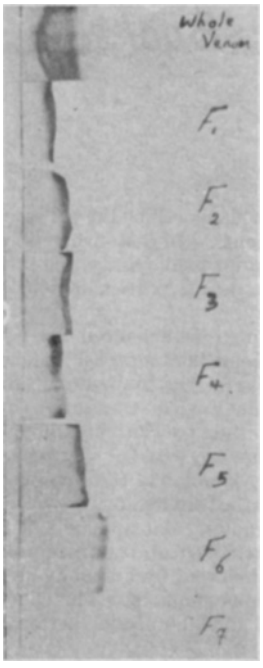

Fig. 2.—The electrophoretic pattern of the Egyptian black snake venom and that of the 7 fractions (F_1, F_2, F_3, F_4, F_5, F_6, and F_7) obtained by fractionation of the venom using a column of Sephadex G-200.

ments of the extinction 280 mμ using a Unicam S.P. 500 spectrophotometer.

Paper strips electrophoresis was carried out on the whole venom as on each of the fractions. A horizontal Shandon tank was used, with constant current and constant voltage. Oxoid 2.5 × 12 cm. strips were used. The volume of venom added to each strip was 0.005 ml. of 1:1000 venom solution. The buffer used in the electrophoresis had pH 8.6 and was of the following composition: sodium acetate, 6.5 Gm.; sodium barbital, 8.87 Gm.; barbital, 1.13 Gm.; in 1 L. of distilled water.

The electrophoretic run was continued for 2 hr. using a current slightly below 0.4 ma./cm. width of the strip. After electrophoresis, the strips were removed with forceps and were dried by suspending them in a hot air over for 20 min. at 100°. The dry strips were left overnight in the staining solution (0.001% nigrosine in 2% aqueous acetic acid). After staining, the strips were washed by running tap water and then dried.

The protein fractions collected from the column were tested for their toxicity. This was done by the subcutaneous injection of 0.5 ml. of the diluted fraction into albino rats weighing about 100 Gm. The fraction which caused the death of the rats within 24 hr. was assumed to contain the toxin. This experiment was repeated several times to confirm the position of the toxic components.

RESULTS AND DISCUSSION

Considerable separation of the protein venom factors was achieved by Sephadex G-200 filtration. Seven fractions showed definite protein extinctions (Fig. 1). By studying the electrophoretic pattern of the whole venom, 6 separate components could be recognized (Fig. 2), indicating that 2 of the gel filtration fractions had the same electrophoretic mobility. The paper strips electrophoresis carried out on each fraction showed that factors 2 and 4 (F_2 and F_4) had the same mobility.

When the toxicity of the fractions was tested, it was found that the fraction corresponding to F_4 and F_6 killed the rats. The death in case of F_6 injection had the same typical symptoms of paralysis as that which occurred when the whole venom was injected (6). This suggested that presence of a neurotoxin in this fraction.

When the animals were injected by F_4, they showed severe itching, excessive salivation, difficult breathing, and then respiratory failure followed by circulatory failure. There were no paralytic symptoms.

The results showed that Sephadex gel filtration may be of considerable value in the separation of the components of the snake venoms.

Probably the most useful application will be in the preparation, physiological study, and the study of enzymes in each factor of the venom separately. Such experiments are being conducted in these laboratories.

REVIEWS

Pharmacognosy. 5th rev. ed. By E. P. CLAUS and V. E. TYLER, JR. Lea & Febiger, 600 Washington Sq., Philadelphia, Pa. 19106. 1965. 572 pp. 16 × 26 cm. Price $15.00

The fifth edition is a rather extensively revised text. It has been brought up to date to conform with U.S.P. XVII and N.F. XII. The introductory material has been rewritten in many of the chapters, and the content in all chapters is in accordance with present day concepts. A major innovation has been the addition throughout the text of considerable information on the recent concepts of biosynthesis of many of the major plant constituents.

The book has retained the material of value for the microscopic study of powdered drugs and thus can serve as a text for this purpose. The authors did a good job of condensing a great amount of knowledge of poisonous fungi as well as higher plants into a new chapter on this subject.

A major asset of the book is the extensive number of references cited throughout the text. Thus the text can well serve as an excellent reference book, although a number of the obsolete drugs had to be dropped to conserve space. The authors stated the reader could refer to earlier editions if he wished specific information about such drugs.

The keyword to this fine text is versatility. It is a book that is suitable for many teaching purposes. The authors have a keen insight into the modern development of pharmacognosy and have written a text which meets the needs accordingly.

Vitamin Assay: Tested Methods. By ROLF STROHECKER and HEINZ M. HENNING. Translated from the German by D. D. LIBMAN. Verlag Chemie, P.O. Box 129/149, Weinheim, Germany, 1965. 360 pp. 17 × 24 cm. Price $12.

This handsome book of 360 pages covers the great majority of useful chemical and microbiological vitamin assay methods published in recent years. The authors stress the fact that they have selected only methods which they have found workable for routine assays, as well as for research purposes. From experience in our own laboratories, the reviewer can concur with this statement.

The methods quoted present a wealth of up-to-date procedures, sufficiently explicit to permit application to the reader's particular problem. At the same time, critical points and pitfalls are evaluated including detailed instructions for carrying out the procedure. Frequently the chemical reaction involved is outlined, as well as the preparation of the necessary reagents. In cases where separation steps are needed prior to the assay, the procedures are described in detail, particularly with respect to chromatography.

The usefulness of the text is enhanced by numerous illustrations and color photographs. Those depicting colored thin-layer chromatograms are particularly striking. The English translation by D. D. Libman is distinguished by clarity, although some of the abbreviations (*e.g.*, G.R. = reagent grade) may not be readily familiar to the American reader. References to the literature are conveniently quoted in footnotes. An appendix lists the composition of microbiological test media in handy table form and is followed by a step-by-step description of the solutions required. This book should prove very useful for laboratories performing vitamin assays.

A Survey of Diabetes Mellitus

By GEORGE N. HOLCOMB

REFERENCE to the disease known to us as diabetes mellitus goes back almost as far as recorded history itself. The Ebers Papyrus, an Egyptian document dating from about 1500 B.C., has outlined the symptoms of diabetes as well as a number of "cures" for the disease. Diabetes was described in some detail by a physician known as Aretaeus the Cappadocian as early as the first century A.D., but it was not until the seventeenth century that Thomas Willis, an English physician, observed that the urine of diabetics had an extremely sweet taste. This appears to have been the first evidence to connect diabetes mellitus with the metabolism of sugars.

A recent study on the prevalence of diabetes (1) indicates that there are somewhat over 2,000,000 known diabetics in the United States. Other evidence cited by the same workers (1) shows that the frequency rate for undiagnosed cases of diabetes in this country is about 8 per 1000 persons. Taking these two figures into account leads to an estimate that there are close to 3,500,000 diabetics in the U. S. alone. This represents nearly 20 diabetics per 1000 population and qualifies the disease as a major medical and public health problem.

THE METABOLIC EFFECTS OF DIABETES

Although more is known about the biochemical basis of diabetes mellitus than for most other diseases, too little is known to give an accurate definition of the disease. Some of the characteristic symptoms of diabetes are hyperglycemia, glycosuria, polyuria, polydipsia, and possible loss of weight and strength. Ketone bodies (acetoacetic acid, acetone, and β-hydroxybutyric acid) may be present in the blood and urine of diabetic subjects.

Diabetes may be classified into at least 2 types (2): the growth-onset (juvenile) type and the maturity-onset (adult) type of diabetes. The juvenile type of diabetes which is contracted early in life is characterized by a greatly diminished capacity to produce insulin (3) which approaches zero within a few years. Maturity-onset diabetics are frequently obese and develop symptoms quite gradually, usually after age 40. These individuals often have substantial quantities of pancreatic insulin (4) and normal or near normal levels of circulating insulin (3).

THE DEVELOPMENT OF INSULIN

The first evidence that the pancreas is concerned with diabetes came as early as 1889 when von Mering and Minkowski showed that pancreatectomy in laboratory animals produced the same symptoms as diabetes. This led workers to propose that the pancreas secretes a substance which regulates blood sugar as well as other factors concerned with diabetes. In 1909 de Meyer coined the name *insuline* to refer to the then hypothetical substance secreted by the islets of Langerhans of the pancreas.

It was not until 1922, however, that the biological activity of insulin was finally demon-

Received from the Department of Pharmaceutical Chemistry, School of Pharmacy, Ferris State College, Big Rapids, Mich.

The author expresses his appreciation to the personnel of The Upjohn Co., Kalamazoo, Mich., for their cooperation and gives particular thanks to Dr. William E. Dulin for his valuable assistance in preparing the manuscript.

strated by Banting and Best (5), who showed that a pancreatic extract could be used to alleviate the symptoms of diabetes. For this monumental discovery, Dr. Banting received a Nobel Prize. Four years later Abel and his associates (6) obtained crystalline insulin by the extraction of animal pancreases, and proposed that insulin was a protein.

Sanger was awarded the Nobel Prize in chemistry in 1958 in recognition of his work on the elucidation of the chemical structure of the insulin molecule. His work involved the cleavage of insulin into 2 peptide chains by performic acid oxidation (7), followed by degradation studies on the 2 individual chains to determine the amino acid sequence of each (8, 9). This work has been summarized by Sanger (10). As a result of the work of Sanger and others, it is known that insulin has a molecular weight of approximately 6,000 and is composed of 2 peptide chains. The A, or glycyl chain, is composed of 21 amino acid residues while the B, or phenylalanyl chain, is composed of 30. The 2 chains are connected by disulfide bridges between A 7 and B 7 and between A 20 and B 19, with a third disulfide bond found in the A chain from A 6 to A 11.

The absolute proof of the structure of insulin must come from the preparation of a synthetic insulin which exhibits a significant amount of insulin activity in a variety of biological assays. Because of this, a great deal of recent research has been directed toward this goal. Katsoyannis and his associates (11–13) prepared the A and B chains of sheep insulin by synthetic procedures requiring over 200 steps. Zahn, Meienhofer, and their co-workers have also reported the synthesis of A and B chains of insulin (14–16).

It can be readily seen that the combination of synthetic A chain with synthetic B chain to produce insulin is no mean task. The number of ways in which the two chains can combine *via* disulfide bonds is extremely high, so it is no surprise that the yields of synthetic insulin prepared in this manner have been extremely low. It has been reported (12) that Dr. G. H. Dixon, working in cooperation with Katsoyannis' group, was able to combine the synthetic A chain with the synthetic B chain to produce a product which showed insulin activity, but the details of the combination experiments have not yet been reported. Zahn and his associates (17) have combined synthetic A and B chains to produce a preparation containing 0.5% of the activity of crystalline insulin. Their calculations are based on a natural insulin preparation containing 26.7 I.U./mg.

A recent publication by a group of Chinese workers (18) describes the cleavage of insulin with sodium sulfite and sodium tetrathionate to produce the *S*-sulfonates of A and B chains. The chains were separated and then recombined by reduction and subsequent reoxidation. The insulin produced in these experiments showed an activity of 12 I.U./mg. when measured by the mouse convulsion test. This represents nearly 50% of the activity of natural insulin. Zahn and Brinkhoff have recently combined natural A chain with natural B chain to produce a product exhibiting 40% of the activity of natural insulin (19). These results make it seem quite likely that the yields for the combination of synthetic A and B chains can be improved significantly in the future.

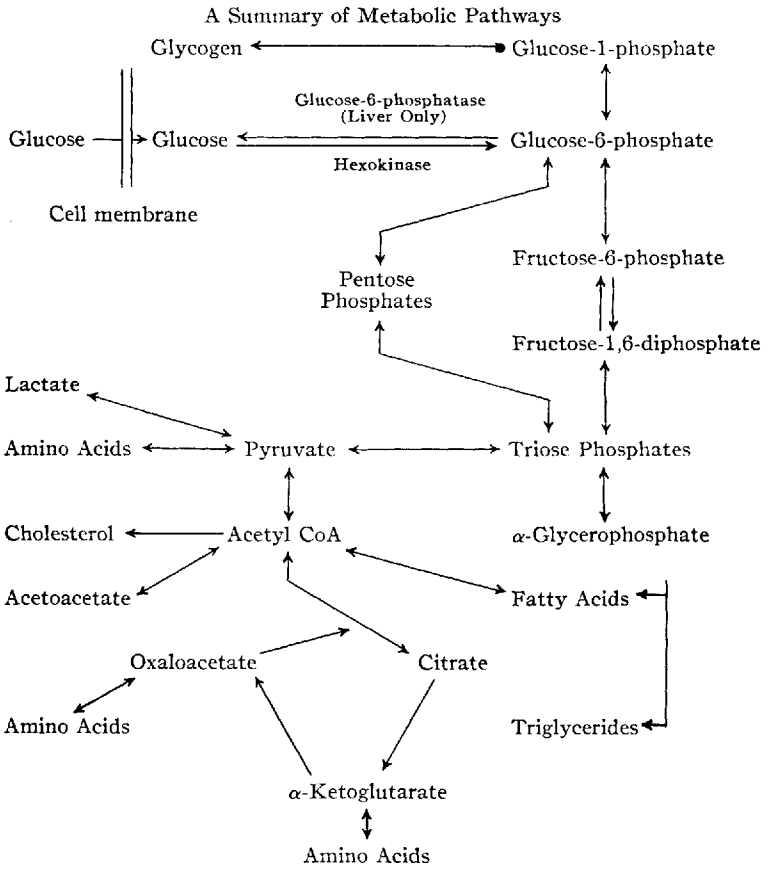
THE BIOLOGICAL EFFECTS OF INSULIN

It is well known that insulin exerts a profound effect not only on carbohydrate metabolism but also on the metabolism of fats and proteins. The biological effects of insulin have been extensively reviewed by numerous authors (20–25) and will not be treated in great detail here. The following discussion will simply summarize the effects of insulin on the metabolism of carbohydrates, fats, and proteins. Scheme I is included to allow the reader to follow the general metabolic pathways of these materials and to emphasize the interrelationship between the metabolism of all 3 classes of compounds.

Effects on Carbohydrate Metabolism

The important sites of carbohydrate metabolism which are sensitive to insulin are the liver, where glycogen is formed, stored, and broken down, the skeletal muscles, where glucose is oxidized to produce energy, and adipose tissue, where glucose may be converted to fatty acids, glycerol phosphate, and triglycerides. An appreciable quantity of glucose is also metabolized in the brain, but this tissue does not respond to insulin stimulation. The effects of insulin on carbohydrate metabolism are therefore different in the various tissues.

Effects in Skeletal Muscle.—Insulin is known to increase the uptake of glucose by skeletal muscle. Gemmil (26, 27) was the first to show that insulin stimulates glucose consumption in the isolated rat diaphragm. This system has been studied thoroughly by Vallance-Owen and has been developed as an assay for insulin in blood and other fluids (3). The increased glycogen synthesis promoted under these conditions is accounted for by Larner and Villar-Palasi (28, 29) by an insulin stimulation of uridine diphosphoglucose glycogen transglucosylase, an enzyme which catalyzes the rate-determining step in glycogen synthesis.



Scheme I

The glucose uptake of most peripheral tissues in humans has been shown to be stimulated by insulin. Evidence for this has been obtained by measuring the difference in glucose concentrations of venous and arterial blood in the limbs of humans (30).

The actual mechanism or mechanisms by which insulin promotes glucose utilization by skeletal muscle are not understood in biochemical terms. It does, however, seem reasonable to suppose that since insulin appears to promote all known pathways of glucose disposal and utilization (31), it probably exerts its primary action early in the metabolic sequence. This observation led to a number of investigations concerning the effect of insulin on the hexokinase reaction, a reaction which must occur before glucose can be metabolized by any route (32–35). Workers have been unable to show that insulin stimulates this reaction, nor have they been able to show consistently that it counteracts inhibitors of the reaction (36). It is, therefore, difficult to connect this reaction with the biochemical mechanism of action of insulin.

More recent studies have been concerned with the effect of insulin on the transfer of glucose and other sugars across cell membranes. Much of the research in this area has been carried out by Levine and his co-workers and has recently been summarized (31). These workers studied the effect of insulin on the transport of galactose, a sugar which is transported in the same manner as glucose but which is not metabolized in skeletal muscle. They observed that insulin definitely stimulates galactose transfer in most tissues. Narahara and Ozand (37) made similar observations in connection with their studies on the transport of 3-*O*-methyl-D-glucose, another non-utilizable sugar. Park and his associates have found that insulin also stimulates glucose transport in isolated muscle (38).

This evidence has led Levine (31) to propose that the primary effect of insulin on carbohydrate metabolism is at the level of the cell membrane. According to this theory, insulin increases the permeability of the cell membrane to glucose, thus allowing glucose to pass freely in either direction. Since the glucose inside of the cell is

rapidly phosphorylated, the process is essentially unidirectional. This idea appears to be in agreement with the available facts, but insulin might also have a specific action on other steps involved with the utilization of glucose.

Effects in Adipose Tissue.—In adipose tissue, carbohydrate metabolism is somewhat different than in muscle. In adipose tissue a large portion of the glucose-6-phosphate is oxidized through the pentose phosphate pathway and much is converted to glycerol phosphate, fatty acids, and triglycerides, whereas in the muscle the major synthetic product is glycogen.

Insulin has been shown to increase glucose oxidation by rat epididymal adipose tissue *in vitro* (39) and also increases the synthesis of fatty acids from glucose in this tissue (40, 41). The work of Winegrad and Renold (42), who worked with the oxidation of glucose-U-^{14}C, glucose-1-^{14}C, and glucose-6-^{14}C in isolated rat epididymal adipose tissue, indicates that in this tissue insulin stimulates catabolism by the pentose phosphate pathway to the same extent as by the Embden-Meyerhof pathway. This further suggests that the major effect of insulin is at a point early in the metabolic pathway. It is believed that the increased oxidation of glucose by adipose tissue in the presence of insulin is a result of an increased transport of the sugar across cell membranes (43).

Effects in the Liver.—Less is known about the effects of insulin on carbohydrate metabolism in the liver than about its effects in skeletal muscle and adipose tissue. It is exceedingly difficult to ascertain which of these effects are direct and which are secondary, thus making it difficult to present a detailed discussion of the exact effects of insulin on carbohydrate metabolism in the liver.

The liver is an important organ in the regulation of blood sugar levels. When blood glucose levels are high the liver takes up glucose and when they are below normal it produces glucose from glycogen. It has been shown (44) that the rate of removal or production of glucose by the liver is directly proportional to the degree of hyper- or hypoglycemia. Unlike skeletal muscle and adipose tissue, the cell membrane in the liver is freely permeable to glucose and other sugars (45) which indicates that transport is not rate limiting and does not account for the effect of insulin on net glucose uptake by the liver.

The fate of glucose in the liver must be considered in searching further for a possible effect of insulin on carbohydrate metabolism in the liver. Glucose is first phosphorylated by ATP to form glucose-6-phosphate; the enzyme catalyzing this reaction in the liver is quite specific and is referred to as "glucokinase." Once it is formed, glucose-6-phosphate may be reconverted to glucose under the influence of glucose-6-phosphatase, an enzyme present in appreciable quantities only in the liver, or it may be converted to glycogen and stored. The glucose-6-phosphate may also be oxidized in the liver, either by Embden-Meyerhof glycolysis or *via* the pentose phosphate pathway (45). The glucokinase reaction limits glucose utilization by the liver (46), and the glucose-6-phosphatase reaction regulates hepatic glucose output (47).

In severe diabetes hepatic glucokinase activity falls to one-fifth of normal, while glucose-6-phosphatase activity doubles (45). Both the decreased glucokinase activity (45) and the increased glucose-6-phosphatase activity of diabetics can be corrected by the administration of insulin over a period of time (45). The effect of insulin on carbohydrate metabolism in the liver then appears to be to decrease net hepatic glucose output.

Initially, it was found to be quite difficult to demonstrate an immediate decrease in hepatic glucose output after the administration of insulin to intact animals, and many workers were unable to produce a prompt effect (48–50). On the other hand, Madison and his associates (51) showed that insulin has a prompt effect on hepatic glucose output in unanesthetized dogs, providing the insulin is administered by slow intravenous infusion. More recently, other workers have shown that insulin promptly depresses net hepatic glucose output in intact animals quite rapidly (52–54). These workers have found that animals on a high carbohydrate diet respond better than those on a high protein diet, presumably because of the higher plasma insulin levels produced by the high carbohydrate diet. Their studies also indicate that significant hypoglycemia must be avoided in order to produce an insulin effect. This may be accomplished by the slow intravenous infusion of insulin and by administering small quantities of glucose to the animals.

Bishop and his co-workers have recently studied the effect of insulin on glucose output in intact dogs quite extensively (55) and have found that the first effect of insulin on the liver is to decrease glycogen breakdown, thereby decreasing the release of free glucose into the bloodstream. A later effect (after 2 hr.) is an increased glucose utilization for glycogen synthesis. The over-all result is then an immediate and sustained depression of net hepatic glucose output.

Effects on Fat Metabolism

The presence of ketone bodies in the blood and urine of uncontrolled diabetics indicates that

these individuals exhibit abnormal fat metabolism as well as abnormal carbohydrate metabolism. Stadie and his group (56) observed that liver slices from pancreatectomized cats produced 5 times more ketone bodies than liver slices from normal cats. This increased production of ketone bodies by diabetic animals results from an increased oxidation of fatty acids in these animals.

The work of Brady and Gurin (57) has shown that liver slices from alloxan-diabetic rats have a reduced ability to synthesize long chain fatty acids from acetate. It has also been demonstrated that insulin is able to stimulate the incorporation of acetate into longer chain fatty acids *in vitro* (58). Insulin has been shown to inhibit the release of free fatty acids (FFA) from glyceride stores in adipose tissue (59). Since insulin is able to stimulate fat synthesis and inhibit fatty acid mobilization in adipose tissue, it comes as no surprise that it is able to lower the elevated FFA levels observed in diabetic subjects (60).

The impaired carbohydrate metabolism of diabetics could be partially responsible for the decreased rate of fatty acid synthesis. This is indicated by the fact that fatty acid synthesis in liver slices is promoted by the presence of glucose in the medium. The problem is, however, probably much more complex than this and insulin undoubtedly has some more direct effect on fat synthesis. Chernick and Chaikoff (61) have demonstrated that the diabetic liver can oxidize lactate, pyruvate, and acetate but cannot incorporate these substrates into fatty acids. This malfunction in fatty acid synthesis can be corrected by treatment of the animal with insulin for several days (24), which is indicative of a direct effect on fatty acid synthesis.

Effects on Protein Metabolism

It is well established that diabetes results in a loss of body weight, a depletion of body protein, and a negative nitrogen balance (22). This nitrogen loss can be prevented by the administration of insulin (62), which suggests that insulin has some effect on the synthesis and/or degradation of proteins.

It is difficult to study the effects of insulin on protein metabolism in intact animals, although certain pertinent observations have been made in this manner. It has been demonstrated (63) that insulin lowers plasma amino acid levels, and it has also been shown (64) that it promotes the uptake of amino acids by skeletal muscle.

The best evidence that insulin affects protein metabolism comes from studies carried out in a number of *in vitro* systems. Numerous workers have used the isolated rat diaphragm to show that insulin stimulates the incorporation of labeled amino acids into protein (65–68). These studies show that insulin concentrations as low as 50 microunits/ml. will stimulate the incorporation of amino acids into proteins in this system. Since it is effective at this low concentration, the response is probably a physiological one.

It was first thought that the effect of insulin on protein synthesis was secondary to its effect on carbohydrate metabolism. It was felt that insulin stimulated glucose metabolism which in turn provided energy that could then be utilized for protein synthesis. More recent research, however, has made it appear highly unlikely that this is the case. Experiments carried out by Wool and Krahl (69) show that the effect of insulin on protein synthesis in the rat diaphragm *in vitro* is independent of the concentration of glucose in the medium for glucose concentrations between zero and 600 mg. %. In the same study it was shown that insulin stimulates the incorporation of labeled amino acids into proteins in diaphragms isolated from fed rats even when there is no extracellular glucose present in the diaphragm. This evidence strongly suggests a more direct effect of insulin on protein synthesis in this system.

It was found (70) that insulin stimulates the uptake of α-aminoisobutyric acid, a nonutilizable amino acid, by the isolated rat diaphragm. This led to the speculation that the effect of insulin on protein synthesis could be a result of its facilitating the transport of amino acids into cells. Further studies by Wool and Krahl (71) have essentially ruled out the possibility that this is the sole effect of insulin on protein synthesis. In these studies, the labeled amino acid was injected into intact rats, thus allowing the amino acid to accumulate in the diaphragm of the intact animals. The animals were then sacrificed, the diaphragms removed and incubated with or without insulin, and the rate of protein synthesis determined. The results showed that insulin stimulates the synthesis of proteins from labeled amino acids even when the amino acids are already present in the diaphragm, thus indicating a direct effect of insulin on protein synthesis.

The results of subsequent studies have led Wool to propose that the effect of insulin on protein synthesis is mediated by its effect on messenger RNA synthesis (72). He believes that the effect results from insulin stimulating the transfer of messenger RNA from the nucleus to the cytoplasm, a proposal which seems to agree with the existing facts.

POSSIBLE CAUSES OF DIABETES

The actual etiology of diabetes is not yet understood, although there are a number of factors which could account for the abnormal glucose tolerance exhibited by diabetics. The 3 most obvious possibilities are (*a*) a decreased production of insulin, (*b*) an increased rate of destruction of the hormone, and (*c*) an inability of tissue to respond to stimulation by insulin.

Juvenile diabetes is quite likely the result of the first. The pancreas loses the ability to produce and secrete insulin and the plasma insulin levels become very low, possibly even reaching zero (73).

As early as the 1940's, Mirsky (74) proposed that diabetes could be due to an increased destruction of insulin by an enzyme which he then referred to as "insulinase." Since that time numerous studies have been carried out to determine the nature of the enzyme responsible for the degradation of insulin. This led to the isolation of a purified preparation from acetone powders of livers which is capable of reducing insulin to its A and B chains (75–78). The reaction utilizes hydrogen from reduced glutathione, and the enzyme is therefore referred to as glutathione insulin transhydrogenase. There is no direct evidence for any increased activity of this enzyme nor any increased destruction of insulin in diabetic subjects, so its connection with the etiology of diabetes has not been established.

Neither of the first 2 factors seems to explain the impairment of glucose tolerance in cases of maturity-onset diabetes since individuals of this type may be characterized by normal or above normal insulin levels (79, 80). According to Lacy (81), the ultrastructure of the β granules in maturity-onset diabetics is similar to that of the normal human β cell. This suggests that the pancreas has not lost its ability to produce insulin, and another possible cause for the disease must be sought.

Maturity-onset diabetes could result from an inability of the peripheral tissue to respond to insulin. This decreased tissue response could very well be the result of the presence of substances which antagonize insulin. Numerous insulin antagonists have been described in some detail, and many of these are themselves hormones. It has been demonstrated (82) that growth hormone and the adrenal corticosteroids can inhibit the effect of insulin on glucose transport. Epinephrine, another insulin antagonist, increases blood sugar levels by increasing hepatic glucose output (83), and a similar effect on the liver is also produced by glucagon (83).

Insulin is a protein of sufficient molecular weight to produce antibodies (84) which are capable of neutralizing its action. This phenomenon may also be referred to as "insulin antagonism."

Bornstein and Hyde (85) have described a pituitary peptide with a molecular weight of about 4,500 which is able to inhibit the uptake of glucose by the isolated rat diaphragm. This substance is also capable of inhibiting the incorporation of acetate into fats by liver slices and the incorporation of amino acids into proteins in rat muscle (86). Its actual physiological significance has not been determined.

The studies of Samaan (87) with "typical" and "atypical" insulin and of Antoniades (88) with "bound" and "free" insulin indicate that binding of insulin to plasma proteins antagonizes its action in certain *in vitro* systems. Antoniades (88) has reported that bound insulin is biologically active in rat epididymal adipose tissue *in vitro* but is inactive in the isolated rat diaphragm, while free insulin is active in both systems. Recent studies (89) indicate that bound insulin increases the incorporation of labeled glucose into glycogen in muscle and adipose tissue and into fat in adipose tissue in intact rats. This suggests that the binding of insulin to plasma proteins does not antagonize its biological activity *in vivo*.

The insulin antagonists which are currently receiving the most attention are the synalbumin antagonist and plasma FFA, either or both of which could contribute significantly to the cause of diabetes.

The Synalbumin Insulin Antagonist.—It has been mentioned previously that insulin promotes the uptake of glucose by the rat diaphragm *in vitro*. This system has been used as a biological assay for insulin and under the proper conditions is an accurate method of determining the amount of insulin present in a given sample (3). The assay has also been used by Vallance-Owen (90) for the detection of insulin antagonism in the plasma of normal and diabetic subjects. His work on insulin antagonism has recently been summarized (91).

Vallance-Owen and Hurlock (92) found that the assay can be carried out using plasma from humans as the incubation medium. If insulin is added *in vitro* to the plasma of normal, fed subjects or obese, nonketotic diabetics, the insulin activity can be recovered almost quantitatively. In contrast to this, it was found that when plasma from uncontrolled or insulin-requiring diabetics is used as the incubation medium, the action of insulin is definitely antagonized.

It was subsequently shown by Vallance-Owen and his co-workers (93, 94) that the antagonist actually resides in the albumin fraction. The

albumin used in these studies was prepared by T.C.A.–ethanol fractionation, a procedure which has been shown by Schwert (95) to produce electrophoretically pure albumin.

Similar antagonism can be demonstrated in plasma-albumin from normal subjects, although this albumin is not nearly so active as that obtained from the plasma of diabetics. Vallance-Owen, Dennes, and Campbell (94) found that concentrations of 3.5–5% of diabetic plasma-albumin will completely antagonize the effect of 1,000 microunits of insulin in the rat hemidiaphragm assay and will also antagonize insulin *in vitro* at concentrations as low as 1.25%. Plasma-albumin from normal subjects will completely antagonize 1,000 microunits of insulin when used at concentrations of 3.5–5%, will show some antagonism at 2.5%, but exhibits no insulin antagonism at a concentration of 1.25%. These observations have recently been confirmed by Alp and Recant (96), who performed similar studies using a wide variety of albumin preparations. These workers studied albumin preparations isolated by the Cohn procedure (97) as well as a series of preparations isolated by the Debro procedure (98). Insulin antagonism was observed in all of these preparations, although the effect was not so great as that demonstrated by Vallance-Owen and his group. All of this evidence suggests that excessive insulin antagonism could have some connection with the etiology of diabetes.

Subsequent work by Vallance-Owen and his group (99) indicates that the antagonist is dependent on the presence of a functioning pituitary gland. This research involved a study of the plasma-albumin from 3 hypophysectomized patients, and the albumin obtained from these patients was found to be nonantagonistic in concentrations as high as 4%. One of the patients had been studied prior to hypophysectomy and his albumin had been shown to be antagonistic at that time.

It has also been shown (100) that the antagonist is dependent on the adrenal steroids. In 2 patients with a bilateral adrenalectomy and with cortisone therapy discontinued for at least 50 hr. prior to testing, the plasma-albumin was found not to antagonize insulin *in vitro*. After 1 of these patients subsequently was sustained on cortisone therapy, his plasma-albumin was retested and was found to be antagonistic.

It has been demonstrated (99) that when antagonistic albumin is passed through a partially acetylated cellulose column, it is nonantagonistic when eluted. This was the first indication that it is not the albumin itself but rather something associated with the albumin which is responsible for the insulin antagonism. Because of this, the term *synalbumin* antagonist was coined.

The synalbumin antagonist can be dialyzed away from the albumin after heat coagulation (100), but this, however, results in some loss in activity of the antagonist. The antagonist cannot be extracted from albumin with ethanol, chloroform, or a mixture of *n*-octane and acetic acid, which indicates that the antagonist is not a lipid, fatty acid, or steroid. This suggests that it is not a simple case of albumin-bound fatty acids inhibiting the action of insulin as shown in the studies of Randle, Garland, Hales, and Newsholme (101). The evidence shows that the antagonist could be a relatively low molecular weight polypeptide which led to the postulation (91) that the synalbumin antagonist might be the B chain of insulin.

Ensinck and Vallance-Owen (102) have shown that when ^{131}I-labeled insulin is administered to humans, the molecule is cleaved enzymatically and some of the reduced ^{131}I B chain becomes bound to the plasma-albumin. The A chain, on the other hand, appears to associate with the α_2 globulin fraction. These workers (102) have pointed out several similarities between B chain and the synalbumin antagonist; for example, both have a molecular weight of less than 4,000, both are capable of binding to albumin, and both dissociate from the albumin at extremes in pH.

Ensinck, Mahler, and Vallance-Owen (103) have recently presented further evidence to support the theory that the synalbumin antagonist could be B chain. They performed a series of experiments using reduced B chain, *S*-sulpho-B chain, and oxidized B chain. Their work showed that *S*-sulpho-B chain and reduced B chain antagonize the action of insulin in the hemidiaphragm assay, while oxidized B chain does not. They found that their *S*-sulpho-B chain preparation contained 0.5–0.9 sulfhydryl groups per mole of the chain. This, they feel, is responsible for the antagonistic activity of the *S*-sulpho-B chain and for the lack of antagonism shown by the oxidized B chain which contains no free sulfhydryl groups. It is indicated that the free sulfhydryl groups are essential for antagonistic activity since the reduced B chain preparations were rendered nonantagonistic by prior incubation with alkylating agents such as iodoacetamide or *N*-ethylmaleimide. The antagonistic activity of the reduced and *S*-sulpho-B chains is enhanced greatly by prior incubation with albumin which is probably because B chain itself is not very soluble unless complexed with albumin. These in-

vestigators (103) further demonstrated that B chain could be dissociated from albumin by passing the complex through an acetylated cellulose column or a Dowex 50 column in the sodium phase. The synalbumin antagonist had previously been shown to behave in a similar fashion.

It is proposed (103) that the B chain could result from the cleavage of insulin by glutathione-insulin transhydrogenase as shown by Tomizawa (104) and by Katzen and Stetten (78). It could antagonize the action of insulin by competing for the insulin binding sites at the cell membrane. It should be emphasized that insulin B chain has never been isolated from human serum or any of its components. If this could be accomplished, it would certainly add credence to the hypothesis that the synalbumin antagonist could be B chain.

Vallance-Owen (105) has shown that the plasma-albumin from prediabetics is antagonistic *in vitro* at a concentration of 1.25%. The term "prediabetes" may be defined as the metabolic state of a person at a period before he or she exhibits definite symptoms of diabetes. The presence of excessive synalbumin antagonism could therefore develop into a method of identifying prediabetics before they become overtly diabetic.

It is generally agreed that diabetes mellitus is hereditary in some way, although the mode of inheritance seems to be open to debate. Vallance-Owen (105) has studied a number of families with regard to the inheritance of excessive synalbumin antagonism, which he feels may indicate "essential diabetes." His evidence indicates that the transmission of excessive synalbumin antagonism could be by a dominant mode of inheritance, although the evidence is far from conclusive.

Lowry, Blanchard, and Phear (106) have performed experiments to show that the synalbumin antagonist does not inhibit the effect of insulin on adipose tissue. This could point to a fallacy in the whole line of reasoning or it could simply mean that synalbumin is capable of antagonizing some, but not all, of the actions of insulin. Also, no one has yet been able to demonstrate antagonistic activity for synalbumin or for B chain *in vivo*. A number of technical problems must be overcome before this can be accomplished; *i.e.*, B chain, if it is the antagonist, is quite insoluble and probably could not be administered alone, which would necessitate complexing it with a rather large quantity of albumin before infusing it into animals.

There are a number of questions yet to be answered about the synalbumin antagonist. For example, if it actually is B chain, does it arise from the incomplete synthesis of insulin or from increased destruction of insulin by glutathione insulin transhydrogenase? Also, what factors regulate the level of antagonist present in the plasma of normal and diabetic subjects? Nevertheless, these proposals merit serious thought and could provide answers to several important questions. It would certainly be advantageous to have a biochemical marker for the identification of prediabetics. This could also conceivably lead to fundamental knowledge about the etiology of diabetes mellitus and to possible ways of treating the disease.

The Glucose Fatty Acid Cycle.—It has been mentioned previously that the diabetic exhibits abnormal lipid metabolism as well as abnormal carbohydrate metabolism. Until quite recently, it had been generally agreed that the disturbance in lipid metabolism was secondary to the abnormalities in carbohydrate metabolism. Recent studies (107) suggest that the over-all disturbance in metabolism could result from high levels of FFA which result from an increased metabolism of fats by the diabetic. The implication is that the relationship between carbohydrate and lipid metabolism is reciprocal, and good evidence has been put forth to help verify this (107).

Randle and his associates (107) propose that the metabolism of glucose by the tissues inhibits the release of FFA from glyceride stores and that conversely the release of FFA inhibits the metabolism of glucose. According to this line of thought, the diabetic is unable to carry on normal carbohydrate metabolism because of elevated FFA levels.

Newsholme and Randle (108) demonstrated that anoxia, salicylate, and 2,4-dinitrophenol increase the rate of phosphorylation of fructose-6-phosphate to form fructose-1,6-diphosphate, a reaction which is catalyzed by phosphofructokinase. The reaction is inhibited in hearts from diabetic or starved rats or in hearts from normal rats which are perfused with media containing fatty acids or ketone bodies.

The stimulation of the phosphofructokinase reaction caused by anoxia is attributed (108) to increased concentrations of AMP and inorganic phosphate, which stimulate the reaction, and decreased concentrations of ATP, which inhibits the reaction. Alloxan-diabetes, starvation, fatty acids, and ketone bodies have no consistent effect on cencentrations of AMP, ATP, and inorganic phosphate and must, therefore, inhibit the reaction by a different mechanism. It is proposed (108) that the inhibition is caused by the increased concentration of citrate which these factors have been shown (109) to produce.

Randle's work (110) shows that the membrane transport of D-arabinose and D-glucose is greater in fed rats than in starved rats, a phenomenon which might be due to the presence of higher insulin concentrations in the fed animals. Fatty acids and ketone bodies will inhibit transport in fed rats but not in starved rats (110). Inhibition of transport by fatty acids and ketone bodies was demonstrated in starved rats when low concentrations (0.5 milliunit/ml.) of insulin but not when high concentrations (0.1 unit/ml.) of insulin were added. These workers feel that the above facts are explained by the hypothesis that fatty acids and ketone bodies impair the sensitivity of the transport system to stimulation by insulin.

Randle and his co-workers (110) also found that the phosphorylation of glucose by the perfused rat heart is inhibited by fatty acids and ketone bodies. A similar inhibition of phosphorylation of glucose was demonstrated in hearts from diabetic or starved rats.

It was found (110) that the rate of glycolysis was decreased in isolated rat hemidiaphragms and perfused rat hearts by fatty acids, ketone bodies, or pyruvate. These workers feel that the decreased rate of glycolysis is a result of a decreased uptake of glucose. The fact that more $^{14}CO_2$ is produced from 1-^{14}C-glucose than from 6-^{14}C-glucose under these conditions is an indication that some glucose is being oxidized through the pentose phosphate pathway.

Garland and Randle (109) showed that fatty acids, ketone bodies, and alloxan-diabetes inhibit the oxidation of pyruvate in the perfused rat heart and isolated hemidiaphragm. It is proposed (109) that this inhibition of pyruvate oxidation is the result of an increased acetyl CoA/CoA ratio which is produced by these conditions.

Garland and Randle (111) have reported that the concentration of fatty acyl CoA was increased in the rat heart *in vitro* by alloxan-diabetes, starvation, and perfusion with fatty acids. This is presumably caused by the increase in concentration of FFA which is due to an increased lipolysis and a decreased rate of fat synthesis. It was further shown (111) that the increased production of fatty acids and fatty acyl CoA could result in an increase in the concentration of citrate which then can inhibit the phosphofructokinase reaction. The concentration of citrate in diabetic rat hearts is lowered by insulin which might account for some of the increased carbohydrate metabolism brought about by insulin.

Garland *et al.* (112) illustrated that the oxidation of glucose in perfused rat hearts is inhibited when the perfusion media contains fatty acids or ketone bodies. They also found, however, that there is no decrease in oxygen consumption under these conditions. This was taken to mean that in the presence of fatty acids and ketone bodies, there is an increased oxidation of fatty acids to compensate for the decrease in glucose oxidation. This is further evidence for the reciprocal relationship between carbohydrate and fat metabolism.

From this evidence it is postulated (111) that the increased release of fatty acids from glyceride stores in diabetic rats results in increased levels of FFA, fatty acyl CoA, and ketone bodies. This in some way causes an increase in citrate concentration, and the over-all result is an inhibition of glucose transport, glucose phosphorylation, the phosphofructokinase reaction, and the oxidation of pyruvate.

INSULIN THERAPY

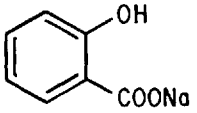
Insulin has been the mainstay of diabetes therapy ever since its discovery by Banting and Best. There are at least 7 different insulin preparations currently available in this country, the principal difference between these being in their duration of action. Crystalline insulin is effective but has an extremely short duration of action (6–12 hr.) (113). Longer acting preparations have been obtained by combining insulin with higher molecular weight proteins such as protamines and globins. Further work in this area resulted in the discovery of the lente insulins (114) in which duration of action can be controlled by a selective precipitation scheme. All of these preparations are insulin and exhibit the biological effects of insulin; they differ only in duration of action.

Although insulin offers many advantages in the treatment of diabetes, it also has a number of disavantages. It is a protein and is capable of producing allergic reactions. This can be further complicated when insulin is combined with a higher molecular weight, more highly antigenic protein, to increase its duration of action. Insulin is not effective orally and must therefore be administered parenterally which is an inconvenience at best. Insulin is a potent hormone and can produce dangerous hypoglycemia when doses are not regulated to correspond with conditions of diet and exercise. Good control of diabetes with insulin does not always prevent the occurrence of complications of diabetes such as diabetic neuropathy, glomerulosclerosis, diabetic retinopathy, and vascular disorders (115). Also, some patients are resistant to insulin (116) and require well over 200 units of insulin a day. This indicates a significant degree of resistance since it has been estimated (117) that a normal daily secretion of

insulin is about 55 units. Because of these numerous disadvantages, a great deal of research has been carried out to produce an insulin substitute which does not have these drawbacks.

ORAL HYPOGLYCEMICS

The Salicylates.—Long before the discovery of insulin it was known that sodium salicylate (I) is capable of lowering blood sugar in diabetics. Ebstein in 1876 (118) and Muller in 1877 (119)

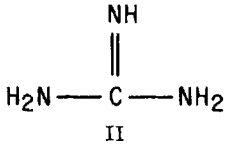


I

published reports on the ability of sodium salicylate to lower blood sugar. Not all salicylates exert this property. Acetylsalicylic acid, for example, has hypoglycemic acitivity when given in suitably high doses, while sodium gentisate which is chemically similar has no hypoglycemic acitivity.

The hypoglycemic salicylates cause an increased oxygen consumption in experimental animals (120) by the uncoupling of oxidative phosphorylation as shown by Brody (121). This uncoupling action increases aerobic glycolysis and increases glucose utilization, but the energy derived from the process is relatively little. The dosage of salicylates necessary to bring about a hypoglycemic effect is very high. It has been reported (122) that a daily dose of 4.8 Gm. is required to produce an adequate hypoglycemic effect. At this dosage level numerous side effects such as nausea, vomiting, hearing difficulties, and tinnitus appear quite frequently and thus the salicylates are not used clinically as hypoglycemic agents.

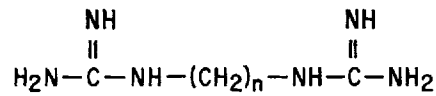
Guanidine.—The first reports on the ability of guanidine (II) to lower blood sugar were in 1918



II

(123). Hollunger (124) has shown that it inhibits respiration which leads to an increased glucose uptake by muscle, an increased glycolysis, and a decrease in blood glucose levels. Because of the relatively high toxicity of guanidine it was never widely used, although it did serve as a pattern for newer compounds which have been used as oral hypoglycemics.

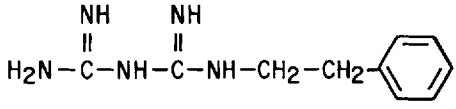
The Diguanidines.—These compounds (III), may be visualized as 2 guanidine molecules joined by a series of methylene groups. For the



III

most part, these compounds are more potent and less toxic than guanidine. Hypoglycemic activity increases with an increase in the number of methylene groups and apparently reaches a maximum in the decamethylene derivative which is 150 times more active than guanidine (125). This substance, known as synthalin A, was introduced into diabetes therapy in the 1920's The dodecamethylene diguanidine (synthalin B) is somewhat less active than synthalin A. Neither of these compounds compares favorably with insulin for effectiveness, and both also have a rather high tendency to cause kidney and liver damage (126), so their use as hypoglycemics was discontinued.

The Biguanides.—Further attempts to produce useful compounds resulted in 1929 in a series of biguanides which exhibited hypoglycemic activity (127). This discovery received little attention at the time, and little work was done in the area until 1957 when Unger and his associates (128) reported on the hypoglycemic activity of phenformin (IV) a newly synthesized biguanide.



IV

As a result of these studies, hundreds of new biguanides were prepared and tested for hypoglycemic activity, but none has been found to be superior to phenformin.

A great deal of information on the effects of phenformin and other biguanides on various biological systems is available, but the exact mechanism by which these compounds lower blood sugar is not understood. Phenformin was shown to increase the glucose uptake of the isolated rat diaphragm (129), but this effect was produced by a higher dose of the drug than is normally found in a physiological system. It has been found that glucose uptake by the diaphragm is accompanied by a decreased oxygen consumption and a decreased glycogen content of the diaphragm (130) which is opposite from the effect of insulin in this system. The increased glucose uptake of the diaphragm in the presence of phenformin appears to be a result of increased anaerobic glycolysis in the muscle (130). This is consistent with the findings of Steiner and Williams (131), who demonstrated that phen-

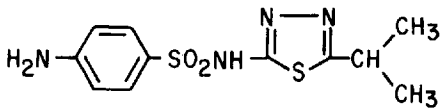
formin produces elevated levels of lactic acid, the end product of anaerobic glycolysis in muscle.

It has been shown (132) that phenformin increases the uptake of glucose by the rat epididymal fat pad *in vitro*. Daweke and Bach (133) used Buformin (N^1-*n*-butylbiguanide) to show an increased oxidation of glucose-1-^{14}C by rat adipose tissue at relatively low concentrations, but on the other hand, Wick and his co-workers (134) found that higher doses of phenformin inhibit glucose oxidation by adipose tissue.

Steiner and Williams (135) have proposed that the biguanides might act by inhibiting certain enzyme systems of the mitochondria which are concerned with Krebs cycle oxidations. This would lead to an indirect stimulation of the anaerobic glycolysis of glucose and in turn would cause an increased uptake of glucose. This theory accounts for the increased lactic acid production associated with biguanide treatment and is also consistent with the observations of Randle and Smith (136), who demonstrated that anaerobiosis can increase the glucose uptake of the isolated rat diaphragm.

The biguanides serve a useful function in diabetes therapy in that they are useful in treating certain cases which are unresponsive to other oralhypoglycemics. They affect carbohydrate metabolism directly but are not used in the absence of some supply of insulin since acidosis develops in such cases. Side effects such as anorexia, nausea, vomiting, weight loss, and muscular weakness occur quite frequently in phenformin treated subjects (137), although this compound does not exhibit the liver toxicity of the parent synthalins (138).

The Sulfonamides.—Savagone (139) was the first to publish information indicating that certain sulfonamides lower blood sugar in man. This led to the investigation of a number of sulfonamides as potential oral hypoglycemic agents. The work of Loubatieres (140) showed that one of the sulfonamides, 2-(*p*-aminobenzenesulfonamide)-5-isopropylthiodiazole (IPTD) (V), lowers



V

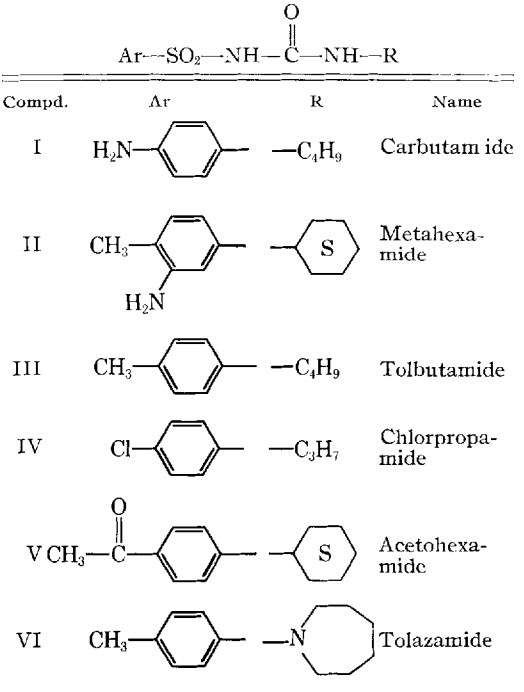
blood sugar levels, apparently by stimulating the β cells to secrete insulin.

Relatively little research was done on the sulfonamides as hypoglycemics until the advent of the sulfonylureas in the 1950's. At that time IPTD was studied clinically in human diabetics (141) and was found to lower blood sugar in some patients. It was found effective in the same general type of cases as the sulfonylureas; but since it is somewhat less potent than most sulfonylureas and has no obvious advantages over the sulfonylureas it never has been marketed.

The Sulfonylureas.—From a practical standpoint the sulfonylureas are currently the most important oral hypoglycemics. Their ability to lower blood sugar was first discovered by a group of German workers in 1951. Carbutamide (BZ 55) was the first of the sulfonylureas to be studied extensively from a clinical standpoint (142–144). The discovery that this compound is capable of controlling the effects of diabetes in some patients led to the synthesis and testing of literally hundreds of analogs and derivatives of carbutamide. It is beyond the scope of this review to consider the chemistry and pharmacology of large numbers of individual sulfonylureas, particularly since there are already numerous excellent reviews on the subject (145–148). This discussion will be concerned primarily with the pharmacological action of the sulfonylureas as a group.

Some of the more familiar sulfonylurea hypoglycemics are listed in Table I. Carbutamide, the first of the series to be studied thoroughly, was found to be an effective hypoglycemic but also exhibits liver toxicity which in some cases proved to be fatal (149). Because of this, the compound was never marketed in the U. S., although it is still in use in some European countries. Metahexamide, a somewhat newer compound, is an

TABLE I. – SULFONYLUREA HYPOGLYCEMICS



effective hypoglycemic (150) but also exhibits liver toxicity and has produced cases of obstructive jaundice (151) so is no longer being used clinically. Tolbutamide, chlorpropamide, and acetohexamide are all effective oral hypoglycemics which are currently in use in this country. Tolazamide, which was first synthesized in 1962 (152), is one of the newer sulfonylureas. It has been tested in animals and humans and shows promise of being a useful oral hypoglycemic (153).

All of the sulfonylurea hypoglycemics appear to act by the same mechanism, produce the same effects, and are effective in the same general types of cases. They differ mainly in potency, duration of action, and the frequency with which side effects occur. Of the many hundreds of sulfonylureas which have been synthesized, only a relatively few have a substantial amount of hypoglycemic activity and many of those are too toxic for clinical use.

The relationship between chemical structure and pharmacological activity for this class of compounds has been summarized by Mahler (147). The benzene ring should contain at least one substituent; best results are obtained when it is in the 4-position. Active compounds have been prepared where this substituent is methyl, amino, acetyl, chlorine, methylthio as well as several other groups or atoms. If a carboxyl, hydroxyl, nitro, or hydroxymethyl group is placed in the 4-position the resulting compound is inactive.

The group attached to the terminal nitrogen of the urea nucleus should be a certain size and should impart lipophilic properties to the molecule. Simple aliphatic groups are quite frequently placed in this position. The methyl derivatives are usually inactive, the ethyl derivatives exhibit some activity, and maximum activity is reached when the substituent contains 3–6 carbons. Activity is lost altogether if the substituent contains as many as 12 carbons. A number of active compounds have been prepared where this substituent is an alicyclic ring (154) with optimal activity usually being attained when this is a 5, 6, or 7 membered ring.

Most of the sulfonylureas are poorly soluble in water at a neutral pH but because of their weakly acidic character are more soluble at a slightly alkaline pH. This facilitates dissolution in the intestinal juices and absorption from the intestine. The absorption of tolbutamide from this site is nearly complete in most species (155). Most of the sulfonylureas are absorbed quite rapidly; Ridolfo and Kirtley (156) showed that carbutamide can be detected in the blood within 30 min. after oral administration.

The mode of metabolism of the sulfonylureas is quite variable and is dependent on the structure of the compound as well as the species of the animal. The mode and rate of metabolism of these drugs is important since many are converted to inactive metabolites, thus governing their potency and duration of action.

Carbutamide, which is structurally similar to the sulfa drugs, is metabolized by acetylation of the 4-nitrogen to produce an inactive metabolite (157). The 4-methyl group of tolbutamide is oxidized in the body to a carboxyl group (158) and the metabolite is without hypoglycemic activity. Chlorpropamide, which has a chlorine in the 4-position, is not metabolized in humans (159) and is excreted in the urine as the free drug. Acetohexamide is metabolized by the reduction of the ketone to a secondary alcohol (160) but the metabolite has hypoglycemic activity (161).

The biological half-life of these drugs is one of the best measures of their duration of action. The term "biological half-life" has been defined as (161) "the time required for the blood levels of the drug to decrease by 50 per cent during the postabsorptive, concentration-dependent disappearance phase." The biological half-life of a drug such as chlorpropamide, which is not metabolized, is dependent only on its rate of excretion. Johnson and his associates (159) determined the biological half-life of this drug to be 35 hr. The biological half-life of a drug which is metabolized in the body is dependent on the rate of metabolism as well as the rate of excretion of the unchanged drug. Baird and Duncan (162) estimated the biological half-life of carbutamide to be between 30 and 60 hr. The half-life of tolbutamide has been reported by a number of authors (163–165), and the average value is in the neighborhood of 5 hr. Recent studies by Smith, Vecchio, and Forist (161) indicate that the half-life of acetohexamide is 1.3 hr., indicating that the drug is metabolized very rapidly. Since the metabolite of this drug is an active hypoglycemic, the half-life of the metabolite should also be taken into consideration in estimating the duration of action of acetohexamide. The half-life for the metabolite is 4.6 hr. (161), which indicates that acetohexamide has a duration of action comparable to that of tolbutamide.

It should be emphasized that, although the duration of action of these compounds is proportional to their biological half-life, the 2 values are not equal to each other. Tolbutamide, for example, has a biological half-life of about 5 hr., but effective blood levels of the active drug are maintained for 12 to 18 hr. after oral administration (161).

Since all of these compounds are metabolized by different routes and at different rates it would be expected that the blood levels of drug would vary from compound to compound. This would quite logically have an effect on the relative hypoglycemic potencies of the compounds. McMahon and his co-workers (148) have determined the relative clinical potencies of a number of the common sulfonylurea hypoglycemics. The clinical potency was arrived at from considering the acute potency as well as the biological half-life of the various compounds. The clinical potencies of some of the more common sulfonylureas are: tolbutamide, 1; carbutamide, 1–3; chlorpropamide, 4–7; metahexamide, 10; acetohexamide, 1–4; and tolazamide, 5–15.

Numerous investigations have been carried out in recent years to determine the exact mechanism of action of the sulfonylurea hypoglycemics. A great deal of information has been accumulated and a number of facts have been well established. Some of the more pertinent observations are mentioned here.

Mirsky and Gitelson (166) have reported results which indicate that these compounds might decrease the activity of the insulin degrading enzyme in the rat liver. The decreased enzymatic activity which was observed was, however, very slight and it required an extremely high concentration of the sulfonylurea to bring it about. On the other hand, it has been found (167) that tolbutamide does not prolong the half-life of injected ^{131}I insulin. Because of this, it is rather doubtful that this effect is very important to the action of these compounds as hypoglycemics.

Some workers (168) have shown that sulfonylureas produce a slight increase in the glucose uptake of the rat diaphragm *in vitro*. This effect was not accompanied by an increased glycogen synthesis by the diaphragm as is the case when glucose uptake is stimulated by insulin. Most workers, however, have been unable to show an increased glucose uptake by the rat diaphragm in the presence of sulfonylurea hypoglycemics (169–171) which is in accord with the theory that sulfonylureas have no direct effect on carbohydrate metabolism.

The effect of sulfonylureas on the oxidation of labeled glucose by the rat epididymal fat pad *in vitro* appears to be somewhat confusing. Renold and his associates have reported that tolbutamide and chlorpropamide have a slight stimulatory effect on the oxidation of glucose by this tissue (172). Marques and Correa (173), on the other hand, found that acetohexamide, carbutamide, and tolbutamide did not increase glucose oxidation by isolated rat epididymal adipose tissue. They found that high concentrations (50 mcg./ml.) of chlorpropamide or tolazamide increased glucose oxidation slightly, but the effect was not nearly so great as that produced by insulin at a concentration of 20 microunits/ml. It is interesting to note that even in Renold's studies there was found to be no stimulation of fatty acid synthesis as is the case when insulin is added to the medium. It should also be pointed out that a number of substances other than hypoglycemics are able to stimulate the oxidation of glucose by adipose tissue *in vitro*. Some of these agents are epinephrine (174), ACTH (175), glucagon (176), serotonin (177), growth hormone (178), and prolactin (179). These observations suggest that even if the sulfonylureas do stimulate glucose oxidation in adipose tissue the effect is not necessarily important to their action as hypoglycemics.

It has been shown (180) that sulfonylureas are able to decrease the glucose output of the liver. This might contribute to their action as hypoglycemics, but it is unlikely to be their major action since Dulin and Johnston (181) have shown that sulfonylureas act as hypoglycemics in hepatectomized animals. It has been shown (182) that sulfonylureas are capable of inhibiting glucose-6-phosphatase activity in liver slices, but the concentration of drug required to bring about this response is well above the concentration normally present in blood. This makes it seem highly improbable that inhibition of glucose-6-phosphatase activity is important to the action of these compounds. It is also interesting that a similar concentration of sulfanilamide can inhibit glucose-6-phosphatase activity (182), but this compound does not lower blood sugar in intact animals.

It is generally agreed that the sulfonylureas are incapable of lowering blood sugar in totally pancreatectomized animals (183, 184, 157). They also have no hypoglycemic effect in alloxan-diabetic animals providing there is complete β cell destruction (181). This indicates that a functioning pancreas is essential to the action of these compounds.

It has been observed that pretreatment of animals with growth hormone or prolonged fasting of the animals decreases the response of these animals to sulfonylureas (185). Both of these conditions are known to decrease the insulin content of the pancreas. This further suggests that the action of the sulfonylureas is dependent on the presence of some insulin.

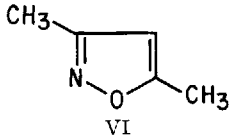
The storage and secretion of insulin by the pancreas has recently been reviewed by Lacy (81), who points out that insulin is stored in the β cells

in the form of β granules which are visible with the electron microscope. The process by which insulin is secreted is referred to as emiocytosis and involves the migration of the β granules to the cell membrane where they are liberated into the intercellular spaces. Williamson, Lacy, and Grisham (186) have demonstrated that tolbutamide stimulates emiocytosis in the β cells of the rat. Other workers (187) have shown a similar effect in the guinea pig. Vallance-Owen and his associates (188) have shown that a single oral dose of tolbutamide will increase plasma insulin-like activity by a factor of 2 within 2.5 hr. Yalow and Berson (189) made similar observations by using an immunoassay to measure plasma insulin levels.

The above observations indicate that the sulfonylureas have no direct effect on the metabolism of carbohydrates. The current feeling is that the primary action of the sulfonylureas is a stimulation of the pancreas to secrete insulin, but it should be emphasized that the mechanism by which they promote this release of insulin is not understood. This theory points out why it is essential to have a functioning pancreas for these compounds to be effective and illustrates why they cannot be used successfully to treat juvenile diabetics.

The sulfonylureas are an important class of therapeutic agents and can be used effectively in a great number of cases, but proper patient selection is an important factor in effective sulfonylurea therapy. In a recent report involving 9,214 diabetics studied over a 6-year period (190) it was concluded that the subject most likely to be controlled on these compounds is one who contracted diabetes after age 40, is overweight, has a daily insulin requirement of less than 30 units, and has had the disease for less than 5 years.

The Pyrazoles and Isoxazoles.—Dulin and Gerritsen were the first to report that 3,5-dimethylisoxazole (VI) is a potent oral hypo-



VI

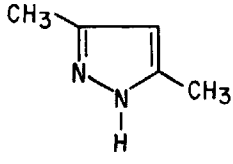
glycemic agent (191) in fasted, intact rats which are injected with 100 mg. of glucose at the time of treatment. The compound is effective at a dose as low as 10 mcg./150 Gm. rat which indicates that it is about 188 times more potent than tolbutamide and is the most potent oral hypoglycemic reported. These observations have opened a whole new area of research in oral hypoglycemics and have led to a great deal of information concerning this compound as well as a number of similar compounds.

This study (191) demonstrated that 3,5-dimethylisoxazole increases the oxidation of labeled glucose by fasted, intact rats, an effect which is shared by insulin but not the biguanides (129). The action of 3,5-dimethylisoxazole is different from that of the sulfonylureas as it is effective in alloxan-diabetic rats and the sulfonylureas are not. The compound was found to be ineffective in lowering blood sugar in spinal transectomized, eviscerated rats, which suggests that the action of the compound is dependent on the liver and/or the intestine.

In a subsequent study by Dulin, Lund, and Gerritsen (192) it was demonstrated that this isoxazole derivative also has a profound effect on fat metabolism as it is capable of lowering plasma FFA levels within 30 min. after oral administration to fasted, glucose-primed, intact rats. The compound had no effect on the rate of oxidation of labeled palmitate which was continuously infused into the animals, but there was an increase in the specific activity of plasma FFA during the infusion of the labeled palmitate. This led the authors to suggest that the depression in plasma FFA was probably due to an inhibition of lipolysis rather than to a stimulation of fatty acid oxidation.

It is interesting to note that the FFA levels are depressed within 30 min., while it requires about 2 hr. for blood sugar to be depressed significantly. This could mean that the effect on blood sugar is secondary to the effect on plasma FFA levels, although there is no proof that the two effects are directly related.

The work with 3,5-dimethylisoxazole has led to subsequent publications dealing with related compounds derived from pyrazole (193, 194). 3,5-Dimethylpyrazole (VII) was found to pro-



VII

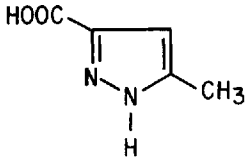
duce biological effects similar to those reported earlier for the analagous isoxazole and was shown to be 50 times as potent as tolbutamide in lowering blood sugar in glucose-primed, fasted, intact rats. It was also found to have a significant effect on fat metabolism (193).

It was shown (193) that 3,5-dimethylpyrazole increases the rate of oxidation of labeled glucose in fasted, intact rats and was also found to be effective in alloxan-diabetic rats. It has no effect

on the rate of oxidation of labeled glucose by rat epididymal adipose tissue *in vitro* and also has no effect on the liberation of FFA from this tissue *in vitro*.

As was found to be the case with 3,5-dimethylisoxazole, the pyrazole was found to lower plasma FFA levels in glucose-primed, fasted, intact rats. The administration of the pyrazole to rats continuously infused with labeled palmitate again resulted in no increased oxidation of the palmitate but did produce an increase in the specific activity of the plasma FFA. This again is suggestive that the FFA depression is probably a result of a decreased mobilization of fatty acids from glycerides in fat depots. The depression of plasma FFA occurred within 15 min., while it required 2 hr. to depress glucose levels significantly, which further suggests that the effect of these compounds on blood glucose levels could be secondary to their effect on fat metabolism.

Since 3,5-dimethylpyrazole depresses fat mobilization *in vivo* but not *in vitro*, since it depresses blood glucose levels in fasted, glucose-primed, intact rats but not in eviscerated animals, and since its action on blood sugar is antagonized by SKF 525-A, an inhibitor of drug metabolism, it was suggested that the action of the compound could be due to a metabolite rather than to the compound itself. A study carried out by Smith, Forist, and Dulin (195) has shown that 3,5-dimethylpyrazole is metabolized to 5-methylpyrazole-3-carboxylic acid (VIII) in the rat. Further work by Gerritsen and Dulin (194) shows that this metabolite is a potent hypoglycemic and is probably responsible for many of the effects which are produced when 3,5-dimethylpyrazole is administered to animals.



VIII

5-Methylpyrazole-3-carboxylic acid is 116 times more potent than tolbutamide in intact, fasted, glucose-primed rats (194). Like the dimethyl derivative, it also increases the rate of oxidation of labeled glucose in fasted, intact rats, is effective in alloxan-diabetic rats, and rapidly depresses plasma FFA. It is readily apparent from Fig. 1 that the depression in plasma FFA occurs much more rapidly than the depression in blood sugar.

This study also points out a number of differences between 3,5-dimethylpyrazole and 5-methylpyrazole-3-carboxylic acid (194). The carboxy compound has hypoglycemic activity in spinal transectomized, eviscerated rats, a property which is not shared by the dimethyl derivative. This indicates that the dimethyl derivative must be oxidized to the acid before it is able to lower blood sugar. The evidence indicates that this oxidation probably occurs in the liver and apparently occurs quite rapidly since blood sugar is depressed within 2 hr. in animals treated with the dimethyl compound.

Another difference between the two pyrazole derivatives is that 5-methylpyrazole-3-carboxylic acid increases glucose oxidation by rat epididymal adipose tissue *in vitro* and also inhibits the release of FFA by the same tissue *in vitro* (194). Neither of these effects is exhibited by 3,5-dimethylpyrazole which further suggests that it is the metabolite which is the active form of the drug. Like other pyrazoles and isoxazoles, but unlike insulin, the carboxy pyrazole derivative does not increase glucose uptake by the isolated rat diaphragm (194).

There is not sufficient information available to understand completely the mechanism of action of these compounds, although a number of points are quite clear. They affect both carbohydrate and fat metabolism in a variety of biological systems; but whether these two effects are related or independent of each other has not been established. If the two effects are related, the effect on fat metabolism is almost certainly the primary effect since this effect is manifested so much more rapidly than the blood sugar depression, a point which is made abundantly clear by Fig. 1. Further evidence for the primary effect on fat metabolism is that there have been no instances reported where these compounds lowered blood sugar without first having lowered plasma FFA levels.

There is good evidence to support the theory

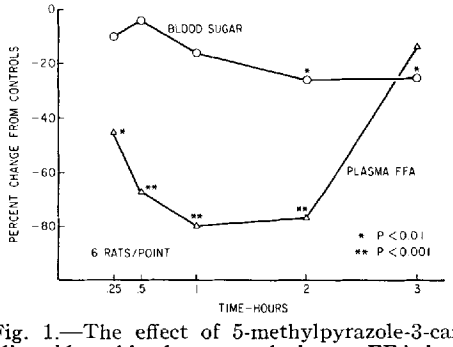


Fig. 1.—The effect of 5-methylpyrazole-3-carboxylic acid on blood sugar and plasma FFA levels in fasted, intact, glucose-primed rats (194). Reprinted with the permission of the *Journal of Pharmacology and Experimental Therapeutics*.

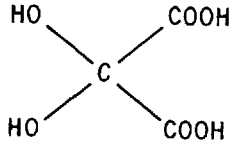
that a depression of plasma FFA levels could produce a depression in blood sugar. At low FFA levels the oxidation of fatty acids is minimized thus allowing for the oxidation of relatively large quantities of glucose for energy production which would result in a lowering of blood sugar levels. This idea is also in agreement with the work of Randle and his associates (107) which shows that high levels of FFA inhibit the utilization of glucose. The exact mechanism of action of these compounds is, however, probably much more complex than this.

One wonders why certain barbiturate anesthetics are able to inhibit the effect of these compounds on carbohydrate metabolism, but not on fat metabolism as shown by Gerritsen and Dulin (193). One possibility is that the barbiturate antagonizes the secondary action of the compounds on carbohydrate metabolism, but not the primary action on fat metabolism. Another question which must be answered is why the effect of 3,5-dimethylpyrazole on carbohydrate metabolism is blocked by evisceration, but the effect on FFA depression is not (193). There appears to be no ready answer to this question at this time.

A recent publication by Wright, Dulin, and Markillie (196) describes the preparation of 41 pyrazole derivatives which were tested for hypoglycemic activity. A number of the compounds having methyl groups in the 3 and 5 positions were found to be active oral hypoglycemics, 1 of them being about 100 times more potent than tolbutamide. It seems likely that these compounds act by the same mechanism as the original isoxazoles and pyrazoles, so little if any difference would be expected.

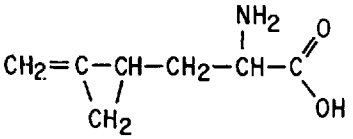
In summary, the pyrazoles and isoxazoles are among the most interesting hypoglycemics to be studied. Further study of this group of compounds could result in the discovery of important information concerning the causes, effects, and treatment of diabetes. It is also conceivable that an effective and useful antidiabetic drug could evolve from the series.

Miscellaneous Hypoglycemics.—Mesoxalic acid (IX) has been reported to decrease blood sugar levels in laboratory animals (197). Relatively little information has been published on the compound, but it appears to have an action similar to the sulfonylureas. It is effective in the presence of some endogenous insulin, but exerts no hypoglycemic effect in totally pancreatectomized animals (197). This led to the speculation (198) that the compound exerts its action by stimulating the β cells to secrete insulin. The calcium salt of this acid is on the Japanese market but has not been studied extensively in this country.



IX

Two compounds, hypoglycin A (X) and hypoglycin B, that have been isolated from the unripe fruit of a tropical tree (*Blighia sapida*) have been found to possess hypoglycemic activity (199). Chen and his associates (200) found hypoglycin A to be more effective than hypoglycin B, but found both compounds to be highly toxic.



X

Patrick (201) has studied the effects of hypoglycin A on various biological systems. He found that it is effective in alloxan-diabetic rats, but its action is different from that of insulin. This compound does not increase oxygen consumption in intact rats nor does it increase muscle glycogen. It does not increase the glucose uptake of the isolated rat diaphragm and does not stimulate the oxidation of glucose by rat epididymal adipose tissue *in vitro*. It does not appear to increase carbohydrate utilization greatly by any biological system. Patrick (201) has proposed that the liver is the primary site of action of the compound.

L-Leucine has been reported to lower blood sugar in some children with idiopathic hypoglycemia (202) and in some patients with islet cell tumors (203). Yalow and Berson (204) have shown that L-leucine produces elevated plasma insulin levels in these patients which probably accounts for its hypoglycemic effect. Fajans and his associates (205) have reported that L-leucine can also reduce blood sugar in normal healthy subjects who have been treated with insulin or sulfonylureas to increase plasma insulin levels. They have also shown that a modest but significant hypoglycemic effect is produced when L-leucine is administered to healthy subjects without sulfonylurea or insulin pretreatment. Fajans (206) has recently summarized his findings which indicate that L-leucine-induced hypoglycemia results from a decreased hepatic glucose output and an increased peripheral utilization of glucose. The stimulation of insulin release is proposed as the primary mechanism producing these effects.

TABLE II.—THE BIOLOGICAL EFFECTS OF VARIOUS HYPOGLYCEMIC AGENTS ON VARIOUS ANIMAL SYSTEMS

Effect	Insulin	Sulfonyl-ureas	Biguanides	3,5-Dimethyl-pyrazole	5-Methyl-pyrazole-3-carboxylic Acid
Effective in alloxan-diabetic animals	+	−	+	+	+
Effective in eviscerate animals	+	−	+	−	+
Increase glucose oxidation in intact animals	+	+	−	+	+
Increase glucose uptake by rat diaphragm *in vitro*	+	−	+	−	−
Increase glycogen content of isolated rat diaphragm	+	−	−	−	−
Increase glucose oxidation by rat epididymal adipose tissue *in vitro*	+	−	−	−	+
Lower plasma FFA levels	+	+	−	+	+

A large number of other substances have been found to exhibit hypoglycemic activity, but most of these show no real advantages over compounds which are in current use. 4-Dimethylamino-*N*-methyl-2,2-diphenylvaleramide was shown to be 4 times more potent than tolbutamide in fasted intact rats (207); it is proposed that it acts by decreasing the glucose output of the liver. Goldner and Jauregui (208) have reported that certain antihistaminic drugs possess hypoglycemic activity. Hultquist (209) has shown that iodoacetic acid and iodoacetamide exhibit hypoglycemic activity in rats, seemingly by the stimulation of the β cells to secrete insulin. Tris-(hydroxymethyl) aminomethane has also been reported to possess hypoglycemic properties (210).

This is only a partial list of substances which have been reported to have significant hypoglycemic activity. A complete list would be far too extensive for the purposes of this review.

Summary.—It may be seen from Table II that, although many different classes of compounds are capable of lowering blood sugar and counteracting certain other effects of diabetes, they do not all act by the same mechanism. It points out that the sulfonylureas, which are dependent on a functioning pancreas for their action, are not effective in alloxan-diabetic or eviscerate animals (181, 184). The biguanides, on the other hand, have been found to lower blood sugar in alloxan-diabetic (129) and eviscerate (138) animals. The biguanides do not increase glucose oxidation in intact animals, whereas insulin and the pyrazoles do (193). The biguanides are the only compounds in the table other than insulin which are generally agreed to stimulate glucose uptake by the isolated rat diaphragm (129), but even these compounds do not increase the glycogen content of the diaphragms as does insulin (211). The pyrazoles (193) and the sulfonylureas (212) as well as insulin are capable of lowering plasma FFA levels in intact animals. The table also illustrates that 5-methylpyrazole-3-carboxylic acid can be differentiated from 3,5-dimethylpyrazole by virtue of the effectiveness of the acid in eviscerate rats as well as by its effect on glucose oxidation in rat epididymal adipose tissue *in vitro* (194). It is obvious by now that none of these compounds qualifies as an oral insulin since none exhibits all of the biological effects of insulin. They are properly classified as "oral hypoglycemics" or "oral insulin substitutes."

CONCLUSIONS

The above observations lead to the realization that although a substantial amount of information about the metabolic effects of diabetes has been accumulated, a great deal more must be learned before certain important conclusions can be reached. The etiology of diabetes is not well understood, nor are its hereditary aspects. The effects of insulin on various biological systems are quite well documented, but the mechanisms by which it produces these effects are not clearly understood. Treatment of diabetes with oral hypoglycemics must be termed only partially successful at this time, and more research in the area is required to produce new compounds which are more similar to insulin in their biological action and which are effective in treating a greater number of diabetic patients. Long-range goals should be aimed at learning more about the causes of diabetes so that steps can be taken to prevent the disease rather than simply treating the symptoms. The cause is a worthy one and merits the vast amount of research being carried out in the area.

Spectra–Structure Correlations of Phenothiazines by Infrared, Ultraviolet, and Nuclear Magnetic Resonance Spectroscopy

By R. J. WARREN, I. B. EISDORFER, W. E. THOMPSON, and J. E. ZAREMBO

The infrared, ultraviolet, and nuclear magnetic resonance spectra of 23 phenothiazines of varying structure have been recorded and analyzed. Spectra–structure correlations and assignments of the absorption bands are presented and discussed. The collection of phenothiazines includes all of the commercially available analogs currently in use in the field of medicine and provides a comprehensive source for the identification and structure elucidation of samples from biological, forensic, and medical research.

ALTHOUGH the literature is replete with publications on phenothiazines, there has been to date no attempt to organize and correlate spectral data on this class of compounds. The purpose of this paper is to report the results of such a spectral study. Infrared, ultraviolet, and nuclear magnetic resonance spectra of 23 phenothiazine derivatives have been analyzed, and the correlations from these spectral data make possible a positive identification of all of the commercially available pharmaceutically useful phenothiazines.

EXPERIMENTAL

The infrared spectra were recorded between 4000–625 cm.$^{-1}$ with a Perkin-Elmer model 21 spectrometer with a sodium chloride prism. The phenothiazines were prepared as natural films.

The ultraviolet spectra were recorded between 200 and 400 mμ with a Cary model 14 recording spectrophotometer using matched fused silica cells with a 1-cm. light path.

The NMR spectra were recorded in $CDCl_3$ with tetramethylsilane as the internal standard on a Varian Associates model A-60 spectrometer.

All spectral data were obtained on the same samples. These were analytical standards with a purity of 98% or greater. (See Table I.)

DISCUSSION OF RESULTS

Infrared Spectra.—The infrared spectra of the phenothiazines are shown in Figs. 1–6. Seventeen of the 23 phenothiazines are substituted in the

Received October 8, 1965, from Smith Kline & French Laboratories, Philadelphia, Pa.

Accepted for publication November 9, 1965.

The authors are grateful to Mrs. Eleanor Cherry, Mr. Peter Begosh, and Mr. Richard Gillespie for their technical assistance in obtaining the spectra presented here; and to E. R. Squibb and Sons, Wyeth Laboratories, Pitman-Moore Co., Sandoz Pharmaceuticals, and Schering Corp. for supplying samples of vespazine, carphenazine, piperacetazine, thiethylperazine dimaleate, acetophenazine dimaleate, and perphenazine, respectively.

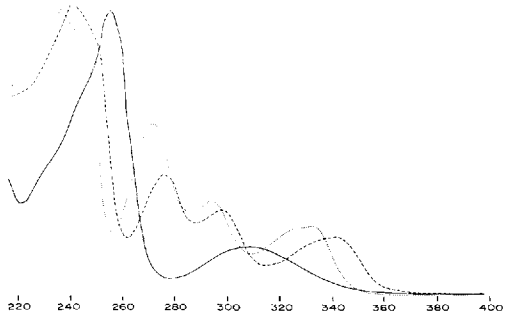

Fig. 7.—Ultraviolet spectra. Key: ——, phenothiazine; ---, sulfoxide; . . ., sulfone.

2,10-positions. These 2,10-disubstituted phenothiazines have a characteristic and unique over-all pattern in the infrared spectrum. There are 4 bands in the region 1000–700 cm.$^{-1}$ which are common to all. These bands occur at 915–928 cm.$^{-1}$, 840–870 cm.$^{-1}$, 785–800 cm.$^{-1}$, and 730–755 cm.$^{-1}$. The band at 785–800 cm.$^{-1}$ exhibits some splitting in certain cases, but it is steady in location. The bands listed are all strong and comprise a definite over-all pattern which dominates the fingerprint range of the spectrum. The bands are assignable to the phenothiazine ring system and the substitution in the 2-position. Bellamy (1) gives the range 770–735 cm.$^{-1}$ for the out-of-plane bending vibration of 4 adjacent hydrogens in an aromatic ring and the 900–800 cm.$^{-1}$ for 1,2,4-trisubstitution.

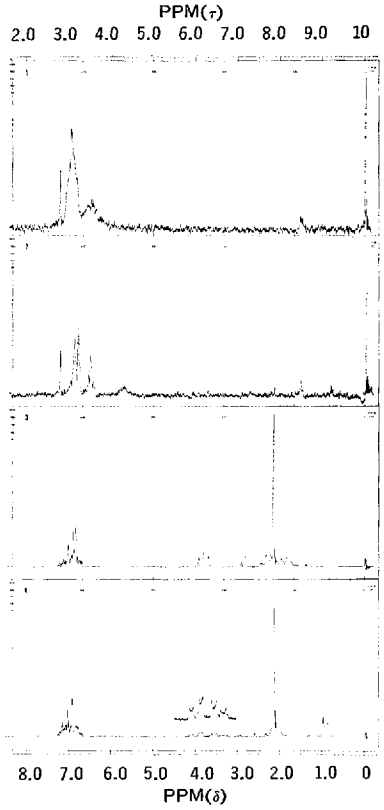

Fig. 8.—NMR spectra 1–4.

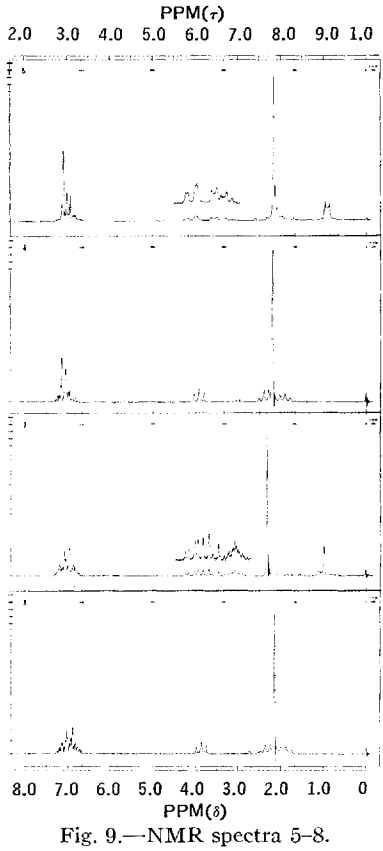

Fig. 9.—NMR spectra 5–8.

Phenothiazines with no substituent in the 2-position all show very strong absorption in the 720–770 cm.$^{-1}$ range which is assignable to the out-of-plane bending vibrations of the 4 adjacent hydrogens of the phenothiazine ring system (1).

Two other characteristic bands for the phenothiazine system are found at 1590 and 1560 cm.$^{-1}$. These bands are quite consistent in location, although they vary as to which is the more intense. They also may be assigned to the aromatic system.

In the case of phenothiazine amine salts (spectrum No. 24, chlorpromazine HCl) a strong, broad band centered between 2300 and 2500 cm.$^{-1}$ is characteristic of the R_3NH^+ ion combined with X^-. The relatively small negative ion X^- can approach the amine cation R_3NH^+ from only one direction, forming the ion pair $R_3NH^+X^-$ with the hydrogen atom bound strongly to the negative ion. Water of hydration tends to raise the frequency and lower the intensity of the absorption (2).

Two of the important oxidation products of phenothiazines are the sulfoxide and sulfone. The presence or absence of these may be determined by examining the spectra for S=O and SO_2 bands. The single S=O band occurs at 1000 cm.$^{-1}$ (±20). The —SO_2 asymmetric stretching band occurs at 1250–1300 cm.$^{-1}$ and the symmetric stretching band at 1140–1160 cm.$^{-1}$. All exhibit strong absorption bands.

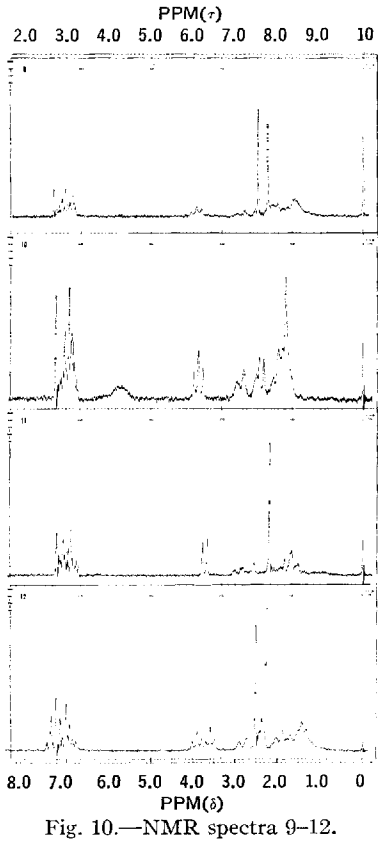

Fig. 10.—NMR spectra 9–12.

Ultraviolet Spectra.—The ultraviolet spectra of the phenothiazines are characteristic both in wavelength and in intensity. Two peaks are observed, the first and most intense in the range 250–265 mμ and the second in the range 300–325 mμ. The exact location of the peaks in both regions is dependent upon the nature of the group in the 2-position. Halogen substituents such as chloro- or trifluoromethyl appear to exert a slight influence in the form of small bathochromic shifts of 2–4 mμ on the more intense peak in the 250–265-mμ region. The trifluoro effects a slightly stronger shift than the chloro analog. It has been further noted that the alkyl side chain containing an amine group causes slight shifts in the peak locations, and the amount of shift is related to the length of the side chain, which is to say the proximity of the amine group to phenothiazine nucleus. The amine group has been found to exert a slight influence even when located at the end of a 4-carbon chain.

Phenothiazines with a carbonyl group in the 2-position are exceptions to the general rule regarding location of the 3 ultraviolet peaks. This type of phenothiazine exhibits strong absorption peaks in the range 240–245 mμ and 275–285 mμ.

Because of the distinctive ultraviolet spectrum and the intense absorption detectable at low concentrations (0.015 mg./ml.), it is possible to make a qualitative determination quickly and with a minimum amount of sample.

The presence or absence of the sulfone and sulfoxide decomposition products is easily ascertained by examining the ultraviolet spectrum. The spectrum of sulfone or sulfoxide is quite different and easily detected (Fig. 7).

Nuclear Magnetic Resonance.—For NMR study (Figs. 8–13) and correlations the phenothiazine spectra can be separated into 5 groups: 4 groups according to the type of side chain on the nitrogen in the 10-position, a fifth group consisting of the oxidation products (sulfone and sulfoxide). The groups to be considered are: (*A*) those having an aliphatic side chain with no heterocyclic ring; (*B*) those having a side chain containing a piperazine ring; (*C*) those having a side chain containing a piperidine ring; (*D*) those containing a pyrrolidine ring; and (*E*) oxidized phenothiazines.

Group A.—All of the compounds belonging to group *A* have features in common. All contain an *N,N*-dimethyl group, all have a CH_2 group attached to the 10-position of the phenothiazine ring, and, of course, all contain aromatic protons from the phenothiazine nucleus itself. It is, therefore, not surprising that their NMR spectra are similar in many respects, and have characteristic absorbance bands unique to their general group. The *N,N*-dimethyl group is found at 131 c.p.s. for the compounds with straight chain amines and at 138 c.p.s. in the case of branched chain amines. The position of the branched chain amine is influenced by its proximity to the ring N. The CH_2 group on

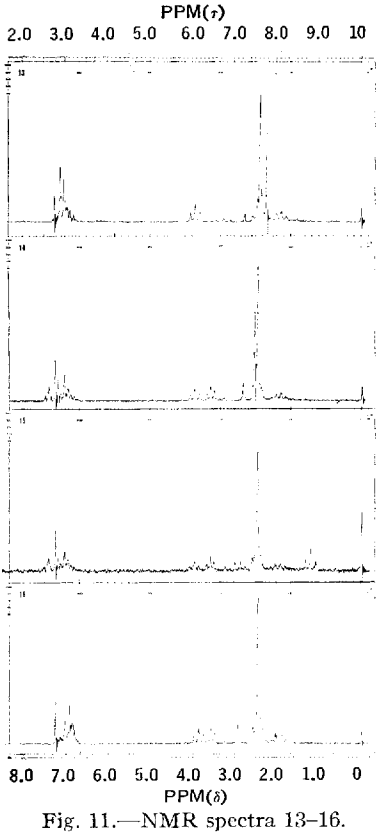

Fig. 11.—NMR spectra 13–16.

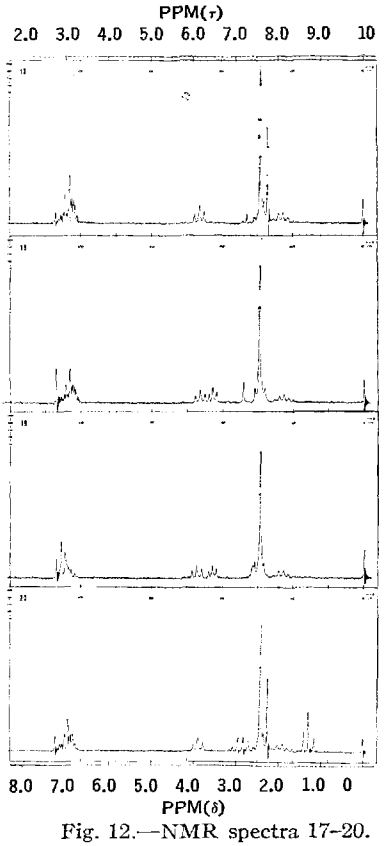

Fig. 12.—NMR spectra 17–20.

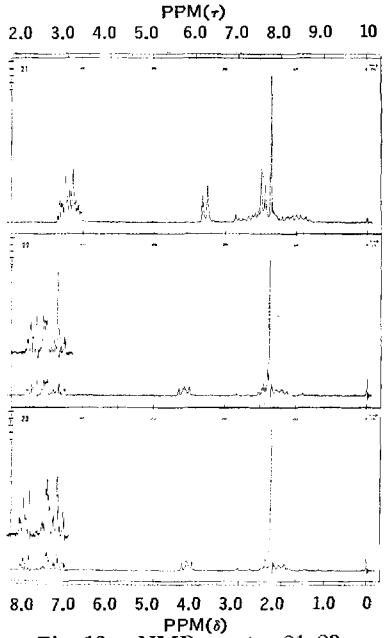

Fig. 13.—NMR spectra 21–23.

the nitrogen atom in the 10-position is found to be a triplet at 232 ± 3 c.p.s. for straight chain amines and in the same area but with more splitting in the case of branched chain amines due to the increased number of adjacent protons. All of the phenothiazine spectra show a complex pattern for the aromatic protons in the area 400–440 c.p.s. (3).

Group B.—Phenothiazines having a piperazine ring in their side chain have common features attributable to their specific group which distinguish them from other phenothiazines. The 8 protons in the piperazine ring being equivalent are found as a single peak at 146 ± 2 c.p.s. This is the strongest peak and the dominant feature of a phenothiazine in this group. The CH_2 attached to the N in the 10-position is found at 234 ± 4 c.p.s. In those piperazine derivatives where the piperazine ring is attached directly to a CH_2 in the chain (6 of the 9 shown) the CH_2 adjacent to the piperazine is located at 215 c.p.s. The complex aromatic pattern is located at 400–450 c.p.s.

Group C.—The phenothiazines containing a piperidine group in the side chain have chemical shifts due to the piperidine ring in the range 90–130 c.p.s., depending on the position and nature of the substitutent. The CH_2 attached to the N at the 10-position is again found at 235 c.p.s. with 1 exception, where the CH_2 is the only link between the N and the piperidine ring. In this case the CH_2 is a doublet located at 220 and 227 c.p.s. The aromatic pattern is found at 400–450 c.p.s.

Group D.—The group containing a pyrrolidine ring shows a chemical shift in the range of 100–180 c.p.s. due to the substitution on the ring. The CH_2 which links the N at 10-position and the pyrrolidine ring is a doublet at 224 and 231 c.p.s.

Group E.—This group contains the sulfoxide and sulfone of chlorpromazine. The effect of the introduction of oxygen into the system is an increase in chemical shift as compared with chlorpromazine. The $N(CH_3)_2$ is shifted 4–6 c.p.s. to 135–137 c.p.s. The CH_2 in position 10 is shifted to 254–256 c.p.s. and the aromatic protons show additional splitting and shift to 490 c.p.s.

SUMMARY

Infrared, ultraviolet, and nuclear magnetic resonance spectral data of phenothiazine compounds have been presented and correlated. On the basis of the information presented here, it is possible to make a rapid identification with a minimum amount of sample of any of the commercially available phenothiazines used in pharmaceutical preparations.

Drug Absorption from the Rectum II

Rates of Absorption and Elimination from the Blood for Various Suppository Bases

By JOSEPH F. BORZELLECA and WERNER LOWENTHAL

To facilitate the calculations involved in Teorell's equation No. 25, a program in Fortran with Format was used in the IBM 1410 digital computer system. Using plasma salicylate levels, the rates of drug absorption and elimination from the blood and the specific apparent body volumes were determined for salicylic acid and sodium salicylate administered in 4 different suppository bases. The rate of absorption for sodium salicylate was found to be greater than that for salicylic acid except for polyoxyethylene sorbitan monostearate base. The rates of elimination from the blood for the 2 drug forms do not vary significantly. The specific apparent volumes for salicylic acid were less than that for the sodium salt, suggesting a lesser degree of storage for the acid form. Since Teorell's equation assumes apparent first-order rates of absorption and elimination from the blood, and this equation describes the data presented, this suggests that salicylic acid and its sodium salt are absorbed into the blood from the 4 bases tested and eliminated from the blood by apparent first-order kinetics. Two sets of data from the literature were also analyzed, and constants for 2 other sets could not be computed because of limitations on the computer.

GARRETT *et al.* (1) used an analog computer to solve a four-factor linear homogeneous equation of exponentials to explain the disappearance of ^{47}Ca from the blood. These authors (2) then programmed a distributive model on the analog computer to determine rate constants.

Riegelman and Crowell (3) using a mathematical solution for radial diffusion, derived equations to explain the absorption of radioactive compounds from the rectum. From the data collected on rats using solutions of ^{131}I compounds (NaI, CHI_3, and triiodophenol), the authors derived an equation which in its simplified form is:

$$\log N - N_f/N_0 - N_f = -kt \qquad \text{(Eq. 1)}$$

where

N = the dose detected at time t,
N_f = the dose detected at the end of the experiment,
N_0 = the total dose administered, and k was characterized as a pseudo first-order constant which included the diffusion coefficient, absorption constant, and any differences due to formulation.

No rate constants to characterize absorption through the rectal membrane, drug disappearance rate from the blood, or rates of elimination were determined.

Teorell (4) originally derived a general equation (equation No. 25) on a theoretical basis to describe the absorption and elimination of drugs administered by routes other than the intravenous. This equation involves 5 variables, 2 of which can be determined experimentally, and 3 are unknown. Because of the difficulty in solving this equation, it has been used only rarely. This could explain why much of the recent work concerned with the kinetics of drug absorption, distribution, and excretion has resulted in derivation of specific equations with limited application. However, the availability of computers makes solving the equation of Teorell a less formidable task.

Recently, Wiegand and Sanders (5), using blood levels determined for 2 drugs given orally as solutions to dogs, or aspirin tablets administered to humans, solved Teorell's equation with a digital computer. A program in Fortran without Format was written to solve the equation for absorption rate constant, drug elimination rate constant from the blood, and specific apparent body volume.

It is the purpose of this paper to apply the equation and a modification of the program presented by Wiegand and Sanders (5) to suppository dosage form, and to show that Teorell's equation combined with computer technology has wide application.

RESULTS AND DISCUSSION

In the work reported here, the program in Fortran without Format was modified to Fortran with Format for use in the IBM 1410 digital computer system. The explanation of the various steps were discussed by Wiegand and Sanders (5). By

TABLE I.—COMPUTER CALCULATED CONSTANTS FOR DATA PRESENTED BY LOWENTHAL AND BORZELLECA (6)

Suppository Base and Drug[a]	$k_a \pm$ (S.E.)[b]	$k_d \pm$ (S.E.)	$V_d \pm$ (S.E.)
Cocoa butter SA	1.275 (0.487)	0.0293 (0.0531)	0.542 (0.108)
Cocoa butter NaS	2.199 (0.377)	−0.0368 (0.0115)	0.814 (0.052)
PEG SA	1.045 (0.105)	−0.0080 (0.0132)	0.697 (0.038)
PEG NaS	1.970 (0.376)	0.0340 (0.0172)	3.342 (0.269)
S-55 SA	0.812 (0.166)	0.0564 (0.0341)	0.359 (0.047)
S-55 NaS	1.245 (0.195)	0.0318 (0.0160)	0.851 (0.067)
PSMS SA	0.927 (0.324)	0.0607 (0.0585)	0.484 (0.103)
PSMS NaS	0.352 (0.530)	0.210 (0.351)	1.211 (1.653)

[a] PEG is polyethylene glycol mixture; S-55 is a synthetic mixture of glycerides; PSMS is polyoxyethylene sorbitan monostearate. SA is salicylic acid and NaS is sodium salicylate. *Reference 6* gives a complete description of the bases. [b] S.E., standard error.

use of the computer program, plasma, serum, or blood drug levels can be used to determine absorption rate constants, drug disappearance rate constants from the blood, and specific apparent body volumes.

The equation to be fitted to the plasma concentration data is:

$$C = \frac{k_a}{V_d(k_a - k_d)} a_0 (e^{-k_d t} - e^{-k_a t}) \quad \text{(Eq. 2)}$$

where

a_0 = the drug dose in mg./Kg.,
C = the plasma, serum, or blood drug concentration in mcg./ml.,
t = time in hours,
k_a = the apparent first-order absorption rate constant in hr.$^{-1}$,
k_d = the apparent first-order drug disappearance rate constant from the blood in hr.$^{-1}$, and
V_d = the specific apparent volume of drug distribution in L./Kg.

The plasma salicylate levels presented in our previous communication (6) were averaged and used to determine k_a, k_d, and V_d. The use of averages has been shown to be an acceptable procedure (5). The initial estimates for k_a, k_d, and V_d, required as input data, were those determined by Wiegand and Sanders (5) for aspirin tablets, and were 1.55, 0.209, and 0.144, respectively. For sodium salicylate in PSMS base, using the data averaged for the 6 dogs, constants could not be calculated even after several attempts using various estimates of k_a, k_d, and V_d. The plasma levels of

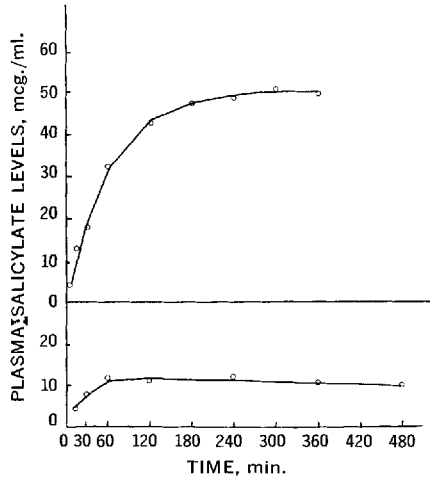

Fig. 3.—Plasma salicylate levels from sodium salicylate in PEG suppository base (bottom) and from salicylic acid in PEG suppository base (top). Key: O, experimental points; —, theoretical curves.

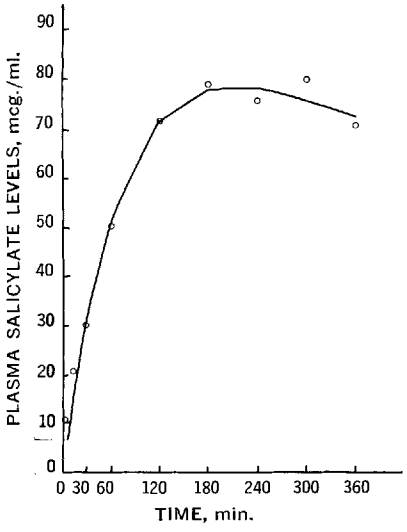

Fig. 4.—Plasma salicylate levels from salicylic acid in S-55 suppository base. Key: O, experimental points; —, theoretical curve.

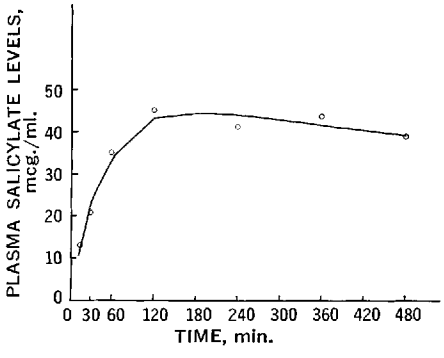

Fig. 5.—Plasma salicylate levels from sodium salicylate in S-55 suppository base. Key: O, experimental points; —, theoretical curve.

1 of the dogs were abnormally high when compared to the other 5 dogs. Constants were readily obtained using the averages obtained from 5 dogs. The calculated constants are given in Table I. Figures 1–6 show the curves for the calculated equation and the experimental data used.

Very few communications give 6 or more blood level concentrations with time data, so that demonstration of the usefulness of this equation and program is made more difficult. Blume and Nohara

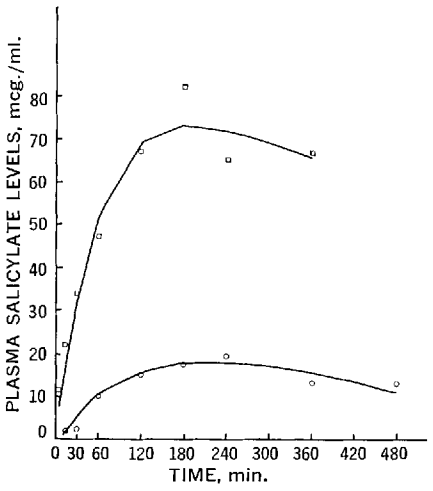

Fig. 6.—Plasma salicylate levels from salicylic acid (□) and sodium salicylate (O) in PSMS suppository base. Key: —, theoretical curves.

(7) gave sodium salicylate solutions orally and rectally to rabbits and determined plasma salicylate levels. From their data the constants were calculated and are shown in Table II; equation and data are plotted in Fig. 7. The same estimates for k_a, k_d, and V_d as listed above were used. Fincher *et al.* (8) administered orally to dogs capsules containing 3 different particle size distributions of sulfisoxazole. The drug in experiment *A* had an average diameter of 1.7 μ; in experiment *B*, 37 μ, and experiment *C*, 95 μ. The constants calculated from these data are shown in Table II and the equations and data plotted in Fig. 8. The estimates of k_a, k_d, and V_d used were 2.30, 0.254, and 3.74, respectively. The data from Swintosky *et al.* (9), and Walkenstein *et al.* (10) had sufficient number of observations and appear to follow Eq. 2. The computer was not able to calculate the constants because it was unable to handle power functions greater than 99. In the power function e^{-kt}, when t becomes large, k does not have to be very large for e to be raised to the 99th power.

In the previous communication (6), it was reported that salicylic acid resulted in higher plasma levels than the sodium salt, but it can be seen from the constants listed in Table I that the salicylic acid is absorbed at a slower rate, except in the case of PSMS base. The rates of elimination from the blood for the 2 forms do not vary significantly. The specific apparent volume for salicylic acid was less than that for the sodium salt, suggesting a

lesser degree of storage for the acid form. This may be due to the slower rate of absorption resulting in less time for storage before excretion. The negative elimination rates obtained with sodium salicylate in cocoa butter and salicylic acid in PEG base indicate that the plasma levels were still rising at the time the experiment was stopped.

Equation 2 assumes apparent first-order rates of drug absorption and elimination from the blood. This equation describes the data presented, suggesting that salicylic acid and the sodium salt are absorbed into the blood from the 4 bases tested and eliminated from the blood by apparent first-order kinetics.

The constants presented in Table II indicate that sodium salicylate was absorbed at a faster rate orally than rectally, and eliminated from the blood at a slower rate. The large V_d indicates a large amount of the drug is stored in tissue. The constants calculated from the data of Fincher *et al.* (8) show that as average particle diameter increases there is a slight and probably nonsignificant decrease in rate of absorption, a decrease in rate of elimination from the blood, and an increase in specific apparent body volume.

Gas Chromatographic Determination of Codeine in Serum and Urine

By EMANUEL SCHMERZLER, WILLIAM YU, M. I. HEWITT, and I. J. GREENBLATT

A method for gas chromatographic detection of codeine in serum is described. An application to a clinical drug evaluation study is given. A method for simultaneous detection of free and total codeine and its metabolites, norcodeine and morphine, in urine is also presented.

USE OF GAS-LIQUID chromatography as a means of comparing serum levels in subjects receiving oral codeine dosages has been investigated. Although an efficient SE30 column enabled detection of nanogram quantities, codeine was not resolved from norcodeine on this nonpolar phase, as previously reported by Anders and Mannering (1). Elliot *et al.* (2) used the acetates formed inside the column (1) to detect higher levels present in urine of narcotic addicts. The authors found small interfering peaks present in blanks which precluded the use of codeine acetate for reliable quantification of low levels present in serum. However, there is a great difference in reaction rate between codeine and norcodeine under mild acetylation conditions. This was used to remove norcodeine before injection on SE30 columns. The specificity and accuracy of the results were checked, using an XE60 column on which free codeine and norcodeine are well resolved.

A method for the estimation of codeine and its metabolites in urine is also described.

METHODS

Codeine in Serum or Urine.—To 2.5 ml. of serum or urine in a 15-ml. glass-stoppered conical centrifuge tube is added 9 ml. of 10% butanol in freshly distilled chloroform (3). The tube is hand shaken 5 sec. Then 0.12 ml. of 16 *N* KOH is added (0.05 ml. for urine). Again mix by hand 5 sec., then mechanically shake in 10 min. After centrifuging, the aqueous serum and jell layers are aspirated. If jell formation is excessive, the aqueous layer is aspirated and the jell broken by vigorous reshaking before recentrifuging. A 7-ml. aliquot of the organic layer is transferred to a clean centrifuge tube. Care must be taken not to transfer any of the strongly basic aqueous layer. A quantity of 1.5 ml. of 0.01 *N* H_2SO_4 is added. Shake 10 min. Mechanical shaking for 3 min. is followed by centrifuging and transfer of the acid layer to a new 15-ml. tube. Quantities of 0.04 ml. of 16 *N* KOH and 8 ml. of distilled chloroform are added. Shake 10 min. After centrifuging, remove the aqueous layer. Dry the chloroform extract with anhydrous sodium sulfate. Evaporate to dryness with a stream of nitrogen at 60° in 2-ml. conical centrifuge tubes. Twenty microliters (50 μl. for urine) of an internal standard solution, 0.1 mg./ml. of cholesterol acetate in ethyl acetate, is added just prior to injection of 2 μl. of this mixture.

On SE 30, codeine and norcodeine are not resolved and peaks observed represent any contributions from either compound. To determine codeine alone, a trace amount of acetic anhydride is added

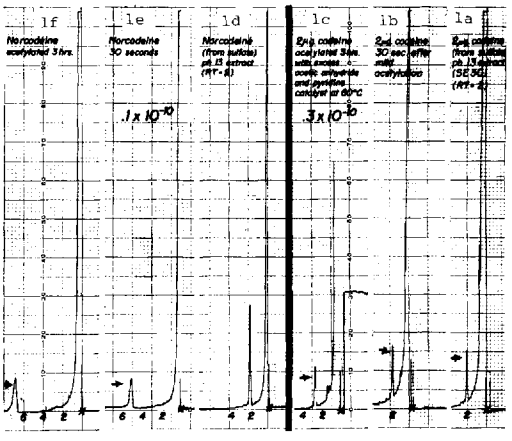

Fig. 1.—Norcodeine removal technique (SE30). Key: (1a) codeine; (1b) codeine injected 30 sec. after mild acetylation; (1c) codeine after acetylating 3 hr. at 60° with pyridine catalyst; (1d) norcodeine; (1e) norcodeine after 30 sec. acetylation; and (1f) norcodeine after 3 hr. acetylation. Note the retention time of codeine = norcodeine = 2 min.

(1 μl. of a 1/50 solution of acetic anhydride in ethyl acetate for serum or 1/10 for urine). The mixture is stirred and 2 μl. injected into the chromatograph within 30 sec. (Fig. 1). Norcodeine may be estimated by difference if an injection before acetylation is made first. Suitable standards and blanks are included with each analysis.

On XE60 the 2 alkaloids are resolved as free compounds, and acetylation is unnecessary.

Codeine and Metabolites in Urine.—Three milliliters of urine is brought to pH 9 with 0.3 Gm. of sodium bicarbonate and 0.3 ml. of 10 *N* sodium hydroxide. Nine milliliters of 10% butanol in chloroform is added and, at this point, the procedure continues as described above through the extraction at pH 2 into dilute sulfuric acid. The acid layer is adjusted to pH 13 with 0.05 ml. of 10 *N* sodium hydroxide. Codeine and norcodeine are extracted into 8 ml. of distilled chloroform. The aqueous layer containing morphine sulfate is completely transferred to another tube, adjusted to pH 9 with 0.2 Gm. of sodium bicarbonate and extracted 10 min. with 8 ml. of chloroform containing 1% ethanol. After centrifuging, the aqueous layer is discarded. Both organic layers are dried with anhydrous sodium sulfate and evaporated to dryness under nitrogen at 60° in 2-ml. centrifuge tubes. The codeine and norcodeine may be chromatographed by dissolving the extract in 50 μl. of internal standard solution and injecting 2 μl. on the XE60 column.

Free morphine tails excessively on XE60 or SE30 and must be acetylated completely to chromatograph well. Acetylation of the pH 9 extract containing free morphine is carried out by adding 0.1 ml. of a mixture of acetic anhydride, pyridine, and ethyl acetate (1:1:1) and warming about 2 hr. at 60°. The solution is evaporated to dryness and dissolved in 50 μl. of internal standard solution.

Total codeine, norcodeine, and morphine are obtained by first hydrolyzing with acid. Concentrated HCl (10% by volume) is added to 3 ml. of urine and the sample placed in a boiling water bath for 1 hr. (4). As a check, or if the presence of occasional interfering compounds compel it, the codeine and norcodeine in the pH 13 extract may be completely acetylated as for morphine.

Gas chromatographic data were obtained on a Jarrel-Ash instrument model 28-710.

SE30 column: 6-ft., 4-mm. i.d., silanized glass column with 5% (w/w) SE30 on acid washed 80/100 mesh Gas-Chrom P. Temperatures: injector, 260°; detector, 260°; column, 240°. Nitrogen carrier flow rate = 70 ml./min. measured at room temperature. Theoretical plates = 1600.

XE60 column: 4 ft., 4-mm. i.d., silanized glass column with 4% (w/w) XE60 on acid washed 90/100 mesh Anakrom A. Temperatures: injector, 260°; detector, 260°; column, 240°. Nitrogen flow = 70 ml./min. measured at room temperature. Theoretical plates = 1500.

The liquid phases were applied by filtration technique (5).

RESULTS

The objective was to determine if a 15-mg. resinated oral codeine preparation[1] would show either slower absorption or last longer in human blood when compared with a nonresinated codeine preparation of the same composition except for absence of resin complexing. Five healthy male volunteers were tested. After 10 days, those individuals who received the resinated material then received the nonresinated material in the same dosage and vice versa. (Table I.)

All 10 blood series were examined for total (unresolved) codeine and norcodeine values on an SE30 column. The peaks were calculated, arbitrarily, using codeine standards in micrograms per 100 ml. of serum. In Table II, these results are recorded

[1] Strional which contains 15 mg. of codeine base as cation exchange resin complex, 10 mg. of methaqualone as cation exchange resin complex, 162 mg. of acetylsalicylic acid U.S.P. Strional was supplied by the Strasenburgh Laboratories, Rochester, N. Y.

TABLE V.— URINARY CODEINE, NORCODEINE, AND MORPHINE ON XE60 (SUBJECT *I*)

Time, hr.	Vol.	pH	Codeine		Norcodeine		Morphine	
			Free	Total	Free	Total	Free	Total
			mcg./100 ml.		mcg./100 ml.		mcg./100 ml.	
4	35	7	40	70	70	170	5	40
11	320	7.5	30	90	75	330	20	100

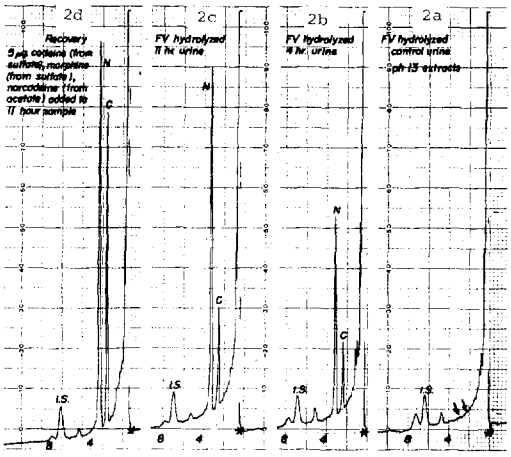

Fig. 2.—Shows hydrolyzed (FV, subject *I*) urine extracted at pH 13 for total codeine (*C*) and norcodeine (*N*). Cholesterol acetate = internal standard (*I. S.*). Key: (2a) control; (2b) 4 hr. after ingestion of resinated codeine; (2c) 11 hr.; (2d) recovery. (XE60.)

in relative units. The averages obtained using resinated or nonresinated preparations are about the same. The specific determination of codeine at key time periods was made in 2 of the individuals (*B* and *E*) by the technique of norcodeine removal on SE30 (Table III). In one case values for free codeine were also checked on an XE60 column (Table IV). Codeine levels for these individuals show the same essential hourly pattern as for the combined alkaloids. In all methods, results were read from standard curves, since these were not quite linear at serum levels. Recoveries of added codeine ranged from 70–140% and averaged 105%.

Codeine Metabolites in Urine.—The method for codeine and metabolites was used to study the urine of a female patient (Table V). After 11 hr., the conjugated forms of all 3 alkaloids are present in greater concentrations than at 4 hr. Figure 2 shows chromatograph for total codeine and norcodeine in this individual.

The urines of 4 patients receiving resinated codeine and 1 patient receiving free oral codeine preparation were examined after 3.5 hr. by norcodeine removal technique on SE30. The data presented in Table VI indicate wide variations in the ratio of codeine to norcodeine.

TABLE VI.—URINARY CODEINE AND NORCODEINE BY NORCODEINE REMOVAL TECHNIQUE ON SE30

Subject	Medication	Codeine, mcg./100 ml.	Norcodeine,[a] mcg./100 ml.
F	Resinated	570	70
G	Resinated	160	90
H	Resinated	220	70
I	Resinated	30	65
J	Nonresinated	260	100

[a] Calculated using standards made by dissolving authentic norcodeine in chloroform. Results based on norcodeine salts carried through extraction procedure give results about 10 times greater.

SUMMARY

Methods are presented for gas chromatographic analysis of codeine in serum and its metabolites in urine. In a comparison of 2 oral codeine preparations, no significant difference in serum levels between resinated and nonresinated codeine was found. Over-all precision of the methods average 100 ± 20% in serum with better precision at the higher levels in urine.

Toxicology of a Series of Phthalate Esters

By DAVID CALLEY, JOHN AUTIAN, and WALLACE L. GUESS

Certain types of plastic materials require the addition of appreciable quantities of plasticizers to impart specific physical-chemical properties to the final item. Presently, many vinyl devices used with drug products may contain plasticizers of the phthalate type. For this reason, a series of phthalic acid esters were evaluated for parenteral toxicity including LD_{50} values and hexobarbital narcosis. Experiments utilized in the study also included i.p. injections in mice for acute toxicity profiles, i.v. administration in rabbits for blood pressure and respiration effects, and intradermal injections into rabbits for irritation effects. A further study was conducted to note what effects repeated i.p. doses of the phthalates would have on mice over a period of time, examining the effects on organs, weight gain, and the blood. Finally, tissue culture experiments were conducted to attempt to correlate certain of the toxicity manifestations. The most salient feature of the toxicity of these compounds was the central depression on the animals and the rather low order of toxicity by the parenteral route of administration.

CERTAIN plastic materials (*e.g.*, polyvinyl chloride) require the introduction of an appreciable quantity of plasticizers to impart specific physicochemical and mechanical properties. In medical practice, these materials are used as bags, tubings, vehicles for administration, and collection or storage devices. A high degree of safety must be established and maintained in order to prevent any adverse effect when and if an ingredient from the plastic device migrates into a parenterally administered product. Previous reports from this laboratory have indicated that certain plastic devices used medically can release one or more ingredients into tissue or solvent systems (1–3). Furthermore, these "migrated" ingredients, when in sufficient concentrations, can elicit definite pharmacological responses. One study by Guess, Autian, and Meyers (4) demonstrated that a group of citric acid esters used as plasticizers for vinyl formulations produced definite toxicological effects when administered by parenteral routes. These same compounds, however, were extremely safe even in large quantities when administered orally to animals.

Presently, one of the most commonly used groups of plasticizers is the phthalic acid esters. These and related compounds generally have low volatility (5), low water solubility (6), some degree of absorption through the skin, and toxicity when taken into the body by the inhalation of vapors or by the oral route (7–9). Little information, however, is available as to the degree of toxicity or modes of actions of the phthalic acid esters when they are introduced parenterally (10, 11). This paper reports a series of biological experiments in which 8 of the esters were evaluated as to parenteral toxicity to mice and rabbits and *in vitro* toxicity to cell cultures.

Received October 22, 1965, from the Drug-Plastic Research and Toxicology Laboratories, College of Pharmacy, University of Texas, Austin.

Accepted for publication November 30, 1965.

Presented to the Scientific Section, A.PH.A., Detroit meeting, March 1965.

This investigation was supported by grant CA-06120 from the National Cancer Institute, U. S. Public Health Service, Bethesda, Md.

EXPERIMENTAL

Materials

Dimethyl phthalate, diethyl phthalate, dibutyl phthalate, di-isobutyl phthalate, di-(methoxyethyl) phthalate (Eastman Chemical Products, Inc.), butyl benzyl phthalate (Monsanto Chemical Co.), di-(2-ethylhexyl) phthalate (Eastman Chemical Products, Inc.), and dicapryl phthalate (Harchem Division, Wallace & Tiernan, Inc.).

All of the compounds were commercial products. Thin-layer chromatography and infrared analysis demonstrated that each of the samples had a relatively high degree of purity.

Methods

Acute Toxicity.—*LD_{50} Determinations.*—These were conducted according to the method and tables described by Thompson and Weil (12) and Weil (13). Each phthalate was administered intraperitoneally in Swiss Webster white mice of uniform weight and age in 4 dosage levels ranging from 0.5 Gm./Kg. to 16 Gm./Kg. Dosage levels were spaced in geometric progression, increasing by a factor of 2.

Effect of Phthalate on Hexobarbital Narcosis.—This study was conducted to measure acute CNS stimulation or depression following sublethal intraperitoneal administration of emulsified phthalates. Groups of 10 white mice weighing 14 to 20 Gm. were administered 500-mg./Kg. doses of the phthalate esters and, after an interval of 30 min., injected i.p. with 60 mg./Kg. of sodium hexobarbital. A control group of 10 mice received an equivalent volume of 3% acacia in place of the phthalate.

Rabbit Intradermal Irritation Tests.—Phthalate emulsions in concentration of 100 mg./ml. were injected 0.2 ml. intradermally into the cleanly shaven backs of rabbits. Inflammatory response at the injection site was measured by injection of 1 ml./Kg. of 1% trypan blue into the marginal ear vein after an interval of 15 min. (14, 15).

Acute Intravenous Toxicity.—Effects of phthalate emulsions on rabbit blood pressure, respiration rate, electrocardiogram pattern, and electroencephalogram pattern were recorded on the Grass Polygraph. Rabbits were anesthetized with approxi-

mately 33 mg./Kg. of sodium pentobarbital. Phthalates were emulsified in buffered 3% acacia solution and administered in repeated doses of 50 mg./Kg. through the cannulated external jugular vein directly into the heart. Blood pressure changes were recorded *via* the cannulated common carotid artery with the Statham transducer. Respiratory changes were determined from the cannulated trachea connected to a low pressure transducer (model PT 5A) through the Grass recorder. The EEG was taken using occipital leads, and the EKG taken from leads inserted subdermally in the limbs and chest. Two rabbits receiving only 3% acacia in equivalent volumes served as controls for record comparison.

Tissue Culture.—Toxicity of the phthalates to strain L 929 mouse fibroblast cells and to chick embryo cells was tested according to a method developed in our laboratory (16). Porous pads were wet with 0.05 ml. of a 50 mg./ml. emulsion of phthalates. The pads were placed on the surface of the agar and the cultures observed over a 48-hr. period for appearance of cell mortality.

Subacute Toxicity Studies.—These studies were conducted using 4 phthalic acid esters: diethyl, di-(methoxyethyl), butyl benzyl, and di-(2-ethylhexyl). From 20 to 30 white mice of uniform initial weight and age were injected daily with an emulsion of each phthalate for a period of 6 weeks. Dosage levels ranged from 125 mg./Kg. to 500 mg./Kg., depending on the toxicity or tolerance level for each. Weight gains were recorded weekly. Organ-to-body weight ratios for liver, kidney, lungs, heart, spleen, and testes were calculated at the end of the study and compared with normal values of a control group receiving only 3% acacia suspension. Pathology studies were made on certain of the organs using the standard formalin fixation and hematoxylin-eosin stains. Blood studies were made before injections began and again at the termination of the project before sacrifice. These studies included white and red cell counts, white cell differential counts, hematocrit, and hemoglobin levels.

RESULTS AND DISCUSSION

Acute Toxicity Studies

LD_{50} Determination.—The results of this study indicated that acute lethal i.p. toxicity of the phthalic acid esters studied was generally of a low order. LD_{50} values ranged from 1.58 Gm./Kg. for dimethyl phthalate to 14.19 Gm./Kg. for di-(2-ethylhexyl) and dicapryl phthalate (Table I). Although water solubility of all the compounds was extremely low, ranging from 1.5 Gm./100 Gm. to insolubility, a correlation appeared to exist between this factor and degree of toxicity indicated by LD_{50} values. The 3 esters with greatest solubility also exhibited greatest toxicity. As would be expected, an inverse relationship existed between toxicity and molecular weight of the compounds.

Effect of Phthalates on Hexobarbital Narcosis.—Sleeping time of the control group was 46 min. (Table II). Only 2 compounds gave indications of CNS stimulation as represented by significantly shortened sleeping time. These were di-(2-ethylhexyl) and dicapryl phthalate, each with a sleeping time of 36 min. These averages were significantly different ($p > 0.05$) from the control average. All other phthalates appeared to demonstrate CNS depression. Notable were diethyl, di-isobutyl, and butyl benzyl phthalates, with sleeping times of 88, 72, and 62 min. These 3 values were also significantly different ($p > 0.05$) from the control group.

TABLE I.—ESTIMATED LD_{50} VALUES FOR A SERIES OF PHTHALATE ESTERS

Phthalate Ester	i.p. LD_{50} in Mice, Gm./Kg.	95% Confidence Limits	Mol. Wt.	Solubility in Water, Gm./100 Gm.
Dimethyl phthalate	1.58	0.98 to 1.99	194	0.45
Diethyl phthalate	2.83	2.42 to 3.29	222	0.1
Dibutyl phthalate	4.00	2.94 to 5.45	278	Insol.
Di-isobutyl phthalate	4.50	3.36 to 6.02	278	0.01
Di-(methoxyethyl) phthalate	2.51	1.82 to 3.45	282	0.85
Butyl benzyl phthalate	3.16	2.51 to 3.98	312	Insol.
Di-(2-ethylhexyl) phthalate	14.19	12.62 to 15.76	390	0.01
Dicapryl phthalate	14.19	11.21 to 15.87	390	0.03

TABLE II.—HEXOBARBITAL SLEEPING TIME IN MICE

	Mice in Group, No.	Sleeping Time ± S.E., min.	CNS Effect: Depression	CNS Effect: Stimulation
Control group (0.5 ml. 3% acacia)	10	46 ± 1.66		...
Dimethyl phthalate	10	52 ± 1.15	+	...
Diethyl phthalate	10	88 ± 2.94[a]	+	...
Dibutyl phthalate	10	55 ± 2.18	+	...
Di-isobutyl phthalate	10	72 ± 2.83[a]	+	...
Di-(methoxyethyl) phthalate	10	50 ± 1.71	+	...
Butyl benzyl phthalate	10	62 ± 2.45[b]	+	...
Di-(2-ethylhexyl) phthalate	10	36 ± 1.14[b]	...	+
Dicapryl phthalate	10	36 ± 1.14[b]	...	+

[a] Indicates significant difference from control value ($p > 0.01$). [b] Indicates significant difference from control value ($p > 0.05$).

No satisfactory explanation for the evidence of CNS stimulation found for di-(2-ethylhexyl) and dicapryl phthalate could be elicited from these experiments, particularly in view of the fact that both of these showed a tendency to lower blood pressure at higher dose levels. The only supporting evidence of stimulation was seen in the EEG patterns after i.v. administration of dicapryl phthalate (see below). The order of the potentiation of narcosis followed the water solubility of the compounds. In view of the extremely lipid nature of the CNS, this order of narcosis potentiation was surprising. However, these compounds were administered as emulsions by the i.p. route, and from this route, the degree of absorption and consequently evidence of narcosis potentiation could have been due to a concentration at the site of action effect.

Rabbit Intradermal Irritation Tests.—Three phthalates—dimethyl, diethyl, and di-(2-ethylhexyl)—caused rapid and intense concentration of extravasated trypan blue at the injected sites (Table III), indicating marked inflammatory response.

TABLE III.—IRRITATIVE RESPONSE IN RABBITS TO INTRADERMAL INJECTIONS OF PHTHALATE ESTERS

Phthalate Ester	Degree of Extravasation[a] 10 min.	15 min.	26 min.
Dimethyl phthalate	++	+++	+++
Diethyl phthalate	+++	+++	+++
Dibutyl phthalate	+	+	++
Di-isobutyl phthalate	−	−	++
Di-(methoxyethyl) phthalate	++	++	++
Butyl benzyl phthalate	−	+	++
Di-(2-ethylhexyl) phthalate	+++	+++	+++
Dicapryl phthalate	−	+	+
0.85% NaCl (negative control)	−	−	−
20.00% EtOH (positive control)	+++	+++	+++

[a] Inflammatory response indicated by degree of dye extravasation; −, no color, negative reaction; +, mild; ++, moderate; +++, marked.

Others exhibited mild to moderate inflammatory response as indicated by low color intensities with greater lapses in time before appearance of the dye at the injection site. Dicapryl phthalate was the least irritating according to this test, showing only mild tissue response during the observation period. It should be noted that with the exception of di-(2-ethylhexyl) phthalate, the activity of these compounds as irritants was related to molecular weight.

Acute Intravenous Toxicity.—*Blood Pressure.*—With the exception of diethyl phthalate, none of the intravenously administered phthalates had dramatic or significant effect on the anesthetized rabbit blood pressure until a minimum total dose level of 350 mg./Kg. had been given. At this point, 4 of the phthalate compounds [diethyl, dimethyl, di-(2-ethylhexyl), and dicapryl] showed some depression of the blood pressure, indicating a vascular response to toxicity. In no case did the electrocardiograms or vector analysis of these results indicate direct cardiac toxicity. Therefore, the available evidence suggests an indirect cardiovascular toxicity at the higher i.v. dose levels. In the case of diethyl phthalate, each dose of 50 mg./Kg. administered i.v. caused a transient (about 3 min. duration) fall in blood pressure of about 20 mm. Hg, or approximately a 22% decrease. The blood pressure then gradually returned to the predose level, and no subsequent change ensued until administration of the next dose. A total dose of 650 mg./Kg. was given i.v. without death or other significant change in the animal, indicating a low order of toxicity. Administration of 5 doses of 3.0 ml. each of the vehicle (3% acacia) in control rabbits elicited no changes in blood pressure.

Respiration.—All of the phthalates administered i.v. caused an increase in the respiratory rate of the anesthetized rabbit. Since all were administered in a buffered (pH 7.0) emulsion over a period of about 2-3 min., the stimulation of respiration could not be attributed to a pH effect on the chemoreceptors. In 3 cases (dimethyl, diethyl, and diisobutyl phthalate), there were significant increases in respiratory rate after the administration of a total dose of 100 mg./Kg. The per cent increase for these 3 were 66.6, 71.2, and 114.3, respectively. The rate gradually returned toward normal over a period of about 5 min. It is of interest to note that these 3 compounds exhibited the highest order of toxicity in the LD_{50} study.

Electroencephalograms.—The electroencephalogram tracings obtained from occipital leads showed varying patterns after the administration of different phthalates intravenously. Figure 1 depicts several of the patterns seen both pre- and post-phthalate administration. The CNS depression pattern, obtained after administration of di-(methoxyethyl) phthalate, shows decreased frequency. The stimulation pattern, obtained after administration of dicapryl phthalate shows increased frequency, which appears to be a confirmation of the CNS stimulation exhibited in the hexobarbital narcosis study. It is also recognized that other influences such as anoxia, etc., may complicate EEG tracings, but no indication of these contingencies were noted in our experiments.

Tissue Culture Toxicity.—None of the phthalate emulsions demonstrated toxicity to chick embryo cells in the amounts used (0.05 ml. of a 50 mg./ml. emulsion). Three of the phthalates did show toxicity to mouse fibroblast cells (L-cells) in these same amounts. Microscopic examination of the dead cell zones revealed that the cells were intact and indicated absence of corrosive activity. Other results have shown that mouse cells are more sensitive to liquid toxicants than chick cells. Table IV shows the results of each phthalate on each system used. It should be noted that only the

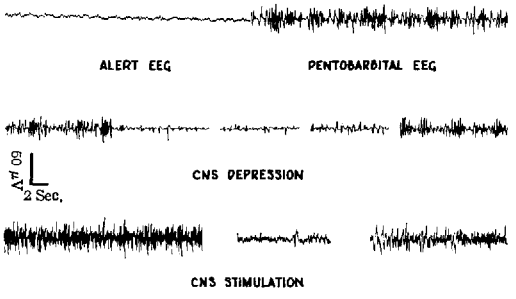

Fig. 1.—Occipital EEG patterns on rabbit. Key: ordinate and abscissa of insert (L) enlarged 2× for legibility of axis captions.

TABLE IV.—TOXICITY OF PHTHALATE ESTERS TO CULTURED CELLS

Phthalate Ester	Chick Embryo Cells, 50 mg./ml.[a]	Mouse Fibroblasts, 50 mg./ml.[a]
Dimethyl phthalate	−	+
Diethyl phthalate	−	+
Dibutyl phthalate	−	−
Di-isobutyl phthalate	−	−
Di-(methoxyethyl) phthalate	−	+
Butyl benzyl phthalate	−	−
Di-(2-ethylhexyl) phthalate	−	−
Dicapryl phthalate	−	−

[a] −, no cell toxicity; +, cell death.

compounds most soluble in water demonstrated toxicity to the cultured cells. This is not too surprising since the cell system is almost entirely aqueous. Two of the 3 exhibiting cell toxicity were also most irritating in the rabbit intradermal tests.

Subacute Toxicity Studies (Mice)

Body Weight Gains.—After 6 weeks of mouse intraperitoneal injections of 4 phthalates—diethyl, di-(methoxyethyl), butyl benzyl, and di-(2-ethylhexyl)—body weight in all groups, including controls, was approximately equal. The control group, however, reached maximum weight by the end of the third week, while in comparison, all phthalate-injected mice exhibited some degree of weight gain retardation, notably those receiving di-(2-ethylhexyl) phthalate, and, to a lesser extent, butyl benzyl phthalate. The diethyl phthalate group showed weekly weight gains most similar to those of the control group, and the di-(methoxyethyl) group exhibited an intermediate pattern. These differences in weight gain patterns may indicate a decreased food intake due to peritoneal cavity irritation caused by the repeated injections. It was observed on autopsy of each group of mice that some degree of peritonitis had been induced by the chemicals. The extent of peritonitis in the group of mice receiving the di-(2-ethylhexyl) phthalate was extreme. In nearly all of these cases, there was extreme adhesion formation, liver abscess, and adhesions to the diaphragm, and even testicle abscesses. These mice writhed and stretched after an injection, further supporting the observation of irritation of the entire peritoneal cavity.

Organ Weight–Body Weight Ratios.—Examination of organ-body weight ratios (Table V) indicated that liver weights in the di-(2-ethylhexyl) group were significantly greater and testis weights in the di-(2-ethylhexyl) and in the di-methoxyethyl) group were significantly less than the control group (in both groups $p > 0.01$). In regard to liver weights, however, it is doubtful that a genuine difference existed. Gross and pathological examination of these organs, particularly in the di-(2-ethylhexyl) group, indicated that organ weights were likely distorted by the effects of peritonitis. Adhesions, lesions, and other anomalies tended to prevent precise excision and cleaning of the organ before weighing. In addition, abscesses in the tissue changed the normal weight ratio. Testis weights indicated atrophy of this organ in the 2 above groups.

Hematology.—The hematological pattern of the several groups of mice receiving daily injections of the phthalate emulsions over a 6-week period indicated no significant deviations from the control group receiving only 3% acacia injections, with the possible exception of di-(2-ethylhexyl) phthalate. In this case, there was a slight decrease from original values in the hematocrit and hemoglobin and a slight increase in the red blood cell count. In all cases including controls there was a slight increase in white cell count, but this is to be expected after 6 weeks of daily injections.

Pathology.—In all of the test mice used in this study, there was some degree of peritonitis. Organs showing evidence of gross abnormalities were submitted for histopathological evaluation. These evaluations confirmed the original observations indicating acute peritonitis. Some organs from the phthalate injected groups were far more severely damaged than organs from the control group. In the case of di-(2-ethylhexyl) phthalate, nearly all organs showed presence of cloudy sedimentation accompanied by adhesions of the diaphragm, liver, and intestines and by abscess formation in the livers of a few. Liver and spleen of mice injected daily with di-(methoxyethyl) phthalate were found to have acute peritonitis and peri-portal hepatitis in the liver and extramedullary hematopoiesis in both the liver and spleen. The same pattern was also observed in the mice receiving the butyl benzyl phthalate, and in 1 testis there was an abscess of unknown etiology. In view of the irritation to rabbit tissue caused by intradermal injection, these results were to be anticipated. In these cases, a fairly strong irritant, comparable to the irritating action of 20% solution of ethanol, was injected daily and this was apparently enough to cause adhesions, peritonitis, and even some abscess

TABLE V.—EFFECT OF PHTHALATE ESTERS ON MOUSE TISSUE WEIGHTS

Group	Dosage, mg./Kg.	Organ Wt.–Body Wt. Ratio × 10^3					
		Liver	Heart	Lungs	Kidney	Spleen	Testes
Control		65.00 ± 1.83	4.72 ± 0.15	7.50 ± 0.36	13.29 ± 0.87	6.97 ± 0.85	6.94 ± 0.53
Diethyl phthalate	125	65.55 ± 3.45	4.51 ± 0.17	8.71 ± 3.78	13.27 ± 0.83	7.02 ± 0.80	7.07 ± 0.41
Di-(methoxyethyl) phthalate	250	65.12 ± 3.84	4.26 ± 0.25	7.56 ± 0.56	11.75 ± 0.75	8.04 ± 0.73	5.65 ± 0.34[a]

[a] Significantly different from control group averages ($p > 0.05$).

formation. The control animals in this study showed no gross or microscopic pathology.

SUMMARY

A group of phthalic acid esters were studied for both acute and subacute toxicity in animals. The acute toxicity experiments included the evaluation of LD_{50}, hexobarbital sleeping time effects, rabbit intradermal tests, acute intravenous toxicity studies, and tissue culture effects. Subacute toxicity dealt with effect on body weight gain, organ–body weight ratios, effect on tissue of various organs, and effect on the hematopoietic system. Results of the study indicated that the group of phthalate esters reported in this paper had a low degree of toxicity when administered parenterally and that their degree of toxicity was parallel to their water solubility (greater solubility, greater activity) and to their molecular weight (lower molecular weight, greater activity). This low order of toxicity to parenteral administration appears to indicate that their use in applications implicated in this study are probably warranted and safe.

Hydrolytic Behavior of Some Alkyl-Substituted Succinanils

By A. K. HERD, III*, LENNART EBERSON†, and TAKERU HIGUCHI

The mechanisms and the relative rates of alkaline hydrolysis of succinanil and methyl-substituted succinanils have been investigated partly to help to elucidate the mechanism of carboxyl facilitated formation and hydrolysis of amides observed in these laboratories and also because a number of important hypnotics possess similar structures. As may be expected, the observed rates for the several imides roughly parallel those found for the corresponding anhydrides, succinanil being more reactive than the methyl-substituted compounds. The relative rates were in the order: unsubstituted > monomethyl > mesodimethyl > 2.2 dimethyl > racemic dimethyl > trimethyl > tetramethyl; the first member of the series reacting 83 times faster than the last. The tetramethyl anil was found to be sufficiently stable to co-exist as the major species in equilibrium with its cleaved product at pH of 8.

ALTHOUGH a number of cyclic imides, including glutethimide, methsuximide, phensuximide, etc., are widely used as drugs, relatively little has appeared in the literature concerning the rate of hydrolysis of such imides. Results of studies on the effect of structure on some aspects of this hydrolytic reaction are presented at this time. In particular, the investigation has been concerned with the influence of alkyl substitution on the rate of hydrolysis of *N*-phenyl succinimides (succinanils) (I). These reactions are of interest

formation. The control animals in this study showed no gross or microscopic pathology.

SUMMARY

A group of phthalic acid esters were studied for both acute and subacute toxicity in animals. The acute toxicity experiments included the evaluation of LD_{50}, hexobarbital sleeping time effects, rabbit intradermal tests, acute intravenous toxicity studies, and tissue culture effects. Subacute toxicity dealt with effect on body weight gain, organ–body weight ratios, effect on tissue of various organs, and effect on the hematopoietic system. Results of the study indicated that the group of phthalate esters reported in this paper had a low degree of toxicity when administered parenterally and that their degree of toxicity was parallel to their water solubility (greater solubility, greater activity) and to their molecular weight (lower molecular weight, greater activity). This low order of toxicity to parenteral administration appears to indicate that their use in applications implicated in this study are probably warranted and safe.

they shed light on possible mechanisms of biochemical reactions.

It has been long recognized that methyl substitution generally increases ring stability. Thorp and Ingold and their students spent 15 years collecting evidence to substantiate this effect (1). Whether methyl substitution leads to greater thermodynamic stability for cyclic compounds than for their open-chain counterparts has not, however, been established with certainty. There is, nevertheless, evidence that methyl substitution aids in stabilization of the cyclic structure by accelerating the rate of ring closure (2). It had not been definitely ascertained, however, that methyl groups also stabilize the cyclic forms by inhibiting the rate of ring opening. Studies comparing anhydrides of dicarboxylic acids with their methyl-substituted analogs indicate that this may be the case (3). Whether this phenomenon is due to a steric hindrance to the attacking nucleophile or a steric hindrance to the linear separation of the 2 carboxylate groups is not yet clear.

Imide hydrolysis in general has not been the subject of great interest in recent literature, and hydrolysis of cyclic imides has received even less attention. Edward and Terry (4) have investigated the hydrolysis of succinimide in basic solutions and have shown that the rate of hydrolysis is first order in hydroxyl ion and first order in undissociated succinimide. Zerner and Bender (5) have shown that the hydroxyl-ion concentration is between pH 3.5 and 6.5.

EXPERIMENTAL

Materials.—The succinanils used in this investigation were prepared according to the method described by Fieser (6) for succinanil and were recrystallized from distilled water. Melting points of the products were compared with values given in the literature. Since the preparative method was straightforward, a good correspondence with melting points given in the literature was assumed as sufficient evidence for the existence of the compounds.

The dioxane used in this investigation was purified and made anhydrous by the treatment of technical grade dioxane as described by Vogel (7). Barium hydroxide solutions were prepared from carbon dioxide-free distilled water and sealed under nitrogen in glass ampuls. These samples were standardized against standard hydrochloric acid solutions. Corrections for appropriate ionic strength and temperature as affecting the partial dissociation of $Ba(OH)^+$ were estimated from the data of Gimblett and Monk (8).

The nitrogen which was used in the kinetic runs on the pH stat was passed over an Ascarite plug and bubbled through aqueous potassium hydroxide solution to remove carbon dioxide and prehumidified in a saturator at the reaction temperature. All the water used in these kinetic studies was freshly boiled and carbon dioxide free.

All other chemicals used in the preparation of buffers, kinetic solutions, and analytical reagents were analytical or reagent grade.

Kinetic Procedures for Hydrolysis of Succinanil and Methyl Succinanil.—The hydrolytic rate constants for these 2 compounds as a function of pH and temperature were determined in phosphate buffers of ionic strength 1.0 in a thermostated oil bath. Since it was found that the phosphate buffer catalyzed the hydrolysis of these compounds, each experiment involved determination of the hydrolysis rate at 5 buffer concentrations at the same pH and extrapolation to zero buffer concentration. The reaction solutions consisted of 99 ml. of the appropriate concentration of phosphate buffer and 1 ml. of a 1.2% solution of the anil in dioxane. The dioxane solution was added after the buffer solution had reached the required temperature in the oil bath. Five-milliliter samples were withdrawn periodically and quenched by diluting to 25 ml. with 0.25 *M* phosphate buffer at pH 6.0. These samples were analyzed spectrophotometrically at 240 mμ which is $\lambda_{max.}$ for the anilic acids. The appearance of the anilic acid was followed in this manner, and plots of $\log (A_\infty - A)$ *versus* time yielded straight lines from which k_{obs} could be calculated. Figure 1 shows plots of k_{obs} *versus* buffer concentration for succinanil at several pH values.

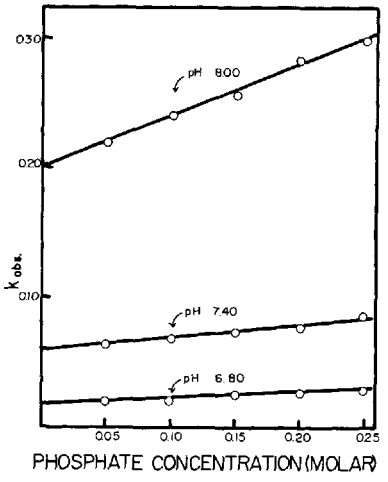

Fig. 1.—Plots of k_{obs} as a function of buffer concentration for hydrolysis of succinanil at 40°.

Kinetic Procedures for Hydrolysis of Methyl; meso-2,3-Dimethyl; 2,2-Dimethyl; Racemic 2,3-Dimethyl; and Trimethyl Succinanils.—The hydrolytic rate constants for this group of compounds were determined by use of a Radiometer TTT 1 automatic titrator with a SBR2 type Titrigraph and a TTA 3 titration assembly. Twenty-five milliliters of carbon dioxide-free water containing 1.45 Gm. of potassium chloride was placed in a water-jacketed beaker attached to a constant-temperature water bath. When the temperature had equilibrated, 1 ml. of a 1.2% solution of the anil in dioxane was added by means of a syringe and needle. The pH of the solution was maintained by the automatic addition of 0.025 *N* sodium hydroxide solution. Since the ml. of base added is directly proportional to the

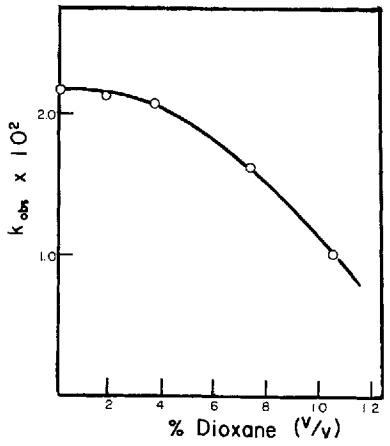

Fig. 2.—Plot showing dependence of k_{obs} for hydrolysis of methyl succinanil on dioxane concentration at 40° and pH 8.85.

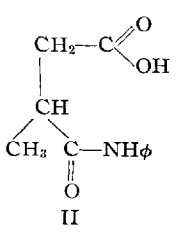
amount of anilic acid being produced, plots of log (ml.$_\infty$ − ml.) *versus* time yielded straight lines from which k_{obs} could be calculated. Spectrophotometric analysis indicated that the reaction had essentially gone to completion.

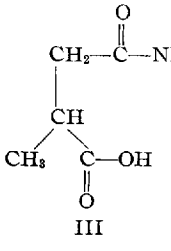
Since dioxane was used in these kinetic runs, the influence of dioxane concentration on k_{obs} was evaluated. Figure 2 shows values of k_{obs} for methyl succinanil as a function of dioxane concentration. At dioxane concentrations used in these experiments (3.84%), k_{obs} differed only slightly from k_{obs} at zero dioxane concentration.

Kinetic Procedure for Hydrolysis of Tetramethyl Succinanil.—Because of its slow rate of hydrolysis at lower pH values and because of the limitations of the pH stat method at higher pH values, the hydrolytic rate constants for tetramethyl succinanil were obtained in barium hydroxide solutions and were carried out directly in the sample cell of a thermostated Cary model 11 spectrophotometer. Twelve microliters of a 1.5% solution of the anil in dioxane was used for each run, along with 3 ml. of the barium hydroxide solution. The formation of tetramethyl succinanilic acid was followed by the change in absorption at 240 mμ. Plots of log (A_∞ − A) *versus* time yielded straight lines from which k_{obs} was calculated. Spectrophotometric analysis at the end of each run indicated that the anil had essentially hydrolyzed completely to the anilic acid.

Identification of Reaction Products.—All reaction products were identified spectrophotometrically. However, it must be mentioned at this time that in the hydrolytic cleavage of certain of the anils studied in this series, 2 different products are possible. For example, hydrolytic cleavage of methyl succinanil can yield the 2 isomers, II and III.



II



III

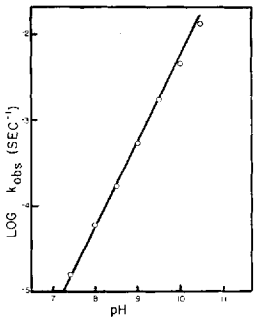


Fig. 3.—pH rate profile for hydrolysis of methyl succinanil at 40°. The solid line has been drawn with a slope of 1.00.

Probably a mixture of II and III is actually produced. Although one may expect purely on steric and electronic considerations that compound II would be the more prominent species, in this investigation no attempt was made to isolate and identify the products. The same was also true for 2,2-dimethyl and trimethyl succinanil.

RESULTS AND OBSERVATIONS

The second-order rate constants for a series of methyl-substituted succinanils were determined at temperatures ranging from 25 to 55°, and the kinetic parameters E_a and $\Delta S^\ddagger$ were calculated. From past work it might be expected that the hydrolysis would be independent of pH at low values (5), but at the pH values employed in this investigation, the reaction has been shown to be first order with respect to hydroxyl-ion concentration. It would appear, therefore, that the rate constants which are to be compared all stem from an identical mechanism. Figure 3 shows a pH-rate profile for the hydrolysis of methyl succinanil at 40°.

Table I lists all the anils studied in this investigation and their second-order rate constants calculated at 25°. The apparent E_a and $\Delta S^\ddagger$ values are shown also. The $\Delta S^\ddagger$ values were all calculated at 25°. The E_a values listed in this table for the first 6 compounds are 12.6 Kcal. less than those values calculated from the slopes of Arrhenius-type plots for runs made at constant pH. This accounts for the change in K_w with temperature.

DISCUSSION

The observed markedly decreased rate of hydrolysis of the succinanils induced by methyl substitution is not altogether unexpected. Although the nature of the activated states involved in the cleavage of these imides differs significantly from those responsible for formation of hydrolysis of the amic acids, there are some similarities. Considering the

TABLE I.—RATE CONSTANTS FOR OH$^-$-CATALYZED HYDROLYSIS OF ANILS AT 25°

Compd.	k (1/m/sec.)	E_a, Kcal./mole	$\Delta S^\ddagger$, (E.U.)

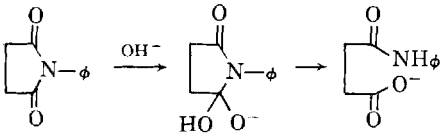
Trimethyl-	0.815	11.7	−22.0
Tetramethyl-	0.0669	9.4	−34.3

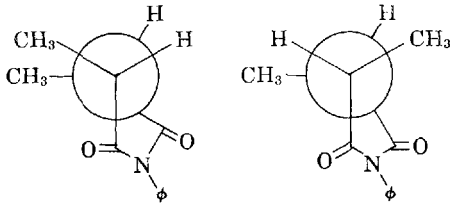
second-order character of the reaction, one can write Scheme I.



Scheme I

From this postulated mechanism, it is obvious that there are 3 general phenomena which could explain the decrease in hydrolytic rate with increased methyl substitution: (*a*) polar contribution of the methyl groups which would tend to reduce the $\delta+$ charge on the carbonyl carbon, thus reducing the rate of hydroxyl attack; (*b*) steric inhibition by the substituted methyl groups to the attacking nucleophile; and (*c*) steric hindrance to ring opening due to the presence of the methyl groups.

This last phenomenon has been pointed out by Bordwell and co-workers (9) in their studies on sultones. These workers show large decreases in rates of hydrolysis with increasing methyl substitution; they attribute this effect largely to steric hindrance of ring opening. They argue that in sultone hydrolysis, the ring opening must occur by a rotation about the bonds holding the severed groups, and that methyl substitution restricts this rotation. This line of reasoning may be applied in the present investigation to explain the difference in hydrolytic rates for the *meso* and racemic isomers of 2,3-dimethyl succinanil. Examination of Newman projections of these compounds indicate that in the *meso* isomer (IV) the methyl groups are already in an



meso IV

Racemic V

eclipsed position, and a rotation on cleavage would reduce this methyl–methyl interaction. On the other hand, a rotation in the racemic isomer (V) would increase methyl–methyl interactions. Since the polar effects and steric inhibition to nucleophilic attack in these two isomers would be expected to be similar, the steric inhibition to ring opening seems to be a reasonable approach for explaining the difference in hydrolytic rates of these 2 compounds (Table I).

Bruice and Pandit (3) have investigated the solvolysis of certain cyclic anhydrides, as well as the solvolysis of mono esters of these anhydrides and concluded that although a restriction of rotation of reacting groups away from each other markedly increases the rate of anhydride formation, it does not decrease the rate of anhydride solvolysis. They point out that although certain mono-esters of maleic acid form the anhydride about 50 times faster than the corresponding succinic monoesters, maleic anhydride solvolysis proceeds about 8 times faster than that of succinic anhydride. Their findings do not actually refute the suggestions of Bordwell *et al.*, since maleic anhydride hydrolysis would not involve a rotation but would probably relieve a strain imposed by the cyclic structure.

From the previous discussion and from the data presented in this investigation, it becomes apparent that no definite conclusions can be drawn concerning the differences in the hydrolytic rates of methyl-substituted succinanils at this time. This, of course, is due to the fact that the 3 possible phenomena which may be responsible for the change in rates cannot be separated. It can be suggested, however, that polar effects and steric inhibition to nucleophilic attack are mostly responsible for the differences in rates among the lower methyl-substituted compounds in this series and that a "steric hindrance to ring opening" effect becomes more pronounced as methyl substitution is increased. This is based on the fact that the relative rates change only slightly in the lower methyl-substituted members, while there is a greater rate change in the tri- and tetramethyl-substituted members of this succinanil series.

SUMMARY

Although hydrolytic cleavage of succinanils is not strictly related to anhydride formation occurring during the formation and hydrolysis of the succinanilic acids in dilute aqueous solutions, certain similarities are thought to exist. The hydrolytic rate constants were determined in aqueous buffered solutions for succinanil and methyl succinanil; in barium hydroxide solutions for tetramethyl succinanil; and by use of a pH stat for methyl, *meso*-2,3-dimethyl, 2,2-dimethyl, racemic 2,3-dimethyl, and trimethyl succinanil.

The fact that increased methyl substitution decreases the rates of hydrolysis in this series was not unexpected in light of previously compiled data. The interpretation of these results appears to be rather complicated since there were probably several factors, such as polar effects, steric inhibition to nucleophilic attack, and steric hindrance to ring opening, which would tend to decrease the hydrolytic rate. Although it was not possible to separate these effects, it is suggested that the last effect became more prominent as methyl substitution was increased.

The findings of this investigation seem to indicate that not only does methyl substitution markedly enhance ring formation, but it is also responsible for increased ring stability.

Interaction of Aqueous Polyethylene Glycol Solutions with Iodine

By C. F. HISKEY and F. F. CANTWELL

An experimental study of the interaction of iodine with the ether linkage of some polyethylene glycols was made. The conditions for producing 1 : 1 complexes of $-CH_2$ \ O : I_2 / $-CH_2$ were determined. Some qualitative observations are presented on the effects of polymer weight, polymer–iodine ratios in solution, and on the behavior of these complexes in analytical reactions.

SINCE the turn of the century (1) it has been known that iodine solutions in pure solvents are either violet or brown. Violet solutions are formed in such solvents as carbon disulfide, carbon tetrachloride, and simple aliphatic hydrocarbons. In these solvents the iodine has an absorption spectrum similar to that which it has in the gaseous state with an absorption maximum in the vicinity of 518 to 520 mμ, and with a molar absorptivity of about 1000 (2). Brown solutions are formed when the iodine is dissolved in alcohols, ethers, ketones, organic acids, and basic nitrogenous solvents. Hildebrand and Glascock (3) showed that, at least in alcohols and ethers, 1:1 complexes were formed, and later Mulliken (4) showed by means of molecular orbital argumentation, that iodine would bind to the oxygen of an ether at right angles to the plane of the molecule. These solutions have an absorption maximum around 450 to 460 mμ with a molar absorptivity a little bit less than that in the violet solution.

The blue form of iodine which is observed in the starch reaction or in the reaction of iodine with the cyclodextrins, benzonitrile, and coumarin complexes appears, from the X-ray diffraction studies of Cramer (5) to be due, not to the normal diatomic iodine form, but instead to a polymeric blue modification kept inside the channels within these inclusion compounds. Hence, these compounds are quite different from the ether–iodine complexes discussed here.

It is a well known phenomenon that the brown solutions tend to become violet when heated, reverting to their original color on cooling. Also it has been observed that in the case of the violet color of the carbon disulfide solution this may be shifted to the brown color as the solution is cooled in a dry ice–ether bath. Beckman (6) by means of precise molecular weight determinations in both the violet and the brown solutions established that the iodine is present in the diatomic state in both instances. Thus, the current view is that when the iodine forms a weak coordination complex the brown color is observed, but these complexes may be easily dissociated merely by heating.

In this paper it is our intention to report some phenomena which were observed when we attempted to do iodometric titrations in the presence of aqueous solutions of some polyethylene glycol polymers[1] (PEG). Their structures may be written as $HOCH_2 \cdot\cdot (CH_2OCH_2)_n \cdot\cdot CH_2OH$, where the average n varies from 7.2 to 8.1 in the case of PEG 400, from 20.1 to 22.3 for PEG 1000, and from 67.0 to 83.0 in the case of PEG 4000. The authors have written the formula this way instead of the usual way, *viz.*, $H(OCH_2CH_2)_{n+1}OH$, because we wish to stress the polyether character of these molecules. From the work of a group of investigators and inventors (8), it is well known that iodine forms complexes with such polymeric materials, but it seemed to us that a qualitative description of what we observed plus some of the quantitative measurements which were made would provide the analyst with an understanding of what occurs in the above-mentioned solutions.

EXPERIMENTAL, RESULTS, AND DISCUSSION

To study the quantitative aspects of the interaction of polyethylene glycols with iodine, it was decided to work with the higher molecular weight PEG 4000 which had qualitatively been observed to yield solid, filterable precipitates with KI_3 solutions. It was anticipated that a PEG which yields a precipitate with iodine in aqueous solutions would permit an evaluation of the limiting molar ratio I_2–PEG in the complex. To make this evaluation it would be necessary to form the precipitates in solutions with large excesses of KI_3 relative to the

Received October 20, 1965, from Endo Laboratories, Inc., Garden City, N. Y.
Accepted for publication December 16, 1965.

[1] Marketed as Carbowax by the Union Carbide and Chemical Co., New York, N. Y.

PEG. For this purpose the concentration of PEG 4000 is expressed as *molarity of* $—CH_2OCH_2—$ (mol. wt. = 44), and the contribution of the end $—CH_2OH$ groups to the molecular weight is neglected.

In the experiment, 10.0 ml. or less of an appropriately diluted stock solution of PEG 4000 was pipeted into ground-glass-stoppered flasks, enough water was added to make 10.0 ml., and then 10.0 ml. of 0.0554 *M* KI_3 solution was added. The mixtures were swirled and set aside in a dark place for from 3 to 6.5 hr., after which time the suspension was vacuum filtered through a membrane filter. An aliquot of each filtrate was pipeted into a flask, about 5 ml. of 1 *N* H_2SO_4 and 10 ml. of H_2O were added, and the solution was titrated to a colorless end point. The amount of unprecipitated iodine in the 20.0-ml. of reaction mixture thus is determined, and by difference the amount of complexed and precipitated iodine is known.

The data obtained are plotted in Fig. 1, with the ordinate representing the number of mmoles

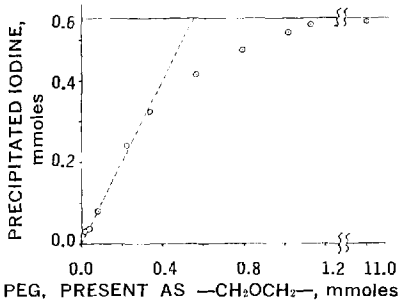

Fig. 1.—Precipitation of I_2 by PEG 4000.

of iodine precipitated and the abscissa representing the mmoles of $—CH_2OCH_2—$ added. It will be observed that at high ratios of iodine to ether, *i.e.*, where very small quantities of $—CH_2OCH_2—$ were added, each mole of $—CH_2OCH_2—$ added precipitated 1 mole of I_2. Thus, initially the points fall on the straight dotted line with a slope of unity. In the light of Hildebrand and Glascock's experimental observations and Mulliken's calculations, cited previously, this is exactly what one would expect.

As the amount of PEG added increases so that the iodine remaining in solution is depleted, a deviation from the straight line is observed, and the experimental points form a curve which asymptotically approaches the limiting value of 0.0554. This can be understood in terms of the competing equilibria in these solutions, the iodine being complexed by both the ether and the iodide ion present in solution. If the iodine–ether complexation constant was very much larger than that of the triple iodide ion, the experimental points would remain on the straight line right up to the limiting value of 0.0554. The fact that they do not merely indicates that they are approximately of the same order of magnitude. The value for the reaction ($I^- + I_2 \rightleftharpoons I_3^-$) is about 725 (9) at 25°.

In the course of the above experiment some interesting qualitative observations were made. These observations concern the color and character of the precipitates. In those solutions where the residual iodine concentration was high, the precipitates were dense and dark black with a submetallic lustre resembling that of iodine itself. On the other hand, where the mole ratio of ether to iodine was large, *i.e.*, 10 and higher, the precipitates were very much more voluminous and were light reddish-brown in color, becoming lighter as the ratio was increased.

Thus, it is apparent that when every ether oxygen is coordinated with iodine, a precipitate resembling iodine crystals in color and lustre is observed, but when the coordination is made to every tenth oxygen or less, the color of the precipitate appears more like that of a dilute ether solution of iodine. It was also evident that only a small fraction of the ether linkages had to be coordinated before the solubility of the PEG was reduced so that precipitation occurred.

Another interesting phenomenon was observed when precipitates with low iodine:$—CH_2OCH_2—$ ratios were washed with distilled water. These light reddish-brown precipitates immediately became much darker in color, and their appearance changed to that of the precipitates with the I_2:$—CH_2OCH_2—$ ratios of approximately 1. This occurred whether they were washed by decantation or directly on filter paper. In addition it was observed that there was a substantial reduction in the volume of the precipitate. Furthermore, the filtrate or the supernatant from such a washing has a light but definite yellow color. A possible explanation of this phenomenon follows.

The PEG 4000 precipitate can be assumed to have the iodine randomly distributed among its ether oxygens, but weighting each individual molecule sufficiently so that it is made insoluble. However, not every oxygen position is coordinated with iodine as evidenced by the light color of the precipitate. On washing, however, disproportionation occurs with iodine from some of the molecules being transferred to others, producing complexes that have a higher I_2:$—CH_2OCH_2—$ ratio and ones which have a much lower ratio. The former of these which approach the 1:1 complex are dark and insoluble, whereas the latter having a relatively small number of ether oxygens complexed with iodine, are light colored and water soluble. The effect is indeed a very striking one to observe.

Additional Qualitative Observations.—In light of the phenomena which have been described above, it was thought appropriate to make a qualitative comparison between the interaction of the KI_3 solutions with PEGs of various molecular weights. Those available were PEG 400, 1000, and 4000. The purpose of this study was to determine the relative ease of precipitating the lighter and heavier PEGs, using minimal amounts of iodine to accomplish that objective. The actual experiment performed was to dissolve 6.0 Gm. of each of the PEGs in 10.0 ml. of water. This makes a solution which is 13.6 *M* in ether linkages. Again the terminal $—CH_2OH$ groups are ignored. These 10.0-ml. portions of PEG solutions were titrated dropwise with an 0.0554 *M* KI_3 solution with continuous agitation. In all 3 cases, as the first drop and each successive drop of KI_3 was added, a reddish-brown precipitate formed in the area where the drop initially contacted the solution. However, it dissolved with agitation to give a yellow solution

TABLE I.—ASSAY RESULTS WITH POLYETHYLENE GLYCOLS

PEG	ml. KI_3 to Achieve Precipitation	mole Ratio, $-CH_2OCH_2-$ / KI_3	I_2, % Easily Titratable
400	8.5	290	98
1000	4.2	585	43
4000	3.5	713	...

which became more and more wine-red in color as more KI_3 was added. Finally, as the titration continued, there came a point at which the reddish-brown turbidity persisted, and further addition of KI_3 only increased the amount of turbidity. The second column of Table I lists the ml. of titrant required just to reach the point of permanent turbidity for each of the PEGs.

It will be seen that as the molecular weight of the PEG increases, the amount of KI_3 needed decreases. In the third column of Table I this is further illustrated by presenting the mole ratio of ether linkages to the KI_3 at that point. After the point of permanent turbidity had been reached, enough additional KI_3 was added to bring the volume of that reagent to 10.0 ml. The precipitates obtained were watched for the next 1.5 hr. to observe alterations in their characteristics. In the case of the PEG 400, the solution initially had a reddish-brown suspension in it, but with time and occasional swirling of the flask, this precipitate coalesced to give a few drops of a dark black liquid. When the supernatant liquid was decanted, these globules collapsed and appeared to wet the glass. The thin films formed in this way were dark red by transmitted light.

In the case of PEG 1000, as the precipitate aged, a dark black portion of liquid material similar to that observed with the PEG 400 and some light reddish-brown wax-like solids were observed. In the case of the PEG 4000, the changes which occurred were not very striking, except that the very light brown precipitates that formed initially appeared to get darker with time and to diminish to some extent in volume. After about 15 min. this precipitate had settled out, leaving a very lightly straw-colored solution above it.

The situation obtained in these solutions after the rapid addition of the additional KI_3 to make the final 10.0 ml. is one where the mole ratio of ether oxygens to iodine is still quite high, being about 246. It is evident for precipitation to occur under such circumstances, that the iodine be concentrated on some molecules, rendering them insoluble, while the bulk of the remaining molecules have so few iodine atoms on them that they remain in solution. This is the final situation which prevails after a period of time sufficiently long to bring the system to equilibrium.

When the lower molecular weight PEG is used, the iodine concentrates on the precipitated molecules to give them an iodine–ether ratio close to unity as evidenced by their dark color. With the higher molecular weight polymers a lower ratio leads to precipitation.

The changes that occurred with time are those associated with bringing the system to this disproportionate equilibrium and to coalescence of the liquid-like product from the lower polymers, and perhaps some aging of the higher polymer precipitates.

Several interesting additional observations were made. The first is concerned with the relative ease of dissociating these precipitated complexes. This was studied by titrating the iodine with standard $Na_2S_2O_3$, employing moderate agitation of the solution during the titration. The titrations were performed rapidly, *i.e.*, in a matter of several minutes, to see how quickly the iodine became available. The titrant was added until the supernatant was just colorless. The per cent recovery of the iodine is given in the fourth column of Table I. In the case of the PEG 400, nearly all of the iodine was recovered immediately, and with vigorous and prolonged agitation, the small residual amount of dark material could be brought into solution with all of the iodine being recovered. With PEG 1000, however, this is not so easily accomplished. The iodine is tenaciously retained by the precipitate and only 43% could be readily recovered. With the PEG 4000, recovery was essentially zero or very little, and also the precipitate interfered with the end point detection.

A second observation, relating to the dissociation of these complexes was made when a solvent like propylene glycol was added. If it was added to the extent of about 50 vol. %, precipitation of the iodine–PEG complexes was avoided completely. If the propylene glycol was added with heating after precipitation had been effected, the precipitates redissolved, and quantitative recovery of the iodine was achieved. The explanation here, of course, is that an additional coordinating reagent has been added which is competing nearly as strongly as the PEG itself for the iodine. Consequently, the PEG coordinates only a small fraction of the iodine, insufficient in amount to achieve precipitation. Furthermore, this alcohol has a greater solvent effect than water, for both the PEG and the PEG–iodine precipitate.

Two additional observations of interest were the following: aqueous solutions of the PEGs can extract, to a degree, the iodine present in the violet-colored chloroform and carbon tetrachloride solutions, and the vapor pressure of iodine over well-dried PEG–iodine precipitates was significantly lower than that of iodine itself. If the PEG 1000–iodine precipitate was heated on a spatula, the iodine could be driven off, but the reaction was slow and the temperature had to be in excess of 100°.

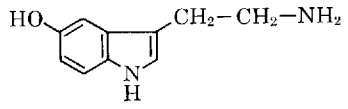
Preparation and Biological Evaluation of Some *N*-Amino Acid Substituted Derivatives of Serotonin

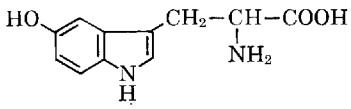
By ALBERT J. FORLANO and ROBERT L. S. AMAI*

A series of *N*-amino acid substituted derivatives of serotonin was prepared. The method entailed condensing the α-halo analogs of alanine, isoleucine, phenylalanine, and valine with 5-benzyloxy-serotonin using a method adapted from Fisher's peptide synthesis. The activity of these compounds was compared with 5-hydroxytryptophan in an Actophotometer to determine their effect on generalized activity in mice. The results are presented along with some possible explanations for the biological observations.

HIGH cerebral levels of serotonin are known to produce a significant increase in central stimulation (1–3). Woolley (4) stated that hallucinations, agitation, and other signs of excitation are found in individuals with elevated cerebral levels of serotonin and that decreased levels can lead to depressive states. There is also an implication that an abnormality in serotonin metabolism may be responsible for schizophrenia (4). The biosynthesis of serotonin (I) in animals commences with the natural amino acid tryptophan which is obtained from dietary sources (5). 5-Hydroxytryptophan (II) is produced by hydroxylation of the amino acid in the 5-position of the indole ring by an enzyme system having NADP as one of the coenzymes. The latter



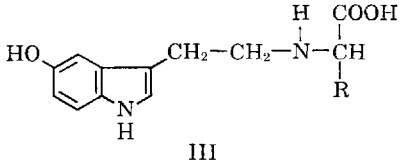
I



II

compound (II) is easily decarboxylated to the hormone serotonin (I) by 5-hydroxytryptophan-decarboxylase, which contains pyridoxal phosphate as a coenzyme. Serotonin is not produced in animals by the direct 5-hydroxylation of tryptamine (5).

Shaw and Woolley reported that exogenous serotonin does not pass from the blood into the brain very readily (6–8). Instead, the parenteral administration of serotonin produces powerful intestinal contractions, increased tissue permeability, and a rise in blood pressure. Therefore, if one wanted to observe the central effects of serotonin, a substance like 5-hydroxytryptophan (II) would be necessary. This compound can pass through the blood brain barrier where it is subsequently converted to serotonin (2, 9). Since serotonin (I) cannot pass from the blood into the brain, it appears likely that the carboxyl group of 5-hydroxytryptophan may be necessary for its transport into the brain. Evered and Randall (10) have shown that it is possible to transport cytoactive drug molecules into cells by linking them to actively transported natural amino acids as carriers. Considering these factors, it was believed that a series of compounds with unique properties could be produced if serotonin was linked to some natural amino acids. These compounds would: (*a*) have the free carboxyl group that appears to be necessary for transport across the blood brain barrier and (*b*) have natural amino acids for anchoring purposes to carrier and metabolic receptor sites. The proposed series of compounds are derivatives of structure III, where R represents the tail portion of the various amino acids used.



III

The synthesis of these compounds was initiated by treating 5-benzyloxyindole (IV) with oxalyl chloride to produce 5-benzyloxy-3-indoleglyoxalyl chloride (V). The acid chloride was converted to the amide (VI) by treatment with concentrated aqueous NH_3 and was subsequently reduced to 5-benzyloxytryptamine (VII) with $LiAlH_4$. The 5-benzyloxy derivatives of III were produced by condensing the appropriate α-

halo analogs of the amino acids with the amine (VII). These were debenzylated by catalytic hydrogenation using Pd/C catalyst. The complete reaction is presented in Scheme I.

EXPERIMENTAL[1]

The first part of this section deals with the preparation of 5-benzyloxytryptamine (VII) which was used as the common intermediate for condensation with the α-halo analogs of the amino acids.

5-Benzyloxytryptamine (VII).—This compound was produced in 41% yield based on the starting material using the method of Lipp *et al.* (11). 5-Benzyloxytryptamine HCl (12) was converted to the base by treatment with aqueous KOH and extraction with diethyl ether.

N - (5 - Hydroxy - 3 - indole - ethyl) Alanine (IIIa).—Compounds (III*a–d*) were prepared by a modification of the method suggested by Fischer and Otto (13, 14) for the synthesis of peptides. Seventeen grams (0.064 mole) of 5-benzyloxytryptamine was dissolved in 50 ml. of recently boiled and cooled *N,N*-dimethylformamide (DMF). In a separate vessel 10.85 Gm. (0.10 mole) of α-chloropropionic acid (Eastman Red Label) was mixed with 20 ml. of DMF and enough 1.0 *N* KOH to neutralize the acid. The 2 solutions were transferred to a reflux flask and water was slowly added until the mixture became homogeneous. An additional 0.01 mole of KOH was added, and the solution was refluxed for 12 hr. During this time more base was added if necessary to maintain the pH slightly basic; however, large excesses were avoided because of the possible hydrolysis of DMF. The reaction mixture was diluted with twice its volume of 1 *N* aqueous KOH and any unreacted amine which precipitated was removed by extraction with ethyl ether. The solution was adjusted to pH 4.0 with glacial acetic acid and placed in a refrigerator for 24 hr. The product *N*-(5-benzyloxy-3-indolethyl) alanine was removed by filtration and washed with hot isopropyl alcohol. It was then suspended in 150 ml. of ethanol and water mixture (1:1) which contained 2.0 Gm. of 10% Pd/C (Matheson, Coleman and Bell). The product was debenzylated in a Parr hydrogenator at a pressure of 50 psig for 1 hr. The catalyst was removed by filtration and the solvent was removed under vacuum. The residue was crystallized from an isopropanol–water mixture and dried yielding 6 Gm. (23% yield) of *N*-(5-hydroxy-3-indole-ethyl) alanine·$1H_2O$, m.p. 238–243° dec.

Anal.—Calcd. for $C_{13}H_{18}N_2O_4$: C, 58.70; H, 6.79; N, 10.55. Found: C, 59.00; H, 6.93; N, 10.30.

N - (5 - Hydroxy - 3 - indole - ethyl) Valine (IIIb).—This compound was prepared in a similar manner to the alanine derivative (III*a*). Seventeen grams (0.064 mole) of 5-benzyloxytryptamine was reacted with 18.1 Gm. (0.10 mole) of α-bromo-

[1] All melting points were taken on a Fisher Johns apparatus and are uncorrected. Microanalyses were performed by Organic Microanalysis, Montreal, Ontario, Canada.

β-methylbutyric acid (Eastman Red Label). The *N*-(5-benzyloxy-3-indole-ethyl) valine derivative had a m.p. of 225–230° after crystallization from an ethanol–water mixture. After debenzylation and crystallization from the isopropanol–water mixture, 7.0 Gm. (25% yield) of the title compound was produced, m.p. 240–245° dec.

Anal.—Calcd. for $C_{15}H_{20}N_2O_3$: C, 65.20; H, 7.30; N, 10.14. Found: C, 64.90; H, 7.19; N, 10.35.

N - (5 - Hydroxy - 3 - indole - ethyl) Phenylalanine (IIIc).—This compound was prepared in a similar manner to the alanine derivative (III*a*). Sixteen grams (0.06 mole) of 5-benzyloxytryptamine was refluxed with 20 Gm. (0.086 mole) of α-bromo-β-phenyl propionic acid (K & K Laboratories, New York, N. Y.) for 3 hr. The benzyloxy derivative had a m.p. of 200–205°. The debenzylated product was crystallized from an isopropanol–water mixture, and 6.5 Gm. (20% yield) of the title compound was produced, m.p. 235–238° dec.

Anal.—Calcd. for $C_{19}H_{20}N_2O_3$: C, 70.35; H, 6.21; N, 8.64. Found: C, 70.03; H, 6.54; N, 8.73.

N - (5 - Hydroxy - 3 - indole - ethyl) Isoleucine (IIId).—This compound was prepared in a similar manner to the alanine derivative (III*a*). Sixteen grams (0.06 mole) of 5-benzyloxytryptamine was refluxed with 20 Gm. (0.10 mole) of α-bromo-β-methyl valeric acid (K & K Laboratories, New York, N. Y.) for 3 hr. yielding the 5-benzyloxy derivative, m.p. 205–210° dec. The debenzylated product was crystallized from an isopropanol–water mixture and 5 Gm. (17.2% yield) of the title compound was produced, m.p. 212–215° dec.

Anal.—Calcd. for $C_{16}H_{22}N_2O_3$: C, 66.18; H, 7.64; N, 9.65. Found: C, 65.39; H, 7.52; N, 9.81.

BIOLOGICAL TESTING

The objective of the biological testing was to determine whether these compounds had any central stimulating activity. Woolley (4) stated that high serotonin levels in the brain caused hallucinations and other signs of excitation. Since cerebral serotonin levels cannot be raised by extracerebral injections of serotonin (2, 9) a precursor substance such as 5-hydroxytryptophan (II) was used as the standard for comparison of the serotonin activity of the new compounds. The test group consisted of four 25-Gm. white mice. All the activity measurements were conducted in an Actophotometer (Metro Industries, Long Island City, N. Y.) which is designed to measure the general activity of the mice. Subcutaneous doses of normal saline solution, 2 mg. of 5-hydroxytryptophan, or the molar equivalent of compounds III*a–d* (2.26, 2.40, 2.94, and 2.62 mg., respectively) were administered, and the activity of the mice was determined periodically during a period of 5 hr. It was necessary to add minimal amounts of 0.1 *N* NaOH to solubilize some of the compounds so that the total dose was contained in 0.2 ml. The second series consisted of the simultaneous injection of equimolar mixtures of 5-hydroxytryptophan (2 mg.) and the test compounds. The results are presented in Tables I and II.

DISCUSSION

While the synthesis of serotonin and 5-benzyloxytryptamine are not new, the preparation of these *N*-substituted amino acid derivatives does represent a new concept. It is well established that natural amino acids can readily pass through cell walls with the aid of active transport systems. Serotonin, however, cannot pass from the blood into the brain very readily (6–8); therefore, the joining of the hormone to an amino acid *via* a covalent bond to assist in transporting it into the brain proposes an interesting concept.

The biological testing of these compounds suggest some reasons for their lack of central activity. The data in Table I show that a 2.0-mg. dose of 5-hydroxytryptophan per mouse slightly lowered

the generalized activity when compared to that of a saline control. This is substantiated by the work of Woolley (15), who also noted that 2.5-mg. doses of 5-hydroxytryptophan per mouse caused either normal or slightly subdued activity. A possible reason for the lack of activity of small doses of 5-hydroxytryptophan is suggested by Gal *et al.* (16), who observed that intracerebral injections of labelled L-tryptophan in rats and pigeons produced a significant increase in cerebral serotonin levels; D-tryptophan, however, did not increase the serotonin levels but in fact caused a decrease. They also noted that intraperitoneal injections of L-tryptophan, at a dose level 17 times greater than the intracerebral dose did not result in the formation of any labelled serotonin in the brain. While it is true that Gal used tryptophan and not 5-hydroxytryptophan, there may be still some analogy. In the present study racemic 5-hydroxytryptophan was injected subcutaneously. Possibly some of the D-5-hydroxytryptophan entered the brain where it acted as an antagonist to the decarboxylation of L-5-hydroxytryptophan resulting in a decreased cerebral serotonin level with generalized reduction of activity. Another factor to be considered is that other organs besides the brain such as the liver can decarboxylate 5-hydroxytryptophan and bind serotonin resulting from extracerebral administration. These factors may account for the lack of stimulation demonstrated by the 2-mg. dose of 5-hydroxytryptophan. Woolley (15) also stated that large doses of 5-hydroxytryptophan (15 mg./mouse) produced marked excitement, convulsions, and agitation. It appears thus that the smaller doses are metabolized outside the brain and produced the classical symptoms on the gastrointestinal tract and blood pressure. The administration of larger amounts may be partially available to the brain because the extracerebral metabolism sites become saturated and allow some to enter the brain, thus resulting in central stimulation.

The data in Tables I and II show that the derivatives do not produce greater stimulation than 5-hydroxytryptophan when used alone or in combination with the latter compound; in fact, there is a diminution of central activity when compared to the saline control. While it is possible that the use of larger doses of the derivatives may have caused some evidence of central activity, higher doses could not be used because of the pain and tissue necrosis at the injection site. Consequently, one would not have been able to determine if the increased activity was due to central stimulation or to pain of injection.

In conclusion, therefore, the reason for the lack of central stimulation is not readily apparent at this time.

SUMMARY AND CONCLUSIONS

1. The synthesis of a series of *N*-(5-hydroxy-3-indole-ethyl) amino acid derivatives containing alanine, valine, phenylalanine, and isoleucine is described.

2. These compounds were evaluated in mice to determine their effect on generalized activity.

3. The results indicated that these compounds when used either alone or in combination with 5-hydroxytryptophan did not produce any significant increase in activity over the 5-hydroxytryptophan standard.

4. The results suggest that these compounds either are unable to enter the brain or that they are functioning as metabolic antagonists of 5-hydroxytryptophan.

Applications of Aqueous Thermometric Titration to Pharmaceutical Analysis

By ALBERT B. DELEO and MARVIN J. STERN*

Aqueous thermometric titration with standard HCl, NaOH, or $AgNO_3$ as titrant was used successfully for the analyses of aminophylline (ethylenediamine and theophylline), chlorpheniramine maleate, chlorpromazine hydrochloride, hydrochlorothiazide, and niacinamide. Most of the determinations were based on titration volumes. In cases where the curvature of the enthalpogram in the vicinity of the end point was severe, the quantitative result was derived from the temperature change due to the reaction. Exploratory studies of the applicability of simple aqueous thermometric titration, without prior separation of ingredients, to the analysis of solid and liquid dosage forms of the above compounds were conducted. With all but 1 of the solid dosage forms investigated, no interferences from inert ingredients were observed. In some of the liquid dosage form systems studied, the vehicles interfered with the titrations, while in others they did not.

THE POSSIBLE application of aqueous thermometric titration to pharmaceutical analysis was reported in a recent communication from this laboratory (1). The present paper describes the procedures and results of the aqueous thermometric titration of selected pure medicinal substances and of some preliminary studies concerning the application of thermometric titration to dosage form analysis.

The large number of systems to which thermometric titration may be applied has been the subject of several reviews.[1] The investigation described in this report was concerned primarily with simple acid-base and precipitation reactions of nitrogenous compounds. It is well known[1] that a thermometric titration will often produce a well-defined end point in a system where free energy methods such as potentiometric titration fail. Thus, in the first phase of this study, compounds whose official or other assay procedures require *nonaqueous* titration were chosen for testing the applicability of *aqueous* thermometric titration.

The second phase of this study was concerned with the assay of dosage forms. At present, "inert" binder, filler, and sealer materials, required to manufacture most solid dosage forms, often necessitate the use of separation procedures prior to the assay of the active ingredients. The problem also exists with liquid dosage forms where "inert" substances in the vehicles often interfere with the use of visual indicators and electrodes. Unfortunately, most separation procedures are tedious as well as time consuming.

While the enthalpogram for a thermometric titration of a single reacting substrate undergoing a single-step reaction is characterized (ideally) by a single "break" at the end point, the enthalpogram for a titration of 2 substrates (or a single substrate undergoing a 2-step reaction) may or may not be characterized by 2 breaks. First, the free energies of the 2 reactions must be sufficiently different so that the reactions do not occur simultaneously. Second, the enthalpies of the 2 reactions must also be sufficiently different so that the point where one reaction ceases and the second commences is discernible. One hopes then that the enthalpogram of a thermometric titration of a dosage form will be characterized by a single end point corresponding to the reaction of the active ingredient (*i.e.*, the other substances present do not react) or, if more than one substance reacts, that the thermodynamic factors are favorable, so that the enthalpogram exhibits a series of end points, the volumes between the end points corresponding to individual reactions occurring during the titration. If either hope is fulfilled, the need for prior separation of the active ingredient is eliminated.

were dried according to standard procedures but not purified further. Dosage forms were purchased on the open market. Standard HCl and NaOH solutions were purchased as certified volumetric solutions. Standard $AgNO_3$ solutions were prepared from reagent grade $AgNO_3$. Only recently boiled water was used throughout. The acetone used in the hydrochlorothiazide titrations was reagent grade.

Apparatus.—The titration cell assembly, which consisted basically of a small stoppered standard Dewar flask, a 2000-ohm bead-in-glass-probe thermistor, a right-angled titrant delivery tip, and a glass stirrer with 4 quadrantal blades, is shown in Fig. 1. The thermistor and delivery tip extended to ~3 mm. above the stirrer blades. The delivery tip was positioned so that the flow of titrant was counter to the flow of the solution in the flask. The stirrer was powered with a Synchro-Tork stirring motor (General Laboratory Supply Co., Paterson, N. J.). Titrant was delivered with a 0.6 ml./min., constant-flow Menisco-matic buret (American Instrument Co., Inc., Silver Spring, Md.).

The titration cell, stirring motor, and buret were enclosed in a constant-temperature air bath, maintained at 25.0 ± 0.1°. The air bath was a closed system in which air was recirculated. Cooling was achieved with copper cooling coils, in and around the air duct, through which cold water was circulated. A 200-w. (at 115 v.a.c.) heating coil in the air duct was set, with an auto-transformer, to maintain the air bath at approximately 24.5°. A 100-w. (at 115 v.a.c.) heating coil, also in the air duct, was controlled with a Micro-Set (mercury-column) thermoregulator (Precision Scientific Co., Chicago, Ill.) set at 25.0°. The voltage to the 100-w. heater was adjusted with a power rheostat to give minimum "overshoot." The exhaust fan and air entry portals were diagonally opposite each other and were equipped with deflector vents to cause turbulent flow of air in the bath. The temperature could be maintained at the desired level over extended periods. The bath was also equipped with a safety

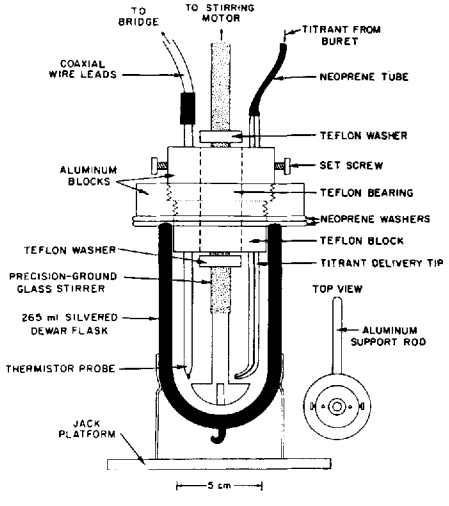

Fig. 1.—Titration cell assembly.

circuit breaker which automatically shut off the 200-w. heater in case the temperature of the bath exceeded 35°. Switches on the air bath permitted the operation of the stirrer and buret from the outside.

The thermistor was actually 1 arm of a simple bridge circuit, only slightly modified from the one described by Jordan and Alleman (2). The imbalance potential of the bridge was recorded with a 5-mv. Dynamaster recorder (The Bristol Co., Waterbury, Conn.). In cases where the magnitude of the heat change was low, the bridge signal was amplified by a factor of 5 with a solid-state variable recorder amplifier (Instruments and Communications, Inc., Wilton, Conn.).

Titration Procedure

Pure Substances.—One-liter volumetric solutions were prepared and allowed to reach thermal equilibrium, along with the standard titrants, for several hours in the air bath. The slow and low solubility of hydrochlorothiazide in water necessitated dissolving the compound in 20 ml. of acetone and slowly dispersing the acetone solution in water while stirring. The small amount of acetone (2%) appeared to have negligible effect on the titrations.

Exactly 100 ml. of solution was placed in the Dewar flask which was then positioned on the stationary titration cell head with a laboratory jack. The stirrer and bridge were turned on and the system allowed to attain thermal equilibrium. Equilibration generally required 5–10 min. and was indicated by a linear base line on the recorder. The buret was then turned on and the titration allowed to proceed until well after the end point(s) was reached.

Dosage Forms.—All dosage forms were titrated without prior separation procedures. A suitable quantity of the dosage form was dispersed, in the Dewar flask, in enough thermally equilibrated (25.0 ± 0.1°) water to make ~100 ml. In the case of hydrochlorothiazide tablets, a slurry of the powdered tablet in 5 ml. of acetone was prepared and then diluted to ~100 ml. with water. Titrations were then performed in the same manner as described for pure substances.

U.S.P. Assays

The pure substances were also analyzed by the procedures (usually nonaqueous titration) given in the U.S.P. (3).

Treatment of Data

An idealized enthalpogram for the thermometric titration of a single substrate undergoing a single reaction is shown in Fig. 2. The factors contributing to the various portions of the curve have been discussed. (See *Footnote 1.*) The section of the curve between the start of the titration and the end point is called the titration branch. The extrapolation method for obtaining the titration volume, ΔV, and the temperature rise *due to the reaction* (in arbitrary units), ΔT, is indicated on the curve.[5] For 1 titration system, chlorpromazine hydrochloride *versus* NaOH, ΔV's were also determined with

[5] Enthalpograms are usually recorded with a temperature rise reflected as an *increased* voltage. In the present investigation, this convention was used.

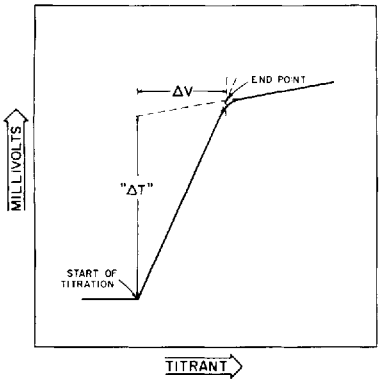

Fig. 2.—Idealized enthalpogram.

an automatic end point determination device. The procedure used has been described (4).

Pure Compounds.—Most of the analyses of the pure compounds were made by calculating the amount of substrate from the measured ΔV and the known concentration of the titrant. In 2 cases, theophylline in aminophylline *versus* NaOH and hydrochlorothiazide *versus* NaOH, the curvature in the vicinity of the end point was too severe to allow reliable extrapolation for measurement of ΔV. In these cases, quantitative determinations were made from the ΔT measurements. ΔT values from titrations of various concentrations (always 100 ml.) of the compound under consideration and of hydrochloric acid *versus* 2.0 *M* NaOH were measured. The slopes, B, of plots of ΔT *versus* molarity of substrate, M, were obtained by least-square fitting to the equation $\Delta T = BM$. The relative slope, B_H/B_C, where the subscripts H and C refer to hydrochloric acid and the compound under consideration, respectively, was evaluated. Since the B's were obtained from titrations of dilute solutions run under essentially the same conditions,[6] the relative slope should be identical to the ratio of the molar enthalpies of the reactions. Once B_H/B_C has been determined, a solution of unknown concentration of the compound under consideration can be analyzed by performing a titration of the unknown and following it with a titration of known concentration of hydrochloric acid run under identical conditions. It is easy to show that

$$M_C = M_H\,(\Delta T_C/\Delta T_H)\,(B_H/B_C) \quad \text{(Eq. 1)}$$

where the relative temperature rise, $\Delta T_C/\Delta T_H$, is determined from the enthalpograms, and M_H is the known concentration of hydrochloric acid.

Dosage Forms.—The amounts of active ingredients in the dosage forms were calculated by an absolute method and/or a standard addition method. In the absolute method, the amount of active ingredient was calculated from ΔV and the concentration of the titrant. In the standard addition method, ΔV for the titration of the dosage form was compared, in the obvious manner, to ΔV for a similar titration of the same amount of dosage form plus an accurately weighed portion of active ingredient. In the standard addition method, the purities of the added portions of active ingredients were taken to be exact.

Dosage form analyses were not carried out with ΔT measurements, because the results of the ΔT analyses of the pure compounds indicated that there are uncertainties involved in measuring relative heats without a calibration heater. In addition, there is no assurance in a dosage form titration that all reactions have ceased after the last observed end point. The later condition is necessary for the application of the back-extrapolation method for obtaining ΔT shown in Fig. 2.

RESULTS AND DISCUSSION

Pure Compounds.—Figures 3 and 4 show typical enthalpograms for the 8 titration systems investigated in detail. The 3 systems represented in Fig. 4 involve precipitate formation.

An enthalpogram for the aqueous thermometric titration of chlorpheniramine maleate *versus* HCl, corresponding to the official nonaqueous titration (3), is shown in Fig. 3, curve A. Although the end point is fairly rounded, extrapolation is not difficult. The 1 end point observed results from the protonation of the pyridine nitrogen of the chlorpheniramine; in the official nonaqueous titration, the

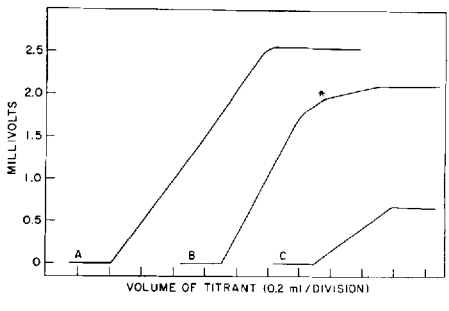

Fig. 4.—Typical enthalpograms. Key: A, 0.005 *M* aminophylline *vs.* 1 *M* $AgNO_3$; B, 0.01 *M* chlorpheniramine maleate *vs.* 2 *M* NaOH; C, 0.01 *M* chlorpromazine hydrochloride *vs.* 2 *M* NaOH.

[6] The only condition which was purposely varied was the bridge sensitivity which was set a factor of 5 more sensitive for the theophylline in aminophylline and hydrochlorothiazide titrations than for the hydrochloric acid titrations. A correction was applied to account for the nonlinearity of the sensitivity scale.

TABLE I.—THERMOMETRIC TITRATIONS OF PURE COMPOUNDS

Compd.	Thermometric Titration Analysis: Concn., 100 ml.	Titrant	Titrations, No.	% Found	U.S.P. Analysis: Titrations, No.	% Found
Chlorpheniramine maleate	0.01 *M*	2.0 *M* HCl	6[a]	99.36 ± 0.30	5	99.64 ± 0.18
	0.01 *M*	2.0 *M* NaOH	5	97.81 ± 0.57[b]		
				99.80 ± 0.23[c]		
Niacinamide	0.01 *M*	2.0 *M* HCl	6	98.62 ± 0.37	5	99.03 ± 0.14
Chlorpromazine hydrochloride	0.01 *M*	2.0 *M* NaOH	6	98.58 ± 0.31	5	99.89 ± 0.20
	0.01 *M*	2.0 *M* NaOH	5[a]	100.15 ± 0.70[d]		
	0.01 *M*	1.0 *M* NaOH	5	99.69 ± 0.33[e]		
Hydrochlorothiazide	0.0027 *M*	1.0 *M* NaOH	5	99.67 ± 0.20[c]	5	100.76 ± 0.29

bimaleate ion is titrated along with the chlorpheniramine.

An enthalpogram for the titration of chlorpheniramine maleate *versus* NaOH is shown in Fig. 4, curve B. Two true end points appear, the first corresponding to the neutralization of the bimaleate ion and the second to the neutralization of the protonated amine moiety of the chlorpheniramine ion. The false "end point" indicated by the asterisk has no stoichiometric relationship and is due to the delayed precipitation of the chlorpheniramine base.

Aqueous titration of niacinamide *versus* HCl, corresponding to the official nonaqueous titration (3), resulted in an enthalpogram (Fig. 3, curve C) with a rounded end point. Extrapolation to the end point is, however, not difficult.

Aqueous thermometric titration of chlorpromazine hydrochloride *versus* HCl, corresponding to the official nonaqueous titration (3), failed to exhibit an end point since the phenothiazine nitrogen is not sufficiently basic to become protonated in aqueous solution. Neutralization of the protonated amine nitrogen with base, however, resulted in an enthalpogram with an extremely sharp end point (Fig. 4, curve C).

The official assay procedure for hydrochlorothiazide requires titration in *n*-butylamine with sodium methoxide in benzene as titrant (3). Aqueous thermometric titration with NaOH involves 2 equivalents of base, since there are 2 sulfonamide groups in hydrochlorothiazide. Midway in the titration branch of the enthalpogram (Fig. 3, curve D), there is a slight change in slope, corresponding to the first end point. The change is not sharp enough to permit precise determination of this end point. The second end point is quite rounded so that extrapolation to either end point is subject to large errors. Thus, for the hydrochlorothiazide determinations, ΔT rather than ΔV analyses were carried out.

Aminophylline is a mixture of 2 moles of theophylline to 1 mole of ethylenediamine. The official assay (3) involves separate procedures for the 2 components. Ethylenediamine is analyzed by aqueous titration with HCl, and theophylline is determined by precipitation with $AgNO_3$ and titration of the excess silver ion with NH_4SCN. Medwick and Schiesswohl (5) have developed a nonaqueous potentiometric analysis for both components which uses acetous perchloric acid as titrant and an acetic acid–acetic anhydride solvent.

Three aqueous thermometric titration systems for aminophylline analysis were investigated. Titration with HCl resulted in an enthalpogram (Fig. 3, curve E) indicating reaction with ethylenediamine only. The change in slope midway in the titration branch is the end point for the protonation of 1 of the amine groups, but this point is difficult to determine precisely. The second end point, however, is extremely sharp.

Aqueous thermometric titration of aminophylline *versus* base is feasible due to the acidic nature of theophylline. The resulting enthalpogram (Fig. 3, curve B) is extremely curved throughout the titration branch so that only ΔT analysis can be performed precisely.

Direct titration of the theophylline in aminophylline *versus* $AgNO_3$ resulted in an enthalpogram (Fig. 4, curve A) with a well-defined end point. There is a very slight change of slope approximately midway in the titration branch which is probably due to initial supersaturation followed by precipitation (similar to the false "end point" in the chlorpheniramine maleate *versus* NaOH system). Keily and Hume have observed similar changes in slope in nonaqueous thermometric titrations involving precipitations (6). The best stoichiometric end point for the aminophylline *versus* $AgNO_3$ titrations resulted from taking an average of the end points obtained by extrapolating segments of the titration branch on both sides of the slight change in slope. However, because the change in slope is so slight, little error (~1%) is introduced if only the final straight portion of the titration branch is used to locate the end point.

The quantitative results of the aqueous thermometric titrations (ΔV analyses) of the 5 compounds under investigation are given in Table I.[7] Included in the table are the results of the official assay procedures. The values obtained from the thermometric analyses are generally slightly lower but still in good agreement with the results of the U.S.P. analyses. The poor results obtained from the first end point in the chlorpheniramine maleate *versus* NaOH thermometric titrations can be ascribed to the difficulty in extrapolating the small segment

[7] All appended error limits in this paper are average deviations unless specified.

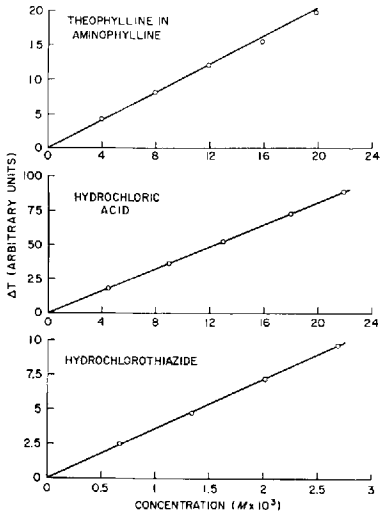

Fig. 5.—Plots of temperature rise *vs.* concentration of substrate for titrations with 2 *M* NaOH. The solid lines represent the least-square fits to $\Delta T = BM$, where the points were weighted as (average deviation)$^{-2}$. The average deviations of the points generally fall within the circles.

between the first end point and the false "end point." The reasonableness of the results of the hydrochlorothiazide *versus* NaOH thermometric titrations must be taken to be fortuitous because of the previously discussed uncertainty in the location of the end point.

Plots of ΔT *versus* concentration for aminophylline *versus* NaOH, HCl *versus* NaOH, and hydrochlorothiazide *versus* NaOH titrations are shown in Fig. 5. The lines drawn through the points were determined by least-square fitting to $\Delta T = BM$ with each point weighted as (average deviation)$^{-2}$. The relative slopes were found to be $B_{HCl}/B_{theophylline} = 4.004 \pm 0.048$ and $B_{HCl}/B_{hydrochlorothiazide} = 1.132 \pm 0.008$, where the appended error limits are estimated standard deviations. These results indicate that the use of Eq. 1 to determine theophylline or hydrochlorothiazide concentrations from thermometric titrations run concurrently with HCl *versus* NaOH titrations should be accurate to ~1%.

Approximately 6 months after the determinations of $B_{HCl}/B_{theophylline}$ and $B_{HCl}/B_{hydrochlorothiazide}$ were made, the ΔT procedure was tested by performing titrations with an entirely new apparatus (bridge, recorder, titration cell, etc.) and calculating the concentrations with Eq. 1. Such analyses yielded for theophylline (0.005 *M* aminophylline; 3 titrations) 94.97 ± 0.36% recovery, as compared to the U.S.P. analysis of 98.60 ± 0.17%. Similar titrations for hydrochlorothiazide (0.0017 *M;* 3 titrations) yielded 95.31 ± 0.44% recovery, as compared to the U.S.P. analysis of 100.76 ± 0.29%. (The U.S.P. analysis result is probably high, due to the broad color change of the indicator.) The poor agreements cast some doubt on the absolute values of the relative slopes.

The proposed method of using an external standard to determine heat changes suffers several disadvantages, especially when it is attempted to translate results from one apparatus to another. Bridge sensitivity nonlinearities are difficult to determine accurately, and they vary, depending on the bridge design, with the age and voltage of the batteries. In addition, it has been found that bridge response changes when switches are opened and closed again. Furthermore, factors such as differences in heat capacities due to differences in composition and volume (it is difficult to dry the titration cell completely between titrations) and distortions of the enthalpograms due to the dilution effect of the titrant can introduce errors. A more reliable method is one in which a calibrated heater immersed in the solution is used as an *internal* heat standard. This method would eliminate most of the possible sources of error discussed above, since the composition and volume of the solution could not change and the bridge need not be turned off or adjusted between calibration and titration. The effects of dilution by the titrant would still be a problem, but these effects should be small if the titrant is always much more concentrated than the solution to be titrated.

Solid Dosage Forms.—Thermometric titration of niacinamide tablets *versus* HCl, chlorpromazine hydrochloride sustained - release capsules *versus* NaOH, hydrochlorothiazide tablets *versus* NaOH, and aminophylline tablets *versus* NaOH resulted in enthalpograms which were almost identical to the enthalpograms obtained from the corresponding titrations of the pure substances. Thus, the inert materials in the dosage forms investigated do not undergo simple acid–base reactions and therefore do not interfere with the titrations of the active ingredients. Thermometric titration of aminophylline tablets *versus* $AgNO_3$ produced an enthalpogram which differed from that of the corresponding titration of pure aminophylline only in that the slight change in slope in the titration branch did not appear. The insoluble materials in the tablets probably act as "seeds" to prevent supersaturation. Enthalpograms for the titration of aminophylline tablets *versus* HCl are shown in Fig. 6. The curves are similar to that of the corresponding titration of pure aminophylline, and the end point is very sharp. The only difference is the fact that in the titration of tablets, the first end point does not appear (curve B) or appears as a slight change in slope (curve A) of opposite direction to that observed in the titration of pure aminophylline. The reason for this difference need not be of concern in strict analytical applications in which the second end point is used.

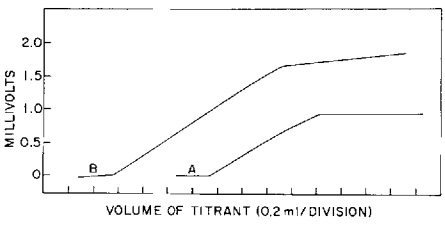

Fig. 6.—Enthalpograms for titrations of aminophylline tablets (100 mg.). Key: A, 2 tablets *vs.* 1 *M* HCl; B, 2 tablets plus 100 mg. aminophylline *vs.* 1 *M* HCl.

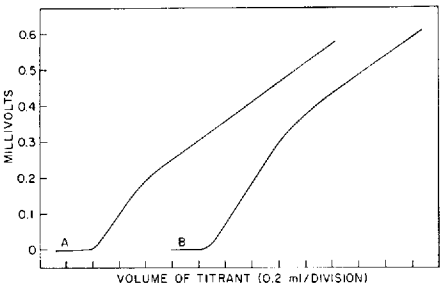

Fig. 7.—Enthalpograms for titrations of chlorpheniramine maleate tablets (4 mg.). Key: A, 30 tablets *vs.* 1 *M* HCl; B, 30 tablets plus 100 mg. chlorpheniramine maleate *vs.* 1 *M* HCl.

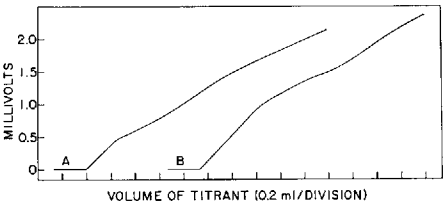

Fig. 8.—Enthalpograms for titrations of chlorpheniramine maleate tablets (4 mg.). Key: A, 30 tablets *vs.* 1 *M* NaOH; B, 30 tablets plus 100 mg. chlorpheniramine maleate *vs.* 1 *M* NaOH.

Enthalpograms for the titration of chlorpheniramine maleate tablets *versus* HCl and of a corresponding standard addition titration are shown in Fig. 7. The roundness at the start of the titration must be due to the reaction of some ingredient in the tablet with the acid. This reaction, however, is not "clean cut," as evidenced by the fact that the region of roundness expanded when additional chlorpheniramine maleate was added prior to the titration. The authors have found no reliable method of determining the initiation of the chlorpheniramine reaction itself. Estimations of ΔV did not yield quantitative results for either the absolute method or the standard addition method.

Titration of chlorpheniramine maleate tablets *versus* NaOH produced an enthalpogram quite different from the curve obtained in the corresponding titration of pure chlorpheniramine maleate. Figure 8 shows typical curves for the titrations of tablets alone and of tablets plus added chlorpheniramine maleate. The high final slopes indicate that some reaction was occurring even after ~2 ml. of 1.0 *M* NaOH had been added (~3 times the amount needed to completely neutralize 120 mg. of chlorpheniramine maleate). None of the breaks is easy to pick out as an end point. Attempts to obtain quantitative results from the first break with both the absolute and standard addition methods were unsuccessful.

The results of the thermometric titrations of the solid dosage forms studied are given in Table II. Although the curvature in the vicinity of the aminophylline *versus* NaOH and hydrochlorothiazide *versus* NaOH end points did not allow accurate extrapolation for absolute analyses, the standard addition method was feasible since errors tend to cancel if the curves are always extrapolated in the same manner. For the hydrochlorothiazide standard additional analyses, "end points" were obtained by extrapolating the initial portions of the titration branches and the final segments of the curves to their intersections; *i.e.*, the fact that there are actually 2 end points was ignored.

Since this phase of the investigation was exploratory in nature, detailed evaluations of precision and accuracy were not attempted. The over-all results are quite favorable and indicate that thermometric titrations of many solid dosage forms without prior separation of the active ingredients are feasible. The rather large error limits encountered with some systems may be due to the fact that individual dosage forms were titrated. The differences between the results of the absolute and standard addition methods may also be due, at least in part, to the use of individual dosage forms as well as to the assumption of 100% purity of the added portion of active ingredient. The latter may be particularly important in the titrations involving aminophylline, which is not always homogeneous.

The most interesting results of these exploratory studies is the fact that, with the exception of the titrations of chlorpheniramine maleate tablets, even the simple acid–base titrations of the solid dosage forms indicated negligible interference due to inert ingredients.

Liquid Dosage Forms.—The general objective of this phase of the investigation was to determine if, without detailed knowledge of the composition of a

liquid dosage form, one could correlate end points of enthalpograms with the reactions of individual active ingredients. Only a few systems were examined and only sparse quantitative data were obtained.

Titrations of a chlorpheniramine maleate syrup (0.5 mg./ml.) *versus* NaOH and *versus* HCl produced enthalpograms exhibiting single end points which did not correlate with the chlorpheniramine maleate content. When additional chlorpheniramine maleate was added to the syrup prior to the titrations, the titration volumes increased, but no correlation with the original chlorpheniramine maleate content could be made by standard addition analysis. The high final slopes of these enthalpograms indicated that reactions were still occurring even after several times the stoichiometric amounts of titrant had been added.

Results similar to those obtained with the chlorpheniramine maleate syrup titrations were obtained with titrations of a syrup containing 10 mg. aminophylline, 2.5 mg. diphenhydramine, 7.5 mg. KI, and 2 mg. $CHCl_3$ per ml. (this syrup will be referred to subsequently as "aminophylline compound syrup") *versus* NaOH and titrations of a chlorpromazine hydrochloride syrup (2 mg./ml.) *versus* NaOH. In the latter titration system, the volume to the end point did not increase upon the addition of excess chlorpromazine hydrochloride. Titration of aminophylline compound syrup *versus* HCl produced an enthalpogram, shown in Fig. 9, curve A, which does not exhibit any real evidence of reaction.

Thus, in all of the above liquid dosage form titration systems, there is interference from other (inert and/or active) ingredients. In the absence of detailed information as to the compositions of the liquids, any discussion of the natures of the interferences would be highly speculative.

On the other hand, titrations of an elixir containing 12.5 mg. aminophylline and 3.125 mg. diphenhydramine per ml. (subsequently referred to as "aminophylline elixir") *versus* HCl, NaOH, or $AgNO_3$ produced enthalpograms almost identical to those obtained in the corresponding titrations of pure aminophylline. (The end points in the HCl titrations were slightly more rounded than in pure aminophylline *versus* HCl titrations.) Quantitative results obtained from the titrations of aminophylline elixir are given in Table III.

Figure 9, curve B, represents the titration of aminophylline compound syrup (content given previously) *versus* $AgNO_3$. The first end point is fairly sharp while the second is broadly rounded. Titrations with added active ingredients indicated that the first end point corresponds to iodide precipitation and the second end point to theophylline precipitation. Quantitative results from a few titrations are given in Table III. The reason for the low per cent recoveries obtained may be the fact that a sample of syrup from a very old, previously opened bottle whose history was unknown was used for the analyses.

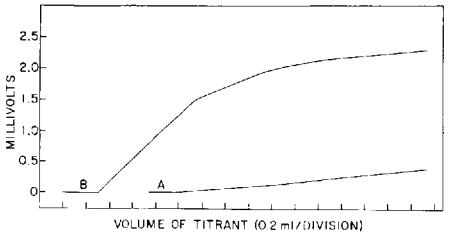

Fig. 9.—Enthalpograms for titrations of aminophylline compound syrup (10 mg. aminophylline, 2.5 mg. diphenhydramine, 7.5 mg. KI, and 2 mg. $CHCl_3$/ml.). Key: A, 25 ml. syrup *vs.* 1 *M* HCl; B, 10 ml. syrup *vs.* 0.5 *M* $AgNO_3$.

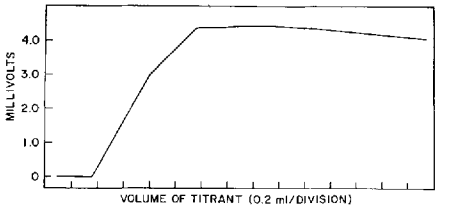

Fig. 10.—Enthalpogram for titration of 15 ml· compound elixir (10 mg. KI, 3 mg. theophylline, 0.8 mg. ephedrine sulfate, 0.4 mg. phenobarbital, and 0.167 mg. isoproterenol hydrochloride/ml.) *vs.* 2 *M* $AgNO_3$.

The last liquid dosage form studied was an elixir containing 10 mg. KI, 3 mg. theophylline, 0.8 mg. ephedrine sulfate, 0.4 mg. phenobarbital, and 0.167 mg. isoproterenol hydrochloride per ml. (This elixir will be referred to subsequently as "compound elixir".) Since several, if not all, of the active ingredients may precipitate silver ion, a complex enthalpogram for titration with $AgNO_3$ would be expected. The actual enthalpogram for such a titration is shown in Fig. 10. Titrations with added KI indicated that the first end point corresponds to iodide precipitation. The volume between the first and second end point is quantitatively in excess of the amount necessary for reaction with all of the other active ingredients combined. When KCl was added to the elixir prior to the titration, this volume increased without introducing any new breaks in the curve. This behavior indicates that the reaction that occurred between the first and second end points was precipitation of excess chloride ion present in the elixir. There is some indication from the enthalpogram that reactions occurred after the second end point, but the breaks are not sharp enough to pick out additional end points. The shape of the curve beyond the second end point was somewhat altered when titrations with added aminophylline were performed, but again no additional end points could be distinguished. Table III includes the results of KI determinations from the first end point in the compound elixir *versus* $AgNO_3$ titrations.

It appears from the rather sparse data presented in this section that simple thermometric titrations of liquid dosage forms are subject to far more interferences than are titrations of solid dosage forms. Some liquid dosage forms may be titrated successfully with nonspecific titrants without prior separation of ingredients. The applicability of such titrations to particular dosage forms must be determined on an individual basis. A more elegant approach, although one requiring knowledge of the composition of the vehicle, would be the use of more selective titrants.

SUMMARY

Aqueous thermometric titrations of chlorpheniramine maleate *versus* HCl or NaOH, niacinamide *versus* HCl, chlorpromazine hydrochloride *versus* NaOH, hydrochlorothiazide *versus* NaOH, ethylenediamine in aminophylline *versus* HCl, and theophylline in aminophylline *versus* NaOH or $AgNO_3$ yielded results with precision and accuracy sufficiently good to propose the methods as alternatives to the official assay procedures (generally nonaqueous titrations). In cases where the end points are extremely rounded (theophylline in aminophylline *versus* NaOH and hydrochlorothiazide *versus* NaOH), the usual volume determinations are not reliable but recourse to temperature-rise determinations is possible. The temperature-rise method used in this investigation employed titrations of HCl *versus* NaOH as heat references. Caution must be exercised if the relative heats determined on one apparatus are used for analyses performed with another apparatus. The use of a calibrated heater is suggested as a more reliable method.

Exploratory studies of aqueous thermometric titrations of solid dosage forms of the compounds listed above were conducted. These titrations employed the same titrants used for the analyses of the corresponding pure compounds. In all except the titrations of chlorpheniramine maleate tablets, negligible interference due to inert ingredients was observed. It appears that successful thermometric titrations of many solid dosage forms can be performed, either by direct volume analysis or by standard addition analysis, without prior separation of active ingredients.

Aqueous thermometric titrations of a few liquid dosage forms were attempted. While in some of the systems studied successful titrations without prior separation of ingredients could not be performed, in other systems no interference from the vehicle was observed. In some titrations of liquid dosage forms with $AgNO_3$, several end points were observed, some of which could be correlated quantitatively with specific ingredients in the mixtures.

Micromeritics of Granular Pharmaceutical Solids I

Physical Properties of Particles Prepared by Five Different Granulation Methods

By DALE E. FONNER, JR., GILBERT S. BANKER, and JAMES SWARBRICK

Granular pharmaceutical solids, prepared by 5 different granulation methods, were evaluated on the basis of repose angle, hardness, density, number of particles per gram, bulk density, shape volume factor, bulk volume, and geometrical form. Particular attention was given to the development of an accurate technique for evaluating shape volume factor as a means of characterizing the over-all shape of a particle. The findings indicated that repose angle was primarily a function of surface roughness and that geometrical form and shape on a volume basis were inversely proportional to bulk volume. The determination of these easily computed parameters is therefore of value in assessing manufacturing procedures which have as their primary objective the production of smooth, spherical particles suitable for pharmaceutical coating purposes.

THE STANDARDIZATION of processing methods, to achieve uniform product specification, is a constant goal of the pharmaceutical industry. Uniformity of drug distribution and standardization of dosage form characteristics, both within a single dosage unit as well as between dosage units, has become increasingly important in view of the more potent drugs in use today and the continual developments in the area of controlled release dosage forms.

Granulation is a key process in the production of many dosage forms involving the controlled release of a drug from coated or matrix-type particles, regardless of whether conventional granulation methods or the newer techniques of spray drying or fluidized bed processing are employed.

The production of uniform tablet dosage units has been shown to be dependent upon several granular properties. Arambulo *et al.* (1) found that as the granule size was decreased, the variation in tablet weight also decreased, reaching a minimum weight variation at a 400–800 μ granule diameter. Further reduction in granule size led to an increase in tablet weight variation. The particle size distribution also affects tablet weight, as well as exerting a marked influence upon tablet hardness (2). Particle size distribution and other particulate properties, by affecting the internal flow and segregation of a granulation, can vary the composition of compressed tablets (3).

Physical properties of granules, such as specific surface, shape, hardness, surface characteristics, and size, can profoundly influence the rate of dissolution of drugs contained in heterogeneous solid dosage forms. According to Wagner (4), when the granule size exceeds 10 μ the rate of dissolution is directly proportional to the surface area. By using spherical inert granules coated with various thicknesses of tolbutamide, Nelson *et al.* (5) demonstrated the dependence of the excretion rate of the drug upon the available surface area. The effect of the granule size upon the dissolution of tripelennamine hydrochloride (6) and aspirin (7) have been investigated also.

To date, most of the physical studies of the properties of granular pharmaceutical solids have been concerned with the evaluation of repose angle (8–12) and particulate density or porosity (13, 14). The application of such physical parameters as shape, bulk density or packing volume, the number of particles per gram, and particulate hardness to the characterization and utilization of granular pharmaceutical solids has apparently gone unreported. With the development of the many new processing methods designed to produce granular particles (15–21), the need to apply physical measurements of a quantitative nature to pharmaceutical granulations to achieve a rational selection of a particular process or piece of equipment is greater than at any previous time. The purpose of this report is to present simple, reproducible procedures which may be used to estimate certain physical parameters of granular pharmaceutical solids, and to compare, on this basis, granules prepared using 5 different granulation methods.

EXPERIMENTAL

Preparation of the Base Formula and Granulating Solution.—A base formula of 90% lactose and 10% starch was selected as the model system for this study. The powders were passed through a 60-mesh screen in batches of 10 Kg. and mixed in a model c-10 Hobart mixer[1] for 15 min. Portions of this mixed

powder were massed with the granulating solution and separately processed by each granulation method (Table I). The granulating solution had the following composition:

Gelatin powder	480.0 Gm.
Acacia powder	160.0 Gm.
Distilled water	4000.0 Gm.
Methylparaben	10.0 Gm.
Propylparaben	2.0 Gm.

The granulating solution was prepared by dissolving the solute components in the hot distilled water. The granulating solution was employed at a temperature of 47°. Each granulation was air dried for 72 hr. at about 26° and 15% R.H. and was then sized through a 12-mesh hand screen. The granulations were stored in air-tight jars at room temperature until required.

Sufficient granulating solution was used to make the granules as hard as possible, and so minimize particulate fracture during the evaluative procedures.

In order to minimize variations of those physical parameters dependent upon particle size, a 20/30-mesh sieve fraction of each granulation was used, except where otherwise stated. The sieve fractions were obtained when required by processing 300–400-Gm. samples of the granulation through a nest of sieves shaken for 15 min. on a Cenco-Meinzer sieve shaker[2] operating on speed setting 5.

The moisture content of each granulation was determined using a Cenco moisture balance[2] operating at a temperature of 115°. The relative humidity was recorded using a Serdex relative humidity indicator, model 122-7005.[3]

Physical Measurements.—*Repose Angle, θ.*—Measurements of repose angle were obtained using an apparatus similar to that described by Pilpel (12), except that the cones were formed on a piece of arithmetic grid graph paper rather than on a brass plate.

One hundred milliliters of 20/30-mesh material was introduced into a copper cylinder, 16.5 cm. in length and 3.8 cm. internal diameter, which then was raised vertically through a pulley drive at the rate of approximately 0.2 mm./sec. The height, l, of the deposited granular cone was determined using a microcathetometer[4] and the base diameter, d, of the cone obtained by noting the cone base dimensions on the graph paper and averaging 2 determinations taken 90° apart. The repose angle, θ, was calculated as follows:

$$\theta = \arctan\left(\frac{1}{d/2}\right) \qquad \text{(Eq. 1)}$$

Humidity conditions and the moisture content of the granules were rechecked after repose angle determinations.

Granule Density, ρ_g.—A pycnometer method was chosen for the determination of particulate or granule density due to its ease of operation and reproducibility (22). The capacity of the pycnometer was 30 ml. and approximately 2 Gm. of 20/30-mesh material was used. Benzene, specific gravity 0.879, was employed as the immersion fluid. Due to the rapid evaporation of benzene, the pycnometer stem was marked half way down and the weight recorded as the meniscus reached this mark.

Particulate Hardness.—Many procedures for evaluating hardness were studied. The final selection made on the grounds of simplicity and the sample size used, involved shaking the granules in a closed container for a constant period of time and then measuring the percentage by weight of material retained on a 30-mesh sieve. Twenty grams of 20/30-mesh material was placed in a dry 3-oz. square bottle and shaken on an Eberbach[5] power shaking unit, model 6000, for 5 min. A 3-in. stroke was used with the reciprocating rate set at 216 c.p.m. The contents of the bottle were then placed on a No. 30 sieve and the fines removed by shaking for 15 sec. on the shaker unit. The hardness index, h, was calculated as the weight fraction of material retained as 30-mesh oversize following shaking.

Number of Particles per Gm., N.—One hundred particles of 20/30-mesh material were weighed and the number of particles/Gm., N, computed.

Bulk Density, ρ_b.—The bulk density determination procedure developed by Butler and Ramsey (23) was employed, with the exception that the cylindrical graduate was dropped 20 times instead of the 3 originally proposed. This modification was found to produce significantly more uniform results. A 30-Gm. sample of 20/30-mesh material was placed in a 100-ml. cylindrical graduate and dropped from a height of 0.75 in. onto a hard wooden surface a total of 20 times. Two seconds were allowed to elapse between each drop. If V is the volume in ml. of W Gm. of material in the cylinder, then ρ_b, the bulk density in Gm./ml., is given by:

$$\rho_b = \frac{W}{V} \qquad \text{(Eq. 2)}$$

Shape Volume Factor, α_v.—By definition (24):

$$\alpha_v = \frac{V}{d_e^3} \qquad \text{(Eq. 3)}$$

TABLE II.—VALUES FOR VARIOUS PHYSICAL PARAMETERS OBTAINED FOR 20/30-MESH PARTICLES PREPARED USING 5 DIFFERENT GRANULATION METHODS

Granulation Method	Colton Upright	Oscillating Granulator	Hand Screen	Fitzpatrick Comminutor	Liquid-Solids V-Blender
Repose angle, θ, in degrees	35.78	34.65	35.77	36.23	35.28
Granule density, ρ_g, in Gm./ml.	1.51	1.54	1.50	1.42	1.45
Hardness index, h	.974	.977	.955	.945	.912
No. of particles/Gm., N	5759	6748	7753	6405	5527
Bulk density, ρ_b, in Gm./ml.	.375	.395	.400	.428	.508
Shape vol. factor, α_v	.1520	.1757	.1634	.2163	.2495
Bulk vol./constant vol. of granules, V_b', ml.	80.05	77.97	75.00	66.36	57.09
Geometrical form, k_e	.1809	.2144	.1912	.2639	.3019
Interspace porosity, e_i	.752	.744	.733	.699	.650
Equivalent projected diam., d_e, μ	910	820	810	800	790

where α_v is the shape volume factor, V is the volume of the particle, and d_e is the equivalent projected diameter. d_e is defined as the diameter of a circle having the same area as the particle when the latter is placed in its most stable position on a horizontal plane and is viewed from above.

A series 10 Micro Star[6] microscope, equipped with a projection screen, was used to view the particles, the outlines of which were traced onto paper. The areas of the traced particles were determined using a compensating planimeter.[7]

Extending Eq. 3 to the case of many particles:

$$\alpha_v = \frac{V_n}{\sum_{i=1}^{n} (d_e)_i^3} \qquad \text{(Eq. 4)}$$

where V_n is the volume of n particles. If p is the power of magnification, then d_e can be obtained readily in terms of the projected area, A. Thus,

$$\frac{A}{p^2} = \frac{\pi(d_e)^2}{4} \qquad \text{(Eq. 5)}$$

and

$$(d_e)^3 = \left(\frac{4A}{\pi p^2}\right)^{3/2} \qquad \text{(Eq. 6)}$$

Substituting Eq. 6 into Eq. 4:

$$\alpha_v = \frac{V_n}{\sum_{i=1}^{n} \left(\frac{4A}{\pi p^2}\right)_i^{3/2}} \qquad \text{(Eq. 7)}$$

or

$$\alpha_v = \frac{V_n}{\left(\frac{4}{\pi p^2}\right)^{3/2} \sum_{i=1}^{n} A_i^{3/2}} \qquad \text{(Eq. 8)}$$

Since more than 600 particles were traced, Eq. 8 was programmed in Fortran and the results computed on an IBM 1620 computer.

About 20 granules of 20/30-mesh material were placed on a microscope slide and the projection of each traced. The particles then were transferred to a tared weighing bottle. This procedure was repeated until approximately 150 particles from each granulation had been traced. The weight of the particles was obtained and their total volume calculated as follows:

$$V_n = \frac{M}{\rho_g} \qquad \text{(Eq. 9)}$$

where V_n is the volume, in ml., of n particles, M is the mass, in Gm., of n particles, and ρ_g is the granule density as determined by benzene displacement. The magnification, p, of the microscope used was 30.5×.

Bulk Volume per Constant Volume of Granules, V_b'.—The bulk volume for a constant granule volume was computed, for each granulation, from a knowledge of ρ_g and ρ_b. Thus:

$$V_b' = \frac{V\rho_g}{\rho_b} \qquad \text{(Eq. 10)}$$

where V_b' is the bulk volume in ml. of a fixed particulate volume V (in this instance, 20 ml.), ρ_g is the granule density, and ρ_b the bulk density. The bulk volume per constant volume of granules represents a term comparable to bulk density but which is freed from particulate density values, which varied from granulation to granulation.

Geometrical Form, k_e.—By definition (25):

$$k_e = \alpha_v m n'^{1/2} \qquad \text{(Eq. 11)}$$

where k_e is the geometrical form, m is the ratio of the particle breadth to its thickness, and n' is the length of the particle divided by its width. Since these granules were made by forcing them through square or spherical openings, the breadth can be expected to approximately equal the thickness. In this case, $m = 1$ and:

$$k_e = \alpha_v n'^{1/2} \qquad \text{(Eq. 12)}$$

Values of n' for particles from each granulation were calculated using 20 randomly selected granules. The longest dimension was taken as the length and a line perpendicular to its midpoint was taken as the width.

RESULTS AND DISCUSSION

Physical Methods.—*Repose Angle, θ.*—The repose angle values listed in Table II are the averages obtained from not less than 11 determinations run on particles from each granulation. The average standard deviation was 0.74°. The relative humidity never exceeded 15% during the determinations. In all cases, the moisture content of the granules was less than 2%.

[6] American Optical Co., Buffalo, N. Y.
[7] Keuffel and Esser Co., Germany.

Analysis of variance and contrast techniques (26) were used in the statistical analysis of the data. The repose angle of particles prepared using the oscillating granulator was found to be significantly lower than those values for particles produced using the other 4 methods, when a significance level of 1% was used. Since particles with smooth and even surfaces generally have a low angle of repose (27), the results obtained suggest that particles prepared from the oscillating granulator have the smoothest surface.

The repose angle was unaffected by static charge. Qualitative observations showed that the particles from the liquid-solids V-blender and the Fitzpatrick comminutor possessed a great deal of static charge. However, as shown in Table II, the repose angle of these granules did not vary significantly from those particles produced by the use of the Colton upright and the hand screen granulation methods, which were observed to have a lower static charge. These findings are in agreement with the predictions of Pilpel (12) who deduced, on theoretical grounds, that the magnitude of a static charge is too small to affect the repose angle.

The repose angle for the different granulations was found to be independent of particle shape. This was brought out in the study of shape volume factors. Thus, particles from the liquid-solids V-blender were found to be the roundest (highest α_v), yet their repose angle was quite high in relation to the repose angle of the irregularly shaped particles from the oscillating granulator. It would appear that, for particles of this size, the repose angle is mainly a function of surface roughness, as predicted by Pilpel (12).

Granule Density, ρ_g.—The density values listed in Table II are the average of 2 determinations. The average standard deviation for the reported values was 0.008 Gm./ml.

Since particles containing crevices or entrapped air give low density readings (22), the data in Table II indicate that granules prepared using the liquid-solids V-blender and Fitzpatrick comminutor have pitted surfaces or entrapped air, or both. These particles have very irregular surfaces, since many air bubbles were observed to rise to the surface of the benzene during the preliminary stages of the density determinations carried out using these granules. This was found not to be the case for the particles prepared by the other granulation methods.

Hardness Index, h.—Each of the hardness index values listed in Table II is the average of 3 or 4 determinations. The hardness index increased directly with the granule density, with the exception of those particles prepared from the Fitzpatrick comminutor.

Number of Particles per Gm., N.—Each value of N in Table II is the average of 5 determinations. Analysis of variance and contrast techniques (26) showed that the granules prepared using the Colton upright and the liquid-solids V-blender had N values which were significantly lower than those particles produced from the other 3 methods. Granules prepared using the hand screen method were found to have a value of N significantly higher than the other granules. In all cases, the significance level used was 1%.

Assuming that the samples consisted of spherical particles having a normal size distribution over the 20/30-mesh range, N would have a value of approximately 3500 particles/Gm. Deviation of the size distribution from normality cannot, alone, explain the high values of N obtained, implying that the particles are not spherical. The validity of this conclusion was confirmed by microscopic examination of the particles and a consideration of the calculated shape volume factors given in Table II. For perfect spheres, α_v is equal to $\pi/6$, or 0.524.

Bulk Density, ρ_b.—Bulk densities were determined twice for 20/30-mesh fraction of each granulation. In all cases, the 2 values were identical.

It is apparent from the results in Table II that the packing arrangements for particles prepared by the various granulating methods are quite different. The packing arrangements, in turn, are mainly determined by the shape of the granules in this size range (28), leading to the conclusion that the particles from the different granulations have very dissimilar shapes. This fact will become more apparent in the following discussion on shape volume factors.

Shape Volume Factor, α_v.—The shape volume factors shown in Table II were computed from Eq. 8 using 100–150 particles of each granulation. Since α_v is dependent upon the geometrical form and proportions of a particle (25), the shape volume factor was plotted against bulk density to establish the existence of a correlation between these parameters (Fig. 1). The linear correlation coefficient was 0.952, indicating that the bulk densities of the particles studied are related to their respective shape volume factors.

Since the densities of the particles from the various granulations differ, the bulk density values are not only a function of the void spaces but also a function of the granule densities, ρ_g. Therefore, the bulk volumes per constant volume of granules, V_b', were calculated since, as seen from Eq. 10, they are independent of granule density. Figure 2 is a plot of values for V_b' given in Table II *versus* shape volume factor. The correlation coefficient in this instance was 0.965.

In an effort to obtain even better correlation for terms representing particle shape and packing volume, a factor for the geometrical form, k_e, was calculated. These values, also listed in Table II, have been plotted against the bulk volume per con-

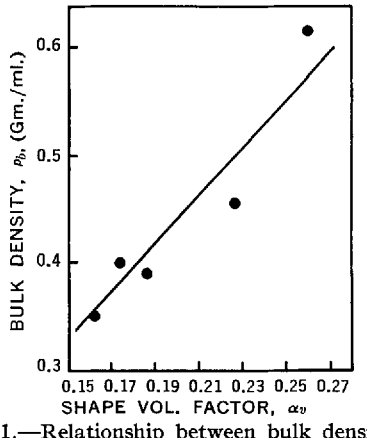

Fig. 1.—Relationship between bulk density and shape volume factor of 20/30-mesh particles prepared by 5 different granulation methods.

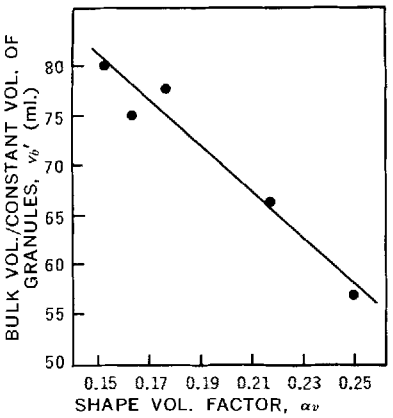

Fig. 2.—Relationship between bulk volume per constant volume of granules and shape volume factor of 20/30-mesh particles prepared by 5 different granulation methods.

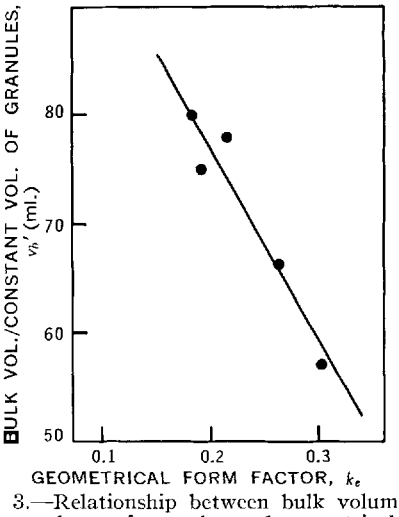

Fig. 3.—Relationship between bulk volume per constant volume of granules and geometrical form factor of 20/30-mesh particles prepared by 5 different granulation methods.

stant volume of granules in Fig. 3. The linear correlation coefficient was 0.961.

The interspace porosity, e_i, is defined as:

$$e_i = 1 - \frac{\rho_b}{\rho_g} \qquad \text{(Eq. 13)}$$

When this parameter was plotted as a function of the shape volume factor, a correlation coefficient of 0.914 was obtained.

Thus, the best correlation was obtained when the bulk volume was plotted against either the shape volume factor or its analog, the geometrical form, indicating that the volume of a packing of particles is a function of their geometrical form and proportions. This finding is important since the easily computed values of V_b' may be used to quickly evaluate procedures in which attempts are being made to obtain spherical particles or granules for coating and/or sustained-release requirements.

To check the accuracy of the computed α_v values, the number of particles per gram, N, was calculated for 20/30-mesh particles from the various granulation methods and compared with those values of N obtained experimentally by counting and weighing techniques. From Eq. 3, and since $N = 1/V\rho_g$ then:

$$N = \frac{1}{\alpha_v \rho_g d_e^3} \qquad \text{(Eq. 14)}$$

where N, α_v, d_e, and ρ_g are as previously defined.

A comparison of the values for N from the 2 techniques is given in Table III. It is readily apparent that the 2 sets of data are in excellent agreement.

Table III.—Comparison of Experimental and Computed Values of N, Number of Particles/Gm., for 20/30-Mesh Fraction

Granulation Method	Exptl. N[a]	Computed N
Liquid-solids V-blender	5527	5606
Colton upright	5759	5782
Fitzpatrick comminutor	6405	6359
Oscillating granulator	6748	6703
Hand screen	7753	7677

[a] These values were obtained from Table II.

Characterization of Granulation Methods.—On the basis of the repose angle studies, those particles prepared from the oscillating granulator were found to have the smoothest surface and can therefore be expected to possess the best flow properties. In addition, these particles were the hardest, even though the percentage of granulating agent used was relatively low (see Table I), indicating that the force of compaction produced by this granulator is high. Due to their relatively high density, the *intraspace* porosity of these particles is low in comparison to granules produced from the other pieces of granulating equipment. These particles are asymmetric, as evidenced by their low shape volume factor.

Since granules possessing smooth surfaces can be uniformly coated more easily than those with uneven surfaces, the oscillating granulator might be expected to produce particles well-suited for film coating purposes. Furthermore, since these were also the hardest granules of those studied, particle breakdown during the coating operation would be at a minimum.

Granules produced from the liquid-solids V-blender and the Fitzpatrick comminutor are relatively porous as evidenced by their granule densities. This was confirmed by the heterogeneous "optical density" of the particles when viewed with the projection microscope. On the basis of shape volume factors, granules from the liquid-solids V-blender and the Fitzpatrick comminutor were the most symmetrical on a volume basis. As a result, these particles assume a very close packing arrangement which is reflected in their high bulk density and low bulk volume. However, because of their surface irregularities, these particles can be expected to have only from average to poor flow properties, since this latter factor is more dependent on surface characteristics than general shape factors. From a consideration of the low density and hardness values for the granules produced by the liquid-solids V-blender and

the Fitzpatrick comminutor, it is apparent that the force of compaction in these 2 pieces of equipment is less than that produced by the oscillating granulator.

Particles produced by use of the hand screen method were intermediate between the 2 groups of granules previously discussed, with respect to repose angle, density, hardness, bulk density, and bulk volume. The number of particles per gram for this granulation was the highest of the 5 granulations; this was due to the low average volume for these particular granules.

Particles produced from the Colton upright were found to be the least spherical, an observation confirmed by the low value for the shape volume factor. These granules, not unexpectedly, also had the lowest bulk density of those studied. The fact that these particles had the highest value for the equivalent projected diameter over the size range of particles studied, accounts for their low degree of symmetry.

SUMMARY

Five standard granulation methods were compared on the basis of the following physical properties of the granules they produced: (*a*) repose angle, (*b*) granule density, (*c*) hardness, (*d*) number of particles per gram, (*e*) bulk density, (*f*) shape volume factor, (*g*) bulk volume per constant volume of granules, and (*h*) geometrical form.

Useful techniques were developed for obtaining some of the more important physical parameters of pharmaceutical granular solids. Particular attention was focused on developing an accurate technique for evaluating the shape volume factor, a parameter important in characterizing the over-all shape of a particle.

The repose angle was found to be primarily a function of surface roughness; in addition, the bulk volume was inversely proportional to particle shape. Thus, the researcher is provided with 2 easy techniques for assessing procedures aimed at producing smooth, spherical pharmaceutical particles.

Interfacial Properties of Antimicrobial Long-Chain Quaternary Ammonium Salts II

Soluble Films at the Oil/Water Interface

By NORMAN D. WEINER, HELIO C. PARREIRA*, and GEORGE ZOGRAFI†

The adsorption of 3 quaternary ammonium salts, dodecylpyridinium chloride, dodecyltrimethylammonium chloride, and dodecyldimethylethylammonium chloride, has been measured at the hexane-, octane-, decane-, dodecane-, and tetradecane-0.1 *M* KCl interface. Adsorption appears to be influenced by interaction between the oil and both the nonpolar and polar portions of the surface-active agents, even though the surface-active agents are not soluble in the oils. The relative effect of chain length of the oil on surface concentration is a function of the bulk concentration of the quaternary ammonium salts.

In a previous publication (1) a study was reported concerning the adsorption of 3 quaternary ammonium salts, dodecylpyridinium chloride (DPC), dodecyltrimethylammonium chloride (DTAC) and dodecyldimethylethylammonium chloride (DEAC), at the air/water interface. The present study is concerned with the properties of these compounds at a number of different oil/water interfaces.

It is well recognized that the interfacial properties of surface-active agents at the air/water surface are quite different than their properties at the oil/water interface (2–6). Hutchinson (3) has suggested that oil molecules are present at the interface along with adsorbed surface-active molecules, and that a competition exists at the interface between the nonpolar portions of like molecules and the nonpolar portions of the oil and surface-active agents. He came to this conclusion by comparing the π-A characteristics of fatty acids adsorbed at various oil/water interfaces and their relative solubility in the oils. Schulman *et al.* (7) have studied the effect of the oil phase on microemulsion formation, and have concluded that oil molecules associate at the interface with surface-active agents. The presence of oil at any particular surface pressure was said to depend on the oil's ability to interact with film molecules and thus resist ejection with increasing film pressure. Zisman (8) has reported that mineral oil molecules appear to penetrate long-chain alcohol monolayers adsorbed at the oil/water interface, and remain as part of the surface film up to surface pressures of about 30 dynes/cm.

Received November 8, 1965, from the College of Pharmacy, Columbia University, New York, N. Y.

Accepted for publication December 17, 1965.

Abstracted in part from a thesis submitted by Norman D. Weiner to Columbia University, New York, N. Y., in partial fulfillment of Doctor of Philosophy degree requirements.

The authors acknowledge the Ciba Pharmaceutical Co., Summit, N. J., for support of this project.

† Present address: College of Pharmacy, University of Michigan, Ann Arbor.

Davies (9) has suggested that compounds having the same polar group, but differing in chain-length, should have the same π-A relationships at an oil/water interface since interactions between hydrocarbon chains of the compounds do not exist or are very weak. Brooks and Pethica (10, 11) have recently compared π-A curves at heptane–water interfaces for dodecyl, octadecyl, and docosyltrimethylammonium bromides. These π-A curves were obtained by applying the Gibbs adsorption equation in the case of the dodecyl compound, and by spreading insoluble monolayers of the other compounds. The π-A curves for these compounds were in good agreement, thus apparently verifying Davies' conclusions. Since the effect of changing the oil phase has not been considered in these systems, the authors chose to measure adsorption from aqueous solution in the presence of a series of straight-chain hydrocarbons, ranging from hexane to tetradecane. Since the quaternary ammonium salts are not soluble in the oils, it was felt that any effect on adsorption, due to changing oils, must be due to changes occurring in the interfacial region. The use of the 3 compounds under consideration also allowed the authors to observe differences due to the polar group, since chain-length and counter-ion were the same in all cases.

EXPERIMENTAL

Materials.—Hexane,[1] octane,[2] decane,[2] dodecane,[2] and tetradecane[2] were purified as follows: 25 ml. of fuming sulfuric acid was added to 500 ml. of oil, and the mixture was shaken in a separator for 5 min. The fuming sulfuric acid layer, which darkened considerably, was then discarded. This procedure was repeated until 3 successive additions of fuming sulfuric acid produced no visible darkening of the acid layer. The oil phase was then washed

[1] Hexane (spectroanalyzed, certified reagent) was purchased from Fisher Scientific Co.

[2] Each of these hydrocarbons (practical grade) was purchased from Eastman Organic Chemicals.

with water 5 times, with 5% sodium bicarbonate solution 5 times, and with water again 5 times. Charcoal and anhydrous sodium sulfate were then added to the oil, and the mixture was allowed to stand overnight. The oil was then filtered and distilled under vacuum. Only the middle 80% was collected. The surface tension of each oil agreed with reported data (12, 13).

Interfacial Tension Measurements.—The drop-volume method was used for all interfacial tension measurements. The apparatus used is the same as that described previously (1). It is a modification of one described recently by Parreira (14).

Calculations of interfacial tension from the drop-volume method were carried out with the Harkins and Brown equation (15),

$$\gamma = \frac{V(d - d')g}{2\pi r\theta} \qquad \text{(Eq. 1)}$$

where V = volume of the drop, cm.^{3}
g = gravity constant (980.3), cm./sec.^{2}
d = density of the aqueous phase, Gm./cm.^{3}
d' = density of the oil phase, Gm./cm.^{3}
π = 3.142
r = radius of the syringe tip, cm.
θ = correction factor obtained from the data of Harkins and Brown (15) for various values of $(r/V^{1/3})$

A syringe tip having a radius of 0.1895 cm. was used for all interfacial tension measurements. A 0.1895-cm. tip allowed at least 3 drops to form without refilling the syringe, even for the most dilute solutions. As with studies at the air/water interface (1), all values for $r/V^{1/3}$ that resulted from interfacial tension measurements with this syringe tip were within the range that allowed a second-order polynomial expression to be used for the calculation of θ.

The densities of hexane, octane, decane, dodecane, and tetradecane are 0.6595, 0.6986, 0.7258, 0.7459, and 0.7610 Gm./ml., respectively. These values do not change, within experimental error, if the oil is saturated with water. The density of water was also unaffected by saturation with oil.

It was observed that, if the syringe was not thoroughly cleaned between fillings, the volumes of the drops varied considerably, even with the same solution. This phenomenon did not occur in previous surface tension studies. It was possible that, if the syringe was not thoroughly cleaned between runs, a small amount of oil remaining on the tip might have been drawn into the syringe with the sample. If proper technique was used, however, the precision of the measurement was always within 0.2 dynes/cm., and in most cases to within 0.1 dynes/cm. In regions of very low interfacial tension, *i.e.*, below 7 dynes/cm., the results were erratic, apparently due to nonuniform wetting of the tip. A change in the size of the tip or the use of a stainless steel tip did not alleviate this difficulty.

It is interesting to note that the interfacial tensions of DPC, DTAC, and DEAC solutions, at all concentrations, were unaffected by the lack of mutual saturation of the aqueous and oil phases. All interfacial tension measurements, therefore, were made in solutions that were not saturated, with frequent checks being made on saturated systems. All solutions were prepared in duplicate. The volumes of at least 3 drops were measured for each sample; the volume of a drop was independent of time if the drop was allowed at least 5 min. to form. All interfacial tension measurements were, therefore, considered to be equilibrium measurements.

Interfacial tension *versus* concentration data were obtained for DPC and DEAC at the hexane–0.1 *M* KCl and dodecane–0.1 *M* KCl interfaces, and for DTAC at the hexane–0.1 *M* KCl, octane–0.1 *M* KCl, decane–0.1 *M* KCl, dodecane–0.1 *M* KCl, and tetradecane–0.1 *M* KCl interfaces. All measurements were carried out at 25 ± 0.1°.

RESULTS

In order to obtain values for the surface concentration and the surface area of each compound at the various interfaces, the Gibbs adsorption equation was applied. Since all measurements were made in the presence of excess electrolyte, the following form of the equation (16) was used:

$$\Gamma = 1/A = (1/kT)(d\pi/d \ln c) \qquad \text{(Eq. 2)}$$

where

Γ = surface concentration (molecules/cm.^{2})
A = surface area (cm.^{2}/molecule)
k = Boltzmann's constant (ergs/degree-molecule)
T = absolute temperature
π = surface pressure (ergs/cm.^{2})
c = bulk concentration (moles/L.)

The slopes of the surface pressure *versus* log bulk concentration plots were estimated with polynomial equations using the least squares method (1). An IBM 7090 digital computer was utilized to obtain the required data. Fourth-order polynomial equations gave the best fit to experimental data; a typical set of interfacial pressure *versus* logarithm molar concentration curves are shown in Fig. 1. The lines represent the empirical polynomial curves and the points represent experimental data.

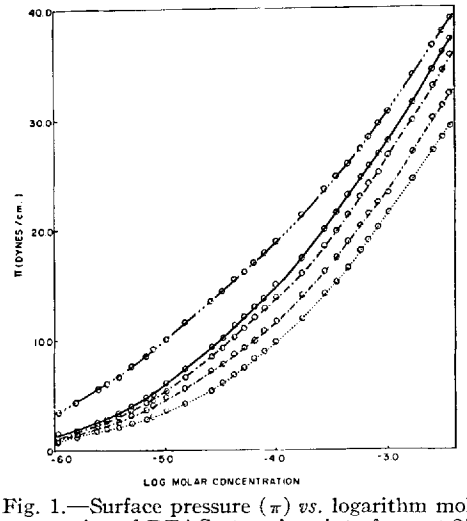

Fig. 1.—Surface pressure (π) *vs.* logarithm molar concentration of DTAC at various interfaces at 25°. (Lines represent empirical polynomial curves.) Key: ·····, hexane–0.1 *M* KCl; ———, octane–0.1 *M* KCl; –·–·–·, decane–0.1 *M* KCl; – – – –, dodecane–0.1 *M* KCl; ....., tetradecane–0.1 *M* KCl.

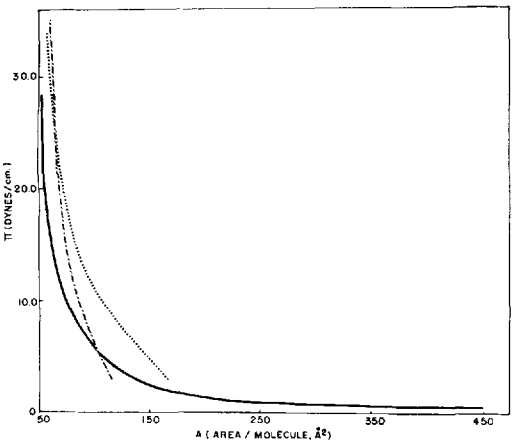

Fig. 2.—Surface pressure (π) *vs.* surface area (A) for DPC at various interfaces at 25°. Key: ———, air–0.1 *M* KCl; . . . . . , dodecane–0.1 *M* KCl; – – – –, hexane–0.1 *M* KCl.

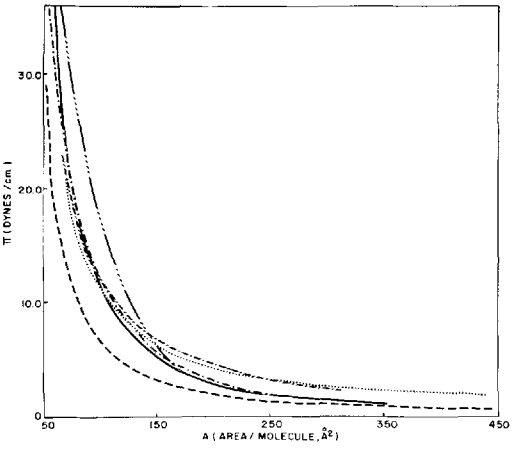

Fig. 3.—Surface pressure (π) *vs.* surface area (A) for DTAC at various interfaces at 25°. Key: – – – –, air–0.1 *M* KCl; —· · ·, hexane–0.1 *M* KCl; ———, octane–0.1 *M* KCl; ·—·—·, decane–0.1 *M* KCl; – — – —, dodecane–0.1 *M* KCl; . . . . . , tetradecane–0.1 *M* KCl.

The π-A curves of DPC, DTAC, and DEAC at the various interfaces are shown in Figs. 2–4. These curves generally indicate that more "condensed" films occur with the lower molecular weight oils (*i.e.*, a marked increased in the surface pressure for a small change in the area per molecule) particularly in regions of high area. The π-A curves for the quaternary ammonium compounds at the air–0.1 *M* KCl, hexane–0.1 *M* KCl, and dodecane–0.1 *M* KCl interfaces are shown in Figs. 5–7, respectively. Whereas the π-A curves of the 3 quaternary ammonium compounds are quite similar at the air/water surface, the π-A curves of DPC appear to be more "condensed" than those of DTAC and DEAC at the oil/water interfaces, particularly at the hexane–0.1 *M* KCl interface.

A region where surface pressure changed linearly with concentration (Traube region) was not observed at any of the oil/water interfaces tested.

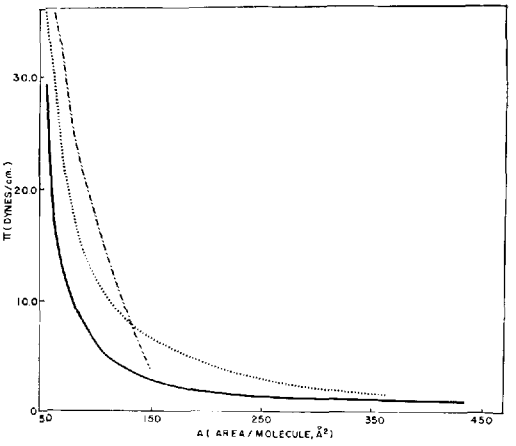

Fig. 4.—Surface pressure (π) *vs.* surface area (A) for DEAC at various interfaces at 25°. Key: ———, air–0.1 *M* KCl; . . . . . , dodecane–0.1 *M* KCl; – – – –, hexane–0.1 *M* KCl.

This observation appears to substantiate Hutchinson's hypothesis (3) that, even for low concentrations of surface-active agents, the hydrocarbon group is immersed in the oil phase, rather than lying parallel to the interface.

DISCUSSION

The greater complexity of the oil/water interface as compared to the air/water surface and differences with different oils is to be expected when one considers the possible interactions between the hydrocarbon portion of the surface-active agent and the oil. Furthermore, it appears that interactions between the polar group of the surface-active agent and the oil are responsible for marked changes in the nature of the surface film. This aspect has not been considered previously.

In order to evaluate the effect of the oil phase, as observed in this study, it will be worthwhile looking at 2 extreme situations. First, the oil does not interact with the hydrocarbon portion of the surface-active agent, and the only interactions of interest are those between the hydrocarbon portion and water at high surface areas, and those between surface-active agent hydrocarbon portions at low areas. In the second case, the oil strongly interacts with the hydrocarbon portion of the surface-active agent and there is minimal hydrocarbon–water interaction at high surface areas, as well as little or no cohesive interaction between surface-active molecules.

If the first case occurs, the hydrocarbon portion of the surface-active agent should be aligned approximately parallel to the interface at high surface areas. This would result in a linear change in surface pressure with concentration (Traube region), as observed at the air/water interface (1), and would mean that the oil phase does not affect the nature of the film. This, of course, is contrary to what is seen in Figs. 3 and 4. At lower areas interaction between the hydrocarbon portions of surface-active agent should result in π-A curves which are the same as those observed at the air/water interface. Again, Figs. 3 and 4 indicate that this is not the case, although at very low areas, expulsion of oil molecules from the surface may be occurring to some extent.

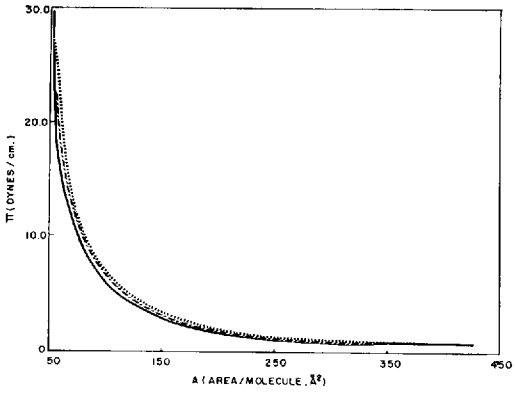

Fig. 5.—Surface pressure (π) *vs.* surface area (A) for the air −0.1 M KCl interface at 25°. Key: ———, DPC; – – – –, DEAC; . . . . . , DTAC.

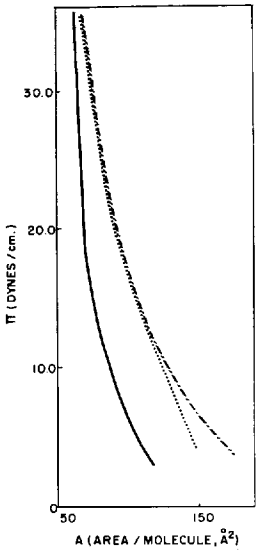

Fig. 6.—Surface pressure (π) *vs.* surface area (A) for the hexane-0.1 M KCl interface at 25°. Key: ———, DPC; – – – –, DEAC; . . . . . , DTAC.

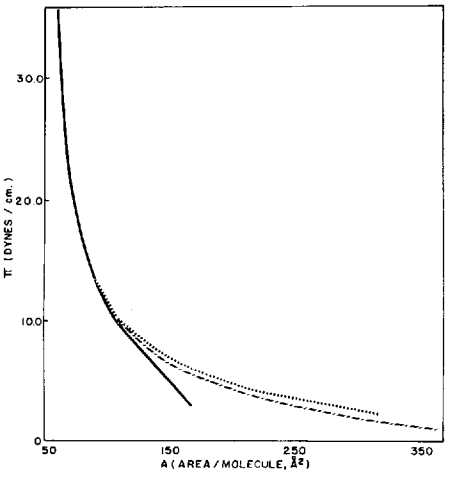

Fig. 7.—Surface pressure (π) *vs.* surface area (A) for the dodecane–0.1 M KCl interface at 25°. Key: ———, DPC; – – – – –, DEAC; . . . . . , DTAC.

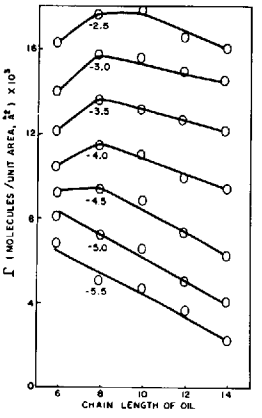

Fig. 8.—Surface concentration (Γ) at the 0.1 M KCl–hydrocarbon interface at 25° *vs.* chain length of hydrocarbon for various bulk concentrations of DTAC (expressed as log of molarity).

If the oil interacts strongly with the surface-active agent, the strong interaction between the hydrocarbon portion of the surface-active agent and the oil should result in an alignment of surface-active molecules approximately perpendicular to the interface, even at high surface areas. It would then be reasonable to expect that the most "condensed" film would result in the dodecane/water interface, since the dodecane–dodecyl quaternary ammonium compound interaction would allow stronger attractive forces than would the other oils tested. Figures 2–4 indicate that this is not the case. In fact, the hexane/water interface results in the most "condensed" films for all 3 quaternary ammonium compounds tested. This extreme would also necessitate the absence of a transition from an "expanded" region (a region where hydrocarbon–water interactions are predominent and small changes in surface pressure produce large changes in area per molecule) to one of saturation adsorption (a region where hydrocarbon–hydrocarbon interactions are predominant and changes in pressure do not produce significant changes in area). Figures 2–4 show that this transition does not always occur, and, in fact, whereas the dodecane/water interface does show such a transition for DTAC and DEAC, the hexane/water interface, at the pressures tested, does not. It therefore appears that the nature of the film is intermediate between the 2 extremes cited. The alignment of the surface-active molecules at the oil/water interface is neither parallel nor perpendicular to the interface, but intermediate between the two.

Plots of the chain length of the oil *versus* the surface concentration of DTAC at various bulk concentrations (Fig. 8) appear to give some indication as to the role of the oil. At low bulk concentrations the surface concentration of DTAC is inversely proportional to the chain length of the oil. At higher bulk concentrations, the octane/water interface contains the highest surface concentration of DTAC. At even higher bulk concentrations, the decane/water interface contains surface concentrations of DTAC which are of equal magnitude to that of the octane/water interface. It seems possible, therefore, that as the bulk concentration of DTAC increases, there is a tendency for the higher chain length hydrocarbons to interact to a greater extent with the DTAC film.

This trend could be accounted for by the fact that, at low bulk concentrations, the DTAC molecules are not aligned perpendicularly to the interface due to

some interaction with water, coiling of the hydrocarbon chains, or both. The size of hexane, as compared to the other hydrocarbons, could make it best suited to interact with the DTAC film at these low concentrations. As the surface concentration increases, it is reasonable to expect that the hydrocarbon portions of the surface-active agents will orient in a more perpendicular direction to the interface. This should improve the chances for the longer-chain hydrocarbons to interact with the exposed groups of the surface-active agents.

The preceding discussion considered only the interactions between the oil and the hydrocarbon group of the surface-active agent. It is important, however, not to neglect the possibility of an interaction between the polar group of the surface-active agent and the oil. Figures 5–7 show that, although the π-A curves of DPC, DTAC, and DEAC are quite similar at the air/water surface, differences between the 3 quaternary ammonium compounds at an oil/water interface do exist. The π-A curves for DPC are "compressed" to a greater extent than those for DTAC and DEAC at the oil/water interfaces, especially at the hexane/water interface. This effect may be due to a dipole-induced dipole interaction between the planer aromatic pyridinium ion and the oil, which is less possible in the case of DTAC or DEAC. Once again, the steric nature of the hexane molecule probably makes it best suited for this interaction.

It appears, therefore, that the nature of the oil phase influences adsorption of water-soluble substances, such as quaternary ammonium salts, and that the oil used in such studies must be considered in any discussion.

Solubilizing Properties of Bile Salt Solutions I

Effect of Temperature and Bile Salt Concentration on Solubilization of Glutethimide, Griseofulvin, and Hexestrol

By THEODORE R. BATES, MILO GIBALDI and JOSEPH L. KANIG

Data on the micellar solubilization of the poorly water-soluble drugs, griseofulvin, hexestrol, and glutethimide, in 0–0.6 *M* aqueous solutions of the sodium salts of cholic, desoxycholic, taurocholic, and glycocholic acids at 3 temperatures are presented. Employing the pseudo two-phase model for micellar solubilization, the thermodynamic functions, ΔF^0, ΔS^0, and ΔH^0 of partitioning of the drug molecule between the aqueous phase and the micellar phase have been determined for hexestrol and griseofulvin. The physical-chemical ramifications and biological implications in these systems are considered.

AQUEOUS solutions of surfactants exhibit a more or less abrupt change in their physical properties over a narrow concentration range. This distinct change in properties is generally accepted to be due to the formation of oriented aggregates or micelles. The narrow surfactant concentration range at which micelles begin to form is referred to as the critical concentration for micelle formation or CMC. Among the more interesting properties of micellar solutions is their ability to solubilize water-insoluble materials.

Micellar solubilization has been defined by McBain (1) as "the spontaneous passage of solute molecules of a substance, insoluble in water, into an aqueous solution of a surfactant in which a thermodynamically stable solution is formed." This process essentially involves the diffusion of the added solubilizate molecules (*i.e.*, the water-insoluble material being solubilized) from the bulk phase into the surfactant micelle. The solubilized system is in a state of equilibrium.

Micellar solubilization has been broadly classified into 3 types (1–3). (*a*) *Nonpolar (nonspecific) solubilization:* the solubilizate is in-

corporated into the hydrocarbon center of the micelle, away from the polar head groups. (*b*) *Polar-nonpolar (specific) solubilization:* the solubilizate is incorporated by penetration into the palisade layer of the micelle with the solubilizate molecule oriented in approximately the same manner as is the surfactant molecule in the micelle. (*c*) *Adsorption solubilization:* in this type of solubilization, the solubilizate is adsorbed onto the polar surfaces of the micelle.

In 1936, Hartley (4) predicted that bile salts, like soaps, should form micellar solutions above their CMC. Equivalent conductivity-concentration (5–7), freezing point (5), dye solubilization (8), and small angle X-ray scattering (9) experiments, as well as the solubilization of 20-methylcholanthrene (10), are some of the numerous investigations that conclusively demonstrate that colloidal aggregates form in conjugated and unconjugated bile salt solutions at a certain minimum concentration.

Numerous investigations have demonstrated the solubilizing properties of bile salts for water-insoluble materials. Verzar (11) showed in 1933 that bile salts were capable of solubilizing aniline, calcium carbonate, calcium phosphate, camphor, quinine, strychnine, paraldehyde, quinoline, and benzaldehyde. McBain and co-workers (8) studied the equilibrium solubility of the dye, Yellow AB, in 1% aqueous solutions of the sodium salts of cholic acid, desoxycholic acid, taurocholic acid, and dehydrocholic acid at 25°. Merrill and McBain (12) compared the solubilities of the dyes, Yellow AB and Orange OT, in 1% aqueous solutions of the same 4 bile salts used in the previously cited study (8). Ekwall (13) reviewed some of the solubilization work done by himself and co-workers with a wide variety of insoluble substances in bile salt solutions. This paper includes: (*a*) solubilization of various carcinogenic polycyclic hydrocarbons at 40° (10, 14, 15); (*b*) solubilization of *p*-xylene in solutions of sodium cholate and desoxycholate; (*c*) solubility of cholic and desoxycholic acids in aqueous solutions of their respective sodium salts (16); (*d*) solubilization of cholesterol in sodium desoxycholate, cholate, and taurocholate; and (*e*) solubilization of C_6–C_{18} fatty acids, lecithin and glyceryl monostearate, in 0.09 *M* sodium taurocholate solutions. Ekwall and Sjöblom (17–19) have studied the solubilization of various steroid hormones in bile salt solutions. The solubilization of the nonsteroidal synthetic estrogen, hexestrol, in 5, 10, and 20% solutions of sodium cholate, desoxycholate, dehydrocholate, and glycocholate at 40° was also considered by these investigators.

Bile salts have been shown also to play an important role in the physiological processes of digestion and absorption of dietary lipids. The most modern theory for fat digestion and absorption is the one proposed by Borgström (20). According to his theory, the breakdown products of fat digestion (*i.e.*, fatty acids and monoglycerides) are absorbed across the intestinal mucosa from a mixed micellar solution composed chiefly of fatty acids, monoglycerides, and conjugated bile salts. In connection with this theory of fat absorption, several *in vitro* investigations have appeared in the literature demonstrating the marked solubilizing ability of conjugated bile salts for fatty acids and monoglycerides (21–24).

Although considerable evidence has appeared in the literature concerning the effects of bile salts on endogenous materials, little work has been done to determine the effects of bile salts on drug molecules. Accordingly, little consideration has been given to the possibility that insoluble drugs may be absorbed by a mechanism involving preliminary solubilization of the drug by the bile salt micelles normally present in the intestine. This consideration prompted an extensive physicochemical investigation of the solubilization of 3 water-insoluble pharmaceuticals in dilute bile salt solutions as well as some of the factors which may influence the extent of their solubilization.

This paper reports some of the findings on the effect of temperature and bile salt concentration and structure on the degree of solubilization of the water-insoluble drugs, griseofulvin, hexestrol, and glutethimide, in dilute aqueous solutions of the sodium salts of cholic, desoxycholic, taurocholic, and glycocholic acids.

THEORY

Micellar solubilization of a poorly water-soluble material can be treated as a process in which the poorly water-soluble material is partitioned between an aqueous phase and a micellar phase formed by the surfactant above its CMC (1). The partition coefficient associated with this process is expressed by the equation:

$$K = \frac{[D_M]}{[D_{NM}]} \qquad \text{(Eq. 1)}$$

where $[D_M]$ is the concentration of drug in the micelle and $[D_{NM}]$ is the concentration of drug in the nonmicellar phase.[1] The brackets denote concentrations expressed in terms of the individual phase volumes, rather than the total volume of the system.

Multiplying the numerator and denominator of Eq. 1 by the total volume of the system, V (*i.e.*, $V_{NM} + V_M$), yields the expression,

$$K = \frac{(D_M)}{(D_{NM})} \cdot \frac{V_{NM}}{V_M} \qquad \text{(Eq. 2)}$$

[1] It was assumed that the activity coefficient of the drugs in the nonmicellar phase closely approximated the activity coefficient in the micellar phase.

where the parenthesis denote concentrations expressed in terms of total volume. V_{NM} and V_M represent the nonmicellar and micellar volumes, respectively.

Expressing Eq. 2 in terms of micellar volume yields

$$K = \frac{(D_M)}{(D_{NM})} \cdot \frac{(V - V_M)}{(V_M)} \qquad \text{(Eq. 3)}$$

However, V_M/V may be represented as M, where M is defined as the volume fraction of surfactant (25, 26). Substituting this relationship into Eq. 3 gives the expression,

$$K = \frac{(D_M)}{(D_{NM})} \cdot \frac{(1 - M)}{(M)} \qquad \text{(Eq. 4)}$$

Assuming M is small as compared to the total volume (25, 26) then $(1 - M)$ is approximately equal to unity and Eq. 5 is obtained.

$$K = \frac{(D_M)}{(D_{NM})} \cdot \frac{1}{M} \qquad \text{(Eq. 5)}$$

Above the CMC of a surfactant an equilibrium exists between monomers and micellar aggregates. The solution is saturated with respect to monomers, and further addition of surfactant molecules results in further aggregation. It has been theorized that additional molecules of surfactant produce an increase in the number rather than in the size of the micelles. Accordingly, micellar volume is a direct function of surfactant concentration. Over a limited range, this is considered to be a reasonable approximation (4, 27). This concept may be expressed as Eq. 6.

$$\frac{C_1}{C_2} = \frac{M_1}{M_2} \qquad \text{(Eq. 6)}$$

where C is the molar concentration of the surfactant. The subscripts, 1 and 2, refer to different concentrations above the CMC of the surfactant.

Inserting the relationship between C and M, as expressed in Eq. 6, into Eq. 5 yields the final equation:

$$\Delta D_M = K D_{NM} \Delta C \qquad \text{(Eq. 7)}$$

It can be seen readily from the form of Eq. 7 that a plot of (D_M) *versus* C should yield a straight line above the CMC of the surfactant. The slope of this linear plot divided by (D_{NM}) will give the value of K, from which the thermodynamic constants can be calculated.

The free energy of partitioning (ΔF^0) may be calculated from

$$\Delta F^0 = -2.3RT \log K \qquad \text{(Eq. 8)}$$

The heat of partitioning (ΔH^0) can be determined with the aid of the relationship

$$\frac{\delta \log K}{\delta(1/T)} = \frac{-\Delta H^0}{2.3R} \qquad \text{(Eq. 9)}$$

by plotting log K at various temperatures *versus* $1/T$ (°K.). From the slope of this linear plot, ΔH^0 can be obtained. This method of acquiring ΔH^0 requires that ΔH remain reasonably constant over the temperature range studied.

The change in entropy (ΔS^0) associated with this process of solubilization would follow from the equation

$$\Delta S^0 = \frac{\Delta H^0 - \Delta F^0}{T} \qquad \text{(Eq. 10)}$$

EXPERIMENTAL

Materials.—Hexestrol,[2] griseofulvin,[3] and glutethimide[4] were used as recieved. The pure bile salts, sodium cholate,[5] sodium desoxycholate,[5] sodium glycocholate,[6] and sodium taurocholate[6] were dried *in vacuo* for 36 hr. prior to use.

Equilibration.—The solubility of each drug was measured in a series of aqueous solutions containing various concentrations of the individual bile salts. Hexestrol and griseofulvin were studied at 27, 37, and 45°. The solubility of glutethimide was determined at 27, 32, and 37°.

In each case an excess amount of drug was added to bile salt solution contained in suitably sealed tubes. The tubes were placed in a shaker-incubator[7] and equilibrated for periods usually not less than 1 week's duration. Equilibrium was determined by repetitive sampling.

Assay Procedure.—Each time the tubes were sampled the shaker was turned off to allow most of the excess solid to settle to the bottom of the tubes. The supernatant liquid then was filtered through a filter (Millipore, 0.45 M pore size) to insure that no undissolved solid was present in the sample taken for analysis. To eliminate any temperature differential during the filtration and sampling steps, precautions were taken to maintain the filtration equipment and pipets at the same temperature as that employed for the equilibrium experiments.

Aliquots of the clear drug solutions were diluted with anhydrous reagent methanol, and the drug concentration was determined spectrophotometrically using a Beckman DB recording spectrophotometer. Methanol–water (10:1) served as the blank for hexestrol and griseofulvin, and methanol–water (8:1) was employed for glutethimide. The peak absorbance of griseofulvin and hexestrol (in 1:10 water–methanol solvent mixture) at 292 mμ and 278 mμ, respectively, and glutethimide (in 1:8 water–methanol solvent mixture) at 257.6 mμ was used to prepare Beer's law plots. In the dilutions required for spectrophotometric analysis, no shifts in absorbance maxima were observed as a result of the presence of surfactant. However, the bile salts do absorb slightly at the wavelength of maximum absorbance of these drugs. Therefore, the absorbance of varying concentrations of the bile salts, at the 3 previously mentioned wavelengths, was plotted *versus* bile salt concentration, and a calibration curve was thus constructed.

To determine the amount of drug that had been solubilized, the absorbance value corresponding to the concentration of bile salt in the final dilution

was subtracted from the observed absorbance values, and the corrected absorbance values were converted to concentrations by the use of the Beer's law plots.

RESULTS AND DISCUSSION

Effect of Bile Salt Type and Concentration on Solubilization.—The solubilization curves for Griseofulvin in varying concentrations of sodium desoxycholate solutions at 27, 37, and 45° are shown in Fig. 1. These data are representative of the type of curves obtained with sodium cholate, sodium glycocholate, and sodium taurocholate solutions. It can be seen from each of these curves that the solubility of griseofulvin increases linearly with bile salt concentration, after a certain minimum concentration of bile salt has been exceeded, *i.e.*, the CMC. The CMC values for the 4 bile salts employed in this study, as determined from the solubilization of griseofulvin and hexestrol, respectively, at 37°, are: sodium cholate (0.014, 0.016), sodium desoxycholate (0.005, 0.010), sodium taurocholate (0.008, 0.014), and sodium glycocholate (0.010, 0.015). These values are in good agreement with those obtained by other investigators employing various solubilizates (9, 13). It should be borne in mind that CMC values determined from solubilization data are only approximate, since the presence of solubilized material may exert an effect on the process of micelle formation (1, 2).

The slope of the linear portion of the solubilization curve, after the CMC, is termed the saturation ratio or capacity, *i.e.*, the ratio of micellar drug to micellar bile salt. The saturation ratios, expressed as moles of solubilized drug per mole of bile salt as well as the inverse of these ratios for griseofulvin in each of the 4 bile salts employed in this study, are presented in Table I. The saturation ratio at 27 and 37° in decreasing order are: cholate ≥ desoxycholate > glycocholate ≥ taurocholate. This sequence also indicates the order of solubility of griseofulvin in a particular concentration of these colloidal electrolytes. At 45° the order of cholate and desoxycholate is reversed, suggesting that at this higher temperature sodium desoxycholate micelles have a higher affinity for griseofulvin than do sodium cholate micelles.

Figures 2 and 3 show the solubility of the synthetic estrogenic hormone, hexestrol, in sodium glycocholate and sodium taurocholate solutions at 27, 37, and 45°. Similar curves were obtained in sodium cholate and sodium desoxycholate solutions. The saturation ratios as well as the inverse of these ratios are listed in Table II. As with griseofulvin, the solubility of hexestrol at all 3 temperatures increases linearly with bile salt concentration above the CMC. The saturation ratios for hexestrol are many times greater than those of griseofulvin, illustrating the well-established fact that the structure of the solubilizate is a critical factor in governing the extent or degree of micellar solubilization (1, 2). The saturation ratios for hexestrol, in decreasing order, at any one temperature, are: glycocholate ≥ taurocholate > cholate > desoxycholate. Thus, in the case of hexestrol, the conjugated bile salt micelles (*i.e.*, sodium glycocholate and sodium taurocholate) show a greater affinity for the solubilizate molecules than do the unconjugated bile salt micelles. The reverse was found to be true for the solubilization of griseofulvin.

Representative solubilization curves for glutethimide in 0–0.06 *M* solutions of sodium cholate at 27, 32, and 37° are shown in Fig. 4. The corresponding saturation ratios (moles of solubilized glutethimide per mole of bile salt) and the inverse of these ratios are reported in Table III. The 32°-

temperature study was included since at 45° the solubilization curve for glutethimide was not linear, suggesting a possible change in the solubilization mechanism at this higher temperature. All experiments were performed in duplicate, and reasonable replication was obtained. Thus, spurious experimental factors were ruled out as contributing to the nonlinearity. In addition, no change in the U.V. spectra of glutethimide was observed. The saturation ratios in decreasing order are: desoxycholate > cholate ≥ taurocholate > glycocholate.

The differences in the order of the saturation ratios obtained in the various bile salt solutions with each drug used in this study are probably due to differences in the arrangement of the bile salt molecules in the micelle as well as differences in the degree and/or type of interaction between the drug molecule and the bile salt micelle. The penetration of the solubilizate may alter significantly the actual organization, shape, and even the size of the resultant bile salt micelle (13). This would explain not only the differences found in the affinity between these bile salts and the individual drug, but also the differences found in the saturation ratio se-

quences of these bile salts and each of the drugs. Unfortunately, at present, very little is known about the structures of the bile salt micelles. However, they are thought to be considerably different from the classical spherical micelles formed by the more common surfactants. A detailed explanation for these observed differences must await a more complete understanding of the molecular arrangement of the bile salt micelles, as well as knowledge of the nature of the interactions that are important in causing micellar aggregation of both the unconjugated and conjugated bile salts.

It can readily be seen from both the saturation ratio and inverse saturation ratio data, presented in Tables I–III, that the solubilities of hexestrol, glutethimide, and griseofulvin in the same bile salt differ greatly. For these solubilizates, the solubilities increase in the following order: griseofulvin < glutethimide < hexestrol. It would appear, based on the higher saturation ratios observed for both hexestrol and glutethimide as compared to griseofulvin, that they are being incorporated predominately into the "palisade layers" of the bile salt micelle as would a relatively polar solubilizate molecule (1–3). On the other hand, griseofulvin is probably more closely associated with the hydrocarbon region of the micelle, similar to a nonpolar solubilizate molecule (1–3).

As previously indicated, knowledge of the exact structure of the bile salt micelles is lacking. In view of this insufficiency, the mechanism by which the molecules of the solubilized substances are incorporated in the micelles must remain speculative until further investigations in this area. It should also be noted that the chemical nature, size, and structure of the solubilized molecules influence in various ways the arrangement of the surfactant molecules in the micelle (9, 13). Experiments presently being conducted in our laboratories, dealing with the effects of amphiphilic and nonpolar additives and inorganic electrolyte on the solubilization characteristics of these drugs should yield an insight to the location of the solubilized drug molecules in the bile salt micelle.

Effect of Temperature on Solubilization.—Temperature is an important factor which has a varying effect on the extent of micellar solubilization. The structure of the surfactant and/or the solubilizate will dictate whether there is an effect and whether it is positive or negative.

Inspection of the saturation ratio values for griseofulvin, presented in Table I, shows that as the temperature of the system increases from 27 to 45° there is a corresponding increase in the degree of micellar solubilization. This positive temperature effect is observed in all of the bile salt solutions studied. Similar temperature effects were observed for both hexestrol (Table II) and glutethimide (Table III). However, temperature appears to have less of an influence on the solubilization of hexestrol in comparison to the other 2 solubilizates.

A positive temperature effect is contrary to the theory proposed for micellar solubilization in solutions of fatty acid soap-type surfactants (3). According to this theory, in a homologous series of fatty acid soaps, below 25°, as the temperature is increased, the CMC of the surfactant decreases, due to an increase in the entropy of the structured water molecules around the hydrocarbon portion of the surfactant molecule. As the temperature is increased above 25°, the kinetic motion of the surfactant molecules in the micelle is enhanced and overshadows this entropy effect. The thermal motion causes a slight increase in the CMC of the surfactant and thus increases the difficulty with which micelles form. Based on these facts, one would expect that at higher temperatures solubilization should decrease.

Although a number of studies have been conducted to examine the effect of temperature on the solubilization process in typical ionic surfactant solutions, relatively few temperature studies have been conducted in bile salt solutions. Merrill and McBain (12) observed a positive temperature coefficient (*i.e.*, the ratio of the saturation ratio at a higher temperature to that at a lower temperature exceeded unity) for the dye Yellow AB in 0.1 *N* sodium desoxycholate solutions. Hofmann observed a similar temperature effect on the solubilization of azobenzene in sodium glycochenodesoxycholate solutions, but observed no effect on the solubilization of the monoglyceride, 1-monoolein (24).

Since micellar solubilization is closely related to micelle formation, one possible explanation for the positive temperature effects observed in the present study is that as the temperature of the system is increased the CMC of the bile salt decreases. However, values determined from the solubilization curves for the individual bile salts show that the CMC values of the bile salts are not significantly altered in the temperature range employed in this study. Thus, the observed temperature effects cannot be explained on the basis of CMC values.

A more plausible explanation has been proposed by McBain and Hutchinson (1). According to these investigators, it may be assumed that the principal effect of temperature is to "change the solubility of the solubilizate in the micelle." Hofmann (24), in his investigations of the effect of temperature on the solubilization of azobenzene and 1-monoolein in sodium glycochenodesoxycholate solutions at 23 and 37°, states that, "the higher saturation ratio observed for the former solubilizate at 37° need not indicate any change in the state of micellar aggregation." This view is in agreement with Hofmann's observations that 1-monoolein had the same saturation ratio at 23 and 37°, thereby indicating that temperature has little effect on the micellar organization.

Thermodynamic Evaluation.—The results of this investigation are consistent with the hypothesis that temperature primarily influences the "solubility" of the solubilizate molecule in the bile salt micelle. Therefore, one would expect that as the temperature of the system is increased so should the degree of interaction between the solubilizate molecule and the bile salt molecules comprising the micelle. In view of this consideration, it was decided to determine the thermodynamics of these bile salt–drug systems so that an appreciation for the magnitude of the energies involved in the process of micellar solubilization in bile salt solutions could be obtained.

In order to determine the thermodynamic constants associated with the solubilization of griseofulvin and hexestrol in bile salt solutions, a pseudo two-phase model was selected. According to this model, the solubilizate molecule is partitioned between an aqueous phase and a micellar phase. This partitioning is similar to that observed for a poorly water-soluble drug between a nonpolar solvent and water. The partition coefficient, K, associated with this process was determined by the use of Eq. 7. The values obtained for griseofulvin, hexestrol, and glutethimide at 3 temperatures are listed in Table IV. The magnitude of these values shows that the poorly water-soluble drugs are preferentially partitioned to the micellar phase.

The data in Table IV also indicate that a decrease in the partition coefficients of both griseofulvin and hexestrol occurs with an increase in temperature. No definite conclusion could be made for the effect of temperature on partition coefficient for glutethimide. A similar decrease in partition coefficient with temperature was observed by Rippie and coworkers (25), in considering the solubilization of a methylprednisolone-21-hemiester in aqueous solutions of polysorbate 80. These investigators partially attribute this negative effect to micellar size changes. In conducting this investigation it was decided to consider the phenomenon on the basis of thermodynamic factors. The heats of solution of

griseofulvin and hexestrol in water and in each of the bile salt solutions was determined from the slope of a Clausius-Clapeyron-type plot (*i.e.*, a plot of log solubility *versus* $1/T$). The heats of solution ($\Delta H_{soln.}$) in the bile salt micelle ranged from −2.5 to −5.0 Kcal./mole for griseofulvin and from approximately zero to −1.4 Kcal./mole for hexestrol, as compared to −7.3 Kcal./mole for griseofulvin and −8.4 Kcal./mole for hexestrol in water. This indicates that the solubility of the drugs in the aqueous phase is affected by temperature more than it is in the bile salt solutions, resulting in the observed decrease in the partition coefficient.

According to Eq. 9, a plot of log K *versus* $1/T$ should be linear. From the slope of such a plot the standard enthalpy change, ΔH^0, associated with this partitioning process can be obtained. Typical van't Hoff-type plots for griseofulvin (Fig. 5) and hexestrol (Fig. 6) show the excellent linearity observed over the temperature range studied. Treatment of the glutethimide data in a similar manner produced plots which were nonlinear. This suggests the possibility that glutethimide is solubilized by a different mechanism than are hexestrol and griseofulvin.

Values for the standard free energy changes (ΔF^0) and entropy changes (ΔS^0) associated with the solubilization process were determined with the aid of Eqs. 8 and 10, respectively. The values of ΔF^0, ΔH^0, and ΔS^0 for the solubilization of griseofulvin in the 4 individual bile salts are presented in Table V, and those for hexestrol in Table VI.

The negative ΔF^0 values obtained is indicative of the spontaneity of the solubilization process. The standard enthalpies, ΔH^0, for each drug in all of the bile salts are quite similar. However, there is a significant difference between the ΔH^0 values for hexestrol and for griseofulvin. This indicates that the enthalpy function is more dependent on the nature of the drug molecule than on the nature of the bile salt molecule. The negative enthalpy changes obtained are consistent with the hypothesis that micellar solubilization is an exothermic process (1, 25, 26).

It has been proposed that because of the loss of freedom experienced by the drug molecule in going from the aqueous phase to the micellar phase a negative entropy change should accompany the solubilization process (26). The small positive entropy values obtained in this investigation indicate that other factors must be taken into consideration. A possible explanation for the positive entropy values is that loss of water structure in the system counterbalances the restriction placed on the drug molecule when it is solubilized by the bile salt micelle.

Biological Implications.—A comparison of the equilibrium ratio of the amount of drug solubilized by a 0.04 M bile salt solution to that in water for the 3 solubilizates at 37° shows that the ratios in decreasing order are: hexestrol > griseofulvin > glutethimide (Table VII). A bile salt concentration of 0.04 M is considered to be the approximate

molarity of the total bile salts present in the small intestine during fat absorption (21, 24, 28). These values show that the bile salts display a significant effect in increasing the solubility of these poorly water-soluble drugs.

TABLE VII.—RATIOS OF THE SOLUBILITIES OF HEXESTROL, GRISEOFULVIN, AND GLUTETHIMIDE IN 0.04 *M* SOLUTIONS OF CONJUGATED AND UNCONJUGATED BILE SALTS TO THAT IN WATER AT 37°

Drug absorption across the gastrointestinal barrier takes place almost exclusively from a solution of the drug (29). Therefore, the drug must be in solution before it can be absorbed. In the case of extremely water-insoluble drugs, dissolution of the drug usually becomes the slow rate-determining step in the absorption process.

Poorly water-soluble drugs will partition between the aqueous phase and a liquid phase, with a relatively large lipid–water partition coefficient. From a physicochemical point of view, one can draw an analogy between these poorly water-soluble drugs and a dietary lipid. Based on this analogy it would be interesting to speculate that the gastrointestinal tract handles these drugs in the same manner as it handles dietary lipids. In view of the *in vitro* evidence it is quite conceivable that relatively water-insoluble drugs may be absorbed by a mechanism involving preliminary solubilization of the drug by bile salt micelles present in the small intestine.

Relative dissolution rate studies indicate that bile salts significantly increase the dissolution rates of griseofulvin and hexestrol over that in water (30). These findings serve to strengthen further the possibility that physiologic surfactants play an important role in the dissolution step of the absorption process.

Lecithin and cholesterol, which are normal components of bile, as well as fatty acids and monoglycerides, which are the normal breakdown products of fat digestion, have been shown to form mixed micelles with the conjugated bile salts in the small intestine. Extensive studies currently are being conducted to determine the effects of these, as well as other additives, on the degree of solubilization of water-insoluble drugs under conditions simulating those existing in the human small intestine during fat digestion and absorption.

Steroid Tablet Assay Involving Automated Sample Preparation and Blue Tetrazolium Reaction

By WILLIAM F. BEYER

Automated homogenization, chloroform extraction, and blue tetrazolium assay of hydrocortisone, methylprednisolone, and prednisolone tablets are described. The coefficients of variation for the determination of the three steroids were 1.39, 1.51, and 2.33 per cent, respectively. Tablets are analyzed at a rate of 20/hr. with Technicon's solid preparatory unit and proportioning pump in conjunction with a commercially available spectrophotometer and a strip chart recorder.

THE MANUAL assay of steroid tablets by the blue tetrazolium procedure requires somewhat time-consuming techniques. Directions of U.S.P. XVII (1) and N.F. XII (2) require disintegration of tablets in water and extraction with chloroform. Aliquots of chloroform are then evaporated, and steroids are redissolved in alcohol. Color is developed by the reduction of blue tetrazolium to form the formazan in a solution buffered with tetramethylammonium hydroxide. After standing 90 min. in the dark, color is read at about 525 mμ. Automation of certain aspects of this procedure was described by Greely *et al.* at the New York Academy of Science Conference on Automation in January 1965 (3). The need for a system capable of doing many single tablet assays and the requirement of tablet content uniformity by U.S.P. XVII and N.F. XII for specified tablets led to the development of a completely automated system. Details of the procedure and assay data are the subject of this report.

EXPERIMENTAL

Equipment.—Solid preparatory unit (Solidprep) proportioning pump and 37° water bath.[1] Spectrophotometer and recorder.[2]

Reagents.—3A alcohol;[3] blue tetrazolium, 0.1% in 3A alcohol; chloroform, analytical grade; distilled water with 0.5 ml. of polyoxyethylene lauryl ether[4] added to each 5 gal.; tetramethylammonium hydroxide, 10% aqueous solution diluted 1:10 with 3A alcohol, filtered before use.

Standards.—Accurately weighed quantities of hydrocortisone, methylprednisolone, and prednisolone reference standards are dissolved in 75% 3A alcohol so that each 10.0 ml. contains an amount of steroid equivalent to each tablet.

Tablets.—Steroid tablets are placed in sample cups with 10.0 ml. of 75% 3A alcohol. Cups are covered and allowed to stand for 1 hr. or until tablets disintegrate.

Procedure.—Reagents are pumped using the manifold flow system shown in Fig. 1, and instrumental units are standardized to give a zero base line. The Solidprep is adjusted to deliver 75 ml. of distilled water with polyoxyethylene lauryl ether and mixer speed positioned at No. 4 setting. Approximately 4 cups of the appropriate standard are placed in the sampler head, followed by cups of disintegrated tablets. Standards are placed thereafter at regular intervals to minimize reagent changes and instrumental variation. Samples are automatically homogenized in the blender assembly of the Solidprep. Steroids contained in dilute alcohol are then automatically extracted with chloroform using 3 (6 in.) extraction coils. Blue tetrazolium and tetramethylammonium hydroxide are added directly to the chloroform, and the reaction mixture passes through 2 small mixing coils placed in a 37° water bath. Absorbance of the solution is measured at 524 mμ using a 1.0-cm. flow cell and automatically recorded on a strip chart recorder.

Calculations are made using corresponding absorbances of standards and tablet samples.

RESULTS AND DISCUSSION

Preliminary studies were made indicating that chloroform solutions of steroid could be used satisfactorily in the blue tetrazolium reaction. Aspiration of sample directly from the blender of the Solidprep and extraction with chloroform was carried out initially; however, owing to irregular

Transmission lines carrying air or aqueous solutions consist of Tygon tubing, those carrying alcohol or chloroform are acidflex.

sampling, a debubbler was introduced, and a bubble-free sample was withdrawn and extracted. The use of the first two extractors in a horizontal position and the last vertical produced an even pumping action and bubble pattern. Attaching a small horizontal mixing coil to the last extractor permitted satisfactory separation of chloroform and water phases.

On occasion, small acidflex lines would not aspirate reagents until primed with a syringe containing the same solution. Minimal difficulty was encountered when the tubes were placed exactly as shown in Fig. 1. Positioning polyethylene end blocks of the manifold so that the tubes were secured by the rounded ends of the tracts instead of under the projections prevented the acidflex tubes from being sheared. With acidflex tubing larger than 0.090 in., Technicon N-4 nipples had to be used, since pressure from pumping and the action of chloroform on the lines caused a separation of the acidflex tubing from smaller nipples. Wherever possible, acidflex tubing was attached directly to glass fittings.

Following construction of a satisfactory manifold

TABLE I.—PERCENTAGE RECOVERIES OF STEROIDS USING AUTOMATED EXTRACTION AND BLUE TETRAZOLIUM REACTION

Hydrocortisone, 5.0 mg.	Methylprednisolone, 4.0 mg.	Prednisolone, 5.0 mg.

and optimizing conditions for the blue tetrazolium reaction, the precision of the automated procedure was determined. Replicate standards of hydrocortisone, methylprednisolone, and prednisolone in 75% 3A alcohol were analyzed, giving coefficients of variation of 1.39, 1.51, and 2.33% for the respective steroids. Table I gives results of this study. The precision for the procedure is considered quite satisfactory, considering that this represents the entire assay error from sample preparation, addition of water diluent, homogenization, chloroform extraction, blue tetrazolium reaction, to recording of absorbance peaks. The entire procedure is completed in approximately 8 min. After the first sample, however, additional results are recorded every 3 min.

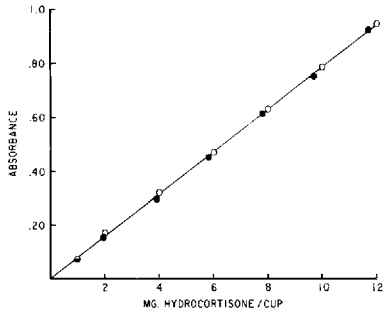

Fig. 5.—Beer's law plot for hydrocortisone originating from standard and tablets. Key: O, hydrocortisone standard; ●, hydrocortisone in pulverized tablet.

Figure 2 shows a recording of various quantities of hydrocortisone standard in 75% 3A alcohol. It can be noted that absorbance is a linear function of concentration. Figures 3 and 4 show that Beer's law is obeyed for methylprednisolone and prednisolone.

To test the recovery of hydrocortisone from varying amounts of 5.0-mg. tablets, 50 tablets were weighed and reduced to a fine powder. Accurately

15	10	5.14 ± 1.95%	4.96

[a] In some instances, the AutoAnalyzer was used for the blue tetrazolium reaction.

weighed quantities of the powder were placed in 10.0 ml. of 75% 3A alcohol and allowed to stand approximately 1 hr. Hydrocortisone standards approximating the steroid content of powder samples were also prepared and analyzed. When absorbances of hydrocortisone standard and powdered tablets are plotted, a single line (Fig. 5) can be drawn through absorbance values for both standard and tablets. Covariance analyses of the data were performed, and no significant differences in results were found.

Studies were performed to determine the efficiency of the automated procedure by adding varying amounts of powdered tablets to a particular standard. Table II shows that recoveries were good.

Assays of steroid tablets were carried out for 5 lots of each particular steroid by the automated procedure and compared to the method essentially as directed by U.S.P. XVII. The data in Table III show good agreement. The automated procedure is suggested for single-tablet assays and should be of value when complying with content-uniformity tests of U.S.P. XVII and N.F. XII.

After completion of this report, several modifications in the automated procedure were made that are considered worthy of reporting. Tetrabutylammonium hydroxide is substituted for tetramethylammonium hydroxide, and filtration of this reagent is no longer a requirement. A small glass wool in-line filter is placed in the flowing stream just prior to the cell debubbler, eliminating the possibility of eroded tubing and other particles entering into the cell.

Design and Operation of a Laboratory Glass Spray Drier

By JOHN D. TOPHAM

A spray drier made from borosilicate glass is described, which has been used to dry streptomycin without loss of activity and also other pharmaceuticals. Its advantages over other spray driers are: low cost, complete vision of the drying process, and its ease of adaptation to produce sterile powders.

MANY PAPERS have been published on the spray drying of pharmaceuticals (1–5) since the erection of a spray drier at Manchester University in 1939 (6). So far, to the author's knowledge, no work has been published on the spray drying of antibiotics, although one manufacturer has installed a spray drier for this purpose. All the spray driers which are used in industry are made of metal, which is not a satisfactory material when solutions of substances, which are very sensitive to oxidation, are to be dried. Since glass is used to replace metal in the apparatus described, oxidative discoloration does not take place when streptomycin is dried in the apparatus. Also, it is difficult to observe the drying process if metal apparatus is used. These 2 considerations, plus cheapness, persuaded the author to design a spray drier made of borosilicate glass.[1]

Received September, 2, 1965, from the School of Pharmacy, Portsmouth College of Technology, Portsmouth, Hampshire, England.
Accepted for publication November 16, 1965.
The author is grateful to the members of the Pharmacy, Physics, and Engineering Departments of this college for their assistance and in particular to Dr. G. Richardson, Messrs. A. Shaw, W. Tyler, and H. Huntley. The author is also indebted to Glaxo Ltd., Greenford, Middlesex, England, for the samples of penicillin and streptomycin.

[1] An application has been made to patent the apparatus.

Temperature.—Borosilicate glass softens at 700° and will crack as a result of thermal shock, if sudden temperature fluctuations take place. Consequently, at no time during the operation of the drier should a temperature of 500° be exceeded. In fact, 320° is the maximum temperature to which the apparatus, described in this article, has been subjected. The temperature range within which the spray drier has been used is 140–220°. The normal operating temperature was 160°.

Wetting.—The contact angle between glass and water is zero. Consequently, any drops of solution which come into contact with the walls of the apparatus will adhere. This difficulty has been overcome by silicone coating the apparatus, using a 2% solution of dimethyldichloro-silane in carbon tetrachloride.

Sealing of Joints.—A film of silicone grease was applied to most joints which were then clipped together using simple metal clips.

Spray.—After considerable experimentation it was found that the best spray was produced using an atomizer device constructed from standard laboratory glassware (Fig. 1). This was con-

weighed quantities of the powder were placed in 10.0 ml. of 75% 3A alcohol and allowed to stand approximately 1 hr. The author is grateful to the members of the Pharmacy, Physics, and Engineering Departments of this college for their assistance and in particular to Dr. G. Richardson, Messrs. A. Shaw, W. Tyler, and H. Huntley. The author is also indebted to Glaxo Ltd., Greenford, Middlesex, England, for the samples of penicillin and streptomycin.

[1] An application has been made to patent the apparatus.

Temperature.—Borosilicate glass softens at 700° and will crack as a result of thermal shock, if sudden temperature fluctuations take place. Consequently, at no time during the operation of the drier should a temperature of 500° be exceeded. In fact, 320° is the maximum temperature to which the apparatus, described in this article, has been subjected. The temperature range within which the spray drier has been used is 140–220°. The normal operating temperature was 160°.

Wetting.—The contact angle between glass and water is zero. Consequently, any drops of solution which come into contact with the walls of the apparatus will adhere. This difficulty has been overcome by silicone coating the apparatus, using a 2% solution of dimethyldichloro-silane in carbon tetrachloride.

Sealing of Joints.—A film of silicone grease was applied to most joints which were then clipped together using simple metal clips.

Spray.—After considerable experimentation it was found that the best spray was produced using an atomizer device constructed from standard laboratory glassware (Fig. 1). This was con-

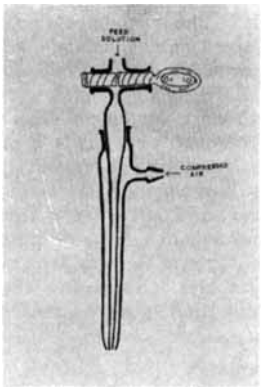

Fig. 1.—Atomizer unit.

nected to an Edwards compression and vacuum pump model RB4, which gave a maximum pressure of 18 lb./sq. in.

Sterilization.—When sterile powders were required, all connecting tubing was sterilized in an autoclave. Sterile filters of nonabsorbent cotton wool 4 cm. thick, supported in calico, were placed at each of the air inlets. The atomizer device and receiver were sterilized by heating in a hot air oven at 160° for 1 hr. The rest of the apparatus was sterilized by passing filtered hot air through the apparatus for 1 hr. at 180–200°.

Method of Operation.—A domestic suction cleaner is used to produce a stream of air at a displacement of approximately 240 L./min. This flows through 4 parallel tubes, each containing a firelighter element of 1.8-kw. capacity. The hot air then enters the drying chamber from above through a fused alumina pipe (Fig. 2). The spray enters the drying chamber alongside the hot air inlet and is dried as it passes through the chamber in the air stream.

The drying temperature can be controlled by switching on and off the heating elements, but greater temperature control is brought about by regulating the rate of flow of the solution through the atomizer.

On leaving the chamber, the dried product and steam pass into a cyclone separator, where the product falls into a previously warmed receiver, and the excess hot air and steam pass out through a dust bag. The receiver must be warmed initially; otherwise water vapor will condense on its inner surfaces, causing the product to become damp.

A positive pressure is required above the surface of the solution to be dried, otherwise air from the atomizer section will blow up the capillary when the feed vessel is almost empty. The rate of drying is 1 L./hr. for concentrated solutions.

Design Considerations.—Ideally, the apparatus should operate from a compressor capable of supplying sterile, oil-free air. This would make possible the continuous production of sterile products.

Originally the hot air inlet tube was made of copper, but it was found that, when streptomycin was spray dried, oxidative discoloration took place, which was due presumably to the catalytic effect of the metal. Hence, the copper tube was replaced by one of fused alumina, although other tubes, constructed of materials which do not contain heavy metals, could be used.

Cleaning.—Each section can be washed in a normal-size sink. The cyclone separator presents some difficulties, but if steel ball bearings are used, the dirt can be "rumbled" away.

EXPERIMENTAL

A 500-ml. quantity of double strength nutrient broth was spray dried in the previously sterilized apparatus. The dry product was collected in 8 sterile containers and sterile water was added to each. These were then incubated at 37° for 3 days, and observed daily for growth. The experiment was duplicated.

Of the 16 containers holding the reconstituted broth 15 were sterile. Growth in the sixteenth container presumably was due to accidental contamination during the transference of the sterile water to the spray-dried product.

After the 3-day incubation period, each sample

was inoculated with a loopful of a culture of *Micrococcus pyogenes*. Every sample became opalescent within 18 hr., indicating that the broth was capable of supporting growth of microorganisms.

Streptomycin sulfate has been spray dried without loss of activity as shown by the assay laid down in the "British Pharmacopoeia," 1958. Four Petri dishes containing seeded nutrient agar were used for each assay. In each dish 4 × 8 mm. holes were bored and the solutions T_1, T_2, S_1, and S_2 added to each plate. The strengths of the standard and test solutions were 5 and 10 units/ml. (Table I). After spray drying, the potency was 100.3% of the original (limits of results 86.7–115.3%).

A similar assay was carried out on sodium benzyl penicillin. The strengths of the test and standard solutions were 3 and 6 units/ml. (Table II). After spray drying, the potency was 96.6% of the original (limits of results 83.9 to 119.1%).

Seaweed extract, coffee, aluminum hydroxide gel, and an aluminum hydroxide complex have also been dried to produce free-flowing powders, which (except for the alumina) readily redissolved in water. Spores of *Bacillus subtilis* have also been dried with a 50% mortality. The powders, when viewed under the microscope, all showed the hollow spheres characteristic of spray-dried powders.

SUMMARY

1. The apparatus permits the drying process to be observed continuously; consequently, any obstruction to flow is readily noticed before damage to the product occurs.

2. It can be used to produce sterile powders more rapidly than freeze drying.

3. It is suitable for drying solutions and suspensions of materials which are prone to oxidation in the presence of metals.

4. The dried products are free flowing and lend themselves to aseptic transfer into sterile containers.

Dissolution Rate–Solubility Behavior of 3-(1-Methyl-2-pyrrolidinyl)-indole as a Function of Hydrogen-Ion Concentration

By W. E. HAMLIN and W. I. HIGUCHI*

An investigation of the hydrogen-ion dependence of the dissolution rate of 3-(1-methyl-2-pyrrolidinyl)-indole (U-11028) is reported. Theoretical equations are developed which are in good agreement with the experimental data. This agreement shows clearly that it is the much greater diffusion coefficient of hydrochloric acid (D_H = 3.1 D_B) that is responsible for the deviation from the Noyes-Whitney theory.

CONSIDERABLE evidence has been presented to show that the initial rate of dissolution of a pellet is directly proportional to the solubility of the compound in a test fluid (1). This relationship, derived from the Noyes-Whitney law (2), states that

$$R = kC_s \qquad \text{(Eq. 1)}$$

where R is the initial dissolution rate per unit surface area of the pellet (mg./cm.²/hr.), k is a constant (2.24 for the given test conditions), and C_s is the solubility of the compound (mg./ml.). However, some data do not follow Eq. 1. One such compound which shows a significant positive deviation is 3-(1-methyl-2-pyrrolidinyl)-indole (U-11028). Since this deviation is observed in 0.05 N HCl but

TABLE I.—SOLUBILITIES AND DISSOLUTION RATES OF 3-(1-METHYL-2-PYRROLIDINYL)-INDOLE AS A FUNCTION OF pH OF THE DISSOLUTION MEDIUM AT 37°

Dissolution Fluid	Initial pH	Solubility at 37°, mg./ml.	Dissolution Rate ±95% C.I. of Rate, mg./cm.²/hr.	Rate-to-Solubility Ratio
0.1 *N* HCl	1.2	21.0	146 ± 17	6.95
0.05 *N* HCl	1.3	10.3	89.5 ± 20.5	8.69
0.01 *N* HCl	2.0	2.35	18.9 ± 1.9	8.04
0.002 *N* HCl (CO_2-free)	2.8	1.02	5.07 ± 0.74	4.97
0.001 *N* HCl (CO_2-free)	3.1	0.837	2.93 ± 0.64	3.50
Distilled H_2O (CO_2-free)	7.0	0.703	1.89 ± 0.21	2.69
Phosphate buffer	7.2	2.36	6.35 ± 0.38	2.69

not in phosphate buffer (pH 7.2), the reason may be the much greater diffusion coefficient for the HCl. The test of this hypothesis is reported.

EXPERIMENTAL

The procedures for determining the initial rate of dissolution and solubility of U-11028 in the test fluids of varying hydrogen-ion concentration were reported previously (1). All tests were run at 37°. The test fluids listed in Table I all have the same ionic strength ($\mu = 0.1$) by adjustment with sodium chloride. Assays were made by ultraviolet spectrophotometry using a Cary model 11 recording spectrophotometer.

The rate of dissolution and solubility data are recorded in Table I as a function of the pH of the test fluid. The rate-to-solubility ratio, equivalent to k in Eq. 1, for each set of data serves as a measure of the deviation from the reference value of 2.69.

An apparent pKa value of 8.9 for this compound was determined by potentiometric titration of a dilute solution in CO_2-free deionized water at room temperature.

RESULTS AND DISCUSSION

Solubility of U-11028 as a Function of Initial H^+.—The important reactions are:

$$B \overset{K_B}{=} BH^+ + OH^- \qquad \text{(Eq. 2)}$$

and

$$OH^- + H^+ \overset{\frac{1}{K_W}}{=} H_2O \qquad \text{(Eq. 3)}$$

Let $(B)_0$ be the unionized base concentration in equilibrium with the solid, and let $(H)_0$ be the initial hydrogen-ion concentration, *i.e.*, the H^+ concentration before addition of any solid base. Let x = moles/L. of BH^+ formed by the reaction given in Eq. 2, and let y = the moles/L. of the reaction in accordance with Eq. 3. Therefore, $x - y$ would be equal to the moles/L. of remaining OH^- at equilibrium and $(H)_0 - y$ the concentration of the remaining H^+.

Therefore,

$$K_B = \frac{x(x - y)}{(B)_0} \qquad \text{(Eq. 4)}$$

and

$$K_W = [(H)_0 - y](x - y) \qquad \text{(Eq. 5)}$$

Neglecting K_W/K_B $(B)_0$ as compared to unity, one obtains from Eqs. 4 and 5

$$x = \frac{(H)_0 + [(H)_0^2 + 4K_B(B)_0]^{1/2}}{2} \qquad \text{(Eq. 6)}$$

Therefore, the total solubility is

$$C_s = (B)_0 + x$$

or

$$C_s = (B)_0 + \frac{(H)_0 + [(H)_0^2 + 4K_B(B)_0]^{1/2}}{2} \qquad \text{(Eq. 7)}$$

Since K_A for U-11028 is about 6×10^{-10}, and since K_W for water is around 2×10^{-14}, $K_B \simeq 3 \times 10^{-5}$. $(B)_0$ may be calculated by taking this value for K_B and the solubility, $C_S = 3.5 \times 10^{-3}M$, for U-11028 in pure water. Noting that $(H)_0 \simeq 1 \times 10^{-7}M$ is negligible compared to $K_B(B)_0$, one obtains from Eq. 7

$$(B)_0 \simeq 3.2 \times 10^{-3}M$$

Therefore, Eq. 7 becomes

$$C_s = 3.2 \times 10^{-3} + \frac{(H)_0 + [(H)_0^2 + 3.8 \times 10^{-7}]^{1/2}}{2} \qquad \text{(Eq. 8)}$$

In Fig. 1, Eq. 8 is plotted (smooth curve) and compared with the experimental data. The agreement of the data with theory is very satisfactory.

Dissolution Rate of U-11028 as a Function of Initial H^+.—Consideration of simultaneous diffusion and chemical reaction leads to the following equation for the initial dissolution rate of a base, B, in HCl solutions (see *Appendix* for derivation). The initial rate, G, is

$$G = \frac{1}{h}\left\{ D_B(B)_0 + \frac{D_H(H)_0 + D_H(H)_0\left[1 + \frac{4D_{OH}K_BD_{BH}(B)_0}{D_H^2(H)_0^2}\right]^{1/2}}{2} \right\} \qquad \text{(Eq. 9)}$$

Here h is the diffusion layer thickness, $(B)_0$ is the free base concentration in equilibrium with the solid, $(H)_0$ is the initial hydrogen-ion concentration in the dissolution medium, and the D's are the respective diffusion coefficients of the species (indicated by subscripts).

Equation 9 may be written

$$\frac{Gh}{D_B} = (B)_0 + \frac{1}{2}\left(\frac{D_H}{D_B}\right)(H)_0 + \frac{1}{2}\left(\frac{D_H}{D_B}\right)(H)_0\left(1 + \frac{4D_{OH}D_{BH}K_B(B)_0}{D_H^2(H)_0^2}\right)^{1/2} \qquad \text{(Eq. 10)}$$

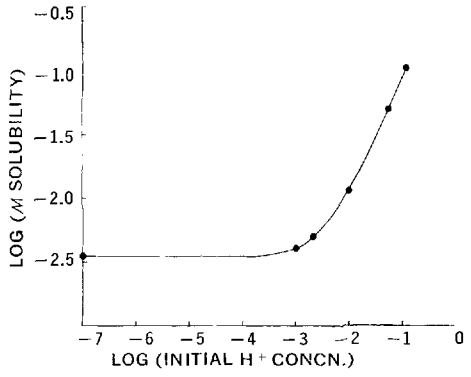

Fig. 1.—Solubility of 3-(1-methyl-2-pyrrolidinyl)-indole as function of initial H^+ concentration. Key: ●, experimental data; ——, theory, Eq. 8.

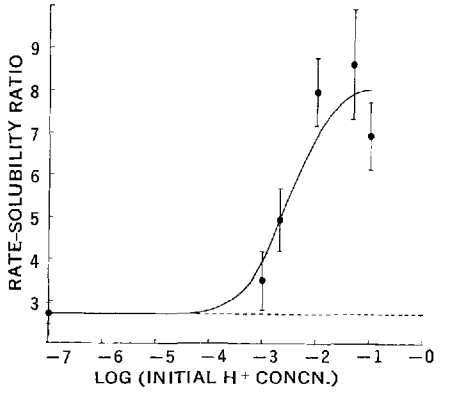

Fig. 2.—The rate-to-solubility ratio for 3-(1-methyl-2-pyrrolidinyl)-indole as a function of initial H^+ concentration in dissolution medium. Key: ●, experimental data; ——, theory (Eq. 10 with D_H/D_B = 3.1); ------, Noyes-Whitney prediction.

It is apparent by comparing Eq. 10 with Eq. 7 that if all of the diffusion coefficients were equal, the dissolution rate would always be directly proportional to the solubility. However, the rate-to-solubility ratio for U-11028 is not constant (Table I) over the range of HCl concentrations. Therefore, consider the possibility that D_H is much greater than D_B.

In Fig. 2, the results of the rate-to-solubility ratios calculated employing Eq. 10 with $D_H = 3.1\ D_B$ are plotted as the smooth curve. In these theoretical calculations, the rate-to-solubility ratio value of 2.69 in distilled water was used to fit the theory to data at this one point.

It is worthwhile to point out that the term involving D_{OH} and D_{BH} in Eq. 10 is small compared to unity, except for the case involving distilled water. Therefore, the choice of values for D_{OH} and D_{BH} is not critical. In the distilled water case, the square root term contributes less than 10% to the rate. So again, the choice of values for D_{OH} and D_{BH} is not critical. Therefore, in these calculations, D_{OH} and D_{BH} were taken to be equal to D_B, the diffusion coefficient for the unprotonated base.

The good agreement of theory with data taken from Table I clearly shows that it is the much greater diffusion coefficient of HCl that is responsible for the deviation from the Noyes-Whitney law. The value of $D_H = 3.1\ D_B$ is reasonable. The diffusion coefficient for HCl in water is about 3.0×10^{-5} cm.^{2} sec.$^{-1}$ at room temperature (3), while that for U-11028 is expected to be as much as 5 times smaller according to Stokes' law. Therefore, although the 3.1 factor appears to be a little low, it is of the right order of magnitude.

As discussed previously (4) where electrolytes are involved, the effective diffusion coefficient of an ion is appreciably influenced by the nature and the concentrations of other ions in the solution. In this regard the primary effect is often the diffusion potential effect which is caused by the greater inherent mobility of 1 ion in the presence of more slowly moving ions of the opposite charge. Thus, the effective diffusion coefficient of the hydrogen ion in an HCl solution is not determined entirely by the inherent mobility of the hydrogen ion, but is influenced greatly by the restraining effect of the chloride ion. Despite the retarding effect of the chloride ion, the diffusion coefficient of HCl is still relatively large. The effective diffusion coefficient of the protonated U-11028 also is influenced by the chloride ion, but, in this instance, the relatively large size of the U-11028 molecule should be the main factor.

It is reasonable then to expect D_H to be relatively large compared to D_B and D_{BH}, with the latter 2 being about the same order of magnitude. While D_{OH} would be expected to be also significantly greater than D_B or D_{BH}, it can be seen from concentration considerations that the OH^- does not play an important role.

APPENDIX

Derivation of Eq. 9.—Consideration of the physical situation allows one to write 2 independent equations for G, the dissolution rate,

$$G = -D_B \frac{d(B)}{dX} - D_{BH} \frac{d(BH)}{dX} \quad \text{(Eq. 1}a\text{)}$$

and

$$G = D_H \frac{d(H)}{dX} - D_B \frac{d(B)}{dX} - D_{OH} \frac{d(OH)}{dX} \quad \text{(Eq. 2}a\text{)}$$

As boundary conditions, at $X = 0$: $(B) = (B)_0$, $(BH) = (BH)_0'$, $(H) = (H)_0'$ and $(OH) = (OH)_0'$, and at $X = h$: $(H) = (H)_0$ and all other species are at 0 concentration. With these boundary conditions and with the approximation that $K_w \ll K_B\ (B)_0$, Eqs. 1*a* and 2*a* may be solved by eliminating $(H)_0'$, $(BH)_0'$, and $(OH)_0'$ to give Eq. 9 in the same manner as was done previously for similar problems (4, 5).

Alkaloids of *Thalictrum* VI.

Isolation of Obamegine from *Thalictrum rugosum*

By TOSHIAKI TOMIMATSU* and JACK L. BEAL

A description is given of the isolation of a phenolic tertiary base from the roots of *T. rugosum* and the identification of this base as obamegine.

THE PRESENCE of magnoflorine and berberine in the roots of *Thalictrum rugosum* Ait. (*T. glaucum* Desf.) has been reported in the previous paper of this series (1). The present report describes the isolation of a phenolic tertiary base from the roots of *T. rugosum* and the identification of this base as obamegine (I).

The tertiary base, m.p. 172° dec., $[\alpha]_D$ + 241° (chloroform), was obtained in crystalline form from the crude tertiary base fraction referred to in the previous paper (1). The U.V. spectrum suggested a benzenoid nucleus, $\lambda_{max.}$ 285 mμ, while in the I.R. spectrum 2 hydroxyl peaks were detected, 3450 cm.$^{-1}$ and 3260 cm.$^{-1}$. The NMR spectrum indicated the presence of 2 methoxyl and 2 *N*-methyl groups. In addition, the NMR spectrum showed the presence of benzene of crystallization. The molecular formula, $C_{36}H_{38}N_2O_6 \cdot 2C_6H_6$, was assigned on the basis of the elemental analysis which also suggested the presence of a benzene adduct.

On treatment of the phenolic base with diazomethane, a product was obtained which possessed 4 methoxyl and 2 *N*-methyl groups thereby verifying that the base contains 2 phenolic hydroxyl groups. Analytical data indicated the phenolic base to be of the berbamine type. Since obamegine (2, 3) has been described as a phenolic base possessing 2 hydroxyl groups and belonging to the berbamine type alkaloids (4), this base was compared with an authentic sample of obamegine.[1]

The phenolic base was shown to be identical with obamegine by comparision of I.R. spectra and a mixed melting point determination. Finally, this base and its *O,O*-dimethylether and *O,O*-diethylether gave NMR spectra identical with the NMR spectra of obamegine, *O,O*-dimethylobamegine, and *O,O*-diethylobamegine.[1]

This is the first report of the isolation of obamegine from a *Thalictrum* species. Previously, aromoline (thalicrine) was isolated from *Thalictrum thunbergii* D.C. by one of the authors (5–7). Aromoline belongs to the oxyacanthine group of alkaloids. Thus, both the berbamine and oxyacanthine type of alkaloids have been isolated from the genus *Thalictrum*. Both obamegine (I) and aromoline (II) have 2 hydroxyl groups in the 7 and 4′ or 4″ positions.

[1] The authors thank Dr. M. Tomita and Dr. T. Ibuka, Kyoto University, for an authentic sample of obamegine which was supplied by them, and for the loan of the NMR spectra charts of obamegine, *O,O*-dimethylobamegine, and *O,O*-diethylobamegine.

EXPERIMENTAL[2]

Material.—Roots of *T. rugosum* were obtained from Wayside Gardens, Mentor, Ohio. A minimum of 100 plants are being cultivated in The Ohio State University College of Pharmacy Medicinal Plant Garden. In addition, herbarium specimens have been made and are on file.

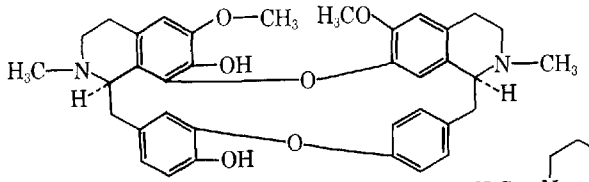
Isolation and Identification of Obamegine from T. Rugosum.—Milled roots, 6.2 Kg., were extracted with methanol in a continuous extractor until a negative test of the extractant for alkaloid was obtained with Valser's reagent. The methanol extract was concentrated almost to dryness, *in vacuo*, and poured while stirring into warm 5% acetic acid. The insoluble material was extracted repeatedly with 5% acetic acid until a negative test was obtained with Valser's reagent. The acidic solution was freed from acidic and neutral substances by extraction with ether, and then made alkaline with ammonium hydroxide solution and extracted exhaustively with ether to remove ether-soluble bases. The ether solution was extracted with 5% potassium hydroxide to remove the phenolic base. The solution containing the phenolic base was made weakly acidic by adding hydrochloric acid and then basic with ammonium hydroxide solution. The alkaline solution was extracted with benzene which was then dried over anhydrous sodium sulfate, filtered, and evaporated to dryness to yield 4.8 Gm. of colorless crystalline residue. Repeated recrystallization from benzene gave colorless needles, m.p. 172° dec. $[\alpha]_D^{30}$ + 241° (chloroform), ultraviolet $\lambda_{max.}$, (ethanol) 285 mμ. The infrared spectrum (chloroform) showed 3450 cm.$^{-1}$, 3260 cm.$^{-1}$ (OH). The NMR spectrum ($CDCl_3$) showed τ 7.60, 7.73 (*N*-methyl), 6.27, 6.36 (*O*-methyl), 2.72 (benzene).

Anal.—Calcd for $C_{36}H_{38}N_2O_6 \cdot 2C_6H_6$: C, 76.80; H, 6.66; N, 3.73. Found: C, 76.52; H, 6.59; N, 3.76.

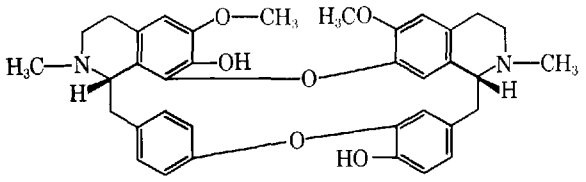
The melting point was not depressed on admixture with an authentic sample of obamegine, m.p. 172° dec. In addition, the infrared spectrum in potassium bromide of the sample was identical with that of an authentic sample of obamegine.

O,O-Dimethyl Ether.—A 0.1-Gm. quantity of the above phenolic base was dissolved in 15 ml. of methanol and added to an ethereal solution of diazomethane which was made from 4.3 Gm. of *p*-tolylsulfonylmethylnitrosamide and 0.8 Gm. of potassium hydroxide in 20 ml. of 96% ethanol. After standing 3 days, the ether and the excess diazomethane were evaporated on a steam bath. The residue was dissolved in 20 ml. of 5% acetic acid solution which was then made basic with aqueous sodium hydroxide and extracted exhaustively with ether. The ether solution was dried

[2] Melting points were determined with a Thomas-Hoover melting point apparatus. Infrared spectra were obtained using a Perkin-Elmer Infracord spectrophotometer, model 237. The NMR spectra were obtained using a Varian Associates 60 megacycle spectrophotometer. The authors thank Dr. David Dalton, Department of Chemistry, for the NMR interpretations and valuable suggestions.



I



II

over anhydrous potassium carbonate and the ether then evaporated on a steam bath. The residue was dissolved in benzene and chromatographed on a column of Woelm, grade 1, neutral alumina (10 Gm., column 1 cm. × 6 cm.) using benzene as the solvent. A single compound was obtained in the eluate. The NMR data ($CDCl_3$) indicated τ 7.46, 7.76 (*N*-methyl), 6.12, 6.29, 6.41, and 6.87 (*O*-methyl), and was identified with that of *O,O*-dimethylobamegine.

O,O-Diethyl Ether.—A 0.1-Gm. sample of the phenolic base was dissolved in 10 ml. of methanol and added to an ethereal solution of diazoethane which was made from 7 Gm. of nitrosoethylurea and 40 Gm. of 50% potassium hydroxide solution. After standing 4 days at room temperature, the solution was treated by the usual method and the residue crystallized from acetone as colorless rosette crystals (0.098 Gm.), m.p. 203–204.° The NMR spectrum ($CDCl_3$) showed τ values at 7.39, 7.71 (*N*-methyl), 6.22, and 6.40 (*O*-methyl). The NMR spectrum was superimposable with that of known *O,O*-diethylobamegine.

Tosylation of *N*-Phenyl-*N'*-(3-hydroxypropyl)urea

By ARTHUR F. FERRIS*, O. LEROY SALERNI, and BEVERLY A. SCHUTZ

Two unexpected products, *N*-phenyl-*N'*-(3-chloropropyl)urea (II) and 2-phenylimino-2,4,5,6-tetrahydro-1,3-oxazine (III), are formed from the reaction of *p*-toluenesulfonyl chloride and *N*-phenyl-*N'*-(3-hydroxypropyl)-urea (I).

As part of a program dealing with the synthesis of potential antiradiation drugs, it became necessary to carry out the reaction of *p*-toluenesulfonyl chloride and *N*-phenyl-*N'*-(3-hydroxypropyl)urea (I). The authors have found that this reaction in pyridine solvent gives 2 unexpected products: *N*-phenyl-*N'*-(3-chloropropyl)urea (II) and 2-phenylimino-2,4,5,6-tetrahydro-1,3-oxazine (III) in total yield of 86%.

Addition at 0–10° of an equivalent of *p*-toluenesulfonyl chloride to the hydroxypropyl urea (I) (prepared from 2 equivalents of phenyl isocyanate with 3-aminopropanol and subsequent basic hydrolysis of the product),[1] followed by acidification gave a white solid. The infrared spectrum of the solid revealed a tosylate ester band at 1340 cm.$^{-1}$ (2), and was totally void of tosylate anion absorption. When dried in a vacuum oven at 55° or allowed to stand at room temperature for 3 days, the solid decomposed. The resulting syrup did not crystallize on cooling, and its infrared spectrum showed intense tosylate anion bands at 1005 and 1020 cm.$^{-1}$ (3). When dissolved in a minimum of ethanol and poured into water, a white solid precipitated; its infrared spectrum did not show tosylate anion bands. A sodium fusion of this material revealed the presence of chlorine, and elemental analysis for C, H, N, and Cl agreed with that calculated for *N*-phenyl-*N'*-(3-chloropropyl)-urea. The yield was 48%.

The conversion of —OH to —Cl during a tosylation reaction is not unprecedented. Under certain conditions and with phenols bearing nitro groups in the nucleus, an abnormal reaction (4, 5) takes place in which the OH group is replaced by chlorine.

The filtrate from the chloro-urea was made strongly basic with 10% sodium hydroxide, and additional white solid precipitated. Again, the infrared spectrum was void of tosylate anion bands. A sodium fusion for sulfur and chlorine was negative and elemental analysis agreed with that calculated for 2-phenylimino-2,4,5,6-tetrahydro-1,3-oxazine. The yield was 38%.

These observations can be rationalized in the following way. The tosylation reaction gives a mixture of the chloro-urea (II) and *N*-phenyl-

II

over anhydrous potassium carbonate and the ether then evaporated on a steam bath. The residue was dissolved in benzene and chromatographed on a column of Woelm, grade 1, neutral alumina (10 Gm., column 1 cm. × 6 cm.) using benzene as the solvent. A single compound was obtained in the eluate. The NMR data ($CDCl_3$) indicated τ 7.46, 7.76 (*N*-methyl), 6.12, 6.29, 6.41, and 6.87 (*O*-methyl), and was identified with that of *O,O*-dimethylobamegine.

O,O-Diethyl Ether.—A 0.1-Gm. sample of the phenolic base was dissolved in 10 ml. of methanol and added to an ethereal solution of diazoethane which was made from 7 Gm. of nitrosoethylurea and 40 Gm. of 50% potassium hydroxide solution. After standing 4 days at room temperature, the solution was treated by the usual method and the residue crystallized from acetone as colorless rosette crystals (0.098 Gm.), m.p. 203–204.° The NMR spectrum ($CDCl_3$) showed τ values at 7.39, 7.71 (*N*-methyl), 6.22, and 6.40 (*O*-methyl). The NMR spectrum was superimposable with that of known *O,O*-diethylobamegine.

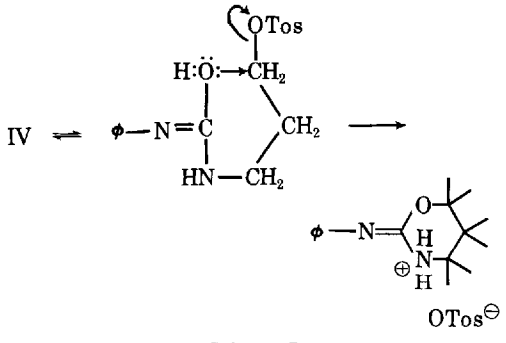
N'-(3-*p*-toluenesulfonyloxypropyl)urea (IV). Such a mixture would explain the lack of tosylate anion absorption in the infrared spectrum of the crude reaction product. On standing or warming in a vacuum oven, the tosylate ester (IV) undergoes cyclization to the oxazine salt as illustrated, thus accounting for the intense tosylate anion bands in the infrared spectrum of the decomposed material. (Scheme I.)



Scheme I

When dissolved in ethanol and poured into water, the insoluble chloro-urea precipitates and the soluble oxazine salt remains in solution. On basification of the filtrate, the free base is liberated from its salt and precipitates.

EXPERIMENTAL[2]

The *N* - phenyl - *N'* - (3 - *N* - phenylcarbamoylpropyl)urea was prepared by the method of Dyer and Read (6).

N - Phenyl - N' - (3 - hydroxypropyl)urea (I).—To a solution of 117.4 Gm. (0.375 mole) of *N*-phenyl - *N'* - (3 - *N* - phenylcarbamoylpropyl) urea in 700 ml. of 95% ethanol was added a solution of 60.0 Gm. (1.5 moles) of sodium hydroxide in 200 ml. of water. The resulting solution was refluxed for 14 hr. with mechanical stirring. A solid (sodium carbonate) separated during the reflux period. The ethanol was removed under reduced pressure, and 500 ml. of water was added to the residue. An oil (aniline) and some solid separated. The mixture was made acid (pH 3–4) by the cautious addition of hydrochloric acid with cooling and stirring. The oil disappeared (aniline hydrochloride was formed) and carbon dioxide evolved. A tan solid separated and was recovered and dried. The yield was 56.0 Gm. (77%), m.p. 106–112°. After 2 recrystallizations from acetonitrile, the compound gave a m.p. 111–113°. This sample was identical to the *N*-phenyl-*N'*-(3-hydroxypropyl)urea prepared by the method of Dyer and Read (6) from phenyl isocyanate and 3-aminopropanol.

N-(3-Chloropropyl)-N'-phenylurea (II) and 2-Phenylimino - 2,4,5,6 - tetrahydro - 1,3 - oxazine (III).—To a solution of 46.0 Gm. (0.237 mole) of *N*-phenyl-*N'*-(3-hydroxypropyl)urea in 127.5 Gm. (1.61 moles) of pyridine was added 50.5 Gm. (0.266 mole) of *p*-toluenesulfonyl chloride. The acid chloride was added in portions, with stirring and cooling, keeping the temperature below 20°. After the addition was complete, the reaction mixture was stirred at 20° or less for 4 hr. A solution of 240 ml. of concentrated hydrochloric acid dissolved in 560 ml. of water was then added with stirring. The temperature was kept below 30°. White solid separated and, after recovery and drying *in vacuo* at room temperature, it amounted to 87.6 Gm., m.p. 84–86°. The solid was then heated *in vacuo* at 50–60° for about 1 hr. It melted[3] and did not solidify on cooling. The syrup was taken up in 125 ml. of warm 95% ethanol and poured into about 1 L. of ice and water. White solid separated which, after drying, amounted to 24.3 Gm. (48%) of 1-(3-chloropropyl)-3-phenylurea (II), m.p. 115.5–121°. Three recrystallizations from acetonitrile afforded an analytical sample, m.p. 128–129.5°.

The filtrate from the chloro-urea was made strongly basic with 10% sodium hydroxide. The solid which separated was recovered and dried *in vacuo*. It amounted to 15.7 Gm. (38%) of 2-phenylimino-2,4,5,6-tetrahydro-1,3-oxazine (III), m.p. 131–134°. Two recrystallizations from acetone gave an analytical sample, m.p. 132–133.5°.

Anal.—(II) Calcd. for $C_{10}H_{13}ClN_2O$: C, 56.47; H, 6.16; Cl, 16.67; N, 13.17. Found: C, 56.60; H, 6.27; Cl, 16.41; N, 13.01.

Anal.—(III) Calcd. for $C_{10}H_{12}N_2O$: C, 68.15; H, 6.87; N, 15.90. Found: C, 68.16; H, 6.90; N, 15.80.

[3] Similar results were obtained when the solid was allowed to stand at room temperature for 3 days.

NMR 1,3-Diaxial Deshielding Effect of the Hydroxyl Group on Ring Hydrogens Studied from Partially Deuterated Six-Membered Ring Compounds

By ALAIN C. HUITRIC, JOHN B. CARR, and WILLIAM F. TRAGER*

The deshielding effect of the hydroxyl group on axial ring protons through 1,3-diaxial spatial interaction has been studied in *trans*-2-*o*-tolyl-*trans*-5-hydroxycyclohexanol-3,3,6,6-d_4 (II) and *trans*-2-*o*-tolyl-*cis*-4-hydroxycyclohexanol-3,3,6,6-d_4 (III) in deuterated chloroform, acetone-d_6, methanol-d_4, acetic acid, and pyridine; in 4-*tert*-butyl-*trans*-1,4-cyclohexanediol-3,3,5,5-d_4 (VI) in methanol-d_4 and pyridine; and in 4-*tert*-butyl-*cis*-1,4-cyclohexanediol-3,3,5,5-d_4 (VII) in pyridine. A consistent downfield shift of about 0.50 p.p.m. was found for the signal of H-1 of II in the first 4 solvents, but a considerably larger shift of 0.90 p.p.m. was obtained in pyridine. A downfield shift of about 0.58 ± 0.05 p.p.m. was found for the signal of H-2 in III in the first 4 solvents while a shift of 0.97 p.p.m. was obtained in pyridine. The deshielding effect of the tertiary hydroxyl groups in VI and VII was found to be smaller than that of the secondary hydroxyl in II and III in a given solvent, but the magnitude of the pyridine solvent effect was about the same in the 2 series.

THE DESHIELDING effect of the hydroxyl group through 1, 3-diaxial spatial interaction is well established in NMR spectroscopy of 6-membered ring compounds. The effect was observed on the NMR signals of angular methyl groups in steroid molecules by Shoolery and Rogers in 1958 (1) and has since been the object of systematic investigations by several authors (2–6). Much of the work has centered around the effect on angular methyl groups in steroids, where the average downfield shift for a large number of steroids measured in chloroform was found to be in the neighborhood of 0.25 p.p.m. (2) but examples of deshielding of axial protons are also known (6). Bhacca and Williams give tabulated data covering both cases (7).

A number of partially deuterated 6-membered ring compounds have been synthesized in this laboratory in recent years (8, 9). Some of these compounds provide excellent models for the investigation of the deshielding effect of an axial hydroxyl group on ring protons in 1,3-diaxial orientation to the hydroxyl group. Remote deuteration greatly simplifies the spectra and often allows more reliable chemical shifts and coupling constants. This is demonstrated in Fig. 1. The deshielding was investigated by comparing the chemical shifts of H-1 in compounds I and II, and H-2 in I and III in 5 different solvents, and by comparing the chemical shifts of the axial protons at positions 2 and 6 in IV and VI in pyridine and deuterated methanol, and V and VII in pyridine. The results are given in Tables I and II.

The origin of the magnetic anisotropy responsible for the 1,3-diaxial long-range deshielding by a hydroxyl group is not clearly understood. Early in the course of this investigation a large difference was observed in the deshielding effect in compounds II and III in pyridine compared to deuterated chloroform. Additional solvents were therefore selected in order to determine if a pattern of solvent effects could be found on the deshielding effects of the axial hydroxyl group in solvents that can associate with the hydroxyl group through hydrogen bonding only by acting as proton acceptors *versus* solvents which can hydrogen bond by acting as proton donors as well as proton acceptors. No such pattern was found in comparing the shift in acetone with that in methanol, acetic acid, and chloroform. In compound II the shift is identical in these 4 solvents; in III there is a slightly larger shift in acetone than in methanol and acetic acid, but the variation is not very large. A much larger difference in the shift was found between pyridine and all other solvents used. It is interesting to note that the downfield shift is not so large in VI and VII as in II or III in the corresponding solvents, but that the difference in the shift between pyridine and methanol is of similar magnitude for VI as for II and III. The smaller shift caused by a tertiary hydroxyl group in the *cis* and *trans* isomers of 4-*tert*-butylcyclohexanediol compared to the shift caused by a secondary hydroxyl

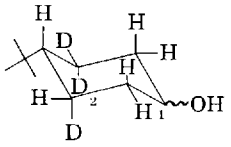
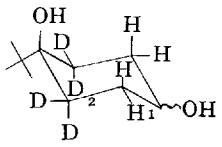
	Pyridine	246	231	145	58

group in II and III in a given solvent could possibly be the result of a greater restriction to rotation about the C—O bond in the 4-*tert*-butyl compounds, causing the OH group to have a different preferred conformation on a time average than in II and III. Any deshielding effect resulting from the anisotropy of the O—H bond or of the unshared electrons of the oxygen atoms will be affected by the orientation of the hydroxyl group.



IV, *cis*, OH axial

V, *trans*, OH equatorial



VI, *trans*-diol, OH-1 axial

VII, *cis*-diol, OH-1 equatorial

TABLE II.—CHEMICAL SHIFTS (ν) IN C.P.S. AT 60 MC. AND DESHIELDING EFFECT OF AXIAL HYDROXYL GROUP ON AXIAL HYDROGENS

Solvent	ν, c.p.s. at 60 mc. Axial H-2 and H-6	Equatorial H-2 and H-6	Deshielding by Axial OH
IV Pyridine	86	119	
Methanol-d_4	85	109	
V Pyridine	83	129	
			($\nu_{VI} - \nu_{IV}$), axial H-2 and H-6
VI Pyridine	132	112	46
Methanol-d_4	110	95	25
			($\nu_{VII} - \nu_V$), axial H-2 and H-6
VII Pyridine	127	121	44

Table I indicates that the introduction of an axial hydroxyl group at C-5 in II has a negligible effect on the chemical shift of H-2, and the introduction of an axial hydroxyl group on C-4 of III has a negligible effect on the chemical shift of H-1 in III in all but the pyridine solvent. The chemical shift of the aromatic methyl group shows very little variation in all solvents for all 3 compounds. Although not given in Table I, the chemical shift of H-5 in II was found to be 251, 254, 252, 260, and 270 c.p.s. in deuterated chloroform, acetone-d_6, methanol-d_4, acetic acid, and pyridine, respectively, and that of H-4 in III was 246, 244, 238, 248, and 257 c.p.s. in the respective solvents.

The spectra of the deuterated compounds II and III allow the determination of accurate coupling constants between H-1 and H-2 from simple AX systems. Compound II gave J_{12} values of 10.5, 10.3, 10.3, 10.4, and 10.5 c.p.s. in chloroform-*d*, acetone-d_6, methanol-d_4, acetic acid, and pyridine, respectively; compound III gave J_{12} values of 10.0, 10.2, 10.3, 10.5, and 10.5 c.p.s. in the same respective solvents. These constant values of J_{12} indicate that there is practically no difference in conformation of these 2 compounds in the various solvents used. The coupling constants of about 10 c.p.s. indicate that H-1 and H-2 have a diaxial orientation and that II and III exist almost exclusively in a chair conformation with the aromatic group in an equatorial orientation in the 5 solvents used (8).

EXPERIMENTAL

trans-2-*o*-Tolylcyclohexanol (I) is a known compound (10).

trans-2-*o*-Tolyl-*trans*-5-hydroxycyclohexanol-3,3,-6,6-d_4 (II) and *trans*-2-*o*-tolyl-*cis*-4-hydroxycyclohexanol-3,3,6,6-d_4 (III) were prepared by the method previously reported for the corresponding nondeuterated compounds (11) except that butadiene-1,1,4,4-d_4 (12) was used in the Diels-Alder condensation step.

cis-4-*tert*-Butylcyclohexanol-3(axial)4,4-d_3 (IV) and the corresponding *trans* isomer (V) have been reported in a previous communication (13). Detailed synthesis of these 2 compounds will be reported in a subsequent publication.

4-*tert*-Butyl-*trans*-1,4-cyclohexanediol-3,3,4,5-d_4 (VI) and the corresponding *cis*-diol (VII) have been reported previously (9).

The NMR spectra were determined with a Varian A-60 spectrometer using tetramethylsilane as internal reference.

Elucidation of the Configuration of an Intermediate in the Synthesis of *cis*-β-Acetoxystyrene II

By BIPIN B. CHAUDHARI*, DONALD T. WITIAK†, and ROGER M. CHRISTIANSEN‡

The configuration of *erythro*-α-hydroxy-β-toluene-*p*-sulfonyloxypropionic acid (III) was proved through conversion to the known methyl *erythro*-β-phenyl-α,β-ditoluene-*p*-sulfonyloxypropionate (VIII). Compound III represents the key intermediate in the conversion of *trans*-β-phenylglycidic acid (II) to *cis*-β-acetoxystyrene (I) and elucidation of the *erythro* configuration for III substantiates the original proposal that decarboxylative elimination of the probable acetate derivative (IV) occurred *trans*.

RECENTLY, the authors reported (1) a stereoselective synthesis for *cis*-β-acetoxystyrene (I) from *trans*-β-phenylglycidic acid (II). The key intermediate in the synthesis involved formation of the α-hydroxy-β-tosyloxy compound (III) through reaction of *trans*-β-phenylglycidic acid with *p*-toluenesulfonic acid in dry ether.

Assignment of the *erythro* configuration to compound III was originally based on the stereoselective formation of *cis*-β-acetoxystyrene (I) which was proposed to have formed by *trans* decarboxylative elimination of the corresponding α-acetoxy derivative (IV). Since the α-acetoxy derivative (IV) was not isolated when compound III was treated with acetic anhydride in pyridine (1)[1] and since some openings of benzylic epoxides with various Bronsted acids in nonpolar medium have been shown to occur with retention of configuration (2) independent evidence for the configuration of the β-tosyloxy-α-

[1] *cis*-β-Acetoxystyrene was formed directly from compound III. Formation of the enol acetate was rationalized on the basis of the instability of the α-carboxy-β-tosyloxy system.

EXPERIMENTAL

trans-2-*o*-Tolylcyclohexanol (I) is a known compound (10).

trans-2-*o*-Tolyl-*trans*-5-hydroxycyclohexanol-3,3,-6,6-d_4 (II) and *trans*-2-*o*-tolyl-*cis*-4-hydroxycyclohexanol-3,3,6,6-d_4 (III) were prepared by the method previously reported for the corresponding nondeuterated compounds (11) except that butadiene-1,1,4,4-d_4 (12) was used in the Diels-Alder condensation step.

cis-4-*tert*-Butylcyclohexanol-3(axial)4,4-d_3 (IV) and the corresponding *trans* isomer (V) have been reported in a previous communication (13). Detailed synthesis of these 2 compounds will be reported in a subsequent publication.

4-*tert*-Butyl-*trans*-1,4-cyclohexanediol-3,3,4,5-d_4 (VI) and the corresponding *cis*-diol (VII) have been reported previously (9).

The NMR spectra were determined with a Varian A-60 spectrometer using tetramethylsilane as internal reference.

Elucidation of the Configuration of an Intermediate in the Synthesis of *cis*-β-Acetoxystyrene II

By BIPIN B. CHAUDHARI*, DONALD T. WITIAK†, and ROGER M. CHRISTIANSEN‡

The configuration of *erythro*-α-hydroxy-β-toluene-*p*-sulfonyloxypropionic acid (III) was proved through conversion to the known methyl *erythro*-β-phenyl-α,β-ditoluene-*p*-sulfonyloxypropionate (VIII). Compound III represents the key intermediate in the conversion of *trans*-β-phenylglycidic acid (II) to *cis*-β-acetoxystyrene (I) and elucidation of the *erythro* configuration for III substantiates the original proposal that decarboxylative elimination of the probable acetate derivative (IV) occurred *trans*.

RECENTLY, the authors reported (1) a stereoselective synthesis for *cis*-β-acetoxystyrene (I) from *trans*-β-phenylglycidic acid (II). The key intermediate in the synthesis involved formation of the α-hydroxy-β-tosyloxy compound (III) through reaction of *trans*-β-phenylglycidic acid with *p*-toluenesulfonic acid in dry ether.

Assignment of the *erythro* configuration to compound III was originally based on the stereoselective formation of *cis*-β-acetoxystyrene (I) which was proposed to have formed by *trans* decarboxylative elimination of the corresponding α-acetoxy derivative (IV). Since the α-acetoxy derivative (IV) was not isolated when compound III was treated with acetic anhydride in pyridine (1)[1] and since some openings of benzylic epoxides with various Bronsted acids in nonpolar medium have been shown to occur with retention of configuration (2) independent evidence for the configuration of the β-tosyloxy-α-

[1] *cis*-β-Acetoxystyrene was formed directly from compound III. Formation of the enol acetate was rationalized on the basis of the instability of the α-carboxy-β-tosyloxy system.

hydroxy acid (III) was desirable. Such evidence would confirm our original proposal that the decarboxylative elimination did indeed occur *trans*.

Our earlier attempts (1) to prepare stable derivatives of compound III which could subsequently be compared to derivatives of the known *erythro* (V) and *threo* (VI) diols (3) were unsuccessful. This was probably due to the instability of the α-carboxy-β-tosyloxy system which readily decomposed under relatively mild conditions. In order to obtain stable derivatives, intermediate III was converted to its methyl ester (VII) through treatment with ethereal diazomethane. Subsequent reaction of compound VII with *p*-toluenesulfonyl chloride in pyridine afforded the ditosyl derivative (VIII) which was identical in all properties to the ditosylated methyl ester which we prepared according to the method of Linstead and co-workers (4) from the known *erythro* diol methyl ester (IX).

Admixture of VIII and the ditosylated methyl ester (X) prepared from the known *threo* diol methyl ester (XI) gave a depression in melting point while admixture with the known *erythro* diol methyl ester gave no such depression. In addition, the infrared spectra of the *erythro* and *threo* ditosylated methyl esters (VIII and X) differed in the region between 8 and 16 μ. The *erythro* ditosylates prepared by either method had additional peaks at 9.70, 10.92, and 11.89 μ, while the *threo* ditosylate exhibited peaks at 10.96 and 12.01 μ. These data prove that the α-hydroxy-β-tosyloxy intermediate has the *erythro* configuration and that decarboxylative elimination of the probable acetate intermediate occurred *trans*.

EXPERIMENTAL[2]

Erythro - α,β - dihydroxy - β - phenylpropionic Acid (V).—A suspension of 28 Gm. (0.15 mole) sodium *trans*-β-phenylglycidate in 420 ml. of 10% sodium hydroxide was heated at reflux for 1.5 hr. After cooling to room temperature, the mixture was acidified with hydrochloric acid and extracted with ether. The ether solution was dried over anhydrous sodium sulfate, filtered, and the solvent was removed under reduced pressure affording a yellow oil. The oil crystallized affording 7.2 Gm. (32.8%) of white crystalline solid. Recrystallization from acetone–ether–skellysolve B yielded 6 Gm. (28%) of product, m.p. 121–121.5°. [Reported m.p. 122° (3).]

Threo - α,β - dihydroxy - β - phenylpropionic Acid (VI).—Utilization of the above procedure with sodium *cis*-β-phenylglycidate (5) afforded the *threo* dihydroxy acid in 67% yield. Recrystallization from ether yielded a white crystalline compound, m.p. 140–141°. [Reported m.p. 141–142° (3).]

Methyl Erythro - α - hydroxy - β - phenyl - β-toluene - p - sulfonyloxypropionate (VII) from Erythro - α - hydroxy - β - phenyl - β - toluene - p-sulfonyloxypropionic Acid (III).—A suspension of 5 Gm. (0.016 mole) of *erythro*-α-hydroxy-β-phenyl-β-toluene-*p*-sulfonyloxypropionic acid in 200 ml. of anhydrous ether was cooled to 0°. To this suspension was added an ethereal solution of diazomethane (6) until evolution of nitrogen ceased and the solution acquired a pale yellow color. Excess diazomethane was destroyed by dropwise addition of glacial acetic acid. Removal of the solvent under reduced pressure afforded 3.5 Gm. (67%) of oil which could not be crystallized in our hands but which was converted directly to the *erythro* ditosylate (VIII).

Methyl Erythro - β - phenyl - α,β - ditoluene - p-sulfonyloxypropionate (VIII) from Methyl Erythro-α-hydroxy-β-phenyl-β-toluene - p - sulfonyloxypropionate (VII).—Methyl *erythro*-α-hydroxy-β-toluene-*p*-sulfonyloxypropionate (1.75 Gm., 0.005 mole) was dissolved in 5 ml. of pyridine and the solution was cooled to 0°. To this solution was added 1.5 Gm. (0.005 mole) of *p*-toluenesulfonyl chloride with vigorous stirring. The mixture was shaken and allowed to stand for 30 min. at 25°, poured onto 50 Gm. of ice, and extracted with two 100-ml. portions of ether. The ether layer was washed with two 100-ml. portions of 5% hydrochloric acid and with 100 ml. of water. The ether solution was dried over anhydrous sodium sulfate, filtered, and the solvent was removed under reduced pressure. A white, solid residue remained weighing 1.5 Gm. (59%). Recrystallization from methanol yielded white needles, m.p. 129–131°. Mixed melting point with an authentic sample of *erythro* ditosylate prepared from the known *erythro* diol was 129–131°. Mixed melting point with the known *threo* ditosylate 110–112°.

Anal.—Calcd. for $C_{24}H_{24}O_8S_2$: C, 57.1; H, 4.8; S, 12.4. Found: C, 56.9; H, 4.5; S, 12.5

[2] All melting points are corrected and were taken with a Thomas-Hoover melting point apparatus. Infrared spectra were taken with a Beckman IR-5A spectrophotometer. Elemental analyses were run by Clark Microanalytical Laboratory, Urbana, Ill., and Crobaugh Laboratories, Charleston, W. Va.

Inhibition of Isolation-Induced Attack Behavior of Mice by Drugs

By EDWARD T. UYENO

Three dose-response experiments indicated that psilocybin, mescaline, and 2-brom-lysergic acid diethylamide (BOL-148) inhibited isolation-induced attack behavior of 11-week-old Swiss-Webster mice, tested at the time of peak effect. The 3 dose-response curves show that the per cent inhibitory effects of these compounds are increasing monotonic functions of dose. The ED_{50} and confidence limits for psilocybin, mescaline, and BOL-148 are 2.096 mg./Kg. (1.334–3.291), 5.413 mg./Kg. (2.904–10.090), and 1.183 mg./Kg. (0.676–2.069), respectively.

In a previous study it was found that the per cent inhibitory effect of 0.1–1.6 mg./Kg. of *d*-lysergic acid diethylamide (LSD-25) on the attack behavior of mice, tested 5 min. after intraperitoneal injection (i.p.) was an increasing monotonic function of dose (1).

The present experiment was conducted in order to compare the results of the LSD-25 study with those obtained with 2 other hallucinogens: psilocybin (an indole derivative like LSD-25) and mescaline (belonging to the phenylethylamine group). Moreover, it was deemed important to compare the effects of 2-brom-lysergic acid diethylamide (BOL-148), a congener of LSD-25, reported to produce LSD-25-like psychic effects (2). More specifically, the effects of psilocybin, mescaline, and BOL-148 on isolation-induced attack behavior of Swiss-Webster male mice were investigated.

METHOD

Six-week-old Swiss Webster male mice were socially isolated for 5 weeks in 18 × 10 × 12 cm. metal cages which had wire mesh fronts and floors. Another group was housed together (30/cage) in 44 × 26 × 16 cm. metal cages, constructed in the similar manner as the smaller cages. All animals were fed *ad libitum* some standardized dietetically optimum pellets.[1]

After 5 weeks, a 5-min. pretest was initiated by placing a "group-housed" mouse into the cage of an isolated mouse until attack behavior was observed. An attack was defined as an aggressive contact involving biting. When an attack occurred, the attack latency was recorded and the "group-housed" mouse was returned to its cage. (The group-housed animals did not attack, and hardly any of them retaliated when they were attacked.) On the basis of their attack latencies, the attackers were matched and assigned to control and 3 experimental groups (3 drugs). Each experimental group was divided into 4 subgroups (4 subgroups/drug).

The Time of Peak Effect.—Experimental animals (n = 20 or 30/subgroup) were tested at 5, 15, 30, or 45 min. after i.p. injection of 4 mg./Kg. of psilocybin, 20 mg./Kg. of mescaline base, administered as the sulfate, or 2 mg./Kg. of BOL-148 in saline solution. The control animals were injected with 0.9% saline solution and were tested for attack behavior 30 min. later. A standard volume of 10 ml./Kg. of drug–saline and saline solution was administered to the experimental and control animals, respectively. Each attacker was paired with the same group-housed animal with which it had been paired in the pretest. The test was conducted in a manner similar to the pretest.

Dose-Response.—Dose-response experiments were conducted with 6-week-old Swiss-Webster male mice that were essentially similar to those used in the peak time study. At the end of a 5-week isolation period, the pretest was given. On the basis of attack latencies, they were assigned into a control and 3 experimental groups (3 drugs) with 4 graded dose groups per drug. (N = 20 or 30/subgroups.) As before, the control animals were injected with 0.9% saline solution. After injection, the control and experimental animals were tested for attack behavior at the time of peak effect as determined from the earlier studies.

RESULTS AND DISCUSSION

In the time of peak effect and dose-response experiments, all control animals attacked the group-housed animals, but many experimental animals did not attack. In the peak time study, the sum of nonattackers in each time group was expressed as a percentage of all the animals in that group (per cent effect). Per cent effect was plotted against post-injection time (Fig. 1). The time of peak inhibitory effects of 4 mg./Kg. of psilocybin and 2 mg./Kg. of BOL-148 was 30 min. after the i.p. injection. For 20 mg./Kg. of mescaline, the peak time was between 15 and 30 min. after the injection.

In the dose-response study the sum and percentage of nonattackers in each dose group were calculated for each compound (Table 1). Per cent effect was plotted against dose on logarithmic probability paper (Figs. 2 and 3). The data show that the per cent inhibitory effect of each compound is an increasing monotonic function of dose. Probit

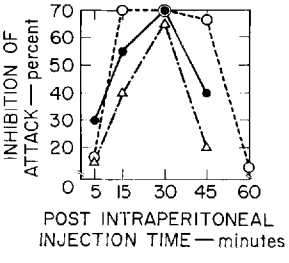

Fig. 1.—Time of peak inhibitory effect of 20 mg./Kg. of mescaline (N = 30/plot), 4 mg./Kg. of psilocybin (N = 20/plot), and 2 mg./Kg. of BOL-148 (N = 20/plot) on attack behavior. Key: △, BOL-148; ●, psilocybin; ○, mescaline.

TABLE I.—PERCENTAGE OF NONATTACKERS IN EACH DOSE GROUP

Compd.	Dose, mg./Kg.	N	Non-attackers	% Effect
Psilocybin	8	20	16	80
	4	20	14	70
	2	20	11	55
	1	20	5	25
Mescaline	30	30	24	80
	20	30	21	70
	10	30	16	53
	1	30	8	27
BOL-148	2.0	20	13	65
	1.5	20	10	50
	1.0	20	9	45
	0.5	20	7	35
LSD-25[a]	0.8	20	20	100
	0.5	20	17	85
	0.4	20	15	75
	0.3	20	10	50
	0.2	20	6	30
	0.1	20	4	20

[a] Data obtained from *Reference 1*.

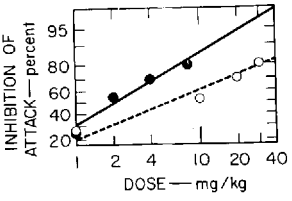

Fig. 2.—Dose response curves. Key: ●, 1.0–8.0 mg./Kg. of psilocybin (N = 20/dose); ○, 1.0–30 mg./Kg. of mescaline (N = 30/dose).

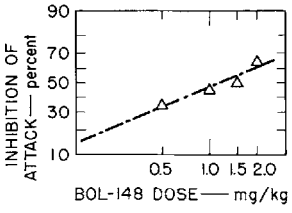

Fig. 3.—Dose response curve. Effect of 0.5–2.0 mg./Kg. of BOL-148 on attack behavior (N = 20/dose).

analysis of the data was conducted by an electronic computer (3). The ED_{50} and the confidence limits for psilocybin, mescaline, and BOL-148 are 2.096 mg./Kg. (1.334–3.291), 5.413 mg./Kg. (2.904–10.090), and 1.183 mg./Kg. (0.676–2.069), respectively. The equations of the 3 curves are: psilocybin, $Y_1 = 4.469 + 1.652\ (X_1)$; mescaline, $Y_2 = 4.314 + 0.935\ (X_2)$; BOL-148, $Y_3 = 4.916 + 1.160\ (X_3)$.

In general, experimental mice withdrew to the rear of the cage, remained inactive [as LSD-25 mice (1)], and did not attack. The latencies of a few that attacked were longer than their pretest latencies. In contrast, the latencies of the control animals were shorter than during the pretest. The inactive reaction of the psilocybin mice appeared to be consistent with that observed by Cerletti (4), who reported that this compound produced a distinct reduction of motor activity in mice, rabbits, and monkeys. Moreover, in humans, Hollister (5) and Delay *et al.* (6) found that an oral dose of 150 mcg./Kg. and 130 mcg./Kg., respectively, induced physical responses indicative of depressant behavior, such as drowsiness, fatigue, and weakness. The results of the mescaline experiment corroborate those of Saxena *et al.* (7), who found that in fish (*colisa lalia*) the fighting response to another male was completely blocked by intramuscular injection of 0.1–0.2 mcg. of mescaline sulfate. The lowered activity and withdrawal reaction of the mescaline mice in the present study are consistent with results reported for cats given 0.3–1.0 mg./Kg. of this compound (8). The depressant effect of mescaline was also observed in a pole climbing performance of rats that increased their latencies when they were injected 20 mg./Kg. i.p. of this compound 15 min. before test (9).

The results indicate that the times of peak effect of 4 mg./Kg. of psilocybin, of 20 mg./Kg. of mescaline, and of 2 mg./Kg. of BOL-148 were later than that (5 min. after the i.p. injection) of 0.4 mg./Kg. of LSD-25 (1), suggesting that the 3 former compounds may have slower rates of passage into the brain. Like LSD-25, the 3 compounds made most of the animals inactive and inhibited their isolation-induced attack behavior. Mescaline with the highest ED_{50} (5.413 mg./Kg.) and LSD-25 (1) with the lowest ED_{50} (0.265 mg./Kg.) seem to suggest the former is the least and the latter the most potent inhibitors of isolation-induced attack behavior.

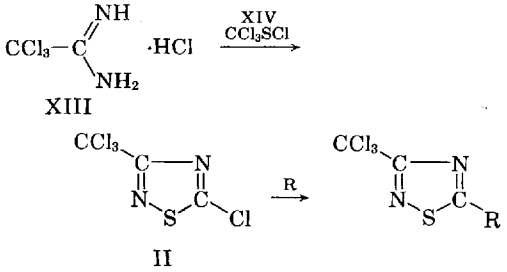
Antifungal Agents I.
5-Substituted-3-(trichloromethyl)-1,2,4-thiadiazoles

By V. L. NARAYANAN, JACK BERNSTEIN, and J. WILLIAMS

Some 5-substituted-3-(trichloromethyl)-1,2,4-thiadiazoles were synthesized by the nucleophilic displacement of the Cl^- ion of 5-chloro-3-(trichloromethyl)-1,2,4-thiadiazole for evaluation as soil fungicides. An interesting O → N migration of the β-hydroxyethyl substituent was observed during the synthesis of 5-(2-hydroxyethoxy)-3-(trichloromethyl)-1,2,4-thiadiazole. All these compounds retained 60–80 per cent of the over-all fungicidal activity of the analogous 5-ethoxy-3-(trichloromethyl)-1,2,4-thiadiazole.

THE DISCOVERY of 5-ethoxy-3-(trichloromethyl)-1,2,4-thiadiazole as an effective soil fungicide (1, 2) led the authors to synthesize the compounds listed in Table I (compounds III–VIII). The objectives were to decrease the volatility of the parent compound and to determine the structure-activity relationships in this series.



Trichloroacetamidine hydrochloride (XIII) was reacted with trichloromethanesulfenyl chloride (XIV) to give a 56% yield of II (3). The displacement of the Cl^- ion of II by the appropriate nucleophiles gave compounds III through VIII. The reactions were achieved by the slow addition of the appropriate nucleophiles, dissolved in suitable solvents, to a solution of II, and stirring for several hours at room temperature. The above general procedure is necessitated because of the instability of the allylic chlorines toward strong bases, especially at elevated temperatures. Furthermore, it takes advantage of the high reactivity of the chlorine at the 5-position toward nucleophilic displacements.

Compound VIII was obtained in almost quantitative yields following the general procedure outlined. A v.p.c. analysis[1] indicated the material to be of 90–95% purity. However, distillation of VIII *in vacuo* led to extensive desulfurization, and a 30% yield of an isomeric mixture (X) was obtained. On the basis of the spectral data,[2] the mixture was estimated to contain approximately 75% of VIII, the major component of the remainder being the *N*-alkylated product (XI). The thermal isomerization could proceed through the mechanism shown in Scheme I.

The fact that the propoxy derivative (VII) distilled unchanged and that it could not be isomerized by heating at 155–165° suggests that the transition state (XII) for the formation of XI may have some ionic character, being stabilized by the polar —OH group.

Attempts to obtain IX by reacting II with the anion $-P(OC_2H_5)_2$ (4), following the general procedure, failed. Although its formation was indicated [I.R., λ $CHCl_3$ 9.7 μ (aryl phosphate)] (5), isolation procedures led to extensive decomposition, and a mixture of unidentified products was obtained. The nature of this reaction was not studied further.

EXPERIMENTAL

All melting points were taken on a Thomas-Hoover melting point apparatus and are uncorrected. The v.p.c. separation was performed on K-22A column at 142° and 30 ml./min. gas flow. The infrared spectra were determined with samples in the form of Nujol mulls, and NMR spectra in deuteriochloroform in the presence of deuterium oxide with tetramethylsilane as the internal standard.

Substituted Thiadiazoles (Table I; III–VIII). General Procedure.—The appropriate nucleophile (0.1 mole) dissolved in a suitable solvent (chloroform or the alcohols from which the nucleophiles were generated) was added dropwise with stirring to a solution of 0.1 mole of 5-chloro-3-(trichloromethyl)-1,2,4-thiadiazole (II) dissolved in the same solvent. The mixture was then stirred for 4–6 hr., and allowed to stand overnight at room temperature. After removal of the solvent *in vacuo*, the product was isolated either by distillation under reduced pressure or by crystallization.

Pertinent data are listed in Table I.

5-(2-Hydroxyethoxy)-3-(trichloromethyl)-1,2,4-thiadiazole (VIII).—Sodium methylate, 2.83 Gm., was dissolved in 30 ml. of absolute methanol, and to this solution 31 Gm. of ethylene glycol, dissolved in 20 ml. of absolute methanol, was added. The mixture was concentrated to remove the methanol, and the remaining solution was then added dropwise at room temperature to a solution of 11.9 Gm. of II in 100 ml. of ether. The reaction mixture was stirred overnight, washed with water, and then dried over $MgSO_4$. Removal of ether gave 12.1 Gm. (92.4%) of the product as a thick pale yellow viscous oil. λ 2.95 μ, broad (bonded OH), and 6.55 μ (C=N), τ 5.25 (t, O—CH_2) and τ 5.95 (t, CH_2).

Anal.—Calcd. for $C_5H_5Cl_3N_2O_2S$: C, 22.51; H, 1.88; N, 10.84. Found: C, 21.87; H, 2.09; N, 10.99.

A v.p.c. analysis indicated the material to be 90–95% pure.

Scheme I

Isomerization of 5-(2-Hydroxyethoxy)-3-(trichloromethyl)-1,2,4-thiadiazole (VIII → XI).—Ten grams of VIII was distilled *in vacuo* under nitrogen, and the fraction that distilled at 153–158°/0.6–0.7 mm. was collected as a thick yellow liquid, weighing 2.8 Gm. λ 2.95 μ broad (bonded OH), 5.85 μ (C=O) and 6.55 μ (C=N); τ 5.25 (t, O—CH_2), τ 5.51 (t, N—CH_2), and τ 5.95 (t, CH_2).

Anal.—Calcd. for $C_5H_5Cl_3N_2O_2S$: C, 22.51; H, 1.88; Cl, 40.48; N, 10.84. Found: C, 22.79; H, 1.92; Cl, 40.37; N, 10.63.

An attempted v.p.c. separation on K-122A column was not successful.

On the basis of the relative intensities of the C=N band at 6.55 μ, XI was estimated to be present to the extent of about 25%.

BIOLOGICAL TESTING

Compounds III–VIII were screened as soil fungicides[3] against 3 different pathogenic fungi, *Fusarium*, *Rhizoctonium*, and *Pythium*. Although no definite pattern of structure-activity relationships was discernible, all these compounds retained about 60–80% of the over-all activity of the analogous 5-ethoxy-3-(trichloromethyl)-1,2,4-thiadiazole. However, in general, they were more phytotoxic than I.

Quantitative Analysis of Anhydrotetracycline on Microcrystalline Cellulose

By D. L. SIMMONS, C. K. KOORENGEVEL, R. KUBELKA, and P. SEERS

A quantitative TLC method for the determination of anhydrotetracycline alone and in the presence of tetracycline has been developed on microcrystalline cellulose. It is a rapid and precise method for determining small amounts of this compound in tetracycline samples, provided one works within the range of 10–40 mcg. of anhydrotetracycline per spot.

IN GENERAL, the separation of tetracycline antibiotics has been performed by chromatographic methods based on pH control of the adsorbent. Early investigators employed complex solvent systems with buffered paper (1, 2) or paper impregnated with sequestering agents (3). The quantitative separation of these antibiotics using a column of powdered cellulose impregnated with tartrate buffer was reported in 1961 by Hrdy and Vesely (4). In 1962 Addison and Clark (5) described a method for the separation of tetracycline from epitetracycline and anhydrotetracyline using a modified Whatman cellulose phosphate cation exchange paper. Kelly (6) employed a column of silicate containing a buffered EDTA solution to effect the resolution of anhydrotetracycline and epianhydrotetracycline in the presence of large quantities of tetracycline.

The application of microcrystalline cellulose to thin-layer chromatography has only recently been investigated (7, 8). Wolfrom and co-workers (9) reported that TLC on a microcrystalline form of cellulose[1] has been more efficient than paper chromatography in resolving certain water-soluble sugars, sugar derivatives, amino acids, and related compounds. This material has almost completely displaced the papergram in their laboratory, and in most cases was found to be superior to silica gel where both systems were applicable. These results combined with the published data on the resolution of tetracycline on paper led the authors to investigate the behavior of anhydrotetracycline on microcrystalline cellulose.

EXPERIMENTAL

Preparation of Anhydrotetracycline.—A solution of tetracycline hydrochloride (15 Gm.) in 0.1 *N* hydrochloric acid (500 ml.) was warmed on a steam bath at 70° for 1 hr. After cooling, the precipitate was collected by filtration and suspended in water (500 ml.). The suspension was adjusted to pH 4.5 with 5 *N* sodium hydroxide solution and extracted with ethyl acetate (2 × 400 ml.). The dried organic extracts were concentrated to approximately 50 ml. and cooled. The product (5.0 Gm.) was collected by filtration and recrystallized from benzene as yellow needles, m.p. 217.5°. [Lit. m.p. 215–220° (10).]

Anal.—Calcd. for $C_{22}H_{22}NO_7$: C, 61.96; H, 5.19. Found: C, 62.18; H, 5.08.

Preparation of Plates.—Microcrystalline cellulose (50 Gm.) was passed through a 100 mesh sieve and mixed in a mortar and pestle for 2 min. with 0.05% ammonium chloride solution (180 ml.). Since microcrystalline cellulose is commonly used in the pharmaceutical industry as a gelling agent, it was decided to employ a dilute salt solution such as ammonium chloride instead of water alone so that the gelling process was minimized. This modification permitted easier manipulation of the cellulose slurry. A 0.25-mm. layer of this homogeneous slurry was then applied to 5 clean glass plates (20 × 20 cm.) with a Desaga variable applicator. Prior to spotting, the plates were allowed to dry at room temperature for 10 min. and then heated in an oven at 90° for 30 min. Unlike silica gel plates, no special storage conditions were necessary.

Plate Development and Recovery of Anhydrotetracycline.—The plates were spotted by applying aliquots (10, 15, 20. . . 60 μl.) of a freshly prepared standard solution of anhydrotetracycline in methanol (1 mcg./μl.) approximately 3 cm. from the edge of each chromatoplate. These quantities are equivalent to 10–60 mcg. of anhydrotetracycline per spot. The plates were then placed in a developing chamber containing 0.1% aqueous ammonium chloride solution (160 ml., pH 5.6); filter paper saturated with the eluant lined the interior chamber walls. The plates were allowed to develop for 20 min., removed from the chamber, and dried for 10 min. under ambient conditions. An area (4 × 6 cm.) was marked off around the visible yellow spot (R_f 0.35), and the surrounding adsorbent was removed by a straight edge spatula and discarded. Individual spots were scraped off and collected in 3-ml. sintered-glass filter funnels, and the anhydrotetracycline was recovered from the adsorbent by washing the contents of the funnel with hot methanol directly into a 10-ml. volumetric flask under vacuum in a vacuum bell jar. The absorbances of the resulting filtrates were determined at 428 mμ against a methanol blank on a Beckman DU spectrophotometer. It was not necessary to employ a methanolic extract of cellulose for blank determinations at this wavelength. The procedure was repeated 5 times for each concentration.

Similar aliquots of the standard solution were transferred directly to 10-ml. volumetric flasks, adjusted to volume with methanol, and the absorbances read at 428 mμ.

Results are summarized in Table I.

Estimation of Anhydrotetracycline in Tetracycline Standard Mixture.—Tetracycline hydrochloride (80 mg.) was dissolved in 8.0 ml. of anhydrotetracycline standard solution in a 10-ml. volumetric flask, and the contents were adjusted to volume with methanol. An aliquot (0.04 ml., equivalent to 32 mcg. of anhydrotetracycline and 320 mcg. tetracycline hydrochloride) was removed by micrometer

20.0	0.041 ± 1.5	0.041 ± 1.9
25.0	0.052 ± 1.2	0.052 ± 1.4
30.0	0.062 ± 1.2	0.063 ± 2.1
35.0	0.072 ± 2.4	0.071 ± 2.4
40.0	0.082 ± 0.54	0.081 ± 1.8
45.0	0.093 ± 0	0.088 ± 0.71
50.0	0.102 ± 0.98	0.096 ± 0.78
60.0	0.122 ± 0.82	0.116 ± 2.0

[a] ± = per cent standard deviation.

syringe and spotted on a cellulose coated plate. The development and recovery of anhydrotetracycline from the mixture was performed in triplicate according to the procedure described previously. Anhydrotetracycline was visible as a yellow spot at R_f 0.35, whereas tetracycline required ultraviolet light for detection at the solvent front. The quantity of anhydro-derivative recovered from the 0.04-ml. application was obtained by multiplying the observed absorbance (A_0) by the concentration of standard (C_{st}) over the corresponding absorbance of standard (A_{st}).

$$\frac{A_0 \times C_{st}}{A_{st}}$$

The total anhydrotetracycline in the sample was then determined by accounting for dilutions and weight conversion (Table II).

RESULTS AND DISCUSSION

Results indicate that quantitative isolation of anhydrotetracycline by microcrystalline cellulose TLC is possible over the 10–40 mcg. range, but deviations from the standard occur at quantities above 40 mcg. (Table I). Fairly extensive tailing of the chromatogram was observed in the 45–60 mcg. range; this is probably due to overloading of the film with anhydrotetracycline and/or its solvent. The anhydrotetracycline can only be recovered quantitatively in this range by extracting the entire cellulose area between origin and spot.

TABLE II.—RECOVERY OF ANHYDROTETRACYCLINE FROM TEST SAMPLE (32 mcg./SPOT)

Absorbance	mcg. Anhydro/Spot
0.064	31.2
0.065	31.7
0.065	31.7

An interesting feature of the procedure described is that significant changes to the pH (1.5–7.8) of the solvent system did not alter the behavior of the chromatogram. This is in contrast to the exacting pH requirements of previous methods.

Initially this chromatographic procedure helped to demonstrate the purity of the anhydrotetracycline. After each recrystallization from benzene, a standard solution (1 mcg./μl.) was prepared and subjected to TLC on cellulose. When the absorbance readings of the direct dilutions of the standard were identical to the dilutions obtained following TLC, the compound was judged to be of analytical purity. Subsequent elemental analysis substantiated this judgment.

Additional evidence for the purity of the anhydrotetracycline standard was obtained by demonstrating the absence of epianhydrotetracycline, an anticipated contaminant, by subjecting the compound to a chromatographic method established for this purpose (3). This method also showed that epimerization of the anhydrotetracycline did not take place under the TLC conditions described in this paper and is in agreement with the findings of Addison and Clark (5). These investigators found that tetracycline in solution in aqueous ammonium chloride remained stable over several hours.

A mixture of anhydrotetracycline and tetracycline did not have an adverse effect on the chromatogram. The authors' demonstrate that the anhydro-derivative can be quantitatively isolated and determined from a test mixture containing anhydrotetracycline and a large quantity of tetracycline.

Since the foregoing method for the quantitative determination of anhydrotetracycline in tetracycline mixtures was established, the authors have developed procedures for the separation and determination of anhydro- and epianhydrotetracyclines in standard tetracycline mixtures and degraded tetracycline products. These procedures will be reported in a future paper.

Structure and Activity in the Schistosomicidal Thiaxanthone and Xanthone Derivatives

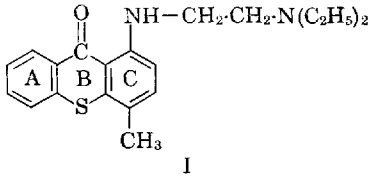
Sir:

1-(2-Diethylaminoethylamino)-4-methyl thiaxanthone (I) possesses schistosomicidal and antitumor activity. Also its analog, 6-chloro-1-(2-diethylaminoethylamino)-4-methyl xanthone (II) shows similar but less potent activity (1, 2).

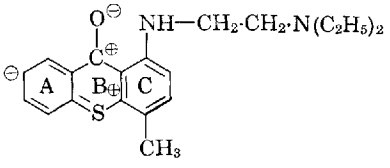
In both areas of application, the activity depends mainly upon the presence of the methyl group at the 4-position *para* to an amino side-chain at the 1-position of ring C. Changes in these groupings caused loss of activity (3).

In previous communications, it was reported that both of the groupings attached to ring C could undergo dehydrogenation through the enzymatic action of peroxidase in the presence of hydrogen peroxide (4). Also, the 4-methyl group could undergo chlorination (5) and Mannich (6) reactions under the appropriate experimental conditions.

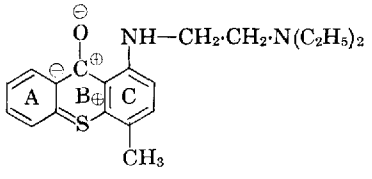
This particular reactivity may be explained by the presence of the polarizable carbonyl group adjacent to the 1-position and the heteroatom (oxygen or sulfur) neighboring the 4-position. As both heteroatoms bear 2 pairs of free electrons



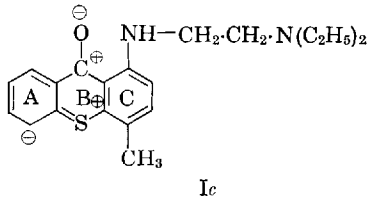
I



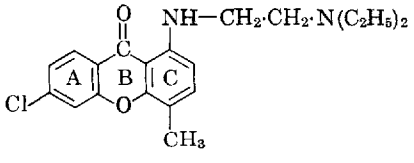
Ia



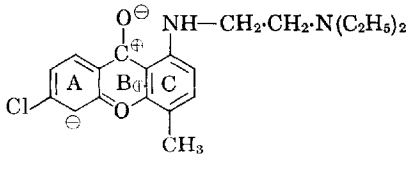
Ib



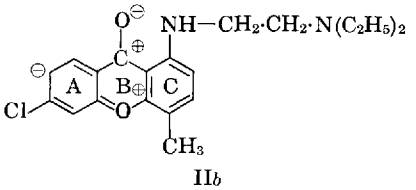
Ic



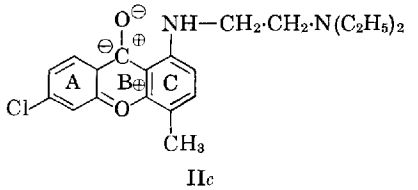
II



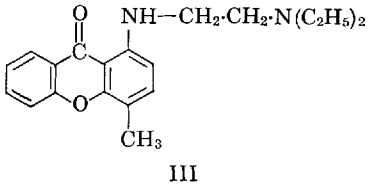
IIa



IIb



IIc



III

and the structures of both molecules (I and II) permit, to different extents, extensive delocalization of these free electrons to be involved in the resonance hybrids I, I*a*, I*b*, I*c*, and II, II*a*, II*b*, II*c* with ring A, the delocalization of the free electrons on the heteroatom preferentially extends toward ring A as ring C bears electron-donating substituents, and this would not favor the resonance hybrids to involve ring C.

This tendency is more pronounced with the sulfur present in I than with the oxygen present in II since oxygen is more electronegative than sulfur. Also, oxygen has an atomic radius of 0.66 Å., which would allow more orbital overlap with the attached carbon atom (atomic radius 0.77 Å.), and this would inhibit to an extent the electron delocalization tendency. This might explain the difference in the biological activity between I, II, and the structural analog, 1-(2-diethylaminoethylamino)-4-methyl xanthone (III) which does not show any noticeable biological activity. In II, the chlorine atom, through its inductive effect, helps to overcome the inhibiting factors of the delocalization of the electrons on oxygen. This effect is missing in III, and thus it is deprived of activity.

In these resonance hybrids, the heteroatom acquires positive charge and ring B becomes loaded with positive charges at both poles, which is electrostatically unfavorable. It tends to compensate for these positive charges by withdrawing electrons in this direction, thus increasing the acidity of the hydrogens attached to the 4-methyl group and the dissociability of that attached to nitrogen at the 1-position of the amino side-chain.

In confirmation of this hypothesis, the NMR measurements of I and II showed that the hydrogens of the 4-methyl group appeared at 7.5 τ which is at the lower part of the field. Aromatic methyl usually appears at 8 τ; thus, slight acidity is implied. In III, it appeared at 7.88 τ, which is at a higher part of the field. Also, the dipole moment of thiaxanthone itself is 5.4 *D* while that of xanthone is 3.11 *D*.

From the biological standpoint, when the carbonyl group in any of the drugs was reduced to the corresponding hydrol, then the activity was lost. In addition, when the sulfur in I was oxidized to sulfone, the drug was no longer active (3).

Role of Sulfate Formation in Biotransformation of Salicylamide in Man

Sir:

Salicylamide is eliminated in man mainly by biotransformation to the ether glucuronide and the ester sulfate (1, 2). Studies of the kinetics of salicylamide sulfate formation as a function of dose, which will be described in detail in a subsequent report (3), have shown that this process reaches a maximum rate and exhibits characteristics of apparent zero-order kinetics in the usual dose range. This preliminary report is presented in view of the theoretical and practical importance of such unusual kinetic characteristics in the elimination of a commonly used drug.

Salicylamide was administered to healthy adult males as an aqueous solution on empty stomach after an overnight fast. It was given in single doses of 150 and 1000 mg. In addition, a single dose of 1000 mg. salicylamide was given with L-cysteine which was administered every hour for 7 doses starting 3 hr. before salicylamide administration. Total urine collections were made every 0.5 hr. for 4 hr., then every hour for 4 hr., finally at convenient intervals up to 24 hr. after drug administration. Total salicylamide, salicylamide glucuronide, and salicylamide sulfate in the urine were determined by a combination of chemical and enzymatic methods (3). The results of these experiments in 2 representative subjects are shown in Table I. Essentially all of the administered drug was recovered in the urine in the form of salicylamide metabolites. About 50% was excreted as salicylamide sulfate after administration of 150 mg. of drug; this fraction decreased to about 30% when the dose was increased to 1000 mg. The maximum excretion rate of salicylamide sulfate increased

and the structures of both molecules (I and II) permit, to different extents, extensive delocalization of these free electrons to be involved in the resonance hybrids I, I*a*, I*b*, I*c*, and II, II*a*, II*b*, II*c* with ring A, the delocalization of the free electrons on the heteroatom preferentially extends toward ring A as ring C bears electron-donating substituents, and this would not favor the resonance hybrids to involve ring C.

About 50% was excreted as salicylamide sulfate after administration of 150 mg. of drug; this fraction decreased to about 30% when the dose was increased to 1000 mg. The maximum excretion rate of salicylamide sulfate increased

TABLE I.—EFFECT OF DOSE AND CYSTEINE ADMINISTRATION ON SULFATE CONJUGATION OF SALICYLAMIDE

	Subject 1			Subject 2		
Dose, mg.	150	1000	1000 + Cysteine	150	1000	1000 + Cysteine
Urinary recovery, % of dose	101	97	99	99	92	98
Per cent excreted as sulfate[a]	53	28	52	49	32	49
Max. sulfate excretion rate, mg./hr.[b]	43	109	268	45	121	241

[a] Per cent of amount recovered in urine. [b] Expressed in terms of salicylamide; based on 0.5 hourly urine collection.

less than threefold despite the 6.7-fold increase in the administered dose. The peak excretion rate of salicylamide sulfate after administration of 1000 mg. salicylamide represents a maximum which is not increased by use of larger doses and apparently reflects the maximum capacity of the body for this conjugation process. Coadministration of L-cysteine with 1000 mg. of salicylamide had a pronounced effect on the formation of the sulfate conjugate. The fraction excreted in the form of this metabolite increased to the value found with the lower dose, and the maximum excretion rate became essentially proportional to the administered dose when compared to the lower dose. Apparently, L-cysteine serves as a precursor for sulfate and thereby increases the capacity of the process responsible for salicylamide sulfate synthesis in the body. The results of these experiments show that man has a limited capacity for salicylamide sulfate formation and suggest that the limiting factor is the availability of sulfate.

Some important implications of these findings are: (*a*) the relative rate of salicylamide elimination decreases with dose, (*b*) pharmaceutical dosage form characteristics which affect the absorption rate of salicylamide will also affect the metabolic fate of this drug, (*c*) studies of salicylamide metabolism for which unusually large doses are employed for assay convenience yield quantitative results which do not apply to lower doses, (*d*) the elimination rate of salicylamide in high doses may be increased by administration of L-cysteine (and probably by absorbable sulfate or other sulfate precursors).

Until recently, ethanol was the only drug known to be metabolized in man by apparent zero-order kinetics in the therapeutic dose range. Salicylate (4) and salicylamide (specifically, glycine conjugation of the former and sulfate formation of the latter) can now be added, and there is preliminary evidence that at least 1 other type of biotransformation process exhibits saturation kinetics in man (5). The general implications of these findings, particularly as reflected in items (*a*) to (*c*) in the preceding paragraph, require therefore serious consideration.

REVIEWS

Interpretation of NMR Spectra: An Empirical Approach. By ROY H. BIBLE, JR. Plenum Press, 227 West 17th St., New York, N. Y. 10011, 1965. x + 150 pp. 15.5 × 23.5 cm. Price $12.50.

The aim of the author is (*a*) to teach organic chemists to interpret their proton NMR spectra and (*b*) to provide handbook data for the job. In the latter aim he has done excellently. As to the first aim, his success is relative to the depth of the interpretation envisioned. He has given little more than recipes for the assignment of chemical shift values and spin-spin coupling constants. There is almost no discussion of physical interpretation.

Though it consists almost exclusively of empirical generalizations, the book is easy to read, owing to the author's lucidity and his use of a generous number of examples. Most of the points discussed in the text are ultimately summarized in tabular form. There are adequate references to the literature.

The earlier chapters describe the variation in chemical shift and coupling constant with structure, with numerous tables and graphs summarizing the experimental data. A wall chart of characteristic chemical shift ranges is furnished. The intensity patterns of first-order splitting comprises one chapter, which is followed by a discussion of the complications arising from higher order splitting. This chapter includes the method of numerical analysis of the ABX spectrum. Methods for simplifying complex spectra for interpretation are presented, and a final chapter outlines an over-all analysis of the spectrum. The appendix includes a glossary to the jargon of the field, which has largely grown out of electronic engineering and quantum physics.

This book will have its best application by those whose primary interest is the routine use of NMR in structural problems. It will also serve a beginner in the field by making easier the reading of Pople, Schneider, and Bernstein. As a virtual summary of the 500 pages of the latter, it is curious that it comes at almost the same price.

Handbook of Ultraviolet Methods. By ROBERT G. WHITE. Plenum Press, 227 W. 17th St., New York, N. Y. 10011, 1965. 356 pp. 17 × 26 cm. Price $17.50.

This book contains more than 1600 references to ultraviolet methods of analysis which have appeared in technical journals during the past 25 years. The references cited deal primarily with substances of biological significance. Emphasis is placed on the material or compound being analyzed rather than on instrumentation or techniques. All entries describe the subject treated and some contain considerable detail. The items are arranged alphabetically by senior author; specific substances are indexed by chemical name with cross-indexing to generic and trivial names. Chemists may find some of the abbreviations used, particularly ASTM CODEN for reference citations, unfamiliar initially. However, this volume should prove a useful and rapid reference to available literature on ultraviolet spectrophotometric methods of analysis.

REVIEWS

Interpretation of NMR Spectra: An Empirical Approach. By ROY H. BIBLE, JR. Plenum Press, 227 West 17th St., New York, N. Y. 10011, 1965. x + 150 pp. 15.5 × 23.5 cm. Price $12.50.

The aim of the author is (*a*) to teach organic chemists to interpret their proton NMR spectra and (*b*) to provide handbook data for the job. In the latter aim he has done excellently. As to the first aim, his success is relative to the depth of the interpretation envisioned. He has given little more than recipes for the assignment of chemical shift values and spin-spin coupling constants. There is almost no discussion of physical interpretation.

Though it consists almost exclusively of empirical generalizations, the book is easy to read, owing to the author's lucidity and his use of a generous number of examples. Biological and Phytochemical Screening of Plants

By NORMAN R. FARNSWORTH

CONTENTS

Received from the School of Pharmacy, University of Pittsburgh, Pittsburgh, Pa.

The author expresses his appreciation to the many people who aided in certain phases of this review. In particular, the staff of the Maurice and Laura Falk Library of the Health Professions and graduate students and staff of the Department of Pharmacognosy, University of Pittsburgh, Pittsburgh, Pa., were most helpful in the acquisition and compilation of references. Special thanks are extended to Dr. H. H. S. Fong and Dr. R. N. Blomster, who aided through their continual interest, criticisms, and helpful suggestions.

Certain of the material presented in this review was determined in our laboratories through support from research grant CA-08228 from the National Cancer Institute, U. S. Public Health Service, Bethesda, Md., from Eli Lilly and Co., Indianapolis, Ind., and from Riker Laboratories, Northridge, Calif.

INTRODUCTION

THE IMPORTANCE of plant-derived medicinals in modern medicine is often underestimated. Such useful compounds as digitoxin, rutin, papain, morphine, codeine, papaverine, atropine, scopolamine, quinine, quinidine, reserpine, ergotamine, ergonovine, cocaine, vincaleukoblastine, leurocristine, *d*-tubocurarine, protoveratrines A and B, ephedrine, sparteine, physostigmine, pilocarpine, colchicine, and caffeine—to mention a few—present a broad and representative range of pharmacologic activities. In addition, crude drugs such as *Digitalis purpurea* leaf and *Rauwolfia serpentina* root are still preferred by many physicians in their practice; whereas extracts from *Podophyllum peltatum* (podophyllin), *Rhamnus purshiana* (anthraquinones), *Cassia* species (anthraquinones), and *Plantago* species (mucilage) are widely utilized for their medicinal activity. In fact, a recent survey has pointed

out that 47% of some 300 million new prescriptions written by physicians in 1961 contained, as one or more active ingredients, a drug of natural origin. Further, between 1950 and 1960, prescriptions containing drugs of natural origin increased by 7.7% (1).

A knowledge of the biological activities and/or chemical constituents of plants is desirable, not only for the discovery of new therapeutic agents, but because such information may be of value in disclosing new sources of such economic materials as tannins (2), industrial oils (3–9), gums (10), precursors for the synthesis of complex chemical substances (11), etc. Also, a novel chemical structure, isolated from plant sources, often prompts the chemist to a successful series of modified semisynthetic compounds, *e.g.*, atropine →homatropine, reserpine→syrosingopine, morphine→*N*-allylnormorphine, which may have some medicinal or otherwise useful economic value. On the other hand, attempts at modification of model natural compounds to enhance their activity have, of course, been unsuccessful (12). A knowledge of the chemical constituents of so-called "toxic" plants could place the treatment of plant poisonings of both humans and animals on a more rational and specific basis. The possibility of discovering new research tools for use in pharmacology, *e.g.*, as has been served by the hallucinogens, should not be discounted. A knowledge of the chemical constituents of plants would further be valuable to those interested in the expanding area of chemotaxonomy (biochemical systematics), to those interested in biosynthesis, and to those interested in deciphering the actual value of folkloric remedies.

This review is intended to present the various approaches used by investigators primarily interested in the discovery of new biologically active plant principles. *Phytopharmacologic Approaches* will consider those methods which involve, as a first step, the observation or detection of biological activity induced by plant products. *Phytochemical Screening Approaches* will describe and evaluate methods used for the detection of phytochemical classes of compounds, examples of which are known to elicit some desirable biological response.

The problems of the natural product investigator interested in biologically active compounds are complex and differ distinctly from those of the organic chemist who synthesizes or manipulates molecules using structure-activity relationships as his theoretical motivation to design. Natural product investigators must initially select their plants to investigate from a total number of available species that has been estimated to be as high as 750,000, excluding the bacteria and fungi (Table I). When this selection has been made, whether it be on theoretical grounds or on the basis of preliminary experimentation, the problems of acquisition and the variability of investigational plant material become complicating factors. These problems have been discussed recently in relationship to drug plants (14). Next, the natural product investigator must enlist the aid of a cooperative pharmacologist, or make other arrangements to insure a suitable biological evaluation for his extracts and isolated compounds. The problems inherent in the biological evaluation of crude plant extracts are in themselves unique, and several will be delineated in this review. Many of these problems remain to be solved, and the personal experiences of this author cause him to believe that those who are concerned with biological evaluations have little interest in crude plant extracts. In effect, priority is usually given to the biological evaluation of crystalline, water-soluble compounds. However, it should be remembered that in natural product studies, these pure compounds are realized only after initial biological tests on crude extracts provide justification for a phytochemical investigation. This lack of interest in the biological evaluation of crude plant preparations will probably continue as the major block to progress in the study of natural products.

The selection of research plant material by the investigator interested in the discovery of new biologically active phytoconstituents is a real problem. Approaches outlined in this review are representative of those which have either been used in the past, or are currently in progress. Each has obvious advantages as well as disadvantages, and the final method or combination of methods to be used by an individual will necessarily reflect his own background, training, interests, and available research facilities.

PHYTOPHARMACOLOGIC APPROACHES

Medicinal Folklore Evaluation

From about the 11th to the 18th centuries a dogma known as the Doctrine of Signatures was almost the sole means by which man attributed medicinal value to certain plants. This dogma held that the color, shape, habitat, or other physical characteristics of a plant were indicative of its medicinal value. Thus, the worm-shaped embryo of chenopodium (wormseed) suggested it to be of value as an anthelmintic, the yellow color of saffron served to point out its value in liver disorders, the serpentine shape of rauwolfia roots (snakeroot) indicated that they should be useful in treating snakebite, etc. Obviously,

TABLE I.—ESTIMATED NUMBER OF PLANT SPECIES[a]

Thallophyta	
Bacteria	1,500
Fungi	100,000
Algae	19,000
Lichens	20,000
Bryophyta	14,000
Pteridophyta	10,000
Spermatophyta	
Gymnosperms	700
Angiosperms	
Monocots	200,000
Dicots	500,000

[a] As put forth by Schultes in 1963 (13).

no rational justification for the use of drugs selected in this manner can be made. However, as man experimented, he found by trial and error, certain plants useful for the treatment of some of his myriad illnesses. Many of the uses of these plants were, in the course of time, documented in various herbals, books on medical botany, in ethnobotanical manuscripts, and even as notes on herbarium specimens. Uses of other alleged medicinal plants remain undocumented in the literature and exist only in the lore of primitive people. Let us consider some of these sources of medicinal folklore.

Herbals.—Space will permit only a token mention of the hundreds of herbals available for scrutiny by those interested in pursuing this approach to uncover new leads to plants with potential medicinal attributes. "The Herbal," by Arber (15), tabulates many of those which are known. A further list of herbals and related works, many of which are rare, has been prepared for the holdings of the Hunt Botanical Library (16, 17). The use of such materials as sources of ideas for new drug plants has been discussed (13, 18, 19).

Medical Botany.—One could spend a lifetime surveying the available published books and periodicals describing the native flora of various regions and the medical uses ascribed for each plant. De Laszlo (20) has compiled a list of some 1500 references on books, journals, and periodicals concerning phytotherapy and Dragendorff's "Die Heilpflanzen der Verschienden Volker und Zeiten" (21) should not be overlooked as a source of new leads. Steinmetz's "Codex Vegetabilis" (22) also lists hundreds of plants together with their synonyms, constituents, and reported uses; however, references to source material are not included in this work. Perhaps because of the Indian system of Ayurvedic medicine, the plants of that country have been reported medicinally useful more often than perhaps those of any other country. At least one gains this impression from the host of available references (23–28). Other countries represented by books or review publications on medical botany are Mexico (29, 30), Poland (31), New Guinea (32), the Philippines (33), Nigeria (34), the U.S.S.R. (35, 36), China (37–39), Burma (40), Puerto Rico (41), Malaya (42), Africa (43), Greece (44), Australia (45), New Zealand (46–49), Taiwan (50, 51), and Haiti (52), as well as others (53–57). These references are to be taken only as selected examples illustrating the type of source material available to the interested investigator. Schultes has recently pointed out, in an excellent article, the opportunities for investigation through an appreciation of medical botany (13).

Of course, simply reading through these works will not automatically assure one of success in his selection of plants for investigation. A great deal of common sense, a broad background in the medical sciences, and some knowledge of plant constituents and of chemotaxonomic relationships are all necessary for one to select the most promising plants for study.

Ethnobotany.—An evaluation of those publications by persons who have studied plants in their relationship to human affairs could uncover many species with potential biological activity. The papers by Train *et al.* (58–61), which describe plants used by the Nevada Indians, are certainly worth examining for new leads. Any person interested in the discovery of new biologically active compounds in plants would do well to become acquainted initially with the ethnobotanical writings on narcotic drug plants by Schultes and others (62–76), since they contain a wealth of information found in few other references.

An interesting ethnobotanical report has described 3 plants, all members of the *Araceae*, that are used by natives in Colombia as oral contraceptives (77). Several years ago, we had occasion to investigate *Dieffenbachia picta* (*Araceae*) because reports forwarded to our laboratory indicated that natives in South America were known to utilize this plant as an oral contraceptive. Our animal experiments failed to confirm this use for *D. picta*, but subsequently an excellent review article on the toxicity of *Dieffenbachia* species was located which described in detail many cases wherein these species had been utilized for their antifertility effects (78). Extracts of *D. seguine* were shown to produce sterility in both male and female rats after 30 to 90 days of either oral or subcutaneous administration. On histological examination it was revealed that complete or partial atrophy of the entire male or female genital apparatus had been induced in the treated animals, thus rendering them sterile (79). This obviously is an undesir-

able effect for an oral contraceptive drug and interest in *Dieffenbachia* species for this purpose appears to have been curtailed. In retrospect, however, it is unusual that natives in South America and in certain of the Caribbean islands chew the leaves of *D. seguine* to impart a 24- to 48-hr. period of sterility, whereas in laboratory animals, extracts of this plant must be administered for several weeks in order to obtain the same effect (78).

Perhaps a specific example, pointing out the value of ethnobotanical studies in the search for new biologically active compounds, would be in order. During early 1956 this author had occasion to review an ethnological manuscript, representing the doctoral dissertation of Philips (80), for possible publication in the form of a book by the University of Pittsburgh Press. The manuscript was concerned, in part, with Lebanese folk cures, the idea for the dissertation arising from contacts with people in Lebanon as well as Lebanese immigrants in Brooklyn. The author found, as her investigation progressed, that the customs of the Lebanese people were greatly influenced by the use of plant drugs as a facet of their culture. Information was derived from personal interviews with 843 people and resulted in a rather extensive list of plants used as drugs. Many of the native uses for these plants could be accounted for on rational grounds through a knowledge of chemical compounds existing in the plants which had known biological activity. Others could not be explained on these bases and seemed worthy of future investigation. As I read the manuscript, a list was prepared of those plants which appeared to be used by the greatest number of people for specific, well defined, disease conditions. The completed list included 15 plant names, the alleged uses for which I could not explain at the time. Several months later an article was noted concerning the isolation and pharmacology of an alkaloid named petaline chloride, in addition to others, from *Leontice leontopetalum* (*Berberidaceae*) (81). Ironically, this plant headed my list taken from the ethnobotanical manuscript as being most likely to yield interesting and biologically active entities. *Leontice leontopetalum* had been used as a folk medicine in Lebanon for years as an aid to the treatment of epilepsy. Petaline chloride was shown to be a central nervous system depressant in mice and rabbits, and the investigators claimed antiacetylcholine activity on isolated frog skeletal muscle. Additional studies to indicate more clearly antiepileptic activity, *i.e.*, effect on chemically or electrically induced convulsions in animals, were not performed, presumably due to an inadequate supply of petaline. To my knowledge, additional pharmacologic evaluations of this alkaloid have not been reported.

Other ethnobotanical manuscripts that offer similar possibilities, or give interesting background material on this approach to the discovery of new drug plants, have been written by Tantaquidgeon (82), Gunther (83), Grover (84), and Schultes (85, 86).

Herbaria.—A rather unusual approach to the search for new leads to biological activity in plants is being pursued at Harvard University. This involves a search of individual herbarium specimens for field notes entered by the botanist making each particular collection. In many instances, as pointed out by von Reis (87), information appears on some specimens that indicates a particular medicinal use for a plant as observed by the collector. The project consists of a sheet by sheet study of the entire collection of flowering plants in the Harvard University Herbarium, which includes some 2,200,000 specimens from the collections of the Arnold Arboretum and the Gray Herbarium. Advantages to this type of study have been summarized by von Reis (87). In the first 6 months of the study, 6 families had been searched, *i.e.*, *Apocynaceae*, *Asclepiadaceae*, *Convolvulaceae*, *Lythraceae*, *Myristicaceae*, and *Rubiaceae*. About 400 species of interest were recorded and separated into several categories, *i.e.*, medicinal uses (40%), suggested medicinal applications or possible physiological activity (33%), substances eaten, but not as normal staples of the diet (13%), poisons (8%), plants collected expressly for the purpose of chemical analysis and possible drug use (3%), and plants which animals were said to be attracted to or that they especially avoided as food or contact substances (1%). It has been conservatively estimated that the study, when completed, should yield some 360 notes concerning new potential medicinal applications for plants.

The only other study of this type which has been publicized is that being conducted by Perry involving a compilation of medicinal flora of southeastern Asia. Included as a part of this effort is a study of field notes on herbarium specimens (88).

Field Exploration.—Throughout history, botanical collecting expeditions have been organized for the specific task of discovering new drugs. In 1716, Peter the Great requested the botanist Breynius, in Danzig, to organize an expedition to explore the botanical resources of Russia for new drugs. The botanist Messer-

schmidt from 1720–1727 made vast collections in Siberia of plants reputed to have medicinal value (89). In 1602 Bartholomew Gosnold, in a ship chartered by Sir Walter Raleigh, sailed the coast of New England specifically to obtain the bark of *Sassafras albidum* for export to England (89). Parke Davis and Co. sponsored expeditions into South America in 1885 which led to the discovery of *Rhamnus purshiana* (cascara) and *Guarea rusbyi* (cocillana), 2 drugs still in use today (89). In 1942, when the quinine source of the world was cut off by the invasion of the Dutch East Indies by the Japanese, American botanists Steere, Fosberg, Camp, and others relocated and identified several quinine-yielding species in South America (89). More recently, the *Strophanthus* hunt in Africa, as well as the search for new steroidal sapogenin and alkaloid-bearing plants of the world, testify to the value of field exploration for new plant products of medicinal and/or economic value. These, along with accounts of the most striking plant explorations of the past, have recently been documented by Kreig (90).

There is controversy regarding the optimal approach to plant exploration if one is to uncover information on drug plants of potential value. Some believe that a semirandom collection of plants which contain specific types of chemicals, *e.g.*, alkaloids, will be most rewarding (91–94). Others consider that a random selection of plants in combination with subsequent broad pharmacological screening will lead to new therapeutic agents (95–98). Still others feel that recording the names of plants used in native medicine by witch doctors, medicine men, etc., directly from the individuals who use the products, will give a greater insight to the selection of plants for subsequent biological evaluation (99, 100).

Schultes, who spent some 12 years in the Amazon, feels that natives are more apt to reveal their secrets (drug plants) only after acquaintance with an invading investigator for a long period of time (13). He has cited several examples from personal experiences that bear out this point (13). Furthermore, Schultes is of the opinion that the most successful explorations for new plant drugs will not be those set up with the express purpose of looking for medicinals and nothing else, but rather those primarily designed to acquire new botanic and ethnobotanic knowledge (13). In the course of such investigations, information regarding new drug plants and related materials should be uncovered during the normal course of events.

Recognizing that the latter approach has merit and could well be the most effective method presented, the need for an inception of such a program is immediate. That is because, as civilization spreads into primitive areas, the first aspect of primitive culture to be lost is knowledge on the use of plants as medicine (13). Schultes, with respect to this matter, has stated, "The rapidity of this disintegration (knowledge of medicinal plants) is frightening" (13). Unfortunately, trained manpower to carry out this type of field exploration program is not available for an extensive undertaking at the present time (13).

Poisonous or Toxic Plants

A documentation of toxicity for any plant material is usually evidence for the presence of biologically active material in the plant cited. The terms "poison" and "toxic" are, of course, often relative where biological activity is concerned. If one discounts reports concerning contact poisons and considers mainly plants reported to cause systemic toxicity, it is possible that proper dose administration of extracts from the particular plant in question will uncover knowledge of pharmacologic activity worthy of further study. A number of books and other periodicals are available which point out plants that have been reported to cause toxicity. Interesting historical background information on this subject has been published by Kingsbury (101) and an excellent review of the toxic plants of the United States and Canada, which is thoroughly referenced, is found in Kingsbury's recent book (102). Other references to toxic plants and fungi of the U. S. are those of Muenscher (103), Duncan *et al.*, (104, 105), Morton (106, 107), and O'Leary (108). African (43), Australian (45), Indian (109, 110), British (111), Venezuelan (112), and the Pacific region (113) toxic plants, have been similarly documented. Again, the references cited above are not meant to constitute a complete listing of all available references to toxic plants. Rather, they are offered as an introduction to the person interested in studying toxic plant constituents and the relationship of these constituents to possible therapeutic applications.

Phytopharmacological Surveys

A number of interesting surveys have been conducted in which plant extracts have been evaluated for various biological activities. Although the data presented in certain of these surveys must be considered as negative, *i.e.*, those regarding antineoplastic evaluations published by the Cancer Chemotherapy National Service Center (114–118) as well as by others (119), these reports are quite helpful to investigators

engaged in similar studies who might not want to duplicate negative efforts. Biological evaluation of plant material presents certain inherent and apparently uncontrollable problems. If one considers the well known fact that phytoconstituents can vary based on climate, habitat, soil nutrients, and time of harvest, in addition to other factors (120–122), and that distinct chemical races of plants are known to exist (123–127), variation in results from one lot of plant material to the next must be expected. Furthermore, the selection of an appropriate extraction solvent, when the chemical nature of the potentially active phytoconstituents is unknown, presents a problem. Also, the conditions to be used in preparing the extracts of plant material could be the difference between demonstration of biological activity and obtaining essentially negative results. The presence of antagonistic substances, as regards to biological activity, could result in a failure to detect either of the 2 or more individually active materials. Since many plants are known to accumulate rather large quantities of toxic inorganic constituents, *i.e.*, selenium, nitrates, copper, etc. (102), the predominant action of any one of these in a plant extract containing organic compounds with potentially interesting biological activity could lead to the dismissal of further interest in the plant. It is interesting to note that we recently isolated leurosine, an alkaloid with a high order of activity against the P-1534 leukemia in DBA/2 mice, from a crude fraction of *Catharanthus lanceus* alkaloids that by itself was shown to be devoid of activity (128). Svoboda (129) also has pointed out that leurocristine and leurosidine, both highly active against the P-1534 leukemia, have also been isolated from crude alkaloid fractions that were devoid of activity against the same neoplasm.

There appears to be a great race to determine the biological activity of plant extracts, but little is being done to investigate the problems mentioned above. When, and if these problems are solved, all negative data obtained with present methods may have to be re-examined, and perhaps duplication of similar studies will be warranted.

Antineoplastic Activity.—The plant kingdom should be a prospective and fruitful hunting ground for new tumor inhibitors. This has been illustrated by the isolation, characterization, and structure elucidation (130) of vincaleukoblastine (vinblastine) (131, 132) and leurocristine (vincristine) (129) from the apocynaceous shrub *Catharanthus roseus* (*Vinca rosea, Lochnera rosea*). Vincaleukoblastine is used clinically for the treatment of Hodgkin's disease (133) and for choriocarcinoma (133), whereas leurocristine is effective in the treatment of acute leukemia in children (133).[1] Noble *et al.* (131) were the first to publish on the antineoplastic and leukopenic activity of *C. roseus* and the isolation of crude vincaleukoblastine. Their studies were initiated by reports that *C. roseus* was used extensively as an oral hypoglycemic agent in folk medicine. Furthermore, the discovery of anticancer activity was made during their blood sugar work, only on the basis of followup studies on a toxicity observed in *C. roseus*-treated animals. Antitumor activity of *C. roseus* extracts also was noted by Svoboda in his laboratory at about the same time that Noble and co-workers made their observations of this activity. Svoboda's observations came about through a routine screen for antitumor activity, as his initial interest in this plant was a potential source of hypoglycemic compounds (134). Subsequent studies by Svoboda (129) led to the isolation of leurocristine, as well as leurosine (132) and leurosidine (129), 3 additional *C. roseus* dimeric antineoplastic alkaloids (133). However, in another laboratory, an alcoholic extract of *C. roseus* (*Lochnera rosea*) whole plant provided negative results when screened against the sarcoma 180 and the L-1210 leukemia (114). Further negative results have been reported for an aqueous extract of *C. roseus* (*Vinca rosea*) seeds on testing against the sarcoma 180, the adenocarcinoma 755, and the L-1210 leukemia (114).

Hartwell (135) has discussed the role of the Cancer Chemotherapy National Service Center (CCNSC) in screening plant extracts, as well as other compounds, for antineoplastic activity. A comprehensive plant collection program by the U. S. Department of Agriculture (USDA) as well as by others, serves to supply plant material to the CCNSC for evaluation. Most plants are semirandomly selected for testing, but home remedies alleged to be useful for the treatment of cancer are not discounted (135). Since its inception, the CCNSC has screened about 26,000 plant extracts. No figures are available to indicate the number of species represented by this number, but it has been estimated that an average of 2 plant parts for each species are tested, and for most plant materials, 2 extracts (*i.e.*, water, ethanol) are prepared. Therefore, one could estimate that about 6500 species have been evaluated to date by the CCNSC. About

[1] Dr. Gordon Zubrod, Director of Intramural Research, National Cancer Institute, Bethesda, Md., told a Fountain Subcommittee hearing on April 23, 1964, that leurocristine is the . . . "Most effective antileukemia agent that has been discovered in the last 5 or 6 or 10 years." [*F-D-C Reports—The Pink Sheet*, **26** (17) (April 27, 1964).]

10% of these species have been found to be "active" against one or more tumors and are considered candidates for phytochemical isolation work. The CCNSC expects that this program will be continued at about its present rate (136).

Although the CCNSC program is still in its infancy, on the basis of the number of compounds and plants that are available for evaluation, reports in the current literature are beginning to identify some of the antitumor and/or cytotoxic constituents of plant extracts that have been determined active in this screening sequence. Kupchan *et al.* (137) have isolated aristolochic acid, active against the adenocarcinoma 755, from *Aristolochia indica* (*Aristolochiaceae*). Aristolochic acid has been found to exert a high order of renal toxicity which will preclude its use in clinical studies (138). Undoubtedly, structural relatives of this compound will be prepared in an attempt to reduce toxicity and yet maintain a high order of antineoplastic activity. Monocrotaline, from *Crotalaria spectabilis* (*Leguminosae*) has also been found to be an active tumor inhibitor (AC-755) (139). Phytochemicals which are cytotoxic for the 9-KB cell culture have been isolated and found to be apocannoside and cymarin from *Apocynum cannabinum* (*Apocynaceae*) (140), podophyllotoxin from *Juniperus virginiana* (*Pinaceae*) and other *Juniperus* species (141), calotropin from *Asclepias curassavica* (*Asclepiadaceae*) (142), cissampareine from *Cissampelos pareira* (*Menispermaceae*) (143), eupatorin from *Eupatorium semiserratum* (*Compositae*) (144), and gaillardin from *Gaillardia pulchella* (*Compositae*) (145). Semipurified fractions from *Rumex hymenosepalus* (*Polygonaceae*) exert significant activity against the Walker 256 tumor and the sarcoma 180 in mice (146). The active material is thought to be a polyphenolic flavonoid tannin. A proteinaceous fraction from *Gutierrezia sarothrae* (*Compositae*) is inhibitory for sarcoma 180 in mice (147). Although many other examples concerning the isolation of active antitumor or cytotoxic plant principles could be cited, the above should serve to point out the broad distribution of antitumor activity in the plant kingdom. Table II lists the names of some 400 plant species in 315 genera and 97 families reported in the literature to be appreciably active as tumor inhibitors. A great variety of chemical classes and structure types are also represented in the known active plant principles, *i.e.*, alkaloids (vincaleukoblastine, leurocristine, tylocrebrine, lochnerinine, cissampareine, monocrotaline), cardenolides (apocannoside, caloptropin, cymarin), lignans (podophyllotoxin), flavonoids (eupatorin), tannins (*Rumex hymenosepalus*), proteins (*Gutierrezia sarothrae*), sesquiterpene lactones (gallardin), tetracyclic triterpenes (elatericin A, elatericin B, elaterin), as well as others (Fig. 1).

If one examines negative as well as positive screening data from plant extracts, it becomes apparent that active antineoplastic compounds are not usually distributed throughout related taxa. The problem of screening plant extracts is further compounded through a knowledge that active inhibitors are often localized in one plant organ and not distributed throughout the plant. Thus, the fruits or seeds of one species could well contain active material, yet evaluation of the whole plant, containing few if any fruits or seeds, would probably give negative results. Seasonal variation has been shown to affect the amount of active material present in certain species (148). Also, the selection of a proper solvent for preparation of extracts to be evaluated could be an important factor. Furthermore, most of the active compounds isolated from higher plants to date, as well as the extracts themselves, are often quite specific in their action for a given tumor or set of test conditions. Additionally, correlation of *in vitro* and *in vivo* testing results, with those of the clinical effects of antitumor agents, remains to be established.

It appears, however, in the light of present knowledge and experience, that a random selection and testing of plants selected from a broad cross section of families and genera will prove of greatest value in attempts to discover new entities for the treatment of clinical malignancies. It is interesting to note that the efforts to arrive at new antitumor agents by chemical synthesis appear to be no more productive than those of the natural product researcher. Even though the net result of these tedious procedures involving the search, collection, identification, processing, and biological evaluation of the flora of the earth does not yield additional compounds of clinical value, the new structures evolving from these efforts should prove of use to the chemist for his work involving structural modifications.

Recent findings (140, 142, 145, 149) that cytotoxicity is associated with the unsaturated lactone of cardenolides and related compounds, attached either to position 17 of the nucleus by a C—C bond or fused to ring D across the 16, 17-position, offer insight to the minimum qualifications for cytotoxicity. Medawar *et al.* (150) were the first to suggest that unsaturated lactones exert a specific inhibitory effect on the growth of tissue. Subsequent investigators confirmed this interesting relationship (151–152). Pike *et al.* (153) synthesized 150

TABLE II.—DISTRIBUTION OF ANTINEOPLASTIC ACTIVITY IN PLANTS[a]

Plant Name[b]	Neoplasm[c]	Ref.
Acanthaceae		
Andrographis paniculata	S-4	(176)
Jacobinia coccinea	C-1, S-4	(166, 176)
Aceraceae		
Acer negundo	C-5	(175)
Acer rubrum	C-1	(161)
Amaryllidaceae		
Agave americana	H-2, S-1	(160)
Agave expansa (A. americana)	C-1	(165)
Agave micracantha	S-1	(160)
Cooperia pedunculata	C-1, S-7	(148, 163, 167)
Galanthus nivalis	S-1	(160)
Haemanthus puniceus	S-1	(160)
Hymenocallis sp.	C-2	(376)
Hymenocallis caribaea	S-1	(160)
Hymenocallis occidentalis	S-1	(160)
Leucojum aestivum	S-1	(160)
Lycoris incarnata	S-1	(160)
Lycoris sprengeri	S-1	(160)
Lycoris squamigera	S-1	(160)
Manfreda maculata	C-1	(165)
Narcissus poetaz var. *geranium*	S-1, S-2	(160)
Narcissus tazetta	C-5, S-13	(171)
Polianthes tuberosa	S-1	(160)
Rhodophiala chilensis	S-1	(160)
Zephyranthes carinata	C-5, S-4, S-10, S-13	(171)
Zephyranthes texana	C-1, S-12	(148, 164, 167)
Anacardiaceae		
Anacardium sp.	C-1	(165)
Loxopterygium huassango	C-1	(158)
Melanorrhoea woodsiana	S-4	(176)
Pistacia chinensis	C-1	(158, 162)
Pistacia lentiscus	C-1	(158, 161, 162, 165, 166)
Pistacia vera	C-1	(161)
Rhus glabra	C-1, C-2	(164)
Rhus javanica	C-7	(171)
Rhus toxicodendron	C-1, C-2	(148, 163, 167)
Rhus typhina	C-2	(166)
Annonaceae		
Annona cherimola	C-1	(161)
Artabotrys suaveolens	S-4	(176)
Apocynaceae		
Apocynum androsaemifolium	S-1	(155)
Apocynum cannabinum	C-1, E-1	(140, 161)
Catharanthus lanceus	C-2, E-1, L-2	(128, 377)
Catharanthus pusillus	E-1	(341)
Catharanthus roseus	L-2	(133, 134)
Ervatamia dichotoma	E-1	(378)
Funtumia sp.	C-1	(158, 165)
Nerium oleander	C-1	(167)
Plumeria obtusa	S-4	(176)
Strophanthus hispidus	C-1	(376)
Trachelospermum asiaticum	C-5	(170, 173)
Aquifoliaceae		
Ilex coriacea	C-1	(161)
Araceae		
Symplocarpus foetidus	S-1	(157)
Araliaceae		
Eleutherococcus senticosus	S-9, S-10	(380)
Panax ginseng	S-9, S-10	(380)
Panax repens	C-5	(173)
Tetrapanax papyriferum	C-5	(172)
Aristolochiaceae		
Aristolochia sp.	C-1	(161)
Aristolochia indica	C-4	(137)
Asarum canadense	C-1	(161)
Asarum reflexum	C-1	(161)
Asclepiadaceae		
Asclepias curassavica	E-1	(142)
Asclepias decumbens	C-1	(148)
Marsdenia cundurango	C-1	(157)
Tylophora crebriflora	L-1	(381)
Berberidaceae		
Berberis aquifolium	C-2	(167)
Podophyllum emodi	S-1	(383)
Podophyllum peltatum	S-1	(382, 383)
Betulaceae		
Alnus serrulata	C-1	(166)
Carpinus caroliniana	C-1	(166)
Corylus americana	C-1	(161)
Ostrya virginiana	C-1	(161, 166)
Bixaceae		
Bixa orellana	C-2	(161)
Boraginaceae		
Alkanna sp.	C-5	(384)
Lithospermum arvense	C-1	(161)
Symphytum officinale	C-1, C-2, C-3	(328, 385)
Bromeliaceae		
Bromelia pinguin	C-1	(166)
Pitcairnia corallina	C-1	(166)
Tillandsia usneoides	C-2, S-2	(167)
Cactaceae		
Opuntia sp.	C-1	(167)
Opuntia maxima	CIT	(386, 387)
Cannabinaceae		
Cannabis sativa	C-1	(164)
Humulus japonicus	C-1	(158)
Capparidaceae		
Forchhammeria watsoni	C-1	(376)
Caprifoliaceae		
Sambucus simpsonii	C-1	(161)
Viburnum acerifolium	C-1	(158)
Viburnum macrocephalum	C-1	(376)
Viburnum prunifolium	C-1	(161)
Caryophyllaceae		
Arenaria caroliniana	C-2	(161)
Celastraceae		
Celastrus scandens	C-4, C-6	(388)
Chenopodiaceae		
Beta vulgaris	C-1, C-2	(167)

(*Continued on next page.*)

TABLE II.—(*Continued*)

Plant Name[b]	Neoplasm[c]	Ref.
Beta vulgaris var. *rubra*	C-5	(389)
Chenopodium ambrosioides var. *anthelminticum*	S-1	(156)
Cistaceae		
Lechea villosa	C-1	(161)
Combretaceae		
Conocarpus erectus	C-1, C-2	(158, 165, 166)
Terminalia bellerica	C-2	(166)
Terminalia chebula	C-5	(390)
Compositae		
Acroptilon picris (*Centaurea picris*)	C-5	(175)
Arnica montana	S-1	(157)
Artemisia tournefortiana	C-5	(175)
Aster pilosus var. *demotus*	C-2	(166)
Bidens pilosa	C-1	(158, 165)
Bigelowia nudata	C-1	(158, 165)
Boltonia diffusa	C-1	(158, 165)
Brauneria pallida (*Echinacea pallida*)	S-1	(157)
Cacalia atriplicifolia	C-1	(165)
Calendula officinalis	C-5	(384)
Centaurea balsamita	C-5	(175)
Chrysopsis tricophylla	C-1, C-2	(161)
Cirsium altissimum	C-1	(158)
Cirsium arvense	C-2	(166)
Coreopsis lanceolata	C-2	(166)
Echinacea pallida	C-2	(166)
Eupatorium semiserratum	E-1	(144)
Gaillardia pulchella	C-1, E-1	(145, 158)
Gutierrezia sarothrae (*G. enthamia*)	S-2	(147)
Inula helenium	C-5	(172)
Lactuca canadensis	C-1	(161)
Liatris punctata	C-1, C-2, S-12	(163, 164, 167)
Mikania scandens	C-1	(158)
Onopordon acanthium	C-5	(384)
Parthenium hysterophorus	C-1, C-2, S-12	(164)
Ratibida pinnata	C-2	(166)
Saussurea sp.	C-5	(175)
Silphium compositum	C-1	(158)
Solidago fistulosa	C-2	(166)
Solidago gigantea	C-2	(166)
Sonchus oleraceus	S-1	(154)
Spilanthes americana (*S. mutisii*)	C-1	(158, 165)
Tanacetum vulgare	C-2	(166)
Tessaria integrifolia	C-1	(161)
Trilisa paniculata	C-2	(161)
Verbesina aristata (*V. nudicaulis*)	C-1, C-2	(161)
Xanthium sp.	C-1	(161)
Convolvulaceae		
Ipomoea orizabensis	S-1	(154)
Cornaceae		
Aucuba japonica	C-5	(170, 173)
Cornus florida	C-2	(161)
Cornus officinalis	C-5	(172)
Cruciferae		
Capsella bursa-pastoris	S-1	(155)
Descurainia pinnatum (*Sisymbrium pinnatum*)	C1-12	(161)
Cucurbitaceae		
Bryonia alba (*B. dioica*)	S-1	(154)
Citrullus colocynthis	C-5, S-1, S-2, S-5	(154, 391, 392)
Cucumis melo	C-1, C-2, C-5	(163, 167, 175)
Cucumis melo var. *cantalupensis*	S-1	(157)
Cucumis myriocarpus	S-1	(157)
Cucumis sativus	C-1	(167)
Cucurbita foetidissima	C-1, C-2, S-12	(163, 164, 167)
Cucurbita pepo	C-1, C-2	(167)
Ecballium elaterium	C-4, C-5, C-6, S-1, S-2, S-5	(154, 388, 392)
Datiscaceae		
Datisca cannabina	C-5	(175)
Dioscoreaceae		
Dioscorea villosa	S-1	(155)

TABLE II.—(*Continued*)

Plant Name[b]	Neoplasm[c]	Ref.
Prunus americana	S-1	(157)
Spiraea ulmaria	S-1	(155)
Rubiaceae		
Cephaelis acuminata	S-1	(157)
Cinchona succirubra	C-5	(173)
Gardenia jasminoides	C-5	(173)
Genipa americana	S-4	(176)
Mussaenda glabra	S-4	(176)
Randia densiflora	S-4	(176)
Randia spinosa	S-4	(176)
Timonius wallichianus	S-4	(176)
Uncaria longifolia	S-4	(176)
Uncaria pteropoda	S-4	(176)
Uncaria roxburghiana	S-4	(176)
Rutaceae		
Atalantia citroides	C-1	(158, 165)
Citrus amblycarpa	C-2	(166)
Evodia roxburghiana	S-4	(176)
Evodia rutaecarpa	C-5, S-10, S-13	(171)
Phellodendron sp.	C-1	(165)
Phellodendron amurense	C-5, II-1, S-4	(173, 412)
Sapindaceae		
Alectryon subcinereum	C-1	(165)
Dodonaea viscosa	C-1	(165)
Nephelium longana	C-5	(172)
Sapindus senegalensis	C-2	(166)
Sapindus utilis	C-1	(158, 165)
Sapotaceae		
Achras sapota	S-4	(176)
Madhuca indica (*Bassia latifolia*)	C-1	(165)
Saxifragaceae		
Dichroa febrifuga	X	(413)
Hydrangea arborescens	S-1	(155)
Scrophulariaceae		
Veronica virginica	S-1	(154)
Simaroubaceae		
Castela nicholsoni texana	S-1	(156)
Simaruba amara	S-1	(156)
Solanaceae		
Cestrum parqui	C-1, C-2	(158, 166)
Datura sp.	C-1	(167)
Datura stramonium	C-1	(167)
Dunalia campanulata	C-2	(166)
Hyoscyamus niger	C-1, C-2	(167)
Lycium halimifolium (*L. vulgare*)	C-2	(166)
Solanum rostratum	C-1	(148, 161, 167)
Solanum torvum	S-4	(176)
Sterculiaceae		
Cola nitida (*C. acuminata*)	S-4	(176)
Thymelaeaceae		
Daphne mezereum	S-1	(157)
Umbelliferae		
Aletes acaulis	C-2	(163)
Angelica brevicaulis	C-5	(175)
Anthriscus neglecta (*A. vulgaris*)	L-1	(414)
Conium maculatum	C-1, C-2	(163, 164, 167)
Pimpinella saxifraga (*P. magna*)	S-1	(157)
Urticaceae		
Parietaria officinalis	S-1	(155)
Vacciniaceae		
Polycodium floridanum (*Vaccinium floridanum*)	C-2	(166)
Vaccinium bracteatum	C-5	(169)
Verbenaceae		
Verbena bipinnatifida	C-2	(167)
Vitaceae		
Vitis candicans	C-2, S-12	(164)
Zingiberaceae		
Zingiber officinale	C-5	(173)
Zygophyllaceae		
Peganum harmala	C-5	(175)

[a] All plants listed were considered active in the original reference against the tumor(s) indicated. Criteria for activity vary and undoubtedly many of the plants listed in this table exert only marginal, if any, real activity. For plant parts used and type extract evaluated, see original reference. [b] Names of plants are entered as found in the original reference except for corrections in spelling. Classification is according to the "Index Kewensis" and its supplements (375). Plant names in parentheses are preferred according to the "Index Kewensis." [c] Key for neoplasms (see reference for host): C-1, carcinoma, C_3H, mammary; C-2, carcinoma, RC, mammary; C-3, carcinoma, mammary, spontaneous; C-4, adenocarcinoma 755; C-5, carcinoma, Ehrlich; C-6, carcinoma, renal; C-7, carcinoma, Bashford, 63; E-1, 9 KB cell culture; L-1, leukemia, L-1210; L-2, leukemia, P-1534; S-1, sarcoma 37; S-2, sarcoma 180; S-3, sarcoma, Crocker; S-4, sarcoma, Yoshida; S-5, sarcoma, Black, SBL-1; S-6, fibrosarcoma; S-7, lymphosarcoma, unspecified; S-8, sarcoma, genital; S-9, sarcoma, DBA; S-10, sarcoma, Walker; S-11, sarcoma, Ehrlich; S-12, sarcoma, DBA; S-13, sarcoma, NF; H-1, hepatoma, ascitic; H-2, lymphoma No. 1; M-1, mastocytoma, P-815; CIT, chemically induced tumor; X, active against several neoplasms (see reference).

steroids and found that 25 were cytotoxic. All of the 25 cytotoxic steroids contained an α-β-unsaturated lactone ring, whereas this moiety was absent in the steroids devoid of cytotoxicity. An inspection of the heterogeneous group of structures making up some of the known antineoplastic or cytotoxic plant constituents suggests that factors other than the α-β-unsaturated lactone ring are involved with cytotoxicity (Fig. 1).

Several extensive surveys for antineoplastic activity in plant extracts have been published. A majority of the studies have been carried out with plants collected in the U. S. (154–167), Japan (168–173), the U.S.S.R. (174, 175), and most recently in Malaya (176). Correlation of data derived from these surveys is difficult because of inconsistencies in the processing of plant extracts, in the test procedures, in the tumor systems utilized, and in the validity of data interpretation.

Antimicrobial Activity.— References concerning the biological screening of plant extracts are encountered most frequently in connection with the determination of antimicrobial activity.

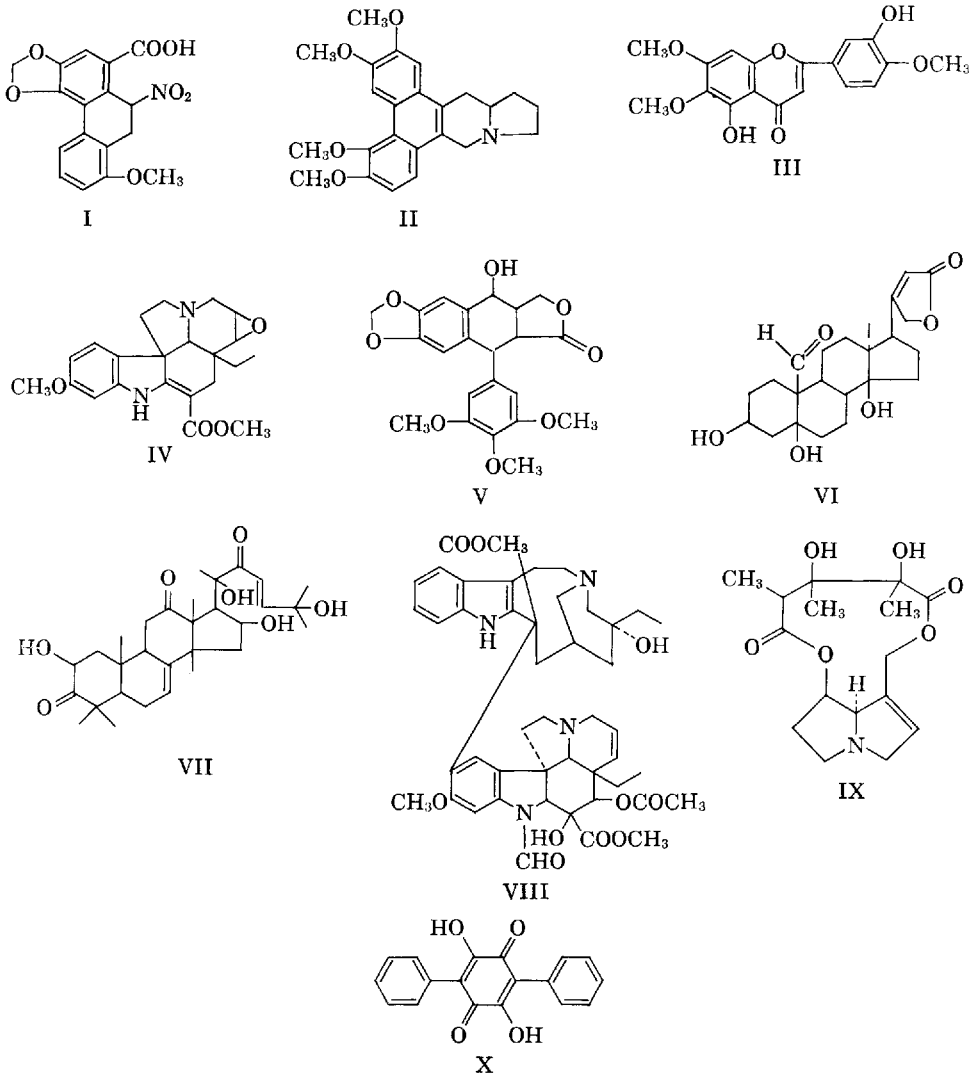

Fig. 1.—Structures of natural products known to have either antineoplastic or cytotoxic properties. Key: I, aristolochic acid (adenocarcinoma 755) (137); II, tylocrebrine (L-1210 leukemia) (381); III, eupatorin (9 KB cell culture) (144); IV, lochnerinine (9 KB cell culture) (341); V, podophyllotoxin (sarcoma 37, 9 KB cell culture) (141, 383); VI, strophanthidin (9 KB cell culture) (149); VII, elatericin A (sarcoma 180) (392); VIII, leurocristine (P-1534 leukemia) (133); IX, monocrotaline (adenocarcinoma 755) (139); X, polyporic acid (L-1210 leukemia) (379).

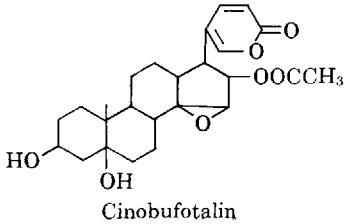
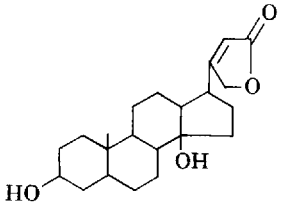
These evaluations are usually carried out by means of standard *in vitro* assays (disk, cup, cylinder, diffusion) utilizing a broad selection of pathogenic as well as nonpathogenic microbes. In most cases, a minimum of 1 Gram-positive and 1 Gram-negative organism, usually *Staphylo-*



Cinobufotalin



Digitoxigenin

Cytotoxic Unsaturated Lactones

coccus aureus and *Escherichia coli*, are included for initial screening. However, filamentous fungi, yeasts, and acid-fast organisms are often included. The studies of Lucas, Gottshall, Frisbey *et al.* are typical surveys of plants for antimicrobial activity (177–184). These investigators screened hundreds of extracts for inhibitory activity against *S. aureus*, *Salmonella typhimurium*, and *Mycobacterium tuberculosis*, and subsequent studies on the most promising plants by this group led to the isolation of many active principles (185–188). Other surveys for antimicrobial activity in plants native to the U.S. have been conducted using plants collected in Southern California (189, 190), Pennsylvania (119), Florida (191, 192), Indiana (193), Ohio and Michigan (194–197), Vermont (198), and Hawaii (199). The study on Hawaiian plants was based on a selection of those used in that area as home remedies. Tucakov (200), Kliewe and Hathmacher (201), Maruzzella and Henry (202), and Okazaki and Oshima (203, 204) studied the antimicrobial effects of a number of essential oils, a group of compounds in which antifungal activity is predominant. Burlage *et al.* investigated several plants reported to be toxic (205, 206). Studies involving fewer numbers of plants, plant parts, or extractives have also been reported (207–217).

Osborn (218) has surveyed more than 2300 different species of plants collected in England, while Australian plants have been extensively examined by Atkinson *et al.* (219–221). The Australian group also surveyed a number of higher fungi for antimicrobial activity (222). Similar surveys have been conducted on the flora of Nova Scotia (223–225), Brazil (226–228), Mexico (228–230), India (231–234), Japan (168, 235–243), China (244), the Philippines (245), as well as the U.S.S.R. (246–255) and other scattered areas (256–260). The antimicrobial substances from algae (261) and mosses have recently been reviewed (262), and their presence was demonstrated in a number of lichens (263, 264). Active substances in seaweed extracts have also been reported (265, 266).

Nickell (267), in a review on this area of investigation, has tabulated results of studies through 1959 in which vascular plants were demonstrated to elicit inhibitory action on microbes. Included in his tables are the plant name, family, class of organism(s) inhibited, type of extract utilized, and the plant part(s) tested. At about the same time, reviews on antibiotics from higher plants were published by Arnold (268), Virtanen (269), and Drobot'ko *et al.* (270) which were preceded by an earlier review by Freerksen (271). Antifungal substances from higher plants similarly were reviewed in 1961 by Sehgal (272).

Of particular interest is a study by Winter (273) in which he compared the antimicrobial properties of 2 groups of plants. One group included randomly collected native plants, whereas the second group comprised plants mentioned in a 300-year-old herbal which suggested that they were useful for the treatment of infections. Only 29.5% of plants from the randomly selected group exhibited antimicrobial activity, while 65% of plants selected because of their mention in the herbal were found to be active.

Karel and Roach (274) and Baron (275) have compiled lists of antibiotic substances isolated from higher plants as well as from microbes and other sources.

Because of the presence in crude plant extracts of substances which could exert antagonistic effects during the testing procedures, or which contain substances that stimulate the growth of the test organism and hence negate the effect of inhibitory substances present, new procedures should be developed. It would seem reasonable to utilize the new technique of thin-layer chromatography for these studies, since a resolution of components in the plant extracts could be expected, thus separating antagonistic and/or microbial stimulant constituents from those which might be active. Developed chromatograms then could be evaluated by means of bioautography, as suggested by either Kline and Golab (276) or Meyers and Smith (277).

Antiviral Activity.—Until the recent introduction of 5-iodo-2′-deoxyuridine (IDU), antiviral therapy in humans was nonexistent. Today, IDU is useful for the treatment of acute ophthalmic herpes simplex infections and is the only drug licensed by the U. S. Food and Drug Administration for the treatment of viral infection. Experimentally, IDU appears to be useful in the treatment of human vaccinia as well as smallpox infections (278). Aside from IDU, other synthetic compounds that appear interesting as antiviral agents are hydroxybenzylbenzimidazole, guanidine, and *N*-methyl-isatin-β-thiosemicarbazole. These compounds, as well as the problems associated with virus chemotherapy, have been reviewed recently by Kaufman (278).

Herrmann (279) has suggested that natural products should be preferable over synthetics as a source for new antiviral agents because naturally occurring mixtures, whether they be plant extracts or antibiotic filtrates, provide both a mixture of compounds, any one of which could be

active, and a diversity of chemical structures not easily obtained from chemical syntheses (279). However, little has been published on attempts to detect antiviral activity in plant extracts. Cochran and Lucas (280) investigated extracts from 46 members of the *Orchidaceae*, 24 species of other higher plants, and 6 species of mushrooms for their ability to protect mice against the polio virus. The orchids were selected because natives of New Guinea were said to use the flowers of certain of these species as drugs for the treatment of contagious diseases. Holobasidiomycetes were included in the study because of previous reports that extracts from selected members of this group, *i.e.*, *Boletus edulis* (281) and *Calvatia* species (280), were active tumor inhibitors. Most of the remaining higher plants tested were selected on the basis of suggested antimicrobial activities from the folklore. It was determined that 21 of 46 strains or species of orchids, 6 species of mushrooms, and *Hypericum perforatum*, *H. prolificum*, *Allium ampeloprasum*, *Kalmia latifolia*, *Maclura pomifera*, *Phellodendron amurense* *Medicago sativa*, and *Ribes hirtellum* exerted varying degrees of protection against poliomyelitis in the infected mice. Goulet *et al.* (282) studied the effects of extracts from 12 species of higher plants and basidiomycetes on 13 ECHO viruses, finding that many of the species were active, but only against specific viruses.

Taylor *et al.* (283), utilizing yolk-sac adapted vaccinia, influenza, eastern equine encephalomyelitis, and ornithosis viruses, evaluated extracts from 44 different species of plants. Extracts from 10 plants were effective in prolonging the survival time of vaccinia-infected chick embryos 20% or more. Four plants were effective against encephalitis, 6 against ornithosis, and 10 against influenza. Only 3 of the plants (*Allium halleri*, *Ambrosia apters*, unidentified native plant) produced 20% or greater survival against one or more viruses, thus substantiating the specificity pointed out by Goulet *et al.* (282). Twenty-two of the 44 species tested were active against one or more of the viruses.

More recently, a study in our laboratories involved the testing of extracts from 200 native plant species against vaccinia, polio type III, and pseudorabies viruses (119). It was found that 6 of the 200 species evaluated were found to have activity against one or more of the test viruses (*Apocynum* sp., *Asclepias incarnata*, *Artemisia* sp., *Aster divaricatus*, *Xanthium* sp., *Sium suave*). Two hundred types of crude drug plants were studied by Goro *et al.* (168) in a broad screening program in which extracts were evaluated for antitumor, antimicrobial, and antiviral activity. Influenza virus was used in this study.

With only a limited number of studies to evaluate the screening of plant extracts for antiviral activity, it appears that there is justification for more extensive studies in this area. As with the distribution of antineoplastic activity in the plant kingdom, antiviral inhibitory effects have been observed in diverse taxa. However, from preliminary observations, it can be noted that at least 13 genera of higher plants distributed in 10 families have been shown to elicit antiviral activity (*Artemisia*, *Ambrosia*, *Aster*, *Xanthium*, *Asclepias*, *Apocynum*, *Kalmia*, *Hypericum*, *Phellodendron*, *Medicago*, *Ribes*, *Maclura*, *Allium*). An inspection of the distribution of antineoplastic activity in the plant kingdom (Table II) discloses that only 5 of the above 13 genera have not given rise to at least 1 active antineoplastic species (*Ambrosia*, *Kalmia*, *Hypericum*, *Medicago*, *Ribes*). This observation, although admittedly based on insignificant numbers, especially those representing antiviral activities, suggests a relationship between antiviral and antineoplastic-cytotoxic activity. Only time and continued research will provide enough evidence to confirm this correlation.

Antimalarial Activity.—Whereas a number of isolated examples can be found in the folklore concerning plants alleged useful for the treatment of malarial infections, "fevers," or for use as "antiperiodics," little experimental evidence has been put forth to substantiate these claims. The most extensive survey of plants intended to detect substances having potential antimalarial activity was that reported in 1947 by Spencer *et al.* (284). They studied the effects of several solvent extracts, from more than 600 species distributed within 126 plant families, on chicks and ducklings infected with *Plasmodium gallinaceum*, *P. cathemerium*, and *P. lophurae*. Plants judged most active as a result of this evaluation were *Hymenocallis caribaea* and *Cooperia pedunculata* (*Amaryllidaceae*); *Castela tortuosa*, *Simaba cedron*, and *Simaruba amara* (*Simaroubaceae*); *Cornus florida* (*Cornaceae*); *Dichroa febrifuga* (*Saxifragaceae*); *Gentiana* sp. (*Gentianaceae*); *Croton* sp. (*Euphorbiaceae*); *Cissampelos pareira* (*Menispermaceae*); *Aristolochia* sp. (*Aristolochiaceae*); *Datisca glomerata* (*Datiscaceae*); and *Eryngium foetidum* (*Umbelliferae*). Eleven of these 13 species have been shown to elicit varying degrees of antineoplastic and/or cytotoxic activity (Table II). Only *Simaba cedron* and *Eryngium foetidum*, of the 13 plants indicated, have not been reported to elicit antineoplastic activity. *Castela tortuosa* also has not been reported, but the related *C.*

nicholsoni is active against sarcoma 37. Kupchan *et al.* have shown that cissampareine is the tumor inhibitor of *Cissampelos pareira* (143) and that aristolochic acid is the antitumor agent in *Aristolochia indica* (137). *Datisca hirta* is a hybrid of *Rhus glabra* and *Rhus typhina*, and while it has not been evaluated for antineoplastic activity *per se*, both of the hybridizing species have been shown to be active against carcinomas (Table II).

Malaria is still a disease of importance in many parts of the world today, and it is necessary to insure the availability of safe and effective drugs for the treatment of this condition. Recent reports indicate that the malarial parasite may well be developing a degree of resistance to the synthetic antimalarial drugs which may return the quinine alkaloids to their position of former importance as therapeutic agents. However, at least at the present time, a shortage of these alkaloids exists (285). In any event, future needs may require a continuation of surveys such as the one initiated by Spencer *et al.* (284), and to a lesser degree by Carlson *et al.* (195), as well as a study of the leads that have evolved from these screening reports.

Insecticide Activity.—Rotenone, nicotine, and the pyrethrins are important naturally derived insecticidal materials. Because of the economic value of insecticides in general, and particularly with regard to these 3 substances, a great deal of interest has been generated over the years to find new naturally occurring as well as synthetic substitutes. Included as part of this interest has been the initiation of several plant collection and screening programs, in addition to subsequent phytochemical investigations on the most promising plants discovered in this manner. McIndoo (286) has compiled all available literature reports on plants containing potential insecticidal substances up to 1941, and Jacobson (287) has extended these compilations through 1953. Since 1953, reviews have appeared by Sobotka in 1956 (288), by Ts'e in 1958 (289), by Hsiung (290) and Liu (291) in 1959, and most recently by Lipa in 1962 (292).

Hypoglycemic Activity.—Recent evidence indicates that orally effective hypoglycemic agents can be obtained from plant sources. Svoboda *et al.* (293) have demonstrated that 6 alkaloids from *Catharanthus roseus* (leurosine sulfate, lochnerine, vindoline, vindolinine dihydrochloride, catharanthine hydrochloride, and tetrahydroalstonine) are at least equal to tolbutamide in hypoglycemic action when administered orally to rats. It is interesting to note that the crude extracts from which the alkaloids were derived failed to elicit a hypoglycemic response (293). Also, the predominant folkloric use for *C. roseus* has been as an oral substitute for insulin; however, several studies have failed to confirm this action. These reports have been summarized by Farnsworth (294). Examples such as this, where biologically active substances can occur in a crude plant extract which apparently is devoid of activity, serve to point out the frustrations encountered in natural product biological evaluations.

Garcia has investigated a number of Philippine plants for which oral hypoglycemic activity is alleged through reports of their use in native medicine for this purpose (295–300). An extract from some of these plants, referred to as "plantisul," has been used with some degree of success as an insulin substitute according to reports in the literature (296, 298–300). *Tecoma* species of plants have been used orally by the natives of Mexico as antidiabetic remedies (301, 302), and a recent report by Hammouda *et al.* (303) claims that tecomine and tecostanine, 2 alkaloids from *Tecoma stans*, are potent hypoglycemic agents. Unfortunately, this report compares the activity of the 2 alkaloids after i.v. administration with tolbutamide administered orally. Similarly, vincamine, the major alkaloid of *Vinca minor*, has been reported to lower blood sugar when administered i.v. (304, 305). A number of common edible plants have been screened for hypoglycemic activity because of previous reports that each had been used for this effect (306, 307), and Mukerji (308) has reviewed the indigenous plants of India alleged to exert hypoglycemic effects. Other plants having potential oral hypoglycemic activity have been pointed out by Aliev and Rachimova (309).

The literature on plants claiming antidiabetic properties is voluminous. However, the validity of data interpretations in many such reports must be considered equivocal. Surely there is a need to evaluate plants which have been widely reported of value when used orally for the treatment of diabetes.

Although many compounds that show promise as hypoglycemic agents (leurosine, lochnerine, vindoline, vindolinine, catharanthine, tetrahydroalstonine, tecomine, tecostanine, vincamine, and others) have been isolated from plants, further studies could well prove them to be undesirable due to toxicity or side effects. In any event, these compounds represent new structures which could serve as models in the synthesis of active and safe hypoglycemic agents.

Cardiotonic Activity.—Hoch (310) has surveyed the literature up to 1961 concerning the

occurrence of cardiac glycosides and genins. His listings, which include only compounds that have been isolated in a pure state, indicate that these phytoconstituents are distributed in 39 genera of 14 plant familes. The importance of the cardiotonic glycosides in medicine has led to several extensive surveys of plants for their presence. Only a few surveys, however, have utilized biological testing exclusively to detect typical cardiotonic activity. Thorp and Watson (311), utilizing anesthetized guinea pigs, evaluated extracts from all of the available apocynaceous and asclepiadaceous plants of Australia. Evidence for the presence of cardiotonic activity was considered positive, following intravenous administration of a hydroalcoholic plant extract, when the heart slowed and contractions became more forceful. Typical cardiotonic activity was observed with extracts of *Carissa*, *Cerbera*, *Thevetia* (*Apocynaceae*), and *Gomphocarpus* (*Asclepiadaceae*) species. A total of 26 species was evaluated. More recently, Patel and Rowson (312) evaluated 33 species of Nigerian plants alleged to be useful as drugs. They utilized the isolated toad heart for detection of cardiotonic activity and found that species of *Allamanda*, *Callichilia*, *Hedranthera* (*Apocynaceae*); *Calotropis*, *Marsdenia*, *Pergularia* (*Asclepiadaceae*); *Vernonia* (*Compositae*); *Urginea* (*Liliaceae*); *Antiaris* (*Moraceae*); *Nauclea* (*Rubiaceae*); *Schwenkia* (*Solanaceae*), and *Mansonia* (*Sterculiaceae*) were active. However, subsequent chemical tests for the typical cardenolide nucleus were negative in all of the apocynaceous plants tested, as well as for the species of *Nauclea* (*Rubiaceae*) and *Schwenkia* (*Solanaceae*). Krider *et al.* (313) evaluated a number of plant extracts first chemically for the presence of typical cardenolides and then, for confirmation, tested all positive results by biological assay using the frog heart. A number of additional surveys of plants for cardiotonic activity have been reported; however, these involve only chemical tests which were designed to detect either the presence of 2-deoxy sugars or the unsaturated lactone, moieties considered characteristic for cardio-active substances. These surveys will be considered under *Phytochemical Screening Approaches*.

Androgenic, Estrogenic, and Related Activities.—The majority of literature reports involving a search for plant androgens, estrogens, and related materials have involved studies on specific folkloric remedies, those which have been alleged useful either as oral contraceptives, as ecbolics, or as emmenagogues. Undoubtedly, the majority of the emmenagogue and ecbolic plants derive their activity from an irritant mechanism such as that induced by the well-known plant purgatives and vesicant oils. Casey (314) has tabulated some 298 Indian plants used for these purposes in native medicine, and therefore the title "298 Alleged Anti-Fertility Plants of India" is misleading. Saha *et al.* (315) have also contributed a list of 277 Indian plants used for these purposes, many of which duplicate Casey's tabulations. The work by Saha and co-workers (315, 316) also included some experimental studies on a few of the most promising folkloric ecbolic plants found on their list. They evaluated extracts from these plants *in vitro* on excised guinea pig uteri and found several to have marked uterine stimulant activity (315, 316). A similar study, comprising 18 species of Indian ecbolic plants, showed 10 to exert varying degrees of stimulant activity on uterine tissue *in vitro* (317).

A search for effective oral contraceptives has been accelerated due to the alarm generated by the rapid increase in world population. Most studies have involved the synthesis of anovulatory compounds, several of which have been made available and apparently are widely used. Administration of antispermatogenic compounds to the male does not appear to be a popular approach to the problem of population control; however, there is some evidence that this may be effective as a means to prevent conception (318).

Jackson (319), in a review on antifertility substances, has pointed out a few alleged antifertility plants, as have Henshaw (320) and Jochle (321) in similar general reviews. DeLaszlo and Henshaw (322), on the other hand, have compiled a list of 60 antifertility plants used by primitive people.

Lithospermum ruderale, first reported by Train *et al.* (61) to be used by squaws of the Nevada Indian tribes as an oral contraceptive, has received considerable attention in laboratory studies. Several phytochemical investigations (323–325) have failed to yield the active antifertility compound generally acknowledged to be present in this plant (319, 325, 326). Gassner *et al.* (325), however, point out that certain extraction conditions used when processing this plant can alter its biological activity. Similar antifertility effects have been noted for *L. officinale* (327, 328), but attempts to isolate the active component(s) have not, as yet, been successful (327, 329). Other plants alleged to have antifertility effects in humans, and for which some

validating evidence in animals has been reported, are *Mallotus philippinensis* (330, 331), *Polygonum hydropiper* (332), *Psoralea corylifera* (333), *Capsella bursa pastoris* (334), *Sanguisorba officinalis* (335), *Withania somnifera* (336), *Punicum granatum* (331), and *Jatropha curcas* (337), as well as others (338).

Although no antifertility screening programs involving large numbers of plants have been reported in the literature, scattered laboratory evidence exists suggesting this area as a fertile one for development. The discovery of an orally effective, nonsynthetic antifertility agent, occurring free in nature could possibily be an acceptable answer to the question of population control.

More specifically, several examples of estrogenic and androgenic activity in plant extracts have been reported. Androgenic activity has been associated with cinchona bark (339) and with *Rhynchosia pyramidalis* (340), but these reports lack confirmation. In the latter instance, we have found no evidence of activity in *R. pyramidalis* using the standard androgen assay with castrate rats, following either oral or i.p. administration of extracts (341). No example of a steroid estrogen isolated from plants thus far has been reported, the majority of the estrogenic activities being attributed to isoflavones or related structures. These compounds, (isoflavones), probably because of their structural relationship to stilbestrol, are generally acknowledged to be weakly estrogenic, *i.e.*, genistin, genistein, biochanin A, prunetin, coumestrol (342), phloretin (343), and the plant stilbenes (342). This area has been reviewed extensively by Biggers (342), Bradbury and White (344), and by Cheng *et al.* (345).

Although estriol (346) and estrone (347) have been reported isolated in crystalline form from female willow catkins and palm kernel residues, respectively, and represent the only apparently clear cut examples for the isolation of steroid estrogens from plants, these reports have recently been challenged by Jacobsohn *et al.* (348). Jacobsohn and co-workers were unsuccessful in their attempts to duplicate the isolation of estrone from palm kernels, even though the methods used must be considered highly sensitive and usually effective for this type of work. There is little doubt that Butenandt and Jacobi (347) did, in fact, isolate authentic estrone (18 mg. from 50 Kg.) of palm kernel extracts. However, the extract from which the isolated estrone was derived had been previously prepared and supplied by the Schering-Kahlbaum, AG, Berlin (348), a fact that does not preclude the possibility of estrone contamination of the palm kernel residues during processing (348). Skarzynski's (346) isolation of estriol from willow catkins, on the other hand, was not so clearly established. He isolated 7.5 mg. of crystals from 65 Kg. of starting material and found them identical with estriol on the basis of comparision of microscopic appearance, solubility in several solvents, ultraviolet spectrum, melting point of acetyl derivatives (126°), and, in addition, the mixed melting point of the isolate and authentic estriol was depressed only 1°. However, the major difference was that the estrogenic activity of the isolate was only one-fourth that of estriol (346–348). From these data, and on the basis of subsequent negative efforts by Jacobsohn *et al.* (347), it appears that the presence of estrone and estriol in higher plants, as well as steroid estrogens in general, remains to be demonstrated unequivocally.

Conversely, a potent estrogenic activity from *Butea superba*, assaying at about 900,000 mouse units/Kg. has been reported (349). Physical data presented for the compound responsible for this activity are insufficient for its characterization; however, from all available data, it appears to lack the qualifications of a steroid (349). Much of the controversy that has developed over the relative estrogenic potency of plant extracts resides, no doubt, in the selection of an appropriate biological assay. Biggers (342) has critically reviewed methods that have been applied to the detection of estrogenic activity in plant extracts, while Cheng *et al.* (345) have specifically surveyed the literature on the estrogenic activity of naturally occurring isoflavones. Also, a broad review on plant estrogens, encompassing all areas of the subject, has been prepared by Bradbury and White (344). In the latter publication, a list of 55 species of estrogenic plants, representing 49 genera and 28 families, has been tabulated.

Further exploitation of the plant kingdom for this interesting and potentially useful group of phytoconstituents, through a broad biological screening program, could very well be rewarding.

General Pharmacological Screening.—Malone and Robichaud have remarked on general screening as follows:

"The basic premise of pharmacologic screening is not to allow true biologic activity to go undetected even though the activity may be new, unexpected and unique. The initial screening procedure must unequivocally establish this activity as well as its probable nature in order to indicate the course of further, more specific pharmacologic evaluation." (98).

These workers have proposed a "Hippocratic Screen," utilizing normal unanesthetized rats, for the detection of biological activities in crude plant extracts. Using a modification of this procedure, which we refer to as the "Mouse Behavior Screen," extracts from 200 native plants have been evaluated for biological activity with the results being categorized as follows: (*a*) CNS depressant (weak, toxic, etc.), (*b*) CNS stimulant (weak, toxic, etc.), (*c*) autonomic (weak, toxic, etc.), (*d*) mixed CNS stimulant and CNS depressant, (*e*) other types of activity (119). It is our intent to continue this type of evaluation and attempt to correlate characteristic biological effects of plants with their respective taxonomic position and thus develop an area of so-called "Biotaxonomy."

Similar evaluations of plant extracts have been made on 163 West Indian medicinal plants (95–97). In addition, these workers have included *in vitro* or *in vivo* studies of 55 extracts (95) on guinea pig ileum, rat uterus, rabbit duodenum, isolated rabbit heart, and also on dog respiration and blood pressure, the rat stomach fundus (5-HT activity), and the rat diaphragm phrenic nerve preparation. The remaining 108 plants were evaluated in a similar manner, although not so completely (96, 97).

Train *et al.* (61), using plants alleged to be useful in Nevada Indian folk medicine, evaluated some 100 species of plants for their effect on rabbit ileum and for effects on dog blood pressure and respiration.

If an investigator in search of biologically active plant materials has no prior ethnobotanic or biosystematic knowledge of his investigational material, studies such as these are invaluable to supply a justification for continued and detailed phytochemical analysis.

Miscellaneous Phytopharmacological Surveys.—In addition to the more extensive screening programs described above, a number of additional efforts have been carried out, usually on fewer specimens of plants, involving the search for biologically active compounds. Borchers and Ackerson (350), in a search for trypsin inhibitors, examined the seeds of 38 species of plants. Similar substances which inhibited the growth of rats and chicks had been reported in legume seeds (350). The inhibitor was found in all *Leguminosae* seed samples analyzed, but it was absent from 8 seed samples representing other plant families.

In a search for new human plasma cholinesterase inhibitors, Orgell has studied extracts from a large number of plant species (351–353), in addition to several alkaloids (354) and other purified natural substances (354). Inhibitors have been found in extracts from plants in 11 families, and among the inhibitory compounds are riboflavin, bishydroxycoumarin, aloin, naringenin, and some 26 different alkaloids, the majority of which are indoles (354). Orgell has suggested that cholinesterase inhibition techniques may be useful for the detection of certain alkaloids and glycosides in plant extracts or crude drugs (354).

Srivastava *et al.* (355) screened 11 species of Indian plants for fibrinolytic and anticoagulant activity using rather simple *in vitro* methods. Recently, a simple test tube arrangement designed for the rapid evaluation of compounds for fibrinolytic activity has been described that could be adapted for use in the rapid screening of large numbers of plant samples (356).

Several extensive surveys of plant material have been reported in the literature with the intent to discover new hemagglutinins (phytohemagglutinins) that might serve as useful blood-typing reagents (357–370). The most recent of these surveys included the evaluation of seed extracts from 311 species of plants, representing 42 families, against 24 different hemagglutinating antigens (368). Specific positive reactions were given by 17 species in 12 families, exclusive of the *Leguminosae*, whereas 32 of 45 *Leguminosae* species gave similar specific results. A number of additional plants from both groups gave nonspecific hemagglutination reactions. Schertz and co-workers have drawn attention to the need for a continuation of similar screening programs and for the subsequent investigation of the more promising plants which give specific reactions (368).

Although remarks in this section of the review have been directed principally to problems and approaches involved in the detection of biologically active substances in higher plants, other fertile natural product areas remain essentially untapped. The biological activities of algae (371, 372), plankton (371), and marine biotoxins (373, 374) point to this fact, and the prospect of discovering new antibiotic producing organisms in the sea should stimulate the fins and gills in many a natural product investigator.

PHYTOCHEMICAL SCREENING APPROACHES

Ultimately, the goal in surveying plants for biologically active or medicinally useful compounds should be to isolate the one or more constituents responsible for a particular activity.

Hence, with the selection of a specific plant for phytochemical investigation, either on the basis of one or more approaches set forth under *Phytopharmacologic Approaches*, or through some other avenue, phytochemical screening techniques can be a valuable aid.

Certain investigators feel that an initial selection of investigational plants should be made, not on evidence that extracts elicit a particular and interesting biological activity, but rather on the basis that certain chemicals are present in the plant, relatives of which can usually be associated with biological activity. Thus, some investigators will select initially only alkaloid-containing plants for study on the premises that (*a*) alkaloids normally exert some type of pharmacologic activity, usually on the central nervous system, but not always so; (*b*) the greatest majority of natural products used in medicine today are alkaloidal in nature; (*c*) tests for the presence of these compounds in plants are simple, can be conducted rapidly, and are reasonably reliable, and (*d*) because of their chemical nature, alkaloids are more easily manipulated making extraction and isolation less of a problem. In addition, economics, as well as other factors associated with biological testing, often force the investigator to pursue a phytochemical approach. However, should a phytochemical group other than alkaloids be selected for investigation, say the flavonols, the diversity of expected biological activities can be enormous. Willaman has surveyed the literature and has found that at least 137 natural flavonoids are known, occurring in some 62 families, 153 genera, and 277 species of plants (415). Also, some 33 different pharmacologic or biological activities have been reported for one or more of 30 flavonoids (415). More recently, Horhammer and Wagner have reviewed the same area, and these numbers are therefore to be increased (416, 417). Also, Orzechowski has considered the role of flavonoids as therapeutic agents (418). Along similar lines, the coumarins have been reported to exert some 31 different biological effects, and according to Soine, their full range of pharmacologic activities is not appreciated by most investigators (419). Other examples pointing out the complexity of expected biological effects for any one category of phytoconstituents could, of course, be made. In any event, publications representing the phytochemical screening approach far outweigh those following phytopharmacologic avenues, not only in numbers of reports, but in representation of total plants examined.

Since the number of chemical categories of plant constituents is great, and each is capable of eliciting biological activity, no attempt will be made in this review to be all inclusive. This section of the review will be restricted to some general considerations of phytochemical screening methodology, followed by discussions of those categories of phytoconstituents which have been represented in major published surveys of screening programs. These will include: alkaloids, glycosides as a general class (heterosides), saponins (steroid and triterpenoid), sterols, cardiac glycosides, cyanogenetic glycosides, *iso*thiocyanate glycosides, anthraquinones, flavonoids and related compounds, tannins, and coumarins and related compounds. Surveys which have been conducted for each of these categories will be discussed along with the general methodology involved. The examples to be cited are intended to be representative of each class and are not meant to include all available published data.

General Considerations

A method for use in phytochemical screening should be (*a*) simple, (*b*) rapid, (*c*) designed for a minimum of equipment, (*d*) reasonably selective for the class of compounds under study, (*e*) quantitative in so far as having a knowledge of the lower limit of detection is concerned, and if possible, (*f*) should give additional information as to the presence or absence of specific members of the group being evaluated. Most published procedures adhere to criteria (*a*) through (*d*), but few are designed to provide the information included in (*e*) and (*f*). In fact, certain procedures cannot be duplicated because of insufficient details included in some reports. For example, Arthur and Cheung (420), in a phytochemical survey of Hong Kong plants, screened 332 species for alkaloids. They equated the precipitates observed following the addition of standard alkaloid precipitating reagents to results obtained by adding the same reagents to standard solutions of 1:100, 1:500, 1:2500, and 1:10,000 quinine sulfate. It is implied that water was the solvent. However, the solubility of quinine sulfate is stated to be 1 Gm. in 810 ml. of water (421). Along similar lines, Wall *et al.* (422) have used the cyanidin test for the detection of the γ-benzopyrone nucleus as indicative of the presence of flavonoids. They compare a test result color with a similar color produced by a 0.1% solution of rutin and equate it as a (+) reaction. Their extraction solvent is 95% ethanol (but fresh plant material was often extracted which would decrease this percentage considerably), and rutin is stated to be only slightly soluble in ethanol and soluble about 1

Gm. in 8 L. of water (421). We find that the maximum solubility of rutin at room temperature is about 0.02% for both 80 and 95% ethanol.

Webb, using a field method, estimated alkaloid precipitates with reagents on a + to ++++ basis but used no reference for comparison (423, 424). He also states, ". . . On the other hand, while the method may yield a percentage of 'false positives,' it has never failed to detect species with alkaloids" (424). If the initial field test did indeed fail to detect alkaloids, perhaps because of a low concentration in the plant, how could it be determined that the test was infallible when only field test positive species were collected for more specific laboratory examination?

One of the most important and fundamental considerations in designing a phytochemical screening procedure is the selection of a proper extraction solvent. It is often difficult to follow general or expected solubility rules for a given class of phytoconstituents since there are often substances of unknown character present in crude plant extracts that affect solubility. For example, Woo (425) has reported the effect of saponin in plant extracts on the solubility of certain normally insoluble compounds using selected solvents. Apparently saponin acts as a wetting agent to enhance the formation of micelles; thus, an increase in solubility of certain constituents is effected. This phenomenon has been noted through the use of synthetic detergents to enhance the solubility, and thus extractability, of alkaloids from Cinchona (426). Since saponins, or other similar surface-active agents, do not occur universally in plants, prediction of general solubilities for a class of phytoconstituents precipitates a major problem. In our laboratory *n*-hexane-soluble extractives from *Catharanthus lanceus* were found to be rich in alkaloids. Subsequent isolation of individual akaloids from the crude mixture proved them to be totally insoluble in *n*-hexane. Presumably the alkaloids occur in the plant, at least in this instance, dissolved in some lipid material, the latter being soluble in *n*-hexane.

No solution is offered for these problems involving solubility except to say that extract residues should always be examined with a variety of solvents to determine whether abnormal solubility phenomena have occurred.

Even though a great many problems are presented by the diverse methodology utilized by investigators in phytochemical screening, much useful information can be derived from published studies. Positive test results are usually clear cut and only the possibility of false-positive results need be further explored. Negative results, on the other hand, must be carefully weighed in terms of being due to a real absence of the test material in the sample being evaluated, or to the methodology employed.

Alkaloid Screening

Prior to a consideration of screening plant material for alkaloids, it would seem in order to define the term "alkaloid" as used in this review; however, the nature of the word itself precludes anything more than a vague definition. Anyone familiar with alkaloids surely has a knowledge of their character, but seldom can one give an acceptable definition. Most authorities agree that chemical, botanical, and pharmacologic implications must be reflected in an acceptable definition. Hegnauer's (427) suggestion that:

> "Alkaloids are more or less toxic substances which act primarily on the central nervous system, have a basic character, contain heterocyclic nitrogen, and are synthesized in plants from amino acids or their immediate derivatives. In most cases they are of limited distribution in the plant kingdom."

seems as acceptable as any. For purposes of this discussion we will utilize Hegnauer's concept except, of course, we cannot be concerned with the site or mechanism of synthesis. Thus, compounds such as aliphatic nitrogenous bases (ephedrine), amides (colchicine), and the amino acids (thiamine) themselves will not be considered as alkaloids.

Estimates for the distribution of alkaloids in vascular plants have been placed as high as 15–20% (427), although this figure appears somewhat high with respect to data derived from several extensive phytochemical screening programs. Wall *et al.* (423, 428–435) have screened more than 4000 species of plants and report a distribution of about 10% alkaloids. Webb (424) in his experience with some 1700 species indicates alkaloid occurrence to be about 14%, whereas the Smith Kline & French survey found that about 10% of 25,000 species screened were positive for alkaloids (436). Since a few of these undoubtedly will be determined through future studies to be false-positive alkaloid containing species, 9–10% seems to be the more logical estimate representing alkaloid-yielding plant species.

Alkaloids are widely distributed in the plant kingdom, although certain groups have been shown to be characteristically devoid of them. Excellent essays on this subject have been published by Willaman and Schubert (93, 94) and by Webb (424). The handbook of alkaloid-bearing plants by Willaman and Schubert is also

useful to establish this relationship among plant taxa (437).

Since alkaloids usually occur in plants as their water-soluble salts, some workers believe that extraction with acidulated water can result in a crude extract which can be tested directly with one or more standard alkaloid precipitating reagents. Other workers feel that the presence in such an extract of materials that are capable of giving false-positive alkaloid tests necessitate a purification procedure before valid results can be obtained. This is usually accomplished by the addition of base and subsequent extraction with a water-immiscible organic solvent. The organic extract can then be tested by application to filter paper, drying, and dipping or spraying with an alkaloid detecting reagent that gives a chromogenic response with alkaloids. If the latter method is not preferred, the organic solution can be re-extracted with dilute acid and the usual alkaloid precipitating reagents added to separate portions of this acid extract.

Another method of removing impurities that are capable of giving false-positive tests (*i.e.*, proteins) from an initial aqueous acidic extract is to "salt out" these materials by the addition of powdered sodium chloride. An additional procedure for alkaloid detection could be based on the addition of alkali directly to the powdered plant sample, followed by extraction with an appropriate organic solvent. This extract could then be purified by partition as described above, or be tested directly.

With respect to these general methods, certain anomalies have been reported in the literature which should be pointed out. There is no implication that these examples are frequently encountered in alkaloid screening; however, one should be aware that they do exist. Certain plants (*i.e.*, *Saussurea lappa*) are known to contain labile nonbasic constituents and may yield nitrogenous materials (pseudoalkaloids) on extraction with ammoniacal solvents (438), while others contain alkaloids that are susceptible to modification by acidic reagents (438). That proteins, which may be present in aqueous or acidic aqueous plant extracts, can precipitate on the addition of heavy metal alkaloid precipitating reagents and thus yield false-positive tests, is well established (438–444). Such proteins can be removed by treatment of the extract with sodium chloride prior to the use of the heavy metal reagent, a procedure which usually salts out the protein (438). However, alkaloids such as alstonine may be quantitatively precipitated as hydrochloride under these conditions (438). In the treatment of a crude plant extract to remove impurities by the acid–base–organic solvent –acid procedure, it is quite possible that plants containing water-soluble alkaloid bases will go undetected. Quaternary bases, amine oxides, betaines, and choline would fall into this category (438).

Variability of results in alkaloid testing of plant material can be induced by a number of factors such as age, climate, habitat, plant part tested, season, time of harvest, chemical races of plants, sensitivity of alkaloid type to reagents, etc. A few examples regarding these factors should serve to point out their importance. *Geijera salicifolia* was found by Webb to give consistently better alkaloid tests as the broad leaf form, than the narrow leaf form, even when the 2 were growing side by side in the field (424). In certain groups of plants (*i.e.*, *Compositae*), alkaloids often are found only in or near the flower tops (438), and in the *Apocynaceae*, alkaloids generally tend to concentrate in the root or bark, often to the exclusion of other parts of the plant (438); thus, the proper selection of plant parts for testing is quite important. To obtain equivalent results, quantitation of precipitates obtained with alkaloid reagents is not always possible, especially when comparing different genera or families. This is exemplified through knowledge that *Galbulimima baccata* (*Himantandraceae*) was found to be rated a ++++ in field tests and subsequent analysis resulted in a yield of 0.01–0.05% of 4 alkaloids. A ++++ rating for *Daphnandra aromatica* (*Monimiaceae*) was determined in the field and subsequent analysis in the laboratory yielded 6+% of crude alkaloids (424). *Antireha putaminosa* (*Rubiaceae*) loses 50% of its alkaloid after 2 months' storage, and high alkaloid decomposition rates have also been noted for *A. tennuifolia*, *Randia racemosa*, and *Gardenia vilhelmii*, 3 additional rubiaceous plants (424). Silica gel drying of *Antirhea tennuifolia* for 1 month resulted in material that gave a ++++ alkaloid test, whereas this same plant dried in the shade for 1 month gave a negative alkaloid test (424). *Acronychia baueri*, on the other hand, gave strong alkaloid positive tests when 124-year-old herbarium specimens were evaluated (424, 445). Along similar lines, Raffauf and Morris have reported that a plant sample identified as *Nicotiana attenuata* (*Solanaceae*), and estimated to be some 1300 years old, gave positive alkaloid tests (446). *Duboisia myoporoides* yielded 3% of hyoscyamine when harvested in October, but when harvested in April of the same year, 3% hyoscine was isolated (424). Examples of alkaloid decomposition as a result of milling

TABLE III.—SOME USEFUL ALKALOID PRECIPITATING REAGENTS

Name	Comp.	Ref.
Bouchardat	Iodine–potassium iodide	(493, 504)
Dragendorff	Bismuth potassium iodide	(447, 496, 504, 632)
Ecolle	Silicotungstic acid	(447, 732)
Gold chloride	Chlorauric acid	(493)
Hager	Picric acid	(448)
Kraut	Iodine–zinc chloriodide	(447)
Marme	Cadmium potassium iodide	(447)
Mayer	Potassium mercuric iodide	(447, 448, 452, 453)
Platinum chloride	Chloroplatinic acid	(448, 493, 781)
Scheibler	Phosphotungstic acid	(448)
Sonnenschein	Ammonium phosphomolybdate	(496)
Valser	Potassium mercuric iodide	(452)
Wagner	Iodine–potassium iodide	(496)
	Bismuth antimony iodide	(782)
	Bromauric acid	(783)
	Bromoplatinic acid	(497)
	Bromothallic acid	(784)
	Picrolonic acid	(785)
	Sodium tetraphenylboron	(786)
	Trinitroresorcinol	(787)

dried plant material have also been cited (424). These examples should suffice to point out just a few of the problems encountered by the natural product investigator who is interested in the detection and isolation of biologically active alkaloids.

Alkaloid Detecting Reagents

For detecting alkaloids in phytochemical screening, two types of reagents are available, *i.e.*, alkaloidal precipitants and spray or dip reagents. Table III lists 20 precipitating reagents commonly used for the detection of alkaloids, whereas Table IV presents 15 reagents that were used in 45 recent phytochemical surveys for alkaloids. At least 2 reagents were used in 38 of the surveys, while 7 surveys depended solely on 1 reagent to establish the presence of alkaloids. Because of the variable sensitivities of these reagents and because of their nonspecificity for alkaloids, many investigators utilize 4 or 5 reagents in their screening of plant extracts, and only samples yielding precipitates with all reagents are considered to contain alkaloids. Fulton (447) has tabulated some 200 of these reagents and presents a great deal of information concerning their specificity and sensitivity. A series of papers by Munch *et al.* (448–451) is concerned with the effect of 17 different alkaloid detecting reagents on several classes of nitrogenous bases. Travell (452) has studied the sensitivity of Mayer's and Valser's reagents, both solutions of potassium mercuric iodide, with the former prepared from mercuric chloride and potassium iodide and the latter from mercuric iodide and potassium iodide.

TABLE IV.—ALKALOID DETECTING REAGENTS EMPLOYED IN SCREENING PROGRAMS

Reagent	Surveys Used in,[a] No.
Mayer's reagent	39
Silicotungstic acid reagent	23
Dragendorff's drop reagent	19
Wagner's reagent	11
Dragendorff's spray reagent	10
Sonnenschein's reagent	9
Hager's reagent	7
Bouchardat's reagent	3
Phosphotungstic acid	2
Valser's reagent	1
Chloroplatinic acid reagent	1
Chlorauric acid reagent	1
Sodium tetraphenylboron reagent	1
Ammonium reineckate reagent	1
Tannic acid reagent	1

[a] Two or more reagents were used in 38 randomly selected surveys; 1 reagent only was employed in 7 surveys.

The reagent used by most investigators for phytochemical screening is essentially the same formula that Mayer originally introduced in 1862. Several investigators have demonstrated, however, that the original formula is perhaps the least sensitive for alkaloid detection, in comparison with many proposed modifications (452–454), and Travell (452) has conclusively demonstrated the superiority of Valser's over Mayer's reagent. In our laboratories we have compared the sensitivity of several common alkaloid precipitating reagents using 40 different alkaloids and representing several different chemical types (454). The reagents tested were Mayer's (3 formulas), Valser's, Wagner's (2 formulas), Bouchardat's, Hager's, Scheibler's, silicotungstic acid, Dragendorff's, Marme's, gold chloride, and Sonnenschein's. It was demonstrated in this study that the various reagents exhibit wide differences in sensitivity for structurally dissimilar

alkaloids. None of the reagents would detect ephedrine at a concentration of 0.1%, but Wagner's, Bouchardat's, Dragendorff's, and Scheibler's each detected all of the other alkaloids at concentrations ranging from 0.001 to 0.1%. Hager's, Marme's, and gold chloride reagents were by far the least effective detecting reagents, failing to react with 13, 12, and 10, respectively, of the 40 test alkaloids. All 3 of the Mayer's formulations were inferior to Valser's reagent with respect to sensitivity and specificity of alkaloid detection (454). It should be pointed out that the majority of these precipitating reagents must be used to detect alkaloids only in acid solution, and furthermore, that a large number of naturally occurring non-nitrogenous plant principles will react to give false-positive tests. These will be discussed subsequently.

Investigators who prefer to use spot tests, or those who prefer to chromatograph concentrated plant extracts for the detection of alkaloids, have a variety of available reagents. The most widely utilized, however, are modifications of the original Dragendorff drop test reagent, which produce orange to red colors with most alkaloids. Although a number of modified formulas have been proposed, each reported to have advantages over the others, the 2 most frequently utilized in phytochemical studies are the 1951 Munier and Macheboeuf (455) and the Thies and Reuther (456) modifications. A literature search has revealed the availability of at least 15 modifications of the Dragendorff spray reagents (457–471). We were prompted to study the stability and sensitivity of one of these modified reagents since a number of published reports had commented on the need for their storage under refrigeration with concomitant protection from light. It was determined that prepared concentrates of the 1951 Munier-Macheboeuf Dragendorff's reagent required a storage period of about 1 week prior to its use in the preparation of the diluted reagent. Also, the diluted spray reagent should be stored for a minimum of 1 week prior to its use for alkaloid detection in order to obtain maximum sensitivity. The reagent maintained its stability and sensitivity for at least 6 months and no special storage conditions were found necessary (472).

Some alkaloid detecting reagents are available which on reaction with certain groups of alkaloids, or with specific functional groups, produce characteristic chromogenic responses. These can be of considerable value in screening work, but only after alkaloids have been determined in the sample being evaluated. A selected list of general as well as specific chromogenic reagents has been prepared and is presented in Table V.

False-Positive Alkaloid Reactions.—Mechanisms for the reaction between alkaloids and detecting reagents are dependent chiefly on the chemical character of the reagent. Fulton (447) classifies alkaloidal precipitants as (*a*) those which react with basic compounds (alkaloids) to form insoluble salts; examples are silicotungstic, phosphomolybdic, and phosphotungstic acids. (*b*) Those which react with alkaloids as loose complexes to form precipitates; examples are Wagner's and Bouchardat's reagents (iodine-potassium iodide). (*c*) Those which react to form insoluble addition products through the alkaloid nitrogen; examples are the complex heavy metal salt reagents, Mayer's, Valser's, Marme's, and Dragendorff's. And (*d*) those which react through the attraction of organic acids with basic alkaloids to form insoluble salts. An example of such a reagent would be Hager's (picric acid). Obviously, these are rather nonspecific reactions and a number of nonalkaloidal plant constituents should be expected to precipitate also from solution on the addition of these reagents to crude plant extracts. These false-positive reactions are most liable to occur when testing an extract that has not been treated by at least one acid-base–organic solvent purification.

The most frequent false-positive reactions have been attributed to the presence of proteins which precipitate on the addition of heavy metal containing reagents (423, 438–444). Included in this category are "albuminous substances" (452), peptones (466), and ptomaines (441, 447). At least one textbook has indicated that amino acids will also precipitate with the general alkaloid reagents (444). However, a study by Winek and Fitzgerald (473) appears to disprove this allegation. Among other substances reported in the literature as the cause of false-positive alkaloid reactions are certain glycosides (444, 474), and carbohydrates (474), betaine (423, 439, 474), choline (474), purines (439), methylated amines (439), tannins (423), and ammonium salts (439, 466). Recently, we were able to show that previous positive alkaloid tests reported for extracts of *Piper methysticum* were due to the α-pyrones: kawain, dihydrokawain, methysticin, dihydromethysticin, and yangonin (475). This prompted an investigation of the mechanism by which nonalkaloidal compounds are able to elicit a positive reaction with an alkaloid detecting reagent, in this case the modified Dragendorff reagent. It was de-

TABLE V.—GENERAL AND SPECIFIC ALKALOID REAGENTS FOR CHROMATOGRAPHY

Alkaloid Type	Reagent	Ref.
Simple amines	1-Fluoro-2,4-dinitrobenzene	(461, 788)
	Ninhydrin	(789, 790)
Free and phenolic-bound OH groups	Potassium ferricyanide–$FeCl_3$	(461)
Aryl amines	Chromosulfuric acid	(461)
	Glucose–H_3PO_4	(461)
Secondary aliphatic and alicyclic amines	Sodium nitroprusside	(461)
Methylene oxide group	Chromotropic acid	(791)
Piperidine–pyrrolidine	Isatin–acetic acid	(792, 793)
Pyridine	Konig's reagent	(461)
Purines	Bromine vapor	(794)
Morphine	Ehrlich's reagent	(795)
Steroid glycoalkaloids	Vanillin–H_3PO_4	(796)
Choline and related compounds	Chargraff's reagent	(461)
	Hydroxamic acid–$FeCl_3$	(461)
	Dragendorff's, modified	(797, 798)
	Dipicrylamine	(798)
Indoles	Aminopyramidine	(799)
	Ceric ammonium sulfate–H_3PO_4	(800–803)
	Ceric sulfate–H_2SO_4	(804–806)
	Cinnamic aldehyde–HCl	(461)
	Perchloric acid–$FeCl_3$	(461)
	2,6-Dichloroquinonechlorimide	(461)
	Van Urk's reagent	(807)
	Prochaska's reagent	(807)
	Keller's reagent	(808, 809)
Indoles, β-substituted	Van Urk's reagent	(808–810)
Indoles, 5,6-dihydroxy	Ehrlich's reagent	(811)
	Hopkin's-Cole reagent	(811)
	Salkowski reagent	(811)
	Gibb's reagent	(811)
	Folin and Ciocalteu's reagent	(811)
	p-Dimethylaminocinnamaldehyde	(811)
	Acidic oxidizing reagent	(811)
	Terephthalaldehyde	(811)
	Nitrose reagent	(811)
	Formaldehyde–HCl reagent	(811)
	Xanthydrol reagent	(811)
	Diazotized *p*-nitroaniline	(811)
	Sodium molybdate–HCl reagent	(811)
	$FeCl_3$–potassium ferricyanide	(811)
	Ferric chloride solution	(811)
	Ammoniacal silver nitrate	(811)
Indoles, ergot	Ehrlich's modified reagent	(461, 808, 812)
	Ehrlich's reagent	(808–810)
	Van Urk's reagent	(808–810)
	Alport-Cocking's reagent	(808)
	Glyoxalic acid	(808)
Indoles, yohimbine type	Modified Keller reaction	(813)
Miscellaneous (special applications)	Sodium tellurite–H_2SO_4	(814)
	Ceric sulfate–trichloracetic acid–sulfuric acid	(461)
	Nessler's reagent	(461)
	Sulfuric acid–methanol (fluorescence)	(461)
	Nitric acid–methanol (fluorescence)	(461)
	Levine-Chargraff reagent	(815)
	Sulfuric acid	(816)
	Dichromate–H_2SO_4	(817)
	Ninhydrin reagent	(818)
	Xanthydrol reagent	(784, 818)
	Hydroxylamine	(819)
	Hydroxylamine–$FeCl_3$	(820)
	Sodium nitroprusside	(821, 822)
General alkaloid reagents	Mayer's	(823)
	Potassium iodoplatinate	(461, 824–832)
	Iodine	(461)
	Dragendorff's reagent, modified	(457–471)

termined that any non-nitrogenous organic compound having conjugated carbonyl (ketone or aldehyde) or lactone functions would react in a manner typical of alkaloids (476). These minimum qualifications are quite prevalent in natural products and undoubtedly many false-positive alkaloid reactions are promulgated through this mechanism. Fortunately, the majority of com-

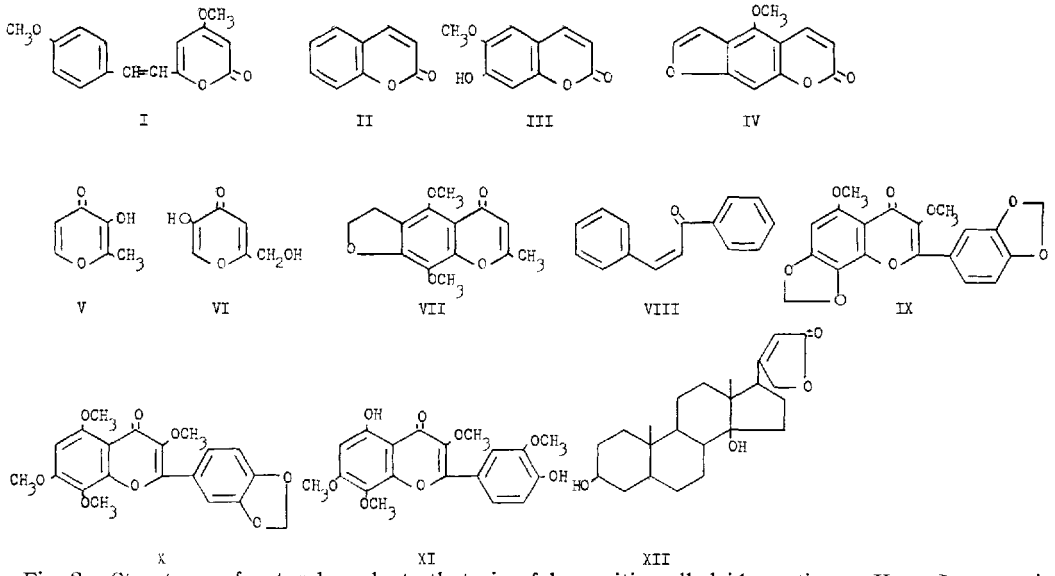


Fig. 2.—Structures of natural products that give false-positive alkaloid reactions. Key: I, yangonin (476); II, coumarin (476); III, scopoletin (476); IV, bergapten (476); V, maltol (476); VI, kojic acid (476); VII, khellin (476); VIII, chalcone (476); IX, meliternatin (477); X, meliternin (477); XI, ternatin (477); XII, digitoxigenin (476).

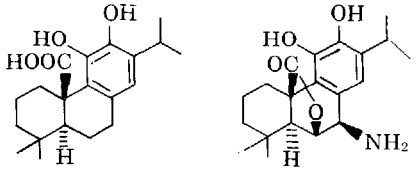
pounds with these functionalities can be separated from the alkaloids by treatment of the extract with base, followed by extraction with organic solvent which, in turn, is extracted with dilute aqueous acid. Another interesting report is that by Briggs and Locker (477), who in 1949 isolated 3 compounds from *Melicope ternata* which gave precipitates with the usual alkaloid reagents and crystalline salts with acids. However, these compounds contained no nitrogen and proved to be the completely alkylated hydroxyflavones, meliternatin, meliternin, and ternatin (Fig. 2). It would appear that, in the light of our work, the false-positive test for alkaloids was due to the presence of the conjugated carbonyl in each molecule rather than, as stated by the authors, the fact that each molecule was completely alkylated. Presumably other flavones would react similarly, as would most of the cardenolides and bufadienolides.

Householder and Camp (850) have recently pointed out that treatment of plant extracts with ammonium hydroxide and acetone can give rise to artifacts which give positive reactions with the standard qualitative alkaloid test reagents. These investigators were unable to identify the condensation products formed in this reaction but presented evidence to show that the rate of formation was affected by exposure to light and the atmosphere.

A recent report by Russian workers (851, 852) presented evidence for the isolation of an alkaloid named rosmaricine from *Rosmarinus officinalis* (*Labiatae*). This anomaly of an alkaloid from a member of the mint family prompted Wenkert and co-workers to investigate the validity of the Russian work (853). They found that rosmaricine was indeed not present in the plant prior to the addition of ammonia (used by the Russian workers in their isolation experiments), and that this "alkaloid" was undoubtedly formed as a result of the action of the base on the precursor carnosic acid (853).



Carnosic acid Rosmaricine

Other anomalous alkaloid reactions have been mentioned in the literature but as yet they cannot be explained. For example, *Samolus repens* (*Primulaceae*) extracts give a black color and precipitate with Dragendorff's reagent (478). We have observed this phenomenon frequently in the field testing of fresh plant material and have assumed the reaction to be one of free iodine in the reagent combining with starch to give a typical blue-black color. Extracts from *Plagianthus divaricatus* (*Malvaceae*) have been reported to give a pink color, but no precipitate, with Dragendorff's reagent (478).

Webb has pointed out that about 9% of species tested in the field for alkaloids were found to be false-positive reactions following subsequent detailed laboratory analysis (424). On the basis of experience resulting from tests on some 25,000 plant species, Douglas has estimated that not more than 5% of initial positive alkaloid tests have been found to be due to nonalkaloid entities (436).

False-Negative Alkaloid Reactions.—If one considers the nonheterocyclic nitrogen bases (protoalkaloids) as alkaloids, it will be noted that the greatest majority of these fail to react with the usual alkaloid precipitating reagents. Certain examples of this can be documented (454, 466). Also, unless certain precautions are observed in the test procedure, quaternary alkaloids and amine oxides (nupharidine, dilupine, trilupine) will not be detected (466). That is, if an acidic plant extract is treated with base and extracted with an immiscible organic solvent, both the aqueous basic layer and the organic layer must be tested for alkaloids. In most alkaloid screening procedures that have been reported, the basic layer has been neglected. Arguments for this omission have been based on the assumption that quaternary alkaloids or amine oxides would not be expected to occur in plants to the exclusion of tertiary bases which would be detected by this procedure. Raffauf points out that this may be an erroneous assumption (466).

Alkaloid Testing of Herbarium Specimens.—The validity of alkaloid tests on plant material derived from herbarium sheets is open to question. Often, for many and varied reasons, it is difficult to find certain plants in their native habitat at the time of collection of indigenous flora, and this alternative to collection has been used by several investigators (423, 424, 478–482) to survey a broad distribution of plant taxa. An obvious disadvantage in the use of such material is that usually only leaves and branches are available and instances are known wherein plants contain alkaloids in other organs, but their leaves and stems are relatively alkaloid-free (424). Also, herbarium material is often quite old, and a number of examples can be cited correlating alkaloid decomposition as a function of time (424). On the other hand, plants 1300 years old have been reported still to give alkaloid positive tests (445). It is common practice in some herbaria to treat specimens with formalin or mercuric chloride as preservatives. Formalin could very well decompose many alkaloids, and mercuric chloride reacts with certain alkaloidal precipitants to form abnormal precipitates. With Mayer's reagent this is evidenced by a bright orange precipitate with yellow streaks which eventually become red, and with Bouchardat's reagent a pale purplish brown precipitate is observed (424). In some herbaria, it is common to mark specimens in a manner that treatment of this type can be easily ascertained, while in others this practice is not carried out. Even with these problems, extensive herbarium specimen testing for alkaloids by Webb has allowed him to acknowledge this procedure as a valuable adjunct to the testing of fresh material (424). Cain *et al.* (479) have indicated that equivalent results were obtained in their studies with fresh plant material and dried herbarium specimens.

Field Tests for Alkaloids in Plants.—Investigators searching for new alkaloid bearing species in remote or distant areas of the world often find it difficult to return to make additional bulk plant collections for laboratory study. Therefore, simple field tests for alkaloids have been developed which are sufficiently reliable to distinguish alkaloid-containing plants, *i.e.*, those containing at least 0.01% of alkaloids, thus enabling bulk collections of these species initially and eliminating the need for a return expedition. These field tests can be classified in the following manner.

Organoleptic Evaluation.—It has been suggested by Webb that at least some of his collections of species for laboratory examination were made on the basis of taste, in conjunction with some knowledge of the botanical characteristics of the samples being evaluated (483). That is, he avoided tasting plants in such families as the *Anacardiaceae*, *Euphorbiaceae*, etc., but bitterness in a group such as the *Lauraceae*, particularly if a *Cryptocarya*, would suggest alkaloids. In Webb's opinion, differentiation of bitter alkaloids and saponins can be made on the basis of taste, but only after considerable experience (483). Also, bitterness in the inner bark of such groups as *Evodia*, *Acronychia*, and *Melicope* (*Rutaceae*), in conjunction with an observation of yellow pigmentation, is suggestive of the presence of alkaloids (acridones). While judgments such as these may be justified by an investigator who has had considerable experience, and whose botanical and chemical background are complementary, the average alkaloid hunter could hardly justify such an approach.

Spot Tests Using Alkaloid Test Paper.—Kraft (484) has developed a simple device for alkaloid detection in fresh plant material, a process which consists of impregnating filter paper with Dragendorff's reagent, followed by

drying. A plant part is incised with a razor blade and a small amount of juice is applied to the test paper which, if alkaloids are present, will give the characteristic orange color indicative of a positive test. This method has been applied to the field testing of about 1200 species of plants by Nikonov and Ban'kovskii (485), who found it to be acceptable with certain reservations. They found it unsuited for plants containing pigments in the sap which masked positive reactions, and it was further determined that protoalkaloids such as ephedrine were not detected. An important point that must be emphasized is that these workers stress that the typical color of an alkaloid-positive reaction must be observed within 30 sec. from the time that the sample was applied to the paper for a test to be considered valid (485). We have used paper similar to this in our laboratory for the detection of alkaloids in organic solvents during chromatographic separations and found that it was necessary to apply water to the paper, after the sample solvent had evaporated, in order for the reaction to take place.

Spot Tests on Paper Using Liquid Reagents.—The most extensive phytochemical survey for alkaloids in the plant kingdom is being conducted by scientists from the Natural Products Section, Smith Kline & French Laboratories, Philadelphia, Pa. This program was initiated in 1954, but extensive alkaloid testing did not begin until 1958. Briefly, their approach consists of a semirandom collection of plants from all parts of the world, with tests for alkaloids made in the field on all accessible parts of each species. Those found to be promising as a source of alkaloids are collected at the test site in sufficient quantity to enable laboratory extraction of the alkaloids for subsequent pharmacologic study. Extracts from

all plants shown to contain alkaloids by this field test are screened for several types of pharmacologic activity (436).

The field test for alkaloids used by this group has been described (466) and is essentially the same as that utilized by Nikonov and Ban'kovskii (*vide supra*) with the exception of the special test paper. Instead, plant sap obtained by making an incision of the appropriate plant part, is applied to filter paper, dried, and a micro drop of specially prepared Dragendorff's reagent is added (466). Positive tests are evaluated as previously described. All positive field tests are confirmed by means of a laboratory alkaloid detection procedure (*vide infra*).

Of 25,000 species evaluted in this manner to date, about 10% have been recorded as alkaloid-positive (436). About 5% of the plants shown to contain alkaloids by the field test were not confirmed by the laboratory procedure (436).

Abisch and Reichstein (486–488) have also utilized this spot test technique for alkaloid detection in their study of plants of the *Apocynaceae*, *Asclepiadaceae*, and *Periplocaceae*. However, their extracts were prepared from dry plant material.

Test Tube Spot Tests.—Culvenor and Fitzgerald (489) have described a simple kit that can be taken into the field for use in testing samples of plant material for alkaloids. About 2–4 Gm. of fresh plant part is ground in a small mortar with sand and sufficient chloroform to make a slurry. Ammoniacal chloroform is added and the mixture stirred for 1 min. prior to filtration into a small test tube. Extraction of the alkaloids from the chloroform is accomplished by shaking the solution with 0.5 ml. of 2 *N* sulfuric acid and separation of the acid layer by means of a medicine dropper. A few drops of this acid extract are then tested with either Mayer's reagent or

silicotungstic acid to ascertain the presence of alkaloids. When samples were analyzed by both the field method and a laboratory procedure, it was found that a number of weakly positive tests recorded through use of the laboratory test were found to be negative in the field test (489). The method, of course, fails to detect quaternary alkaloids and this appears to be its major drawback.

Presumably, many of the plants collected for laboratory alkaloid testing by Webb (423, 424, 483), Amarasingham *et al.* (490), and Arthur (491) were field analyzed in a similar manner to that described above. However, their respective reports failed to point out any consistency with regard to this matter.

Alkaloid Surveys.—Although surveys for alkaloids, representing tests on more than 15,000 species of plants, have been published (5, 99, 100, 168, 176, 312, 420, 423, 424, 428–435, 478–483, 485–488, 491–546, 854) (Table VI), the data that they present are often inconsistent because of variations in testing methodology. That is, some of the procedures will detect both quaternary and tertiary alkaloids, but the former group is omitted from most survey reports. Certain procedures involve treatment of the alkaloid fraction to remove substances that often give rise to false-positive alkaloid reactions, whereas others do not include this extra step. Some methods are semiquantitative, while others lack this desirable feature. A survey of the most extensive and more frequently reported methods allows them to be classified into 6 major categories (Table VII). Perhaps the simplest method is that represented by group *A* in which either an acidic or aqueous plant extract is prepared, with or without the use of heat, followed by filtration and the addition of one or more alkaloidal reagents to separate portions of the filtrate. Most investigators assess a rating of 0, or +1 to +4 on the lack of, or degree of precipitation following use of the reagents. However, there is seldom any indication of the alkaloid equivalent of these ratings. This undoubtedly could present a problem to either a novice or one who is attempting to duplicate results in a different laboratory. On the other hand, a person experienced in alkaloid screening can usually assess this +1 to +4 rating system by a rule of thumb. The major drawback of this method is that it results in the greatest number of false-positive reactions. An inspection of the compounds presented in Fig. 2, which are representative of a great number of nonalkaloidal plant constituents capable of giving false-positive alkaloid reactions, shows that for the most part they would be soluble in either aqueous or acidic media. Also, although this method would not differentiate between quaternary and tertiary alkaloids, neither would it fail to detect one or the other.

Group *B* testing differs from group *A* only in that the filtrate is made basic and extracted with an organic solvent (usually chloroform or ether), followed by extraction of the alkaloids from the organic solution with dilute aqueous acid. The usual alkaloidal precipitants are then added to separate portions of the acid extract. This method has the advantage over the group *A* procedure of eliminating a great number of compounds from the final test extract that are capable of eliciting false-positive alkaloid reactions; however, any quaternary alkaloids present would also be eliminated. Simple modifications in this method would allow one to test for the latter group of alkaloids.

TABLE VII.—ALKALOID TEST METHODS USED IN PHYTOCHEMICAL SCREENING

Group	Method	Ref.[a]
A	Acidic or aqueous extracts.	(5, 420, 423, 424, 478–483, 490, 496, 497)
B	Acidic or aqueous extract, followed by alkali treatment, immiscible solvent extraction, and partition with dilute acid.	(507, 536)
C	Alcohol extraction followed by concentrating and addition of acid.	
	1, No additional treatment.	(100[b], 422[b], 428–435[b], 478–482, 542[b], 545[b], 546[b])
	2, Partition purification, test made only on tertiary alkaloid fraction.	(99, 100, 422, 428–435, 507, 538, 545, 546)
	3, Partition purification, tests made both for tertiary and quaternary alkaloids.	(312, 486–488, 498, 509, 511, 535, 542)
D	Extraction of alkalinized sample with organic solvent.	(502–504)
E	Prollius fluid extraction, concentration, addition of acid.	(420, 423, 424, 483, 491, 496)
F	Procedures involving chromatography.	(99, 100, 176, 537)

[a] Only laboratory methods are presented; see earlier discussions for field testing methods. [b] Preliminary test only; additional testing employed.

Since water will extract a number of nonalkaloidal constituents from plants, and because there is a possibility of free alkaloid bases existing in the plant as such and these would be water insoluble, most investigators utilize alcohol (methanol or ethanol) or alcohol–water mixtures as a primary extraction medium. Group *C* test methods involve preparation of an alcohol extract followed by removal of solvent and the addition of dilute acid to dissolve any alkaloids. Some investigators test the resultant acid extract directly (312, 478–482) and stop at this point (group *C-1*). The advantages and disadvantages for this type of testing are similar to those discussed for the group *A* methods (*vide supra*). Others will confirm initial positive reactions following a base–organic solvent–acid extraction. These are the group *C-2* methods which are designed primarily to eliminate substances capable of eliciting false-positive alkaloid reactions. The group *C-1* and *C-2* methods were designed and used most extensively by Wall and co-workers (422), but there are 2 important features that should be discussed concerning these procedures. First, the test involves precipitation of free alkaloid bases from the initial acid extract with NaOH rather than with NH_4OH. Thus, if a majority of the alkaloids in the sample were phenolic in character (highly improbable), the phenolates formed on the addition of fixed alkali would be insoluble in the immiscible organic solvent used for the extraction of the basic alkaloid-containing solution. Subsequent extraction with dilute acid would then result in a solution free from phenolic alkaloids and would therefore not be representative of the true alkaloid content of the sample. A second problem associated with this method was recognized by the workers themselves after screening the first 4000 accessions. Because they were experiencing a lesser number of positive results than would be expected from statistical averages, they increased the concentration of test solution so that 1 ml. would be equivalent to 4.0 Gm. of dry plant material (434, 435). Previous test results in the series (422, 428–433) were reported on solutions which represented only 0.2 Gm. of dry sample. This, of course, made any negative alkaloid test results reported in the first 4000 accessions (422, 428–433) open to question. Recognizing this problem, plants yielding negative results from the latter group, if available, were retested and the results included in reports on the final 2000 accessions (434, 435). The method does not include specific provisions for the detection of quaternary bases, but as indicated previously, modifications could be made so that this procedure would detect these compounds.

Various modifications of group *C-2* methodologies have been proposed in order to detect quaternary alkaloids and report them as a separate group. In group *C-3* methods the aqueous alkaline solution, after extraction with an organic solvent, is treated with a mineral acid until it is distinctly acid to litmus, followed by the subsequent addition of any of the usual alkaloidal precipitants to this acidic solution. It should be emphasized that a weak positive test at this point need not necessarily imply the presence of quaternary alkaloids. To the contrary, a weak test must be expected because of incomplete extraction of tertiary alkaloids with the organic solvent, and would be evidenced by a slight cloudiness of the solution following addition of the reagent. A positive test, on the other hand, would be noted as a definite heavy flocculation or precipitation on addition of the reagent.

Group *D* methods involve the addition of alkali to the drug, followed by extraction with an organic solvent and partition of the concentrated extract with dilute aqueous acid prior to the addition of precipitating reagents. These procedures fail to detect quaternary alkaloids, but the final test solution is relatively free from many substances associated with false-positive reactions.

Extraction of dry plant material with Prollius fluid (ether–chloroform–ethanol–NH_4OH) (25:8:2.5:1) (547), followed by evaporation of the solvent and addition of dilute acid, is the representative procedure for group *E* methods. Webb (423) has indicated that certain plants give negative tests with Prollius fluid, but +4 reactions when acidic aqueous extracts of the same plant were tested (group *A*). He suggests that this is due to a poor solubility of quaternary bases in Prollius fluid. However, several instances wherein the reversal of these positive and negative tests using Prollius fluid and dilute acid extracts were also observed (423). In our laboratories, we found this method to be unsatisfactory when compared with others in an evaluation of testing procedures using plant samples of known alkaloid content (548).

Group *F* methods involve the use of chromatography to detect alkaloids in dry plant material. These allow not only for the detection of alkaloids, but also for an estimate of the number present. In addition, the use of selective chromogenic spray reagents could serve to tentatively classify alkaloids in the samples into general groups. We have described a method

utilizing thin-layer chromatography which requires only small samples, eliminates most compounds suspected of yielding false-positive reactions, and differentiates tertiary and quaternary alkaloids (549). Several alkaloid detecting reagents used in chromatography are presented in Tables IV and V.

The comparative efficiencies of the alkaloid screening procedures of Wall *et al.* (422), Webb (423), Kiang and Douglas (503), Swanholm *et al.* (496, 497), Abisch and Reichstein (486), and Arthur (491) have been studied using 28 plant samples known to contain alkaloids and 8 samples known to be devoid of alkaloids. The latter group included several plants known to yield false-positive alkaloid reactions. Alkaloid-containing plants were selected so that they represented several different chemical classes of alkaloids (549). The surveys under comparison employed groups *A*, *C-1*, *C-2*, *D*, and *E* methodologies. It was determined that the Wall *et al.* (422) and Kiang and Douglas (503) methods were most satisfactory, and that the direct acid extraction method of Webb (422) was the most rapid and also gave acceptable results. The Prollius fluid extraction (422) and the Abisch and Reichstein (486) techniques gave the poorest results, and the latter procedure was quite time consuming (549). All plant samples known to contain alkaloids were detected using the Kiang and Douglas (503), and Webb (423) acid extraction methods. However, these 2 procedures also gave the greatest number of false-positive reactions with the plant samples known to be devoid of alkaloids (549). False-positive alkaloid reactions were completely eliminated by use of either the Wall *et al.* confirmatory test (422) or the Abisch and Reichstein method A (486). Other studies have shown that significant differences exist in these methods with regard to their ability to remove alkaloids for testing from plant material (454).

Screening for Heterosides (Glycosides).—Heterosides are organic compounds in which a hemiacetal linkage usually connects the anomeric carbon of a sugar (glycone) with an alcohol or phenolic hydroxyl of a second nonsugar molecule (aglycone). This type of linkage gives rise to the so-called *O*-heterosides (*e.g.*, salicin), the most common type of heteroside found in plants. If the anomeric carbon of the glycone is attached to an aglycone through sulfur, the *S*-heterosides are formed (*e.g.*, sinigrin). A third group are the *N*-heterosides which involve attachment of the glycone to an amino group of an aglycone (*e.g.*, vicine, crotonoside). Finally, the C-heterosides involve a carbon to carbon linkage of glycone and aglycone (*e.g.*, aloin).

As a general rule, plant heterosides are easily hydrolyzed with dilute acids or appropriate enzymes. The C-heterosides are a notable exception, as they are resistant to the usual type of acid hydrolysis, and require ferric chloride for this purpose.

A number of different sugars are known to occur in plants in combination with an equally large number of diverse aglycones. Paris (550) has recently reviewed plant heterosides with particular reference to the types and distribution in plants.

In most instances, the biological activity of heterosides can be attributed to the aglycone moiety. The glycone is mainly associated with the degree or modification of activity, primarily induced by the aglycone. However, the cardiac heterosides can be pointed out as a group that have no useful biological activity unless the heteroside is intact (310). Thus, we have the economically important saponin heterosides and the medicinally useful anthraquinone, flavonoid, cyanogenetic, *iso*thiocyanate, and cardiac groups.

From a chemical point of view, there are 3 parts of the heteroside molecule that can be used as a means of detecting this group of compounds in plant material. First, the hemiacetal linkage between aglycone and glycone is usually not associated with biological activity, nor can it be associated with any specific aglycone.[2] This part of the molecule does not appear attractive as a means of detecting plant heterosides. Because of the usual correlation of biological activity with the aglycone moiety of heterosides, and because this part of the molecule often has chemical properties amenable to ready detection, most investigators have used it as a means of screening plant material indirectly for heterosides.

If, however, heterosides must be intact to exert their potential biological activity, it would appear most fruitful to detect the hemiacetal linkage in plant extracts as an identifying feature of the presence of heterosides. Several investigators have proposed methods to accomplish this, but a lack of published applications of these to the screening of plants for heterosides, attests to their complexity or inefficiency. Bourquelot (551) proposed a method for detecting and identifying heterosides based on the determination of an "Enzymolytic Index of Reduction" obtained by measuring the optical

[2] The notable exception is concerned with deoxysugars commonly found only in combination with cardiac heterosides.

rotation of a heteroside-containing plant extract before and after hydrolysis with specific enzymes. Although the method has some value, it is time consuming and requires large amounts of plant material; therefore, it would be difficult to adapt to a large-scale screening program. Bliss and Ramstad (552), devised a simple procedure that could be adapted for routine screening. It consists of (*a*) separation of the heterosides in an extract by paper chromatography, (*b*) hydrolysis of the heterosides on the chromatogram with proper enzymes (*i.e.*, α-glucosidase–invertin; β-glucosidase–emulsin), and (*c*) location of the reducing sugars formed on the chromatogram by means of an appropriate reagent spray. This method appears to be least objectionable of many proposed. However, it will detect only those heterosides for which the selected enzymes have a hydrolytic specificity. Also, optimal reaction conditions such as time, temperature, and pH would have to be determined for a large number of substrate heterosides to propose operating conditions that would allow detection of the greatest number of compounds. Janot *et al.* (553) and Paris (554) have suggested chromatographic methods for detecting heterosides similar to the method of Bliss and Ramstad, but acid hydrolysis of the sample is included to supplement the action of enzymes. Other methods have been proposed, but either they have not been applied successfully to plant samples, or certain limiting factors make them of doubtful value for general screening (555, 556).

Knapp and Beal (557) have proposed a method involving (*a*) the selective extraction of heterosides from plant material using 80% ethanol, (*b*) oxidation of the free sugars in the extract to their corresponding carboxylic acids so that they will not be detected after hydrolysis of the heterosides, (*c*) hydrolysis of the heterosides in the extract using 0.15 *N* sulfuric acid and heat (100°) and (*d*) detection of hydrolyzed glycones by means of paper chromatography. The major objection to this procedure is that holosides, especially sucrose which is widespread in plants, are detected; thus, the method is of decreased value.

Abisch and Reichstein (486) have utilized a rather simple procedure which involves the preparation of an extract devoid of free sugars, hydrolysis of the extract with the Kiliani acid mixture, and testing of the hydrolysis products with Fehling's solution for evidence of reduction. These investigators have pointed out the nonspecificity of the test; however, in a broad screening program, false-positive reactions must be accepted, especially in the absence of a completely acceptable and specific method of detection.

It does not appear that adequate methodology has been developed to allow for an extensive screening of plants for heterosides based on the approaches described above. As indicated previously, the majority of studies involving a search for heterosides in plant material have been concerned with tests designed to detect specific aglycones. The more important of these will now be considered.

Screening for Saponins and Related Compounds

Several types of compounds must be considered whenever saponin testing is to be conducted. Of major import are the steroidal and triterpenoid saponins and their respective sapogenins, as well as saturated sterols, saturated terpenes, diterpenes, and other steroidal plant constituents (*e.g.*, cardenolides). The economic importance of steroidal sapogenins, mainly because of their facile conversion to the medicinally useful steroid hormones, has been reviewed by Correll *et al.* (11). Discussions concerning this group of compounds will be directed primarily at the detection and/or differentiation of steroidal saponins from other types of saponins and polycyclic phytoconstituents.

A number of surveys have been conducted which have been designed to detect saponins in plant material (99, 100, 168, 422, 428–435, 478–483, 490–492, 494, 499, 506, 507, 513, 529, 558–580). Saponins have several characteristic properties that can be used as a basis for simple detection tests. (*a*) They are all capable of hemolyzing red blood cells, (*b*) in aqueous media they will produce a characteristic honeycomb froth which persists for at least 30 min. after vigorous shaking of the solution; (*c*) they are toxic for fish, causing paralysis of the gills; and (*d*) they produce characteristic color reactions in the Liebermann-Burchard test. All of these properties have been utilized in one or more screening tests for the detection of saponins in plant material, and each merits discussion to show the limitations and value of these test procedures (Table VIII).

All known triterpenoid and steroidal saponins are hemolytic (584, 585), as undoubtedly are certain other plant constituents. The former group occurs both as the heteroside and as free triterpenes, whereas steroidal saponins are never found as free sapogenins in plant material (584, 585). This is an unusual phenomenon since specific steroidal saponases are known to be present in steroidal saponin-containing plants

(586). Since all saponins are soluble to some extent in 80% alcohol, they are usually extracted with this solvent (584, 585), and if such a plant extract is mixed with a standardized red blood cell suspension (585) and hemolysis of the cells takes place, it can be assumed that saponins are present. On the other hand, terpenoid and steroidal saponins act similarly in this respect and cannot be differentiated on this basis alone. Wall *et al.* (585), Walens *et al.* (587), and Rothman *et al.* (588) have developed standard procedures which have been successfully used by many investigators for the detection and estimation of steroidal sapogenins, and which differentiate triterpenoid from steroidal types. The procedure involves (*a*) hemolytic detection of saponins in the plant extract (585), (*b*) isolation of crude sapogenins following hydrolysis (585), and (*c*) subjecting the crude sapogenin acetates to infrared (585) or ultraviolet (587) spectral analysis. Initially, the extraction procedure eliminates to a great degree the starch, sugars, and protein which, if present, would produce troublesome tars as a result of the acid hydrolysis (588). The presence of these materials in the extract would necessitate larger amounts of acid, with subsequent destruction of some sapogenin. It has been determined by using the recommended extraction procedure (585), that 2 *N* HCl in alcohol at reflux temperature or 0.5 *N* HCl under pressure will completely hydrolyze saponins (584, 588). Characteristic infrared and ultraviolet absorption spectra of the hydrolysates then serve to indicate whether the saponins causing hemolysis in the sample are steroidal or triterpenoid.

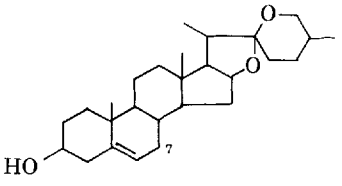
The appearance of a characteristic honeycomb froth, which persists for at last 30 min. after shaking an aqueous boiled (3–5 min.) mixture containing the plant material, is presumptive evidence for the presence of saponins. This method of detection is rapid, simple, and requires little equipment, but it will not differentiate triterpenoid from steroidal saponins. It has been used, however, by several investigators (Table VIII). If only a small froth is produced by this treatment, which is stable for only a few minutes, proteins, certain plant acids, or a low concentration of saponin may be the cause (558). Evidence exists that the froth test is not infallible since the saponin of *Castanospermum australe* is an active hemolytic agent at a dilution of 1:20,000; however, at this dilution no frothing occurs (558). The addition of aqueous sodium carbonate to a boiled aqueous plant extract which froths poorly, or not at all, may result in the production of a stable and dense froth. If this occurs, the presence of free acids (*e.g.*, stearic acid, diterpene acids, triterpene dicarboxylic acids) is indicated (558).

TABLE IX.—DIFFERENTIATION OF POLYCYCLIC SUBSTANCES IN PLANTS

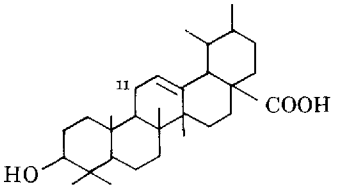
Hemolysis Test	Froth Test	Liebermann-Burchard Test	Substances Present
+	+	+ Blue or green	Saponins, probably steroidal.
+	+	+ Red, pink, purple or violet	Saponins, probably triterpenoid.
+	+	− Pale yellow	Saponins, possibly heterosides of saturated sterols or saturated triterpenes.
±	−	+ Red, pink, purple or violet	Saponins absent, free triterpenes, diterpenes, sterols or related polycyclic substances present.
−	−	− Pale yellow	Saponins absent, also unsaturated triterpenes, sterols, etc., absent, but may contain saturated sterols or saturated triterpenes.
−	+[a]	± Pale yellow, red, pink, purple or violet	Saponins absent, probably free diterpene acids.

[a] Froth only evident after addition of sodium carbonate and shaking.

Some investigators have included a test for unsaturated sterols in their phytochemical surveys. In most instances, the Liebermann-Burchard (L-B) test[3] has been used to detect this class of compounds (422, 428–435, 478–483, 491, 558, 616), and it has been used to advantage in the differentiation of triterpenoid and steroidal saponins (558). According to Simes *et al.* (558), blue or blue-green colors are formed in the L-B test with steroidal saponins, and red, pink, or purple colors result if triterpenoids are present. However, when these workers applied the L-B test either directly to powdered plant material, or to a solution of extracted material, they noted that there was variation in the colors produced, depending on the manner in which the test was conducted. For example, ursolic acid (triterpenoid) gives a blue-green color in solution, but if the test is applied directly to solid material, the colors noted are only purple or violet (558). Simes *et al.* (558) do not comment on the time required to observe these characteristic reactions, whereas Wall *et al.* (422), using chloroform extracts of plant material, point out that interfering substances such as carotene and xanthophylls produce immediate color changes in the L-B test, as also do saturated sterols. However, when interfering substances are absent, unsaturated sterols give a minimal color density at the start of the test, and slowly reach a maximum after about 15 min. This delayed color reaction has also been observed by others (589, 591). Brieskorn and Herrig (592), in an investigation of the mechanism of the L-B reaction, found the following features essential for color formation. In the steroids, two conjugated double bonds in ring B, or one double bond and an unhindered methylene group at C_7 which can undergo oxidation and dehydration, are essential. In pentacyclic triterpenes, however, it is the methylene group at C_{11} in ring C that is involved. Steroid esters were shown to give a more intense color reaction in the L-B test than the corresponding alcohols, while the opposite was true for pentacyclic triterpenes and their esters.



Steroid Sapogenin



Pentacyclic Triterpenoid Sapogenin

The use of the froth test, in conjunction with the L-B reaction, has been found useful for the detection and differentiation of triterpenoid and steroidal saponins, triterpenoid sapogenins, free sterols, and other polycyclic substances (558). An outline of methods used for these identifications using the froth test, L-B reaction, and hemolysis, is presented in Table IX.

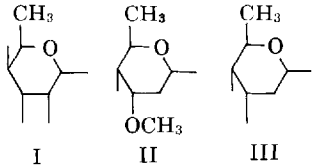
Willaman and Wadley (593) have found an interesting correlation existing between *Agave* and *Dioscorea* species with respect to the presence or absence of unsaturated sterols and steroidal saponins. They point out that strong positive sterol (L-B) tests on extracts from these 2 genera usually indicate an absence or very low steroidal saponin content. However, with *Yucca*, and undoubtedly with other groups of plants, no such association was indicated.

[3] The L-B test is usually conducted by adding a small amount of acetic anhydride–sulfuric acid mixture (19:1) to a solution of the sterol in suitable anhydrous solvent. A history of the test has been given by Dam (590).

It would appear that chromatographic differentiation of polycyclic substances in plant extracts could be used to advantage, especially since the advent of thin-layer chromatography which allows the use of corrosive reagents, since a great variety of steroid detecting reagents are available, *e.g.*, vanillin–phosphoric acid (594, 595), antimony trichloride (596–600), antimony pentachloride (596, 601), sulfuric acid (602), 50% sulfuric acid (603, 604), sulfuric acid–acetic anhydride (599, 605), chlorosulfonic acid (599), silicotungstic acid (596), phosphotungstic acid (606), zinc chloride (607), anthrone (608), furfural–sulfuric acid (609), sodium nitroprusside (610), Nessler's reagent (611), Millon's reagent (596), tetrazolium blue (612), phosphomolybdic acid (596, 613, 614), and Dragendorff's reagent (341). Axelrod and Pulliam (615) have developed several micro-methods for the detection of characteristic functional groups on the steroid nucleus which can be adapted to paper or thin-layer chromatography and which should be of great value in phytochemical screening.

Cardiac Glycosides

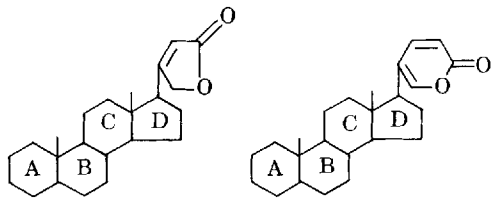
The importance of cardiac glycosides as therapeutic agents requires no elaboration. Their status in medicine, however, is not reflected in the number of published efforts to seek new and better agents of this type in the plant kingdom. As previously mentioned, a few surveys have been conducted in which plant extracts were evaluated for cardiotonic activity either through *in vitro* or *in vivo* biological tests (311–313). In the case of cardiac glycosides, the minimum structural features required for biological activity are so well defined that the substitution of a strictly chemical means of detection is an accepted procedure. All cardioactive glycosides are classified as steroids (sterols), having the cyclopentanoperhydrophenanthrene nucleus, an α-β-unsaturated lactone ring (5- or 6-membered) at C_{17}, a β-oriented hydroxyl at C_{14}, a *cis* fusion of the C and D rings at C_{13}-C_{14}, and the attachment at C_3 of one or more sugars, usually deoxyhexomethyloses (310). A 5-membered unsaturated lactone at C_{17} categorizes the glycoside



I II III

I, L-Rhamnose
II, D-Cymarose
III, D-Digitoxose

as a cardenolide, whereas a 6-membered unsaturated lactone at the same position exemplifies the bufadienolides. Of these 2 groups the cardenolides are the most frequently encountered and the most useful as therapeutic agents.



Cardenolides Bufadienolides

Detection of cardiac glycosides in plants has been effected by means of chemical tests applied either directly to a crude or semipurified extract, or following chromatographic separation of the glycosides. The latter method is to be preferred since a judicious selection of solvent systems and chromatographic conditions will free the glycosides from extraneous plant substances that either interfere with or mask the evidence of positive chemical tests.

Several methods for preparing an initial extract of the plant material have been reported, and methanol, 85% ethanol, or 80% ethanol appear to be the most useful solvents. The latter is advantageous since starch will not be extracted (617). Although a certain amount of enzymatic degradation of the native glycosides will occur, either as a result of the drying procedure or because of some processing step, this will not usually affect qualitative methods of detection since most of these are applicable to both native and secondary glycosides, as well as their aglycones. Bieleski (618) has considered the problem of halting enzyme action when extracting plant tissues, with respect to plant phosphatases, and although the situation may not be analogous, the general precautions and approach to the problem are worthwhile. The cardenolide detection method of Krider *et al.* (313) employs a paper chromatographic separation of a semipurified extract prior to the application of chemical detection methods. This purification is effected by means of lead hydroxide precipitation of nonglycosidic interfering substances. Certain extracts encountered in routine screening work, however, would require little purification, a step that is often time consuming and tedious.

Chemical tests applied to the detection of cardiotonic glycosides and/or aglycones are carried out by applying one or more reagents to a chromatogram of the extract (619–635) or to a piece of filter paper on which the extract was applied (486–488), or directly to the liquid extract (312). The available reagents are designed to detect

TABLE X.—CHROMOGENIC REAGENTS USED FOR THE DETECTION OF CARDIAC GLYCOSIDES

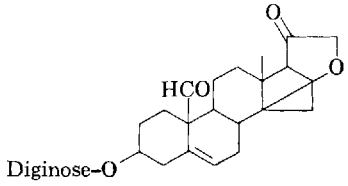
Reaction Site[a]	Common Name of Test	Major Constituent(s) of Reagent	Ref.
A	Baljet	2,4,6-Trinitrophenol–alkali	(630, 637, 833, 834)
A	Kedde	3,5-Dinitrobenzoic acid–alkali	(313, 627, 635, 638, 835)
A	Raymond	*m*-Dinitrobenzene–alkali	(630, 639, 640, 835)
A	Legal	Sodium nitroprusside–alkali	(630, 639, 641, 836)
A		1,3,5-Trinitrobenzene–alkali	(837, 838)
A		2,4-Dinitrodiphenylsulfone–alkali	(846)
A		1,2-Naphthoquinonesulfonate–alkali	(839)
A		Tetradinitrophenyl–alkali	(631)
A		*o*-Dinitrobenzaldehyde	(639)
A		1,3-Dinitrobenzaldehyde	(840)
A		Tetranitromethane	(841)
B	Kiliani	Ferric sulfate–sulfuric acid	(644)
B	Keller	Ferric chloride–acetic acid	(645, 842)
B	Keller-Kiliani	Ferric chloride–sulfuric acid–acetic acid	(632)
B	Pesez	Xanthydrol	(647, 649)
B	Tollens	Silver nitrate–ammonia	(646, 836)
B	Langejan	Orcinol–hydrochloric acid	(843)
B		Naphthoresorcinol–hydrochloric acid	(639)
B		*p*-Dimethylaminobenzaldehyde–phosphoric acid	(844)
C	Liebermann	Acetic anhydride–sulfuric acid	(589, 64)
C	Carr-Price	Antimony trichloride–acetic anhydride	(630, 649, 845)
C		Trichloracetic acid	(629, 630)
C		Trichloracetic acid–chloramine	(629, 630)
C		Sulfuric acid–ferric chloride–H_3PO_4	(847)
C		Sulfuric acid, 84%	(848)

[a] A, unsaturated lactone; B, desoxy sugar; C, steroid nucleus.

either the unsaturated lactone moiety at C_{17}, the deoxy sugar at C_3, or the steroid nucleus, the latter being the least specific for cardiotonic glycosides. These reagents are listed in Table X, together with common names frequently associated with tests involving their usage.

Most frequently utilized for the qualitative, as well as the quantitative evaluation of cardiac glycosides, have been the Baljet (2,4,6-trinitrophenol) (636, 637), Kedde (3,5-dinitrobenzoic acid) (638), Raymond (*m*-dinitrobenzene) (639, 640), or the Legal (sodium nitroprusside) reagents (641) which react with active methylene groups as found in the C_{17}-unsaturated lactone moiety (642, 643). These reagents give orange, purple, blue, and violet colors, respectively, with cardiac glycosides. Also utilized, but to a lesser extent, are reagents that react with the deoxysugar moiety of cardiac glycosides, negative tests of course being expected for aglycones. These include the Kiliani (ferric sulfate–sulfuric acid) (644), Keller (ferric chloride–acetic acid) (645), Tollens (silver nitrate–ammonia) (646), and Pesez (xanthydrol) (647) reagents. For detection of the steroid nucleus, the Liebermann (acetic anhydride–sulfuric acid) (648), and Carr-Price (antimony trichloride–acetic anhydride) (649) reagents are commonly used. Recent and thorough discussions of cardiac glycoside-detecting reagents have been published by Jensen (630), Rosenthaler (650), Cerri (651), and Frerejacque and DeGraeve (652). The latter paper is of particular value since it tabulates most of the useful reagents, gives formulas for their preparation, techniques for use, and presents remarks concerning the specificity and limitations of each.

In a phytochemical screening program for cardiac glycosides, initial positive tests on plant extracts using any one reagent should be confirmed with reagents specific for the 2 additional reactive sites (*vide supra*). For example, an initial positive Keller reaction is indicative only of the presence of a deoxy sugar. This should be followed by a second test which might be the Liebermann reaction for the steroid nucleus. Assuming that a positive reaction was also noted, a third and confirming test might be the Legal or Kedde test which denotes an unsaturated lactone at C_{17}. Positive tests with all 3 reagents offer reasonable assurance of the presence of cardioactive glycosides. If a negative test was noted with the Legal or Kedde reagent, in conjunction with positive reactions from the Liebermann and Keller tests, the presence of digitanol



Diginin—A Digitanol Glycoside

glycosides (diginin, digifolein, etc.) would be indicated since they lack the α-β-unsaturated lactone at C_{17} of the normal cardioactive glycosides and as a group are pharmacologically inactive substances (653).

Of particular importance in the interpretation of these tests is the observation of chromogenic reactions which may be transient, those which may change rapidly, or be dependent to a great degree on concentration of cardiac glycoside present. Certain of the older literature presents color reactions which are erroneous and confusing since the purity of either the glycosides being investigated, or the chemicals used in the reagents, must be questioned. Cook (589) has reviewed the color reactions of steroids in the Liebermann-Burchard reactions and presents a variety of possible colors for these compounds. In addition, he points out that in many instances, the chromogenic reactions are often delayed.

Using the tests enumerated herein may result in a few false-positive reactions for cardiac glycosides since deoxy sugars, α-β-unsaturated lactones, and steroids exist in other molecules found in plants (310). However, the use of tests for all 3 of these groups should greatly reduce the incidence of false-positive interpretations.

Table XI presents a summary of several phytochemical surveys that have been published concerning the detection of cardiac glycosides in a number of different plants. These and other data (310) point out that cardiac glycosides are present in at least 39 genera of 14 plant families.

Flavonoids and Related Compounds

The flavonoids are plant pigments based on the C_6-C_3-C_6 carbon skeleton as found in flavones, flavonols, isoflavones, flavonones, catechins, leucoanthocyanins, anthocyanins, aurones, and chalcones (Fig. 3). Although more than 33 different biological activities had been reported for some 30 of 137 known natural flavonoids up to the year 1955 (415), rutin is still the major useful member of this class of compounds as a medicinal agent. Several reviews on the biological activities and place in drug therapy of the flavonoids have been published (342, 344, 345, 415–418, 655), as have essays on their economic nonmedicinal applications (656–658). More recently, reports concerning the antiviral (659), anti-inflammatory (660), and cytotoxic (144, 661) activities of flavonoids have served to make them an exciting group of compounds for the researcher interested in biologically active phytoconstituents.

Flavonoids are widely distributed throughout the plant kingdom in the form of aglycones as well as heterosides. However, the latter are most frequently found in flowers, fruits, and leaves, whereas the former are usually most abundant in woody tissues. Some compounds are never found as heterosides, such as the nonhydroxylated and fully alkylated flavones, nobiletin, tangeretin, and meliternatin, and the polymethoxychalcone, pedicellin. These flavonoids have no hydroxyl groups with which a sugar residue can combine. It is difficult to state a general solubility rule for flavonoids because they range from water-soluble, ether-soluble (highly methylated nonheterosides), to ether- and alcohol-soluble (hydroxyflavone, flavanone, and isoflavone aglycones), to water-soluble, ether-insoluble (heterosides with up to 3 sugars) forms. However, when fresh plant material is extracted, methanol or ethanol will usually remove most flavonoids. Both flavonoid heterosides and aglycones are, as a general rule, insoluble in petroleum ether, and advantage can be taken of this fact to defat the sample prior to alcohol extraction. When dry plant material is to be extracted, several solvents should be sequentially used to insure complete removal of all flavonoids; however, in a screening program this is not usually feasible. Wall *et al.* (422, 428–435) have used 80% ethanol routinely in screening some 6000 plant accessions for flavonoids,

the majority of the samples consisting of dry plant material.

A number of specific color reactions for various types of flavonoids have been reported that could be adapted to screening large numbers of plant samples, but specificity of a sort is usually not desirable for the initial testing. One of the most useful general tests is the so-called cyanidin reaction of Willstatter (662) which will detect compounds having the γ-benzopyrone nucleus. To an alcoholic solution of plant material is added a small piece of magnesium ribbon, followed by the dropwise addition of concentrated HCl.

Colors ranging from orange to red (flavones), red to crimson (flavanols), crimson to magenta (flavanones), and occasionally to green or blue are taken as evidence for a positive reaction for either the aglycone or heteroside. Colors usually develop within 1–2 min. following addition of the acid and are, of course, subject to variation in intensity depending on the concentration of flavonoid present in the sample (663). Problems often arise in the interpretation of positive tests when the plant extract being tested is highly pigmented. Bryant has modified the method so that heterosides and their aglycones can be differentiated (664). Xanthones have also been observed to give a positive cyanidin reaction (663).

Chalcones and aurones will not give the cyanidin reaction under the reducing conditions of this test. Direct addition of concentrated HCl to an ethanol extract of plant material containing either of these types of flavonoids, however, will result in an immediate red color (663).

Anthocyanins can be identified in plant material by extraction with cold 1% HCl followed by boiling and observation of the color at the boiling point. These plant pigments vary in color from orange-red to blue-red. Robinson and Robinson (665–668) first introduced this test which, through the use of immiscible solvent extractions, can differentiate many of the anthocyanins. A number of surveys for anthocyanins have been conducted, representing hundreds of plant species (665–680), and representative reviews on the subject of anthocyanins have been published (681–684).

Leucoanthocyanins can easily be detected by the method of Bate-Smith and Metcalfe (685) which has been utilized by Cain *et al.* (478–482) in their extensive screening of the New Zealand flora. The test involves digesting a small sample of plant material with 2 *N* HCl in 1-propanol for 15–30 min. A slow development of a strong red or violet color is indicative of a positive reaction.

Catechins give a blue or green color with ferric

chloride, but this test is of little value when crude plant extracts are being evaluated because of many other compounds that can give similar tests. Extraction of plant material with benzene, followed by extraction with ether, will yield a catechin-containing ethereal extract. Chromatography of this extract, followed by treatment of the chromatogram with 3% ethanolic *p*-toluenesulfonic acid and warming, will yield yellow spots if catechins are present (686).

A summary of flavonoid color reactions, following treatment with various reagents on paper chromatograms, is presented in Table XII.

In addition to the specific flavonoid surveys cited above, others of a more general nature have been published (99, 506, 507, 687–692). General review articles are available which should be of value to those who are interested in more specific information on testing for individual flavonoids such as the catechins (686), isoflavonoids (693–695), flavones (695–697), flavonols (697–698), dihydroflavonols (699), flavanones (700), chalcones (700), aurones (700), leucoanthocyanins (701), and the flavonoids generally (702–709).

Tannins

Two groups of phenolic constituents, hydrolyzable and condensed, comprise the tannins, substances which are important economically as agents for the tanning of leather, and for certain medicinal purposes. More recently, evidence has been presented in support of their potential value as cytotoxic and/or antineoplastic agents (146).

Hydrolyzable tannins are yellow-brown amorphous substances which dissolve in hot water to form colloidal dispersions. They are astringent and have the ability to tan hide. Chemically speaking, they are esters which can be hydrolyzed by boiling with dilute acid to yield a phenolic compound, usually a derivative of gallic acid, and a sugar. These are often referred to as pyrogallol tannins.

Condensed tannins (catechin tannins, phlobatannins) are polymers of phenolic compounds related to the flavonoids and are similar in general properties to the hydrolyzable tannins, but are not very soluble in water, and following treatment with boiling dilute acid, red-brown insoluble polymers known as phlobaphenes or tannin-reds are formed.

Tannins are detected most simply in plant extracts by the use of the so-called gelatin–salt block test (710) which has been utilized extensively in the phytochemical surveys of Wall *et al.* (422, 428–435). This test employs aqueous extracts prepared from 80% ethanol extracted plant material. A sodium chloride solution is added to one portion of the test extract, of 1% gelatin solution to a second portion, and the gelatin–salt reagent (710) to a third portion. Precipitation with the latter reagent, or with both the gelatin and gelatin–salt reagents is indicative of the presence of tannins. If precipitation is observed only with the salt solution (control), a false-positive test is indicated. Positive tests are confirmed by the addition of ferric chloride solution to the extract and should result in a blue, blue-black, green, or blue-green color and precipitate. Hoch (711) has applied some 33 different classical tannin detecting reagents to several tannin extracts; however, the nonspecificity of many of these would render them im-

practical for use in general phytochemical screening work.

Several phytochemical surveys for tannins in plants of Argentina (712), Bulgaria (713), China (495), Japan (168), Mexico (507), Nigeria (99, 100), Pakistan (714), Tibet (513), the U.S.S.R. (715–718), as well as from hundreds of additional miscellaneous plants (2, 5, 422, 428–435, 529), have been conducted. Happich *et al.* (2) have emphasized, from a practical viewpoint, the requirements necessary in a tannin for it to be of commercial value.

Coumarins

Coumarins are benz-α-pyrone derivatives found widely distributed in plants; however, they occur most frequently in members of the *Gramineae, Orchidaceae, Leguminosae, Umbelliferae, Rutaceae,* and *Labiatae.* They rarely, if ever, occur in the *Liliaceae, Onagraceae, Pinaceae,* or *Cactaceae.* The medicinal value of certain coumarin derivatives (bishydroxycoumarin, 8-methoxypsoralen) is well known; however, according to Soine (419), the full range of biological activities for these compounds is not appreciated by most investigators. Reviews by Bose (719) in 1958, and more recently by Soine (419) in 1964, have served to point out the biological activities of coumarins, a group which appear most interesting because of their anticoagulant, estrogenic, dermal photosensitizing, antibacterial, vasodilator, molluscacidal, anthelmintic, sedative and hypnotic, analgesic, and hypothermal effects (419, 719).

Several types of coumarin derivatives have been found in plants, the substituted coumarins, furanocoumarins, pyranocoumarins, benzocoumarins, phenylcoumarins, and others.

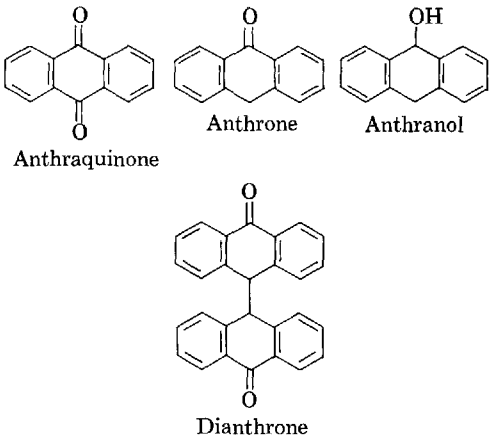
Coumarin itself can be easily detected in plant material simply by placing a small amount of moistened sample in a test tube and covering the tube with filter paper moistened with dilute sodium hydroxide solution. The covered test tube is then placed in a boiling water bath for several minutes, the paper removed and exposed to ultraviolet light. If coumarin is present, a yellow-green fluorescence appears within a few minutes (720). This procedure, however, is applicable only to coumarin and related volatile compounds. Most methods that appear useful for detecting coumarins in plant material are based on extraction of the plant sample, followed by chromatography of the extract and revelation of the coumarins with spray reagents such as diphenylboric acid, β-aminoethyl ester (721), KOH and diazotized sulfanilic acid (722), or uranyl acetate (723).

Plant material is best extracted by first quick-washing it with ice cold petroleum ether to remove lipids. Most coumarins are insoluble in this solvent, especially if it is kept cold. The defatted sample can then be extracted with warm, dilute alkali hydroxides which form the water-soluble coumarinate. Neutral organic impurities then are extracted with ether and on acidification of the aqueous coumarinate solution, the parent coumarin reforms and is removed by ether extraction. Acidic impurities are then removed by extraction with sodium bicarbonate solution. The ether solution can then be concentrated and used for chromatographic studies with specific reagents (*vide supra*), or as a spot test in which a drop of concentrate is treated, in a porcelain dish, with a drop of saturated solution of hydroxylamine hydrochloride in alcohol and 1 drop of saturated alcoholic solution of KOH. This mixture is heated over an open flame until it begins to bubble. After cooling, 0.5 *N* HCl is added to acidify the mixture, followed by a drop of 1% ferric chloride solution. A positive test consists of a violet color and is indicative of the presence of lactones (724). Other tests (725–728) have been utilized for the detection of coumarins in plant materials; however, only a slight interest has been noted in testing for coumarins, as evidenced by limited inclusion of tests for this group in phytochemical surveys (494, 513, 616).

Anthraquinones

The largest group of naturally occurring quinone substances are the anthraquinones. Although they have a widespread use as dyes, their chief medicinal value is dependent upon their cathartic action. They are of restricted distribution in the plant kingdom and are found most frequently in members of the *Rhamnaceae, Polygonaceae, Rubiaceae, Leguminosae,* and *Liliaceae.* As found in plants, they are usually carboxylated, methylated, or hydroxylated derivatives of the anthracenes, anthrone, anthranol, anthraquinone, or dianthrone. Hydroxylated anthracenes often occur as heterosides linked with various sugars through one of the hydroxyl groups (*O*-heterosides). Other types of anthracene heterosides are represented as C-heterosides in which the sugar and aglycone are linked by a carbon to carbon bond.

For the qualitative detection of anthraquinones in plant material, the Borntrager reaction, as modified by Kraus (729), appears to be simplest to perform in the application to phytochemical screening. The powdered sample (0.3 Gm.) is boiled for a few minutes with 0.5 *N* KOH (10 ml.) to which is added 1 ml. of dilute hydrogen per-



oxide solution. After cooling, the mixture is filtered and 5 ml. acidified with 10 drops of acetic acid. This acidulated mixture is then extracted by shaking with 10 ml. of benzene in a separator and the benzene layer takes on a yellow color. A 5-ml. sample of this benzene extract is shaken with 2.5 ml. of ammonium hydroxide, and a positive reaction for the presence of anthraquinones is evidenced by the formation of a red color in the alkaline layer. Normally, if C-glycosides are present in a sample being evaluated for anthraquinones, they will not be detected by the usual Borntrager reaction, as C-glycosides require special methods for cleaving the sugar from the aglycone. This can be done with ferric chloride, sodium dithionate or, as described above, with peroxide in an alkaline medium. It has been shown that this method results in a mixture of products (730); however, this is not a disadvantage for a general screening test. Other simple and rapid spot tests, which involve the direct addition of a reagent to the solid sample (powdered drug), have been described. They should be useful in phytochemical screening (731, 732), but to date have not been shown to be applicable for this type of work.

Phytochemical surveys for anthraquinones have been found only infrequently in the literature (494, 513).

Cyanogenetic Glycosides

Compounds in plants that liberate hydrocyanic acid (HCN) following hydrolysis are of major importance because of their potential danger as poisons to livestock as well as humans (733–735). Also, the use of at least one cyanogenetic glycoside, (−)-mandelonitrile-β-glucuronoside (laetrile), for the treatment of human neoplastic disease has been suggested (736), but this remains as a controversial subject. Should cyanogenetic glycosides prove useful in this respect, the plant kingdom should be expected to be a source for new and similar compounds.

It is generally recognized that a small amount of HCN occurs free in plants, but that the greatest amount is combined in glycosidic linkage (737). Although high concentrations of cyanogenetic glycosides have been reported present in the seeds of only a few species of plants, *i.e.*, those of *Rosaceae*, lesser amounts have been reported in almost every plant tissue from certain other plants. No general rule can be established with regard to the distribution of these compounds in various plant tissues. Cyanogenetic compounds are widely distributed, having been detected in more than 50 natural orders of plants, including ferns, basidiomycetes, and phycomycetes (737). Wherever cyanogenetic compounds are found in plants, specific hydrolytic enzymes are also known to exist, although a few exceptions are known (737). Also, there is some evidence that emulsin, ordinarily thought to be specific as a catalyst for the hydrolysis of all cyanogenetic glycosides, will hydrolyze certain of these compounds only with difficulty, and some are known to be unreactive in the presence of this enzyme (737).

Methods for the qualitative as well as quantitative determination of cyanogenetic glycosides in plant and animal tissues have been extensively reviewed by van der Walt, who considers such methods as the Guignard, Vortman, phenolphthalein, guaiac–copper, benzidine acetate–copper acetate, iodine–starch, Prussian blue, and the ferrous–uranic nitrate tests (735). The most widely used of these tests for the qualitative detection of cyanogenetic glycosides in plants has been the Guignard test. According to van der Walt (735), it is nonspecific since any volatile reducing agent such as hydrogen sulfide, sulfur dioxide, or aldehydes will give a positive test. Volatile reducing agents in plant extracts, however, are not frequently encountered and the Guignard test appears to be the simplest, most rapid, and accurate means by which the presence of cyanogenetic compounds can be established in plant specimens. This test, as described by Burnside (733), is conducted by placing about 2 Gm. of moist shredded plant material or crushed seeds in a small test tube, followed by the addition of 4 drops of chloroform (to enhance enzyme activity, see *reference 738*). Sodium picrate solution (5 Gm. Na_2CO_3, 0.5 Gm. picric acid, water *q.s.* 100 ml.; stable for 4 months if kept cool and well stoppered) is prepared and strips of filter paper are saturated with the solution. The strips then are blotted dry and inserted between

split cork stoppers which are then introduced into the neck of the test tube containing the reaction mixture. Care should be exercised to insure that the paper strips do not touch the inner sides of the test tube. The test tube and contents are then warmed at 30–35° for up to 3 hr. Large concentrations of HCN are detected within 15 min. as evidenced by a change in color of the yellow picrate test paper to various shades of red. Absence of a red color after 3 hr. is taken as a negative test.

Plant materials not analyzed for HCN at the time of collection can lose a large amount of their cyanogenetic glycoside content through spontaneous hydrolysis. Briese and Couch have shown that if chopped fresh plant material is stored in an aqueous mercuric chloride solution (1 Gm. $HgCl_2$ for each 100 Gm. of fresh plant material), the cyanogenetic glycosides present in the preserved specimens will remain stable for up to 6 months, presumably through an inactivation of the hydrolytic enzymes (739). van der Walt (735), however, claims that the relationship of mercuric chloride to the water volume in the preservative is more important than the mercuric chloride–plant material ratio for glycoside stabilization.

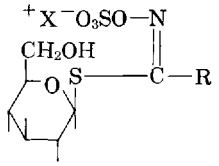
To insure that hydrolysis of cyanogenetic glycosides will indeed take place, some investigators have added emulsin (or other specific enzymes) to all plants being evaluated for the presence of these compounds. Other investigators have carried out the hydrolysis in the presence of buffer (740). Although it has been determined that cyanogenetic glycosides are hydrolyzed by dilute acids to yield HCN, this method has not been applied to the screening of plants for cyanogenetic glycosides (737). Concentrated mineral acids are to be avoided since HCN is not released under these conditions (737).

Although it appears that the Guignard test is adequate for screening plants for cyanogenetic glycosides, the precautions enumerated above should be taken into consideration if the results are to be meaningful.

Several screening programs have been conducted for the presence of cyanogenetic compounds in plants from Africa (735), Australia (423), Hong Kong (499), North Borneo (491), and the U.S.S.R. (741), in addition to others (734, 742–745).

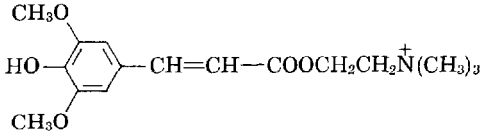
Isothiocyanate Glycosides

This group of interesting compounds will be discussed since plants containing isothiocyanates have been implicated in human as well as livestock poisoning (746), because of the antibacterial and fungistatic potential of the glycosides (747) and because of their unique, yet restricted distribution, which makes them valuable in chemotaxonomic studies (748–753). Isothiocyanate glycosides are found most abundantly in the *Cruciferae*, as well as in the related families *Capparidaceae*, *Moringaceae*, and *Resedaceae* of the Rhoeadales (746). Also, their unexpected occurrence in the taxonomically remote *Caricaceae*, *Euphorbiaceae*, *Limnanthaceae*, *Phytolaccaceae*, *Plantaginaceae*, *Salvadoraceae*, and *Tropaeolaceae* has been reported (746). Whenever mustard oil glycosides are found in a particular species, they appear to accumulate chiefly in seeds, as well as being found throughout the plant (746). The general type formula for these colorless, water-soluble compounds is illustrated.



Isothiocyanates

In all cases observed to date, glucose has been found to be the glycone moiety of isothiocyanate glycosides, thus substantiating the more common designation of this class of compounds as isothiocyanate glucosides. Because of the preponderence of potassium in plants, this element is usually found as the cation of the sulfuric acid residue. Sinalbin, the classical glucoside of white mustard, is unique in that it contains sinapine, a quaternary base, as its cationic moiety.



Sinapine

Myrosinase (myrosin), the specific enzyme catalyzing the hydrolysis of all isothiocyanate glycosides has been found in all plants containing this substrate. However, it accumulates in particular cells (idioblasts) which do not contain the glycosides (746). This enzyme has been stated to be most active at pH 6.5–7.5 and at a temperature of 30–40° (746).

About half of the known 30 or more natural mustard oils are nonvolatile isothiocyanates (cheirolin, erysolin, *p*-hydroxybenzylisothiocyanate) and as such are not steam distillable. Therefore, the practice of referring to this class of

compounds as "essential oils" should be discontinued.

Early methods for the detection of isothiocyanates consisted of hydrolysis followed by organoleptic evaluation of the liberated aglycone. As a result, only the volatile isothiocyanates were recorded. Today, however, with the availability of chromatographic techniques and rather specific detecting reagents, the analysis of plant material for isothiocyanates has become much more exacting. Although a number of microchemical tests for isothiocyanates and their glycosides have been reported (754–756), the preferred method for their detection in plant material appears to be through extraction of small samples (2–5 Gm.), followed by conversion of the natural *iso*thiocyanates into thiourea derivatives, and paper chromatographic separation of the mixture using water-saturated chloroform (757), ethyl acetate–water (758), 2-butanone–water (758), pyridine–amyl alcohol–water (759, 760), heptane–90% formic acid–*n*-butanol (759, 760), or *n*-butanol–ethanol–water (761). Visualization of the separated compounds is then accomplished by means of Grote's reagent (modified nitroprusside) (757), by silver nitrate (762, 763), or by the iodineazide reagent of Feigl (764) as modified by Kjaer (757).

A useful list of mustard oil-containing plants known up to 1938 has been published by Schmalfuss and Muller (765). Schneider (766) presents a reliable key to the older literature on isothiocyanates, and recent reviews on this topic have been published by Delaveau (748–750), Hegnauer (751), Zinner (752), and Kjaer (753, 767, 768). In addition, several surveys for isothiocyanates in plants have been conducted (767–773).

Essential Oils

Essential oils (volatile oils), in addition to their value as flavoring agents and perfumes, have been reported to have excellent antibacterial (201, 202, 204) and antifungal (202–204) properties.

A few reports have been published which include an evaluation of plant samples for the presence of essential oils (168, 491, 499, 500, 513, 774–778). For maximum efficiency, tests should be conducted on fresh material since most of the volatile constituents of plants are lost during drying. In most instances the methods that have been employed to detect essential oils have been crude since they have of necessity been conducted in the field as organoleptic examinations. More elaborate laboratory examinations have involved steam distillation followed by measurement of the water-immiscible oil and, in some cases, followed by the application of chemical tests for terpenes.

Arthur (491, 499, 500) studied more than 700 species in North Borneo and Hong Kong, and simply chopped a small amount of fresh plant with a razor, introduced this into a test tube, added hot water, and boiled the mixture. Any characteristic odor of essential oils was then recorded. Kohlmunzer (777) evaluated some 59 species of plants from genera known to have previously yielded economically important essential oils (*Salvia*, *Lavandula*, *Mentha*, *Rosmarinus*, *Thymus*, etc.). Following steam distillation and subsequent measurement of the separated oil, chemical tests for cineol were applied. On the other hand, Betts (779) has devised a method employing thin-layer chromatography for the evaluation of petroleum ether extracts, from umbelliferous fruits, in which essential oils are universally soluble. Fluorescein-treated plates of his extracts were first viewed under ultraviolet light to note the presence of dark quenching spots against a bright yellow background. Unsaturated compounds were then detected as spots by exposure of the plates to bromine vapor which converted the fluorescein to eosin, and subsequent ultraviolet examination then indicated unsaturated compounds against a dull background. Plates were then sprayed with 2,4-dinitrophenylhydrazine which revealed ketones and aldehydes as orange spots.

A simple microcohobation still for the estimation of quantities of essential oil ranging from 2–50 μl. in small (0.4 Gm.) samples of plant material has been shown to give accurate results and could be of value in screening large numbers of plant samples for essential oils on a quantitative basis (780). At least this would be some improvement over current organoleptic methodology.

SUMMARY

This review, to the best of this author's knowledge, is the first dealing with phytochemical and phytopharmacologic screening to be published. Therefore, out of necessity, a number of perhaps important topics were not discussed, and certainly some of those included were treated to a lesser degree than one might consider adequate.

It was the desire of this author to make several facts evident through a review of the areas covered in this manuscript: (*a*) that natural products have been, and still remain as, an interesting and important source of biologically active substances, the major sources of which remain untapped; (*b*) that although many methods are

available for the biological as well as chemical screening of plants, these are largely inadequate, and there is a great need for an increased interest in the development of improved methodology; (*c*) that a great deal of needless duplication of effort is evident in certain of the results presented in this review; and (*d*) correlations made and reported here point out the need for a restimulus of interest in this area of research.

The number of published reports on phytochemical and phytopharmacologic surveys is exceedingly small in view of the amount of effort that is undoubtedly being expended in these areas. Several explanations for this are suggested: (*a*) some investigators feel that this type of research should not be published because much of it represents so-called "negative" data; (*b*) others undoubtedly do not care to be associated with "screening" publications; and (*c*) a great deal of this work is being conducted in laboratories having a vested and commercial interest so that publication of their results would reveal methodology and approaches to this area of investigation that might be considered "unique" and/or classified. However, those reluctant to publish these types of data are usually exceedingly interested in hearing of, or utilizing similar results by others, in planning their own approach to phytochemical-phytopharmacologic problems, or in making certain correlations with their own data.

Natural product studies involving the search for new biologically active substances present unique challenges and problems not fully appreciated by many persons having only a limited appreciation and breadth of knowledge in biological areas. Many of the problems, either enumerated or suggested by studies reported here, can be solved if proper attention is given to the remedies. In the past, at least in this country, we have not had the organizational tools through which natural product studies could be considered in their own light. This is not true today, for with proper effort expended in its own behalf, the area of natural products can assume a more important place in the scientific community to serve humanity better.

Those of us interested in new biologically active phytoconstituents are constantly reminded, either verbally, through innuendo, or by means of restricted budgets and limited availability of research funds, of the "scientifically" unsound approaches that are used in our quest for new drugs. But, can methods other than those delineated in this review be suggested? And the work must continue.

Excretion of Nortriptyline Hydrochloride in Man I

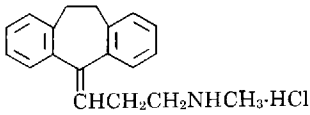
Detection and Determination of Urinary Nortriptyline

By M. E. AMUNDSON* and J. A. MANTHEY

A quantitative U.V. spectrophotometric assay procedure has been developed for the determination of urinary nortriptyline in man. A thin-layer chromatographic system is described which allows rapid detection of the presence of the drug and its metabolites in urine. The drug was found to be slowly eliminated as a mixture of free drug and metabolites.

NORTRIPTYLINE hydrochloride,[1] 5-(3-methylaminopropylidene) - 10,11 - dihydro - 5*H*-dibenzo[*a*,*d*]cycloheptene hydrochloride, has recently been introduced as an antidepressant. This communication describes an assay procedure for the quantitative determination of the drug in the urine of patients receiving therapeutic doses.

The need for urine tests for the detection and/



$CHCH_2CH_2NHCH_3 \cdot HCl$

Nortriptyline HCl

or determination of phenothiazine and related drugs in chronic mental patients has been established (1). The assay method reported here permits a reliable evaluation of drug intake by patients treated with nortriptyline hydrochloride.

EXPERIMENTAL

Drug Administration and Urine Collection.—All subjects except the normal male used for the single dose experiments were under treatment at Central State Hospital, Indianapolis, Ind., and were on a regular oral dosage schedule which ranged from 50–150 mg./day depending upon the individual patient. Twenty-four hour urine collections were made from 7:30 a.m.–7:30 a.m. For the single-dose experiments, the subject received an oral dose of 25 or 30 mg., and urine was collected at regular intervals up to as long as 72 hr. after dosage.

Assay Method.—*Method A.*—An aliquot of the urine (25 ml. for chronic studies, 100 ml. for single dose studies) was transferred to a 250-ml. separator. The urine was made distinctly alkaline with 50% sodium hydroxide and was extracted for 3 min. with 2 successive 50-ml. portions of ether. The extracted urine was saved for *Method B*. The ether was washed with 25 ml. of 0.1 *N* sodium hydroxide and 25 ml. of water, respectively. The washes were discarded. The ether was extracted for 3 min. with 2 successive 10-ml. portions of 0.1 *N* hydrochloric acid. The acid extracts were collected in a 25-ml. volumetric flask, and the solution was made to 25 ml. with additional acid. The absorbance of this solution (solution *A*) then was determined on a suitable spectrophotometer at the $\lambda_{max.}$ of approximately 240 mμ.

Method B.—The extracted urine from *Method A* was neutralized with 6 *N* hydrochloric acid and 0.2 vol. of concentrated hydrochloric acid was added. The solution was heated on a steam bath for 1 hr. and then was allowed to cool to room temperature. The solution was made alkaline with 50% sodium hydroxide using an ice bath, if necessary, to prevent excessive warming. The solution was then extracted with ether as in *Method A*. The absorbance of the acid extract (solution *B*) was determined at the $\lambda_{max.}$ of approximately 290 mμ.

Method C.—One-tenth volume of concentrated hydrochloric acid was added to an accurately measured aliquot of solution *A*. After heating for 1 hr. on a steam bath, the solution was allowed to cool and was diluted to an appropriate volume with water. The absorbance of this solution was determined at the $\lambda_{max.}$ of approximately 290 mμ.

Methods *A*, *B*, and *C* were repeated on an equal volume of control urine to establish blank urine values.

Calculations.—All results were calculated as equivalents of nortriptyline hydrochloride.

Received October 25, 1965, from the Analytical Development Department, Eli Lilly and Co., Indianapolis, Ind.

same as for calculation of Y = mg. "free" hydroxylated nortriptyline (Z)

$X - Z$ = mg. unchanged nortriptyline hydrochloride, and $X + Y$ = total mg. excreted expressed as nortriptyline hydrochloride equivalents.

Thin-Layer Chromatography.—Ether extracts of several urine samples were examined chromatographically for the presence of unchanged drug and metabolites. Standard size (20 × 20 cm.) glass plates were coated with a 250-μ layer of Silica Gel G. The plates were air-dried overnight before use. The developing solvent consisted of isopropanol–water, (88:12), one-third saturated with sodium chloride. The presence of free drug and metabolites was detected by spraying the plates with 1:1 3A ethanol–sulfuric acid followed by heating in a 90–100° oven for 75 min.

Figure 1 is a representative chromatogram of the extracts from 2 urine samples from patients who had received nortriptyline hydrochloride. The urine was extracted with ether as in *Method A* of the assay procedure. After washing with alkali and water, the ether was evaporated to dryness. The residue was redissolved in a small volume of methanol and was applied to the plates. The plates were placed in the developing solvent for approximately 2.5 hr. The plates were removed, air-dried, and sprayed with the ethanolic sulfuric acid. The plate was then placed in the oven to develop the characteristic colors given in Fig. 1.

RESULTS AND DISCUSSION

McMahon *et al.* (2) investigated the metabolism of nortriptyline-*N*-methyl-^{14}C in rats, and *N*-demethylation and hydroxylation of one of the bridgehead carbons were the major metabolic changes observed. Hucker (3) reported that the 2 major metabolic reactions of amitryptyline, the dimethylamino analog of nortriptyline, were also *N*-demethylation and hydroxylation. The metabolism of nortriptyline in man is currently under investigation and will be the subject of a future report.

The findings of McMahon *et al.* (2) were applied to the development of this assay method. When urine from a patient who had received nortriptyline was extracted with ether, a considerable amount of material which absorbed at 240 mμ was obtained. However, only a small percentage of this material was identified as unchanged nortriptyline by thin-layer chromatography (Fig. 1). Acid hydrolysis of the extracted urine yielded upon subsequent extraction a material which exhibited 290 mμ absorbance which is characteristic of the molecule in which the dimethylene bridge of nortriptyline has been replaced by a double bond as previously reported (2, 4). Acid hydrolysis of the material which had been obtained initially by ether extrac-

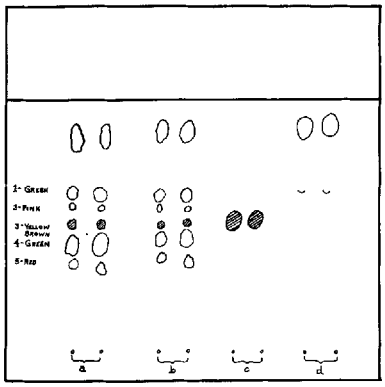

Fig. 1.—Thin-layer chromatography of urine extracts from patients receiving continued doses of nortriptyline hydrochloride. Key: a, urine extract No. 1902; b, urine extract No. 1903; c, nortriptyline; and d, control urine extract. Zone 3 identified as nortriptyline and zone 4 tentatively identified as 10-hydroxy nortriptyline. Colors shown are those observed after spraying with 1:1 ethanol–sulfuric acid and heating the plate in a 90–100° oven for 75 min.

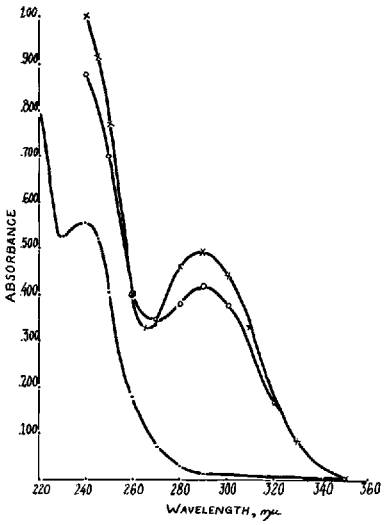

Fig. 2.—Typical U.V. absorption curves obtained on assay solutions. Key: ●, solution A = unchanged nortriptyline + "free" hydroxy derivative; ×, solution B = "bound" hydroxy derivative; and ○, solution C = "free" hydroxy derivative. Curves B and C were obtained after acid hydrolysis.

[2] 0.482 is the measured absorbance of a 10 mcg./ml. solution of nortriptyline hydrochloride in 0.1 *N* hydrochloric acid.

[3] 0.433 is the calculated absorbance of a 10 mcg./ml. solution of acid-hydrolyzed hydroxylated nortriptyline.

[4] 0.85 represents the recovery factor determined by adding hydroxylated nortriptyline to urine and hydrolyzing with acid as in *B* and *C*.

tion of the urine exhibited the same U.V. absorption pattern. Typical curves obtained from extracts of urine before and after hydrolysis are shown in Fig. 2. It is assumed, therefore, that hydroxylation of nortriptyline does occur in man and that only part of this metabolite is subsequently conjugated.

Additional metabolites are present in the urine of man as evidenced by the chromatogram shown in Fig. 1. Only small amounts of unchanged drug were excreted (zone 3). Four metabolites were apparent in the extracts. Zone 4 has been tentatively identified as 10-hydroxynortriptyline and is present in the greatest concentration. The remaining 3 metabolites are currently under investigation. The relatively large zones near the solvent front apparently have no relationship to the metabolism of nortriptyline and represent extraneous material carried through the extraction procedure.

Triplicate assays of a urine sample by the above procedure showed a total excretion of 61.2 ± 1.8 (S.D.) mg. of nortriptyline equivalents.

Pure 10-hydroxy nortriptyline was not available to use as a standard in the assay procedure. The 0.433 absorbance value used in the calculations was calculated from the data of Villani *et al.* (4) on amitryptyline and its derivatives and represents the theoretical absorbance of a 10 mcg./ml. solution of the hydrochloride salt of the unsaturated molecule which results from the acid hydrolysis of the 10-hydroxy metabolite. Addition of a known concentration of impure 10-hydroxy material, obtained by extraction of a patient's urine to a control urine and subsequent acid hydrolysis and extraction, resulted in a recovery of 85% based on the calculated absorbance of 0.433.

Several of the patients received other drugs in addition to nortriptyline hydrochloride. Phenaglycodol[5] (1200 mg. daily), chlorothiazide[6] (500 mg. daily), perphenazine[7] (24 mg. daily), trifluoperazine[8] (45 mg. daily), and fluphenazine[9] (15 mg. daily) did not interfere with the assay procedure. Chlorpromazine[10] (300 mg. daily) did interfere in the extraction procedure, as was evidenced by the U.V. absorption curve obtained on the extract.

It was not possible to obtain control urine specimens from the patients: therefore, the results obtained from these patients are uncorrected. A 25-ml. sample of control urine from a normal female gave insignificant absorption readings when carried through methods *A* and *C*, and the blank resulting from hydrolysis of the extracted urine sample (*Method B*) was equivalent to 1.1 mcg. of nortriptyline equivalents per ml. of urine. Control urine collected from the subject, who was given a single dose of the drug, gave values of 1.5, 2.1, and 2.1 mcg. of nortriptyline equivalents per ml. of urine for methods *A*, *B*, and *C*, respectively, and the results were corrected. In this instance 100 ml. of urine was used as the aliquot for assay. Since 25-ml. aliquots were used for all assays on the chronic administration study, blank values would be relatively insignificant.

Table I is a summary of the data obtained on 24-hr. urine collections from patients on a chronic dosage regimen of nortriptyline hydrochloride. All patients had been receiving the drug for several months. In the limited number of patients studied there appears to be a correlation between the dose administered and the amount of drug recovered in the urine. Individual fluctuations in the rate of excretion of the drug are quite apparent, however. It is evident that only small amounts of unchanged nortriptyline are excreted and that a somewhat larger amount of the hydroxy metabolite is excreted in the "free" than in the "bound" or conjugated form. In the 8 patients studied, an average of about 58% of the administered dose was excreted in the urine in a 24-hr. period.

Single doses of 25 and 30 mg. were given to a normal, healthy male to determine the excretion pattern after a single dose. These data are given in Table II. In this subject the maximum excretion

TABLE II.—NORTRIPTYLINE HYDROCHLORIDE EXCRETION AFTER SINGLE DOSES

Dose, mg.	Collection Interval, hr.	Nortriptyline HCl	"Free" Metabolite	"Bound" Metabolite	Total	% of Dose
25	0–24	Negligible	4.6	4.9	9.5	38.0
30	0–24	1.0	3.2	3.4	7.6	25.3
	24–48	0.8	2.1	2.0	4.9	16.3
	48–72	0.8	0.7	1.7	3.2	10.7
	Totals	2.6	6.0	7.1	15.7	52.3

TABLE III.—NORTRIPTYLINE HYDROCHLORIDE EXCRETION AFTER 3 SUCCESSIVE DAILY 10-mg. DOSES

Day	Dose, mg.	Nortriptyline HCl	Nortriptyline Equivalents, mg.[a] "Free" Metabolite	"Bound" Metabolite	Total
1	10	0.96	0.98	1.91	3.85
2	10	0.95	0.84	2.35	4.14
3	10	0.90	2.36	2.52	5.78
4	None	0.93	2.03	3.22	6.18

[a] Urine was collected during the 24-hr. interval between doses and during the 24-hr. interval following the final dose.

rate was found to occur in the 4–8-hr. interval after dosage. The drug is slowly excreted in the urine and substantial levels were found 2–3 days after dosage. Within the 0–24-hr. interval a lower percentage of the administered dose is recovered in the urine than from those patients on chronic administration of the drug.

The data in Table III show the gradual increase in the amount of drug excreted daily as the dose is maintained over a period of 3 days. These data were obtained on the same subject as was used in the single dose study.

From the data presented, it is evident that the assay method described is capable of permitting a reliable evaluation of nortriptyline hydrochloride ingestion. If one is interested only in whether a patient has taken his medication and is not interested in the total amount of nortryptyline present in the urine, it would be necessary to carry out only *Method A* of the assay procedure. The presence of the drug can also be detected by the TLC system described.

SUMMARY

1. A quantitative U.V. spectrophotometric assay method has been developed for the determination of nortriptyline hydrochloride and its principal metabolites in the urine of man.

2. The drug is slowly excreted in the urine primarily as conjugated and unconjugated 10-hydroxy nortriptyline. Little unchanged nortriptyline is excreted.

3. An average of 58% of the daily dose was recovered in 24-hr. urine samples from patients on a continuing dosage regimen of the drug. An average of 34% of the dose was recovered from the 24-hr. urine of a subject given single doses.

4. A thin-layer chromatographic system is described which permits rapid identification of the presence of the drug and/or metabolites in the urine.

Adrenolytic Activity of Atropine, (+)-Hyoscyamine, Atroscine, Homatropine, and Related Compounds

By F. P. LUDUENA and MARY-JANE BRANIN

The adrenolytic activity of atropine, (+) and (−) hyoscyamine, (−)-hyoscine, atroscine, and related compounds was determined by their ability to antagonize the lethal effect of epinephrine in rats. (+)-Hyoscyamine was found to be more active than atropine, and atropine was slightly more active than atroscine (racemic hyoscine). The *levo*-isomers, (−)-hyoscyamine and (−)-hyoscine, were inactive. These results indicate that (+)-hyoscyamine and (+)-hyoscine are responsible for the effect of atropine and atroscine, respectively. Homatropine and benztropine, but not tropine itself, were active. Benztropine was approximately one-fiftieth as active as phentolamine. A pair of esters of tropine had weak adrenolytic activity, but their pseudotropine isomers were inactive. Atropine aminoxide (genatropin) and atropine methyl nitrate had no adrenolytic activity.

IT HAS long been known that atropine, in high doses, inhibited or reduced the effect of epinephrine and sympathetic stimulation on various arterial beds (1). Those results included the effect of epinephrine on arterial strips from horses, oxen, and rabbits and perfused arterial

Dose, mg.	Collection Interval, hr.	Nortriptyline HCl	"Free" Metabolite	"Bound" Metabolite	Total	% of Dose
25	0–24	Negligible	4.6	4.9	9.5	38.0
30	0–24	1.0	3.2	3.4	7.6	25.3
	24–48	0.8	2.1	2.0	4.9	16.3
	48–72	0.8	0.7	1.7	3.2	10.7
	Totals	2.6	6.0	7.1	15.7	52.3

TABLE III.—NORTRIPTYLINE HYDROCHLORIDE EXCRETION AFTER 3 SUCCESSIVE DAILY 10-mg. DOSES

Day	Dose, mg.	Nortriptyline HCl	Nortriptyline Equivalents, mg.[a] "Free" Metabolite	"Bound" Metabolite	Total
1	10	0.96	0.98	1.91	3.85
2	10	0.95	0.84	2.35	4.14
3	10	0.90	2.36	2.52	5.78
4	None	0.93	2.03	3.22	6.18

[a] Urine was collected during the 24-hr. interval between doses and during the 24-hr. interval following the final dose.

rate was found to occur in the 4–8-hr. interval after dosage. The drug is slowly excreted in the urine and substantial levels were found 2–3 days after dosage. Within the 0–24-hr. interval a lower percentage of the administered dose is recovered in the urine than from those patients on chronic administration of the drug.

The data in Table III show the gradual increase in the amount of drug excreted daily as the dose is maintained over a period of 3 days. These data were obtained on the same subject as was used in the single dose study.

From the data presented, it is evident that the assay method described is capable of permitting a reliable evaluation of nortriptyline hydrochloride ingestion. If one is interested only in whether a patient has taken his medication and is not interested in the total amount of nortryptyline present in the urine, it would be necessary to carry out only *Method A* of the assay procedure. The presence of the drug can also be detected by the TLC system described.

SUMMARY

1. A quantitative U.V. spectrophotometric assay method has been developed for the determination of nortriptyline hydrochloride and its principal metabolites in the urine of man.

2. The drug is slowly excreted in the urine primarily as conjugated and unconjugated 10-hydroxy nortriptyline. Little unchanged nortriptyline is excreted.

3. An average of 58% of the daily dose was recovered in 24-hr. urine samples from patients on a continuing dosage regimen of the drug. An average of 34% of the dose was recovered from the 24-hr. urine of a subject given single doses.

4. A thin-layer chromatographic system is described which permits rapid identification of the presence of the drug and/or metabolites in the urine.

Adrenolytic Activity of Atropine, (+)-Hyoscyamine, Atroscine, Homatropine, and Related Compounds

By F. P. LUDUENA and MARY-JANE BRANIN

The adrenolytic activity of atropine, (+) and (−) hyoscyamine, (−)-hyoscine, atroscine, and related compounds was determined by their ability to antagonize the lethal effect of epinephrine in rats. (+)-Hyoscyamine was found to be more active than atropine, and atropine was slightly more active than atroscine (racemic hyoscine). The *levo*-isomers, (−)-hyoscyamine and (−)-hyoscine, were inactive. These results indicate that (+)-hyoscyamine and (+)-hyoscine are responsible for the effect of atropine and atroscine, respectively. Homatropine and benztropine, but not tropine itself, were active. Benztropine was approximately one-fiftieth as active as phentolamine. A pair of esters of tropine had weak adrenolytic activity, but their pseudotropine isomers were inactive. Atropine aminoxide (genatropin) and atropine methyl nitrate had no adrenolytic activity.

IT HAS long been known that atropine, in high doses, inhibited or reduced the effect of epinephrine and sympathetic stimulation on various arterial beds (1). Those results included the effect of epinephrine on arterial strips from horses, oxen, and rabbits and perfused arterial

Received November 19, 1965, from the Sterling-Winthrop Research Institute, Rensselaer, N. Y.

beds of frogs, dogs, and rabbits. Bussell (1) showed that atropine reduced the effect of epinephrine on the blood pressure of the spinal cat, the dog perfused leg, the cat nictitating membrane, the perfused rabbit ear, and the rabbit uterus. He found that (−)-hyoscyamine was inactive or had very little activity. More recent studies have confirmed these results. Graham (2) demonstrated that atropine and (−)-homatropine blocked the constricting effect of epinephrine on the duck duodenum, while (−)-hyoscyamine and (−)-hyoscine were inactive. He also reported that the relaxation of the hen's caecum induced by epinephrine was not changed by atropine. Ruegg (3) found that atropine reduced the effect of epinephrine and norepinephrine on the rabbit iris dilator *in vitro*.

The general conclusion to be drawn from the literature data is that atropine blocks or reduces the effect of epinephrine and other catecholamines on sympathetic α-receptors and has no effect on β-receptors. In other words, atropine has adrenolytic (α-sympatholytic) activity.

The experiments described below were carried out to compare the adrenolytic activity of atropine with that of related compounds and, since (−)-hyoscyamine had been reported to be inactive, to determine whether the activity of atropine (racemic hyoscyamine) was that of the *dextro*-isomer in the mixture.

EXPERIMENTAL

Method.—The method was based on the ability of adrenolytics to antagonize the lethal effect of epinephrine in rats. The rationale for the selection of the rat as experimental animal, the intravenous route of administration, and the injection of epinephrine with the antagonist in the same solution has been discussed earlier (4). Two slightly different techniques were used. *Method A*, described earlier (4), follows.

Method A.—Male white rats, weighing between 80–110 Gm., were injected intravenously with a 200-mcg./Kg. (2.7–5 × LD_{50}) dose of epinephrine together with one of a series of graded doses of the compound to be tested. Using 0.3-log intervals, the dose of the compound under study was varied, while the concentration of epinephrine was kept constant. To obtain the ED_{50}, the percentage mortality was plotted against dose on log probit paper.

Method B.—*Method B* was employed when the adrenolytic activity of the compound was too weak to be observed by *Method A*. Similarly, a combined injection of epinephrine and the compound to be tested was administered intravenously to male white rats. In this case, however, the dose of the compound was kept constant, while the concentration of epinephrine was varied, at 0.2-log intervals. Again, plotting per cent mortality *versus* dose, the LD_{50} of epinephrine, as affected by the weak adrenolytic, was determined. In comparing this value with values obtained by determining the toxicity of epinephrine alone, slight adrenolytic activity could be detected. In Table II the results obtained with the 2 techniques are shown in different columns. In the case of *Method B*, the control LD_{50} for epinephrine, obtained with animals from the same batch, is included also. Doses of phentolamine, smaller than the ED_{50} obtained by *Method A*, were tested by *Method B*. The results in Table II show that even the smaller of the 2 doses used reduced the intravenous toxicity of epinephrine.

Compounds Used.—Atropine sulfate [(±)-hyoscyamine (Merck)], (+)-hyoscyamine 1-2-oxobornanesulfonate, (−)-hyoscyamine sulfate, homatropine hydrobromide (Merck), benztropine methanesulfonate[1] (3-diphenyl methoxytropane methane sulfonate), apoatropine hydrochloride, and tropine hydrochloride.

Compound I (tropyl diphenylacetate hydrochloride), compound II (pseudo-tropyl diphenylacetate hydrochloride), compound III (tropyl-2-cyclopentyl - 4 - methylpentanoate hydrochloride), compound IV (pseudo - tropyl -2 - cyclopentyl - 4-methylpentanoate hydrochloride), atropine aminoxide chlorhydrate (American Roland Co.), atropine methyl nitrate,[2] and (−)-hyoscine-hydrobromide (scopolamine hydrobromide) (Merck.).

(±)-Hyoscine (atroscine) prepared by racemization of (−)-hyoscine by Dr. Benjamin F. Tullar, diphenhydramine[3] (Parke, Davis and Co.), compound V (3-phenyltropane hydrochloride), phentolamine HCl,[4] papaverine hydrochloride (Merck), and pronethalol hydrochloride[5] (nethalide HCl).

RESULTS

Examination of the results summarized in Table I shows that some of the compounds tested had adrenolytic activity.

Of the 2 optical isomers of atropine only (+)-hyoscyamine antagonized the lethal effect of epinephrine; (−)-hyoscyamine in a dose of 40 mg./Kg. failed to protect the rats injected with a 200-mcg./Kg. dose of epinephrine.

The activity of (+)-hyoscyamine was low; phentolamine tested in the same manner was approximately 400 times more active.

The results showed clearly that there is no correlation between cholinolytic and adrenolytic activities. The cholinolytic action of (−)-hyoscyamine was found by Long *et al.* to be 110–250 times higher than that of the (+) isomer. This (−)/(+)-activity ratio is considerably higher than those reported by others (6–8). [Lower ratios may indicate (−)-isomer contamination of the (+)-hyoscyamine sample.]

Atropine aminoxide (genatropine) and atropine methyl nitrate had no adrenolytic activity.

Scopolamine [(−)-hyoscine] was inactive at the highest dose tested (40 mg./Kg.). Racemic hyoscine (atroscine) was slightly less active than atropine; this indicates that (+)-hyoscine is the

active isomer and that substitution of scopine for the tropine ring in atropine does not abolish adrenolytic activity.

Pronethalol and papaverine, at the doses tested, did not protect rats from the lethal effect of epinephrine.

The most active of the compounds tested was benztropine, its activity being approximately one-fiftieth of that of phentolamine. Homatropine and 2 other tropanol esters (I and III) were slightly less active than atropine. The pseudotropanol analogs (II and IV) of the last 2 compounds had no activity.

Substitution of a dimethylamino ethanol group in compound I for the tropanol moiety abolished adrenolytic activity. (I *versus* diphenhydramine.)

Most of the compounds tested had cholinolytic activity. Since paralysis of the vagi and cholinergic vasodilators by cholinolytics may increase the magnitude and the duration of epinephrine hypertensive effect, the following experiment was performed. Graded doses of epinephrine were injected together with a dose of 1 mg./Kg. of (−)-hyoscyamine. As expected, the toxicity of epinephrine was slightly increased. [LD_{50} of epinephrine alone was 37.5 ± 4 mcg./Kg.; when 1 mg./Kg. of (−)-hyoscyamine was added to each of the graded doses of epinephrine the LD_{50} was 27 ± 2.7 mcg./Kg.] These results suggest that the adrenolytic effect of the active compounds tested had to be exerted against an epinephrine toxicity somewhat greater than that obtained on control rats.

DISCUSSION

The experiments reported above have confirmed, by a different method, reports in the literature which showed that atropine (1) and homatropine (2) had adrenolytic activity and that (−)-hyoscyamine was inactive (1, 2). Although (+)-hyoscyamine had not been tested before, the fact that (−)-hyoscyamine was inactive strongly suggested that the known weak adrenolytic activity of atropine was due to (+)-hyoscyamine. Our experiments have demonstrated that (+)-hyoscyamine is, indeed, an adrenolytic of a potency greater than that of atropine.

Since (−)-hyoscine (scopolamine) is inactive the activity of racemic hyoscine (atroscine) must be due, as in the case of atropine, to the action of the *dextro*-isomer.

In the series of compounds studied, with the exception of atroscine, the adrenolytic activity is associated with the presence of the tropanol moiety in the molecule, although tropine itself is inactive. Substitution of scopine for the tropine ring in atropine did not abolish activity but only reduced it. The presence of a tertiary amine group appears to be important—both atropine aminoxide and atropine methyl nitrate were inactive.

The activity of (+)-hyoscyamine was approximately $^1/_{100}$ of that of phentolamine. Assuming that the activity of atropine is 50% of that of (+)-hyoscyamine, the phentolamine/atropine activity ratio of 800 differs from that reported by Fleckenstein (9), who found a molar activity ratio of 375 in experiments on the perfused rabbit ear. He also found that diphenhydramine, inactive in our test, was as active as atropine. Since in Fleckenstein's experiments the adrenolytic was perfused, the con-

centration of diphenhydramine at the biophase, when distribution equilibrium had been reached, may have been much higher than that of atropine. In our experiments higher doses of diphenhydramine could not be administered because of toxicity.

The steric configuration of the tropyl moiety in atropine and atroscine plays an important role, since in both cases only the *dextro*-isomers are active. Cushny (10) reported that atropine was 200 times more active as a cholinolytic than its desoxy analog. This ratio is within the range of the *levo/dextro* hyoscyamine activity ratios obtained by Long *et al.* (5), suggesting, in accordance with Easson and Stedman's (11) theory, that the side chain OH group contributes to the attachment to the parasympathetic receptor. With the information available we can only theorize on the influence of the OH group in the tropyl moiety on adrenolytic activity. Only one of the enantiomorphs may have a configuration that provides an extra bond (hydrogen) for attachment to α-sympathetic receptors. Or possibly, adrenolytic activity may occur in atropine and racemic hyoscine only when the OH group is "pointing away" from the receptor, as appears to be the case with the adrenolytic activity of (+)-isoproterenol (12). In this case the OH group is not essential since the β-desoxy analog is equally active. The desoxy analogs of atropine and hyoscine could not be tested because they were unavailable. However, a closely related compound of atropine, apoatropine, was found inactive at 10 mg./Kg. (The toxicity of the compound prevented the use of higher doses.)

In examining the method we employed, the question may be raised of whether the antagonism of the lethal effect of epinephrine is a measure of adrenolytic activity (blockade of α-sympathetic receptors), or could protection against epinephrine toxicity be obtained with other types of drugs? To investigate this problem, 2 drugs which were known to antagonize some of the effects of epinephrine without acting on α-receptors—a smooth muscle relaxant, papaverine, and a β-receptor blocker, pronethanol—were tested.

As discussed in a previous paper (4), the data in the literature indicate that the fatal pulmonary edema which follows the intravenous injection of high doses of epinephrine is due to a pronounced rise of arterial and pulmonary venous pressure. Theoretically, antagonists of the effect of epinephrine on the blood vessels or the heart could act as epinephrine antidotes. However, pronethalol, a β-receptor blocker, in doses of 1, 2, or 4 mg./Kg., had no antidotal effect when injected together with epinephrine (100 mcg./Kg.). Nonadrenolytic vasodilators, such as (−)-isoproterenol (12) and papaverine, do not reduce the toxicity of epinephrine in the rat.

In addition to adrenolysis, the only pharmacological property which is known to protect rats (4) against the lethal effect of epinephrine is that of methacholine, *i.e.*, muscarinic activity. Obviously, the positive readings reported above cannot be due to muscarinic activity, since the active compounds have an antagonistic, not an agonistic action on the muscarinic receptors.

The compounds we tested had weak protective action compared with phentolamine, and as in all cases of weak inhibitory activity, the identification of the type of activity involved is not clear cut. The ED_{50} of phentolamine and those of other adrenolytics (4) are considerably lower than the doses required to reverse the pressor effect of epinephrine. Therefore, if the term "adrenolytic" is applied only to those that reverse the pressor effect of epinephrine, the weakest members of the α-receptor blockers may not be included, although they may show antiepinephrine effect on isolated vessel preparations (rabbit uterus, vas deferens, etc.). Atropine and homatropine were known to reduce the effect of epinephrine on various test objects; our tests confirmed the α-receptor blocking effect of homatropine and identified the optical isomer responsible for the effect of atropine. The chemical similarity of hyoscine and the fact that the racemic mixture, but not the levorotatory isomer, was active strongly suggest that the same mechanism of action is involved. Less is known about the pharmacological actions of compounds I and III which were found weakly active in our tests. However, the chemical relationship with active compounds in our series and the absence of an alternative mechanism of action suggest that the protection against epinephrine toxicity is due to α-receptor blockade.

Factors Affecting the Absorption of Riboflavin in Man

By GERHARD LEVY and WILLIAM J. JUSKO

The urinary recovery of riboflavin as a function of dose after oral administration to fasted normal humans shows that the process responsible for the absorption of this vitamin is saturable. The saturation effect is not evident when riboflavin doses as high as 30 mg. are administered after a meal. The enhanced absorption of riboflavin in the presence of food appears to be due to a decrease in intestinal transit rate which causes the vitamin to be retained at absorption sites in the small intestine for a longer period of time. The site specificity and saturability of riboflavin absorption suggest that the vitamin is absorbed by specialized transport rather than by passive diffusion. This conclusion is supported by kinetic and physical-chemical data, as well as by the results of studies of the effect of route of administration on the recovery of riboflavin in the urine.

SEVERAL GROUPS of investigators have found a linear relationship between the dose of riboflavin administered orally in solution or in other rapidly available forms and the urinary recovery of this vitamin (1–4). Melnick *et al.* (1) recovered an average of about 46% of the dose after administration of up to 10 mg. of riboflavin in solution. Brewer *et al.* (2) recovered about 50% in the dose range of 2 to 7 mg. but demonstrated that doses under 2 mg. are retained more completely. Morrison and Campbell (3) reported an average urinary recovery of 61% in the dose range of 1 to 20 mg., and Morrison *et al.* (4) recovered 56% of the dose after oral administration of 5 and 10 mg. of riboflavin. It has been suggested (5), on the basis of these observations, that riboflavin is absorbed by passive diffusion. In the course of a study of the effect of viscosity on gastrointestinal absorption in man (6), in which riboflavin was used as a model drug, results were obtained which appeared to be completely incompatible with the published observations of others. A thorough review of the data revealed only one potentially significant difference between the experimental designs employed by other investigators and that used in this laboratory: the other investigators administered riboflavin after a meal, while in this laboratory the vitamin was given on an empty stomach. Consequently, a formal study of the effect of time of administration (*i.e.*, before or after breakfast) on the urinary recovery of riboflavin was instituted. The study was designed to yield kinetic data as well, and was expanded subsequently to include an evaluation of the effect of route of administration on riboflavin excretion.

Received December 3, 1965, from the Biopharmaceutics Laboratory, School of Pharmacy, State University of New York at Buffalo.

Accepted for publication December 28, 1965.

This investigation was supported in part by grant R01 AM 08753-02 PET from the U. S. Public Health Service, Bethesda, Md.

EXPERIMENTAL

Absorption Study.—Four healthy male volunteers, ranging in age from 22–37 years, served as test subjects. Each subject received 5, 10, and 30 mg. of riboflavin U. S. P. in 100 ml. of 0.02 *N* acetic acid, followed by a small amount of water either on an empty stomach (after an overnight fast) or immediately after a standard breakfast consisting of 60 Gm. of cornflakes with sugar and 500 ml. of milk. One subject received also doses of 3 and 20 mg. of riboflavin on an empty stomach. Total urine collections were carried out at 0, 0.5, 1.0, 1.5, 2, 3, 4, and 6 hr. after riboflavin administration, and at convenient timed intervals thereafter up to 24 hr. Immediately after collection the urines were placed in brown opaque plastic bottles, glacial acetic acid (about 3 ml./100 ml. of urine) was added, and the bottles were placed in a refrigerator. The subjects were instructed to drink about 100 ml. of water every hour to maintain adequate urine output. When riboflavin was given on an empty stomach, breakfast was withheld for 2 hr. after the start of the experiment. The subjects were asked to avoid eating certain foods known to contain appreciable amounts of riboflavin and to refrain from taking vitamin preparations or drugs for at least 48 hr. prior to and during the experiment.

A similar protocol was followed when riboflavin was administered by other than the oral route. The vitamin was administered intravenously by rapid injection of a commercial preparation stated to contain 5 mg. of riboflavin (actual assay: 4.5 mg.) solubilized with nicotinamide (item No. 398, Eli Lilly & Co.). Rectal administration of riboflavin was carried out by means of a polyethylene syringe fitted with a 25-cm. catheter tube which was inserted fully in the rectum. The rectal solution consisted of 5 mg. riboflavin dissolved in 50 ml. of 0.5% methylcellulose (Methocel 4000 60 HG, Dow Chemical Co.) in water. This solution was retained in the colon.

At least two 24-hr. blank urine collections, with and without breakfast, were carried out in each subject. Control urine collections were carried out also after oral administration of 200 mg. of nicotinamide.

Analytical Methods.—Riboflavin in the urine was determined fluorometrically by the method of Burch *et al.* (7) as well as by a method based on the U. S. P. XVI assay procedure (8), using the Turner fluorometer, model 111, with primary filter 47-B and

secondary filter 2A-12. The Burch assay involves extraction of riboflavin into benzyl alcohol, while the modified U. S. P. XVI procedure does not require extraction. In the latter procedure, 5 ml. of suitably diluted urine is mixed with 1 ml. of pH 4.8 acetate buffer (1 *N*). One milliliter of 4% potassium permanganate and, subsequently, 1 ml. of 3% hydrogen peroxide are added. The fluorescence intensity of this solution is determined before and after reduction of riboflavin with sodium hydrosulfite. All data were corrected for blank values which averaged 0.6 mg./24 hr. by the Burch procedure and 1.0 mg./24 hr. by the modified U. S. P. procedure. Nicotinamide was found not to interfere in the assay of riboflavin, both *in vitro* (aqueous solutions) and *in vivo* (urines after nicotinamide administration).

Determination of Partition Coefficients.—Chloroform and 0.1 *N* hydrochloric acid or pH 7.0 phosphate buffer (0.1 *M*) were used as the organic and aqueous phases, respectively. The organic–aqueous phase volume ratio was 50:1, and the initial concentration of riboflavin in the aqueous phase was 5 mg./100 ml. The phases were shaken at 37° for 14 hr. The aqueous phase then was removed, centrifuged, adjusted to pH 4.8 with 0.1 *N* acetate buffer, and assayed fluorometrically by the modified U. S. P. method. Control experiments without riboflavin were carried out in parallel and yielded negligible fluorescence readings.

RESULTS

Both assay procedures employed in this investigation yielded essentially identical results. For example, the average urinary recovery after oral administration of 5 mg. of riboflavin after breakfast was 61.3% by the Burch assay and 60.5% by the modified U. S. P. procedure. The significance of these findings will be discussed in a subsequent report on the metabolic fate of riboflavin and riboflavin-5′-phosphate, respectively (9). All data presented in this report are based on the results obtained with the assay procedure of Burch *et al.* (7).

The urinary recoveries of riboflavin as a function of dose when given on an empty stomach and after a standard meal, respectively, are listed in Tables I and II. As shown in Fig. 1, there was a linear relationship between dose and the amount excreted when the vitamin was taken immediately after a standard breakfast. The average recovery of riboflavin was 62%, which is essentially identical to the 61% recovery obtained by Morrison and Campbell (3). When riboflavin was taken on an empty stomach, the per cent recovered in the urine decreased with increasing dose. In agreement with the observations of others [for example, Everson *et al.* (10)], there were consistently high and low excretors of riboflavin, respectively, regardless of dose and experimental conditions. The relationship between dose and urinary recovery of riboflavin given on an empty stomach is depicted in a Lineweaver-Burk-type plot (11) for the "high excretor," subject *M*, and the "low excretor," subject *J* (Fig. 2). The linear relationship obtained in each case indicates a limited capacity for riboflavin absorption under the experimental conditions.

Figure 3 depicts the excretion rate of riboflavin as a function of time after oral administration of 10 mg. either on an empty stomach or after breakfast. The plot on Cartesian coordinates shows the dif-

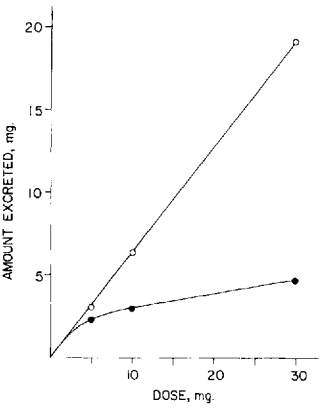

Fig. 1.—Urinary recovery of orally administered riboflavin as a function of dose when given on an empty stomach (●) and after a standard breakfast (○). Mean of 4 subjects.

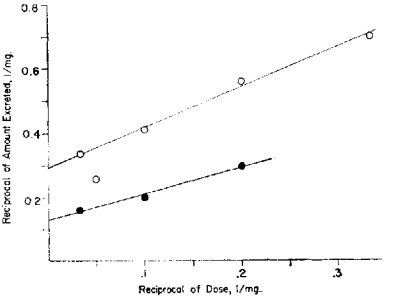

Fig. 2.—Lineweaver-Burk-type plot of the reciprocal of the amount of riboflavin recovered in the urine *vs.* the reciprocal of the oral dose given on an empty stomach. Key: ○, subject *J*; ●, subject *M*.

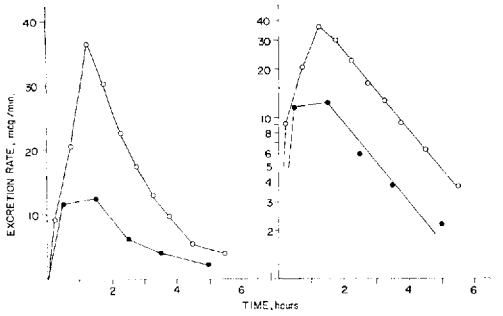

Fig. 3.—Excretion rate of riboflavin as a function of time after oral administration of 10 mg. of riboflavin in aqueous solution to 4 subjects on an empty stomach (●) and after a standard breakfast (○). Data are plotted on Cartesian coordinates (left) and in semilogarithmic form (right).

ference in the areas under the respective curves (which reflects the different amounts absorbed and excreted under the different experimental conditions) and indicates the very rapid absorption of the vitamin. The shapes of the 2 curves suggest that absorption under the 2 experimental conditions occurred at about the same rate initially, but continued for a longer period of time when the vitamin was given after breakfast. The semilogarithmic plot in Fig. 3 shows an exponential decline of excretion rate as a function of time, with an average half-life of 1.1 hr. (range of individual half-lives: 0.9 to 1.4 hr.). There was a consistent decrease in slope after 6 hr., when only a very small fraction of the total excreted amount remained to be excreted.

The effect of route of administration on riboflavin recovery is shown in Table III for subject *J*. The dose had to be restricted to 5 mg. to permit intravenous and rectal administration of the vitamin in solution. The viscosity of the rectal solution was increased by addition of methylcellulose to permit retention of the solution without leakage. The possibility of complex formation between riboflavin and the polymer was ruled out by equilibrium dialysis (6).

The kinetics of elimination of riboflavin after intravenous administration are depicted in Fig. 4. The experimental data could be resolved into a rapid and a slow component with half-lives of about 0.2 and 8 hr., respectively.

DISCUSSION

Site Specificity of Riboflavin Absorption.—Evidence which suggests that riboflavin is absorbed mainly in the proximal region of the intestinal tract has been reviewed by Campbell and Morrison (5).

TABLE III.—EFFECT OF ROUTE OF ADMINISTRATION ON URINARY RECOVERY OF A 5-mg. DOSE OF RIBOFLAVIN IN A FASTING SUBJECT

Rt. of Admin.	Recovery, %
Oral, empty stomach	35.8
Oral, after breakfast	49.8
Intravenous[a]	72.0
Rectal[b]	6.2

[a] Actual dose, 4.5 mg. [b] Retention enema.

For example, they point out that riboflavin absorption is decreased if the vitamin is administered in certain coated tablets or sustained-release preparations which do not release riboflavin relatively promptly. Moreover, administration of riboflavin in a number of sustained-release preparations having markedly different release characteristics has yielded excretion rate *versus* time curves which tend to drop off at about the same (early) times as curves obtained after giving the vitamin in rapidly available form.

Colonic absorption of riboflavin is practically insignificant (Table III). The present findings are in agreement with those of Everson *et al.* (10) and Campbell and Morrison (5). Najjar *et al.* (12) noted some absorption of riboflavin after administering 20 mg. as a rectal enema, but presented no quantitative data. It has been shown that rectally administered enemas and even suppositories spread in a retrograde manner at least to the mid-descending and frequently to the ascending colon (13, 14). In the present study, particular emphasis was placed upon introducing the riboflavin solution as high up the colon as possible by use of a 25-cm. catheter. The very low absorption of riboflavin after rectal administration is considered, therefore, to reflect an intrinsically poor absorbability of this vitamin in the colon, rather than being due to limited contact with colonic membranes.

It has been suggested (4) that the apparent site specificity of riboflavin absorption could be due to degradation of the vitamin in the lower bowel. This suggestion is based on a report by Selye (15) who stated, on the basis of very limited and indirect evidence, that riboflavin is rapidly destroyed in the large intestine of rats. The theory that the site-specificity of riboflavin absorption is due to degradation of the vitamin in the large intestine is rather untenable on kinetic grounds. If the degradation process is first order, a constant fraction of each dose, regardless of size, would be destroyed. If the process is apparent zero order (perhaps due to a limited metabolic capacity of a microbial population involved in this process), the fraction of a dose which will be destroyed would decrease with increasing dose. The experimental data (Table I) show exactly the opposite relationship. To explain this phenomenon on the basis of degradation in the lower gastrointestinal tract requires that one invoke such

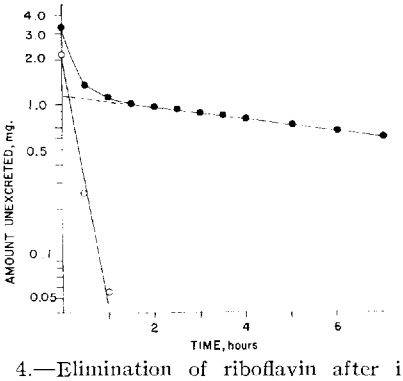

Fig. 4.—Elimination of riboflavin after intravenous administration (subject *J*). Key: ○, difference between experimental data; ●, extrapolated line.

possibilities as substrate inhibition of an enzymic system, or a dose-dependent effect of riboflavin on gastrointestinal motility. Neither of these possibilities is realistic in terms of present knowledge or in relation to the enhanced absorption observed when riboflavin is taken after a meal. Another remote possibility is that the decreased absorption of riboflavin with increasing dose is due to the dimerization of the vitamin at higher concentrations and that this is practically abolished in the presence of other interacting substances ingested as food. However, there is evidence that biologic membranes have a dissociating effect on homo-complexes and that dimerization will not affect absorption rate (28).

Saturability of Riboflavin Absorption.—The observation that the urinary recovery of riboflavin is decreased with increasing dose when the vitamin is taken on an empty stomach (Table I) suggests strongly that the process responsible for riboflavin absorption is saturable. There is no evidence that renal excretion of riboflavin is saturable in the concentration range encountered in the present experiments (*cf.* subsequent paragraph concerning elimination kinetics), and this possibility may, therefore, be ruled out as accounting for the experimental observations. Since given individuals appear to have relatively constant intestinal transit rates (16), the amount of an incompletely absorbed substance (given in solution) which is absorbed can be used as a relative measure of absorption rate in the individual. On this basis, Lineweaver-Burk plots have been prepared by plotting the reciprocal of the amount of riboflavin absorbed on an empty stomach against the reciprocal of the dose. Figure 2 shows such plots for a high and a low excretor of riboflavin. Each of these plots is linear and indicates an absorption maximum, as is characteristic of active transport processes (17). The magnitude of the extrapolated maximum values cannot be compared directly between different individuals, because they are a function also of intestinal transit rate and of the fraction of absorbed riboflavin which is excreted in the urine. These characteristics show appreciable intersubject variations. For example, the data listed in Table II show that subject *M* intrinsically excretes a larger fraction of riboflavin than does subject *J*.

The Effect of Food.—Food and viscous liquids slow gastric emptying and intestinal transit (18, 19). It is reasonable to assume that the presence of food causes riboflavin to be in contact with optimum absorption sites in the proximal region of the intestinal tract for a longer period of time, and thus, brings about the complete absorption of the vitamin over a wider dose range. The data in Table II indicate that riboflavin given after breakfast is absorbed either completely or that the same fraction of the dose is absorbed[1] in the dose range of 5 to 30 mg. While it would be desirable to demonstrate that saturation of riboflavin absorption is possible even when the vitamin is given after meals, results of such experiments would be equivocal since the limited solubility of riboflavin would require that the large doses necessary for such a study be given in suspension. If the amount of undissolved riboflavin is greater than that which can be dissolved relatively rapidly in gastric and upper intestinal fluids, the absorption kinetics would be apparent zero order for physicochemical rather than for physiologic reasons. However, if experiments now in progress in this laboratory show that riboflavin-5′-phosphate (FMN) has similar absorption characteristics as does riboflavin, large doses of the more water-soluble FMN will be given in solution after a meal to see if saturation effects can be demonstrated.[2]

It is of interest that apparently only Morrison and Campbell (3) have administered riboflavin also on an empty stomach. They used a 5-mg. dose only and reported "similar" urinary recovery to that obtained after breakfast, but did not present quantitative data. Their findings are explained readily by reference to Fig. 1, which shows that recovery of riboflavin given before or after breakfast is indeed "similar" at doses of 5 mg.; the differences become appreciable only when larger doses are given.

The Evidence for Specialized Intestinal Transport of Riboflavin in Man.—Two of the major characteristics of specialized intestinal transport processes are site specificity and saturability (20). These characteristics are evident in the absorption of riboflavin. The vitamin has a molecular weight of almost 400 which precludes rapid absorption by the pore route. Its chloroform–water partition coefficient, when the pH of the aqueous phase is either 1 or 7, is very small (< 0.001). Substances with such properties are not absorbed or only very poorly absorbed by passive diffusion (20). Yet riboflavin is absorbed very rapidly, as is evident from Fig. 3 and from the report by Wiegand *et al.* (21), who have estimated that the rate constant for riboflavin absorption (in doses of 5 mg. or less) is in excess of 30 reciprocal hr.! Although Wiegand *et al.* point out that a rate constant of this magnitude is not meaningful (it indicates that absorption is 95% complete in 6 min. or less), the value does reflect the very rapid absorption of the vitamin. It is inconsistent with present knowledge that such rapid absorption of a large, lipoid-insoluble substance can occur other than by some form of specialized transport.

Animal Experiments.—Spencer and Zamcheck (22) have studied riboflavin absorption with everted intestinal sacs from rats and hamsters and by the *in vivo* ligated loop technique in rats. They did not find any accumulation of riboflavin against a concentration gradient and noted that the intestinal sac appeared relatively impermeable to the vitamin. However, they used an almost saturated solution of riboflavin, and the high concentration alone can account for their inability to find serosal to mucosal concentration ratios greater than unity. The observed low permeability of the intestinal sac to riboflavin shows, regardless of other considerations, that the absorption of this substance by passive diffusion is at best very poor. Spencer and Zamcheck conclude that "the scant evidence available suggests that riboflavin may cross the intestine by diffusion rather than by specific transport," but add that "it is possible that in the presence of lower concentra-

[1] This would be the case if riboflavin is partially destroyed in the intestinal tract.

[2] After completion of this manuscript, the recent paper by Stripp [*Acta Pharmacol. Toxicol.*, **22**, 353(1965)] was received. He found that 50- to 500-mg. doses of FMN, given in solution after a meal, yielded the same riboflavin in blood levels and the same amounts excreted despite the 10-fold difference in dose. This demonstrates unequivocally the existence of an absorption maximum even when the vitamin is administered after a meal.

tions of the vitamin and with the admixture of food materials there may be other mechanisms of riboflavin absorption by the intestine" (22).

The significance of the study by Turner and Hughes (23), who used rat intestine preparations, is also limited by the high concentration of riboflavin used. They concluded that in rats all B group vitamins are absorbed by passive diffusion, but it is of interest that Spencer and Brody (24) have shown subsequently that at least one of these, biotin, is absorbed by specialized transport in the white mouse, hamster, and squirrel, though not in the rat, rabbit, and guinea pig. Thus the possibility of species differences alone limits the applicability of the results of animal studies to the elucidation of the mechanism of riboflavin absorption in man. A study by Middleton and Grice (25) is of interest because these workers administered riboflavin by stomach tube to intact rats. Their results show a relative site specificity for riboflavin absorption as well as definite apparent zero-order absorption kinetics which is compatible with the existence of a saturable transport process.

Kinetics of Riboflavin Elimination in Man.—Excretion of riboflavin after intravenous administration was very rapid initially and decreased after the first hour (Fig. 4). The experimental curve could be resolved into a rapid and a slow exponential component. Similar results are obtained upon graphical analysis of the data of Axelrod *et al.* (26), who administered intravenously 0.2 or 0.4 mg. of riboflavin per Kg. body weight to 4 subjects. They found that 30 to 40% of the dose was excreted within 1 hr. after injection. Evaluation of rate constants for their subject III yield essentially the same values as were obtained in the experiment depicted in Fig. 4. The data of Axelrod *et al.* (26) show riboflavin excretion rates of more than 6 mg./hr. and give no indication of possible saturation of excretory function.[3] The existence of an initial rapid elimination phase followed by a much slower phase is also evident from the study of Najjar and Holt (27), who administered 1 mg. riboflavin intravenously to 10 subjects after an overnight fast. They recovered 32 to 72% of the dose in the urine. Najjar *et al.* (12) established in a subsequent study that large doses of intravenously administered riboflavin do not cause an increase in fecal riboflavin output. This suggests that the incomplete recovery of absorbed riboflavin is due to biotransformation and/or metabolic retention of riboflavin, rather than to fecal excretion. All the available data suggest that riboflavin, when given intravenously, is relatively slowly distributed and therefore very rapidly eliminated initially. A variable fraction is either metabolized or retained in some form (probably as flavoprotein), and a small fraction is eliminated rather slowly.

The kinetics of riboflavin elimination after oral administration yield a somewhat different picture (Fig. 3). Excretion rate decreases exponentially with time, with an apparent half-life of about 1.1 hr. However, a slower elimination component was noted after 6 hr. in the present study and is evident also in the study of Morrison *et al.* (4). This slow component is probably identical to that found after intravenous administration and may reflect the elimination of riboflavin from a "deep" compartment. The more rapid early phase of riboflavin elimination after oral administration may reflect a combination of a distally decreasing intestinal absorption gradient and slow diffusion of the vitamin from blood into tissues, or it may represent an effect of route of administration on the distribution of riboflavin in the body.

[3] The same is evident from Fig. 3 of the present study.

Synthesis and Preliminary Pharmacological Evaluation of Alkylpiperazine Esters

By ELDA CRESCENZI, ERNESTA MARAZZI-UBERTI, and GERMANO COPPI

Twenty-nine alkylpiperazine esters have been synthesized and tested for the action on the CNS and for anti-inflammatory, analgesic, antipyretic, antispasmodic, and antimicrobic activities. Many of the compounds tested, in particular XV, display analgesic, anti-inflammatory, and antipyretic properties.

MANY ALKYLPIPERAZINE esters, mainly acrylates, have been synthesized and investigated chiefly for their anti-inflammatory, antispasmodic, and antimicrobic activities. This research was suggested by the known anti-inflammatory activity of β-4-biphenylylacrylic acid (1, 2), and of other acrylic acids (3), by the autonomotropic properties exerted by amino-alcohol esters (4), and by the antimicrobic properties observed for various acrylic acids (5–9) and quaternary ammonium salts of their basic esters (10). The activity on the CNS was also tested together with the analgesic and antipyretic activities.

The compounds dealt with in the present paper are mainly symmetrical dialkylpiperazine bis-acrylates and asymmetrical alkylpiperazine mono-acrylates. Only X, XI, and XXIX are esters of saturated aliphatic acids. They have been synthesized for the purpose of determining the influence produced by the disappearance of the double olefine bond on the pharmacological properties studied.

The synthesis methods used are the general ones for esters; *i.e.*, the reaction of acid chlorides with alcohols, or the reaction of acids or their sodium salts with chloro-derivatives. In the latter case, the use of isopropyl alcohol, in which the sodium salts of the acids are soluble to a certain extent, is particularly advantageous. I and II were isolated from the reaction mixture directly as the hydrochlorides.

The new esters are colorless crystalline solids, except for XVIII, which is a very viscous oil. Their properties are given in Tables I and II. The hydrochlorides of the esters are sparingly soluble in water, except for those in which an atom of nonpiperazine nitrogen is also present.

EXPERIMENTAL

Chemistry.—Melting points were taken on a Townson-Mercer melting point apparatus and are corrected.

Received September 7, 1965, from the Research Laboratories, Istituto De Angeli S.p.A., Milan, Italy.
Accepted for publication November 4, 1965.
The authors thank Mr. G. Bietti and Mrs. F. Donini for technical assistance, Dr. G. Erba for cooperation in performing the pharmacological tests, and Dr. G. Sekules for microanalyses.

Intermediates.—The references for the synthesis of the required acrylic acids have already been reported by the authors in another paper (3). 3-(3-Pyridyl)-propionic acid was prepared according to Merz and Stolte (11), and 2-(4-biphenylyl)-butyric acid according to Cavallini and Massarani (12).

The intermediate piperazines, *i.e.*, 1,4-bis-(1-methyl-2-chloroethyl)-piperazine (b. p. 150–152°/15 mm.), 1-(4-chlorophenyl)-4-(2-chloroethyl)-piperazine dihydrochloride (m. p. 201–203° dec.), 1-benzyl-4-(2-chloroethyl)-piperazine dihydrochloride (m. p. 304–308° dec.), 1-(4-methoxyphenyl)-4-(2-chloroethyl)-piperazine dihydrochloride (m. p. 220–222° dec.), and 1-(4-tolyl)-4-(2-chloroethyl)-piperazine dihydrochloride (m. p. 221–223° dec.) were prepared according to the general methods for the preparation of chloroamines described by Wilson and Tishler (13). 1-(4-Fluorophenyl)-4-(2-chloroethyl)-piperazine dihydrochloride was prepared according to Janssen (14) and 1-(2-chloroethyl)-piperazine dihydrochloride according to Hromatka and Engel (15).

Esters

1,4-bis[2-(Crotonyloxy)ethyl]-piperazine Dihydrochloride (I).—*Method A.*—A mixture of 48.9 Gm. of α-crotonic acid, 64 Gm. of 1,4-bis (2-chloroethyl)-piperazine (13), 45 Gm. of anhydrous potassium carbonate, and 1300 ml. of anhydrous benzene are refluxed for 16 hr., with stirring. After cooling to room temperature, potassium chloride and the excess potassium carbonate are removed by filtration and the benzene solution thoroughly washed, first with dilute sodium carbonate solution, and then with water. Finally, after drying over sodium sulfate, hydrogen chloride is bubbled through. The filtered product, washed with anhydrous ether and dried under vacuum at 50°, weighs 71.7 Gm. After crystallization from ethanol, it melts at 221.5–223.5° dec.

1,4-bis{2-[3-(1-Naphthyl)acrylyloxy]ethyl}-piperazine Dihydrochloride (II).—*Method B.*—A 8.71-Gm. quantity of 1,4-bis(2-hydroxyethyl)-piperazine (4) is added to a solution of 21.66 Gm. of 3-(1-naphthyl)-acrylyl chloride (10) in 100 ml. of anhydrous benzene. The reaction mixture is refluxed for 2 hr., and, after standing overnight at room temperature, the solid precipitate is filtered off and dried at 50° under vacuum. The product (17.9 Gm.) is crystallized from ethanol and gives colorless crystals, m.p. 269–271° dec.

1,4-bis{2-[3-(3-Pyridyl)acrylyloxy]ethyl}-piperazine (IV).—*Method C.*—A 77-Gm. quantity of sodium 3-(3-pyridyl)-acrylate (3) and 43 Gm. of 1,4-

bis(2-chloroethyl)piperazine are refluxed for 15 hr. in 700 ml. of isopropanol. At the end the reaction mixture is cooled to room temperature, and the suspended solid filtered off. The mother liquor from the reaction is concentrated to a small volume, and the solid separating is filtered and added to the previously isolated precipitate. The combined solids are taken up in chloroform, rejecting the insoluble portion, and the chloroform solution, after filtration with charcoal, is evaporated under reduced pressure, to give 63.7 Gm. of product. After crystallization from isopropanol, IV melts at 123–124°.

1 - (4 - Chlorophenyl) - 4 - [2 - (cinnamoyloxy) - ethyl]-piperazine (XII).—*Method D.*—A solution of sodium ethylate, prepared from 1.87 Gm. of sodium and 45 ml. of ethanol, is added dropwise to a suspension of 14 Gm. of 1-(4-chlorophenyl)-4-(2-chloroethyl)-piperazine dihydrochloride in 70 ml. of ethanol, at 0°. The mixture is stirred for 30 min. at room temperature and then concentrated under reduced pressure, until a thick mush is obtained. A 140-ml. quantity of isopropanol and 7.16 Gm. of sodium *trans*-cinnamate are added to this, then refluxed for 48 hr. with continuous stirring. At the end the mixture is cooled to room temperature, and the suspended solid filtered. The mother liquor from the reaction is concentrated to a small volume, and the separated solid filtered and combined with the previously isolated precipitate. The combined solids are taken up in chloroform, rejecting the insoluble portion, and the chloroform solution, washed with water and filtered with charcoal, is evaporated under reduced pressure to give 11.2 Gm. of product which, after crystallization from isopropanol, melts 125–126.5°.

PHARMACOLOGICAL RESULTS

The new compounds were submitted to preliminary pharmacological screening comprising the action on the CNS (16), the anti-inflammatory (17), analgesic (18), antipyretic (19), antispasmodic (20), antibacterial and antifungal actions (10), and the acute toxicity. The highest dosage level that did not provoke an obvious toxic symptomatology in experimental animals was used for each test. In all cases the compounds were administered by intraperitoneal injection. Phenylbutazone and morphine were used as standards for comparison of the anti-inflammatory, analgesic, and antipyretic actions.

The results of the activity tests considered most interesting are reported in Tables III and IV; they show that many of the compounds have a mild general depressive action on the CNS. Several compounds (II, III, IV, V, VI, VII, VIII, IX, XVII, XVIII, XIX, XX, XXI) display significant inhibition of formalin-induced edema. As for the analgesic action, XII, XV, XVI, XXI, XXII, and XXIX greatly increase the pain threshold of mice, in particular, XV, VI, VII, IX, XVIII, and XXI show a significant antipyretic effect. All the compounds have been found to be inactive regarding antispasmodic, antibacterial, and antifungal actions. It is interesting to note that, within the sphere of the authors' investigations, the over-all pharmacological outline of the 3 esters of saturated aliphatic acids (X, XI, XXIX) does not substantially differ from that of the acrylic esters.

In the light of the above results, the authors con-

Analogs of Tetrahydrofolic Acid XXXII

Hydrophobic Bonding to Dihydrofolic Reductase IV. Inhibition by *p*-Substituted Benzoic and Benzoyl-L-glutamic Acids

By B. R. BAKER*, THOMAS J. SCHWAN, JAROSLAV NOVOTNY, and BENG-THONG HO

A series of *p*-substituted benzoic acids and benzoyl-L-glutamic acids were synthesized and evaluated as inhibitors of dihydrofolic reductase in order to gain information on the position of the hydrophobic bonding region of the enzyme with respect to the position of the substrate, dihydrofolate, when the latter is complexed to the enzyme. Hydrophobic bonding by the *p*-substituted benzoyl-L-glutamic acids was reached 4–8 atoms from the *p*-position, thus indicating that the hydrophobic bonding region was not between the pyrimidyl and *p*-aminobenzoyl moieties of the substrate, dihydrofolate; in contrast, hydrophobic bonding with *p*-substituted benzoic acids was reached 1–4 atoms from the *p*-position, thus indicating that the *p*-substituted benzoic acids were complexed in a different region of the enzyme than the *p*-substituted benzoyl-L-glutamic acids.

THE DISCOVERY of strong hydrophobic bonding to dihydrofolic reductance with alkyl pyrimidines and 1,2-dihydro-*s*-triazines (1) has led to a major program in this laboratory on the nature, stereochemistry, and position of this hydrophobic bonding. That the aryl group of 1-aryl-1,2-dihydro-*s*-triazines and 5-arylpyrimidines of the pyrimethamine[1] type is also most probably complexed to dihydrofolic reductase by hydrophobic bonding has received strong experimental support (2). Furthermore, the 5-alkyl group of 5-alkyl-2,4-diamino-6-pyrimidines had maximum hydrophobic bonding with the 3-methylbutyl group (3); less binding was observed with 2-methylbutyl, butyl, and 1-methylbutyl, in that order. Furthermore, cyclohexyl was as good as *n*-butyl, but cyclopentyl was considerably poorer; thus, there are definite conformational requirements for alkyl groups to give maximum hydrophobic bonding (3). The magnitude of hydrophobic bonding to dihydrofolic reductase can be enormous; the phenylbutyl group of I alone had a free energy of binding of 6.0 Kcal./mole, equivalent to 80% of the total binding of the substrate, dihydrofolate. This binding by the phenylbutyl group could be calculated from the increment of 40,000 observed between I and II in their relative ability to inhibit dihydrofolic reductase.

VII, R = H

The discovery of this hydrophobic bonding creates a serious problem from the standpoint of design of an active-site-directed irreversible inhibitor (4) of dihydrofolic reductase—namely, where is the hydrophobic region with respect to the binding region for the *p*-aminobenzoyl moiety of folic acid (III) on dihydrofolic reductase? Is this hydrophobic region between the *p*-aminobenzoyl and the pyrimidine moieties or is it elsewhere, such as near the region where the 4-oxo group of folic acid is in the enzyme–inhibitor complex? If the hydrophobic region is not between these 2 moieties, then the anilino group of IV would probably not be complexed with the *p*-aminobenzoyl locus. If the anilino group of IV is complexed with a different locus, then an inhibitor of type IV (5) would not have its alkylating function sufficiently neighboring to the glutamate binding points of folic acid (III) to alkylate irreversibly such a binding point. Furthermore, if the anilino group of IV is complexed to a hydrophobic region, then by definition there is apt not to be a nucleophilic group in this region of the enzyme. A variety of approaches to answer this important question were initiated, since it could be expected to be difficult to obtain an unequivocal answer; one approach is the subject of this paper.

DISCUSSION

p-Aminobenzoyl-L-glutamic acid (VI) was measured as an inhibitor of dihydrofolic reductase. With the consideration that VI did not have the pyrimidyl moiety of the prototype inhibitor, V (6), the 12 m*M* concentration of VI needed for 50% inhibition (Table I) compared favorably with V, where 0.10 m*M* was needed for 50% inhibition (5). The 120-fold difference in binding between V and VI is a difference of 2.9 Kcal./mole. Since it can be calculated that 2-amino-6-methyl-4-pyrimidinol has a free energy of binding to dihydrofolic reductase of 3.0 Kcal./mole (1), the agreement is fairly reasonable for the amount of inhibition that can be expected when the pyrimidyl moiety is removed from V to give VI; these results support the suggestion that *p*-aminobenzoyl-L-glutamate (VI) binds to the same region of dihydrofolic reductase that complexes this moiety of V.

With the now reasonable assumption that *p*-aminobenzoyl-L-glutamic acid (VI) binds at the same locus as the *p*-aminobenzoyl-L-glutamate moiety of folic acid (III) then hydrophobic bonding by alkyl, aryl, or aralkyl groups substituted at the *p*-position of VII should be observed if the hydrophobic bonding region were between the pyrimidyl and *p*-aminobenzoyl-L-glutamate moieties of folic acid (III). Note that the *p*-amino group of VI contributed little to inhibition since benzoyl-L-glutamic acid (VII) was about as good an inhibitor (Table I). Little, if any, hydrophobic bonding occurred when a 3-bromopropyl (X) or a phenyl group (XIV) was introduced into the *p*-position. However, when the *p*-substitutent was lengthened to *n*-octyl (XII), about a ninetyfold increase in binding occurred (Table I). These data clearly show that the hydrophobic region begins at least 3 atoms away from the *p*-position of benzoyl-L-glutamic acid (VII). Since the distance between the pyrimidyl and benzoyl-L-glutamate moieties of folic acid (III) consists of a 4-atom chain, it is clear that the hydrophobic region is elsewhere than between these 2 moieties. It should again be emphasized that this interpretation contains the assumption that VII and the *p*-aminobenzoyl-L-glutamate moiety of folic acid (III) are complexed to the same region on the enzyme. Although this interpretation is quite reasonable, it is not unequivocal.

A previous study on the relative contribution of the functional groups (XXIII–XXVI) of the carboxy-L-glutamate moiety of the prototype inhibitor (V) to folic reductase (7), is now open to question on the validity of the interpretations, since it was made prior to the discovery of the strong hydrophobic bonding to dihydrofolic reductase (1). A particularly plaguing inconsistency was the fact that pteroic acid was eightyfold less effective than folic acid (III) as an inhibitor of dihydrofolic reductase (8), whereas XXVI was as good or better an inhibitor than V (5, 7). Although V may be complexed in the same manner as folic acid (III) to dihydrofolic reductase, the possibility existed that the less polar relatives (XXIII–XXVI) were complexed with the hydrophobic region rather than the *p*-amino benzoyl-L-glutamate region. Furthermore, it was previously noted that XXIV was almost as effective as V when assayed with the dihydrofolic reductase system (5); in the folic reductase system, XXIV was one-sixth as effective as V and XXV was about one-half as effective as V (7).

In Table I it can be noted that *p*-aminobenzoyl-L-glutamic acid (VI) was a greater than seventeenfold better inhibitor than *p*-aminohippuric acid (XXI)

TABLE I.—INHIBITION OF DIHYDROFOLIC REDUCTASE BY

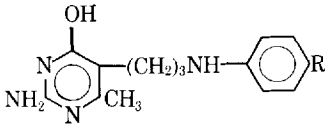
Dihydrofolic reductase was a 45–90% saturated ammonium sulfate fraction that was prepared and assayed with 6 μM dihydrofolate and 12 μM TPNH in 0.05 M Tris buffer (pH 7.4) containing 10 mM mercaptoethanol and 1 mM Versene as previously described (20). Solutions of inhibitors were prepared in the 0.05 M Tris buffer by adjustment of the pH to 7.4 with 0.1 N KOH, unless otherwise indicated. [a] GL = L-glutamate. [b] The concentration for 50% inhibition was determined by plotting V_0/VI against I for several concentrations of I that would give 30–70% inhibition, where V_0 = velocity without inhibitor, VI = velocity with inhibitor, and I = concentration of inhibitor; the concentration for 50% inhibition was obtained where $V_0/VI = 2$ (21, 22). When 50% inhibition could not be reached due to lack of solubility, the line was extended to the 50% inhibition point; the less the maximum inhibition, the greater is the error in the estimated concentration for 50% inhibition. [c] Since 20% inhibition is readily detectable, the concentration for 50% inhibition is greater than 4 times the concentration measured. [d] Solution of inhibitor prepared in 1:1 N,N-dimethylformamide–Tris buffer by adjusting the pH to 7.4 with Tris base in 50% aqueous N,N-dimethylformamide; the assay was run in 10% N,N-dimethylformamide. [e] Maximum solubility in cell in 10% N,N-dimethylformamide. [f] Commercial sample. [g] See *Reference 7* for preparation.

and greater than a 33-fold better inhibitor than γ-(*p*-aminobenzoyl)butyric acid (XXII). If it is again assumed that *p*-amino benzoyl-L-glutamate *per se* as well as this moiety of V are complexed to the binding locus for the *p*-aminobenzoyl-L-glutamate moiety of folic acid (III), it follows that XXI–XXVI are complexed elsewhere, perhaps in the hydrophobic region.



V, R = —CONHCH(CH$_2$CH$_2$COOH)COOH

XXIII, R = H

XXIV, R = CONHCH$_2$COOH

XXV, R = CONHCH(CH$_2$CH$_2$COOH)CH$_2$

XXVI, R = COOH

In order to obtain experimental evidence for or against this hypothesis, some *p*-substituted benzoic acids were investigated for their ability to inhibit dihydrofolic reductase.

Note that benzoic acid (VIII) showed no inhibition at a concentration of 75 mM, but that *p*-substitution with a bromopropyl gave a compound (IX) that showed 50% inhibition at 17 mM. Lengthening the chain to bromobutyl (XVI) or chloropentyl (XVII) gave still better inhibitors, with 50% inhibition at about 6 mM. Furthermore, *p*-phenyl-(XIII), *p*-benzyl-(XV), and *p*-benzoylbenzoic (XVIII) acids showed 50% inhibition in the 6–13 mM range. Thus, these hydrophobic groups could give as much as a greater than fiftyfold increase in binding compared to benzoic acid (VIII). Whether there were limitations on the length of this *p*-group for hydrophobic bonding could not be shown by XI, XIX, or XX due to insolubility; however, it was apparent that longer groups in XI and XX could not have given much further increment in hydrophobic bonding. Thus the hydrophobic region begins soon after the first atom in the *p*-position of benzoic acid, when these benzoic acids are complexed to dihydrofolic reductase; in contrast, the *p*-position of benzoyl-L-glutamate must have greater than a 4-

atom chain before hydrophobic bonding is detected.

That hydrophobic bonding can occur also with *N*-substituents on *p*-aminobenzoic acid is shown with the *m*-aminobenzyl and the *m*-nitrobenzyl derivatives, XXVI and XXXVIII (Table I); XXVI is actually the best benzoate-type inhibitor in Table I. Surprisingly, *N*-acetylation on the *p*-amino group led to a greater than 47-fold loss in binding to dihydrofolic reductase. A possible interpretation of this result will be discussed (9).

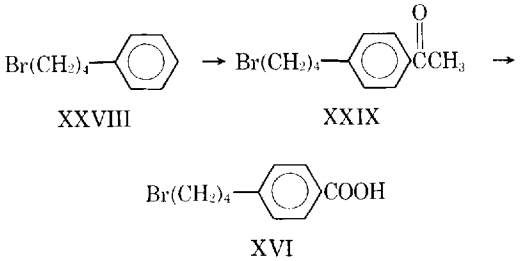
Regardless of the mode of binding of benzoyl-L-glutamic acid (VII) and the substituted benzoic acids, it is clear that the benzoyl group of the 2 classes of inhibitors are complexed to different regions of the enzyme. Whether the benzoyl-L-glutamates are complexed to the normal region for this moiety in folic acid, and the benzoic acids are complexed in hydrophobic region cannot yet be proven unequivocally. However, as a working hypothesis, such modes of binding have led to useful results which could not have been accrued otherwise. These results on the nature and position of hydrophobic bonding are the subjects of additional papers to be submitted in the near future.

EXPERIMENTAL

Methods.—*p*-(4-Bromobutyl)benzoic acid (XVI) was synthesized from 4-(bromobutyl)benzene (XXVIII) by Friedel-Crafts acetylation to XXIX followed by hypobromite oxidation; similarly, XVII was synthesized. (Scheme I.) The synthesis of IX (10) and XI (11) by this route have been previously recorded.

The *p*-substituted benzoyl-L-glutamic acids (X, XII, and XIV) were synthesized by condensation of the appropriate acid chloride in an organic solution with an aqueous sodium carbonate solution of L-glutamic acid; the known benzoyl-L-glutamic acid (VII) (12) was also synthesized in this manner. All but XIV were isolated as the bis-cyclohexylammonium salts, which were readily crystallized and purified, in contrast to the free acids which were difficult to crystallize or purify, or both.

4′-Nitrodiphenic acid (XXXII) was synthesized by modification of a procedure in the patent literature (13, 14) by Friedel-Crafts acetylation of XXX in nitrobenzene to XXXI followed by sodium hypobromite oxidation to XXXII without isolation of XXXI. Catalytic reduction to XXXIII proceeded smoothly in a 50% ethanolic solution of the sodium salt in the presence of Raney nickel; this method was considered to be more convenient than the ammonium sulfide reduction described previously (15). Acylation with 4-methylvaleroyl chloride to XIX in acetone in the presence of potassium carbonate proceeded satisfactorily. Similarly, acylation of



XXVIII XXIX XVI

Scheme I

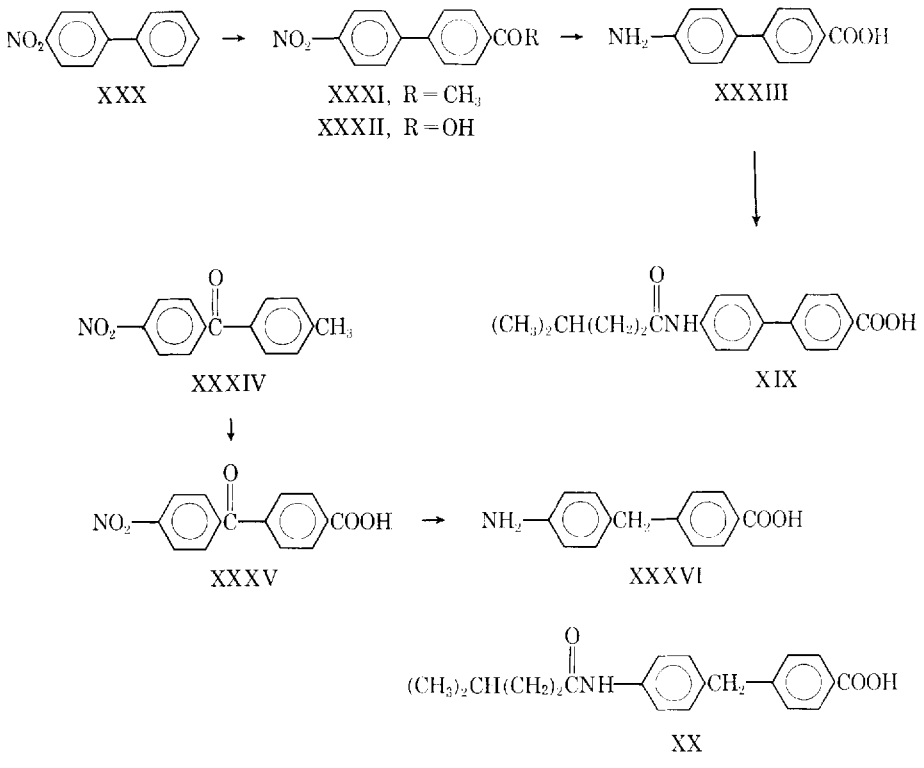
XXXVI to XX was performed. The required intermediate amino acid (XXXVI), although known in the literature (15), was prepared by an alternate route. Oxidation of 4-methyl-4′-nitrobenzophenone (XXXIV) (16) with chromium trioxide in acetic acid gave the acid (XXXV) in 55% yield of analytically pure material. Oxidation of XXXIV to XXXV with potassium permanganate in aqueous alkali or in acetone proceeded poorly due to overoxidation to water-soluble products. Huang-Minlon reduction of the carbonyl group of XXXV with hydrazine in diethyleneglycol containing potassium hydroxide also gave concomitant reduction of the nitro group; the desired amino acid (XXXVI) was obtained in 82% yield. (Scheme II.)

Condensation of *m*-nitrobenzaldehyde with *p*-aminobenzoic acid in ethanol gave the anil (XXXVII) in 96% yield. Reduction of a suspension of the anil in methanol with sodium borohydride gave the benzylamine (XXXVIII) in 98% yield. Further hydrogenation in 2-methoxyethanol with a platinum oxide catalyst afforded the desired amino acid (XXVI). Acetylation of XXXVIII with boiling acetic anhydride gave an anhydride of the desired *N*-acetyl derivative which was readily converted to XXXIX with 1 *N* sodium hydroxide in quantitative over-all yield. Catalytic reduction in ethanol afforded the requisite amino acid (XXVII) in good yield. (Scheme III.)

Synthesis.—Melting points were taken on a Fisher-Johns apparatus or a Mel-Temp block, and those below 230° are corrected. Infrared spectra were determined in KBr disk with a Perkin-Elmer 137B spectrophotometer unless otherwise indicated; ultraviolet spectra were determined with a Perkin-Elmer 202 spectrophotometer.

p-(4-Bromobutyl)benzoic Acid (XVI).—To a stirred suspension of 5.6 Gm. (42 mmoles) of anhydrous aluminum chloride in 21 ml. of carbon disulfide, cooled in an ice bath and protected from moisture, was added 3.0 ml. (42 mmoles) of acetyl chloride over a period of 10 min. Then a mixture of 10.2 Gm. (48 mmoles) of 4-bromobutylbenzene (17) and 6.5 ml. (90 mmoles) of acetyl chloride was added as rapidly as reflux would allow. After the addition was complete, the mixture was stirred for 2.5 hr., then poured into a mixture of 50 Gm. of ice and 10 ml. of 12 *N* aqueous hydrochloric acid. To the mixture was added 40 ml. of benzene; an insoluble yellow solid was removed by filtration. The separated aqueous layer was extracted with three 10-ml. portions of benzene. The combined benzene extracts were washed successively with 10% hydrochloric acid, 2 *N* aqueous potassium hydroxide, and water. Dried with magnesium sulfate, the benzene solution was spin-evaporated *in vacuo* leaving 12.6 Gm. of the crude acetophenone, XXIX (18).

To an ice cold solution of 1.55 ml. (0.02 mmole) of bromine in 28 ml. of water containing 3.3 Gm. of sodium hydroxide was added 15 ml. of dioxane. Then a solution of 2.5 Gm. (10 mmoles) of crude XXIX in 5 ml. of dioxane was added over a period of 45 min. After being stirred for an additional 2 hr. in the ice bath, the solution was acidified with 10 ml. of 12 *N* aqueous hydrochloric acid. A brown oil separated that soon solidified. The product was collected on a filter and washed with water until the washings were colorless; yield, 1.21 Gm. (46% based on XXVIII), m.p. 135–137°.



Scheme II

Recrystallization from benzene–petroleum ether (b.p. 30–60°) gave white needles, m.p. 136–137°. $\nu_{max.}$ 2680–2550 (acidic OH); 1680 (C=O); 859 cm.$^{-1}$ (*p*-C_6H_4).

Anal.—Calcd. for $C_{11}H_{13}BrO_2$: C, 51.4; H, 5.08. Found: C, 51.2; H, 5.06.

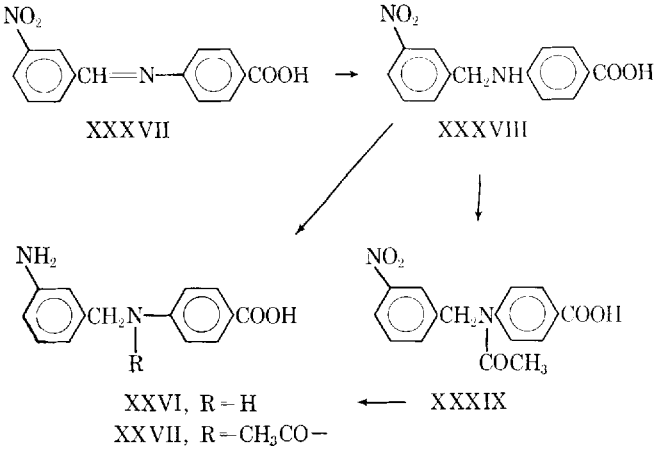
Similarly, IX (10) and XI (11) were prepared.

p-(5-Chloropentyl)benzoic Acid (XVII).—This compound was prepared in 46% over-all yield from 5-chloropentylbenzene as described for XVI. Recrystallization from benzene–petroleum ether (b.p. 30–60°) gave white crystals, m.p. 109–111°. $\nu_{max.}$ 1690 (C=O); 860, 840 cm.$^{-1}$ (*p*-C_6H_4).

Anal.—Calcd. for $C_{12}H_{15}ClO_2$: C, 63.6; H, 6.65. Found: C, 63.3; H, 6.49.

That this was a *p*-substituted benzoic acid, as indicated by the infrared spectrum, was further verified by oxidation to terephthalic acid.

p-(n-Octyl)benzoyl-L-glutamic Acid (XII) (Cyclohexylammonium Salt).—A solution of 351 mg. (1.5 mmoles) of XI, 10 ml. of chloroform, 0.9 Gm. of thionyl chloride, and a trace of pyridine was refluxed for 30 min. when gas evolution was complete. Solvent was removed by evaporation *in vacuo*. A solution of the residual acid chloride in 3 ml. of acetone was added in 1 portion to a magnetically



Scheme III

stirred solution of 147 mg. (1 mmole) of L-glutamic acid, in 0.67 ml. of 3 *N* sodium hydroxide (2 mmoles) and 5 ml. of water containing 160 mg. (1.5 mmoles) of sodium carbonate. After being stirred overnight at ambient temperature, the reaction mixture was spin-evaporated until the acetone was removed, then the solution was diluted with 50 ml. of water and adjusted to about pH 5 with dilute hydrochloric acid. After standing for a few hours, the mixture was filtered, and the recovered XI was washed with water. The filtrate was adjusted to about pH 1 with 3 *N* hydrochloric acid. The semisolid (XII) which separated (224 mg., 0.62 mmole) was dissolved in 5 ml. of methanol, and 155 mg. of cyclohexylamine (1.55 mmoles, 25% excess) was added. The solution was spin-evaporated *in vacuo* yield, 348 mg. (62%) of crude product. The residue was recrystallized twice from absolute ethanol–ether; yield, 71 mg. (13%) of analytically pure material, m.p. 170–175°. $\lambda_{max.}$ (pH 1, 13) 245 mμ; $\nu_{max.}$ (Nujol) 2200 (NH^+), 1670–1640, 1560–1500 cm.$^{-1}$ (COO^-, amide I and II, C=C).

Anal.—Calcd. for $C_{32}H_{55}N_3O_5$: C, 68.4; H, 9.87; N, 7.48. Found: C, 68.5; H, 9.96; N, 7.59.

No attempt was made to isolate additional material from the mother liquors.

p-(3-Bromopropyl)benzoyl-L-glutamic Acid (X) (Cyclohexylammonium Salt).—This compound was prepared as described for XII except that five 40-ml. extractions with ethyl acetate were employed since the product was fairly water soluble. Recrystallization from methanol–acetone afforded a 30% yield of the bis-cyclohexylammonium salt of X, m.p. 145–150°. A second recrystallization from the same solvent pair gave white crystals, m.p. 149–152°. $\nu_{max.}$ (Nujol) 2220 (NH^+); 1610–1640, 1590–1510 cm.$^{-1}$ (COO^-, amide I and II, C=C).

Anal.—Calcd. for $C_{27}H_{44}BrN_3O_5$: C, 56.8; H, 7.77; N, 7.36. Found: C, 56.6; H, 7.55; N, 7.12.

p-Phenylbenzoyl-L-glutamic Acid (XIV).—A mixture of 1.93 Gm. (10 mmoles) of 4-biphenylcarboxylic acid, 20 ml. of chloroform, 4 ml. (50 mmoles) of thionyl chloride, and a trace of pyridine was refluxed for 16 hr., then spin-evaporated *in vacuo*. The residual crystalline acid chloride was dissolved in 15 ml. of carbon tetrachloride, then added over a period of 1 hr. to a stirred solution of 1.47 Gm. (10 mmoles) of L-glutamic acid, and 3.41 Gm. (32.5 mmoles) of sodium carbonate in 15 ml. of water that was layered with 8 ml. of carbon tetrachloride. After being stirred for an additional 24 hr., the layers were separated; the aqueous layer was adjusted to pH 5.5 with 3 *N* hydrochloric acid, then washed with chloroform to remove 4-biphenylcarboxylic acid. The aqueous solution then was adjusted to pH 1.5. The white, difficultly filterable precipitate was collected by centrifugation, then washed with water. Recrystallization from aqueous acetone gave 1.08 Gm. (33%) of white crystals, m.p. 178–179°. The compound moved as a single spot on thin-layer chromatography on Silica Gel G with propanol–water (37:13) when viewed under ultraviolet light. The compound has $\nu_{max.}$ 3320 (amide NH), 3000, 2650, 2550 (broad acidic OH); 1700 (carboxyl C=O), 1630, 1600, 1580, 1520, 1500 (amide I and II, C=C); 850 (*p*-C_6H_4); 750, 685 cm.$^{-1}$ (C_6H_5); $\lambda_{max.}$ (pH 1) 273 mμ (ε 25,700); (pH 13) 272 mμ (ε 28,500).

Anal.—Calcd. for $C_{18}H_{17}NO_5$: C, 66.0; H, 5.23; N, 4.28. Found: C, 65.8; H, 4.99; N, 4.22.

Benzoyl-L-glutamic Acid (VII) (Cyclohexylammonium Salt).—A solution of L-glutamic acid (10 mmoles) in aqueous sodium carbonate was acylated with 1.42 ml. (15 mmoles) of benzoyl chloride in 8 ml. of carbon tetrachloride as described for the preparation of XIV. After removal of the benzoic acid at pH 1, the filtrate was spin-evaporated to dryness *in vacuo*. The residue was extracted with acetone. The filtered solution was spin-evaporated *in vacuo* leaving 2.20 Gm. (88%) of VII as an oil which solidified after several days, m.p. 125–130°. [Lit. m.p. 139–140° (12).]

To a solution of 638 mg. (2.5 mmoles) of VII in 5 ml. of ethanol was added 550 mg. (5.5 mmoles) of cyclohexylamine. Some of the cyclohexylammonium salt (449 mg., m.p. 186–190°) separated immediately, and an additional 600 mg. (total 94%), m.p. 180–190°, was isolated from the filtrate. Recrystallization from absolute ethanol–ether gave 849 mg. (75%) of white crystals, m.p. 191–193°. $\nu_{max.}$ 3250 (NH), 3000–2600, 2200 (NH^+); 1660, 1640, 1580–1520 (COO^-, amide I and II, C=C); 712, 692 cm.$^{-1}$ (C_6H_5); $\lambda_{max.}$ (pH 1, 7) 229 (ε 14,500), 245 mμ (sh) (ε 8000).

Anal.—Calcd. for $C_{24}H_{39}N_3O_5$: C, 64.4; H, 8.74; N, 9.35. Found: C, 64.4; H, 8.70; N, 9.40.

4′-Nitro-4-biphenylcarboxylic Acid (XXXII).—To a stirred solution of 30 Gm. (0.15 mole) of 4-nitrobiphenyl in 100 ml. of nitrobenzene protected from moisture was added 39 Gm. (0.29 mole) of anhydrous aluminum chloride. The mixture was heated to 50–53°, then a solution of 19.5 Gm. of acetyl chloride in 17 ml. nitrobenzene was added over a period of 8 hr. After being heated an additional 4 hr. at 62–64°, the mixture was stirred overnight at ambient temperature, then poured into 400 ml. of iced water. The separated nitrobenzene layer was washed with water (3 × 50 ml.), then poured in a thin stream into an ice-cooled stirred solution of 72 Gm. of bromine in 100 ml. of water containing 50 Gm. of sodium hydroxide and 300 Gm. of ice. The stirred mixture was gradually warmed to 70° over a period of about 30 min., then maintained at 60–70° for 1.5 hr.; during this time it was necessary to remove the heating bath occasionally to keep the temperature from rising above 70°. The mixture then was stirred under a reflux condensor in a bath at 100–105° for 2 hr. The orange sodium salt was collected by filtration after chilling at 15° for 3 hr. The sodium salt was extracted with three 800-ml. portions of boiling water, filtering the solution each time through glass wool to remove a brown insoluble by-product. The combined filtrates were reheated to dissolve the sodium salt, then acidified to pH 2–3 with 12 *N* hydrochloric acid; yield, 10.2 Gm. (28%), m.p. 338–342° dec. Recrystallization from 2-methoxyethanol gave 6.65 Gm. (18%), m.p. 345–348° dec. [Lit. m.p. 340°, 345° (13, 14).]

4′-Amino-4-biphenylcarboxylic Acid (XXXIII).—A solution of 243 mg. (1 mmole) of XXXII in 100 ml. of 50% ethanol and 2 ml. of 2 *N* sodium hydroxide was shaken with hydrogen at 2–3 Atm. in the presence of about 1 Gm. of Raney nickel; reduction was complete in 30 min. The filtered solution was adjusted to pH 6 with glacial acetic acid, then spin-evaporated *in vacuo* to about 50 ml. The product

was collected on a filter and washed with water. Yield, 170 mg. (80%), m.p. 245–248°. [Lit. m.p. 243–246° (15).]

4-(4′-Nitrobenzoyl)benzoic Acid (XXXV).—4-Methyl-4′-nitrobenzophenone (XXXIV) was prepared from *p*-nitrobenzoyl chloride, toluene, and aluminum chloride; the yield, after recrystallization from ethanol was 95%, m.p. 120–121° (16).

To a stirred solution of 9.05 Gm. (37.5 mmoles) of XXXIV in 100 ml. of glacial acetic acid was added 9.5 Gm. (95 mmoles) of chromium trioxide in portions over a period of 1 hr. The mixture was refluxed for 16 hr., then poured into 1 L. of ice water. The product was collected on a pad of Celite, then washed with water until the washings were colorless. The filter cake was stirred at about 90° with 300 ml. of 3 *N* aqueous sodium hydroxide, then filtered hot. The filtrate was rewarmed to dissolve the sodium salt, then the hot solution was acidified to about pH 1 with hydrochloric acid. The product was collected on a filter and washed with water; yield, 6.71 Gm. (66%). Recrystallization from methanol gave 5.86 Gm. (55%) of light yellow crystals, m.p. 257–258°. $\nu_{max.}$ 3000, 2650, 2550 (broad acidic OH); 1670 (carboxyl C=O); 1650 (ketone C=O); 1600 (C=C); 1520 cm.$^{-1}$ (NO_2); $\lambda_{max.}$ (pH 1) 227 (ϵ 13,300), 273 mμ (ϵ 26,100); (pH 13) 276 mμ (ϵ 24,200)

Anal.—Calcd. for $C_{14}H_{19}NO_5$: C, 62.0; H, 3.34; N, 5.16. Found: C, 61.8; H, 3.35; N, 4.96.

4-(4′-Aminobenzyl)benzoic Acid (XXXVI).—To a solution of 6.87 Gm. of potassium hydroxide in 120 ml. of diethyleneglycol was added 9.49 Gm. (35 mmoles) of XXXV and 7 ml. of hydrazine hydrate. After being refluxed for 2 hr., the solution was slowly distilled until 10 ml. of liquid was collected over 2 hr. After being refluxed 1 hr. more, the solution was diluted with several volumes of water, then acidified to pH 4.8 with 3 *N* hydrochloric acid. The product was collected on a filter and washed with water; yield, 6.51 Gm. (82%), m.p. 220–223°, that was suitable for further transformations. Recrystallization of a sample from methanol with the aid of Norit gave slightly pink crystals, m.p. 227–228°. [Lit. m.p. 228° (15).]

p-Benzylbenzoic Acid (XV).—Reduction of *p*-benzoylbenzoic acid, as described for the preparation of XXXVI, gave (after recrystallization from aqueous methanol) a 60% yield of product, m.p. 159–160°; an additional 24%, m.p. 152–153°, was isolated from the filtrate. [Lit. m.p. 156–157° (19).]

4-[4′-(4-Methylvaleramido)benzyl]benzoic Acid (XX).—To a stirred mixture of 908 mg. (4 mmoles) of XXXVI and 4.16 Gm. (30 mmoles) of potassium carbonate and 20 ml. of acetone was added 0.94 ml. (7.2 mmoles) of 4-methylvaleroyl chloride. After being stirred for 3 hr. at 40–50° under a reflux condensor, the mixture was poured into 20 ml. of 1 *N* aqueous hydrochloric acid, then cooled. The product was collected on a filter and washed with water; yield, 982 mg. (75%), m.p. 229–231°. Recrystallization from ethanol gave 769 mg. (59%) of white prisms, m.p. 237–238°. $\nu_{max.}$ 3300 (NH); 2800, 2650, 2540 (broad acidic OH); 1680 (carboxyl C=O); 1650 (amide I); 1600, 1580, 1570 (C=C); 1520 (amide II); 830 cm.$^{-1}$ (*p*-C_6H_4); $\lambda_{max.}$ (pH 1) 258 mμ (ϵ 10,800); (pH 13) 247 mμ (ϵ 25,400).

Anal.—Calcd. for $C_{20}H_{23}NO_3$: C, 73.8; H, 7.12; N, 4.30. Found: C, 74.0; H, 7.26; N, 4.35.

4′-(4-Methylvaleramido)-4-biphenylcarboxylic Acid (XIX).—This compound was prepared in 60% yield from XXXIII as described for the preparation of XX. Recrystallization from ethanol with the aid of Norit gave white plates, m.p. 318–320°; the principal peaks in the infrared spectrum were similar to those of XX. $\lambda_{max.}$ (pH 1) 300 mμ (ϵ 19,000); (pH 13) 288 mμ (ϵ 38,500).

Anal.—Calcd. for $C_{19}H_{21}NO_3$: C, 73.3; H, 6.80; N, 4.50. Found: C, 73.0; H, 6.92; N, 4.27.

N-(m-Nitrobenzylidene)-p-aminobenzoic Acid (XXXVII).—To a stirred hot solution of 3.47 Gm. (20 mmoles) of *p*-aminobenzoic acid in 10 ml. of 95% ethanol was added a hot solution of 3.02 Gm. (20 mmoles) of *m*-nitrobenzaldehyde in 10 ml. of ethanol. The product rapidly separated. The mixture was heated to the b.p., then cooled to room temperature. The product was collected on a filter and washed with ethanol; yield, 5.19 Gm. (96%), m.p. 252–253°. Recrystallization from aqueous methanol gave yellow crystals, m.p. 251–257°. $\nu_{max.}$ 1680 (carboxyl C=O); 1640, 1600, 1575 (C=C, C=N); 1520, 1350 cm.$^{-1}$ (NO_2).

Anal.—Calcd. for $C_{14}H_{10}N_2O_4$: C, 62.2; H, 3.73; N, 10.4. Found: C, 62.1; H, 3.81; N, 10.4.

N-(m-Nitrobenzyl)-p-aminobenzoic Acid (XXXVIII).—To a stirred suspension of 4.05 Gm. (15 mmoles) of XXXVII in 80 ml. of methanol was added in portions over a period of about 30 min., 2.3 Gm. (60 mmoles) of sodium borohydride. The amber solution was refluxed for 15 min., then spin-evaporated *in vacuo*. The residual sodium salt was dissolved in 50 ml. of water, then the solution was acidified to pH 6. The product was collected on a filter and washed with water; yield, 4.01 Gm. (98%), m.p. 237–238°. Recrystallization from aqueous 2-methoxyethanol gave yellow crystals, m.p. 247–248°. $\nu_{max.}$ 3400 (NH); 1670 (carboxyl C=O); 1600, 1575 (C=C, NH); 1520, 1350 (NO_2); 838 (*p*-C_6H_4); 769 cm.$^{-1}$ (*m*-C_6H_4).

Anal.—Calcd. for $C_{14}H_{12}N_2O_4$: C, 61.7; H, 4.44; N, 10.3. Found: C, 61.7; H, 4.60; N, 10.4.

N-Acetyl-N-(m-nitrobenzyl)-p-aminobenzoic Acid (XXXIX).—A mixture of 2.50 Gm. (9.18 mmoles) of XXXVIII and 15 ml. of acetic anhydride was refluxed for 30 min., then poured into 30 Gm. of iced water. The oily product was extracted with chloroform (3 × 10 ml.). The combined extracts, dried with magnesium sulfate, were spin-evaporated *in vacuo*, leaving an oil which solidified on trituration with petroleum ether to a solid (3.16 Gm.), m.p. 91–94°; the infrared spectrum showed anhydride bands at 1800 and 1725 cm.$^{-1}$. The anhydride was warmed with 30 ml. of 1 *N* aqueous sodium hydroxide until solution was essentially complete. The solution was clarified by filtration, then acidified to pH 2 with 3 *N* hydrochloric acid. The product was collected on a filter and washed with water; yield, 2.84 Gm. (99%), m.p. 209–211°. Recrystallization from aqueous ethanol afforded 2.69 Gm. (93%) of nearly white needles, m.p. 212–213°. $\nu_{max.}$ 2600–2500 (broad acidic OH); 1680 (carboxyl C=O); 1625 (amide C=O); 1625, 1580, 1525 (C=C); 1525, 1340 (NO_2); 870 (*p*-C_6H_4); 785 cm.$^{-1}$ (*m*-C_6H_4).

Anal.—Calcd. for $C_{16}H_{14}N_2O_5$: C, 61.1; H, 4.49; N, 8.92. Found: C, 61.1; H, 4.29; N, 8.81.

N-(m-Aminobenzyl)-p-aminobenzoic Acid (XXVI).—A solution of 2.72 Gm. (10 mmoles) of

XXXVIII in 200 ml. of 2-methoxyethanol was shaken with hydrogen at 2–3 Atm. in the presence of 100 mg. of platinum oxide catalyst; reduction was complete in 90 min. The filtered solution was spin-evaporated *in vacuo* and the residue was recrystallized from aqueous 2-methoxyethanol; yield, 2.04 Gm. (84%) of buff-colored crystals, m.p. 193–194°. Recrystallization from aqueous 2-methoxyethanol gave nearly white crystals with unchanged m.p. $\nu_{max.}$ 3550 (NH); 1680 (carboxyl C=O); 1620, 1550, 1505 (C=C, NH); 825 (*p*-C_6H_4); 765 (*m*-C_6H_4); no NO_2 near 1520 or 1340 cm.$^{-1}$.

Anal.—Calcd. for $C_{14}H_{14}N_2O_2$: C, 69.4; H, 5.82; N, 11.5. Found: C, 69.5; H, 6.00; N, 11.3.

N - Acetyl - N - (m - aminobenzyl) - p - aminobenzoic Acid (XXVII).—A solution of 942 mg. (3 mmoles) of XXXIX in 100 ml. of ethanol was shaken with hydrogen at 2–3 Atm. in the presence of 60 mg. of platinum oxide catalyst; reduction was complete in about 15 min. The filtered solution was spin-evaporated *in vacuo* leaving 849 mg. (99%) of a glassy residue which showed 2 spots on TLC in methanol. After separation by preparative TLC, the material still could not be crystallized.

To a solution of 400 mg. of the crude product in 5 ml. of absolute ethanol was added 172 mg. (25% excess) of cyclohexylamine. Addition of 20 ml. of ether caused the separation of a gum (228 mg.). The supernatant liquid was decanted and deposited 127 mg. of crystals on standing which had m.p. 170–174°. Two recrystallizations from absolute alcohol–ether gave 90 mg. of pure cyclohexylammonium salt, as white crystals, m.p. 168–170°. $\nu_{max.}$ 3450, 3400 (NH); 2200, 2150 (NH^+); 1660 (amide C=O), 1600 (COO^-); 1625, 1540, 1500 cm.$^{-1}$ (NH, C=C).

Anal.—Calcd. for $C_{16}H_{16}N_2O_3 \cdot C_6H_{11}NH_2$: C, 68.9; H, 7.62; N, 11.0. Found: C, 68.7; H, 7.80; N, 10.8.

The free acid could be obtained as a glass free of other organic matter in 73% over-all yield by preparative thin-layer chromatography on Silica Gel HF_{254} with methanol as solvent. Since the compound would not dissolve in acetone or chloroform, methanol was used for elution; the resultant product had a C/N ratio of 6.89 (calcd. 6.86), but could not be freed of about 10% of extracted silica.

Analogs of Tetrahydrofolic Acid XXXIII

Hydrophobic Bonding to Dihydrofolic Reductase V. Inhibition by Some Pyrimidines Bridged to Benzoic Acid

By B. R. BAKER*, BENG-THONG HO, JAMES K. COWARD, and DANIEL V. SANTI

Folic acid (I), pteroic acid (IV), and a series of 2-amino-6-methyl-4-pyrimidinols bridged from its 5-position to the *p*-position of benzoic acid with aminopropyl (VII), butyl (X), carbamoylpropyl (XIII), sulfonamidopropyl (XV), and *N*-acetylaminopropyl (XVI) were compared as inhibitors of dihydrofolic reductase. Evidence was presented that VII and X probably had their side chains off of the 5-position of the pyrimidine complexed to the hydrophobic region of the enzyme, whereas XIII, XV, and XVI probably had their side chains complexed to the locus on the enzyme that normally binds the *p*-aminobenzoyl moiety of folic acid (I).

In the preceding paper of this series (1), experimental evidence was presented that the hydrophobic bonding region of dihydrofolic reductase (2) is probably not between the binding regions for the pyrimidyl and *p*-aminobenzoyl-L-glutamate moieties of folic acid (I) or dihydrofolic acid. If the hydrophobic bonding area is in some other region, then of the hundreds of compounds, such as type II, evaluated as dihydrofolic reductase inhibitors and presented in previous

Analogs of Tetrahydrofolic Acid XXXIII

Hydrophobic Bonding to Dihydrofolic Reductase V. Inhibition by Some Pyrimidines Bridged to Benzoic Acid

By B. R. BAKER*, BENG-THONG HO, JAMES K. COWARD, and DANIEL V. SANTI

Folic acid (I), pteroic acid (IV), and a series of 2-amino-6-methyl-4-pyrimidinols bridged from its 5-position to the *p*-position of benzoic acid with aminopropyl (VII), butyl (X), carbamoylpropyl (XIII), sulfonamidopropyl (XV), and *N*-acetylaminopropyl (XVI) were compared as inhibitors of dihydrofolic reductase. Evidence was presented that VII and X probably had their side chains off of the 5-position of the pyrimidine complexed to the hydrophobic region of the enzyme, whereas XIII, XV, and XVI probably had their side chains complexed to the locus on the enzyme that normally binds the *p*-aminobenzoyl moiety of folic acid (I).

In the preceding paper of this series (1), experimental evidence was presented that the hydrophobic bonding region of dihydrofolic reductase (2) is probably not between the binding regions for the pyrimidyl and *p*-aminobenzoyl-L-glutamate moieties of folic acid (I) or dihydrofolic acid. If the hydrophobic bonding area is in some other region, then of the hundreds of compounds, such as type II, evaluated as dihydrofolic reductase inhibitors and presented in previous

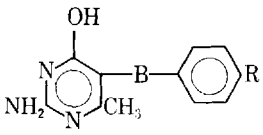
I



II, R = H
III, R = COOH

papers of this series, which have side chains on the heterocycles that complex with this hydrophobic region and which have side chains that complex with the *p*-aminobenzoyl locus? As a side chain is made more and more polar or has added groups that can complex at one or more of the points of the glutamate locus, at what stage does the side chain shift from the hydrophobic bonding region to the more polar *p*-aminobenzoyl-L-glutamate binding region? Such information is considered crucial for rational design of active-site-directed irreversible inhibitors (3), since the covalent bond-forming group on the inhibitor must be juxtapositioned to a nucleophilic group on the enzyme in order to operate; such a nucleophilic group is polar by definition and is less apt to be present in a hydrophobic region of the enzyme. One possible approach to the problem is to compare effects of binding to dihydrofolic reductase when a given pyrimidine bridged to a benzene ring such as II is substituted on the phenyl ring by a *p*-carboxyl group as in III. The results of such a study are the subject of this paper.

DISCUSSION

In a previous study (4) it was noted that the pyrimidyl prototype inhibitor (VI) of dihydrofolic reductase with the intact *p*-aminobenzoyl-L-glutamate moiety (5) was consistently slightly less effective than the corresponding inhibitor (VII) derived from *p*-aminobenzoic acid (Table I). In contrast, folic acid (I) was complexed about eightyfold more effectively than pteroic acid (V) as inhibitors of dihydrofolic reductase (6). These conflicting data on removal of the L-glutamate moiety from the 2 types of inhibitors were in part resolved in the preceding paper of this series (1); that is, it appeared that the propylaminobenzoate side chain of VII was complexed in the hydrophobic region of dihydrofolic reductase rather than at the *p*-aminobenzoyl locus normally complexing this moiety of folic acid (I). The prototype inhibitor (VI) appeared to be complexed in the same manner as folic acid (I). It should also be noted that removal of the carboxyl group of VII gave an inhibitor (VIII) that was only tenfold less effective than VII.

Since both VII and VIII are believed to have their pyrimidyl side chains complexed in the hydrophobic region, 3 other types of side chains previously studied were converted to their *p*-carboxy derivatives to determine if a similar increase in magnitude of binding observed with VII and VIII would be obtained. If a similar increment were obtained, then this increment could be used as evidence for the hypothesis that the side chain in question was complexed to the hydrophobic region of the enzyme. The following 3 side chains were selected: (*a*) the phenylbutyl side chain (IX), since this side chain gave 27-fold better inhibition than the anilinopropyl side chain (VIII) (7); (*b*) the benzamidopropyl side chain (XI), since this side chain gave an inhibitor about as effective as VIII (8); and (*c*) the *p*-tolylsulfonamidopropyl side chain (XIV), since this side chain gave an inhibitor less effective than VIII (8).

Introduction of the *p*-carboxyl (X) into the phenylbutyl side chain (IX) gave a twelvefold enhancement in binding (Table I), thus indicating that the phenylbutyl side chains (IX and X) and the anilinopropyl side chain (VII and VIII) were complexed in the same region of the enzyme, presumably the hydrophobic region. In contrast, introduction of the carboxyl group on the benzamidopropyl side chain (XII) to give XIII or on the benzenesulfonamidopropyl side chain (XIV) to give XV showed no enhancement in binding; these data would indicate that these two side chains of XII and XIV are not complexed in the hydrophobic region, and could be presumed to be complexed to the *p*-aminobenzoyl locus where folic acid (I) is normally complexed.[1] However, such an interpretation would require considerable substantiation since other explanations are possible, for example, (*a*) the chain length between the pyrimidyl and benzene moieties of XII and XIV are 1 atom longer than in the case of the anilinopropyl (VIII) or phenylbutyl series (X); (*b*) the ground-state staggered conformations about the $C_6H_5CH_2CH_2$ group of X or the $C_6H_5NHCH_2$— group of VIII are different than the ground-state planar conformations of the $C_6H_5CONCH_2$ group of XII or conformation of the $C_6H_5SO_2NCH_2$ group of XIV which is not quite so near planarity as the amide.

Bertino *et al.* (6) recently noted that 10-formyl folic acid (IV) was a twentyfold better inhibitor of dihydrofolic reductase than folic acid (I) (Table I). It was interesting to observe that acetylation of VII on the "10-position" corresponding to folic acid gave an inhibitor (XVI) that was less than twofold better than VII and as an inhibitor. A similar small increment has been observed previously on acetylation of 2-amino-5-(3-anilinopropyl)-6-methyl-4-pyrimidinethiol (9). This lack of appreciable increase in binding after acylation could be interpreted to indicate that folic acid (I) and presumably pteroic acid (V) are complexing differently to dihydrofolic reductase than are the 5-anilinopropyl-pyrimidine types (VII and VIII).

[1] Since the *N*-butyl benzamidopropyl and *N*-butyl *p*-tolylsulfonamidopropyl side chains previously studied (8) are less polar, these may be complexed by hydrophobic bonding to the hydrophobic region.

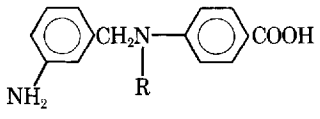
[a] Dihydrofolic reductase was a 45–90% saturated ammonium sulfate fraction from pigeon liver which was prepared and assayed with 6 μM dihydrofolate and 12 μM TPNH in 0.05 M Tris buffer (pH 7.4) containing 10 mM mercaptoethanol and 1 mM Versene as previously described (12). The technical assistance of Mrs. Shirley Humphrey, Miss Karen Smith, and Mrs. Gail Salomon is acknowledged. [b] Data of Bertino *et al.* (6). They used the dihydrofolic reductase from Ehrlich ascites carcinoma cells with dihydrofolate as substrate at pH 7.5; dihydrofolate had apparent K_m 1.3×10^{-6}. [c] Data from *Reference 15*. [d] Data from *Reference 4*. [e] For assay the inhibitor was dissolved in 0.05 M Tris buffer containing 10 mM mercaptoethanol and 1 mM Versene, then the pH was readjusted to 7.4 with 0.1 N KOH. [f] Data from *Reference 7*. [g] The inhibitor was dissolved in N,N-dimethylformamide and the assay was run in the presence of 10% N,N-dimethylformamide. [h] The same results were obtained with or without 10% N,N-dimethylformamide in the assay. [i] Data from *Reference 8*.

That 10-formyl folic acid (IV) is a twentyfold better inhibitor of dihydrofolic reductase than folic acid (I) (6) has considerable bearing on the mode of binding of folic acid to dihydrofolic reductase. In the $—C_6H_4—\underset{|}{N}—CH_2—$ moiety of folic acid (I) the bond angles about the nitrogen are pyramidal, whereas the same bonds are nearly planar in the 10-formyl folic acid (IV) due to the amide resonance. Therefore, it is probable that either folic acid or the enzyme or both undergo an energetically unfavorable conformational change to accommodate the nonplanarity of the N_{10} bonds in folic acid (1); this energy formation of the complex between the enzyme and folic acid (I), being reflected in less net binding energy. Then the planar N_{10} of 10-formyl folic acid is presumably in a more favorable ground-state conformation for complexing with the enzyme, being reflected in better net energy of binding than in the case of folic acid (1).

It was previously noted that XVII was a relatively good inhibitor of dihydrofolic reductase showing 50% inhibition at 0.76 mM (1), about the same as the 5-anilinopropyl pyrimidine (VIII) (1). The aminobenzyl group and part of the benzoate group of XVII were believed to be complexed to the hydrophobic region, but the carboxyl group was probably not in contact with the hydrophobic region of the enzyme surface (1). It was noted that N-acetylation of XVII on the p-amino group gave a compound (XVIII) that failed to inhibit dihydrofolic reductase at 12 times the concentration required for XVII to show 50% inhibition. The planarity about the "N_{10}" (*para*)nitrogen of XVIII is apparently unfavorable for complexing to the hydrophobic region



XVII, R = H
XVIII, R = CH_3CO

of enzyme particularly when a terminal carboxylate is present.

Since acylation of folic acid (I) gives an inhibitor (IV) that is 20 times more effective than I, but acylation of XVII gives an inhibitor (XVIII) that is less than one-fortieth as effective as XVII, it is quite reasonable that XVI has its side chain complexed at the *p*-aminobenzoyl locus; this is in contrast to VII, which probably has its side chain complexed to the hydrophobic region. Again this deduction has the tenuous assumption that VII and XVII have the same conformation in the complex.

A problem that still remains is how a carboxyl group can increase the phenyl binding to the hydrophobic region since the carboxyl is ionized at the pH of the assay to the highly polar carboxylate anion; it is therefore obvious that the carboxylate cannot be in direct contact with the hydrophobic region. That the carboxyl of a compound such as X does not exert an inductive effect on binding of the phenyl is clear from the relative binding of X and its ester, XI. The ester (XI) is only one-fifth as effective as the carboxylate (X), but the ester is still 2–3 times as effective as the parent phenyl compound, IX. It was previously noted that an *n*-octyl group gave no more hydrophobic bonding than an *n*-butyl group, but placement of a phenyl on the terminus of the *n*-butyl group did give an increment in binding (2); these results were interpreted to indicate that a flat interaction between the phenyl and the enzyme was required which an aliphatic group could not duplicate. If the hydrophobic region ends at the end of the phenylbutyl group of IX, then an additional carboxylate may form a hydrogen bond with the enzyme in this region; the ester group of XI could then form a somewhat weaker hydrogen bond to account for the relative order of activity of X > XI > IX. Such a hypothesis might be verified by replacing the carboxyl group of X by a bromomethyl to determine if an active-site-directed irreversible inhibitor (3) would be obtained that would presumably operate by alkylation of this carboxylate binding point to the enzyme.

To put these working hypotheses presented here on a firmer basis would require considerably more investigation of related compounds. However, these working hypotheses in this and in the accompanying papers appeared attractive enough to warrant pursuit of the design of active-site-directed irreversible inhibitors (3) that can bind to both the hydrophobic and the *p*-aminobenzoyl loci of the enzyme. Such studies are being pursued as direct evidence for these 2 binding loci. Initial results with several potential active-site-directed irreversible inhibitors built on the hypothesis have been successful; when the results are on completely firm ground, they will be presented in future papers.

Although it cannot be unequivocally stated at this time that a molecule such as 2-amino-5-(*p*-carboxyphenylbutyl)-6-methyl-4-pyrimidinol (X) has its side chain complexed to the hydrophobic region of the enzyme, the unequivocal result remains that X is the most effective 2-amino-4-pyrimidinol type of dihydrofolic reductase inhibitor yet observed.

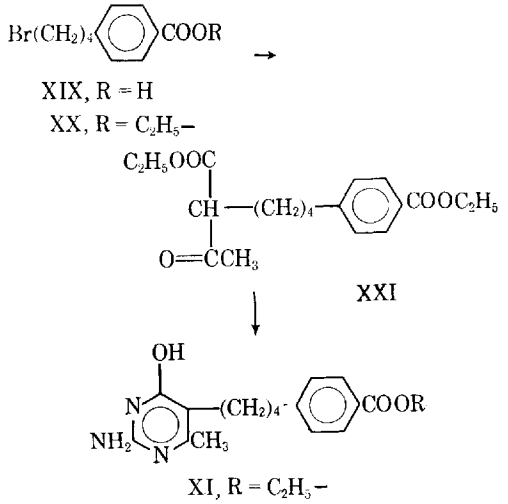
EXPERIMENTAL

Synthesis.—Ethyl *p*-(4-bromobutyl)benzoate (XIX) was prepared by esterification of the corresponding acid (XX) (1) in 92% yield. Alkylation of ethyl acetoacetate with XX was performed with sodium hydride in *tert*-butyl alcohol to avoid alcoholysis of the alkylated keto ester (XXI) (9). The crude keto ester (XXI) was condensed with guanidine carbonate in *tert*-butyl alcohol (9) to give a 21% over-all yield of the crystalline pyrimidine ester (XI). Saponification of XI with aqueous 1 *N* sodium hydroxide proceeded in 97% yield to the desired *p*-carboxyphenylbutyl pyrimidine (X). (Scheme I.)

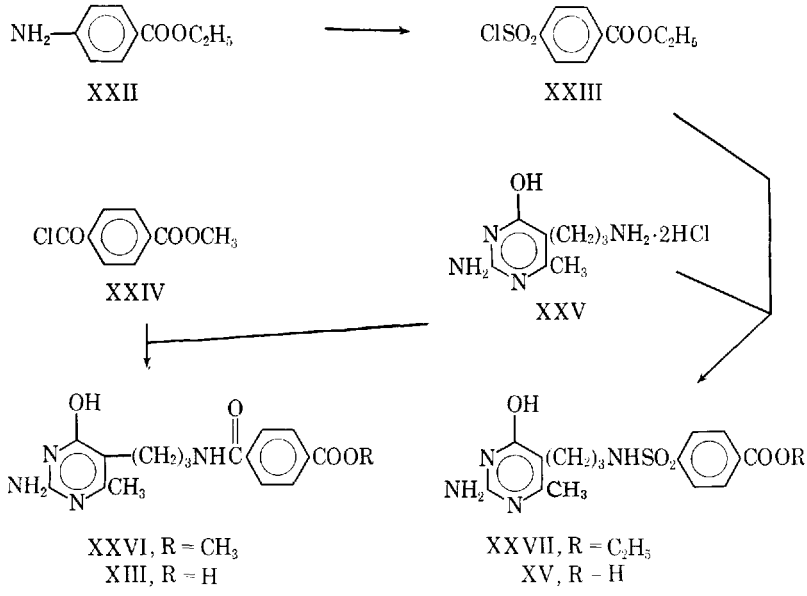
p-Carbomethoxybenzoyl chloride (XXIV) was prepared from dimethyl terephthalate by modification of the procedure of Williams *et al.* (10). Acylation of the pyrimidyl propylamine (XXV) (8) as its free base with XXIV in aqueous acetone proceeded smoothly to the pyrimidyl ester (XXVI) in 79% yield. Saponification of XXVI with 1 *N* aqueous sodium hydroxide at room temperature afforded XIII in 80% yield. (Scheme II.)

p-Carbethoxybenzenesulfonyl chloride (XXIII) was prepared in 81% yield by the Sandmeyer reaction (11); that is, the treatment of the diazonium salt derived from ethyl *p*-aminobenzoate (XXII) with sulfur dioxide catalyzed by cuprous chloride. Reaction of the sulfonyl chloride (XXIII) with the free base of XXV in aqueous acetone also proceeded smoothly in 81% yield. Saponification with 1 *N* aqueous sodium hydroxide gave the requisite carboxy pyrimidine (XV) in 80% yield. (Scheme II.)

Acetylation of the anilino NH-group of VII (14) with acetic anhydride in pyridine was sufficiently slowed by the electron-withdrawing *p*-carboxyl group so that acetylation of the 2-amino group (12) became competitive and selective acetylation of the anilino group was not feasible. In previous successful selective acylations of this type, an electron-withdrawing *p*-group was not present (7). Therefore, both amino groups were allowed to acetylate (13) giving XXVIII in 86% yield. Since the acetyl on the 2-amino group is considerably more labile than the acetyl group on the anilino moiety,



Scheme I



Scheme II

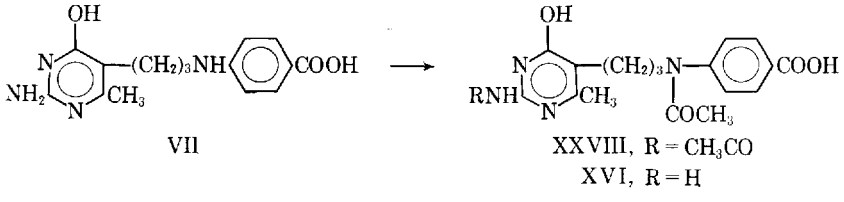
selective removal was achieved with *n*-butylamine in boiling methanol (13). The reaction was readily followed by the difference in ultraviolet spectra of XXVIII and XVI in 0.1 *N* acid, particularly at 247 mμ. After a 3-hr. treatment, XVI could be isolated analytically pure in 74% yield from XXVIII. (Scheme III.)

Methods.—Melting points were taken on a Mel-Temp block in capillary tubes and those below 230° are corrected. Infrared spectra were determined in KBr pellet, unless otherwise indicated, with a Perkin-Elmer 137B spectrophotometer. Ultraviolet spectra were determined in water, unless otherwise indicated, with a Perkin-Elmer 202 spectrophotometer.

2 - Amino - 5 - (p - carbethoxyphenylbutyl) - 6-methyl-4-pyrimidinol (XI).—A solution of 1.00 Gm. (3.89 mmoles) of XIX (1) in 10 ml. of ethanol and 1 ml. of ethanesulfonic acid was refluxed for 24 hr., then spin-evaporated *in vacuo*. The residue was dissolved in 20 ml. of chloroform, and the solution was washed with 3 *N* aqueous ammonia (2 × 10 ml.), then water (2 × 10 ml.). Dried with magnesium sulfate, the chloroform solution was spin-evaporated *in vacuo* leaving 1.02 Gm. (92%) of XX as an oil with $\nu_{max.}$(film) 1720 (ester C=O), 1270, 1100 cm.$^{-1}$ (ester C—O—C).

To a solution of 800 mg. (6.1 mmoles) of ethyl acetoacetate in 15 ml. of *tert*-butyl alcohol was added portionwise 273 mg. (6.1 mmoles) of a 53.5% dispersion of sodium hydride in mineral oil. When solution was complete, 1.51 Gm. (5.3 mmoles) of XX was added, then the solution was refluxed gently with magnetic stirring for 20 hr. The mixture, acidified with glacial acetic acid, was spin-evaporated *in vacuo*. The residue was partitioned between 20 ml. of chloroform and 10 ml. of water. The separated aqueous layer was extracted with 5 ml. of chloroform. Dried with magnesium sulfate, the combined extracts were spin-evaporated *in vacuo*, finally at less than 1 mm. (bath 90°) to remove the excess ethyl acetoacetate; yield, 872 mg. of crude XXI with $\lambda_{max.}$ (1 *N* methanolic sodium methoxide) 244, 284 mμ.

A mixture of 870 mg. (2.6 mmoles) of crude XXI, 234 mg. (1.3 mmoles) of guanidine carbonate, and 10 ml. of *tert*-butyl alcohol (9) was refluxed gently with magnetic stirring for 60 hr. The solution was clarified by filtration, neutralized with glacial acetic acid, then spin-evaporated *in vacuo*. The residue was partitioned between 25 ml. of chloroform and 10 ml. of water. The product which separated was collected on a filter and washed with water; yield, 341 mg., m.p. 163–165°. An additional 23 mg. (total 21% based on XX), m.p. 156–159°, was obtained by concentration of the chloroform layer.



Scheme III

Recrystallization of 290 mg. from aqueous ethanol gave 227 mg. (16%), m.p. 148–150°. A second recrystallization afforded 201 mg. (14%) of white crystals, m.p. 150–152°. $\nu_{max.}$ 3400, 3200 (NH); 1715 (ester C=O); 1650, 1630, 1600, 1530, 1510 (C=O, C=N, C=C, NH); 1280, 1110 cm.$^{-1}$ (ester C—O—C); $\lambda_{max.}$ (ethanol) 290 mμ.

Anal.—Calcd. for $C_{15}H_{23}N_3O_3$: C, 65.6; H, 7.04; N, 12.8. Found: C, 65.4; H, 6.92; N, 12.9.

2 - Amino - 5 - (p - carboxyphenylbutyl) - 6-methyl-4-pyrimidinol (X).—A solution of 164 mg. (0.5 mmole) of XI in 3 ml. of 1 *N* aqueous sodium hydroxide was heated at 100° for 30 min. The cooled solution was clarified by filtration, then adjusted to pH 4–5 with acetic acid. The product was collected on a filter and washed with water; yield, 146 mg. (97%), m.p. 295–297°. Recrystallization from aqueous 2-methoxyethanol afforded 108 mg. (72%) of white crystals, m.p. 311–312°, unchanged on further recrystallization. $\nu_{max.}$ 3350, 3150 (NH); 1690, 1670, 1600, 1545–1500 (C=O, NH, C=N, C=C); no ester band near 1280 cm.$^{-1}$; $\lambda_{max.}$ (pH 1) 243, 274 mμ (inflection); (pH 13) 235, 280 mμ.

Anal.—Calcd. for $C_{16}H_{19}N_3O_3$: C, 63.8; H, 6.35; N, 13.9. Found: C, 63.6; H, 6.55; N, 13.7.

p-Carbomethoxybenzoyl Chloride (XXIV).—Dimethyl terephthalate was partially hydrolyzed as described by Williams *et al.* (10); they record a crude yield of 66%, but no melting point is given until after purification. The crude product contained considerable terephthalic acid. Solution in acetone at ambient temperature was more satisfactory than water (10) for removing the insoluble terephthalic acid.

A suspension of 270 mg. (1.5 mmoles) of *p*-carbomethoxybenzoic acid in 7 ml. of chloroform, 0.29 ml. (6 mmoles) of thionyl chloride, and a drop of pyridine was refluxed for 3 hr., solution being complete at that time. Spin-evaporation *in vacuo* gave the acid chloride as a crystalline solid with $\nu_{max.}$ (Nujol) 1780 cm.$^{-1}$ (acid chloride C=O) that was used immediately in the next step.

2 - Amino - 5 - (p - carbomethoxybenzamidopropyl)-6-methyl-4-pyrimidinol (XXVI).—To a magnetically stirred solution of 255 mg. (1 mmole) of XXV (8) and 0.67 ml. of 3 *N* aqueous sodium hydroxide and 0.5 ml. of water containing 159 mg. (1.5 mmoles) of sodium carbonate was added 1 ml. of acetone; then a solution of the crude XXIV from 270 mg. of acid in 2.5 ml. of acetone was added. After being stirred for 4 hr., during which time the product separated, the mixture was diluted with several volumes of water. The product was collected on a filter and washed with water; yield, 272 mg. (79%). Recrystallization from 2-methoxyethanol gave 210 mg. (61%) of white crystals, m.p. 240–242° dec. $\nu_{max.}$ 3300, 3100 (NH); 1720 (ester C=O); 1690, 1630 (sh), 1610, 1525 (C=O, NH, C=N, C=C), 1280 1100 cm.$^{-1}$ (ester C—O—C); $\lambda_{max.}$ (pH 13) 276 mμ (sh).

Anal.—Calcd. for $C_{17}H_{20}N_4O_4 \cdot H_2O$: C, 56.3; H, 6.12; N, 15.5. Found: C, 56.0; H, 6.10; N, 15.9.

2 - Amino - 5 - (p - carboxybenzamidopropyl) - 6-methyl-4-pyrimidinol (XIII).—A suspension of 638 mg. (1.85 mmoles) of crude XXVI in 10 ml. of 1 *N* aqueous sodium hydroxide was magnetically stirred for 20 hr. at ambient temperature, during which time solution took place. Acidification to about pH 5 with 4 *N* aqueous hydrochloric acid precipitated the product which was collected on a filter and washed with water. The crude product was dissolved in 1 *N* aqueous sodium bicarbonate; the solution was clarified by filtration, then acidified to about pH 5. The product was collected by centrifugation and washed well with water; yield, 486 mg. (80%), of white solid, m.p. 290–295° dec. $\nu_{max.}$ 3450–3300 (NH); 1700 (carboxyl C=O); 1660, 1620, 1550 (C=O, C=N, C=C, N—H); no 1280 or 1100 cm.$^{-1}$ ester C—O—C bands; $\lambda_{max.}$ (pH 13) 276 mμ. The compound moved on paper as a single spot (R_f 0.7) in 5% aqueous K_2HPO_4.

Anal.—Calcd. for $C_{16}H_{18}N_4O_4 \cdot H_2O$: C, 55.2; H, 5.78; N, 16.1. Found: C, 54.8; H, 5.79; N, 16.3.

2 - Amino - 5 - (p - carbethoxybenzenesulfonamidopropyl) - 6 - methyl - 4 - pyrimidinol (XXVII).—Treatment of 255 mg. (1 mmole) of XXV (8) with 372 mg. of XXIII (prepared in 81% yield as described for the methyl ester) (11) as described for preparation of XXVI, gave 369 mg. (94%) of crude product, m.p. 220–223°. Recrystallization from 85% ethanol afforded 319 mg. (81%) of white crystals, m.p. 223–224°. $\nu_{max.}$ 3300, 3100 (NH); 1710 (ester C=O); 1645, 1600 (sh), 1540 (NH, C=O, C=C, C=N); 1385, 1160 (SO_2); 1270, 1100 cm.$^{-1}$ (ester C—O—C); $\lambda_{max.}$ (pH 13) 279 mμ.

Anal.—Calcd. for $C_{17}H_{22}N_4O_5S$: C, 51.8; H, 5.62; N, 14.2. Found: C, 51.5; H, 5.68; N, 14.1.

2 - Amino - 5 - (p - carboxybenzenesulfonamidopropyl) - 6 - methyl - 4 - pyrimidinol (XV).—A suspension of 394 mg. (1 mmole) of XXVII in 10 ml. of 1 *N* aqueous sodium hydroxide was magnetically stirred at room temperature for 2 days, during which time solution was complete. The product was isolated and reprecipitated from sodium bicarbonate solution as described for XIII; yield, 293 mg. (80%) of white solid, m.p. 310–315° dec.; $\nu_{max.}$ 3400, 3250 (NH); 1680, 1650 (C=N, C=C, C=O, NH); 1385, 1150 (SO_2); no 1280 or 1100 cm.$^{-1}$ ester C—O—C bands; $\lambda_{max.}$ (pH 13) 278 mμ.

Anal.—Calcd. for $C_{15}H_{18}N_4O_5S$: C, 49.2; H, 4.95; N, 15.3. Found: C, 49.1; H, 5.03; N, 15.4.

2 - Acetamido - 5 - (N - acetyl - p - carboxyanilinopropyl) - 6 - methyl - 4 - pyrimidinol (XXVIII).—A solution of 250 mg. (0.83 mmole) of VII (14) in 5 ml. of reagent pyridine and 5 ml. of acetic anhydride was heated in a bath at 95° for 2 hr., then spin-evaporated *in vacuo*. Crystallization from aqueous ethanol with the aid of decolorizing carbon gave 275 mg. (86%) of white crystals, m.p. 225–226°. $\lambda_{max.}$ (pH 1) 247, 265 mμ (inflect.) (*A* 260/280, 1.89); (pH 13) 245, 273 mμ (inflect.) (*A* 260/280, 1.45).

Anal.—Calcd. for $C_{19}H_{22}N_4O_5$: C, 59.1; H, 5.74; N, 14.5. Found: C, 58.8; H, 5.61; N, 14.4.

2 - Amino - 5 - (N - acetyl - p - carboxyanilinopropyl)-6-methyl-4-pyrimidinol (XVI).—A solution of 230 mg. (0.6 mmole) of XXVIII and 0.1 ml. of *n*-butylamine in 8 ml. of methanol was refluxed for 3 hr. when an aliquot no longer showed any change in the absorbance at 247 mμ in 0.1 *N* hydrochloric acid. The solution was spin-evaporated *in vacuo*. The residue was dissolved in 4 ml. of hot methanol, 8.0 ml. of 0.2 *N* aqueous acetic acid was added, then the solution was chilled. The product was collected on a filter; yield, 148 mg. (74%), m.p.

239–240°. $\lambda_{max.}$ (pH 1) 234, 263 mμ (*A* 260/280, 1.80); (pH 13) 235, 278 mμ (*A* 260/280, 1.04).

Anal.—Calcd. for $C_{17}H_{20}N_4O_4$: C, 59.3; H, 5.85; N, 16.3. Found: C, 59.0; H, 5.98; N, 16.0.

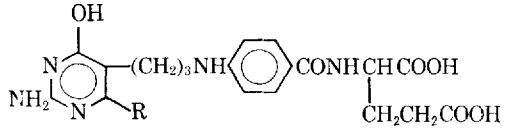
Analogs of Tetrahydrofolic Acid XXXIV

Hydrophobic Bonding to Dihydrofolic Reductase VI. Mode of Phenyl Binding of Some 6-Arylpyrimidines

By B. R. BAKER* and HOWARD S. SHAPIRO

New data are presented which strongly support the concept that the increment in better binding observed by substituting a phenyl group on the 6-position of 4-pyrimidinol is due to hydrophobic bonding of the phenyl group. Furthermore, 11 6-phenylpyrimidines with various substituents at the 2,4, and 5-positions were compared with 18 5-aryl and 5-arylalkylpyrimidines as inhibitors of dihydrofolic reductase. The results cannot be explained by a single conformation of the pyrimidine being complexed to the enzyme; therefore, a number of rotational conformers for the pyrimidine ring are proposed where the strong hydrophobic bonding by the phenyl or phenylalkyl substituent is the determining factor for the particular preferred conformation of a given inhibitor. Such a hypothesis has previously been invoked to explain the inhibitor and substrate binding to chymotrypsin by Niemann *et al.*

THE 6-PHENYLPYRIMIDINE analog (I) (1) of tetrahydrofolic acid was observed to be a twelvefold better inhibitor of dihydrofolic reductase at pH 7.4 than the prototype 6-methylpyrimidine analog (II) (2, 3). When assayed



I, R = C_6H_5
II, R = CH_3

with folic acid as substrate at pH 6.1, I was found to be a twentyfold better inhibitor of the reductase than II (1, 4). Three possible explanations for this increased binding were proposed (1)—namely, (*a*) a charge-transfer complex, (*b*) the phenyl influences the binding of the pyrimidine ring, and (*c*) hydrophobic bonding. Since inductive effects by substitutents on the phenyl ring could not be completely correlated (5), explanations (*a*) and (*b*) can now be considered unlikely. The emergence of strong hydrophobic bonding by 5-alkylpyrimidines (6) and the further experimental evidence (7, 8) for hydrophobic bonding by the aryl group of 1-aryl-1,2-dihydro-*s*-triazines, 2-aryl-*s*-triazines, and 5-arylpyrimidines suggested that the mode of phenyl binding of 6-phenylpyrimidines be further investigated from the standpoint of hydrophobic bonding.

Rather than proceeding chronologically on the development of the possible hydrophobic bonding of the phenyl group of 6-phenylpyrimidines—as is customarily done with papers from this laboratory—it is somewhat easier to follow the evidence if the assumptions on binding are presented in logical order rather than by order arrived at from the tortuous trail of chronology.

DISCUSSION

The following recent developments on binding of inhibitors to dihydrofolic reductase are pertinent to the arguments to follow.

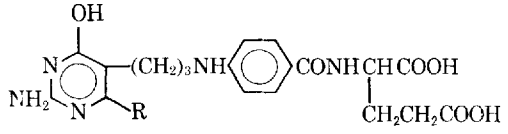
Analogs of Tetrahydrofolic Acid XXXIV

Hydrophobic Bonding to Dihydrofolic Reductase VI. Mode of Phenyl Binding of Some 6-Arylpyrimidines

By B. R. BAKER* and HOWARD S. SHAPIRO

New data are presented which strongly support the concept that the increment in better binding observed by substituting a phenyl group on the 6-position of 4-pyrimidinol is due to hydrophobic bonding of the phenyl group. Furthermore, 11 6-phenylpyrimidines with various substituents at the 2,4, and 5-positions were compared with 18 5-aryl and 5-arylalkylpyrimidines as inhibitors of dihydrofolic reductase. The results cannot be explained by a single conformation of the pyrimidine being complexed to the enzyme; therefore, a number of rotational conformers for the pyrimidine ring are proposed where the strong hydrophobic bonding by the phenyl or phenylalkyl substituent is the determining factor for the particular preferred conformation of a given inhibitor. Such a hypothesis has previously been invoked to explain the inhibitor and substrate binding to chymotrypsin by Niemann *et al.*

THE 6-PHENYLPYRIMIDINE analog (I) (1) of tetrahydrofolic acid was observed to be a twelvefold better inhibitor of dihydrofolic reductase at pH 7.4 than the prototype 6-methylpyrimidine analog (II) (2, 3). When assayed



I, R = C_6H_5
II, R = CH_3

with folic acid as substrate at pH 6.1, I was found to be a twentyfold better inhibitor of the reductase than II (1, 4). Three possible explanations for this increased binding were proposed (1)—namely, (*a*) a charge-transfer complex, (*b*) the phenyl influences the binding of the pyrimidine ring, and (*c*) hydrophobic bonding. Since inductive effects by substitutents on the phenyl ring could not be completely correlated (5), explanations (*a*) and (*b*) can now be considered unlikely. The emergence of strong hydrophobic bonding by 5-alkylpyrimidines (6) and the further experimental evidence (7, 8) for hydrophobic bonding by the aryl group of 1-aryl-1,2-dihydro-*s*-triazines, 2-aryl-*s*-triazines, and 5-arylpyrimidines suggested that the mode of phenyl binding of 6-phenylpyrimidines be further investigated from the standpoint of hydrophobic bonding.

Rather than proceeding chronologically on the development of the possible hydrophobic bonding of the phenyl group of 6-phenylpyrimidines—as is customarily done with papers from this laboratory—it is somewhat easier to follow the evidence if the assumptions on binding are presented in logical order rather than by order arrived at from the tortuous trail of chronology.

DISCUSSION

The following recent developments on binding of inhibitors to dihydrofolic reductase are pertinent to the arguments to follow.

III

(*a*) The pH profiles for some strongly basic and some weakly basic pyrimidine-type inhibitors were determined (9, 10). These results gave experimental evidence to support the hypothesis that the pyrimidines had only 2 binding points to the enzyme and that a variety of conformations of the pyrimidines were possible for complexing to the enzyme; the points of binding of the pyrimidine proposed were: first, a general bonding to the electron-rich π-cloud of the pyrimidine ring by a weakly acidic group on the enzyme, and second, 1 additional hydrogen bond.

(*b*) Experimental evidence has been presented (11, 12) that the hydrophobic bonding region most probably is not between the binding regions for the pyrimidyl and *p*-aminobenzoyl moieties of inhibitors such as II or folic acid.

Since folic acid (III) and aminopterin are good inhibitors of dihydrofolic reductase (9, 13), both inhibitors and the substrate, dihydrofolate, must have a definite conformation when complexed to the enzyme. The conformation of the pteridin moiety of folic acid (III) and aminopterin can be assigned as in III and the enzyme can then take a conformation in space that will fit the pteridine as written. The conformation of the various pyrimidines will then be written with relationship to the assigned conformation of the pteridine moiety of III. The assumption has already been made that pyrimidines and pteridines have 2 binding points to the enzyme and that the pyrimidines may have any one of a number of conformations when complexed to the enzyme, depending upon the substituents attached to the pyrimidine (9, 10).

A single conformation for pyrimidine binding cannot explain all the inconsistencies on binding

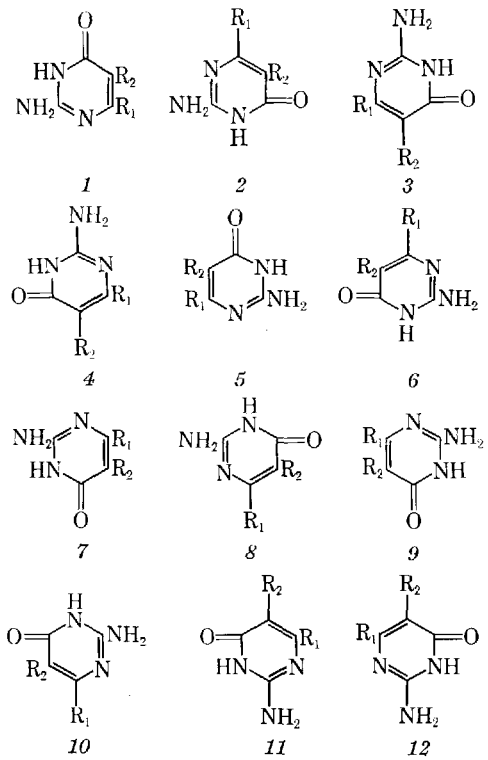
[a] Dihydrofolic reductase was a 45–95% saturated ammonium sulfate fraction prepared from pigeon liver acetone powder and assayed with 6 μM dihydrofolate, and 12 μM TPNH in 0.05 M Tris buffer (pH 7.4) containing 10 mM mercaptoethanol and 1 mM Versene as previously described (14). The 50% inhibition points were determined by plotting V_0/V_I against I, where V_0 = velocity without inhibitor, V_I = velocity with inhibitor, and I = inhibitor concentration; the 50% inhibition point occurs at the intercept of $V_0/V_I = 2$ (35, 36). The technical assistance of Miss Maureen Baker, Mrs. Shirley Humphrey, Mrs. Gail Salomon, and Miss Karen Smith is acknowledged. [b] See Table II. [c] Data from *Reference 14*. [d] Cell contained 10% *N,N*-dimethylformamide. [e] Too insoluble to determine 50% inhibition point with this assay. However, with folic acid as a substrate at pH 6.0, VI had $Ki = 1.8 \times 10^{-6}$, XXVI had $Ki = 0.58 \times 10^{-6}$, VII had $Ki = 9.8 \times 10^{-6}$, IV had $Ki = 63 \times 10^{-6}$, and V had $Ki = 4.5 \times 10^{-6}$ (5). [f] Since 20% inhibition is readily detectable, the concentration for 50% inhibition is at least 4 times greater than the concentration measured. [g] Data from *Reference 15*. [h] Data from *Reference 3*. [i] Data from *Reference 8*. [j] Same result obtained with or without *N,N*-dimethylformamide present. [k] Data from *Reference 37*. [l] Estimated from $V_0/V_I = 1.30$, and the error is larger than when $V_0/V_I = 2$.

previously observed, such as (*a*) 2-amino-5-(anilinopropyl)-6-methyl-4-pyrimidinethiol (V) is a better inhibitor than the 4-pyrimidinol (IV) (14), but in the 6-phenyl series (VI and VII) the reverse is true (5). (*b*) 2-Amino-5-(anilinopropyl)-6-methyl-4-pyrimidinol (IV) still binds as well to the enzyme when the 4-oxo group is removed (VIII) (14), but in the 6-phenyl series, removal of the oxo group of VI gives an inhibitor (IX) that has a large loss in binding compared to IV (Table I). (*c*) 2,4-Diamino-6-methyl-5-(phenylbutyl)pyrimidine (X) is a considerably better inhibitor than the corresponding 5-anilinopropyl pyrimidine (XI) (15) (Table I), but in the 6-phenyl series, the 2 compounds (XII and XIII) give about the same inhibition (5). (*d*) In contrast to (*b*), 2,4-diamino-6-phenylpyrimidine (XV) is a better inhibitor than 2,4-diamino-6-methylpyrimidine (XIV) (8), but when an *n*-butyl or a phenylbutyl side chain is introduced, the 6-methyl series (XVI and X) is better than the 6-phenyl series (XVII and XII) (Table I). There are numerous other examples. By the use of several conformations for pyrimidine binding, but using only a 2-point attachment of the pyrimidine ring, all of these inconsistencies can be suitably rationalized.

If no assumptions on binding are made, then there are 12 major possible conformations for pyrimidine binding (Table II) including the *1* conformation given for folic acid and aminopterin.

TABLE II.—POSSIBLE BINDING CONFORMATIONS FOR 2-AMINO-5,6-DISUBSTITUTED-4-PYRIMIDINOLS TO DIHYDROFOLIC REDUCTASE



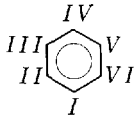
1 *2* *3*

4 *5* *6*

7 *8* *9*

10 *11* *12*

If one considers that 60°-twists between the 12 conformations could be further split into fraction of degrees of rotation, there are an infinite number of conformations; for example, the difference between *conformation 1* and *conformation 11* is a 60° twist. It might be argued that other conformers with smaller rotations between *1* and *11* should be considered, but as a first approximation, these 60° *rotational conformers* listed in Table II can be used to rationalize most of the inhibitor data. The designation of pyrimidine numbering cannot be used to signify the position of a group with respect to the given conformation of folic acid, *1*, with other conformers unless the particular conformer is also named; therefore the binding areas in Table II are numbered, based on conformer *1*, as follows:



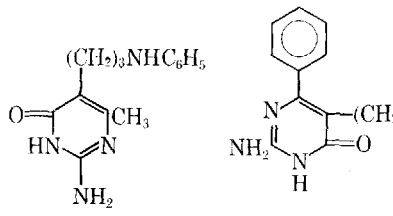
As pointed out previously, the pyrimidine probably has 2 binding points: (*a*) between a weakly acidic group on the enzyme to the electron-rich π-cloud of the pyrimidine ring and (*b*) a hydrogen bond to the enzyme where the pyrimidine group is an electron donor to the enzyme (9). The first bond (*a*) would be fairly independent of conformation since it is somewhat centralized, but the second bond must be in one of the areas *I* to *VI*.

Assume that the hydrogen bond (*b*) is at area *VI*. It should be noted among the 12 conformers that an NH_2, ring N, or C=O can be an electron donor for a hydrogen bond, but the acidic ring NH cannot and a C=S can donate for a hydrogen bond only poorly. On this basis the following conformers are possible for the 2-aminopyrimidines depending upon the 4-substituent. (*a*) 2-Amino-4-oxo: *2, 3, 5, 6, 10, 11*. (*b*) 2,4-Diamino: *2, 3, 5, 6, 9, 10, 11, 12*. (*c*) Among the conformations possible for (*a*) and (*b*), the 2-amino-4-H and 2-amino-4-thione can have conformations *5, 6, 9, 10, 11*, if binding is as good as 2-amino-4-oxo, but *2*, or *3*, if binding is poorer than 2-amino-4-oxo.

If *additional binding* occurs at the *p*-aminobenzoyl locus (area *V*) by R_1 or R_2, then the following conformations of those cited still remain possible. (*a*) 2-Amino-4-oxo: *2, 11*. (*b*) 2,4-Diamino: *2, 11*. (*c*) 2-Amino-4-H or 2-amino-4-thione: *11* if binding is as good as 2-amino-4-oxo, but *2*, if binding is poorer than 2-amino-4-oxo.

Assume that additional hydrophobic bonding occurs in area *IV*. Then the following conformations are still possible if either R_1 or R_2 bonds to the hydrophobic region, regardless of whether there is binding at the *p*-aminobenzoyl locus. (*a*) 2-Amino-4-oxo: *2, 6, 11*. (*b*) 2,4-Diamino: *2, 6, 11, 12*. (*c*) Among the conformations for (*a*) and (*b*), the 2-amino-4-H and 2-amino-4-thione can have conformations *6* and *11* if binding is as good as 2-amino-4-oxo, but only *2* if binding is poorer than 4-oxo.

Consider the specific case of 2-amino-5-(anilinopropyl)-6-methylpyrimidine with a 4-substituent. Since R_2 = anilinopropyl is the only group that can hydrophobically bond at region *IV* or complex to the *p*-aminobenzoyl locus (region *V*), and since both the 4-mercapto and 4-H compounds bind better than the 4-oxo compound, the following conforma-



IV–*11* VI–*2*

tions are possible if the anilinopropyl group is complexed to the hydrophobic region. (*a*) 2-Amino-4-oxo: *2* and *11*, but not *6*. (*b*) 2,4-Diamino: *2*, *11*, and *12*, but not *6*. (*c*) 2-Amino-4-H and 2-amino-4-SH: *11* since these compounds bind better than the 2-amino-4-oxo, but not conformation *2*.

The binding of the anilinopropyl group to the *p*-aminobenzoyl locus can only be by conformation *2* since *11* has the R_2 group placed incorrectly. Since the replacement of the 4-oxo group by 4-thione or 4-H gave better inhibitors, conformation *2* is not possible. Therefore, the anilinopropyl group cannot complex with the *p*-aminobenzoyl region *V*, but can only be hydrophobically bonded to the *IV* region. Either conformation *11* or *12* is satisfactory for 2,4-diamino and 2-amino-4-H, but only *11* is satisfactory for the 2-amino-4-oxo and 4-thione derivatives. Again it should be pointed out that *12* is not satisfactory when an acidic NH is present at the *VI* region needed for hydrogen bonding, but *12* is satisfactory with the 4-amino or 4-H since the acidic hydrogen of *12* has been removed. Evidence that *12* is the preferred conformation for the 2,4-diamino compound will be presented later in the fine points on interpretation.

Now consider the specific case of 2-amino-5-(anilinopropyl)-6-phenylpyrimidine with various 4-substituents. This case differs from the 6-methyl case in that either the 5- or 6-side chain of the pyrimidine could be complexed to the hydrophobic region. The following conformations are possible. (*a*) 2-amino-4-oxo: *2*, *6*, *11*. (*b*) 2,4-Diamino: *2*, *6*, *11*, *12*. (*c*) Of the conformations possible in (*a*) and (*b*), the 2-amino-4-H gives poorer binding than 2-amino-4-oxo only in conformation *2*.

Therefore, conformation *2* will explain all the binding of the 2-amino-5-(anilinopropyl)-6-phenylpyrimidines with 4-substituents. Conformation *2* places the anilinopropyl group at the *p*-aminobenzoyl locus and the 6-phenyl group in the hydrophobic region *IV*. There is additional information which supports the suggestion that the 6-phenyl group is hydrophobically bonded and that will be discussed later.

Although all of the data can be explained by the assumptions that there are 2 bonds from the enzyme to a pyrimidine—one which is complexed with the electron-rich π-cloud of the pyrimidine and the other is at the *VI*-region—are there other sets of assumptions which can or cannot explain the observed inhibition data?

First, is it necessary to assume that one of the 2 bonds is to the electron-rich π-cloud of the pyrimidine? Cannot there be 2 bonds to 2 definite groups in regions *I–VI*? In such a consideration, one can eliminate immediately any bonding by the hydrogen of an acidic NH, otherwise 2-amino-4-pyrimidinols would be better inhibitors than 2,4-diaminopyrimidines rather than vice versa. Assume that there are 2 hydrogen bonds to the *II* and *VI* regions; then the following conformations in Table II are possible. (*a*) 2-Amino-4-oxo: *2*, *6*. (*b*) 2,4-Diamino: *2*, *6*, *11*, *12*. (*c*) Of the possible conformations in (*a*) and (*b*), the 2-amino-4-H can have conformation *11* or *12* if it binds as good as 2-amino-4-oxo.

Therefore, the assumption of 2 hydrogen bonds to areas *II* and *VI* is invalid, since the 4-oxo derivative cannot bind in conformation *11* or *12* and the 4-H derivative cannot bind in conformation *2* or *6*. Similarly, 2 hydrogen bonds to areas *II* and *IV*, or areas *IV* and *VI*, or areas *I* and *IV* can be eliminated.

Assume that there are 2 hydrogen bonds to areas *I* and *II*, then the following conformations in Table II are possible. (*a*) 2-Amino-4-oxo: *1*, *12*. (*b*) 2,4-Diamino: *1*, *2*, *6*, *7*, *11*, *12*. (*c*) Of the possible conformations in (*a*) and (*b*), the 2-amino-4-H can have conformations *1* and *12* if it binds as good as 2-amino-4-oxo.

With these 2 particular hydrogen bonds it is not possible to account for 2-amino-5-(3-anilinopropyl)-6-phenylpyrimidine (IX) being a poorer inhibitor than the corresponding 4-oxopyrimidine (VI), since both allowable 4-oxo conformations, *11* and *12*, would not lose a binding group if the 4-oxo group were removed. Therefore, the assumption that pyrimidine binding occurs through 2 hydrogen bonds at the *I* and *II* regions is invalid. Similarly, hydrogen bonds to areas *I* and *VI* can be eliminated. Thus, all 10 combinations of 2 hydrogen bonds to discrete areas are eliminated. Similarly, 3 or 4 hydrogen bonds can be eliminated, the 4 hydrogen bond theory (16) having been eliminated by other means (9, 10).

With the assumption that 1 of the bonds to the pyrimidine is a general one depending on the electron-rich π-cloud (general basicity) of the pyrimidine, how much can the other two assumptions made earlier be varied and explain the data? These other 2 assumptions agreeing with the data were that (*a*) a hydrogen bond to the *VI* region was present, and (*b*) hydrophobic bonding was in the *IV* region.

First, keep (*a*) constant and vary (*b*). If the hydrophobic bonding region were at the *III* area, then the following conformations are possible. (*a*) 2-Amino-4-oxo: *5*, *6*. (*b*) 2,4-Diamino: *5*, *6*, *9*, *12*. (*c*) Of the possible conformations in (*a*) and (*b*), the 2-amino-4-H can have conformations *5*, *6*, *9*, and *12* if binding is as good as 4-oxo, but there is no possible conformation for the 4-H being poorer than 4-oxo.

Therefore, these parameters will not allow for a conformation that will bind 2-amino-5-(anilinopropyl)-6-phenylpyrimidine with a 4-oxo group (VI), but that will not bind to the corresponding 4-H pyrimidine (IX). Thus, the assumption of hydrophobic bonding at the *III* region is invalid. By similar arguments, hydrophobic bonding at regions *I*, *II*, and *V* can be eliminated.

There is 1 other set of assumptions which will explain all the data—namely, (*a*) 1 general bond due to the electron-rich π-cloud of the pyrimidine, (*b*) a hydrogen bond to the *IV* region, and (*c*) hydrophobic bonding at the *VI* region. Conformation *1* will accommodate the 6-phenyl series and conformation *7* will accommodate the 6-methyl series; note that *1* is a "flipped-over" conformation of *2*, and *7* is a "flipped-over" conformation of *11*. To dis-

tinguish this mode of binding from a hydrogen bond to the *VI* area and hydrophobic bonding to the *IV* area is not possible with the compounds in Table I; such a useful differentiation will require, and is worthy of, further study. Whether there are other combinations of these 3 basic assumptions that will explain all the data would probably require computer techniques to make sure that no possibilities have been overlooked.

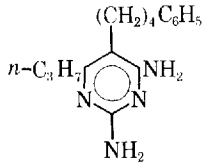
Additional evidence that the 6-phenyl group of 6-phenylpyrimidines is hydrophobically bonded to dihydrofolic reductase can be gleaned from Table I. (*a*) 2,4-Diamino-6-phenylpyrimidine (XV) is a sevenfold better inhibitor than 2,4-diamino-6-methylpyrimidine (XIV) (Table I). (*b*) The hydrophobic region is already complexed by the 6-phenyl of XV, since introduction of a *n*-butyl group on XV gives an inhibitor (XVII) that is only fivefold better. In contrast, the 5-*n*-butyl-6-methylpyrimidine (XVI) is a 550-fold better inhibitor than the corresponding 5-H pyrimidine (XIV). (*c*) Further change of the *n*-butyl group of the 6-phenylpyrimidine (XVII) to anilinopropyl (XIII) or phenylbutyl (XII) gives about the same thirtyfold increment in binding indicating that the aryl 5-side-chain group of XII and XIII is not complexed in the hydrophobic region but more likely is complexed to the *p*-aminobenzoyl locus. In contrast, change of the butyl group of the 6-methylpyrimidine (XVI) to anilinopropyl (XI) gives no increment, but change to phenylbutyl (X) gives an 85-fold increment in binding, indicating that this terminal aryl group in the 6-methyl series is complexed to the hydrophobic region where phenylbutyl would be expected to bind better than anilinopropyl.

These 3 basic assumptions explain the following points.

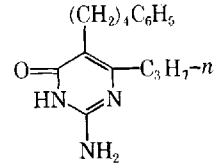
(*a*) In the 6-phenyl series with binding in conformation *2*, replacement of the 4-oxo group (VI) by 4-H (IX) or 4-thione (VII) decreases the binding, whereas in the 6-methyl series with conformation *11*, replacement of the 4-oxo group (IV) by 4-H (VIII) or 4-thione (V) gave better binding.

(*b*) The 4-thione group of V in conformation *11* is adjacent to the hydrophobic region and could lead to better binding than the 4-oxo group of IV, since the former is better tolerated in a hydrophobic region. In the 4-H series (VIII), one might expect VIII to be even less repulsed in the *III* region; however, it is possible that the highly polar 3-N of VIII is water solvated which could then make VIII about the same as IV as an inhibitor.

(*c*) A new point that is now explainable is in the comparison of the 6-methyl series (X, XXI) and 6-propyl series (XIX, XX). Note that with 2,4-diamino substituents, X and XIX are equal in effectiveness, but the 2-amino-4-oxo derivative in the 6-methyl series (XXI) is a thirtyfold better inhibitor than in the 6-propyl series (XX). The conformational binding assignments for 2,4-diamino-6-methylpyrimidines with a 5-side chain were *11* and *12*, whereas the 2-amino-4-oxo-6-methyl pyrimidines could only have conformation *11*. Conformation *11* forces the *n*-propyl group into region *V*, a probable hydrophilic region, whereas conformation *12* allows the propyl group to be in a hydrophobic region *III*. Thus, some repulsion of a propyl group in conformation *11* could occur which would explain the difference between XX and XXI. The opposite type of repulsion has been



XIX-*12*



XX-*11*

observed with 5-phenylbutyl-2,4,6-triaminopyrimidine (6, 17); since conformations *11* and *12* are equivalent with the 4,6-diaminopyrimidines, 1 amino group must project into the hydrophobic *III* region with resultant repulsion of the polar amino group. One would expect the order of repulsion in the *III* region to be $NH_2 > =O > =S$.

(*d*) The fact that 2,4-diamino-5-phenylbutyl-6-benzyl pyrimidine (XXV) is an elevenfold better inhibitor than the corresponding 5-anilinopropyl pyrimidine (XXIV) indicates that XXIV and XXV have conformation *12*, where the 5-side chain is hydrophobically bonded to area *IV*; conformation *2* is unlikely with the 6-benzyl hydrophobically bonded since one would expect less difference between the anilinopropyl and phenylbutyl side chains as previously noted with the comparison of XII and XIII in the 6-phenyl series. Note, however, that in the 2-amino-4-oxo-6-benzyl series, conformation *12* is not allowable due to the acidic NH in the *VI* region. Therefore, in this series, conformations *2* and *11* must be considered. It was previously reported (5) that in the 6-benzyl series the 5-anilinopropylpyrimidine (XXVIII) was about twice as effective as the corresponding 5-phenylbutylpyrimidine (XXVII). Since there is so little difference in binding between these two 5-side chains, conformation *2* is preferred which places the 5-side chain at the *p*-aminobenzoyl locus where the phenylbutyl and anilinopropyl side chains could be expected to have a similar amount of binding (note the similar comparison of XII and XIII in Table I where conformation *2* is favored). Even though the phenylbutyl side chain could be expected to give much stronger hydrophobic bonding than a benzyl side chain (19), the combination of probable hydrophilic repulsion of the benzyl group in conformation *11* could be sufficient to give the best net binding in conformation *2*. Where the balance between hydrophobic bonding in region *IV* and *p*-aminobenzoyl locus binding in region *V* is close, it is quite difficult to differentiate the preferred conformations. For example, these results could also be explained by XXVIII having conformation *2* and XXVII conformation *11*; if such were the case, then the 6-methyl 5-(phenylbutyl)-4-pyrimidinol (XXI) should bind the same as XXVII-*11*—since there is no hydrophobic bonding by the benzyl group in XXVII-*11*. With the anilinopropyl side chain, conformation XXVIII-*2* could bind better in the 6-benzyl series—with its benzyl hydropho-

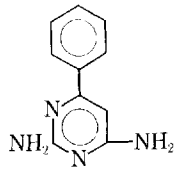
XXIII–*2*, R = H

bically bonded and the anilino bonded at the *p*-aminobenzoyl locus in region *V*—than can the 6-methyl pyrimidine (IV) which can have hydrophobic bonding in conformation *11*, but with no additional binding at the *p*-aminobenzoyl locus.

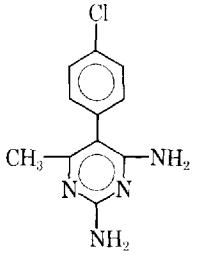
(*e*) It might be possible that 2,4-diamino-5-phenylbutyl-6-phenylpyrimidine (XII) is complexed in the *6*-conformation if the added increment in binding between XII and the *n*-butylpyrimidine (XVII) is due to hydrophobic bonding by the ω-phenyl in the *III–IV* region. If such were the case, then the corresponding 4-H pyrimidine (XXIII) should be as good an inhibitor, complexed in the conformation *6*, as the 4-oxopyrimidine (XXVI). Unfortunately, XXVI was too insoluble to determine the concentration necessary for 50% inhibition of dihydrofolic reductase; therefore, a less direct comparison was made. In the 6-methyl series, removal of the 4-amino group of XI to give VIII led to a 220-fold decrease in binding—due primarily to a loss of basicity (9, 10)—but VIII and IV were similar in binding. In the 6-phenyl series, removal of the 4-amino group of XII to give XXIII led to a 3500-fold decrease in binding. The sixteen-fold difference in these 2 increments is about what could be expected if 1 binding point were missing in XXIII, the remaining 220-fold decrease between XII and XXIII being presumably due to decreased basicity (9, 10). Therefore, this quite tenuous interpretation indicates that XII and XXIII bind in conformation *2*, and not in conformation *6*.

An important difference remains in rationalizing why a 6-phenylpyrimidine such as XV with conformation *2* gives only about a sixfold increment by hydrophobic bonding, but a 5-phenyl pyrimidine such as XXIX or a 1-phenyl-dihydro-*s*-triazine (XXX) in conformation *12* gives about a 1000-fold increment in binding (6). There are some obvious possibilities, such as (*a*) the 6-phenyl pyrimidine (XV) may be a weaker base than XXIX (pKa 7.7) or XXX (pKa 11.2) (21); (*b*) the 3-point attachment of pyrimidine π-cloud, hydrogen bond, and hydrophobic region are juxtapositioned somewhat differently in the case of XV *versus* the case XXIX or XXX, that is, a lateral movement of XV-*2* to the left by 1 atom distance compared to XXIX or XXX would be necessary for the same hydrogen bonding in the *VI* region; (*c*) the π-cloud overlaps between the phenyl and pyrimidine rings may be more favorable for π-cloud and hydrophobic interaction for XXIX with the enzyme than XV; (*d*) if the 4-NH_2 group of XV-*2* is less basic than the 3-N of XXIX-*12* or the 5-N of XXX-*12*, then XV-*2* will bind less effectively, but not so much as the 150-fold less effectiveness noted.

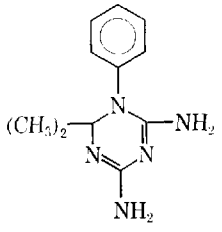
Spectrophotometric determination of the pKa of XV afforded a value of 6.23. Thus, XV is 6.4% protonated at the pH 7.4 of the assay, XXIX is 67% protonated, and XXXII is 99.9%.



XV-*2*



XXIX-*12*

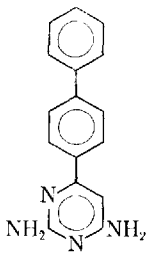


XXX-*12*

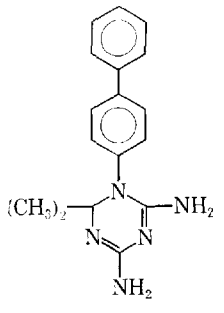
The difference in binding observed between XXIX and the totally unprotonated 6-trifluoromethyl analog of XXIX was only 250-fold (10). Thus, the 800-fold difference in binding between XV and XXIX is only partially accounted for by the difference in their respective basicities.

That the aryl group of XV-*2* was not placed in the hydrophobic region in exactly the same manner as the aryl group of XXX-*12* was clearly shown by comparison of the *p*-biphenyl analog (XVIII-*2*) with the *p*-biphenyl-*s*-triazine (XXXI-*12*). The 6-(*p*-biphenyl)pyrimidine (XVIII-*2*) was a five-fold better inhibitor than the corresponding 6-phenylpyrimidine (XV-*2*), indicating some additional hydrophobic bonding compared to XV-*2*; in contrast, the *p*-biphenyl-*s*-triazine (XXXI-*12*) was 1400-fold less effective than the corresponding phenyl-*s*-triazine (XXX-*12*) (7). It should be noted that the steric interference of the *p*-phenyl group of XXXI-*12* with enzyme binding was greatly reduced in the corresponding *m*-biphenyl-*s*-triazine (XXXII-*12*) which was only elevenfold less effective than XXX-*12* (7).

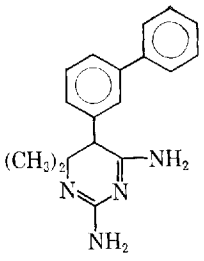
Another important difference exists between 2,4-diamino-6-phenyl-5-(phenylbutyl)pyrimidine (XII) and the corresponding 6-methyl (X) and 6-propyl analogs (XIX). If a 5-phenylbutyl group in conformation *11* or *12* can give so much stronger hydrophobic bonding than 6-phenyl in conformation *2*, why does not the 6-phenyl analog (XII) assume



XVIII-*2*



XXXI-*12*



XXXII-*12*

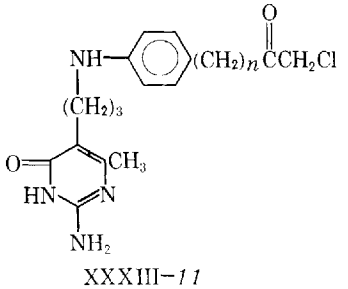
conformation *11* or *12* in order to get maximum hydrophobic bonding from the phenylbutyl group? If such were the case, then X, XII, and XIX would be expected to be equally effective. Since XII is so much less effective, it can only be concluded that XII cannot complex to the enzyme in conformation *12* due to steric interaction with the enzyme when the flat coplanar benzene ring is placed in the *III* region. If XII assumed conformation *11*, this would place the 4-amino group in the *III* region, a position believed to be the cause of a 130-fold repulsion as noted previously with 2,4,6-triamino-5-(phenylbutyl)pyrimidine compared to X (6, 17). Since this 130-fold repulsion is even larger than the 41-fold observed difference between the 6-methyl (X) and 6-phenyl pyrimidine (XII), conformation *2* might be preferred for XII. Although conformation *11* could be a possibility, conformation *11* would predict that XII would be a ten to thirty-fold better inhibitor than the anilinopropyl pyrimidine (XIII) which it is not. It is also possible that the preferred conformation for XII is *11*, but for XIII it is *2*. Ultimately, it should be possible to differentiate the conformational preference for *2* or *11* with a particular 5-side chain by comparison of active-site-directed irreversible inhibitors (18) which vary only in the hydrophobic or hydrophilic nature of the bridge between the 5-position of the pyrimidine and the terminal aryl group.

In summary, the inhibition of dihydrofolic reductase observed with a variety of phenyl and phenylalkyl pyrimidines cannot be rationalized with a single rotational conformer; therefore, a number of rotational conformers are proposed and the strong hydrophobic bonding is the determining factor for the particular preferred conformation of a given inhibitor. Such a concept for enzyme binding is not new. Complexing to chromotrypsin can occur in a number of rotational conformations where an aryl or large alkyl group on the substrate or inhibitor is determinant (22, 23); this bonding by aryl or alkyl groups to chymotrypsin is probably of a hydrophobic nature (24, 25). Similarly, 3-(β-D-ribofuranosyl)adenine and its nucleotide analogs can bind to some enzymes normally requiring adenosine or its corresponding nucleotide derivatives. Since the strong binding by the sugar moiety is apparently determinant, it has been proposed (26, 27) that a "flip" conformation for the adenine of the 3-ribosyl derivatives can account for the binding data.

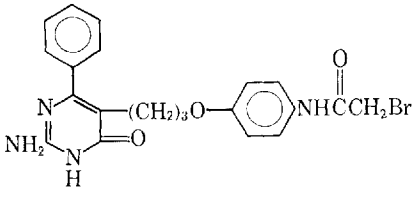
The most important deduction that arises from the derivations presented here is that if only 1 hydrophobic group is present on an inhibitor of dihydrofolic reductase, then this group will be complexed in a particular conformer that allows the hydrophobic bonding to be determinant. Therefore, a potential active-site-directed irreversible inhibitor (18) of dihydrofolic reductase such as XXIIII (3) would have its alkylating function in the hydrophobic area; by definition, the hydrophobic area of the enzyme has no polar groups that could be attacked by XXXIII in its favored conformation *11*. However, if 2 side chains are present, at least 1 of which is hydrophobic, then the hydrophobic group will complex in the hydrophobic region in a conformation that will project the second side chain in a hydrophilic region of the enzyme. Thus, XXXIV in conformation *2* is an active-site-directed irreversible inhibitor (18) of dihydrofolic reductase (28). By similar reasoning, XXXV, which should complex in conformation *11*, was synthesized and was also an active-site-directed irreversible inhibitor (29). These results will be presented in future papers.

EXPERIMENTAL

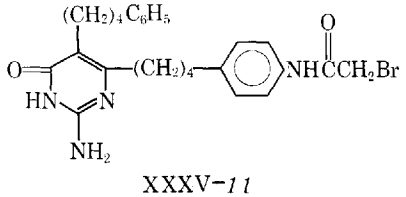
Methods.—The required 2-amino-5,6-disubstituted-4-pyrimidinols (XX, XXIX, and XL) were synthesized by alkylation of the appropriate β-keto ester followed by condensation with guanidine (30). The 2,4-diaminopyrimidines (XVII–XIX) were synthesized from the 4-pyrimidinols *via* the 4-chloro-



XXXIII-*11*



XXXIV-*2*



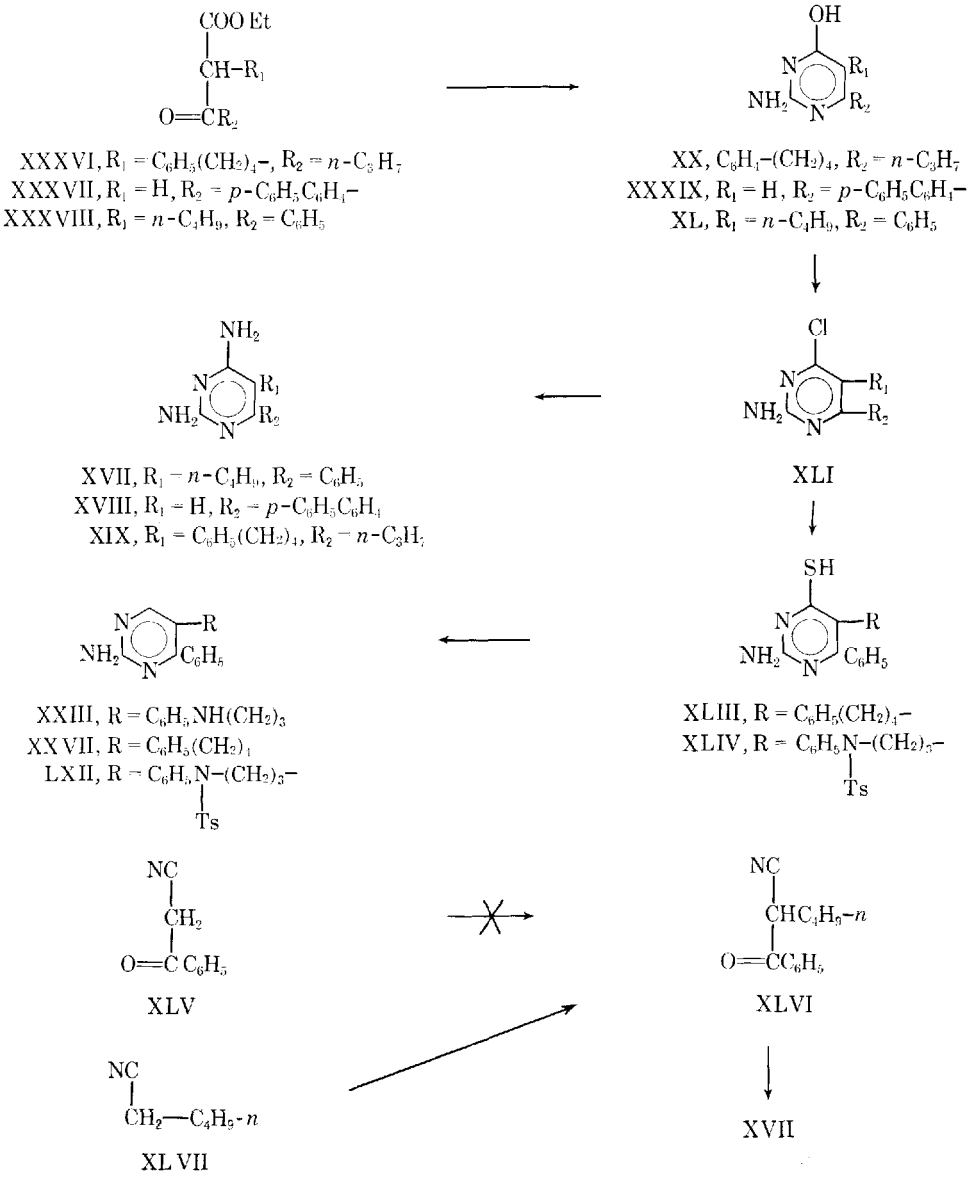
XXXV-*11*

pyrimidines (XLI) by treatment with ammonia (31). Reaction of the appropriate 4-chloro-6-phenylpyrimidine (XLI) with thiourea (5) afforded the 4-mercaptopyrimidines (XLIII and XLIV) which were desulfurized with Raney nickel (31) to the 2-amino-4-H-pyrimidines (XXVII and LXII). Treatment of LXII with hydrogen bromide in acetic acid (30, 32) removed the *N*-tosyl blocking group to give the required XXIII. (Scheme I.)

An alternate route to 5-alkyl-2,4-diamino-6-phenylpyrimidines such as XVII *via* α-butylbenzoylacetonitrile (XLVI) was investigated since it would be of general utility. Attempts to prepare XLVI by alkylation of benzoylacetonitrile (XLV) with sodium hydride and *n*-butyl bromide in such diverse solvents as dimethylsulfoxide or benzene gave only *O*-alkylation. However, XLVI could be prepared by Claisen condensation of hexanonitrile (XLVII) with ethyl benzoate (33). Condensation of XLVI with guanidine carbonate by fusion at 180° gave the 2,4-diaminopyrimidine (XVII) directly in 21% yield. (Scheme I.)

Synthesis.—Melting points were determined in capillary tubes on a Mel-Temp block and those below 230° are corrected. Infrared spectra were determined in KBr disk (unless otherwise indicated) with a Perkin-Elmer model 137B spectrophotometer; ultraviolet spectra were determined with a Perkin-Elmer model 202 spectrophotometer. Thin-layer chromatograms (TLC) were run on silica gel GF_{254} (Brinkmann), and spots were detected under ultraviolet light.

2 - Amino - 5 - phenylbutyl - 6 - n - propyl - 4-pyrimidinol (XX).—To a magnetically stirred solution of 3.1 Gm. (20 mmoles) of ethyl *n*-butyroylacetate in 10 ml. of reagent dimethylsulfoxide pro-



Scheme I

tected from moisture was added portionwise 0.867 Gm. (20 mmoles) of 55.6% dispersion of sodium hydride in mineral oil. When the evolution of hydrogen had ceased, 3.85 Gm. (18 mmoles) of 4-phenylbutyl bromide (34) was added. After being stirred for about 18 hr., the mixture was warmed on a steam bath for 30 min. and then neutralized with acetic acid. The warm mixture was poured into a stirred mixture of 50 ml. of benzene and 30 ml. of water. The separated aqueous phase was extracted once more with benzene. The combined benzene solutions were washed with several portions of ice cold 3% aqueous sodium hydroxide, then water. Dried with magnesium sulfate, the benzene solution was spin-evaporated *in vacuo* leaving 5 Gm. of crude XXXVI as an oil.

The crude XXXVI was dissolved in 25 ml. of absolute ethanol, then refluxed with 1.62 Gm. (9 mmoles) of guanidine carbonate for 19 hr. The cooled reaction mixture was neutralized to near pH 7 with 3 *N* aqueous hydrochloric acid. The product was collected on a filter and washed with ethanol; yield, 1.54 Gm., m.p. 209–215°. By concentration of the filtrate an additional 1.17 Gm. (total 53%) was obtained, m.p. 209–215°. Recrystallization of a portion from aqueous ethanol gave white crystals, m.p. 209–215°, which moved as one spot on TLC in 3:1 benzene–methanol. The compound had $\lambda_{max.}$ 2.98 (NH); 6.05, 6.10, 6.50, 6.70, (NH, C=O, C=C, C=N); 13.5, 14.3 μ (C_6H_5); $\lambda_{max.}$ (pH 1): 269 mμ (ϵ 7800); (pH 7): 275 mμ (ϵ 4400); (pH 13): 282 mμ (ϵ 9800).

Anal.—Calcd. for $C_{17}H_{23}N_3O$: C, 71.6; H, 8.07; N, 14.7. Found: C, 71.6; H, 8.20; N, 14.7.

2 - Amino - 5 - n - butyl - 6 - phenyl - 4 - pyrimidinol (XL).—Alkylation of 5 Gm. of ethyl benzoylacetate with *n*-butyl bromide in *tert*-butyl alcohol followed by condensation with guanidine carbonate in the same solvent, as described for the preparation of a related 6-phenylpyrimidinol (30), gave 2.24 Gm. (39%) of product, m.p. 309–314°. Recrystallization from ethanol–toluene gave white crystals, m.p. 310–315° dec. $\lambda_{max.}$ 2.83 (NH); 6.05, 6.12, 6.35 (NH, C=O, C=N, C=C); 14.3 μ (C_6H_5); $\lambda_{max.}$ (pH 1): 233 (ϵ 14,400), 280 mμ (ϵ 10,900); (pH 7): 235 (ϵ 17,400), 300 mμ (ϵ 8100); (pH 13): 289 mμ (ϵ 9600).

Anal.—Calcd. for $C_{14}H_{17}N_3O$: C, 69.1; H, 6.99; N, 17.3. Found: C, 69.4; H, 7.18; N, 16.9.

2 - Amino - 6 - (4 - biphenylyl) - 4 - pyrimidinol (XXXIX).—To a solution of 5.3 Gm. (23.4 mmoles) of ethyl 4-biphenylylcarboxylate in 7.2 Gm. (82 mmoles) of reagent ethyl acetate was added 3.16 Gm. (58.5 mmoles) of sodium methoxide. The mixture was heated in a bath at 80° under a condenser with stirring and protected from moisture for 20 hr. The cooled reaction mixture was diluted with several volumes of benzene, then neutralized with glacial acetic acid. The sodium acetate was removed by filtration and washed with benzene. The combined filtrate and washings were spin-evaporated *in vacuo;* ethyl acetoacetate was then removed by continued spin-evaporation in a hot water bath in high vacuum leaving 6.23 Gm. of crude XXXVII as an oil.

A solution of 4.82 Gm. (18 mmoles) of crude XXXVII in 40 ml. of absolute ethanol was refluxed with 1.8 Gm. (10 mmoles) of guanidine carbonate with magnetic stirring for 17 hr. The cooled reaction mixture was filtered and the product washed with alcohol, then water; yield, 1.57 Gm., m.p. 370–372° dec. From the filtrate was isolated an additional 0.87 Gm. (total, 52% over-all), m.p. 373–376° dec. Two recrystallizations from aqueous 2-methoxyethanol afforded white crystals, m.p. 378–380° dec. $\lambda_{max.}$ 2.95 (NH); 5.85, 6.02, 6.08 (NH, C=O, C=C, C=N); 12.2, 14.5 μ (phenyl); $\lambda_{max.}$ (pH 1): 308 mμ (ϵ 25,300); (pH 7): 285 mμ (ϵ 32,100); (pH 13): 295 mμ (ϵ 16,700).

Anal.—Calcd. for $C_{16}H_{13}N_3O$: C, 73.0; H, 4.94; N, 15.9. Found: C, 72.7; H, 5.07; N, 15.6.

2,4 - Diamino - 5 - phenylbutyl - 6 - n - propylpyrimidine (XIX).—A mixture of 500 mg. (1.76 mmoles) of XX and 4 ml. of phosphorus oxychloride was heated for 45 min. under a reflux condenser in a bath preheated and maintained at 110°. The cooled mixture was poured into 35 Gm. of ice and 40 ml. of ether with stirring. After 15 min., the layers were separated. The ether layer was washed with 5% aqueous sodium bicarbonate (2 × 30 ml.) and water (2 × 30 ml.), then dried with magnesium sulfate. Spin-evaporation *in vacuo* left XLI (R_1 = C_6H_5—$(CH_2)_4$—, R_2 = *n*-C_3H_7) as a gum which could not be crystallized, but had $\lambda_{max.}$ (pH 1): 315 mμ (*cf. Reference 31*).

The crude gum was dissolved in 40 ml. of methanol saturated with ammonia, then heated in a steel bomb at 150° for 24 hr. The solution was clarified by filtration through a Celite pad, then spin-evaporated *in vacuo* to a small volume. The solution was made strongly alkaline with 10% aqueous sodium hydroxide, then diluted with water to turbidity and cooled at −4°. The crude product was collected on a filter and recrystallized twice from aqueous methanol; yield, 115 mg. (23%), m.p. 121–127°. For analysis, the material was dissolved in warm 10% aqueous acetic acid. The solution was clarified by filtration, then the product was precipitated by addition of excess 10% aqueous sodium hydroxide. Recrystallization from aqueous ethanol gave 70 mg. (14%) of analytically pure product, m.p. 126–128°. $\lambda_{max.}$ 2.80, 3.00 (NH); 6.05, 6.39 (NH, C=C, C=N); 13.03, 14.43 μ (C_6H_5); $\lambda_{max.}$ (pH 1): 280 mμ (ϵ 7400); (pH 7): 289 mμ (ϵ 7300); (pH 13): 301 mμ (ϵ 7900).

Anal.—Calcd. for $C_{17}H_{24}N_3$: C, 71.8; H, 8.45; N, 19.7. Found: C, 71.8; H, 8.60; N, 19.4.

5 - n - Butyl - 2,4 - diamino - 6 - phenylpyrimidine (XVII).—*Preparation A.*—Conversion of 500 mg. (2.06 mmoles) of XL to XVII *via* LXI, as described for the preparation of XIX, gave 143 mg. (29%) of analytically pure product, m.p. 149–152°. $\lambda_{max.}$ 2.80, 2.95 (NH); 6.05, 6.20, 6.40 (NH, C=C, C=N); 13.05, 14.25 μ (C_6H_5).

Anal.—Calcd. for $C_{14}H_{18}N_4$: C, 69.4; H, 7.44; N, 23.1. Found: C, 69.6; H, 7.57; N, 23.3.

Preparation B.—α-Benzoylhexanonitrile (XLVI) was prepared by Claisen condensation of hexanonitrile and ethyl benzoate; a yield of 60% has been recorded (33). A mixture of 1 Gm. (5 mmoles) of XLVI and 450 mg. (2.5 mmoles) of guanidine carbonate was placed in a bath preheated to 120°, then the temperature was raised to 180° over a period of 30 min. After an additional 10 min. at 180°, gas evolution was complete. The cooled residue was extracted with hot ethanol. The filtered solution was spin-evaporated *in vacuo*. The residue was extracted with hot 10% aqueous acetic acid

and separated from some insoluble gum. The cooled extract was poured into an excess of cold 10% aqueous sodium hydroxide. The product was collected and recrystallized from aqueous ethanol with the aid of charcoal; yield, 256 mg. (21%) of white crystals, m.p. 151–152°, that were identical with *Preparation A* as shown by mixed melting point, infrared spectra, and TLC in 3:1 benzene–methanol.

6 - (4 - Biphenylyl) - 2,4 - diaminopyrimidine (XVIII).—A mixture of 1.00 Gm. (3.8 mmoles) of XXXIX, 10 ml. of phosphorus oxychloride, and 1 ml. of triethylamine was refluxed for 75 min., then processed and treated with ammonia as described for the preparation of XIX; the yield of analytically pure white crystals after recrystallization from 2-methoxyethanol by addition of water was 145 mg. (15%), m.p. 273–275°. $\lambda_{max.}$ 2.92, 3.00 (NH); 6.25, 6.35, 6.50 (NH, C=C, C=N); 12.3, 13.71, 14.50 μ (phenyl); $\lambda_{max.}$ (pH 1): 313 mμ (ϵ 25,000); (pH 7, 13): 278 mμ (ϵ 28,000).

Anal.—Calcd. for $C_{16}H_{14}N_4$: C, 73.3; H, 5.34; N, 21.4. Found: C, 73.7; H, 5.43; N, 21.2.

2 - Amino - 6 - phenyl - 5 - phenylbutyl - 4 - pyrimidinethiol (XLIII).—To a solution of 675 mg. (2 mmoles) of XLI [R_1 = $C_6H_5(CH_2)_4$—, R_2 = C_6H_5] (5) in 20 ml. of *tert*-butyl alcohol was added 160 mg. (2.1 mmoles) of thiourea. After being refluxed for 2 hr., the solution was treated with 12 ml. of 10% aqueous sodium hydroxide, then was refluxed for 15 min. more. The mixture was diluted with 20 ml. of water and then acidified to about pH 5 with 3 *N* hydrochloric acid. The yellow precipitate was collected on a filter and washed with water; yield, 448 mg., m.p. 186–198°. The solid was dissolved in hot ethanol, filtered from some insoluble material, then the solution was diluted to turbidity with water; yield, 239 mg. (36%) of analytical sample, m.p. 225–227°, which moved as one spot on TLC in 3:1 benzene–methanol. $\lambda_{max.}$ 2.90, 2.98 (NH); 6.08, 6.40, 6.49 (NH, C=C, C=N); 13.3, 14.4 μ (C_6H_5).

Anal.—Calcd. for $C_{20}H_{21}N_3S$: C, 71.6; H, 6.27; N, 12.5. Found: C, 71.6; H, 6.32; N, 12.3.

2 - Amino - 6 - phenyl - 5 - phenylbutylpyrimidine (XXVII) Hydrochloride.—To a solution of 100 mg. (0.30 mmole) of XLIII in 10 ml. of ethanol was added about 200 mg. of Raney nickel. The mixture was refluxed with magnetic stirring for 1 hr., then filtered through a Celite pad. The ethanol solution was spin-evaporated *in vacuo* leaving 50 mg. of a glass. A solution of this glass in ether was treated with excess hydrogen chloride gas. The gummy hydrochloride was crystallized from ethyl acetate–petroleum ether (b.p. 60–110°); yield, 30 mg. (30%) of white crystals, m.p. 147–149°, that moved as a single spot on TLC in 3:1 benzene–methanol. $\lambda_{max.}$ 5.88 ($C=NH^+$), 5.99, 6.25 (NH, C=C, C=N); 13.5, 14.1, 14.4 μ (C_6H_5).

Anal.—Calcd. for $C_{20}H_{21}N_3 \cdot HCl$: C, 70.5; H, 6.47; N, 12.4. Found: C, 70.4; H, 6.60; N, 12.5.

2 - Amino - 5 - (3 - anilinopropyl) - 6 - phenylpyrimidine (XXIII).—A solution of 500 mg. of XLIV (5) in 20 ml. of ethanol was refluxed with about 600 mg. of Raney nickel for 2 hr. The clarified solution was evaporated *in vacuo*. The residue was dissolved in chloroform; the solution was clarified by filtration, then spin-evaporated *in vacuo* leaving 200 mg. (43%) of crude LXII as a glass.

To the crude LXII was added 86 mg. of phenol and 4 ml. of 30% hydrogen bromide in acetic acid. The mixture was magnetically stirred for 18 hr. protected from moisture, then poured into several volumes of ether. The solid which separated was triturated with fresh ether, then collected on a filter. The hydrobromide salt was dissolved in 25 ml. of water, then the solution was made strongly alkaline with 10% sodium hydroxide. The product was collected on a filter, washed with water, then recrystallized from aqueous ethanol with the aid of charcoal; yield, 86 mg. (64%) of analytically pure material, m.p. 131–132°. $\lambda_{max.}$ 2.85 (NH); 6.20, 6.25, 6.39 (NH, C=C, C=N); 13.41, 14.45 μ (C_6H_5); $\lambda_{max.}$ (pH 1): 233 (ϵ 17,400), 285 (ϵ 6400), 325 mμ (ϵ 6900); (pH 7, 13): 313 mμ (ϵ 6600).

Anal.—Calcd. for $C_{19}H_{20}N_4$: C, 75.0; H, 6.56; N, 18.4. Found: C, 74.7; H, 6.53; N, 18.4.

Water/Oil Emulsions Prepared by Low Pressure Capillary Homogenization I

Effects of Emulsator and Composition Variables on Mannide Mono-oleate Stabilized Systems

By C. DAVID FOX* and RALPH F. SHANGRAW

An automated reciprocating capillary emulsator is described which duplicates the low-pressure homogenization principle of the interconnected glass syringe method used to prepare repository w/o emulsions. The w/o emulsions produced by this emulsator were evaluated by rotational viscometry and optical microscopy. Rheological flow curves of concentrated emulsions could be correlated with the extent of dispersion and degree of coalescence. Coalescence rates were found to be an inverse function of the surfactant concentration, with 20 per cent mannide mono-oleate furnishing the best relative stability for water-in-mineral oil emulsions. The rate of shear was found to govern the degree of emulsification, with a short capillary of large diameter producing the finest dispersion.

IT HAS been shown that antibody production in animals can be enhanced and prolonged when the aqueous immunologic agent is emulsified in mineral oil and injected intramuscularly to provide a depot of slowly released antigen (1). Since the work of Henle and Henle in 1945 (2), many clinicians have developed their own w/o emulsions of various agents in efforts to achieve a sustained immunologic response in humans (3–6). The best clinical results to date have been obtained by using light mineral oil as the external phase, since it cannot be metabolized by the human body. It is theorized that the mineral oil is removed by a slow phagocytosic process which appears to be the rate-limiting step in the release of antigen from the internal phase (7).

Although numerous reports have confirmed the efficacy of this innovation in hyposensitization therapy for influenza and pollinosis, there is considerable diversity of opinion among clinicians as to which emulsification method and formulation will yield the most stable emulsion with a uniform small particle size. Standardized w/o emulsions of various antigens for annual repository injection are not commercially available. Thus, the physician has had to develop his own individual formulation and emulsification techniques, determine the degree of dispersion, and estimate the appropriate dosage. The most widely used method for preparing these emulsions consists of placing the components to be emulsified in a 10-ml. glass hypodermic syringe and then connecting this syringe to a second 10-ml. syringe by means of a double-hubbed hypodermic needle. The shearing force required for emulsification is achieved by repeatedly forcing the components from one syringe to the other, either manually (4), or by means of an automated device[1] that pneumatically reciprocates the syringe pistons (8).

This low-pressure capillary homogenization project was designed to study the effect of variation in certain operating conditions on emulsification efficiency and to determine how various factors affect the stability of the w/o emulsions prepared. The variables studied were phase volume ratio, concentration of the emulsifying agent, homogenization pressure, capillary hypodermic needle diameter and length, and the number of processing cycles. The definite interrelationship that exists among the numerous variables was found to be reflected in the emulsion flow properties or rheologic behavior. For this reason, the evaluation of the experimental emulsions was based on particle size determination and rheologic flow curves, with an attempt to correlate these 2 parameters.

Mannide mono-oleate[2] was chosen as the emulsifying agent since it has received extensive toxicity evaluation and is generally accepted for use in w/o repository emulsions (9, 10). A purified grade of light mineral oil[3] was selected as the oil

phase since its suitability and safety is well documented (11).

The maximum volume of 10 ml. of emulsion produced by the glass syringe method is obviously inadequate for extensive evaluation. It was therefore decided to construct an automated capillary homogenizer based on the interconnected glass syringe principle, but capable of producing sufficient emulsion for rheological and stability studies (12).

Description of the Capillary Emulsator.—The emulsator designed and constructed in this laboratory consists of 2 modified hydraulic cylinders interconnected by a double-hubbed hypodermic needle. The emulsion components are introduced into 1 of the cylinders, and the system is then closed. Under a constant preset pneumatic force, the cylinder pistons alternately force the components repeatedly through the capillary hypodermic needle, producing the shearing action required for emulsification. A front view of the emulsator is shown in Fig. 1. The emulsator constructed has a maximum capacity of 114 ml., but larger volumes of emulsion could be produced with cylinders of increased bore or stroke.

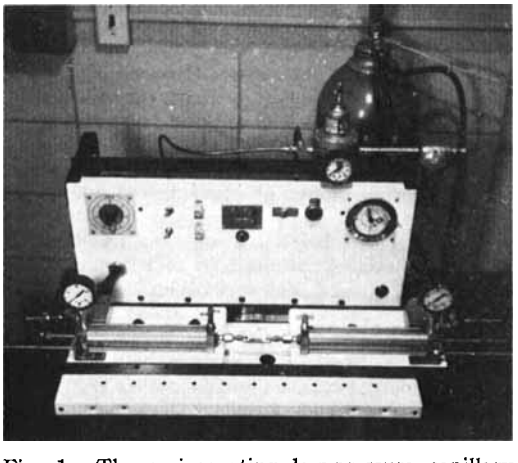

Fig. 1.—The reciprocating low-pressure capillary emulsator.

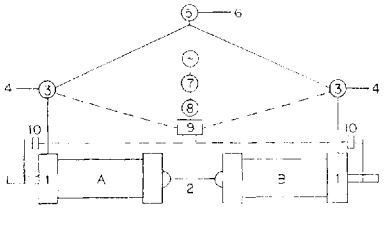

Fig. 2.—The reciprocating low-pressure capillary emulsator. Electrical system (– – –), pneumatic system (——). Key: 1, hydraulic cylinders, 1⅛ in. bore, 7 in. stroke; 2, double-hubbed hypodermic needle; 3, solenoid valves; 4, exhaust lines; 5, air pressure regulator; 6, compressed air source; 7, clock timer; 8, interval timer; 9, impulse relay; 10, microlimit switches.

The reciprocating action of the cylinder pistons is controlled by an impulse switching relay. This relay alternately activates 2 independent circuits—a pneumatic and an electrical circuit to each of two 3-way electromagnetic solenoid valves. A schematic diagram of the pneumatic and electrical system is shown in Fig. 2.

Air pressure on cylinder piston A forces the emulsion in cylinder A through the hypodermic needle into cylinder B. A micro-limit switch is tripped when cylinder piston A has forced all the emulsion into cylinder B. The limit switch directs a pulse of current to the impulse relay which switches current from the cylinder A solenoid to the cylinder B solenoid. This simultaneously exhausts cylinder A, and air pressure is directed into cylinder B. When cylinder piston B has forced the emulsion back into cylinder A, another limit switch is tripped, and the cycle commences again. An electrically operated digital counter is connected to the impulse relay. Each time the relay switches circuits, 1 count is recorded, with 2 counts indicating 1 complete cycle.

The emulsator can be set to commence and cease operation automatically at any desired time within a 12-hr. period, since a clock timer and an interval timer are included in the electrical circuit.

The machine parameters of operation time, capillary diameter, capillary length, and shearing stress can be held constant enabling a valid comparison among emulsions since the dispersions are produced under reproducible and well-defined conditions.

EXPERIMENTAL

Preparation of Emulsions.—In this study, the external phase of all emulsions is composed of light mineral oil and mannide mono-oleate, while the internal phase is distilled water. It should be noted that when all components were placed in 1 cylinder of the emulsator, a stable o/w emulsion is invariably produced when the ratio of oil phase to water phase is 1:1. This was unexpected since mannide mono-oleate is oil-soluble and should tend to produce w/o emulsions. It was therefore necessary to inject the aqueous phase into the oil phase on the first stroke to obtain the desired w/o emulsion. The ease with which mineral oil–mannide mono-oleate systems form o/w emulsions has not been reported in the literature.

Measurement of Flow Properties.—The instrument used in this study was the Haake Rotovisko rotational viscometer (Gebrüder Haake K.G., Berlin, Germany), with a rotor radius of 2.004 cm. and a cup radius of 2.10 cm., which gave a range of shear

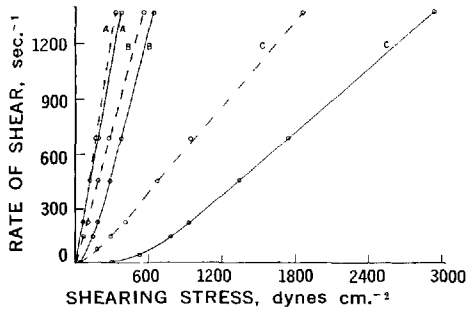

Fig. 3.—Effect of phase volume variation on w/o emulsion flow curves. Key: ———, initial; – – – –, 30 days. (Distilled water internal phase) A, 5%; B, 20%; C, 50%.

rate from 7×10^{-2} to 1.14×10^{3} sec.$^{-1}$ and a range of shear stress from 15 to 3×10^{3} dynes/cm.^{2} All determinations were made immediately after homogenization and after a 30-day storage period, at a temperature of 30°.

Particle Size Determination.—Dark-field microscopy was chosen as the method for particle size analysis. Although this method has inherent limitations in measuring submicron particles, it was still preferable to the problems of coping with sedimentation or light-scattering techniques when applied to w/o systems. A size–frequency analysis was performed on each emulsion immediately after homogenization and again after 30 days, with a Leitz Ortholux dark-field microscope (E. Leitz, G. m. b. H., Wetzlar, Germany) equipped with a 95/1.32 N.A. fluorite oil immersion objective, immersed substage condenser, and 25× oculars for a total magnification of 2375×. A small aliquot of each emulsion was diluted 1:400 with light mineral oil and a drop placed in a Petroff-Hauser bacteria counting chamber (Arthur H. Thomas Co.) of 0.02-mm. cell depth and covered with a cover glass of 0.25-mm. thickness, thus permitting critical focusing. Fields from 2 slides were examined with the diameters of 400 particles being measured with a screw micrometer eyepiece.

Storage of Emulsions.—The portion of each emulsion used for the initial rheological determination was discarded and the remainder stored in 4-oz. clear glass bottles for 30 days at room temperature.

Effect of Variation in Phase Volume.—Representative flow curves for w/o emulsions containing 5, 20, and 50 vol. % of distilled water are shown in Fig. 3, with size–frequency data presented in Table I. These emulsions all contain 20% mannide mono-oleate. Emulsions containing smaller amounts of emulsifying agent exhibited lower apparent viscosities, but their flow curves had the same general shape. Emulsator constants were: homogenizing pressure, 50 psig; capillary diameter, 18 gauge; capillary length, 1.25 cm.; and cycles, 25.

It can be seen that emulsions containing 5% internal phase possess Newtonian flow properties, and despite the high degree of coalescence that occurred in 30 days, little change is reflected in the flow curve. Emulsions containing 50% water in the internal phase, however, exhibit flow curves which show a high degree of correlation with the extent of droplet coalescence. Furthermore, this concentration is the one most commonly utilized by clinicians for their repository emulsions.

Effect of Variation in Mannide Mono-oleate Concentration.—The effect of 4 different concentrations of mannide mono-oleate on simple 50:50 w/o systems is shown by the size–frequency distribution data presented in Table II. Concentrations of 2, 5, 10, and 20 vol.% were used in the light mineral oil external phase replacing the oil, and each emulsion contained 50% distilled water internal phase. Emulsator constants were: homogenizing pressure, 50 psig; capillary diameter, 18 gauge; capillary length, 1.25 cm.; and cycles, 25. Varying each of the constants in turn for emulsions of identical composition yielded similar data. It is evident that a high percentage of mannide mono-oleate is required to furnish the best relative stability; hence, a concentration of 20% was used for the emulsions in the remainder of this study.

Effect of Variation in Homogenizing Pressure.—The first emulsator parameter to be investigated was that of homogenizing pressure, and the influence of pressures varying from 20 to 75 psig is shown in the flow curves of Fig. 4. Each emulsion is composed of mannide mono-oleate, light mineral oil, and distilled water in the volume ratio of 2:3:5, respectively. Emulsator constants were: capillary diameter, 18 gauge; capillary length, 1.25 cm.; and cycles, 25.

A microscopical examination of the freshly prepared emulsions revealed that droplet diameters in each emulsion were essentially all below 1 μ. Since a decreased particle size is the only factor which could have caused the increased apparent viscosities, it is assumed that the increase in pressure resulted in a small but significant decrease in droplet diameters. Previous work in this laboratory had shown that droplet diameters below 1 μ have a profound influence on flow curves of concentrated emulsions. However, in this study, significant differences in particle diameters below 1 μ could not be discerned due to the inherent limitations of the microscope technique employed. It was decided to keep the homogenizing pressure constant at 50 psig for all subsequent emulsions since this is the maximum pressure that 10-ml. glass syringes will withstand without leakage past the plungers.

Effect of Variation in Capillary Diameter.—Emulsions were prepared using hypodermic needles of 20, 18, and 15 gauge (nominal inside diameters of 0.58, 0.84, and 1.37 mm., respectively). An analysis of the rheological and micromeritical data for these emulsions showed that, among the gauges used, an

increase in capillary diameter resulted in emulsions with slightly higher apparent viscosities and a more uniform particle size distribution.

Effect of Variation in Capillary Length.—The effect of variation in the capillary length on flow curves for w/o emulsions is shown in the flow curves of Fig. 5. Each emulsion is composed of mannide mono-oleate, light mineral oil, and distilled water in the volume ratio of 2:3:5, respectively. Emulsator constants were: homogenizing pressure, 50 psig; capillary diameter, 18 gauge; and cycles, 25. It is readily evident that as the needle length is decreased, apparent viscosities increase, again undoubtedly due to a decrease in droplet size and increased uniformity. The same effect is also noted in using either 20- or 15-gauge capillaries of various lengths. Thus, all subsequent emulsions were prepared with the largest diameter and shortest length double-hubbed capillary hypodermic needle, *i.e.*, 15 gauge and 0.625 cm., respectively.

Effect of Variation in Processing Cycles.—The final emulsator variable to be studied was the number of homogenization cycles to which the emulsion is subjected. The number of cycles was varied from 13 to 100. For any given set of conditions, essentially constant rheological values were obtained after 25 cycles, and no discernible improvement in particle size reduction could be observed by continuing the homogenization process for more than 25 cycles.

DISCUSSION

Since 1945, the formulation and production of w/o repository emulsions for human use has undergone extensive improvement. These improvements have, for the most part, resulted from subjective observations and appear to have been empirically derived. At present, most reported formulations are composed of mannide mono-oleate, light mineral oil, and aqueous antigenic extract in the volume ratio of 2:3:5, respectively, and it is generally recognized that a droplet diameter of less than 1 μ is an essential requirement for satisfactory *in vivo* sustained antibody production (13).

Previous workers have probably been misled by the limitations of their optical equipment. It is quite likely they have reported lower particle size limits above those which actually existed. No attempt is made in this work to claim accurate particle size distributions in the submicron range, but only to make comparisons of those particles which can be accurately determined, since, for the purpose of this research, it was of greater importance to know the size–frequency distribution of droplets greater than 1 μ. The measurement of the droplets in the experimental emulsions was facilitated by the fact that Brownian motion was negligible, an observation directly opposed to that reported by Silverman (14), who stated that Brownian motion was especially significant in his series of w/o emulsions, which are similar in composition to the ones used in this study.

In the area of particle size and its effect on viscosity, this investigation has confirmed the opinion of Sherman (15, 16), who reported that the observed increase in apparent viscosity of homogenized emulsions is due to a decrease in droplet size. This leads to increased interfacial area and interaction among droplets in concentrated emulsions, especially when the droplet diameters are below 2 μ.

The representative flow curves furnish additional evidence to establish the fact that particle size can be correlated with rheological data, *i.e.*, the relative extent of flow curve deviation after storage when

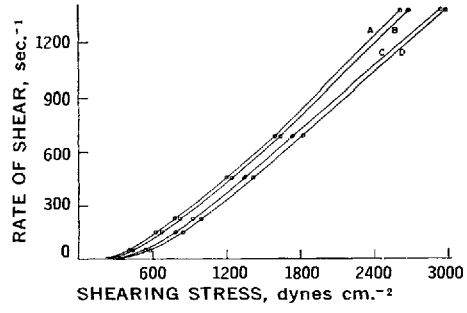

Fig. 4.—Effect of homogenizing pressure on flow curves of 50:50 w/o emulsions. Key: A, 20 psig; B, 25 psig; C, 50 psig; D, 75 psig.

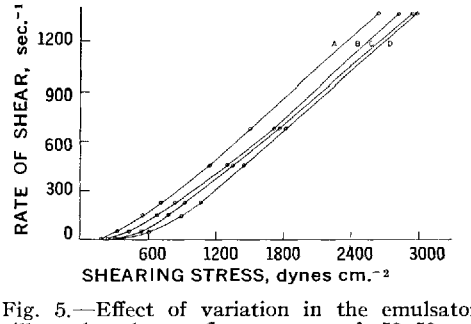

Fig. 5.—Effect of variation in the emulsator's capillary length on flow curves of 50:50 w/o emulsions. Key: A, 5.0 cm.; B, 2.50 cm.; C, 1.25 cm.; D, 0.625 cm.

compared with the initial flow curve is a direct indication of the extent of droplet coalescence. As shown in Fig. 3, the validity of the above statement increases as the volume per cent internal phase increases. When emulsions contain a low percentage of internal phase, the extent of particle–particle interaction is only a minor contributing factor to the over-all rheologic behavior of the system, and the flow curve is influenced primarily by the viscosity of the external phase. The anomalous flow behavior and high viscosity of concentrated homogenized emulsions is due primarily to the high resistance to flow offered by the tightly packed droplets and the increased adsorption of emulsifying agent at the greatly extended interface. As the droplets coalesce, the emulsion becomes polydisperse and cubic-packing decreases with a concomitant reduction in interfacial area and contact among droplets. The net result of these reductions will be reflected in the flow curve by a significant decrease in both apparent viscosities and shear dependence. This work confirms the rotational viscometric work of Saunders (17), who observed that when the internal phase volume becomes greater than 5%, shear dependence increases due to hydrodynamic interference. Sherman (18), however, has reported observing Newtonian flow in w/o emulsions at internal phase volumes of up to 50%, as determined by capillary viscometry, a method which possesses definite inherent limitations when used to obtain rheological data on shear dependent systems.

While o/w emulsions can generally be stabilized by low concentrations of surfactants, w/o repository emulsions require extremely high concentrations of mannide mono-oleate, with 1 report stating that 35% was required (19). This research has confirmed the fact that high percentages of mannide mono-oleate are required, but as repository w/o emulsions prepared by the interconnected glass syringe method are subjected to very low shear conditions, this would not be unexpected. The majority of emulsions in this study were homogenized at 50 psig to correlate the data with that reported by workers in the repository emulsion field.

The development of automatic devices for the production of small quantities of repository w/o emulsions has enabled the physician to achieve some degree of process standardization, but a review of the literature reveals that tremendous variations exist in methods of preparing essentially identical emulsions in interconnected glass syringes with pneumatically operated syringe plungers. The double-hubbed hypodermic needle length, in almost all cases where reported, is given as 5 cm., but the needle gauge and process time vary over an extremely wide range, as illustrated by 1 report which states emulsions were homogenized for 1 hr. through an 18-gauge needle and then for 3 hr. through a 22-gauge needle (20). Another author reports processing 50 min. through an 18-gauge needle, followed by 20 min. through a 22-gauge needle, and finally, 20 min. through a 25-gauge needle (6).

In reviewing the data, it was noted that an increase in capillary diameter, an increase in homogenizing pressure, and a decrease in capillary length were each associated with an increased emulsion velocity through the capillary. This is in agreement with Poiseuille's law for liquid flow through capillaries, which states that the volumetric flow rate is a direct function of the the capillary radius and pressure differential, and an inverse function of capillary length. The fact that an increased emulsion velocity through the capillary resulted in increased apparent viscosities with concomitant decreases in the mean diameter of the dispersed droplets would indicate that the degree and uniformity of dispersion is influenced by the rate of shear to which the emulsion is subjected. While commercial homogenizers operate in the range of 1000 to 5000 psig and can subject dispersions to shear rates of several hundred thousand reciprocal seconds, the highest approximate rates of shear encountered in this study, as calculated by the method of Henderson *et al.* (21), were 17,800, 20,00, and 20,900 sec.$^{-1}$ for 3 emulsions of identical composition prepared using 20, 18, and 15-gauge capillaries, respectively, of 0.625 cm. length at 100 psig. The majority of emulsions, however, were prepared under approximate shear rate conditions of 10,000 sec.$^{-1}$. In attempting to extend the calculations of rheologic parameters based directly and rigorously on capillary tube viscometry and Newtonian liquids to the highly viscoelastic non-Newtonian systems encountered in this study, it is realized that considerable error is introduced by the assumptions made and by failure to include additional parameters to account for the effects of viscoelasticity. However, approximate calculations of the Reynolds number for representative emulsions in this study yielded values less than 100, indicating that under the conditions employed, velocity profiles could be assumed laminar, thus permitting reasonable approximations of the mean shear rates.

On the basis of the data presented, and as noted by other authors (22, 23), the use of capillary needles 5 cm. in length and of gauges larger than 18, *i.e.*, smaller diameter, actually will hinder effective emulsification by reducing the rate of shear which consequently reduces the work done on the dispersion. However, the lengthy process time reported by the majority of clinicians undoubtedly offsets the decreased dispersion efficiency resulting from lower rates of shear. Thus, where repository emulsions are prepared by means of 2 interconnected glass syringes, the use of a very short, large-diameter doubled-hubbed capillary (0.625 cm., 15 gauge) for a short interval will result in a greater work input and subsequent particle size reduction than can be achieved by the use of a long and smaller diameter capillary for extended periods of time.

Although the interconnected glass syringe method of emulsification is extensively employed for the extemporaneous preparation of small quantities of repository w/o emulsions, the recently developed Mulsi-Churn unit (Mulsi-Jet Inc., Elmhurst, Ill.) (24) for the preparation of these emulsions would appear to be more suitable due to the extremely high shear rate produced by jet velocities of 300 to 800 in./sec. which would tend to insure a maximum dispersion of the aqueous antigenic extract in a minimum of time. However, this device was not evaluated in this study.

SUMMARY AND CONCLUSIONS

1. An automated reciprocating capillary emulsator has been developed which duplicates the low-pressure capillary homogenization principle of the 2 interconnected glass syringe method for preparing repository w/o emulsions.

2. The evaluation of w/o emulsions by the use of flow curves obtained with a concentric cylinder viscometer is demonstrated. Rheological flow curves were found to be an effective method for indicating the extent of dispersion and degree of droplet coalescence in concentrated emulsions, which behave as general plastic solids.

3. Under low shear conditions, concentrations of mannide mono-oleate in excess of 10% are required to prepare and furnish adequate relative stability to water-in-mineral oil emulsions, although absolute stability is poor.

4. The rate of shear governs the degree of emulsification where the emulsion components are repeatedly forced through a double-hubbed hypodermic needle, and a short capillary of large diameter produced the finest dispersion.

5. For any given set of preparative conditions, a maximum degree of particle size reduction is achieved quite rapidly, and emulsator operation for extended time periods appears unnecessary.

6. For the preparation of w/o repository emulsions, high shear rate emulsators would appear to offer substantial advantages over the low shear rate interconnected glass syringe method.

Water/Oil Emulsions Prepared by Low Pressure Capillary Homogenization II

Stabilizing Influence of Inorganic Electrolytes, Secondary Emulsifiers, and Temperature

By C. DAVID FOX* and RALPH F. SHANGRAW

Aqueous dispersions in light mineral oil stabilized with mannide mono-oleate were prepared under a set of standard conditions and evaluated by rotational viscometry in conjunction with optical microscopy. Inorganic electrolytes in the aqueous internal phase, at concentrations as low as 0.01 *M*, increased apparent viscosity, retarded sedimentation, and had a marked stabilizing influence. The addition of small amounts of water-soluble surfactants to the internal phase yielded extremely fine dispersions, but these agents decreased stability and tended to cause inversion. Storage of w/o emulsions at 5° had a definite stabilizing influence when compared to room temperature storage.

IN AN earlier report (1), a reciprocating capillary emulsator was described which is similar in principle to an emulsator[1] that is in general use by physicians for the extemporaneous preparation of small quantities of repository antigenic w/o emulsions. However, the new emulsator produces a quantity of emulsion sufficient for experimental purposes and allows a much greater flexibility in controlling shearing stress. It was also shown that rheological flow curves furnish an adequate means for evaluating w/o emulsion stability, thus obviating the necessity for tedious size-frequency analyses. Fine dispersions of water-in-mineral oil were found to require high concentrations of mannide mono-oleate,[2] but the

2. The evaluation of w/o emulsions by the use of flow curves obtained with a concentric cylinder viscometer is demonstrated. Rheological flow curves were found to be an effective method for indicating the extent of dispersion and degree of droplet coalescence in concentrated emulsions, which behave as general plastic solids.

3. Under low shear conditions, concentrations of mannide mono-oleate in excess of 10% are required to prepare and furnish adequate relative stability to water-in-mineral oil emulsions, although absolute stability is poor.

4. The rate of shear governs the degree of emulsification where the emulsion components are repeatedly forced through a double-hubbed hypodermic needle, and a short capillary of large diameter produced the finest dispersion.

5. For any given set of preparative conditions, a maximum degree of particle size reduction is achieved quite rapidly, and emulsator operation for extended time periods appears unnecessary.

6. For the preparation of w/o repository emulsions, high shear rate emulsators would appear to offer substantial advantages over the low shear rate interconnected glass syringe method.

Water/Oil Emulsions Prepared by Low Pressure Capillary Homogenization II

Stabilizing Influence of Inorganic Electrolytes, Secondary Emulsifiers, and Temperature

By C. DAVID FOX* and RALPH F. SHANGRAW

Aqueous dispersions in light mineral oil stabilized with mannide mono-oleate were prepared under a set of standard conditions and evaluated by rotational viscometry in conjunction with optical microscopy. Inorganic electrolytes in the aqueous internal phase, at concentrations as low as 0.01 *M*, increased apparent viscosity, retarded sedimentation, and had a marked stabilizing influence. The addition of small amounts of water-soluble surfactants to the internal phase yielded extremely fine dispersions, but these agents decreased stability and tended to cause inversion. Storage of w/o emulsions at 5° had a definite stabilizing influence when compared to room temperature storage.

IN AN earlier report (1), a reciprocating capillary emulsator was described which is similar in principle to an emulsator[1] that is in general use by physicians for the extemporaneous preparation of small quantities of repository antigenic w/o emulsions. However, the new emulsator produces a quantity of emulsion sufficient for experimental purposes and allows a much greater flexibility in controlling shearing stress. It was also shown that rheological flow curves furnish an adequate means for evaluating w/o emulsion stability, thus obviating the necessity for tedious size-frequency analyses. Fine dispersions of water-in-mineral oil were found to require high concentrations of mannide mono-oleate,[2] but the

absolute stability was poor and droplet coalescence progressed to an appreciable extent in 30 days. In the present paper, the same technique of preparation and evaluation as previously reported has been used to study more complex dispersion systems in efforts directed toward reducing the rate of droplet coalescence. The major objective in this study was a determination of factors contributing to the objective formulation and preparation of repository antigenic emulsions.

EXPERIMENTAL

Apparatus.—All w/o emulsions in this study were prepared by means of the reciprocating capillary emulsator described earlier in detail (1). Each emulsion was homogenized by means of 50 passes through a 15-gauge (1.37-mm. i.d.) double-hubbed hypodermic needle, 0.625 cm. in length, at a constant pressure of 50 psig.

Materials.—Mannide mono-oleate was used as the primary oil-soluble emulsifying agent, and a purified grade of light mineral oil[3] made up the remainder of the external oil phase. Three water-soluble surface-active agents, polyoxyethylene sorbitan mono-oleate,[4] alkyl phenoxy polyethoxy ethanol,[5] and dioctyl sodium sulfosuccinate,[6] were selected for evaluation as secondary emulsifying agents. All inorganic electrolytes used were of the purest grade commercially available.

Procedure.—The rheological behavior of each emulsion at 30° was determined at the time of manufacture, and after a 30-day storage period with the Haake Rotovisko rotational viscometer (Gebrüder Haake K. G., Berlin, Germany) using the same cup and bob as in the earlier study (1). Size–frequency determinations were also performed on each emulsion by an optical method previously described (1). Unless otherwise stated, emulsions were stored at room temperature.

Influence of Inorganic Electrolytes.—In his later publications, Brown (2, 3) has stated that the use of a "truly" isotonic fluid as a vehicle for repository emulsified antigenic extracts will eliminate any local irritation that results when physiological saline or Coca's fluid is used. The formula for the isotonic fluid recommended by Brown is as follows:

Calcium chloride, hydrate	0.367 Gm.
Magnesium chloride, hydrate	0.301 Gm.
Potassium chloride	0.373 Gm.
Glycine	1.201 Gm.
Sodium sulfate, anhydrous	0.071 Gm.
Sodium bicarbonate	2.270 Gm.
Sodium phosphate, dibasic	0.142 Gm.
Lactic acid, 85%	0.636 mg.
Hydrochloric acid, 0.5 *N*	180 ml.
Sodium hydroxide, 0.5 *N*	224 ml.
Distilled water *q.s. ad*	1000 ml.

Although the rationale behind adjusting tonicity of w/o emulsions is questionable, dramatic effects on emulsion stability were noted when the Brown isotonic fluid was utilized for the internal phase of w/o systems. Emulsions exhibited sharply increased apparent viscosities, diminished sedimentation rates, and a marked improvement in stability as evidenced by a reduced coalescence rate. These effects are shown by the flow curves of Fig. 1 for emulsions containing mannide mono-oleate, light mineral oil, and Brown's isotonic fluid in the volume ratio of 2:3:5, respectively.

On the basis of these preliminary results, emulsions containing different concentrations of various electrolytes were prepared to determine the cause and extent of this influence as functions of concentration and valency. Each emulsion was composed of mannide mono-oleate, light mineral oil, and aqueous phase in the volume ratio of 2:3:5, respectively.

The first studies utilized sodium chloride in molar concentrations of 0.01, 0.10, 0.154, 0.25, and 0.50. Some flow curves for the freshly prepared emulsions are presented in Fig. 2.

Concentrations of sodium chloride greater than 0.10 *M* produced no further change in the initial flow curves and are not shown in Fig. 2. A concentration of 0.154 *M* sodium chloride, however, did influence the stability as confirmed by the 30-day size–frequency data. This stabilizing influence can be seen in the flow curves of Fig. 3, which reflect the extent of droplet coalescence. The marked retardation of sedimentation is illustrated in Fig. 4.

Additional emulsions were prepared to determine if this electrolytic effect could be modified by polyvalent cationic electrolytes, and w/o systems were produced containing calcium chloride, ferric chloride, and aluminum chloride, in concentrations of 0.01 and

0.25 *M*. A review of the rheological and micromeritical data for these emulsions indicated that the divalent and trivalent cations exerted essentially the same influence as the monovalent sodium cation, both initially and after 30 days' storage.

Since an influence dependent on cationic valency could not be demonstrated, w/o emulsions containing 0.01 and 0.25 *M* sodium sulfate in the internal phase were prepared to determine if the existence of a relation dependent upon anionic valency could be shown. The results obtained indicated that the divalent sulfate anion exerted a much greater stabilizing influence than did the monovalent chloride anion. After 30 days, a microscopical examination gave no evidence of droplet coalescence in the emulsion containing 0.25 *M* sodium sulfate, with all droplet diameters being less than 1 μ. A flow curve was obtained identical to that of the freshly prepared emulsion, except for the 2 highest rates of shear where the apparent viscosities had actually increased after storage. These flow curves are shown in Fig. 5.

The emulsion containing 0.01 *M* sodium sulfate gave an initial flow curve with apparent viscosities greater than those obtained from the emulsion containing 0.25 *M* sodium sulfate. Furthermore, after 30 days the apparent viscosities were essentially identical to those of the freshly prepared emulsion at all except the 3 highest rates of shear, where again, as noted with the 0.25 *M* system at high rates of shear, apparent viscosities had increased after storage. Droplet coalescence was negligible and all particles were less than 1 μ in diameter. Flow curves for the 0.01 *M* sodium sulfate emulsion are shown in Fig. 6, with the 0.01 *M* sodium chloride system included for comparison. The decreased apparent viscosities noted with the 0.25 *M* sodium sulfate emulsion, when compared with the 0.01 *M* system, may possibly be the result of the extremely hydrophilic nature of this electrolyte. The higher concentration could conceivably cause a "salting out" effect on the adsorbed mannide mono-oleate, thereby weakening the interfacial film.

Effect of Secondary Surfactants.—An investigation was undertaken to determine what effect the inclusion of small amounts of water-soluble surfactants in the aqueous phase would have on the formation and stability of w/o emulsions.

Polyoxyethylene sorbitan mono-oleate in concentrations of 0.02, 0.2, 1, and 2% were prepared in physiological saline solution (0.154 *M* sodium chloride), and these solutions were emulsified in equal volumes of a solution containing light mineral oil (60%) and mannide mono-oleate (40%). Flow

curves for the freshly prepared emulsions containing 0.02 and 0.2% polyoxyethylene sorbitan mono-oleate were superimposable upon that of the control which contained only saline solution in the internal phase.

Emulsions containing 1 and 2% polyoxyethylene sorbitan mono-oleate exhibited progressive increases in apparent viscosities at all rates of shear.

After a 30-day storage period, however, marked differences were noted and the effect of the various concentrations of surfactant on emulsion stability is shown by the flow curves of Fig. 7. The emulsion containing 2% polyoxyethylene sorbitan mono-oleate had completely broken in 30 days.

Emulsions containing 1% alkyl phenoxy polyethoxy ethanol and 1% dioctyl sodium sulfosuccinate in the aqueous internal phase were also prepared. As noted with 1 and 2% polyoxyethylene sorbitan mono-oleate, the freshly prepared emulsions have the majority of droplet diameters below the limit of optical microscope resolution, *i.e.*, less than 0.2 μ. The apparent viscosities are correspondingly very high, as shown by Fig. 8, in which the initial flow curves for 50:50 w/o emulsions containing distilled water and 1% dioctyl sodium sulfosuccinate in the internal phase are compared. All emulsions contained 20% mannide mono-oleate in the external oil phase. After 30 days' storage at room temperature, however, the emulsions containing 1% alkyl phenoxy polyethoxy ethanol and 1% dioctyl sodium sulfosuccinate had completely broken.

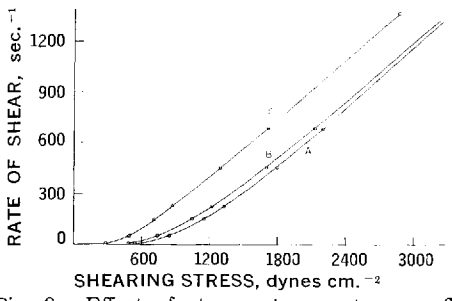

Fig. 9.—Effect of storage temperature on flow curves of a 50:50 w/o emulsion. Key: A, initial flow curve; B, 30 days' storage at 5°; C, 30 days' storage at 25°.

It should be noted that the w/o emulsions containing 1% or more of the previously mentioned water-soluble surfactants were extremely difficult to prepare in the usual manner. The aqueous phase had to be added dropwise to the oil phase with stirring prior to capillary homogenization to prevent an almost immediate inversion to an o/w system.

Effect of Storage Temperature.—Emulsions containing giant ragweed extract in the internal phase were also prepared. The giant ragweed antigen used for this study was a commercial extract[7] containing 5% w/v antigen in Coca's fluid. For each experimental emulsion, 30 ml. of the aqueous antigenic extract was diluted to 50 ml. with physiological saline solution and emulsified in 50 ml. of oil phase containing 30 ml. of light mineral oil and 20 ml. of mannide mono-oleate. The resultant w/o emulsion contained 10,000 pollen units/ml. of emulsion, the highest concentration usually employed for the repository hyposensitization treatment of hay fever.

Since all antigenic extracts must be stored under refrigeration for therapeutic stability, experiments were carried out to determine the effect of refrigeration storage on w/o emulsions. In comparing the rheological and micromeritical data for portions of the same emulsion stored at 25 and 5°, it was evident that storage at 5° resulted in a flow curve almost identical with that of the freshly prepared emulsion and only a slight change in droplet size and distribution was noted. The flow curves shown in Fig. 9, for a representative w/o emulsion, demonstrate the stabilizing influence of storage at 5°. Regardless of storage temperature, all flow curve determinations were made at a constant temperature of 30°.

DISCUSSION

Previous studies have shown that the apparent viscosities of w/o emulsions can be markedly increased by a reduction in the size of the dispersed droplets. However, the addition of inorganic electrolytes to the aqueous phase did not result in a particle size reduction greater than that observed with distilled water. Therefore, it is obvious that the observed rheological effect must result from some other factor which, in all likelihood, is electrical in nature, with the negative charge in the predominant role.

The conclusion, based on this research, that electric charges have an important stabilizing effect on

[7] Supplied through the courtesy of Abbott Laboratories, North Chicago, Ill.

w/o emulsions is contradictory to the work of Albers and Overbeek (4, 5), who have stated that electric charges cannot be expected to stabilize w/o emulsions of more than extremely low concentrations, and that no correlation exists between zeta potential and coalescence rate. Schulman and Cockbain (6) have stated that the droplets in w/o emulsions cannot possess a charge and hence cannot be electrically stabilized. On the other hand, Verwey (7) has suggested that in w/o emulsions, the major part of the potential drop occurs in the oil phase, as this has the lower dielectric constant, and that the interaction of the double layers of the droplets will determine the stability of an emulsion.

Several authors have indicated that the electrical double layer surrounding the water droplets is several microns in thickness for w/o emulsions. This thickness would therefore be greater than the distance between the dispersed phase droplets of the emulsions prepared for this investigation, where diameters were usually less than 1 μ. If the diffuse double layer is several microns in thickness, as appears reasonable, then obviously these double layers surrounding the droplets must overlap in concentrated emulsions, with a concomitant reduction in the potential energy of repulsion. The occurrence of rapid flocculation and sedimentation in those experimental emulsions that contained only distilled water would indicate that a substantial energy barrier is absent and may only be on the order of $1kT$ or $2kT$ (k, Boltzmann's constant; T, absolute temperature), depending on the droplet size and volume of the internal phase. The thermal agitation supplied by room temperature would be sufficient to overcome this energy barrier. However, the fact that inorganic electrolytes effectively prevented flocculation would imply that the presence of potential-determining ions in the systems resulted in a significant increase in the height of the potential energy barrier. This increased energy barrier could well result from a marked increase in the zeta potential by a compact charge density of counter-ions, which will increase the energy of repulsion. The extent of this increased zeta potential appears to be directly related to the valency of the electrolyte anion. Thus, the emulsion droplets are stabilized by the formation of an electrokinetic charge to a degree considerably in excess of the mechanical stabilization achieved by the use of nonionic emulsifiers alone.

In addition to the significant electrokinetic stabilization, the observed increases in apparent viscosities after storage, noted only in those emulsions containing sodium sulfate, could well be the result of an increased adsorption of emulsifying agent at the oil/water interface with the formation of a semirigid film which would contribute considerable mechanical stability. With coalescence effectively hindered, the film of mannide mono-oleate surrounding each water droplet would grow thicker and stronger with age, creating an interfacial condition that would be reflected in the flow behavior by increased apparent viscosities only at higher rates of shear where mechanical resistance to droplet deformation would become more evident.

It is well recognized that sometimes combinations of nonionic emulsifiers may be more effective than a single emulsifier in stabilizing an emulsion. The inclusion of small amounts of the water-soluble surfactant, polyoxyethylene sorbitan mono-oleate, in concentrations ranging from 0.02 to 2% in the aqueous phase, has been reported as being effective for w/o repository emulsions (8–10), but the authors present no evidence to substantiate this view. As indicated by the flow curves in Fig. 7 and confirmed by optical size–frequency analyses, the adverse effect of polyoxyethylene sorbitan mono-oleate on the stability of w/o emulsions is a direct function of its concentration in the internal phase. Increasing the concentration of this surfactant results in an increased coalescence rate and degree of polydispersity, the extent of which is reflected in the flow curves.

Emulsions containing dioctyl sodium sulfosuccinate in the internal phase exhibited a degree of anomalous flow behavior far greater than any dispersion investigated in this study, as shown by Fig. 8. Although the systems were extremely unstable, the apparent viscosity at the time of preparation could not be calculated at 1370 sec.$^{-1}$, since the shearing stress exceeded 3600 dynes cm.$^{-2}$, the maximum stress possible with the 500 Gm.-cm. torsion spring and an annular gap of 0.96 mm. in the viscometer. All droplets were below the limit of optical resolution, a condition undoubtedly responsible for the high viscosity. Unfortunately, methods for obtaining an initial size–frequency distribution in the submicron range were not available. The majority of physicians have reported the preparation of emulsions with droplet diameters of 0.1 to 1 μ, although Brown (11) has reported a much smaller size as evidenced by electron microscopic examination of films of flash-frozen emulsion. However, the electron microscopic work by Brown is questionable since he states that the frozen emulsion film (−35°) is less than 200 Å. (0.02 μ) in thickness, and then reports observing a droplet diameter distribution extending from 0.02 up to 0.1 μ, a condition difficult to reconcile with such a thin film.

The fact that water-soluble surfactants have an adverse effect on the stability of w/o emulsions definitely precludes their use in repository emulsions. Concentrations greater than 0.2% appear to result in an initial finer dispersion of the aqueous phase, but this advantage is offset by the increased coalescence rate that results. These observations may help to explain the results of Gaillard *et al.* (12, 13), who noted that their w/o repository emulsions of aqueous insect venom could not be stabilized for longer than 21 days, even with concentrations of mannide mono-oleate as high as 35%. The authors attributed the rapid cracking to an alteration of the mannide mono-oleate interfacial film by some component in the insect venom. Since it is known that insect venom contains an appreciable quantity of water-soluble surface-active compounds, these surfactants may have been the causative agents responsible for the instability.

It is a well recognized fact that solutions of allergenic materials must be stored under refrigeration at 5° to retain their effectiveness, although it is not known what changes occur at room temperature which result in decreased potency. Since any w/o repository emulsion containing an allergen would also require refrigeration, the temperature studies were undertaken and as indicated by Fig. 9, a storage temperature of 5° has a definite influence in retarding the rate of droplet coalescence. As a further confirmation of the adverse effect of water-soluble

surfactants discussed previously, emulsions stored at 5° containing polyoxyethylene sorbitan mono-oleate, when compared to those without it, were found to have a greater degree of droplet coalescence and lower apparent viscosities in spite of the stabilizing influence of refrigeration temperature.

It is interesting to note that although allergenic materials theoretically require refrigeration to maintain their potency, repository w/o emulsions after intramuscular injection are maintained at body temperature for periods of up to 1 year with no reported decrease in effectiveness.

The unqualified success of repository emulsion therapy may well depend upon elucidation of the specific agent responsible for individual allergic reactions, since the formulation of a stable w/o emulsion, consistent with the desired objectives, certainly is not insurmountable when the exact chemical composition of the components is known. Difficulties arise from the introduction of the unknown variables that undoubtedly exist in current antigenic extracts. The production methods for the extracts are a consideration since they are not standardized. The units of potency measurement constitute another variable since 3 different systems are in common use among allergists. The product may also vary as a result of variation in the amount of active principle in the raw material.

Considering the tremendous number of variables involved in the techniques of preparing and standardizing extracts of pollen and the extremely wide variations reported by physicians in the emulsification and administration of the extracts in repository form, the success that has been achieved is remarkable.

SUMMARY

This investigation has been concerned primarily with an evaluation of aqueous dispersions in light mineral oil stabilized with mannide mono-oleate and prepared under a set of standard conditions. The results obtained indicate the following.

1. Inorganic electrolytes, at concentrations as low as 0.01 *M*, in the aqueous internal phase of w/o emulsions, increase the apparent viscosities, hinder sedimentation, and have a marked stabilizing influence. This electrokinetic effect appears to be directly related to the valency of the anion.

2. The addition of water-soluble surfactants to the internal phase of w/o emulsions facilitates emulsification. However, these agents decrease stability and tend to cause inversion.

3. The storage of w/o emulsions at 5° has a definite stabilizing influence when compared to room temperature storage.

Critical Evaluation of the Compactor

By R. COHN, H. HEILIG, and A. DELORIMIER

With the assistance of a suitably prepared experimental design a compactor was optimized to prepare a basic granulation to which other drugs could be added and directly compressed into tablets. An IBM 1620 computor was employed to evaluate the data and to extrapolate additional information for the preparation of contour charts. The contour charts permitted a simple and accurate interpretation of the data and allowed selection of a set of optimum processing conditions. Additional trials confirmed the reliability of this technique.

A NUMBER OF investigations (1–3) in the chemical processing industry have employed continuous compacting equipment for the unit operation of particle size enlargement. They have shown the compaction process to be useful in the conversion of fine powders into larger agglomerated units. These particulates generally exhibited a reduced tendency to cake, improved flowability, increased bulk density, less dust, and

SUMMARY

This investigation has been concerned primarily with an evaluation of aqueous dispersions in light mineral oil stabilized with mannide mono-oleate and prepared under a set of standard conditions. The results obtained indicate the following.

1. Inorganic electrolytes, at concentrations as low as 0.01 *M*, in the aqueous internal phase of w/o emulsions, increase the apparent viscosities, hinder sedimentation, and have a marked stabilizing influence. This electrokinetic effect appears to be directly related to the valency of the anion.

2. The addition of water-soluble surfactants to the internal phase of w/o emulsions facilitates emulsification. However, these agents decrease stability and tend to cause inversion.

3. The storage of w/o emulsions at 5° has a definite stabilizing influence when compared to room temperature storage.

Critical Evaluation of the Compactor

By R. COHN, H. HEILIG, and A. DELORIMIER

With the assistance of a suitably prepared experimental design a compactor was optimized to prepare a basic granulation to which other drugs could be added and directly compressed into tablets. An IBM 1620 computor was employed to evaluate the data and to extrapolate additional information for the preparation of contour charts. The contour charts permitted a simple and accurate interpretation of the data and allowed selection of a set of optimum processing conditions. Additional trials confirmed the reliability of this technique.

A NUMBER OF investigations (1–3) in the chemical processing industry have employed continuous compacting equipment for the unit operation of particle size enlargement. They have shown the compaction process to be useful in the conversion of fine powders into larger agglomerated units. These particulates generally exhibited a reduced tendency to cake, improved flowability, increased bulk density, less dust, and

Accepted for publication January 5, 1966.
The authors thank Mr. Sam Rock for his help in analyzing the data.

a modified dissolution rate. On the basis of these earlier studies, it was expected that the compaction process would be applicable for the preparation of pharmaceutical granulations in large volumes.

A study was undertaken to utilize a compactor[1] for the preparation of a basic granulation to which other drugs would be added and directly compressed into tablets. Potassium chloride, which is a major component of a number of this company's marketed products, was selected as the test material.

The facilities of the Squibb Scientific Computing Center were employed for the preparation of an experimental design and the interpretation of the resultant data.

A photograph of the compactor utilized is presented in Fig. 1.

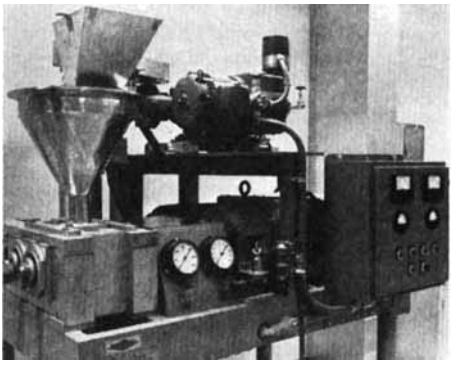

Fig. 1.—Photograph of the compactor.

EXPERIMENTAL

The experimental design permitted controlled modifications to be made on the 4 primary processing variables shown in Table I.

TABLE I.—PHASE *A* PROCESSING VARIABLES AND THEIR RANGES FOR THE COMPACTOR

Variable	Ranges
Oil pressure	220–800 p.s.i.
Roll speed	20–80% (10–40 r.p.m.)
Feed screw speed	20–80 (23–92 r.p.m.)
Added moisture	0–1%

Moisture evaluation of the test material was limited to the range of 0–1%, since it was observed that the addition of more than 1% moisture impeded material flow from the hopper of the compactor to the compacting rolls.

The criteria that were used to evaluate the quality of the granulation and the compressed tablets subsequently produced in the first phase study are shown in Table II.

The flow properties of the granulations were measured as a function of their angle of repose (4). Particle size distributions were obtained by sieve analysis. Loss on drying after 3 hr. at 160° F. under vacuum was used to define the moisture content of the granulation. The term "per cent fines" refers to the amount of potassium chloride that sifted through the compactor without being compacted.

TABLE II.—CRITERIA FOR EVALUATING PHASE *A* RESPONSES

Granulation	Tablet
Particle flow	Weight uniformity
Particle size distribution	Individual tablet assay
Moisture content	Binding
Per cent fines	Picking
	Capping
	Hardness
	Friability
	Disintegration time

A Colton 216 tablet machine was employed for the preparation of the tablet cores. The criteria referred to as binding, picking, capping, hardness, friability, and disintegration time were determined by standard procedures. Statistically sampled tablets were separately weighed on an analytical balance. To determine drug distribution, individual tablet assays were performed on 10 tablets selected at random from each trial.

On the basis of the data obtained from the full replicate factorial design of 18 runs shown in Table III, the IBM 1620 computer was able to extrapolate a total of approximately 2000 responses. Satisfactory correlations were obtained between the theoretical computer responses and the actual trial results.

A statistical analysis of the data obtained from these first 18 trials indicated that, aside from the moisture content of the granulations, the per cent fines, and the tablet hardness, all responses listed in Table II met the proposed specifications over the entire range of the experiment. Hence, these were not considered to be of primary importance in planning the second phase of the study.

During the course of the experiment, it was noted that under certain processing conditions the

18	800	20	20	1.0

[1] Model SN Chilsonator, manufactured by the Fitzpatrick Co.

amperage sensor on the drive motor indicated that the motor was being overloaded. It thus became apparent that the motor amperage response would become a very significant factor in the selection of an optimum processing condition. Hence, the responses for this factor were recorded for each trial and were used in the preparation of the contour charts.

Plotting of several contour charts from the tabulation of phase *A* responses led to the design for phase *B*. It was determined from analysis of phase *A* data that satisfactory responses for moisture, fines, hardness, and motor amperage could be obtained within the limits of the processing variables as shown in Table IV.

TABLE IV.—PHASE *B* PROCESSING VARIABLES AND THEIR RANGES

Variable	Range
Oil pressure	300–500 p.s.i.
Roll speed	70–90% (35–45 r.p.m.)
Feed screw speed	50–70% (57–80 r.p.m.)
Added moisture	0 %

RESULTS AND DISCUSSION

Data from the phase *B* trials were combined with those from phase *A* for a comprehensive analysis and determination of an optimum operating condition. The selected data are listed in Table V.

The perusal of the initial trial responses indicated that the factors of primary concern were *per cent fines, motor amperage,* and tablet hardness. Hence, these responses were evaluated for the preparation of a contour chart.

In order to prepare this type of descriptive diagram it was necessary to fix 2 of the 4 processing variables listed in Table I. Due to the inherent simplicity of processing dry powders and the lack of any significantly enhanced responses, moisture was held at a level of 0%. With added moisture fixed at 0%, roll speed could be set at 80% of the maximum. The results indicated that at these settings the most satisfactory set of responses would be attained and in addition, maximum throughput of material could be achieved in the shortest period of time.

Figures 2–4 illustrate the preparation of a contour chart and its use in determining optimum processing conditions. The contour lines are drawn by connecting responses of equal magnitude. For clarity the numerical responses that were obtained from the computer were removed from Figs. 3 and 4.

It can be observed from Fig. 2 that there was a relatively simple relationship between amperage data and the processing variables. It was observed that as the effective throughput of material or the forces acting on the compression rollers were increased, more power had to be expended. Since this work was measured as a function of motor amperage, any increase in either or both of these factors causes a corresponding increase in amperage levels. The maximum amperage at which the drive motor could be satisfactorily operated was 17. Hence, any set of processing conditions which would result in an amperage reading of less than 17 was satisfactory.

Hardness values have been superimposed on the amperage graph in Fig. 3.

The hardness data were obtained by measuring 20 individual tablets for each trial on a pneumatically

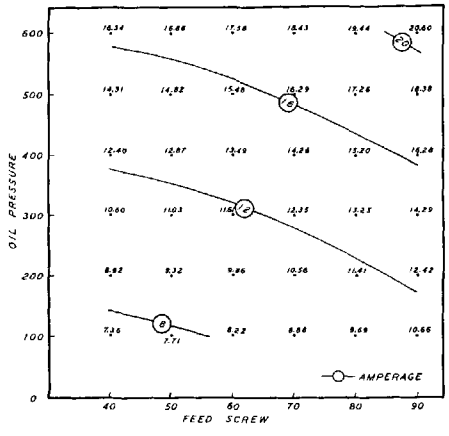

Fig. 2.—Amperage responses plotted as a function of feed screw speed and oil pressure. Moisture, 0%; roll speed, 80%.

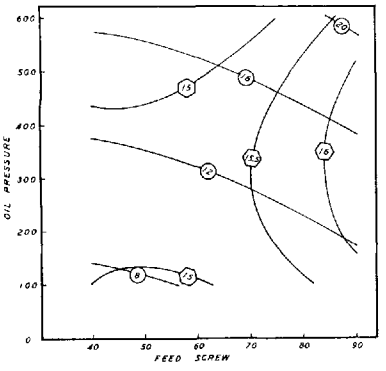

Fig. 3.—Tablet hardness values superimposed on the amperage plot. Moisture, 0%; roll speed, 80%. Key: O, amperage; ○, hardness.

operated Strong-Cobb hardness tester. Although one would hardly expect a significant difference in tablet quality for hardness values of 15.5 and 16.0, due to the relatively large number of samples (approximately 400), a noticeable trend was observed. That is, although the individually reported results did not appear to be significantly different, the data that were obtained to arrive at these numbers were different.

A perusal of this figure indicated that a simple relationship between the variables and the responses

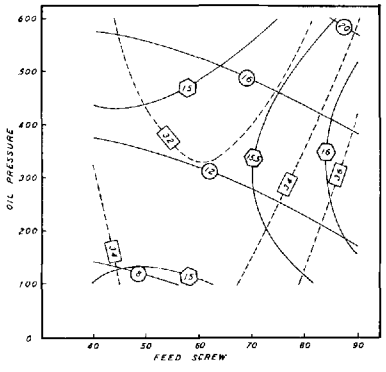

Fig. 4.—Per cent fines, amperage, and tablet hardness values displayed as functions of roll speed and oil pressure. Moisture, 0%; roll speed, 80%. Key: O, amperage; ○, hardness; □, fines.

did not exist, although a review of the tables of data confirmed that maximum feed screw speed was important to maximize this response.

The responses measured as functions of the processing variables were fairly difficult to interpret for the analysis of the amount of fines that sifted through the compactor without being compacted. It was observed that reduced feed screw speed tended to reduce the magnitude of this result. Since one of the major difficulties of the compactor was leakage of powders between the roller seals, as less material was brought in contact with the seals, less was forced through without being compacted. The assumption that increased pressure prevented or reduced the tendency of material to pass between the rollers without compression is probably incorrect. It was the authors' experience that a better fit of the compactor roller and seals was obtained under increased pressure, as less fines were observed under conditions of higher oil pressure. In actual usage, the fines were recycled back to the compactor and did not effect later processing elements.

Thus, as can be observed from Fig. 4, for the following fixed levels of moisture, 0%, and roll speed, 80%, the variable processing conditions of feed screw speed, 65%, and oil pressure, 400 p.s.i., yielded a product which manifested the maximum number of satisfactory responses.

A second and third series of contour charts were drawn with moisture fixed at 0%, but with roll speed fixed at 70 and 90%, respectively, at maximum conditions. The resultant data indicated that at optimum conditions the responses were slightly inferior to those obtained at a fixed roll speed of 80%.

A confirmatory trial was performed at the machine settings suggested by an analysis of the contour charts at moisture, 0%, roll speed, 80%, feed screw, 65%, and oil pressure, 400 p.s.i., with the result that satisfactory correlations of the actual responses to theoretical values were obtained. Excellent tablets were prepared when portions of the aforementioned compacted material were employed for the preparation of other potassium chloride-containing products.

Comparative Study of Selected Disintegrating Agents

By WILLIAM FEINSTEIN* and ANDREW J. BARTILUCCI

Five tablet disintegrants were evaluated using 2 especially formulated bases alone and with active ingredients. The test tablet bases included a highly soluble formulation and an insoluble one. The materials evaluated were Veegum WG, Solka Floc BW-200, Jaguar A-20-B, Purity 825 cornstarch, and Landalgine P. An evaluation of the latter 2 previously was unreported. Purity 825 cornstarch and Jaguar A-20-B at 10 per cent levels were found to be the most effective. No significant change in disintegration time was noted upon the incorporation of a low concentration of an active ingredient, or upon the incorporation of a high concentration of a soluble medicament.

COMPRESSED tablets afford a convenient method for administering drugs. Most compressed tablets are formulated so as to contain fillers, binding agents, lubricants, and disintegrating agents, in addition to the active medicament. Excluding the disintegrating agent, the aforementioned components contribute chiefly to the smooth machine operation in the preparation of the finished compressed tablet. Fillers provide for a convenient tablet size and/or carrier for small amounts of active ingredients. Binding agents bring about a cohesive bond between the particles. Lubricants reduce friction and thereby permit the free flow of the granulation through the hopper and the ready ejection of the tablet from the die. It is the function of the disintegrating agent to cause the compressed tablet to break apart or disintegrate when in the presence of fluids to allow for a more favorable condition for the absorption of the contained medicament.

The literature is replete with reports pertaining to the evaluation of disintegrating agents under a variety of conditions. Factors influencing disintegration time include mechanical apparatus, materials, formulations, and techniques employed (1, 2). Several investigators (1, 3, 4) used cornstarch in the base formulation as a filler and/or binder. Kwan *et al.* (4) and Krebs (5) reported that cornstarch, when used as a filler and binder, caused significant changes in tablet disintegration times. Other investigators (6–8) reported the mutually potentiating effect of cornstarch when combined with other disintegrating agents or with substances that are capable of influencing the disintegration time of compressed tablets. Therefore, in an evaluation of disintegrating agents, the disintegration time values obtained when cornstarch is used as a binder or filler are not truly comparative representations of the disintegrating agent's ability. A more valid approach in evaluating disintegrating agents would involve the formulation of a granulation or base formula containing ingredients that did not in themselves act as disintegrating agents.

Employing a variety of active ingredients, the amounts of which were selected because they produced satisfactory tablets, many investigators (3, 7, 9–17) reported that these had an effect on disintegration time.

One objective of this investigation was the evaluation of representative disintegrating agents from each of the most commonly used chemical categories of disintegrants utilizing base formulations containing ingredients that did not themselves possess disintegrating properties. Disintegrating agents may be chemically classified as starches, clays, celluloses, algins, and gums. Two substances from the starch and algin categories, Purity 825 cornstarch and Landalgine P, respectively, not reported previously were included. Furthermore, the effect on disintegration time of 3 representative types of active ingredients present in realistic quantities was to be determined.

EXPERIMENTAL

Materials Used.—The chemicals employed were of U.S.P. or N.F. quality, or were offered by the manufacturer for drug use. The representative disintegrators were selected from several in each of the chemical categories on the basis of superior performance in preliminary experimental batches utilizing an aspirin granulation. The agents tested included: cornstarch U.S.P. and Purity 825[1] (a low moisture cornstarch) as representative of starches; Solka Floc[2] BW-40 and BW-200, Avicel,[3] and Methocel[4] MC 400 cps. as representative of celluloses; Jaguar[5] (guar gum) A-20-B and A-20-D as representative of gums; Landalgine[6] P and Kelacid[7] as representative of algins; and Veegum[8] (magnesium

aluminum silicate) F and WG as representative of clays. Those included in the study of this report appear in Table II. The tableting properties of Purity 825 cornstarch and Landalgine P do not appear in the literature.

Development of Base and Test Formulations.—Two base formulations were sought that would yield a uniformly granular material of sufficient hardness that could be readily tableted, have significantly different disintegrating times and solubilities, and be free of materials that would contribute to the disintegration of the tablet by swelling when moist. Experimental batches of tablet granulations were prepared and tested. The 2 base formulations finally selected appear in Table I, with the concentration of each ingredient and the concentration of disintegrating agent utilized at each percentage level. The formulations produced uniform granulations which had a minimum of fines and tableted readily. Base LS formulations contained ingredients of low solubility while base HS formulations contained more soluble ingredients. The disintegrating agents were incorporated with the base formulations at concentrations of 2.5, 5.0, and 10.0%. Disintegrating agents at the 5.0 or 10.0% level were selected for formulation with the active medicaments, prednisone, sulfadiazine, and sodium sulfadiazine (Tables III and IV). The concentration of disintegrant represented the most effective level from Table II. The concentration of active ingredient incorporated in the formulation represented a realistic therapeutically prescribed amount. Thus, prednisone tablets were studied at the 5 mg. level and the sulfa drugs at the 300 mg. level. Disintegration times of tablets containing active ingredients appear in Table V.

TABLE V.—AVERAGE DISINTEGRATION TIME (min.) OF TABLETS CONTAINING ACTIVE MEDICAMENTS, BASE FORMULATION MATERIALS, AND DISINTEGRANTS

[a] Whiteness/uniformity of appearance: −, off-white or mottled; +, white or nonmottled.

Manufacturing and Testing Procedures.—The powders were blended and passed through a No. 40 mesh screen. Purified water was added, and the mass was granulated by hand. The wet mass was forced through a No. 8 mesh screen, spread on trays, and dried in an oven at 38° for 14 hr. The dried granulation was forced through a No. 14 mesh screen. The fines smaller than No. 40 mesh were separated. The lubricating and disintegrating agents were mixed and passed through a No. 80 mesh screen and then blended with the granulation fines. These fines were incorporated in the granulation, and the granulation was compressed.

In the preparation of the prednisone tablets, the medicament was mixed with the fines, and these were incorporated into the granulation. The sulfadiazine tablets and the sodium sulfadiazine tablets were prepared by mixing the medicament with the filler before wet granulating. Two thousand tablets per batch were compressed on a Colton 216 rotary tablet machine utilizing $^{13}/_{32}$-in. standard concave punches and dies. The weight of each tablet was maintained at 450 ± 5 mg., and the hardness, as measured on the Stokes hardness tester, at 5 to 7 ± 0.5 Kg.

The disintegration tests were performed soon after compression using the U.S.P. (18) apparatus and method for uncoated tablets. In addition, formulations containing the active medicaments were reexamined after a minimum of 5 months' storage at room temperature. Test tablets were selected at random from each batch. Three determinations were made for each batch.

RESULTS AND DISCUSSION

It is often assumed that the disintegration time may be decreased by increasing the concentration of disintegrant. The results in Table II show this to be the case with Purity 825 cornstarch and Jaguar A-20-B. A concentration level for optimum effectiveness appears to apply with Veegum WG, Solka Floc BW-200, and Landalgine P, albeit the data are too limited to be definitive. The most effective disintegrants in the formulations studied were Purity 825 cornstarch and Jaguar A-20-B at 10% levels.

A study of Tables II and V reveals that no significant change in disintegration time occurred upon the incorporation of a low concentration of the active ingredient, prednisone, nor upon the incorporation of a high concentration of the soluble active ingredient, sodium sulfadiazine. The inclusion of a high concentration of the insoluble active ingredient, sulfadiazine, markedly increased the disintegration time of the tablets.

No significant change in disintegration time or tablet hardness was observed after storage at room temperature for 5 months.

To provide additional comparative information on the previously unreported Landalgine P and Purity 825 cornstarch, a description of the gross appearance of finished tablets appears in Table VI.

New Approach to Development and Manufacture of Enteric Compression Coatings

By RAGHUNATH SRINIVAS, H. GEORGE DEKAY, and GILBERT S. BANKER

Five commercially available polymers were evaluated for the preparation of enteric compression coatings utilizing a unique polymer incorporation method, which was part of the granulation process, and which was applicable to all of the polymers with slight modifications. The effect of polymer plasticization, the various methods of polymer incorporation, diluent ingredient properties, and physical factors of the compression coating operation were related wherever possible to the enteric disintegration properties of the manufactured tablets. The compression coating formulations developed of 4 polymers were indicated to be enteric by *in vitro* disintegration tests, but only 3 of the polymer formulations were clearly enteric according to preliminary *in vivo* tests using an X-ray technique and human volunteers.

THE CONVENTIONAL method of enteric coating in a coating pan is time consuming, empirical, difficult to reproduce, and cumbersome. For large-scale production, newer methods of enteric coating have been developed. These include film coating and compression coating. The problem of developing highly satisfactory enteric film coatings, which will be stable in the gastric environment and at the same time will be impermeable to water and prevent leaching of the drug, is difficult to resolve. In the enteric coating field, compression coating appears to have the most potential based on greater precision and reliability of fabrication, in comparison to the pan-coating operation which is the other primary enteric coating technique.

Zapapas *et al.* (1) developed an enteric coating formulation of triethanolamine, lactose, and magnesium stearate. James *et al.* (2) developed an enteric compression coating formulation with a carboxylated polymer of vinyl acetate. Swintosky obtained a U. S. patent (3) for an enteric compression coating formulation consisting of 50 to 90% of a pharmaceutically available organic acid and a pharmaceutical binder. Miller and Lindner (4) patented an enteric compression coating formulation of penicillin, a water-soluble sulfonamide, and ammoniated polyvinyl acetate phthalate.

In this study a new method of enteric granulation preparation was utilized which may be more rapid and economical than other conventional compression coating granulation manufacturing procedures. The factors of formulation, granulation manufacture, compression properties, and probable mechanisms of enteric action were studied for their effects on the enteric characteristics of the final tablet coatings.

Presented to the Scientific Section, A.PH.A., New York City meeting, August 1964.

EXPERIMENTAL

Polymeric Materials

The polymers studied (Table I) were selected for evaluation on the basis of meeting the following criteria as completely as possible: (*a*) water insolubility or substantial insolubility at pH values of 1.2 to 5, with increasing solubility at higher pH values, (*b*) resistance to moisture and water, (*c*) solubility in common organic solvents, (*d*) stability to heat and light under extreme conditions of pharmaceutical storage, (*e*) white or light in color and free from objectionable taste or odor, (*f*) chemical and physiological inertness, and (*g*) compressibility alone or in combination with other ingredients in the formulation. Cellulose acetate hydrogen phthalate was selected as a standard based on its wide use as an enteric coating.

Granulation Preparation Procedures

Core Formulations.—Cores of 2 dissimilar inert commonly used diluents, lactose and calcium sulfate dihydrate, as well as a radiopaque core of barium sulfate (Table II) were prepared. Lactose represented an organic soluble diluent and calcium sulfate an inorganic insoluble diluent.

Twelve-mesh core granulations of lactose and calcium sulfate and 16-mesh granulations of barium sulfate were prepared by wet granulation using a Stokes oscillator[1] and drying at 45° for 12 hr. The other formula ingredients were added to the sized granulations. Amaranth was incorporated in the cores to indicate leaching of a soluble ingredient through the coat.

Coat Granulations.—The coat formulations were prepared using the basic components and composition ranges given in Table III.

The granulations were prepared by mixing the dry polymer, coat diluent, polyethylene glycol 6000; massing the mixed powder with the granulating solvent containing the plasticizer (Table IV), if any, for 15 min. in a planary mixer to produce a very wet mass; reduction of the wet mass to pieces of about 1-in. diameter; and oven drying at 45° for 12 hr. (38° for the CAP granulations). The dried pieces were coarse-sized through a Fitzpatrick comminutor[2] operated at high speed with knives forward using a punched plate screen with 0.5-in.

diameter openings. The coarse granules so obtained were further sized through a 12-mesh screen with a Stokes oscillator.

All compression-coated tablets were prepared with a Manesty DryCota series 500[3] compression coating machine with $^{5}/_{16}$ in. and $^{7}/_{16}$ in. s. c. punches on the core side and coat side, respectively. The cores and coated tablets had the following average specifications:

	Core	Coated Tablet
Weight	185.0 mg.	650.0 mg.
Hardness	0.5 Kg.	17–25 Kg.
Diameter	0.795 cm.	1.114 cm.
Crown thickness	0.355 cm.	0.634 cm.

RESULTS

The following factors were systematically investigated for their effect on the *in vitro* enteric disintegration, core centering, and other properties of the tablets: (*a*) the concentration of the polymer required in the coat composition, (*b*) the coat diluent materials employed, (*c*) the granulating solvent system employed, (*d*) the necessity for a plasticizer, (*e*) the addition of lubricant–intergranular enteric bonding agent and granule binder, and (*f*) the particle size and particle size distribution of the granulation.

In Vitro Enteric Properties

Each polymer (Table I) was prepared in a series of coating granulations according to the basic coat formula in the range of component concentrations shown in Table III. Based on *in vitro* enteric disintegration testing, the following results were obtained.

None of the initial CAP formulations tested, using polymer concentrations up to 30%, produced a product with enteric protection in gastric fluid. Such enteric protection was achieved when the plasticizers (Table III) were added in a compatible solvent system. Actual plasticization of the polymer in the granulations was reflected by the elastic nature of the granules. Drying the plasticized CAP granulations above 38° diminished the plasticization effect and produced brittle granules with a resultant loss of enteric properties. As with all the polymers studied, to achieve satisfactory enteric properties *in vitro*, an intergranular bonding agent (5% magnesium stearate) and a granule binder (5% PVP) were required. A 30% plasticized CAP formula (formula 1*b*, Table IV) thus prepared, produced a satisfactory enteric product by *in vitro* test. The resultant tablets were highly speckled. To produce a more elegant nonspeckled tablet, the 30% CAP granulation could be successfully combined with an insoluble granulation (formula 1*a*, Table IV) in combinations containing as little as 30% of the CAP formula. The tablets thus obtained were nonspeckled and resistant to darkening at elevated storage temperatures.

Lubricant and intergranular enteric bonding agent[b]	2.0–5.0
Granule binder[c] (powdered acacia or PVP)[d]	1.0–5.0
Organic solvent (Table IV)	*q. s.*

[a] This material was present to promote core-coat bonding. In some combinations, the material used for lubricant-intergranular enteric bonding would also promote core-coat bonding. [b] Magnesium stearate, stearic acid, polyethylene glycol 4000, and calcium stearate were evaluated. [c] A substance which serves as a strong adhesive material and holds the granules together during exposure to gastric fluid. [d] Polyvinylpyrrolidone. Plasdone K-39, General Aniline & Film Corp., New York, N. Y.

PVM/MA 169, as the anhydride, was granulated with acetone to maintain the slowly soluble anhydride form. At a level of 10% polymer, using 3% magnesium stearate intergranular bonding agent and 3% PVP granule binder, satisfactory *in vitro* enteric properties were obtained when all the fines below 60 mesh were removed from the coat granulations (Table IV).

The 2 grades of carboxylated vinyl acetate copolymers, at a 30% concentration in the coat granulation produced tablets with a disintegration time in intestinal fluid which exceeded 2 hr. At a 20% polymer concentration, when granulation fines below 60 mesh were removed, satisfactory *in vitro* enteric properties were obtained with as little as 1% magnesium stearate and 2% PVP (Table IV).

PVAc, due to its swelling properties, could not be successfully developed as an enteric coat by the granulation method described here. All formulas studied prematurely liberated the soluble dye in gastric fluid. Plasticization did not improve this property.

Of the 4 lubricant-intergranular enteric bonding agents (Table III), at the range of concentrations studied, magnesium stearate was found to be the most efficient. However, none of the intergranular bonding agents when incorporated alone resisted the action of gastric fluid. It was also necessary to employ an efficient granule binder (PVP) to prevent tablet splitting during *in vitro* disintegration testing. The compositions of the 4 final enteric compression coating formulations are summarized in Table IV. When lactose was replaced with calcium sulfate dihydrate as the coating diluent in these formulations, the coated tablets split in simulated gastric fluid in 30 min.

Isopropanol alone did not prove to be a satisfactory granulating solvent for any of the polymer systems studied. It was necessary to use an intermediate polarity mixed organic solvent system (Table IV) as a granulating agent. Also, it was found advantageous to use a warm solvent system, with the exception of the CAP granulation.

The mechanism of *in vitro* disintegration of each formulation was studied by subjecting the coated tablets to the following disintegration tests in the U.S.P. apparatus: (*a*) 3 hr. in U.S.P. XVI simulated gastric fluid, (*b*) and (*c*) 1 hr. in U.S.P. XVI simulated gastric fluid followed by immersion in U.S.P. XVI simulated intestinal fluid with and without pancreatin. The CAP formulations were also subjected to disintegration test in intestinal fluids of pH 6.9 and 7.5. The tablets were evaluated during the above tests for leaching (release of soluble dye from the core through the coat), intergranular corrosion (erosion of the coat surface particularly along the granular boundaries), coat splitting, swelling, or disintegration.

The PVM/MA 169 compression coating formulations satisfactorily resisted gastric fluid *in vitro* for up to 1 hr. with slight swelling. The tablets compression coated with PVAc-C-H and PVAc-C-L formulations resisted gastric fluid *in vitro* for 2 hr. after which they demonstrated substantial coat erosion and slow leaching of the core ingredients. Tablets compression coated with CAP were intact after 3-hr. exposure to simulated gastric fluid. Pancreatin had no effect on the disintegration of tablets coated with any of the 4 formulations.

Physical and Mechanical Properties

Selected physical and mechanical properties of the 4 compression coating formulations having satisfactory enteric properties by *in vitro* tests, were evaluated as follows.

Particle Size Distribution.—The particle size distribution of the 4 coat formulations is given in Table V. To prevent or adequately retard intergranular corrosion in gastric media, it was found necessary to remove the fines below 60 mesh from the coat formulations *2*, *3*, and *4* (Table IV). The

[a] Determined with a Cenco-Meinzer sieve shaker at setting No. 1 for 5 min. [b] Coat formulations were freed of fines below 60 mesh.

percentage of fines removed and discarded averaged about 5% for granulations *2*, *3*, and *4*.

The selected coat formulations of each polymer, compressed over cores of calcium sulfate dihydrate and lactose, were evaluated by the following tests.

Hardness.—An average hardness of 10 coated tablets, randomly selected, was determined on a Dillon prototype direct force hardness tester.[4] In a comparison of Dillon, Monsanto, and Strong Cobb, the following relationships were found (5): 1 unit on the Dillon = 1 unit on the Monsanto, and 1.5 unit on the Dillon = 1 unit on the Strong Cobb.

Compression-coated tablet hardness was found to be a very important property affecting the enteric properties of the tablets. The approximate optimum hardness range to achieve *in vitro* enteric properties for the 4 coat formulations is summarized in Table VI. Tablets having a hardness below the optimum hardness range were subject to core composition leaching, and except for tablets coated with CAP, those which had a hardness above the optimum hardness range did not disintegrate in simulated intestinal fluid within 2 hr.

TABLE VI.—OPTIMUM HARDNESS RANGE FOR ENTERIC COMPRESSION COATED TABLETS

No.	Coat Formulation	Optimum Hardness Range, Kg. Calcium Sulfate Dihydrate and Lactose Cores[a]	Barium Sulfate Cores[a]
1	CAP	4–6	4–6
2	PVM/MA 169	24–25	15–18
3	PVAc-C-H	24–25	22–25
4	PVAc-C-L	24–25	22–25

[a] The compositions of the core tablets are given under *Experimental*.

Friability.—The friability of the tablets was determined in a 5.5-in. diameter baffled cylinder, revolving at 50 r.p.m. (6). A loss in tablet weight of less than 1% in 20 tablets for 100 rev. was not considered significant. At their optimum hardness range, none of the tablets were friable, according to this test.

Weight Variation.—The enteric compression-coated tablets as well as the cores were found to vary less than 1% in weight.

Horizontal Expansion and Centering of Cores.—At a machine speed of 250 tablets/min. and with the same die fill and pressure settings, 1500 tablets of the 4 successful coat formulations with lactose and calcium sulfate cores were collected and observed for visible off-centering. The percentage increase in diameter and decrease in crown thickness of a sample of the sectioned exposed cores of the coated tablets were compared with uncoated cores (Table VII). In every case, the calcium sulfate cores underwent less dislocation but demonstrated a greater decrease in crown thickness than did the lactose cores. Core composition appeared to have a much greater effect on centering properties than did the polymer coat formulation.

Minimum Coat Thickness.—Cores with an average weight of 120.0 mg., average diameter of 7.93 mm., and an average crown thickness of 3.20 mm. were compression coated with varying thicknesses of the 4 different coat formulations, keeping the hardness of the coated tablets within the optimum range for each coating. The minimum coat thickness required to give adequate enteric protection by *in vitro* standards was 1.3 mm. for all formulations.

[4] W. C. Dillon and Co., Inc., Van Nuys, Calif.

TABLE VII.—INFLUENCE OF CORE COMPOSITION ON THE OFF-CENTERING OF TABLETS COMPRESSION COATED WITH CAP, PVM/MA 169, PVAc-C-H, AND PVAc-C-L

Coat Formulation	Core Comp.	Av. % Off-Centering	Decrease in Crown Thickness, %	Increase in Tablet Core Diam., %
CAP	Lactose	7.2	24.03	2.14
CAP	$CaSO_4$	5.0	31.99	2.40
PVM/MA 169	Lactose	7.5	15.37	3.15
PVM/MA 169	$CaSO_4$	6.0	31.28	1.15
PVAc-C-H	Lactose	5.18	20.11	1.50
PVAc-C-H	$CaSO_4$	2.2	25.52	1.00
PVAc-C-L	Lactose	5.0	13.41	3.39
PVAc-C-L	$CaSO_4$	2.2	31.29	2.14

Storage Stability Tests.—The final tablet formulations of each polymer with the core compositions were stored in capped bottles at 50 ± 1°, 25 ± 2°, and 2 ± 1° for a period of 8 weeks. The *in vitro* disintegration properties of none of the 4 final tablet formulations were affected by any of the above storage conditions. The tablets, enteric compression-coated with PVAc-C-H and PVAc-C-L formulations progressively increased in hardness by 5 to 10 Kg. when stored for 8 weeks at 50°. This increase in hardness did not affect the disintegration properties of the formulations.

In Vivo Evaluation[5]

The preliminary *in vivo* evaluation of the enteric compression coated tablets was based on an X-ray examination of the tablets in the gastrointestinal tract of human volunteers, using 3 to 5 volunteers for each coat formulation.

Each volunteer was given 3 tablets. The second tablet was administered 2 to 3.5 hr. after the first tablet, and the third tablet was administered 1 to 3 hr. after the second tablet. The first and third tablets were of the same size and the second was of a different size ($^3/_8$-in. and $^7/_{16}$-in. tablets with 0.25-in. and $^5/_{16}$-in. barium sulfate cores, respectively). The radiographs were taken at calculated intervals after localization of the tablets using a Fluoricon image intensifier. Figures 1 to 4 are photographic reproductions of the X-ray films as they appear on a viewer.

CAP formulations were found to be intact in the stomach of human volunteers as long as 4 hr. and 15 min., while PVAc-C-L and PVAc-C-H tablets were found intact as long as 4 hr. and 35 min. and 4 hr. and 25 min., respectively, following administration. In the intestinal tract, CAP formulations were found to disintegrate within 6 hr. and 45 min. total time following administration, while PVAc-C-L and PVAc-C-H tablets were found to disintegrate within 6 hr. and 45 min. and 7 hr. and 30 min. or less, respectively.

[5] The authors are indebted to Dr. P. L. Webster, Radiologist, and Mr. James Barbee, Student Health Center, Purdue University, for their help in this study.

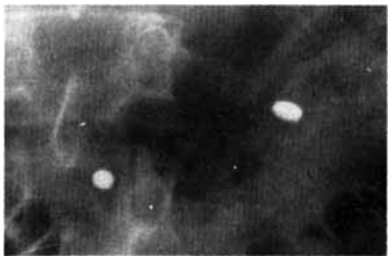

Fig. 1.—Film A_1 for cellulose acetate phthalate, illustrating second and third tablets intact in the stomach after 7 hr. and 10 min. and 3 hr. and 10 min., respectively.

Fig. 2.—Film A_4 for cellulose acetate phthalate, illustrating the third tablet disintegrating in the intestinal tract after 6 hr. and 50 min.

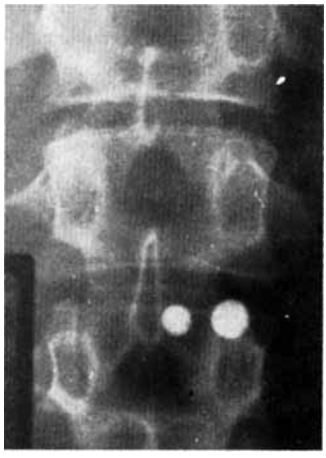

Fig. 3.—Film F_1 for PVAc-C-H formulation, illustrating second and third tablets intact in the stomach after 4 hr. and 27 min. and 3 hr. and 22 min., respectively.

Fig. 4.—Film D_2 for PVAc-C-H formulation, illustrating the first tablet disintegrating in the intestinal tract after 6 hr. and 49 min.

In the case of tablets enteric compression-coated with PVM/MA 169, 1 tablet was found broken in the stomach after 6 hr. and 25 min. in 1 volunteer, but 4 tablets were found to be intact in the intestinal tract of other subjects where the disintegration time appeared to be 6 hr. and 35 min. or less. Thus, this formulation appears to have an enteric coating potential. The failure of 1 of the tablets in the stomach is due to the slow swelling rate of this polymer at gastric pH and the unduly long sojourn of the tablet in the stomach.

DISCUSSION

In this study, the respective polymers (Table I) were dry mixed with the coat diluent and granulated with an organic solvent system (Table IV) in which the polymer was soluble. This simple reproducible granulation–polymer incorporation method had the potential advantage, in addition to circumventing a formal coating step, of permitting the convenient uniform incorporation of higher proportions of polymers with much less solvent than would be feasible if the polymer was added in solution form.

The main objective of an enteric compression coating is to produce a strongly bonded coat layer over the core, without cracks or flaws, so that the coat will resist the penetration of gastric fluid and leaching of the core ingredients. This study indicated that this objective can be approached using the direct coat granulation method described and the following principles.

(*a*) Use of materials which weaken the interparticular bond. Shotten and Ganderton (7) refer to such materials as interparticular bonding agents. An interparticular bonding agent produces a strongly bonded tablet thereby minimizing premature intergranular corrosion and coat failure. In this application interparticular bonding agents were sought which were also enteric.

(*b*) Use of a "granule binder." This serves as a strong adhesive material and holds the granules together during exposure to gastric fluid.

(*c*) Removal of fines and fine granules. Petch (8) has reported that a coarser granule fraction gave a stronger bond.

One of the critical factors in this study, in addition to the selection of the polymeric material, was the role played by the nonpolymeric coating diluent in determining the enteric characteristics of the coat. To visualize gastric fluid permeability into the compression coatings, tablets were sectioned following

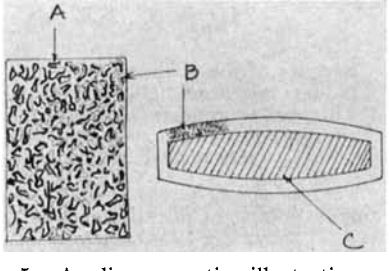

Fig. 5.—A diagrammatic illustration of the probable structure of the successful enteric compression coating layer. Key: A, matrix of partially coated granules; B, bed of intergranular enteric bonding agent—granule binder mixture; C, core.

varying periods of disintegration testing, and microscopically examined for soluble dye migration through the coat layer. Calcium sulfate dihydrate, due to its water absorbant character, drew test fluid into the coating resulting in coat failure. Lactose, though completely soluble, did not have the water-sorptive character of calcium sulfate, and was a satisfactory coat diluent in this study. Microscopic examinations of tablet cross sections also indicated that enteric compression coatings were produced when the matrix of partially coated granules is bound by the intergranular enteric bonding agent forming an impervious coat as illustrated in Fig. 5.

The greater off-centering found with the lactose cores in all of the compression-coated tablets, regardless of coat formulation (Table VII), is probably related to the greater expansion of the lactose cores during recovery which accentuates the core dislocation (9). Experiments by Kaplan and Wolff (10) have shown that calcium sulfate dihydrate is more compressible than lactose under the same conditions.

Of the 4 carboxyl-containing polymers evaluated in this study, 3 were subject to slow swelling or coat erosion in gastric fluid *in vitro*. The principle of enteric disintegration of PVM/MA 169, PVAc-C-H, and PVAc-C-L formulations appeared to be slow solubility at lower simulated gastric pH values and faster rates of solubility at higher simulated intestinal pH values. Bauer and Masucci (11) found that the disintegration of CAP coatings in intestinal contents of pH 6.9 is the result of the hydrolytic action of intestinal esterases. In this experiment pancreatin was found to have no influence on the disintegration of tablets compression coated with CAP in intestinal fluids of pH 6.9 and 7.5. This probably is due to the modification of the enteric properties of the polymer by the plasticizer, triacetin.

PVM/MA 169, which most quickly swelled *in vitro* was observed to fail in 1 subject *in vivo* as an enteric coating. A partially esterified derivative of the polymer (12, 13) with a slower dissolution rate would probably produce a more satisfactory enteric coating.

CONCLUSIONS

A method has been developed for the incorporation of slowly soluble polymer materials in a diluent by simple mixing and standard granulation procedures to produce enteric compression coatings. The granulations thus produced with each of 4 polymer materials when mixed with an intergranular enteric bonding agent, magnesium stearate, and an effective granule binder, polyvinylpyrrolidone, and compression coated at an optimum hardness range was found to be enteric by *in vitro* disintegration tests. The formulation factors, physical and tablet properties of the formulations, were investigated for their effect on *in vitro* enteric properties. *In vivo* evaluation using an X-ray technique and human volunteers indicated that 3 of the polymer systems studied were enteric and that the reported simplified method of polymer incorporation to produce enteric compression coatings is feasible.

Evaluation of Amylose as a Dry Binder for Direct Compression

By K. C. KWAN* and GEORGE MILOSOVICH†

Because of the economies of direct compression, there exists a need for good dry binders which will effect compression of drugs at relatively low filler-to-drug ratios. This paper reports an evaluation of amylose for this purpose. The results on compression effects, physical properties, stability, and drug availability show that this material has the characteristics desired of the ideal binder.

THE DEVELOPMENT of forced-feed mechanisms for tableting presses and relatively free flowing tablet excipients has stimulated interest in commercial tableting by direct compression (1). The objective of direct compression is to produce pharmaceutically elegant tablets with a minimum of processing time and cost. Since many drugs cannot be compressed directly, 1 or more agents must be added to impart suitable compression properties. Unfortunately, many of these addi-

varying periods of disintegration testing, and microscopically examined for soluble dye migration through the coat layer. Calcium sulfate dihydrate, due to its water absorbant character, drew test fluid into the coating resulting in coat failure. Lactose, though completely soluble, did not have the water-sorptive character of calcium sulfate, and was a satisfactory coat diluent in this study. Microscopic examinations of tablet cross sections also indicated that enteric compression coatings were produced when the matrix of partially coated granules is bound by the intergranular enteric bonding agent forming an impervious coat as illustrated in Fig. 5.

The greater off-centering found with the lactose cores in all of the compression-coated tablets, regardless of coat formulation (Table VII), is probably related to the greater expansion of the lactose cores during recovery which accentuates the core dislocation (9). Experiments by Kaplan and Wolff (10) have shown that calcium sulfate dihydrate is more compressible than lactose under the same conditions.

Of the 4 carboxyl-containing polymers evaluated in this study, 3 were subject to slow swelling or coat erosion in gastric fluid *in vitro*. The principle of enteric disintegration of PVM/MA 169, PVAc-C-H, and PVAc-C-L formulations appeared to be slow solubility at lower simulated gastric pH values and faster rates of solubility at higher simulated intestinal pH values. Bauer and Masucci (11) found that the disintegration of CAP coatings in intestinal contents of pH 6.9 is the result of the hydrolytic action of intestinal esterases. In this experiment pancreatin was found to have no influence on the disintegration of tablets compression coated with CAP in intestinal fluids of pH 6.9 and 7.5. This probably is due to the modification of the enteric properties of the polymer by the plasticizer, triacetin.

PVM/MA 169, which most quickly swelled *in vitro* was observed to fail in 1 subject *in vivo* as an enteric coating. A partially esterified derivative of the polymer (12, 13) with a slower dissolution rate would probably produce a more satisfactory enteric coating.

CONCLUSIONS

A method has been developed for the incorporation of slowly soluble polymer materials in a diluent by simple mixing and standard granulation procedures to produce enteric compression coatings. The granulations thus produced with each of 4 polymer materials when mixed with an intergranular enteric bonding agent, magnesium stearate, and an effective granule binder, polyvinylpyrrolidone, and compression coated at an optimum hardness range was found to be enteric by *in vitro* disintegration tests. The formulation factors, physical and tablet properties of the formulations, were investigated for their effect on *in vitro* enteric properties. *In vivo* evaluation using an X-ray technique and human volunteers indicated that 3 of the polymer systems studied were enteric and that the reported simplified method of polymer incorporation to produce enteric compression coatings is feasible.

tives are either too costly or react with the active ingredients to decrease stability. Also, the ratio of these fillers to the drug necessary to effect compression may preclude use with higher dosage drugs.

The amylose used in this study[1] is unusual in that it can be tableted directly into pharmaceutically acceptable tablets. It is free-flowing, self-lubricating, and self-disintegrating so that it, by itself, functions as the filler, lubricant, and disintegrant. Since amylose is composed of large molecular weight polymers of glucose attached through 1–4 linkages, it has a minimum of reducing groups; thus, it should have very little, if any, reactivity with drug molecules. It does, however, require about 10–12% moisture for optimum compression and may be unsuitable for use with drugs subject to hydrolytic decomposition.

It was the purpose of this investigation to evaluate this amylose for its potential usefulness in direct compression applications.

EXPERIMENTAL

Six drugs known to be difficult to compress directly were selected for this study. Sulfathiazole, sodium *p*-aminosalicylate, ascorbic acid, sodium phenobarbital, phenacetin, and aspirin either do not form tablets of adequate hardness when compressed directly or form tablets with poor weight variation. Each of these materials, received from their respective suppliers as U.S.P. or N.F. grade, was mixed with an equal amount of amylose for 5 min. in a twin shell blender (Paterson-Kelly model LB2630). The resulting mixes then were tableted on a Colton 216 using $^5/_{16}$-in. standard concave punches and the standard feed frame. All tablets were prepared at maximum pressure obtainable with this press. Appropriate changes in the 1:1 formula were then made to establish the minimum amylose-to-drug ratio necessary for suitable tablets. The resulting tablets were tested for disintegration, hardness, friability, and weight variation.

To assess the possibility of classification and bridging in these powder mixes, weight variation and drug content were determined on samples removed periodically during tableting of a full hopper (2.0 Kg.) of mix. Aspirin, 200-mesh powder and 40-mesh crystals, and ascorbic acid, 200-mesh powder and 40/80-mesh crystals, were chosen to represent the range in particle sizes and amylose-to-drug ratio used in this investigation.

Aspirin and ascorbic acid tablets were chosen also to test the effect of amylose on chemical stability. These and commercially available tablets were powdered using a mortar and pestle and were stored in loosely capped vials at 3 elevated temperatures and 2 relative humidities. The sample vials were arranged randomly in each desiccator and were withdrawn in a random manner to eliminate possible bias due to variation in storage conditions. Periodic assays were conducted using the U.S.P. method for acetylsalicylic acid tablets (2) and the method of Barakat *et al.* (3) for ascorbic acid.

To estimate the effect of aging on physical properties, tablets of each drug were stored in tightly capped amber bottles at 55° for 24 days, and their respective hardness, friability, disintegration time, and appearance were re-evaluated.

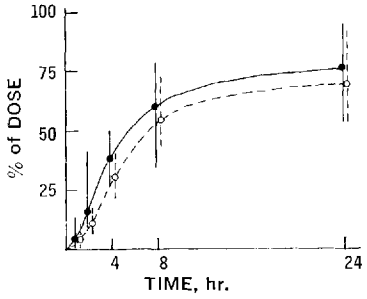

Fig. 1.—Cumulative urinary excretion of salicylates following ingestion of amylose and commercial aspirin tablets. Key: —●—, average of 8 subjects, amylose tablets; --○--, average of 8 subjects, commercial tablets; vertical lines, ranges of individual values obtained.

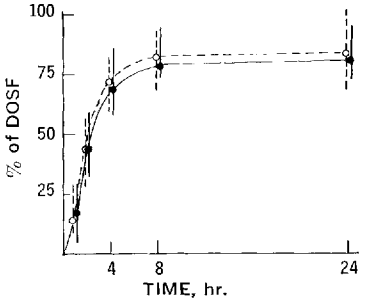

Fig. 2.—Cumulative urinary excretion of aromatic amines following ingestion of amylose and commercial sodium *p*-aminosalicylate tablets. Key: —●—, average of 8 subjects, amylose tablets; --○--, average of subjects, commercial tablets; vertical lines, ranges of individual values obtained.

Aspirin and sodium *p*-aminosalicylate tablets were chosen for investigation of drug release from amylose-based tablets. These tablets represented the 2 extremes in the *in vitro* disintegration test. Eight apparently healthy males were used in a crossover experiment, and urinary excretion data were obtained following controlled ingestion of test and commercially available control tablets. Prior to breakfast, each subject voided completely and was given 240 ml. of water. One hour later the subjects voided and were given their respective doses with an additional 240 ml. of water. They were then allowed to eat regular meals commencing 1 hr. after dosing. Urine samples were collected at 0, 1, 2, 4, 8, and 24 hr. for assay. Aspirin was determined on the basis of total salicylate content using Trinder's reagent, and sodium *p*-aminosalicylate by the method of Way *et al.* (4) for aromatic amines.

RESULTS

Amylose to Drug Ratios.—Table I gives the results obtained with the 6 test drugs. Acceptable tablets were obtained with each drug, although the proportion of amylose required varied from 20% for aspirin to 80% for phenacetin. The physical properties would be considered statisfactory for pharmaceutical application except for the relatively poor disintegration of sodium *p*-aminosalicylate. This was attributed to the basicity of this compound which may be sufficient to dissolve amylose to form a viscous gummy coating at the tablet surface retarding further penetration of water. From these results it appears that amylose can be used to effect successful direct compression of even the most difficult materials. It is expected that the amount of amylose required will depend on the inherent compression characteristics of a drug and that minimum amounts of amylose will suffice for drugs approaching aspirin in compression properties.

Weight and Drug Content in Extended Operation.—The data obtained from tablets made during extended operation in which the pressure and fill settings were held constant are given in Table II. The constancy of tablet weight and drug content during the time required to empty the hopper is a strong indication that classification was not prevalent for these mixes. Since these mixes represent wide ranges in both particle size and amylose-to-drug ratio, it is expected that classification will not be a problem with most amylose–drug mixes.

Stability.—Considering that amylose contains 10–12% water and can absorb considerably more at high humidity, it was expected that amylose would accelerate the hydrolytic degradation of aspirin. The results of this study showed, however, that even at 75% R.H. and 55°, amylose-based aspirin was equivalent in stability to the control. Since there was much more water in the amylose system, it appears that this water was bound tightly and not free for reaction.

The ascorbic acid powders exhibited considerably more decomposition than was evidenced with aspirin. Table III gives the $T_{.90}$ values for the various storage conditions. It is known that ascorbic acid degradation is very complex and no attempt is made to interpret these results. The important consideration is that there was no significant difference in

stability between amylose and the commercial control.

The results of accelerated aging on amylose-based tablets are shown in Table IV. It can be seen that physical stability was relatively good, even in cases where chemical decomposition was marked. Although changes in hardness, disintegration, and friability occurred, they were still well within the limits for acceptable tablets. Data on sodium *p*-aminosalicylate tablets are not included since this compound degraded to such an extent that the tablets were destroyed under the conditions of this test.

Drug Availability.—The results of the availability experiments are shown graphically in Figs. 1 and 2, where the mean and range of cumulative urinary excretion are plotted for each time period. It can be seen that even for the sodium *p*-aminosalicylate tablets showing poor *in vitro* disintegration the availability is essentially the same as for the control. Apparently the viscous surface film which retarded *in vitro* disintegration was mechanically eroded in the gastrointestinal tract.

CONCLUSIONS

It appears, from the results of this investigation, that amylose merits serious consideration for use as a direct compression tablet binder. In the form used in this study it can effect compression of problem drugs at relatively low concentration and yields tablets possessing the characteristics desired for pharmaceutical use. Although each drug formulation is unique and must be thoroughly tested, there is every indication from these results that successful application can be obtained. It should be pointed out that these results relate only to this particular amylose and may not extrapolate to other amyloses or amylose derivatives.

xanthine system through an aliphatic chain containing sulfur as the thioether, sulfoxy, or sulfonyl group. The presence of a pyridyl group in these compounds intensifies their basic character in comparison with previously described sulfur-containing xanthine derivatives (1, 2).

The authors obtained 2- and 4-pyridylthioethyl derivatives of theobromine, and theophylline (I–IV) through condensation of 1-β-chloroethyltheobromine or 7-β-bromoethyltheophylline with sodium salts of 2- or 4-mercaptopyridines in anhydrous ethanol solution. Compounds I–IV are colorless, crystalline, easily soluble in alcohols, well soluble in dilute mineral acid solutions, and less soluble in water. They give stable picrates. By oxidation of I, III, and IV with an equimolar quantity of hydrogen peroxide in glacial acetic acid at room temperature, V, VI, and VII were formed. From comparison of physicochemical properties of V, VI, and VII with those of isomeric *N*-oxides (VIII and IX), it can be concluded that the former have a sulfoxide grouping. VIII and IX were prepared in an unambiguous way, in the reaction of halogentoethyl derivatives of theobromine resp. theophylline with the well-known 2-mercapto (6) or 4-mercapto-pyridine *N*-oxides (7). It is also in accordance with observations of other authors that in the oxidation conditions used, the pyridine *N*-oxides are formed only on heat (8–10) whereas the *S*-oxides are formed readily at room temperature. Alkyl-pyridyl sulfides give, by oxidation with hydrogen peroxide in acetic acid or with perbenzoic acid, the respective sulfoxides (6, 11). Taking into account the fact that purines are either degradated or unaffected by hydrogen peroxide (12), it may be assumed that purine *N*-oxides are not formed in the applied conditions of oxidation. Compound VI ($\lambda_{max.}$ 272 mμ, log ε 5.04) and IX ($\lambda_{max.}$ 291 mμ, log ε 5.71) showed no absorption band at ~230 mμ, which is characteristic for purine *N*-oxides (in neutral or alkaline solution) (13, 14). Similar results were obtained by U.V. examination of hydrogen peroxide oxidation products of sulfides I and IV. This supports the presence of a sulfoxide group in compounds V, VI, and VII. When, for the oxidation of I, III, and IV, an excess of hydrogen peroxide was used under analogous conditions the sulfonyl compounds (X, XI, XII) were obtained. The latter can be prepared also by oxidation of the corresponding sulfoxides. Sulfones (X, XI, XII) in the series of sulfide-sulfoxide-sulfone, have the highest melting points. X, XI, and XII, are readily soluble in ethanol and insoluble in water. Moreover, the condensation of pyridine-3-methanthiol (15) with 1-β-chloroethyltheobromine carried out in a manner analogous to compounds I–IV gives 1-β-(pyridyl-3′-methyl)-thioethyltheobromine (XIII), with a relatively low melting point.[1]

Analyses are reported in Table I.

EXPERIMENTAL[2]

1-β-(2′-Pyridyl)-thioethyltheobromine (I).—To a solution of 0.23 Gm. (0.001 mole) of sodium in 20 ml. of absolute ethanol, 1.11 Gm. (0.01 mole) of 2-mercaptopyridine (16) and 2.42 Gm. (0.01 mole) of 1-β-chloroethyltheobromine (17) were added, and the mixture was refluxed for 10 hr. The solvent was evaporated under reduced pressure, and the residue was crystallized from ethanol to obtain colorless needles, m.p. 197°. Picrate, m.p. 185° (from ethanol).

1-β-(4′-Pyridyl)-thioethyltheobromine (II), 7-β-(2′-pyridyl)-thioethyltheophylline (III), and 7-β-(4′-pyridyl)-thioethyltheophylline (IV) were obtained similarly.

1-β-(2′-Pyridyl)-sulfoxyethyltheobromine (V).—To a solution of 0.95 Gm. (0.003 mole) of 1-β-(2′-pyridyl)-thioethyltheobromine (I) in 10 ml. of glacial acetic acid, 1 drop of sulfuric acid solution and 0.34 ml. (0.003 mole) of 30% hydrogen peroxide were added. The mixture was allowed to stand for 3 days at room temperature. Acetic acid then was evaporated *in vacuo*, and the residue was crystallized from 70% ethanol to obtain colorless needles, m.p. 181°.

Similarly, the sulfoxides (VI and VII) were obtained from II and III, correspondingly.

1-β-(2′-Pyridyl)-sulfonylethyltheobromine (X).—*Method A.*—To a solution of 1.19 Gm. (0.006 mole) of 1-β-(2′-pyridyl)-thioethyltheobromine (I) in 20 ml. of glacial acetic acid, 1 drop of sulfuric acid in acetic acid solution (10 ml. of acetic acid + 2 drops of concentrated sulfuric acid), and 1.4 ml. (0.012 mole) of 30% hydrogen peroxide were added. The mixture was kept at room temperature for 3 days. After vacuum evaporation of the acetic acid, the residue was crystallized from 50% ethanol, and a colorless product, m.p. 216°, was obtained.

---

[1] It is probably due to the presence of a methylene bridge between the pyridine ring and sulfur. Similarly, 7-γ-picolyltheophylline has a lower melting point than 7-γ-pyridinetheophylline (5).

[2] Melting points were determined by the open capillary tube method and are not corrected. The analyses were done by T. Kulawik and Z. Pasternak from this laboratory.

TABLE I.—PYRIDYLTHIOETHYL DERIVATIVES OF THEOBROMINE AND THEOPHYLLINE

				Ethanol	331.38	Found			21.49

[a] T = the 7-theophyllinyl, resp. 1-theobrominyl rest. [b] Picrate m.p. 185° from ethanol. *Anal.*—Calcd. for $C_{20}H_{18}O_9N_8S$: C, 43.87; H, 3.33. Found: C, 43.97; H, 3.50.

The sulfones (XI and XII) were prepared similarly.

Method B.—To a solution of 0.5 Gm. (0.0015 mole) of 1-β-(2′-pyridyl)-sulfoxyethyltheobromine (V) in 20 ml. of glacial acetic acid with the catalytic amount of sulfuric acid, 0.2 ml. (0.0018 mole) of 30% hydrogen peroxide was added, and the mixture kept at room temperature for 2–3 days. After evaporation of acetic acid *in vacuo*, the residue crystallized from 50% ethanol yielded the product, m.p. 215°. No melting point depression was found for a mixture of the 2 products.

N-Oxide of 1-β-(2′-Pyridyl)-thioethyltheobromine (VIII).—A solution of 0.23 Gm. (0.01 mole) of sodium and 1.27 Gm. (0.01 mole) of 2-mercaptopyridine *N*-oxide (6) in 25 ml. of ethanol was added dropwise to a boiling solution of 2.42 Gm. (0.01 mole) of 1-β-chloroethyltheobromine in 25 ml. of ethanol. Heating was continued for 4 hr.; the hot solution was filtered and then cooled. The precipitate recrystallized from ethanol yielded the product, m.p. 201°. *N*-Oxide of 7-β-(4′-pyridyl)-thioethyltheophylline (IX) was obtained in the above manner by condensation of 7-β-bromoethyltheophylline (18) with 4-mercaptopyridine *N*-oxide (7) in ethanolic sodium ethoxide solution.

1 - β - (Pyridyl - 3′ - methyl) - thioethyltheobromine (XIII).—To the solution of 0.23 Gm. (0.01 mole) of sodium and 1.23 Gm. (0.01 mole) of 3-mercaptomethylpyridine (16) in 20 ml. of ethanol, 2.42 Gm. (0.01 mole) of 1-β-chloroethyltheobromine was added, and the mixture was heated under reflux for 8 hr. The solvent was evaporated under reduced pressure, and the residue was crystallized from ethanol to obtain a colorless product, m.p. 124°.

Oxygen Flask Method for Iodine Determination in Thyroid Protein

By W. F. DEVLIN and SARAH P. ROSS

Nitrogenous oxidation products formed during the combustion of thyroid powder give rise to an appreciable error in the oxygen flask method for total iodine as described in the British Pharmacopoeia. This error can be reduced to negligible proportions by the use of a sulfamic acid reagent and an increased period of stirring of the combustion residue before the addition of excess iodide and titration with thiosulfate.

THE OXYGEN flask combustion method as applied to halogen determination in organic material (1) was modified by Vickers and Johnson (2) for the analysis of iodine in certain pharmaceuticals. More recently this method has been adopted by the British Pharmacopoeia (3) for iodine determination in thyroid. Vickers and Johnson mentioned that the presence of nitrogenous oxidation products in their method was undesirable. This communication describes the magnitude of the error thus caused in thyroid iodine measurements and assesses the effectiveness of sulfamic acid as used by Backer (4) to eliminate it.

EXPERIMENTAL

Equipment.—A Thomas-Lisk combustion flask, black wrappers with fuse, magnetic stirring apparatus with Teflon covered bar and ring as supplied by A. H. Thomas Co., Philadelphia, Pa., or similar equipment.

Reagents.—Prepare reagent solutions as described by Vickers and Johnson (2), using water which has been distilled over alkaline permanganate.

Bromine Solution.—Dissolve 100 Gm. of potassium acetate in glacial acetic acid, add 4 ml. of bromine, and dilute to 1 L. with glacial acetic acid.

Sulfamic Acid.—Dissolve 4 Gm. of sulfamic acid in 200 ml. of water.

Sodium Thiosulfate.—Standardize accurately to about 0.005 *N*.

Formic Acid.—88% H_2CO_2.

Starch Indicator.—0.5% in water.

Procedure.—Accurately weigh an amount of thyroid containing 0.2–0.5 mg. of iodine and enclose in a black paper wrapper. Use not more than 100 mg. of protein material when combustion is to be performed in a 1-L. flask. With larger amounts, combustion was often incomplete. Add 10 ml. of water and 2 ml. of *N* NaOH to the flask.[1] Place the magnetic stirring bar in the bottom of the flask and thoroughly flush the flask with 100% oxygen. After combustion of the thyroid powder, stir the residue for 15 min. rather than 5 min. as required in the B. P. procedure. Add 5 ml. of bromine reagent and let stand for 2 min. Add 0.5 ml. of formic acid and flush out the bromine vapors with air. Carefully wash down the sides of the flask with 15 to 20 ml. of water, add 2 ml. of sulfamic acid reagent, and allow to stand a further 2 min. Finally, add 1 Gm. of crystalline potassium iodide to the flask and titrate immediately with 0.005 *N* sodium thiosulfate using starch indicator as the end point is approached.

For combustion of standard amounts of *o*-monoiodobenzoic acid (MIB) accurately prepare alcoholic solutions containing about 10 mg. of MIB/ml. Apply carefully measured aliquots of these solutions directly on the black wrappers. Prepare dry mixes in mortars containing nicotinic acid and urea, respectively, and 80–100 mg. of MIB/10 Gm. total weight. For the preparation of combustion packets weigh the dry mixes or thyroid powders directly on the wrappers, enclose, and place in the platinum basket with wick protruding.

RESULTS AND DISCUSSION

Carbon Dioxide and Iodine Determination.—There was no appearance of free iodine or evidence of erroneous recoveries of added iodate when, following the usual procedure, 100 mg. of lactose was burned in a 120-mg. black paper wrapper. Carbon dioxide, and other oxidative residues which may result from the wrapper, did not therefore seem to produce an error.

Nitrogenous Oxidation Products of Urea Combustion.—Urea, if it is chemically pure, will yield only water, carbon dioxide, and nitrogenous oxides during combustion. Table I illustrates the extent of oxidation of iodide by nitrogenous products of urea combustion in this method. When an amount of urea containing 32 mg. of nitrogen (≡200 mg. of protein) was burned and the combustion residue stirred for 5 min. there appeared 0.20 meq. of free iodine following addition of excess iodide. When the stirring time was increased to 15 min. the amount of iodine appearing at the time of titration was reduced to 0.002 meq. Similarly, if sulfamate were added to the combustion residue after a 5-min. stirring period and the usual bromine treatment, the amount of free iodine appearing at the time of titration was also reduced to about 0.002 meq. When the longer stirring period was combined with the sulfamate treatment in the prescribed manner, there was no detectable iodine present at the time of titration.

It is reasonable to presume that at least some of the gaseous nitrogenous products of combustion will form nitrites in solution. Sulfamic acid reacts with nitrite in the manner indicated by the equation (5):

$$NH_2SO_3H + HNO_2 \rightarrow H_2O + N_2 + H_2SO_4$$

In view of the effectiveness of the sulfamic acid in prevention of the undesirable iodide oxidation, it seemed probable that the part of the nitrogenous oxidation products, which was present as, or could give rise to nitrites, caused most or all of the error. As confirmation of this hypothesis, a sensitive test

Received November 12, 1965, from the Research Laboratories, Food and Drug Directorate, Department of National Health and Welfare, Ottawa, Ontario, Canada.

Accepted for publication December 28, 1965.

[1] With the use of a magnetic stirring apparatus and a 1-L. round-bottom flask it has been found that the alkalinity and volume constituted by 10 ml. of water and 2 ml. of *N* NaOH is adequate to capture the iodine products of combustion. The B. P. procedure employs a 50-ml. volume of water in a 2-L. flask and 2 ml. of *N* NaOH. Excluding this minor departure, the term "B.P. method" in this text is as described in the "British Pharmacopoeia," 1963, p. 835.

for the presence of nitrite was performed on combustion residues. By this method, if nitrite is present in the test solution the diazonium derivative of sulfanilic acid is formed and couples with α-naphthylamine giving a red-colored solution (6). In this manner, nitrite was demonstrated to be present in urea and thyroid powder combustion residues both before and after treatment with bromine, notwithstanding a greatly diminished color intensity in the latter instance. After treatment of the combustion residues with sulfamic acid in the prescribed way, no nitrite could be detected by this method.

The recommended procedure, therefore, included the addition of sulfamate as well as the longer stirring period for the combustion residue. The longer stirring period evidently allowed the flask solution to reach a new chemical equilibrium which favored the disappearance of nitrite.

The Recovery of Iodine from Combustion of MIB.—When alcoholic solutions of MIB were applied to the black paper wrappers and the combustion and iodine measurement carried out in the recommended manner, it was possible to recover only about 90% of the theoretical amount (Table II). The recoveries of iodine under these conditions were observed when the iodine present on the wrapper ranged from 0.1 to 2.5 mg. The fluctuating recovery values suggested that combustion of the wrapper and MIB did not uniformly convert all the iodine to an inorganic form. When the combustion of MIB was carried out in the presence of organic nitrogenous material, as represented by urea and nicotinic acid, there was a distinct increase in recoverable iodine. Recoveries under these conditions ranged from about 96% to the theoretical value. Evidently, the slower burning, which would be expected with the greater bulk of organic material, allowed the iodine to reach an inorganic state before burning ceased.

Iodine Determination in Thyroid Powders.—Four different thyroid samples were analyzed for their iodine content by the (*a*) U.S.P., (*b*) B.P. (3) or Vickers-Johnson, and (*c*) B.P. modified procedures. The results are shown in Table III. The B.P. modified procedure included the 15-min. stirring period and the addition of sulfamic acid. The U.S.P. procedure (7) employs a carbonate ashing step at 675 to 700°, bromine treatment to convert all iodine to iodate, subsequent acidification with phosphoric acid, and expulsion of excess bromine by boiling. Traces of remaining bromine are organically bound by addition of a phenol solution, and the iodine is measured by a thiosulfate titration. With the proposed modifications in the oxygen flask procedure, the observed iodine levels are indistinguishable from those given by the U. S. P. method. These results indicate that, under the prescribed conditions, oxygen flask combustion of thyroid combined with bromine treatment of the residue, converts the organically bound iodine to iodate, and retains it in that form at least as efficiently as the U.S.P. method. Iodate is the required chemical state of iodine before addition of excess iodine and thiosulfate titration.

The B.P. method gave as much as 15% higher values than those obtained by the authors' modified

TABLE III.—A COMPARISON OF RESULTS OF IODINE ANALYSIS ON THYROID POWDERS AS DETERMINED BY THE U.S.P. AND OXYGEN FLASK PROCEDURES[a]

Thyroid Sample	U. S. P. XVII Procedure	Oxygen Flask: B. P.	Oxygen Flask: B. P. Modified
1	0.970	1.14	1.01
	0.977	1.16	1.02
	0.960	1.17	1.01
		1.08	1.00
2	0.730	0.864	0.740
	0.748	0.849	0.714
		0.812	0.718
		0.796	0.728
3	0.196	0.220	0.206
	0.206	0.226	0.207
	0.203	0.234	0.206
		0.240	0.209
4	0.516	0.632	0.549
	0.543	0.678	0.545
	0.560	0.644	0.543
		0.583	0.555

[a] All concentrations are expressed as per cent by weight iodine.

method. The difference, it is contended, is due to the spurious oxidation of iodide by nitrite. Furthermore, the noticeably greater variation between individual determinations may possibly be due to the recurring end point which is a characteristic of the B.P. method.

Recovery of Iodide from Thyroid Combustion Residues.—Iodine was added as potassium iodide to a thyroid powder combustion residue immediately after the 15-min. stirring period, and the iodine determination was carried out in the usual manner.

TABLE IV.—THE RECOVERY OF IODINE ADDED TO A THYROID POWDER COMBUSTION RESIDUE

Thyroid (0.548% I), mg.[a]	Iodine, mg.: From Thyroid	Added as KI	Recovered	% Recovery
50.8	0.278	0.200	0.476	99.5
48.7	0.266	0.200	0.466	100.0

[a] This iodine concentration is the average of the 4 determinations listed for sample *4* in Table III.

Table IV demonstrates that the recovery of the added iodine was quantitative, and, therefore, it appears that no combustion product of thyroid affected the titration conditions.

SUMMARY AND CONCLUSIONS

The British Pharmacopoeia method for the determination of iodine in thyroid was modified by the adoption of a 15-min. stirring period for the combustion residue and later addition of sulfamic acid to remove nitrites. With these modifications, the iodine levels obtained in thyroid powder analyses were comparable to those obtained by the U.S.P. procedure.

These measurements were performed on amounts of thyroid containing between 1.5×10^{-6} and 6×10^{-6} Gm. equivalent iodine. Tomlinson (8) has drawn attention to the error in halogen determination at this concentration due to high blank values caused by the wrapping material. It was demonstrated that the wrappers employed here do not give a blank value. He also pointed out that combustion may be incomplete by the very nature of the combustion operation. This was not in evidence in this investigation where sample size was restricted to 100 mg. or less and where the iodine constituted between 0.2 and 1.0% of the total organic substance burned. However, when amounts of MIB containing comparable quantities of iodine were burned with the wrappers only (120 mg.), the iodine could not be quantitatively recovered. The combination in thyroid powders of organic material and iodine in what appears to be fortuitous proportions, makes the oxygen flask method for iodine determination in thyroid most attractive. This procedure can be completed in 30 min. and there is no transfer of solutions.

Synthesis of Certain 5-Nitropyridine Derivatives Structurally Related to Some Chemotherapeutic Agents

By K. M. GHONEIM, M. KHALIFA, and Y. M. ABOU-ZEID

The condensation of 2-chloro-5-nitropyridine with 1-aminohydantoin, sulfaguanidine, and semicarbazide is described. With sulfaguanidine the N^4 derivative was always obtained even under the conditions supposed to afford the N^1 derivative. With semicarbazide the condensation in all cases yielded a disubstitution product even when equimolecular amounts of the reactants were used. With aminohydantoin the condensation was effected in 1 per cent hydrochloric acid while in 10 per cent acid no condensation took place, and the haloheterocycle was hydrolyzed to the corresponding hydroxy compound. On the other hand, attempts to condense the halonitropyridine with 3-amino-2-oxazolidone were unsuccessful.

In recent years, heterocycles with a nitro group in position 5- gained success as antimicrobials, *e.g.*, nitrofurans (1), and as amebicides, *e.g.*, 2-diethanolamino-5-nitropyridine (2, 3). As a consequence the authors decided to synthesize compounds having the 5-nitropyridyl radical together with different side chains in position 2- in the hope that the new products would show superior amebicidal action[1] with lower toxicity. For the synthesis of such compounds 2-chloro-5-nitropyridine was condensed with certain amino derivatives.

2-Chloro-5-nitropyridine was prepared from 2-aminopyridine by a procedure derived from the method of Phillips (4), and that of Caldwell (5). The aminopyridine was first nitrated to the corresponding nitraminopyridine which was then rearranged with concentrated sulfuric acid to 2-amino-5-nitropyridine and its isomer the 3-nitro derivative, with the former predominating. The crude 5-nitro compound was then converted to the hydroxy derivative by treatment with sodium nitrite in presence of dilute sulfuric acid (4, 5). The chloronitropyridine was finally obtained from the hydroxy compound by reacting with phosphorus pentachloride in the presence of a small amount of the oxychloride.

Phillips reported that when sulfanilamide was condensed with 2-chloro-5-nitropyridine according to (*a*) Bobranski's (6) and (*b*) Ullmann's conditions (7), the reaction afforded the N^4 derivative in the former case and a mixture of the N^4 and N^1 derivatives in the latter case. However, when the sulfaguanidine was condensed with 2-chloro-5-nitropyridine adopting the two procedures mentioned above, the authors obtained the same product in both cases. This was shown qualitatively to be the N^4 derivative since it failed to diazotize and this conclusion was confirmed by ultraviolet analysis.[2] The absorption spectrum of the condensation product in methanol shows 2 maxima at 263.5 mμ (log ϵ 4.28), and 368 mμ (log ϵ 4.44). The former band is attributed to absorption of sulfanilamido chromophore ($\lambda_{max.}$ 262 mμ; log ϵ 4.25, in ethanol) (8), while the latter may be ascribed to the absorption of the *N*-substituted 2-amino-5-nitropyridine. The absorption in methanolic 2 *N* hydrochloric acid shows 2 maxima at 266.5 mμ (log ϵ 4.01) and 364 mμ (log ϵ 4.30). The hypsochromic shift and the hypochromic effect are due to salt formation. Such a phenomenon is observed in all aromatic amines (*cf.* the absorption spectra of *p*-nitroaniline in ethanol and in HCl). The absorption spectrum in 1 *N* sodium hydroxide shows 3 bands: 337.5 mμ (log ϵ 4.18), 295 mμ (log ϵ 3.92), and 465 mμ (log ϵ 4.46). The latter band which is indicative of a highly conjugated system may be ascribed to the aci-form I of the N^4 derivative which is expected to be present in the alkaline medium (I).

The strong bathochromic shift observed in alkaline solution indicates that the condensation product is the N^4 derivative and not the N^1, since the latter is expected to be insoluble in alkali and possesses identical spectra both in alkaline and neutral solutions.

Condensation of 2-chloro-5-nitropyridine with 1-aminohydantoin in dry pyridine, according to a method reported by Whitmore *et al.* (9), resulted in decomposition of the aminohydantoin with liberation of ammonia (confirmed qualitatively) which caused ammonolysis of the halonitropyridine yielding 2-amino-5-nitropyridine. The same happened when 1-aminohydantoin was replaced with 3-amino-2-oxazolidone. However, when the condensation of the aminohydantoin and the aminooxazolidone with 2-chloro-5-nitropyridine was conducted in aqueous hydrochloric acid in the presence of ethanol following Banks' directions (10), in 10% acid, the haloheterocycle was hydrolyzed to the corresponding hydroxy compound while with 1% acid the condensation was successful with the former amine and with the latter the starting materials were recovered unaffected. Furthermore, in the case of aminooxazolidone, no success attended Mangini's method (11–13), which consists of heating the reactants under reflux with absolute alcohol in presence of fused sodium acetate.

2-Chloro-5-nitropyridine was condensed with semicarbazide by refluxing together equimolecular quantities of the 2 reactants in the presence of 1% hydrochloric acid and ethanol. From the reaction mixture a high melting substance was isolated. It was obvious from the microanalytical data that 2 molecules of the halonitropyridine had condensed with 1 molecule of semicarbazide. Theoretically, 5 structures are possible for such a condensation product (II).

Structures II*a* and II*b* were excluded by the fact that no ammonia evolved when the condensation

Received October 29, 1965, from the Organic Chemistry Department, Faculty of Pharmacy, Cairo University, Cairo, United Arab Republic.

Accepted for publication December 21, 1965.

The authors express their appreciation to Eaton Laboratories, Norwich, N. Y., for a donation of 1-aminohydantoin and 3-amino-2-oxazolidone and their thanks to Professor Baddar, Faculty of Science, A'In Shams University, Cairo, for his interest in this work.

[1] The products at present are under preliminary screening for possible amebicidal action or any other useful pharmacological activity.

[2] The ultraviolet and infrared spectra were run on Spectracord model 4000 A and Infracord model 137 spectrophotometers, respectively.

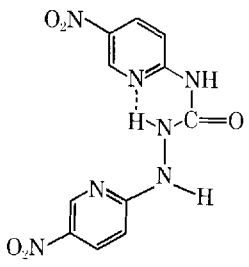
IId = R in 2,4; IIe = R in 1,4; R = O_2N- 
product was heated with sodium hydroxide. Obviously, the reasons which prevented the formation of a compound having the structure IIa and IIb would also prevent the formation of IIc or IId. These reasons are probably steric effects. On the other hand, the infrared analysis[2] favored structure IIe and showed that it did exist in the chelated form (III).



III

The observed frequency of about 2985–3080 cm.$^{-1}$ (broad) may be ascribed to the chelated NH (*Reference 14*, p.195), while the sharp band at 3400 cm.$^{-1}$ may be assigned to the NH stretching frequency of the secondary amide (*Reference 14*, p. 176). Furthermore, the carbonyl stretching frequency of 5-nitro-2-acetylaminopyridine was found to occur at 1700 cm.$^{-1}$. Accordingly, the frequency of 1724 cm.$^{-1}$ may be attributed to the amide I band. Finally, the bands at 1997 and 1550 cm.$^{-1}$ may be assigned to the C=N (*Reference 14*, p. 226) and NO_2 (*Reference 14*, p. 250) stretch vibrations, respectively.

EXPERIMENTAL[3]

5-Nitro-2-acetylaminopyridine.—This compound was prepared from 5-nitro-2-aminopyridine by acetylation with acetic anhydride. The product was crystallized from benzene and it melted at 196° as reported (15).

p - (5 - Nitro - 2 - pyridylamino)benzenesulfonylguanidine.—*Method A.*—A mixture of 2-chloro-5-nitropyridine (3.16 Gm.) and sulfaguanidine (4.64 Gm.) was fused at 130–150° for 20 min. (Bobranski's conditions). The solid cake resulting was then extracted with boiling 2 *N* sodium hydroxide solution. The deep red extract was acidified with dilute hydrochloric acid and buffered by the addition of excess saturated solution of sodium acetate. The product which was obtained in 52% yield (3.3 Gm.) melted at 265–266° after 1 crystallization from ethanol.

Anal.[4]—Calcd. for $C_{12}H_{12}N_6O_4S$: C, 42.85; H, 3.57; N, 25.00; S, 9.52. Found: C, 42.90; H, 3.70; N, 24.30; S, 9.80.

Method B.—The above experiment was repeated but in the presence of anhydrous potassium carbonate (2.7 Gm.) and copper powder (0.2 Gm.) and the fusion conducted at 100–130° for 1 hr. (Ullmann's conditions). The solid cake thus obtained was then extracted with hot water, and the aqueous extract was acidified with 2 *N* acetic acid. The product after being crystallized from ethanol melted at 265–266°, and the melting point was not depressed on admixture with a pure specimen prepared by *Method A*.

5′ - Nitro - 2′ - pyridyl - 1 - aminohydantoin and N^1, N^4-Di(5′-nitro-2′-pyridyl) Semicarbazide.—These were prepared by the following general method.

A mixture of equimolecular amounts of 2-chloro-5-nitropyridine and the amino compound[5] (1-aminohydantoin in the former and semicarbazide in the latter) was refluxed with hydrochloric acid solution (1 ml. concentrated HCl, d 1.19, in 80 ml. of water and 20 ml. of ethanol) for 30–32 hr. The reaction mixture was then concentrated under diminished pressure to about 15–20 ml. when the condensation product separated out. The yield in both cases was 25% and the product was crystallized from ethanol.

The former compound melted at 247–249°.

Anal.—Calcd. for $C_8H_7N_5O_4$: C, 40.50; H, 2.95; N, 29.50. Found: C, 40.68; H, 3.05; N, 29.37.

The latter compound did not melt until 350°.

Anal.—Calcd. for $C_{11}H_9N_7O_5$: C, 41.00; H, 2.80; N, 30.70. Found: C, 41.13; H, 2.89; N, 31.02.

[3] Melting points are uncorrected.

[4] Analyses were performed by Alfred Bernhardt, Germany.

[5] In the case of semicarbazide the 25% yield was obtained when 1 mole was condensed with 2 moles of the haloheterocycle, while with equimolecular amounts poorer yields were obtained.

Synthesis of Methylglyoxal-^{14}C

By VICTOR C. BRUM

Methylglyoxal-1,3-^{14}C and methylglyoxal-2-^{14}C of relatively high specific activity were prepared by the oxidation of acetone with selenium dioxide followed by distillation under a nitrogen atmosphere and concentration under reduced pressure. Analysis of the synthesized compounds by melting point determination and also by paper and gas-liquid chromatography indicated the samples were of high purity.

THE OCCURRENCE of methylglyoxal in the form of an aberrant metabolite in vitamin B_1 deficiency has held the interest of many investigators (1–8) in the field of nutrition and carbohydrate metabolism. Its existence in the aminoacetone cycle (9), its accumulation in dystrophic muscle (10), and its possible role as a carcinostatic agent (11) have resulted in a revived interest in this compound.

In order to study the metabolic pathway and fate of this compound in animals, radioactive methylglyoxal-1,3-^{14}C and methylglyoxal-2-^{14}C were prepared.

Three methods were considered for the preparation of the labeled compound. (*a*) The conversion of acetone to isonitroacetone and warming the latter with dilute sulfuric acid (12). (*b*) The distillation of dihydroxyacetone in a dilute aqueous solution from calcium carbonate or by *in vacuo* distillation from phosphorus pentoxide (13). (*c*) The oxidation of acetone with selenium dioxide followed by distillation under a nitrogen atmosphere and concentration under reduced pressure (14, 15).

Both methylglyoxal-2-^{14}C ($CH_3{}^{14}COCHO$) and methylglyoxal-1,3-^{14}C ($^{14}CH_3CO{}^{14}CHO$) may be obtained by method (*a*) utilizing ^{14}C-labeled acetone as a precursor. The preparation by method (*b*) requires ^{14}C-labeled dihydroxyacetone which can be prepared enzymatically utilizing ^{14}C-labeled glycerol as a precursor. Both methods (*a*) and (*b*) result in the formation of the following contaminants which are difficult to separate from methylglyoxal: glycols, formaldehyde, and formic acid.

These disadvantages do not exist for method (*c*) which was, therefore, selected for the synthesis of methylglyoxal-^{14}C.

Methylglyoxal-1,3-^{14}C was prepared from 0.5 mc. of acetone-1,3-^{14}C with a specific activity of 9.1 mc./mmole.[1] Methylglyoxal-2-^{14}C was prepared from 0.5 mc. of acetone-2-^{14}C with a specific activity of 5.4 mc./mmole.[1]

METHOD

Procedure for Refluxing.—To a 125-ml. conical flask containing 16.0 ml. (0.19 mole) of *p*-dioxane and 1.1 ml. of water was added 3.04 Gm. (0.027 mole) of purified selenium dioxide. The mixture was slowly brought up to 50° and maintained at this temperature while being constantly stirred by a hot plate magnetic stirrer. The selenium dioxide was completely dissolved in 20 min. The solution was cooled to 25° and transferred to a 50-ml. pear-shaped distillation flask. To this solution was added 2.0 ml. of the radioactive acetone and carrier. A water-cooled upright Leibig condenser was attached to the flask and the mixture was allowed to reflux gently for 4 hr. in an oil bath maintained at 100°. At the completion of the reflux period the solution was dark and tarry in appearance.

Procedure for Distillation.—On completion of the refluxing the distillation flask was removed and attached to a distillation assembly. A capillary was introduced into the distillation flask and served as an inlet tube for the admission of nitrogen gas at a pressure slightly above atmospheric. During the entire distillation process nitrogen gas was allowed to slowly bubble in to prevent the oxidation of methylglyoxal. The mixture was distilled over an oil bath by slowly raising the temperature to 130°. Three separate distillate fractions were collected in an ice bath.

Fraction I consisted of 5 ml. of a clear distillate collected at a vapor temperature of 80 to 90°. It was found to contain less than 5% methylglyoxal as determined by the *m*-nitrobenzhydrazide reaction.

Fraction II consisted of 8 ml. of a pale yellow distillate collected at a vapor temperature of 90 to 100° and contained a 15% solution of methylglyoxal in water and dioxane.

Fraction III consisted of 5 ml. of a distillate collected at a vapor temperature of 100 to 105° and contained a mixture of dioxane, water, oily droplets, and an unstable selenium methylglyoxal complex.

By collecting three fractions it was found that the highest yield came over in fraction II at a vapor temperature of 90 to 100°. Fractions I and III which distilled over at lower and higher temperatures, respectively, produced lower yields and indicated that the ideal temperature range for maximum yield was that of fraction II.

Procedure for Concentration.—The distillate fractions were transferred to a 50-ml. pear-shaped flask and attached to a vacuum system containing two 29 × 200 mm. culture tubes connected in series and immersed in Dewar flasks containing liquid nitrogen. These tubes served as traps for the lower boiling solvents.

At the end of 6 hr. of vacuum distillation at 50 mm. of mercury, water and dioxane were removed and 2 ml. of a solution pale yellow in color and syrupy in consistency remained.

Quantitative Determination of Methylglyoxal-^{14}C as the m-Nitrobenzoylosazone Derivative.—The methylglyoxal-1,3-^{14}C and methylglyoxal-2-^{14}C yields and specific activities were determined by diluting 25.0 μl. of the concentrate in 100 ml. of water and then adding 10 ml. of *m*-nitrobenzhydrazide reagent (16). The precipitate formed was quantitatively transferred to preweighed stainless steel planchets, dried to constant weight, and the radioactive samples counted using a proportional flow counter with a laboratory scaler. A 45.6% yield

Received December 13, 1965, from the General Medical Research Laboratory, Veterans Administration Center, Togus, Me.
Accepted for publication January 14, 1966.

[1] Both ^{14}C labeled acetone precursors were obtained from Nuclear-Chicago Corp., Des Plaines, Ill.

of methylglyoxal-1,3-^{14}C with a specific activity of 9.0 mc./mmole and a 16.6% yield of methylglyoxal-2-^{14}C with a specific activity of 5.0 mc./mmole was obtained.

The purity of the radioactive compounds was assayed by melting point determinations, paper, and gas-liquid chromatography.

The melting point of the 2,4-dinitrophenylhydrazine derivatives of the ^{14}C-labeled methylglyoxal determined on a Fisher-Johns apparatus was found to be 297–298°, uncorrected, in agreement with the theoretical value (17).

Analysis by paper chromatography (18, 19) was carried out with the following modifications. To a solution containing 50.0 mcg. of methylglyoxal-^{14}C was added 0.2 ml. of a 2,4-dinitrophenylhydrazine reagent (0.1% in 2 *N* hydrochloride). After the mixture was allowed to stand for 1 hr., 1 ml. of chloroform was added. The hydrazone formed was extracted by vigorous shaking followed by a 5-min. period of centrifugation at 2000 r.p.m. to separate the layers.

A 100.0 μl. aliquot of the chloroform layer was spotted on Whatman No. 1 paper. The ascending technique was employed and the development solvent used was *n*-butanol–ethanol–aqueous 2 *N* ammonium hydroxide (7:1:2, by volume). After 16 hr., the paper was dried at room temperature in a fume hood and sprayed with alcoholic sodium hydroxide solution (2% sodium hydroxide in 90% ethanol).

The colored spots were identified by comparison with the color and R_f values of a known standard run simultaneously.

Two isomers of methylglyoxal were observed: a blue-violet spot with an R_f value of 0.00 and a pinkish-brown spot with an R_f value of 0.90. Values were in agreement with those reported in the literature (19).

The colored spots identified as methylglyoxal were cut from the paper, macerated 3 times with 0.5-ml. aliquots of 1 *N* ammonium hydroxide, and each quantity was centrifuged. The supernatants of the washings were pooled, transferred to a planchet, evaporated to dryness, and counted. All samples prepared in this manner and identified as methylglyoxal-^{14}C were found to be highly radioactive.

The samples of ^{14}C-labeled methylglyoxal and standards were successfully analyzed by gas-liquid chromatography. The purpose of analyzing the radiolabeled methylglyoxal-^{14}C by gas chromatography was to determine its purity and not its radioactivity since the radioactivity of the compound had previously been established by both paper chromatography and as the *m*-nitrobenzoylosazone of methylglyoxal-^{14}C. The instrument used was a Perkin-Elmer gas chromatograph model 801 with a 6 ft. × 0.085 in. i. d.

The stationary phase used was SE 30/EPON 1001 with a gas-chrom P as the support (ratio of 4/0.2%). Helium gas was used as the carrier gas and introduced at a flow rate of 40 ml./min. The instrument utilized a flame detector and the analysis was carried out using hydrogen gas at 18 psig and air at 46 psig. The temperature of the injection block was 280°, detector 220°, and the initial temperature of the column 200°. A Leeds and Northrop model G (5 MV range) was used and the data recorded at a chart speed of 0.5 in./min.

One major peak was recorded with another following 2.0 cm. behind which represented the other isomer. There was no decomposition, little tailing, and the purity of the methylglyoxal-^{14}C appeared satisfactory from a quantitative as well as qualitative point of view.

Separation and Analysis of Degradation Products of Tetracycline by Gel Filtration on Sephadex G-25

By B. W. GRIFFITHS

The anhydrotetracycline and 4-epi-anhydrotetracycline degradation products of tetracycline have been found to separate from tetracycline on a column of Sephadex G-25. The tetracycline elutes as the "fast" component, whereas the degradation products which are not separated from each other elute as the "slow" component. The ease of column preparation, rapidity of analysis, and repetitive use of a single column make the technique a useful screening procedure for gross contamination of tetracycline preparations with anhydro- and 4-epi-anhydrotetracycline degradation products.

In view of recent findings that relate a reversible Fanconi-type syndrome to the ingestion of degraded tetracycline capsules (1–5), interest has developed in the analytical determination of products of degradation of tetracycline (TC). Particular interest has centered on the 4-epi-anhydrotetracycline derivative, since a similar syndrome to the above was induced in rats and dogs on the ingestion of large doses of this compound (6).

A column chromatographic method has been developed by Kelly (7) for the determination of both anhydrotetracycline (ATC) and 4-epi-anhydrotetracycline (EATC) in the presence of large quantities of TC. In the author's experience the method was found workable and reproducible but had the disadvantage of tedious column preparation and the limitation of a single analysis per column.

During a search for an alternative method, it was found that a partially degraded TC compound separated into 2 colored components on a column of Sephadex G-25. The "fast" component was found to have the U.V. characteristics of TC while the "slow" one had those of ATC or EATC. The potential of this observation for use in analysis was studied and a test was developed for the gross analysis of ATC and EATC in pharmaceutical preparations of TC. Although the method is not expected to be a substitute for one providing a separate analysis for ATC and the epimer, the features of ease of column preparation, rapidity of analysis, and repetitive use of the same column make it a technique highly useful for the routine screening of TC preparations for gross ATC and EATC content.

EXPERIMENTAL

Reagents and Materials

Compounds of Tetracycline and Derivatives.—Commercial tetracycline HCl (TC) of a high degree of purity by microbiological assay was used. Anhydrotetracycline (ATC) and 4-epi-anhydrotetracycline (EATC) were obtained from Lederle Laboratories.

Sephadex Columns.—*Acid Column.*—A pledget of glass wool was placed in the outlet of a glass column (1.8 × 35 cm.) over which were placed small glass beads to a depth of 1 cm. The Sephadex G-25 (medium) previously swollen in 0.03 *N* HCl was applied as a slurry to the closed column. At this normality the epimerization rate of tetracycline is small and acid-catalyzed dehydration to anhydrotetracycline does not occur (8). After about 5 min. the outlet was opened and more slurry added until a bed length of 23 cm. was attained. Flow rates of 180–200 ml./hr. were obtained. An overhead volume of about 400 ml. provided continuous delivery of solvent. Fractions were collected usually in 5-ml. portions with the aid of an LKB Radi-Rac fraction collector.

Alkaline Column.—The Sephadex was equilibrated with 0.04 *M* phosphate buffer, pH 7.7–7.8. The column preparation followed the above outline with the exception that the length of the bed was 30.5 cm.

Method for Tetracyline Oral Preparations

The powdered tablet or capsule material is accurately weighed and dissolved in 0.03 *N* HCl to give 20 mg. of TC/ml. The insoluble residue is centrifuged and 0.5 ml. of the supernatant is applied to the acid column and washed in gently with the HCl solvent. The TC passes rapidly through the column while the ATC and EATC elute as a slower single component which is visible as a diffuse, bright yellow band. This band, which is eluted after approximately 115 ml. of solvent has passed over the column, is detected by U.V. analysis at 273 mμ. The routine collection of samples is implemented at a slightly earlier stage in the elution, and the occasional check of samples at 273 mμ indicates the complete elution of the band. The contents of the tubes are transferred to a volumetric flask (100 or 250-ml.) and corrected to volume with the dilute HCl. The absorption is read at 273 mμ, and the content of degradation product is expressed as ATC. The absorptivity (defined as absorbance/mcg. ATC/ml., 1-cm. light path) of ATC at wavelength maximum of 273 mμ was found to be 1.01×10^{-1}. The ATC obeyed Beer's law over the range of 1.0–10 mcg./ml.

The oral suspensions and syrups are diluted with a volume of solvent to give an estimated tetracycline concentration of 10 mg./ml. A volume of 0.5 ml. of the solution (centrifugation is necessary for clarification of the suspension) is transferred to the column and eluted with either the acid or phosphate buffer solvent. When the analysis is carried out with the latter solvent the absorption of the pooled tube contents from the second U.V. peak is read at wavelength maximum of 269.5 mμ. The ATC absorptivity at this wavelength was found to be 8.2×10^{-2}. The absorptivities for EATC at the wavelength maxima of 273 and 269.5 mμ were slightly lower than those for ATC 9.6×10^{-2} and 7.1×10^{-2}, respectively.

RESULTS AND DISCUSSION

In an initial experiment it was observed that a partly degraded commercial tetracycline preparation separated into 2 colored components on Sephadex

Received November 12, 1965, from the Biologics Control Laboratory, Laboratory of Hygiene, Department of National Health and Welfare, Ottawa, Ontario, Canada.
Accepted for publication December 22, 1965.
The technical assistance of Mr. D. Roy is appreciated.

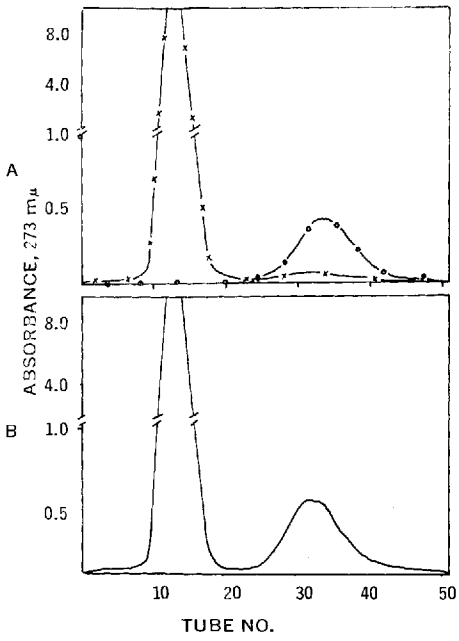

Fig. 1.—*A*. The elution diagram of tetracycline HCl and anhydrotetracycline on Sephadex G-25. Key: ×, tetracycline HCl, applied 1.0 ml. of 5 mg./ml.; O, anhydrotetracycline, applied 1.0 ml. of 200 mcg./ml. Sephadex column, 1.8 × 23 cm. Elution solvent, 0.03 *N* HCl. *B*. The elution diagram of 5 mg./ml. tetracycline HCl containing 200 mcg./ml. anhydrotetracycline: 1.0 ml. solution added to column; solvent and column conditions as above; collected 5-ml. samples.

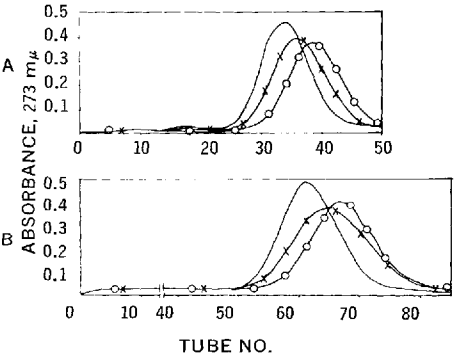

Fig. 2.—Key: ——, the elution diagrams of anhydrotetracycline; O, 4-epi-anhydrotetracycline; ×, an equal mixture of the 2 compounds. All samples were added in 1.0-ml. vol.; ATC = 200 mcg., EATC + ATC = 100 mcg. each and, EATC = 200 mcg., the elution solvent was 0.03 *N* HCl; the Sephadex column in *A* was 1.8 × 23 cm.; the Sephadex column in *B* was 1.8 × 45 cm.; collected 5-ml. samples.

G-25. The first elution band had the U.V. characteristics of tetracycline while the second had those of anhydrotetracycline and/or 4-epi-anhydrotetracycline.

Confirmation of this observation was made by the application of pure products of TC, ATC, and EATC to Sephadex G-25 (Figs. 1 and 2). In Fig. 1, *A*, TC and ATC, when applied separately to the same acid column, were found to elute as 2 distant peaks. It may be seen that the TC contained a small percentage of ATC as evidenced by the significant absorption in the region of the ATC elution. The TC showed full recovery of biological activity by microbiological plate assay. Figure 1, *B*, shows the identical elution pattern for a mixture of TC and ATC.

Figure 2, *A*, outlines the elution diagrams of ATC, EATC, and an equal mixture of the latter from the same acid column of Sephadex. It is of interest that the ATC and EATC exhibited slightly different elution rates when they were applied separately to the column, whereas an admixture eluted as a single band with an elution rate which was an apparent mean of that for the separate components. Figure 2, *B*, shows a similar effect on a longer column of Sephadex.

The time required for the elution of the TC degradation products from either the acid or alkaline columns was about 1 hr., and continuous sampling allowed for the analysis of several TC preparations in 1 day on a single column. In 2 experiments in which 200 mcg. of ATC was applied to a column, the recoveries were 92.5 and 97%. The recovery of EATC under the same conditions was 97.1%. No significant changes in the absorptivities were found for ATC and EATC in either 0.03 *N* HCl or 0.04 *M* phosphate buffer for periods of up to 4 hr.

During the analysis of certain syrups of TC containing amaranth dye on acid columns, it was found that the dye contaminated the ATC band to produce false high results. An examination of several solvents of varied pH revealed that the amaranth was retarded at pH 7.7 so as to completely separate from the "faster" ATC band. The slight overlap of the

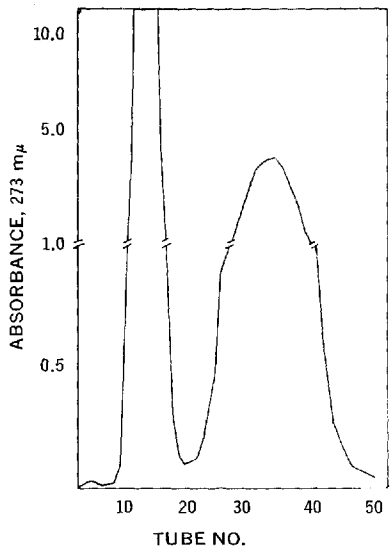

Fig. 3.—The gel filtration of tetracycline syrup on Sephadex G-25. Sephadex column, 1.8 × 23 cm.; elution solvent, 0.03 *N* HCl; 0.5 ml. of syrup (25 mg./ml. tetracycline HCl) added to column; collected 5-ml. samples.

TC band with the ATC band under these conditions required that the column be lengthened for their adequate separation.

Although the main effect of Sephadex is to separate molecules with respect to size, some secondary effects have been noted. Porath (9) and Gelotte (10) have found that heterocyclic and aromatic compounds interact with the Sephadex bed material which results in their delayed elution. The differences in elution rates between TC and ATC (as well as ATC and EATC) are presumed to be due to a similar adsorption phenomenon.

Of a group of about 50 tetracycline preparations analyzed on Sephadex, only about 7 of these contained degradation products in excess of 1% of the labeled amount of tetracycline. This figure of 1% represents the arbitrary amount (tentative) above which the samples were analyzed for both ATC and EATC by the partition chromatography method (7). Figure 3 shows the elution diagram of a tetracycline syrup containing an unusually high quantity of degradation products. The amount expressed as ATC was found to be 4.35 mg./ml. of syrup. The analysis of the same product by the partition chromatography method gave a gross value of 4.10 mg./ml. syrup, most of which was in the form of EATC. In general, the analysis of the TC degradation products by Sephadex analysis has been in close agreement with that by partition chromatography when appreciable quantities were present.

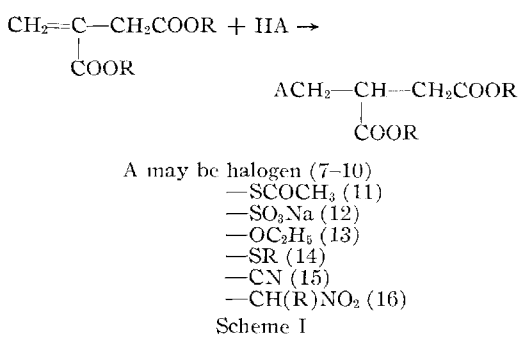
Synthesis of 1,2-Diethyl-4-(2-hydroxyethyl)pyrazolidine

By MILTON J. KORNET

The reaction of 1,2-diethylhydrazine with monomethyl itaconate has been investigated and found to give a mixture of 1,2-diethyl-4-carbomethoxymethyl-3-pyrazolidinone and its hydrolysis product, the corresponding acid. Reduction of either the ester or the acid affords 1,2-diethyl-4-(2-hydroxyethyl)pyrazolidine.

THE AUTHOR'S interest in compounds which contain both an alcoholic hydroxyl group and an alkylated hydrazine group as necessary intermediates in the synthesis of new medicinals prompted the preparation of the title compound. Recently the synthesis of 1,2-diethyl-3-hydroxymethylpyrazolidine, a molecule which embodies the above structural features, was accomplished. Esterification of the latter alcohol with several aromatic acids afforded esters whose hydrochloride salts exhibited local anesthetic activity (1). As the first step in the synthesis of 1,2-diethyl-4-(2-hydroxyethyl)pyrazolidine, it was decided to investigate the reaction of 1,2-diethylhydrazine with an itaconic acid derivative.

A large number of reagents have been added to itaconic acid and its esters (2–16). Unsymmetrical reagents add contrary to Markovnikoff's rule and the addition may be represented by Scheme I.



Scheme I

Itaconic acid reacts with primary amines to give 1-substituted-4-carboxy-2-pyrrolidinones (17). The latter are formed by the addition of the amine to the β-carbon of the double bond followed by ring closure to the 5-membered ring with the elimination of a molecule of water.

In the reaction of 1,2-diethylhydrazine, with an itaconic acid derivative, ring closure to either a 5- or 6-membered ring is possible. Because of this possibility monomethyl itaconate was utilized. Separation of products could be more easily achieved since a mixture would consist of a 5-membered ring methyl ester and a 6-membered ring carboxylic acid. Treatment of 1,2-diethylhydrazine (I) with monomethyl itaconate (II) afforded a mixture of 43.9% of 1,2-diethyl-4-carbomethoxymethyl-3-pyrazolidinone (IV) and 44.6% of its hydrolysis product, 1,2-diethyl-4-carboxymethyl-3-pyrazolidinone (IV*a*). Both compounds gave crystalline picrate derivatives. Compound IV can be visualized as arising from an addition of I to the β-carbon of the double bond of II followed by ring closure *via* the carboxyl group with the elimination of water. The acid (IV*a*) undoubtedly arises from the hydrolysis of IV during the course of the reaction. Elemental analyses and infrared spectra are in agreement with the proposed structures for IV and IV*a*. That the isomeric acid, (III) which would arise from the addition of I to the β-carbon of the double bond of II followed by ring closure *via* the ester carbonyl with simultaneous

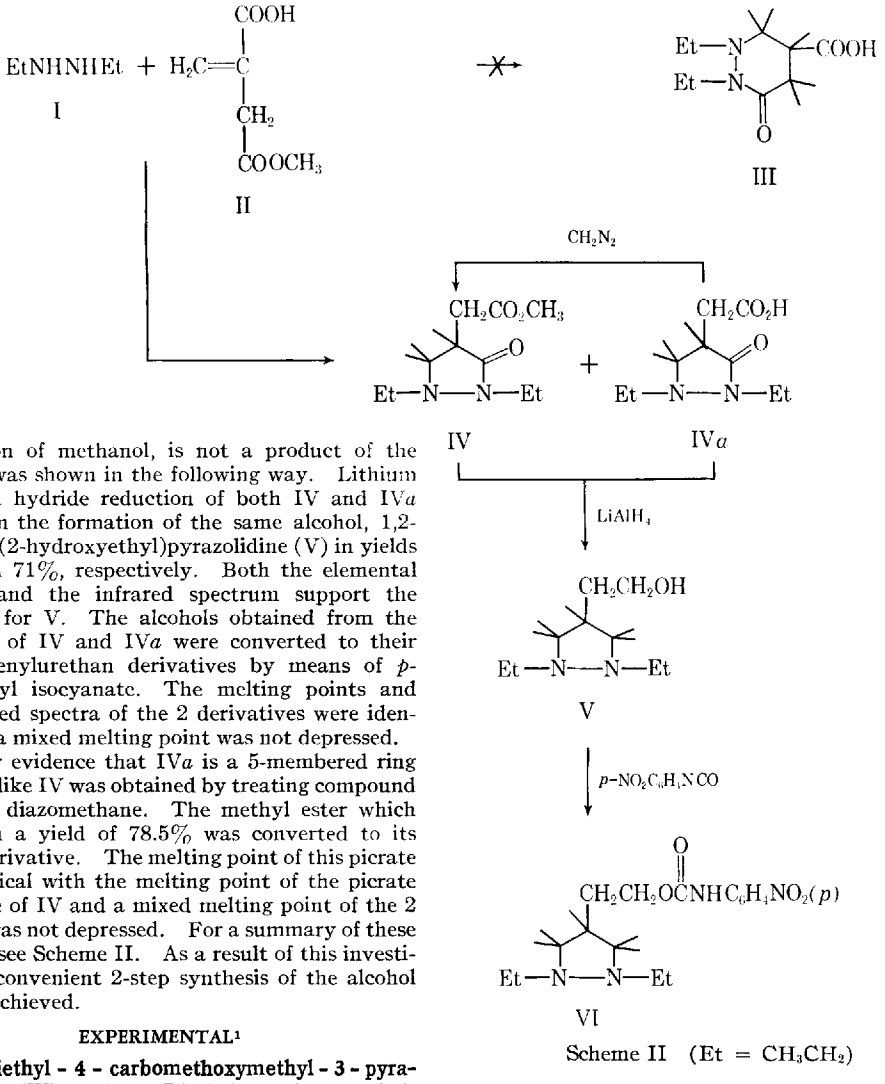

Scheme II (Et = CH_3CH_2)

elimination of methanol, is not a product of the reaction was shown in the following way. Lithium aluminum hydride reduction of both IV and IV*a* resulted in the formation of the same alcohol, 1,2-diethyl-4-(2-hydroxyethyl)pyrazolidine (V) in yields of 70 and 71%, respectively. Both the elemental analysis and the infrared spectrum support the structure for V. The alcohols obtained from the reduction of IV and IV*a* were converted to their *p*-nitrophenylurethan derivatives by means of *p*-nitrophenyl isocyanate. The melting points and the infrared spectra of the 2 derivatives were identical and a mixed melting point was not depressed.

Further evidence that IV*a* is a 5-membered ring structure like IV was obtained by treating compound IV*a* with diazomethane. The methyl ester which formed in a yield of 78.5% was converted to its picrate derivative. The melting point of this picrate was identical with the melting point of the picrate derivative of IV and a mixed melting point of the 2 picrates was not depressed. For a summary of these reactions see Scheme II. As a result of this investigation a convenient 2-step synthesis of the alcohol (V) was achieved.

EXPERIMENTAL[1]

1,2 - Diethyl - 4 - carbomethoxymethyl - 3 - pyrazolidinone (IV) and 1,2-Diethyl-4-carboxymethyl-3-pyrazolidinone (IVa).—To a solution of 9.25 Gm. (0.105 mole) of 1,2-diethylhydrazine (I) (18) in 5 ml. of anhydrous methanol was added dropwise a solution of 14.4 Gm. (0.100 mole) of monomethyl itaconate (II) in 13 ml. of absolute methanol with stirring (magnetic) and ice-bath cooling. The reaction mixture was allowed to stir and come to room temperature overnight and then refluxed for 4.5 hr. The methanol was distilled *in vacuo* on a water bath and the residue was distilled under reduced pressure and gave 9.39 Gm. (43.9%) of the ester (IV), b.p. 90° (0.1 mm.), n_D^{20} 1.4724, $\lambda_{max.}^{CHCl_3}$ 5.8 μ (ester C=O), 6.0 μ (amide C=O), and 8.93 Gm. (44.6%) of the corresponding acid (IV*a*), b.p. 169° (0.18 mm.), n_D^{20} 1.4943, $\lambda_{max.}^{CHCl_3}$ 5.8–6.2 μ (carbonyl of acid and amide), 2.8–4.2 μ (associated OH of acid).

Anal.—Calcd. for $C_{10}H_{18}N_2O_3$ (ester): C, 56.05; H, 8.46; N, 13.08. Found: C, 55.74; H, 8.52; N, 12.90.

Anal.—Calcd. for $C_9H_{16}N_2O_3$ (acid): C, 53.98; H, 8.05; N, 13.99. Found: C, 53.59; H, 8.32; N, 13.90.

The ester was converted into its picrate derivative and recrystallized from absolute ethanol, m.p. 119–120.5°.

Anal.—Calcd. for $C_{16}H_{21}N_5O_{10}$: C, 43.34; H, 4.77; N, 15.80. Found: C, 43.47; H, 4.99; N, 15.91.

The acid was converted into its picrate derivative and recrystallized from absolute ethanol, m.p. 131–132°.

Anal.—Calcd. for $C_{15}H_{19}N_5O_{10}$: C, 41.96; H, 4.46; N, 16.31. Found: C, 41.73; H, 4.86; N, 16.24.

1,2-Diethyl-4-(2-hydroxyethyl)pyrazolidine (V) by Reduction of the Ester (IV).—A solution of 7.57 Gm. (0.0354 mole) of IV in 10 ml. of anhydrous ether was added dropwise to a suspension of 1.97 Gm. (0.052 mole) of lithium aluminum hydride in

[1] Melting points were determined with the Fisher-Johns melting point apparatus and are corrected. Infrared spectra were recorded on a Beckman IR 8 spectrophotometer using sodium chloride optics. Microanalyses were performed by Dr. Kurt Eder, Geneva, Switzerland.

30 ml. of ether with stirring (magnetic). After refluxing overnight the complex was decomposed with 40% KOH, and the salts were extracted with ether. The combined ether layers were dried over $MgSO_4$, and the ether was distilled on a water bath. The residue remaining was distilled and gave 4.28 Gm. (70.3%) of a colorless oil, b.p. 86° (0.33 mm.), n_D^{20} 1.4763, $\lambda_{max.}^{CHCl_3}$ 2.8–3.3 μ (OH).

Anal.—Calcd. for $C_9H_{20}N_2O$: C, 62.75; H, 11.70; N, 16.26. Found: C, 62.75; H, 11.73; N, 16.21.

A *p*-nitrophenylurethan derivative (19) was prepared and recrystallized from carbon tetrachloride, m.p. 115.5–116.5°, $\lambda_{max.}^{KBr}$ 2.94 μ (NH), 5.76 μ (C=O).

Anal.—Calcd. for $C_{16}H_{24}N_4O_4$: C, 57.13; H, 7.19; N, 16.66. Found: C, 57.20; H, 7.00; N, 16.76.

1,2 - Diethyl - 4 - (2 - hydroxyethyl)pyrazolidine (V) by Reduction of the Acid (IVa).—The procedure for the reduction of the acid (IV*a*) was analogous to that used for reduction of the ester (IV). The alcohol (V), b.p. 80° (0.22 mm.), n_D^{20} 1.4780, was obtained in 71.5% yield. It was converted to its *p*-nitrophenylurethan derivative and recrystallized from carbon tetrachloride, m.p. 115.5–116.5°. The identity of this derivative was confirmed by a mixed melting point and comparison of infrared spectra.

Methylation of 1,2-Diethyl-4-carboxymethyl-3-pyrazolidinone.—To a solution of 7.90 Gm. (0.0395 mole) of IV*a* in 25 ml. of ether was added sufficient ethereal diazomethane to give a yellow color which persisted. The solution was dried with $MgSO_4$ and the ether was evaporated on a steam bath. The remaining residue was distilled, b.p. 90° (0.1 mm.), n_D^{20} 1.4728, to give 6.64 Gm. (78.5%) of the ester. A picrate was prepared and recrystallized from absolute ethanol, m.p. 119–120.5°. The identity of this picrate was confirmed by a mixed melting point.

Books

REVIEWS

Dictionary of Organic Compounds. Fourth revised edition in five volumes, and *First Supplement, 1965.* Oxford University Press, New York, N. Y., 1965. xxx + 3282 pp. 20 × 26.5 cm. Price $280.00.

The Fourth Edition of the "Dictionary of Organic Compounds" has undergone extensive revision from the preceding 3rd edition published in November 1953. The entries, which total 12,000 and represent 7,000 new compounds, are contained in five volumes instead of four.

A major change is the general policy of adopting chemical synonyms as principal entries with appropriate cross-references to popular or trivial names used predominantly in previous editions of the "Dictionary." A second important change is the inclusion of three double bonds for benzenoid rings in place of the simple hexagon to denote aromatic compounds. The implications of this revision are twofold. First, the aromatic compounds are more easily distinguished at first glance, and second a simplification of the structural formulas of saturated ring compounds has been made possible. The latter are now represented by a simple polygon and the compact structure saves considerable space alloted to the structural formula.

Improvements in the "Dictionary" are noted by the inclusion of stereochemical relationships in molecules and substantially more supplemental information for many compounds (*i.e.*, recrystallizing solvents, specific reactions, derivatives with melting points). The numbering systems for structural formulas including rings have been made to conform to the internationally accepted rules laid down by the I.U.P.A.C. A supplement to the present edition exists and further supplements are to be added annually to cover revision of existing entries and inclusion of new entries from the chemical literature.

The "Dictionary" can be improved in two respects. First by adopting the arrangement of symbols in organic formulas in strict alphabetical order following carbon and hydrogen if also present. This system typified by *Chemical Abstracts* has gained wide acceptance and allows ready comparison of formulas from multiple sources. A second area of concern pertains to the melting points included for many principal entries and certain important derivatives which are used as drugs. These melting ranges carried over from each previous

30 ml. of ether with stirring (magnetic). After refluxing overnight the complex was decomposed with 40% KOH, and the salts were extracted with ether. The combined ether layers were dried over $MgSO_4$, and the ether was distilled on a water bath. The residue remaining was distilled and gave 4.28 Gm. The Fourth Edition of the "Dictionary of Organic Compounds" has undergone extensive revision from the preceding 3rd edition published in November 1953. The entries, which total 12,000 and represent 7,000 new compounds, are contained in five volumes instead of four.

A major change is the general policy of adopting chemical synonyms as principal entries with appropriate cross-references to popular or trivial names used predominantly in previous editions of the "Dictionary." A second important change is the inclusion of three double bonds for benzenoid rings in place of the simple hexagon to denote aromatic compounds. The implications of this revision are twofold. First, the aromatic compounds are more easily distinguished at first glance, and second a simplification of the structural formulas of saturated ring compounds has been made possible. The latter are now represented by a simple polygon and the compact structure saves considerable space alloted to the structural formula.

Improvements in the "Dictionary" are noted by the inclusion of stereochemical relationships in molecules and substantially more supplemental information for many compounds (*i.e.*, recrystallizing solvents, specific reactions, derivatives with melting points). The numbering systems for structural formulas including rings have been made to conform to the internationally accepted rules laid down by the I.U.P.A.C. A supplement to the present edition exists and further supplements are to be added annually to cover revision of existing entries and inclusion of new entries from the chemical literature.

The "Dictionary" can be improved in two respects. First by adopting the arrangement of symbols in organic formulas in strict alphabetical order following carbon and hydrogen if also present. This system typified by *Chemical Abstracts* has gained wide acceptance and allows ready comparison of formulas from multiple sources. A second area of concern pertains to the melting points included for many principal entries and certain important derivatives which are used as drugs. These melting ranges carried over from each previous

edition do not coincide with current literature values. Admittedly, it would constitute a major undertaking to research and revise the melting points of the principal entries, but such effort would be cognizant of the high quality of standards associated with this "Dictionary."

The Uniqueness of Biological Materials. By A. E. NEEDHAM. Pergamon Press, Inc., 122 East 55th Street, New York, N. Y. 10022, 1965. xi + 593 pp. 16 × 23 cm. Price $15.00.

"Is the uniqueness of life inherent in the material of living organisms?" By posing this question the author states one of the reasons for writing the book. The other reason is a practical one. It was prompted by the need to persuade students that the study of the properties of biological materials such as lipids, carbohydrates, proteins, nucleic acids, and other cell components is not only essential but also very interesting.

The evidence as surveyed in the various chapters of the book seems to show rather consistently that the compounds used by living organisms are outstanding if not absolutely unique among the materials available on earth. It is further pointed out that these substances are unique in respects which make them ideal for some particular biological function.

All of the relevant elements and compounds are surveyed systematically. The author concentrates on the significance and interpretation of the properties studied rather than on the properties themselves. Biological rather than any other applications of the properties are stressed. Illustrations by use of figures, tables, and formulas are numerous.

The coverage of the subject matter is comprehensive; the bibliography, while not too extensive, is up-to-date and ample.

The concluding chapter entitled, "The Origin and Evolution of Biological Uniqueness," is very stimulating.

The book is very valuable to not only students of biochemistry, biology, and zoology, but also to students of chemistry. Students of pharmacy will find the text very informative and interesting.

The Structure of Lipids by Spectroscopic and X-Ray Techniques. By D. CHAPMAN. John Wiley & Sons, Inc., New York, N. Y., 1965. xii + 323 pp. 16 × 24 cm. Price $10.50.

In the past ten to fifteen years there has been a considerable increase in research in the field of lipids. This intensified interest in this class of compounds has stemmed largely from the growing interest in the causes of lipid diseases such as atherosclerosis.

In this book the author has described a number of modern physicochemical experimental methods that have been used extensively in recent years to study lipid molecules in the solid and liquid states. In each instance a great deal of data are presented and their relationships to intra- and intermolecular structure and interactions are discussed. More than one-half of the book is devoted to X-ray diffraction and infrared spectroscopic studies with particular emphasis on crystal polymorphism. Separation techniques, ultraviolet, nuclear magnetic resonance, electron spin resonance, and mass spectroscopy and their application to lipids are discussed in the remainder of the book. It is shown that the combined applications of these techniques, particularly X-ray, infrared, and NMR, have unraveled a number of difficult problems such as the existence of the multiple melting points of triglycerides and their relationship to X-ray data.

The author has chosen to organize the subject matter from the standpoint of experimental techniques rather than from that of lipid chemistry. As a result, the book is somewhat difficult to read; but, on the other hand, this arrangement has permitted the presentation of a large amount of data.

It is the reviewer's opinion that the book is an outstanding contribution to the field and very useful for researchers in the field.

Review Article

The Adrenergic Receptor

By RAYMOND P. AHLQUIST

At this moment in time it is appropriate to review briefly the status of the adrenergic receptor.

The nomenclature of α and β receptors introduced by this laboratory in 1948 (1) is now used internationally (27, 37, 48, 70, 77, 105).

A new class of drugs having potential therapeutic value, the β adrenergic blocking agents, has appeared (23, 24, 26, 44, 70, 77, 115, 117, 118, 125).

In the study of receptors the biological approach based on observations of tissue and organ response is yielding to a biochemical approach based on studies of binding, membranes, and enzyme kinetics. Therefore, this review will attempt only to summarize the biological studies of the adrenergic receptor. Some biochemical views will be found in papers by Ariens (12, 13), Belleau (19), Burn (34), Furchgott (64–67), Volle (139), and Bloom (26).

For purposes of this review the adrenergic receptor is defined as the specific molecular site or structure in or on effector cells with which molecules of adrenergic agonists (epinephrine, etc.) react in order to elicit the characteristic response of the cell (67). There is some tendency to call any and all sites of uptake or binding receptors (85). However, the receptor is usually considered to be the site of drug-effector interaction that produces an observable response.

Received from the Medical College of Georgia, Augusta. Studies from the author's laboratory cited in the review were supported by grant HE-03514 from the National Institutes of Health, U. S. Public Health Service, Bethesda, Md.

It is the opinion of this reviewer that the adrenergic receptor is the most important link in the adrenergic neuroeffector transmission chain. Effector cells without adrenergic receptors, the ciliary muscle of the eye, for example, cannot respond to adrenergic agonists. This is true whether the agonist is administered by a pharmacologist, a nerve end, or the adrenal medulla. Although this is obviously circular reasoning (the response depends on a receptor and the receptor is defined by the response) it is, however, the way in which all receptors have originated. Regardless of the exact chemical structure of the adrenergic transmitter the effector response is controlled by the receptor and by the natural function of the effector cell.

There are others, however, that do not place much importance on the receptor. For example, Euler puts most emphasis on structure, synthesis, storage release, and uptake of the transmitter (60).

There are two classic ways to characterize biologically the adrenergic receptors; Sir Henry Dale pioneered both methods. One is to compare responses to structurally different but chemically related agonists (16). The other is to compare responses to specific receptor blocking agents (47). This review will consider both views of the adrenergic receptor.

As previously pointed out by this reviewer (4), experimental design, deliberate or unconscious, favors results that best support the experimenter's currently held notions. Reviewers, including the

present one, are not immune to this phenomenon. Therefore, comparative potencies assigned to various agonists are not necessarily the same as those assigned by the authors of the quoted papers. In some cases the authors made no estimates of comparative potency although their published results give sufficient information to allow these estimates to be made. In other cases, older papers have been reinterpreted in the light of newer ideas.

HISTORICAL VIEW

Ehrlich proposed the basic ideas of receptor theory (52). He considered chemicals as having two functional parts: a selective group that governs distribution in the body, tissues, and cells, and a pharmacophore group that evokes the specific effect produced by the chemical. In modern terms, affinity and intrinsic activity (13) could be substituted for Ehrlich's terms.

Dale was the first to make significant use of the receptor concept in connection with the sympathetic nervous system (47). He recognized that the sympathetic neuromyal junction could be viewed as "the receptive mechanism for adrenaline," and he used this concept to explain the differential blocking effect of the ergot alkaloids.

Initiated by the work and ideas of Cannon (38), theories of differential activity based on the chemical structure of the transmitter started to develop. Cannon's sympathins E and I were followed by sympathins A (from adrenal) and N (from adrenergic nerves) (14, 58, 59); sympathin A was thought to be epinephrine and N norepinephrine.

In the course of a search for a compound to prevent the myometrial stimulation induced by vasopressin some unexpected (to this experimenter) observations were made. These were: phenylephrine, a potent vasoconstrictor, *relaxed* the smooth muscle of the gut while a methyl derivative of epinephrine, a potent depressor agent, did not as readily relax the gut; isoproterenol in high dosage *contracted* rabbit uterus; and arterenol was *less* potent than epinephrine as a vasoconstrictor. These findings suggested a more thorough comparison of closely related catecholamines. The relative potencies of five amines, including epinephrine, were studied on a variety of effectors. The conclusions drawn from the results were as follows (1, 4, 5, 7).

1. There are two distinct types of adrenotropic (adrenergic) receptors as determined by their relative responsiveness to closely related sympathomimetic amines.

(*a*) The α receptor is associated with most of the excitatory functions (vasoconstriction, and contraction of the smooth muscle of the uterus, nictitating membrane, ureter, and pupillary dilator) and one important inhibitory function (intestinal relaxation).

(*b*) The β receptor is associated with most of the inhibitory functions (vasodilation, and inhibition of the uterine and bronchial smooth muscle) and one excitatory function (myocardial stimulation).

2. Epinephrine is the one amine that is most active on both α and β receptors; the adrenergic receptor seems to be designed to fit best with the molecular shape of epinephrine (5).

Two of the catecholamines used in this study, the l-methyl derivatives of arterenol and epinephrine, were dropped from the experimental procedures because of questionable purity and optical activity. Furthermore, the *levo*-rotatory isomer of arterenol (levarterenol) became commonly available. Therefore, for testing adrenergic receptors by the comparative potency method only epinephrine,[1] levarterenol,[1] and isoproterenol[1] are usually considered.

Two other adrenergic receptor theories have been proposed. Lands (86), on the basis of responses to a large variety of sympathomimetic amines, suggested receptors A c (excitatory), A r (inhibitory), and A cr (undifferentiated). The undifferentiated receptor was to be found in the heart and presumably the intestine, and responded equally to almost all sympathomimetic amines. Furchgott (65) added two receptors. The γ receptor for glycogenolysis and the δ receptor for intestinal inhibition. As will be described below the receptor blocking agents seem to have clarified partly the cardiac and intestinal receptor. However, catecholamine metabolic effects, including glycogenolysis, may require a different receptive mechanism.

ALPHA ADRENERGIC RECEPTORS

The α receptor is characterized by being most responsive to epinephrine and least responsive to isoproterenol. In terms of comparative potency the order of activity is, epinephrine is more potent than levarterenol which is more potent than isoproterenol.

Eye.—There is no doubt that epinephrine is the most potent catecholamine on the adrenergically controlled smooth muscle of the eye. This is true whether the racemic or *levo* forms of epinephrine and norepinephrine are com-

[1] In discussing comparative potencies of the catecholamines it should be understood that epinephrine and levarterenol are *levo* rotatory compounds and that isoproterenol is a racemic mixture. These are the forms compared unless otherwise specified. In some of the older studies, prior to 1948, racemic epinephrine was compared to racemic norepinephrine (arterenol). In some more recent studies *levo* isoproterenol has been used.

pared. This is shown by mydriasis produced by intra-arterial injection in the intact cat (1, 58, 78), by intraocular injection in the dog or rabbit (21), or in the isolated eye of the rat (18).

The smooth muscle controlling the nictitating membrane, usually studied in the cat, has long been used to show the difference in potency between epinephrine and levarterenol (1, 33, 134, 142). On the isolated membrane of the cat, epinephrine is five times more potent than levarterenol (133). The chronically denervated or cocaine pretreated nictitating membrane becomes supersensitive to both epinephrine and levarterenol (33, 134). The increase in sensitivity to the latter exceeds that to the former so that the potency difference between these amines becomes smaller. However, epinephrine remains the more potent.

The smooth muscle of the orbit of the eye seems to be more sensitive to epinephrine than to levarterenol (personal observation). However, a quantitative study has apparently been done only in the rat; epinephrine was found to be about twice as potent as levarterenol (68).

What is the effect of isoproterenol on the iris dilator and the nictitating membrane? On intraocular administration, this amine produces mydriasis by causing contraction of the radial muscle (62); this is an α receptor response as shown below by tests with specific blocking agents. A similar result is obtained in the isolated eye of the rat (18). In the intact eye of the cat mydriasis is obtained only with very large doses of isoproterenol (1). On the isolated nictitating membrane of the cat isoproterenol in a concentration of 1 mcg./ml. produces relaxation if the muscle is in spasm (123); a concentration of 10 mcg./ml. produces only contraction (133). In summary, isoproterenol activates the α receptors associated with the eye, and its potency is a tenth to a hundredth that of epinephrine, depending on the test method used to compare the drugs.

Spleen.—The smooth muscle of this organ is contracted by the catecholamines. Epinephrine is more potent than levarterenol. This has been determined using measurements of whole spleen size in anesthetized dogs (9, 41), contraction of isolated strips of cat spleen (22), and by hematocrit increases in sheep (135). Isoproterenol in relatively high dosage also produces splenic contraction in the dog or cat (22, 102).

Seminal Vesicles.—When tested on isolated preparations from the rat, epinephrine is more potent than levarterenol in causing contraction (42, 126).

Retractor Penis.—The smooth muscle of this canine structure *in situ* is contracted by catecholamines. Epinephrine is more potent than levarterenol (91, 95). Occasionally, high doses of isoproterenol will produce contraction.

Myometrium.—It has long been known that the myometrial response to epinephrine varies from species to species and depends on the hormonal status at the time of experiment (72). Rabbit or dog uterus, *in situ* or isolated, contracts in response to epinephrine or levarterenol; the former is the more potent (1, 3, 58, 142). Results similar to those obtained in the rabbit have recently been found in the sloth (*Choloepus hoffman* Peters) (114). Isoproterenol produces both relaxation and contraction, the latter occurring only with high concentrations (1). The uterus of the pregnant cat also responds to epinephrine and levarterenol with contraction, but the latter is now the more potent (142). This is due to the fact that the inhibitory receptor is dominant over the excitatory receptor. The dominance between receptors varies from the rabbit, in which the excitatory is predominant, to the rat, in which the inhibitory is dominant. In the human female both receptors are apparently present since epinephrine can produce either relaxation or contraction depending on dosage, and levarterenol produces contraction (43, 81, 116, 145).

Arterial Pressure (Pressor Response).—The acute transient rise in mean arterial pressure in the anesthetized animal is the classic hallmark of sympathomimetic activity. Levarterenol under ordinary circumstances, administered intravenously, is a more potent pressor agent than epinephrine (1, 16, 42, 58, 78, 94, 95, 142). However, epinephrine is the more potent agent in eviscerated dogs (42), in dogs anesthetized with ether (131), and in rabbits (1).

Isoproterenol produces a depressor response in most species of animals. In the rabbit a pressor response may occur (1).

While it is true that arterial blood pressure responses give clues as to how drugs effect the peripheral resistance and cardiac action, other more direct measurements are needed. Arterial pressure can be elevated by either vasoconstriction or cardiac stimulation. Reflex effects initiated by pressure changes can conceal or even reverse the responses due to direct drug action.

Vasoconstriction.—Epinephrine is the most potent adrenergic vasoconstrictor. This has been demonstrated in dogs in the renal circulation (1, 9, 124), in the skin (75), in the mesenteric circulation (1, 73), and in the femoral

circulation (9). Epinephrine is more potent than levarterenol as an intracutaneous vasoconstrictor (42, 78, 95). It is also more potent in the perfused rabbit ear (95) and perfused frog (142).

Levarterenol is more potent than epinephrine as a vasoconstrictor in the canine skeletal muscle vascular bed (74). This is due to the fact that epinephrine is a more potent vasodilator than is levarterenol (see below).

Coronary blood flow is increased by the catecholamines. There is, however, little conclusive evidence that this is a direct relaxing effect on coronary smooth muscle. Changes in heart rate, ventricular contractile force, and diastolic pressure can markedly change coronary flow by mechanical or metabolic means. These effects complicate and obscure attempts to measure the direct coronary effects of the catecholamines. It is possible that epinephrine and levarterenol are direct coronary vasoconstrictors.

Aortic Muscle.—The smooth muscle in rabbit aorta is contracted by the catecholamines. Epinephrine is equipotent with levarterenol, and isoproterenol is the least potent (63, 64, 144). These studies include blocking agents, and the results are consistent with existence of a single receptor (α).

Intestinal Smooth Muscle.—On the two standard experimental preparations for testing drugs on the gut, isolated rabbit ileum and intact canine intestine, *all catecholamines and all sympathomimetics*, produce an inhibitory effect. In comparing epinephrine and levarterenol the majority of studies show epinephrine to be the more potent (1, 9, 33, 37, 58, 142). Isoproterenol is sometimes the least potent of the three catecholamines, and sometimes the most potent. And in intact animals, isoproterenol often produces stimulation of the ileum instead of inhibition. Although an α receptor could be assigned to intestinal smooth muscle, it will be shown below that this would not be a complete explanation.

BETA ADRENERGIC RECEPTOR

The β receptor is most responsive to isoproterenol and epinephrine and in general is least responsive to levarterenol. In terms of potency: isoproterenol > epinephrine > levarterenol. Only two smooth muscle inhibitory responses seem unequivocally to be controlled by a β receptor. These are: the bronchial smooth muscle and the rat myometrium. All other smooth muscle adrenergic responses are best described as being controlled by a balance between α and β activity.

Bronchial Smooth Muscle.—The relative potencies of the catecholamines on this muscle are, isoproterenol > epinephrine > levarterenol (42, 78, 95). This relationship is the same whether the test method used is protection against histamine asthma in guinea pigs, perfusion of the isolated lung, or mechanical response of tracheal ring chains.

Myometrium.—The isolated uterus of the rat is relaxed by all of the catecholamines and, indeed, by all sympathomimetic compounds tested. The relative potencies of the catecholamines are: isoproterenol > epinephrine > levarterenol (1, 95, 142). As stated above, the myometrium of other species appears to have both α and β receptors. As will be described below the myometrium can be used to detect the specific blocking agents of these receptors.

Arterial Pressure (Depressor Response).—Isoproterenol injected intravenously produces a transient but well marked fall in pressure in most species (1, 87, 114). There is no unequivocal evidence that epinephrine or levarterenol can produce a similar depressor response. However, after an α adrenergic blocking agent (see below) epinephrine evokes a depressor response. This change from a pressor response to a depressor response is termed epinephrine reversal. This is considered to be due to an unmasking of a vasodilator action that is normally concealed by a predominant vasoconstricting effect. In addition, epinephrine and levarterenol evoke special depressor reflexes (2, 76).

Vasodilation.—Intra-arterial injections of epinephrine produce vasodilation in the vascular bed of skeletal muscle of dog and man (15, 74, 121). Epinephrine is said to increase hepatic blood flow in man (17).

Isoproterenol produces vasodilation when injected intra-arterially in the femoral and mesenteric vascular beds (1). In the renal vascular bed isoproterenol has either no significant effect (1) or produces some vasoconstriction (124).

Although there have been few detailed comparative studies of the potency of the three principal catecholamines the information available shows isoproterenol > epinephrine > levarterenol as direct vasodilators.

Heart.—Isoproterenol is the most potent of the three catecholamines in producing a positive chronotropic effect on the heart (1, 80, 87). Epinephrine is probably more potent than norepinephrine (11), but reflexes due to pressure changes can obscure the positive chronotropic effect. For example, in animals with intact buffer reflexes, vagal bradycardia may

completely overshadow any tachycardia. Levarterenol in this case produces more bradycardia (less positive chronotropic effect) than epinephrine (9).

In man, levarterenol produces reflex bradycardia while epinephrine produces sinus tachycardia (71, 145).

The relative potency for producing a positive inotropic cardiac effect is isoproterenol > epinephrine = levarterenol (46, 61, 78, 87, 120). In certain amphibia epinephrine is definitely more potent than levarterenol (142) and the same is true in isolated rabbit hearts under some experimental conditions (1).

Intestinal Smooth Muscle.—The potency of isoproterenol as compared to epinephrine and levarterenol is difficult to determine. On isolated strips of rabbit ileum the response seems to depend on the order of administration. Using equimolar doses, if isoproterenol is applied first, and applied only once to each strip, it is the least potent catecholamine in producing cessation of movement. On the other hand, if isoproterenol is applied repeatedly or after the other two amines, it appears to be the most potent. If the strip is pretreated with atropine its response to isoproterenol becomes more uniform, but the relative potency is still variable. The evidence makes it difficult to assign either an α or a β receptor on the basis of relative response to the catecholamines. Furchgott (64) assigned a δ receptor. However, an alternative explanation will be presented below under β adrenergic blocking agents.

ALPHA RECEPTOR BLOCKADE

The classical adrenergic blocking agents such as dibenamine, phenoxybenzine, and phentolamine have long been known to block most of the excitatory responses to epinephrine and other catecholamines. The excitatory responses that are not blocked are the positive inotropic and chronotropic effects on the heart. This class of drugs has been reviewed extensively (110, 111). Green and co-workers have published extensively on adrenergic block in skeletal muscle vascular bed (74), mesenteric bed (73), and skin (75). The iris has been studied by Bennet *et al.* (21), the spleen by Bickerton (22), and the isolated seminal vesicles by Stone and Loew (126).

Levy and Ahlquist (91) have described a general method for examining adrenergic blocking agents. This consists of recording arterial pressure, heart rate, intestinal contraction, and contractions of the retractor penis in the anesthetized dog. Four test amines are administered before and after the unknown blocking agents. These are: epinephrine and ethylnorepinephrine (α and β activators), phenylephrine (a relatively pure α activator), and isoproterenol (the most potent β activator). An α blocking agent diminishes or prevents the effect of epinephrine and phenylephrine on the retractor penis, blocks the pressor action of phenylephrine, reverses the pressor action of epinephrine, and does not essentially alter the responses to isoproterenol.

It was found that these blocking agents also blocked the inhibitory effect of phenylephrine on the intestine (8).

It is fair to say that all responses described above as being controlled by α receptors are blocked by the agents known as classic adrenergic blocking agents. This includes vasoconstriction and contraction of iris dilator, seminal vesicle, spleen, and retractor penis.

BETA ADRENERGIC BLOCKADE

In 1958 Powell and Slater described the actions of the dichloro analog of isoproterenol, DCI (114). This compound had effects that could only be described as due to blockade of the β adrenergic receptors (122). Moran (106) suggested that the term "*beta* adrenergic blocking agent" was most appropriate. This was the start of a continuing search for new β adrenergic blocking agents for possible therapeutic use in cardiac arrhythmias.

It is of historical interest that at least two compounds preceded dichloroisoproterenol as β blocking agents. Ethylnorepinephrine, to be described in greater detail below, in large doses had β adrenergic blocking activity. The first dose of this compound administered intravenously produced a transient pressor response followed by a more prolonged depressor response. If the dose was immediately repeated the pressor response increased and the depressor response decreased. After three or four doses of about 0.5 mg./Kg., ethylnorepinephrine produced only a pressor response (132). The reason for this "reversal" was not found until 25 years later (90).

Butylsympatol blocked the depressor response to isoproterenol and increased the pressor response to epinephrine (41, 113).

Many substances have been found to have β adrenergic receptor blocking properties. At the present time the principal compounds are as follows.

Dichloroisoproterenol, DCI (88, 90, 115).

Naphthylisoproterenol, 1-(2-naphthyl)-2-isopropylaminoethanol, nethalide, pronethalol (24).[2]

[2] Trademarked as Alderlin.

1 - Isopropylamine - 3 - (1 - naphthyloxy) - 2-propanol, propranolol (23).[3]

4 - (2 - Isopropylamino - 1 - hydroxyethyl) methanesulfanilide, MJ1999 (51, 125).

4 - (2 - Methylamino - 1 - hydroxypropyl) methanesulfonanilide, MJ1998 (51, 125).

Arterial Pressure.—The β adrenergic blocking agents diminish or block the depressor response to isoproterenol (91). This effect can serve as a basic indicator for these compounds. A more sensitive screening test has been described; this is known as the "ethylnorepinephrine reversal" test (90). This catecholamine in a dose of 50 mcg./Kg. in anesthetized dogs treated with atropine consistently produces a small pressor response followed by a more prolonged depressor response. Blood flow studies show this to be due to vasoconstriction followed by vasodilation. Following an effective dose of a β blocking agent, ethylnorepinephrine produces only a pressor response due to peripheral vasoconstriction. Many vasoconstrictors of prolonged action also produce ethylnorepinephrine reversal by obscuring the dilator effect of this catecholamine. Therefore, to be certain only β receptor blockade is involved, blood flow studies should be done. Isoproterenol block *but not reversal* must also be present.

The β blocking agents also potentiate the pressor action of epinephrine (6). This is consistent with the idea that the pressor response to epinephrine is reduced by the vasodilating action of this catecholamine.

Bronchial Smooth Muscle.—The bronchodilation produced by epinephrine, norepinephrine, or isoproterenol is blocked by β adrenergic blocking agents (100). Epinephrine and levarterenol now produce a contraction that is blocked by α adrenergic blocking agents.

Myometrium.—Inhibition of the feline myometrium *in situ* produced by epinephrine is blocked by β adrenergic blocking agents (122). Inhibition of isolated uteri by epinephrine is also blocked by these agents (65, 92, 115). All of the β blocking agents have some intrinsic activating effect on the β receptors. This renders the assessment of blockade of inhibitory adrenergic effects difficult (137). For example, isolated strips of rat myometrium, are persistently relaxed by the β blocking agents.

Intestinal Smooth Muscle.—The inhibitory effect of isoproterenol on the canine intestine *in situ* is blocked by a β blocking agent (4, 87). In the same experiments the inhibitory effect of phenylephrine was blocked by an α blocking agent. When it became apparent that the inhibitory effect of epinephrine was blocked only by a combination of an α and a β blocker the conclusion was drawn that the intestine has both types of receptors and that both control inhibition. Confirmatory results have been obtained using isolated intestine (96, 143).

Myocardium.—Cotton *et al.* (45) found evidence that led them to believe that the α blocking agents, phenoxybenzamine and phentolamine, blocked the positive inotropic effect of epinephrine in the open-chest dog. Following the description of the blockade of the myocardial actions of epinephrine by dichloroisoproterenol (49, 50, 106) the effect of blocking agents was re-examined. It was found that the relative increase in force of contraction produced by epinephrine was reduced by phenoxybenzamine. However, the α blocking agent had by itself markedly increased the force of contraction. This increase in control level resulted in the decrease in relative response to epinephrine. The absolute increase, however, was not reduced. Therefore, the suggestion that α blocking agents prevent the cardiac effects of the catecholamines was withdawn (107, 112).

DCI blocks the effects of catecholamines in dog heart-lung preparations (62) and blocks action of epinephrine to increase automaticity in isolated hearts (50).

Pronethalol blocks positive inotropic and chronotropic effects of catecholamines (24, 83, 84). This substance also prevents hydrocarbon-epinephrine fibrillation (108), fibrillation due to cardiac glycosides (138), and blocks catecholamine induced heart rate increases in man (40). It also blocks the effects of catecholamines on the heart-lung preparation (48).

Propranolol is somewhat more potent in blocking action than pronethalol and is said to have practically no intrinsic β activating effect (23). It also acts as an antifibrillatory substance (20). In man propranolol decreases heart rate, cardiac output, arterial pressure, and cardiac work (57).

Any agent that blocks the positive chronotropic effects of catecholamines should be a potential antiarrhythmic drug. Propranolol is now undergoing extensive clinical testing (70, 77, 117, 118). There is some question, however, whether the demonstrable antiarrhythmic effect is due to β blockade or to some other effect (69, 93).

A modification of the ethylnorepinephrine reversal test (see above) based on the blockade of the positive chronotropic effect has been suggested (130). In anesthetized dogs with intact buffer reflexes, slight, transient direct, and reflex tachycardia is produced by ethylnorepinephrine.

[3] Trademarked as Inderal.

Following β blocking agents this response is converted to one of reflex bradycardia. This test is sensitive enough to detect the β blocking activity of 10–50 mcg./Kg. of pronethalol.

METABOLIC EFFECTS OF CATECHOLAMINES

In addition to the effects on smooth and cardiac muscle, epinephrine and related compounds produce a variety of metabolic effects. This includes hepatic glycogenolysis, lipolysis in adipose tissue, and an increase in blood lactic acid. It is tempting to assign an α or β receptor for each of these actions. However, as will be pointed out, this is not possible at the present time.

Comparative Potencies of Catecholamines.—As far as these metabolic effects are concerned the only consistent finding reported is that epinephrine is the most potent catecholamine when all effects are considered. This has been found for hyperglycemia in rabbits (42), hyperglycemia in rats (136), hepatic glycogenolysis (54, 140), increase in hepatic active phosphorylase in rabbit liver slices (127), lipolysis from adipose tissue (141, 146), and increased blood lactic acid (54, 99).

It is the lack of uniformity of the comparative potency of isoproterenol to epinephrine that prevents a clear assignment of a receptor. In some cases isoproterenol is the least potent. In some cases it is even inactive, for example, in producing hepatic glycogenolysis (82). Only in the case of increasing active phosphorylase in the heart (101) and the increase in cyclic 3-5-AMP (128) is isoproterenol the more potent.

On the basis of comparative potencies it is not possible to assign a single receptor, although it seems that a β type receptor would be appropriate.

Blocking Agents.—The β adrenergic receptor blocking agents have been found to block epinephrine induced hyperglycemia in cats (53, 55), myocardial and skeletal muscle glycogenolysis (82), increase in active phosphorylase in the dog heart (101), rat diaphragm and liver (10), increase in plasma free fatty acid (35), and free fatty acid release from adipose tissue (28).

Many of the same effects are also blocked by α blocking agents (10, 28, 29, 39, 53). In addition, the compound isopropylmethoxamine which is not a β blocking agent (89, 129) blocks these effects too. And most recently, the compound *N*-tertiary butyl methoxamine, another substance with no β blocking properties has been shown to block these metabolic effects (36). However, there is some evidence that methoxamine itself may have some β blocking properties (25).

In the opinion of the reviewer the adrenergic metabolic actions do not seem to be controlled by a receptor that fits with the smooth or cardiac muscle effects. Celander's (39) idea that the sympathetic adrenergic nerves and the adrenal medulla have two different general controlling effects seems most attractive. In his view epinephrine from the adrenal should be regarded solely as a metabolic hormone. The theory set forth by the Lundholms (97, 98) that the vasodilator and inhibitory actions of the catecholamines are secondary to metabolic changes deserves further study. Furchgott's original suggestion of a γ adrenergic receptor (65) for metabolic effects appears to be useful.

CONCLUSIONS

1. How valid is the adrenergic receptor concept? It is as valid as any other receptor mechanism. It would be better to define a site of drug or hormone action by the actual enzyme or enzymes involved. However, if these are not known, some other way to characterize sites of action is needed.

The receptor concept correctly describes the site of drug-effector interaction as belonging to the effector cell. The effector responds to the drug (or hormone). Drugs do not act on just any cell.

2. What is the usefulness of the adrenergic receptor concept? In the first place it allows prediction of drug action. For example, the β receptor blocking agents were characterized before any such compounds were recognized. Dale (47) and Rothlin *et al.* (119) suggested that ergot alkaloids could block the effects of epinephrine on the heart and on the gut. However, the predominant α adrenergic blocking actions of these alkaloids strongly interfered with early definitive studies of β blockade. Holzbauer and Vogt (79) tested 27 different substances, including classical adrenergic blocking agents, on the rat uterus without finding a single β blocker.

It also follows that different kinds of chemicals than previously thought to be adrenergic blocking agents should be sought to block the metabolic effects of catecholamines.

Prediction of drug response is also necessary in determining what are the active parts of a given chemical structure. Biochemical studies of drug-enzyme interactions have usually been based on structure-response studies.

3. Can adrenergic receptor studies determine the nature of the adrenergic neuro-transmitter? Considering all adrenergic responses, epinephrine is the most potent catecholamine. Therefore, if potency is a measure of drug-receptor interac-

tion, the adrenergic receptor seems to be designed to "fit" epinephrine. However, potency can also reflect changes in metabolism, binding to inactive sites, membrane penetration, and other things beside drug-receptor interaction. However, epinephrine is the most potent, *in vivo* or *in vitro*, and under many different circumstances. From this we must assume that the superior potency of epinephrine is a true drug-receptor property.

Until definitive evidence to the contrary is obtained there is no reason for this reviewer to discard his assumption that epinephrine is the ultimate adrenergic neuro-hormone. Epinephrine is the end product of the catecholamine biosynthetic pathway (30). It is the receptor that determines the effector response. The reviewer has no information on the exact mechanism of the transmitter-receptor interaction. Therefore, it can be assumed that although adrenergic transmission is based on epinephrine as the transmitter the receptor would allow precursors such as levarterenol or even dopamine to affect transmission if necessary.

4. On the basis of relative responsiveness to sympathomimetic amines, and on the basis of specific blockade, the α receptor is associated with all adrenergic excitatory smooth muscle responses and with intestinal relaxation.

On the same basis the β receptor is associated with all adrenergic inhibitory effects on smooth muscle and with the adrenergic positive inotropic and chronotropic cardiac effects.

On the basis that epinephrine is usually the most potent catecholamine metabolically, and that a specific class of blocking agents for these effects has not yet been found, a γ receptor could be assigned to the adrenergic metabolic effects.

5. The adrenergic receptor concept should not interfere with or negate other studies or findings in regard to the cellular responses to catecholamines. The biophysical changes as described by Bulbring (31), for example, are a step beyond the drug-receptor interaction.
